Introduction to Mitochondrial Toxicity

Yvonne Will and James A. Dykens

CONTENTS

1 INTRODUCTION

Mitochondria have been the subject of study since their independent discovery in the mid-to-late 1800s by cytologists, including Kölliker and Flemming, who described them as 'granules' or 'filaments', respectively. In 1890 Altmann used fuchsin staining to demonstrate that mitochondria, which he presciently characterized as 'elementary living particles' and called 'bioblasts', are present in almost all cells. In 1898, using alizarin and crystal violet stains, Benda coined the name mitochondrion to reflect their plastic morphology *in situ*: mitos (Greek: a thread), khondrion (Greek: a grain). The gradual illumination of the central role mitochondria play in bioenergetics has led to several Nobel prizes: Otto Warburg in 1931 for the discovery that oxygen consumption resides within the mitochondria; Hans Krebs in 1953 for the elucidation of the citric-acid cycle; Peter Mitchell in 1978 for his insights and description of the chemiosmotic coupling of electron transfer reactions and phosphorylation and John E. Walker and Paul D. Boyer in 1997 for their work revealing the molecular structure of adenosine triphosphatase (ATPase) (ATP synthase, Complex V) that allows its function as a rotating motor complete with stators.

Mitochondriology has enjoyed a recent renaissance, sparked by the observations that mitochondrial dysfunction caused disease (Luft *et al*., 1962), that mutations in mitochondrial DNA (mtDNA) are linked to diseases, that mitochondria are key players in apoptosis, and that mitochondria have signalling function. Most recently, study of mitochondria has accelerated in response to findings that many xenobiotics and pharmaceuticals with unexplained organ toxicity and adverse clinical events impair mitochondrial function as an 'off-target' effect.

Mitochondria generate 95% of the cell's energy, and also most of the reactive oxygen- and nitrogen-centred

free radicals that undermine cell integrity. In this light, it should not be surprising that loss of mitochondrial capacity or functional impairment due to xenobiotic exposure could contribute to untoward drug toxicity. Nevertheless, that this is indeed the case has only recently gained appreciation, in large measure due to inadequacies in the techniques typically used to assess potential toxicity during preclinical drug development.

In this chapter we will provide a brief overview of mitochondrial morphology and function, followed by a discussion of drugs that undermine function and organ toxicities related to mitochondrial toxicity. We will then provide selected examples of recently developed methodologies to study mitochondrial toxicities *in vitro* and *in vivo*. We will close with consideration of how such mitochondrial impairment translates into cytotoxicity and organ toxicity via threshold effects, how bioaccumulation of mitotoxicants confounds classical pharmacokinetics, and how these provide a new model of previously unexplained idiosyncratic drug toxicity. Throughout, in the citations we have emphasized comprehensive literature reviews that will introduce the interested reader to the more detailed primary publications, and we apologize to our many colleagues whose work has been slighted as a result.

2 OVERVIEW OF MITOCHONDRIAL BIOLOGY

2.1 Morphology

Most of our knowledge of mitochondrial structure has been founded upon electron-microscopic examination. Today, three-dimensional reconstruction using computer tomography and confocal and electron microscopy have broadened our understanding of mitochondrial morphology. Whereas electron microscopy projected mitochondria as individual round or threadlike organelles (depending on the tissue), we now know that mitochondria form a dynamic reticulum that is constantly undergoing fission and fusion, depending on the metabolic or pathological state of the cell, to form individual organelles or merge into back into the network (**Figure 1**).

From the first ultrastructural studies it was apparent that mitochondria are composed of four compartments: an outer membrane, an inner membrane, an intermembrane space and an interior chamber called the matrix. Both membranes are a mixture of phospholipids and integral and peripheral proteins. In the outer membrane the proportion of proteins and lipids is approximately 1:1, which is typical of most cellular membranes. However, the inner membrane contains a much higher proportion of proteins (80%) and only 20% phospholipids, of which 10% is cardiolipin, an atypical phospholipid with four acyl tails that is only found in the inner mitochondrial membrane. The inner membrane is impermeable to protons, which is crucial for mitochondrial ATP production, and so has many transmembrane transporters that regulate import and export of metabolites, including the adenine nucleotide translocator (ANT) that exchanges adenosine diphosphate (ADP) for ATP.

The outer membrane is freely permeable to solutes up to 5000 Da and contains ion channels, such as voltage dependent anion channels (VDACs) that work in concert with transporters in the inner membrane. For larger molecules, shuttles and carriers are in place (**Figure 2**).

The impermeable inner mitochondrial membrane can be passively crossed only by weak acids, lipophilic cations, depending on chemical characteristics, oxygen and ammonia. Electrically charged and hydrophilic compounds, such as carboxylic anions (including respiratory substrates) and inorganic ions, are unable to pass the inner membrane without participation of specialized transport-protein carriers. This impermeability is required to maintain the coupling of the proton gradient generated by the redox reactions of the electron transport system (ETS) to phosphorylation. ETS and its reduction of oxygen is separate from, but coupled with, phosphorylation, and when taken together are called oxidative phosphorylation (OXPHOS); they are mediated by a series of respiratory complexes numbered I–V, all embedded in (Complexes, I, III–V) or adjacent to (Complex II), the inner membrane.

2.2 Oxidative Phosphorylation

The complete oxidation of glucose yields 38 ATPs:

$$C_6H_{12}O_6 + 6O_2 + 38ADP \longrightarrow 38ATP + 6CO_2 + 6H_2O \quad (1)$$

Of the 38 ATPs, two are from glycolysis, so that mitochondria generate 95% of the cells energy ((2/38)*100 = 5.3). Under physiological conditions (as opposed to standard) the overall efficiency is approximately 50%, with the remaining energy lost as heat. A simple calculation demonstrates the importance of mitochondrial functional integrity to organismal energetic budgets. Human resting metabolism, for example, while sitting quietly in a chair or lying at ease on a cot, is a function of gender, but averages 6127 and 7983 kJ day^{-1} in women and men, respectively (De Lorenzo *et al*., 2001). Under physiological conditions, ATP hydrolysis yields 42–50 kJ mol^{-1} (Campbell, 1993), with the result that women turn over ~133 mol ATP day^{-1} and men ~173 mol ATP day^{-1}. The molecular weight of ATP is 507 g mol^{-1}, so that women turn over 67 431 g day^{-1} (=148 lbs), and men turn over 87 711 g day^{-1} (=193 lbs). We essentially turn over our body weight or more in ATP every day! Moreover, humans have aerobic scope (i.e. can increase activity) of between 10- and 20-fold over rest, so a well-trained marathon runner could turn over >1 kg of ATP per minute.

This ATP production is due to the mitochondrial ETS that contains four respiratory complexes plus ATP synthase. Details are beyond the scope of this review, and can be found in several reviews and biochemistry books (Lehninger *et al*., 2008; Scheffler, 2007; Berg *et al*., 2006). Nevertheless, the process bears some attention in the context of drug-induced impairment.

Pyruvate from glycolysis is transported across the inner mitochondrial membrane by a specific transporter (Halestrap, 1978) that is a member of the mitochondrial carrier family with homologues in all other species examined thus far (Hildyard and Halestrap, 2003). Once inside the matrix, pyruvate dehydrogenase (PDH) catalyses the highly exergonic (irreversible) decarboxylation reaction between pyruvate and coenzyme A to yield the key metabolic intermediate acetyl CoA, plus CO_2 and NADH (nicotinamide adenine dinucleotide). PDH is an interesting enzyme because it is part of a huge (4600 kDa) PDH complex made up of some 60 subunits that constitute the three enzymes, cofactors and regulatory components necessary for the complete reaction (Lodish *et al*., 1995). Acetyl CoA is also a key intermediary in the β-oxidation of fatty acids within the mitochondria, and from amino-acid catabolism of the ketoacid following deamination. Regardless of the source, acetyl CoA enters the Krebs cycle (citric acid cycle) by condensing with oxaloacetate to yield citrate, which, in a series of eight reactions, yields reducing equivalents in the form of six NADH and two FADH (flavin adenine dinucleotide), plus four CO_2 molecules and one substrate-level phosphorylation.

The potential energy inherent in reducing equivalents of NADH and FADH is gradually released during mitochondrial OXPHOS by passing the electrons down a redox gradient from Complex I (NADH-ubiquinone-oxidoreductase) to oxygen as the terminal acceptor in a process called respiration (see **Figure 3**, which is the electron transport chain, ETC). Electrons also enter via Complex II (succinate dehydrogenase), and are passed from both Complexes I and II via a membrane-bound carrier, ubiquinone, to Complex III (ubiquinol-cytochrome-c-oxidoreductase). From Complex III, the electrons are carried to Complex IV (cytochrome c oxidase) via cytochrome c, where four electrons are collected, and used to tetravalently reduce oxygen to water.

At Complexes I, II and IV, the potential energy of the redox reaction is sufficient to translocate a proton from the matrix, against a gradient, into the inner membrane space. This yields a membrane potential of some 180 mV (matrix negative) due to the charge of the electric potential ($\Delta\Psi$), plus an additional 40–60 mV from the proton ion pH gradient (ΔpH) of about 1 pH unit, so that the average mitochondrial proton motive force (PMF) is about 220 mV (matrix negative). Clearly, if the inner membrane were permeable to protons, they would diffuse back down the gradient as fast as they are pumped out, with no energy captured (i.e. lost as heat and doing no work). But as long as the inner membrane is impermeable, this gradient persists, and it can be thought of resistance that the ETS must work against. In response to decreases in PMF, ETS can accelerate to a maximum flux.

As an aside, generations of students learned this process as the 'electron transport chain', which connotes a one-to-one linkage between the various components.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat021
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

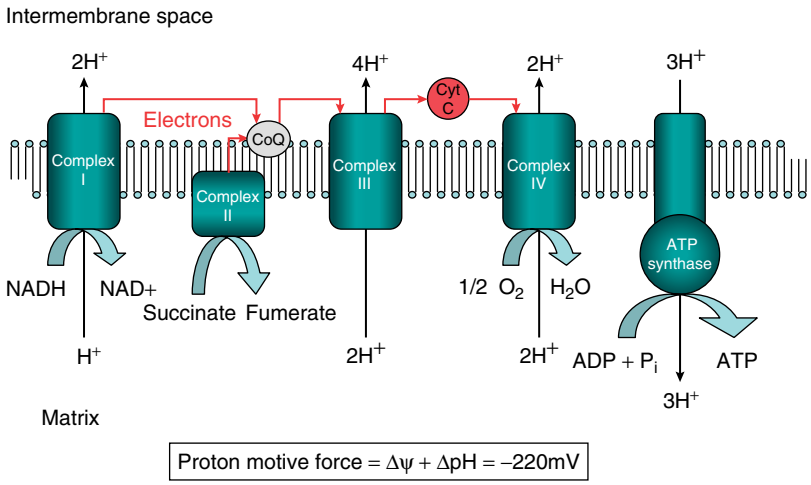

Figure 3 The mitochondrial electron transport chain (ETC) consists of Complex I (NADH-oxidoreductase), Complex II (succinate-dehydrogenase), Complex III (ubiquinol-cytochrome-c-oxidoreductase), Complex IV (cytochrome oxidase) and Complex V (ATPase). Electrons are passed from either Complex I or II to Complex III via the mobile carrier, ubiquinone. Electrons are passed to Complex IV, the final electron acceptor at which oxygen undergoes the four-electron reduction to combine with hydrogen to yield water. The energy released in this process is used to drive ATP synthesis.

However, the molar ratios between the various components are not equal; for every mole of Complex I, there are 3 moles of Complex III, 7 of Complex IV, 9 of cytochrome c and 50 of ubiquinone. Only when the lateral diffusion coefficients are included in the analysis does the equation approach unity for rates of electrons transport (Chazotte and Hackenbrock, 1988). In this light, this process is more akin to an ETS rather than a serial chain. Moreover, recent evidence indicates that the complexes aggregate into 'super complexes' that facilitate the requisite redox reactions (Genova *et al.*, 2003).

Regardless of the molecular architecture of the ETS, the potential energy inherent in the PMF is captured by Complex V (F_0F_1-ATPase) as the flow of protons down the ion and pH gradient into the matrix is transformed into phosphorylation of ADP. The molecular mechanism of Complex V is wonderfully elegant; it is a complex protein motor where protons pass through a channel, and the catalytic domains rotate on an axle held in place by an arching external stator.

Note that ETS and flow of electrons to oxygen is coupled to phosphorylation of ADP by Complex V (OXPHOS), and that such coupling is dependent on the integrity of the inner membrane. If this membrane becomes permeable to protons, ETS is no longer coupled to phosphorylation and ATP production declines to the extent of this uncoupling, reaching zero if ETS can not accelerate and re-establish the PMF. Under these uncoupled conditions, respiration is unopposed by PMF, and oxygen reduction reaches maximum rates. In addition, respiration does not respond to ADP availability. Conversely, under coupled conditions and in the presence of ample substrate and cofactors, respiration accelerates to close to maximum upon exposure to ADP, and then it returns to basal rates after all ADP has been phosphorylated.

2.3 Free-Radical Production and Antioxidants

Molecular oxygen has a high affinity for electrons ($E = +0.82$ V), larger than all the other components of the ETS. As such, any of the 'upstream' components are capable of passing the transiting electron to molecular oxygen. Because of orbital spin restrictions, molecular oxygen preferentially undergoes univalent reductions, the first product of which is the superoxide anion, a free radical (contains an unpaired electron in the outermost orbital). This is thought to underlie the selection pressures resulting in the reaction dynamics at Complex IV, where four electrons accumulate to completely reduce oxygen to water avoiding serial reduction through several reactive products. Superoxide spontaneously dismutates (dismutation is a reaction in which two identical reactants yield two different products, most commonly via simultaneous reduction and oxidation) at fairly fast rates ($\sim 10^5\ M^{-1}\ s^{-1}$ at pH 7) to yield hydrogen peroxide (H_2O_2) and O_2 (ground state). However, this reaction is catalysed by the enzyme superoxide dismutase more than 70 000 times faster ($7 \times 10^9\ M^{-1}\ s^{-1}$), with essentially diffusion-limited kinetics. All aero-tolerant organisms contain at least one form of this metalloenzyme, and mammals have three: a dimeric Cu-Zn superoxide dismutase (SOD) 1 in the cytoplasm and mitochondrial intermembrane space, a Mn-containing tetramer SOD

2 in the mitochondrial matrix and a Cu-Zn tetrameric isozyme excreted into the intercellular space.

Superoxide is reactive; it can depolymerize hyaluronate, but the Fe–S centres found in several of the electron transport complexes are especially susceptible, resulting in impairment of respiration. Although superoxide is a reactive radical, in the presence of reduced transition metals plentiful in biology, such as Cu and Fe, the H_2O_2 that results from superoxide undergoes Fenton chemistry via the Haber–Weiss reaction to yield the hydroxyl radical (OH·), the most reactive radical known from biological systems:

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH\cdot + OH^- \qquad (2)$$

Hydroxyl reacts extraordinarily rapidly with a half-life of 10^{-9} s and so rarely diffuses further than five atomic radii, which essentially precludes enzymic mechanisms to remove it. The radical damages all types of macromolecules, including nucleic acids, yielding mutations, and lipids, initiating peroxidation chain reactions that destabilize membranes, among many other injurious reactions. Importantly, superoxide also efficiently reacts with nitric oxide radicals to yield peroxynitrite ($ONOO^-$), a strong oxidizing agent, that in turn can react with CO_2 to form nitrosoperoxycarbonate ($ONOOCO_2^-$) that homolyses to form the carbonate radical and nitrogen dioxide. The conjugate acid of $ONOO^-$ is peroxynitrous acid (ONOOH), and with a pK_a of ~6, it can also homolyse to yield the hydroxyl radical. It bears reiteration that although in the context here, free-radical production is deleterious, these same reactive molecules are essential for killing pathogens during the inflammatory response, among other signalling and physiological processes.

Regardless of the complexity of the ensuing biological chemistry, production of superoxide is the initial domino in this deleterious cascade, and all organisms maintain antioxidant defences against radicals and the damage they cause that can lead to cell death via either necrotic or apoptotic pathways. The protective systems include a number of low-molecular-weight antioxidants and enzymatic systems. The former category includes vitamin C and vitamin E, as well as reduced glutathione (GSH) and the reduced pyridine nucleotides NADH and NADPH (nicotinamide adenosine dinucleotide phosphate). The first step in the detoxification of the superoxide anion is catalysed by superoxide dismutase (Mn-SOD), which converts two superoxide anions into H_2O_2. The subsequent detoxification of H_2O_2 is catalysed by catalase, which is believed to be intrinsic to heart mitochondria. Another enzyme detoxifying H_2O_2 is glutathione peroxidase, which reacts with reduced GSH as an electron (or oxygen) acceptor, oxidizing it to glutathione disulfide (GSSG).

GSSG resulting from the reactions catalysed by glutathione peroxidases must be reduced back to GSH to enable the process to continue. This is catalysed by glutathione reductase and specifically utilizes NADPH as the electron donor. NADPH can be generated from isocitrate or malate by the action of the respective dehydrogenases, $NADP^+$-dependent mitochondrial isocitrate dehydrogenase or decarboxylating malate dehydrogenase. Thus, regeneration of reduced GSH is an energy-consuming process and can compete with ATP synthesis for the PMF or respiratory substrates, which means that protection against oxidative stress is energetically costly.

There are at least two sites that autoxidize to yield superoxide; Complexes I and III are the primary ones, although under pathogenic conditions other components, such as partially reduced ubiquinone (ubisemiquinone) can also. It stands to reason that when ETS is impaired, particularly if blockade is 'downstream' of these two components, they remain in the fully reduced state, which increases the probability of autoxidation to superoxide, and this can be demonstrated pharmacologically with inhibitors such as antimycin. Under normal conditions, however, when mitochondria are exposed to conditions that induce the irreversible permeability transition (PT; see next section) that uncouples OXPHOS, superoxide and hydroxyl radicals are directly detected using spin trapping and electron paramagnetic resonance technologies. See **Figure 4**, which is the ETC with superoxide formation at Complexes I and III).

2.4 Mitochondria and Ca^{2+} Homoeostasis

In most mammalian cells, the concentration gradient of Ca^{2+} across the plasma membrane is around 10 000-fold, in contrast with that for Na^+ (12-fold), K^+ (35-fold) or Cl^- (29-fold) (Star *et al*., 1987). These gradients are actively maintained via plasma-membrane ion-dependent ATPase that translocates ions against the concentration gradients, often in exchange for a cotransported ion, for example, Na^+-K^+ ATPase. The steep gradient for Ca^{2+} reflects its utility as a cell signal in a wide variety of physiological processes. For example, excitation contraction coupling of muscle cells and neurotransmitter release at neuronal synapses are mediated by transient increases in cytosolic Ca^{2+}. In muscle cells, relaxation is mediated by removal of Ca^{2+} by ATP-dependent sequestration into the sarcoplasmic reticulum and in most other cells into the endoplasmic reticulum and also back out via the plasma membrane. Mitochondria figure prominently in Ca^{2+} homoeostasis because it is rapidly accumulated into the matrix via a trans-inner-membrane transporter, the Ca^{2+} uniporter, driven by the net negative mitochondrial membrane potential. The uniporter has an extraordinarily high V_{max} and is more reasonably considered a channel rather than an classical ion transporter

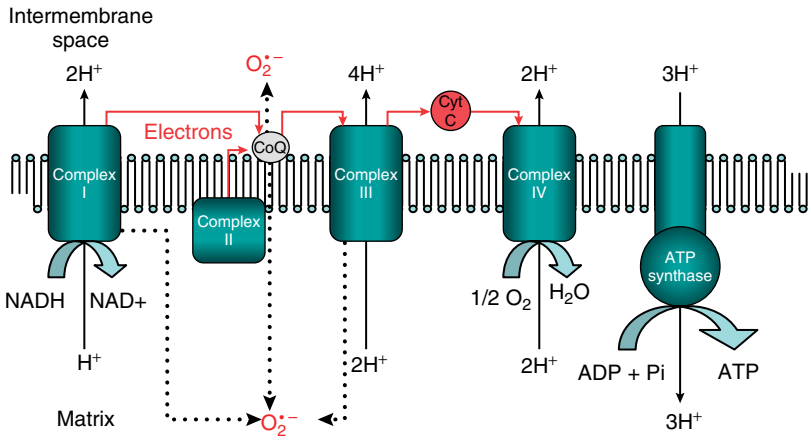

Figure 4 Superoxide production in the ETC by Complexes I and III.

or exchanger such as Na+/K^+-ATPase (Kirichok *et al.*, 2004).

Under physiological conditions, such Ca^{2+} uptake is benign, and even beneficial in that modest Ca^{2+} increases accelerate Krebs cycle fluxes (Szabadkai and Duchen, 2008; Rimessi *et al.*, 2008). Similarly, under physiological conditions, the accumulated Ca^{2+} is pumped out of the mitochondria and reticulia, and hence out of the cell, via ion-dependent exchangers, some of which require ATP directly, while others dissipate membrane potential to fuel ion exchange, and so secondarily require cell energy. However, when cytosolic Ca^{2+} increases beyond a finite level, and/or when such exposures persist, Ca^{2+} accumulates in the mitochondria and gradually destabilizes them and imperils the cell. This is a continuum, ranging from modest to lethal Ca^{2+} exposures, that is influenced by timing issues and whether coincident pathology is afoot, such as hypoxia (Dong *et al.*, 2006). For example, if such Ca^{2+} exposure is rapid, excessive and especially when accompanied by hypoxia, which further reduces ATP production, mitochondria undergo irreversible collapse by a process called the permeability transition (see next section). In the absence of ATP to fuel transmembrane ion-dependent ATPases, the cell undergoes an acute osmotic crisis, and dies by necrosis, eliciting an inflammatory response. When such Ca^{2+} exposure is more gradual, the cell will continue to respond until to a threshold is reached where the Ca^{2+} buffering capacity of the reticulum and mitochondrial compartments is exceeded, and mitochondrial PT will induce apoptosis rather than necrosis.

2.5 Mitochondrial Permeability Transition

The mitochondrial permeability transition (MPT) refers to the opening of a nonselective pore in the inner mitochondrial membrane, which results in permeability to solutes up to 1500 Da. When MPT occurs, mitochondrial membrane potential will collapse and mitochondria will swell (Hunter *et al.*, 1976). The molecular composition of the pore has been subject to many studies and several models have been postulated. In one model, the pore consists of the adenine nucleotide translocator (ANT), the VDAC and cyclophilin D (CypD), which is capable of binding cyclosporin A (CyA), a potent inhibitor of the PT (Halestrap and Brennerb, 2003; Crompton *et al.*, 1999). Recently, it has been reported that MPT can occur in ANT-, VDAC- and CypD-deficient mitochondria, which challenges the proposed model (Kokoszka *et al.*, 2004; Basso *et al.*, 2005; Baines *et al.*, 2007). Another model describes the MPT as being formed from misfolded membrane proteins, which aggregate. In this model, CypD and other chaperones are thought to protect mitochondria from depolarization and swelling. When the formation of pores exceeds the amount of chaperones, unregulated MPT will occur, which in this case cannot be protected by CyA (He and Lemasters, 2002).

2.6 mtDNA Transcription/Translation

Mammalian mitochondria contain a circular genome (mtDNA) with ~16 500 bp, which is well preserved between species. The mtDNA encodes two ribosomal RNAs (rRNAs) for the large and small ribosomal subunits, 22 tRNAs and 13 proteins that are subunits of four of the five OXPHOS complexes of the electron transport chain. From proteomic studies it is estimated that mitochondria contain >1000 distinct proteins, of which ~600–800 have been definitely identified by mass spectroscopy. Thus, the vast majority of proteins in mitochondria are imported.

Mitochondria also contain their own transcriptional and translational machinery necessary to synthesize the 13 essential proteins. The mechanism of mtDNA replication is relatively well understood. There is a major

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and specific mtDNA polymerase belonging to the polymerase gamma family. This enzyme functions not only in DNA replication, but also in mtDNA repair, and in recombination. The mitochondrial translation system in the mammalian organelle is responsible for the synthesis of 13 proteins that constitute subunits in the complexes (I–IV) of the electron transport chain and ATP synthase (V), but not Complex II. Seven subunits are found in Complex I (NADH-ubiquinone-oxidoreductase), one subunit is found in Complex III (the bc1 complex, or ubiquinone-cytochrome-c-oxidoreductase), three subunits form the core of Complex IV (cytochrome c oxidase) and two subunits are part of the ATP synthase (Complex V).

3 OVERVIEW ON DRUG-INDUCED MITOCHONDRIAL TOXICITY

Figure 5 shows the many ways drugs can cause mitochondrial toxicity. Drugs can inhibit the individual OXPHOS complexes, including ATPase, and many drug classes have been shown to do so. Many studies have been performed using classical inhibitors. For example, rotenone, a plant poison still used for fish killing in the Amazon, inhibits Complex I of the ETC. Rotenone is also used to model Parkinson-like syndromes in rats, as it selectively targets the x neurons in the brain. 3-Propionic acid, an inhibitor of OXPHOS Complex II, succinate dehydrogenase, is a model compound to study Huntington's disease, a condition characterized by progressive motor impersistence, chorea and physical instability, accompanied by cognitive decline leading eventually to frank dementia. Antimycin A, an antibiotic, is an inhibitor of OXPHOS Complex III. Incubation of mitochondria with either rotenone or antimycin will generate superoxide, which can lead to oxidative stress, damaging proteins, lipids and DNA within the mitochondria, leading to dysfunction.

The classical compound to inhibit OXPHOS Complex IV, cytochrome oxidase, is KCN. Oligomycin, another antibiotic inhibits ATPase. More than 50 drug classes have been shown to inhibit OXPHOS Complex I, which might not be surprising considering the complexity of Complex I, with more than 50 polypeptides. Another way to cause mitochondrial dysfunction is through uncoupling of the OXPHOS from ATP synthesis, through uncontrolled hydrogen shuttling (uncoupling) across the inner mitochondrial membrane, resulting in dissipation of the mitochondrial transmembrane potential and subsequent energy depletion and injury to the organelle. Compounds can achieve this either through hydrogen shuttling across the membrane, though channel formation or simply through disturbance of the bilayer. Examples are nonsteroidal anti-inflammatory drugs (NSAIDs).

Another mechanism leading to mitochondrial toxicity is through inhibition of mitochondrial carrier proteins such as ANT, and anion and cation carriers. This will lead to substrate depletion, resulting in decreased ATP production. Another way to lead to mitochondrial toxicity is through the inhibition of mtDNA replication and mitochondrial protein synthesis, as described for antivirals (nucleoside reverse transcriptase inhibitors; NRTIs) and antibiotics (tetracyclines, oxazolidinediones), respectively.

Oxidative stress can also lead to mitochondrial dysfunction and can be produced through redox cycling or depletion of antioxidants such as GSH. Drugs can also induce apoptosis through induction of the MPT, which leads to loss of important mitochondrial components (<1200K) such as ATP, NAD, GSH. The result is intrusion of water into the mitochondria leading to swelling, and mitochondrial and cell death. Many cancer drugs will induce the MPT. Drugs can also inhibit enzymes within the glycolytic and FA (Fanconi anaemia) pathways and also in the citric-acid cycle, leading to depletion of substrates.

The following section will provide examples for these different mechanisms in more depth. **Table 1** summarizes the text below and provides relevant references.

4 EXAMPLES OF DRUGS CAUSING MITOCHONDRIAL TOXICITY

4.1 Drugs Effecting Complexes I–V

4.1.1 Complex I

Complex I inhibitors are found throughout many different drug classes. The most studied xenobiotic is rotenone, which is found in plants and is still used as an insecticide. Rotenone is an irreversible inhibitor of Complex I, inhibiting it at two sites, one buried in the hydrophobic part of the inner membrane and the other at an external site on the matrix face. This binding blocks electron transport from the dehydrogenase iron–sulphur cluster to coenzyme Q and results in reactive oxygen species (ROS) formation. Rotenone acts as a semiquinone antagonist and Complex I ROS formation has been attributed to autoxidation of the flavin semiquinone of NADH dehydrogenase. Rotenone treatment of rats leads to selective Complex I inhibition in the brain and can cause Parkinson-like symptoms, which makes it a useful model in Parkinson's research (Horgan *et al.*, 1968).

Another model compound for Parkinson's is MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), identified as a by-product of the 'new heroin' (meperin) synthesis in 1983, when illicit drug users were diagnosed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

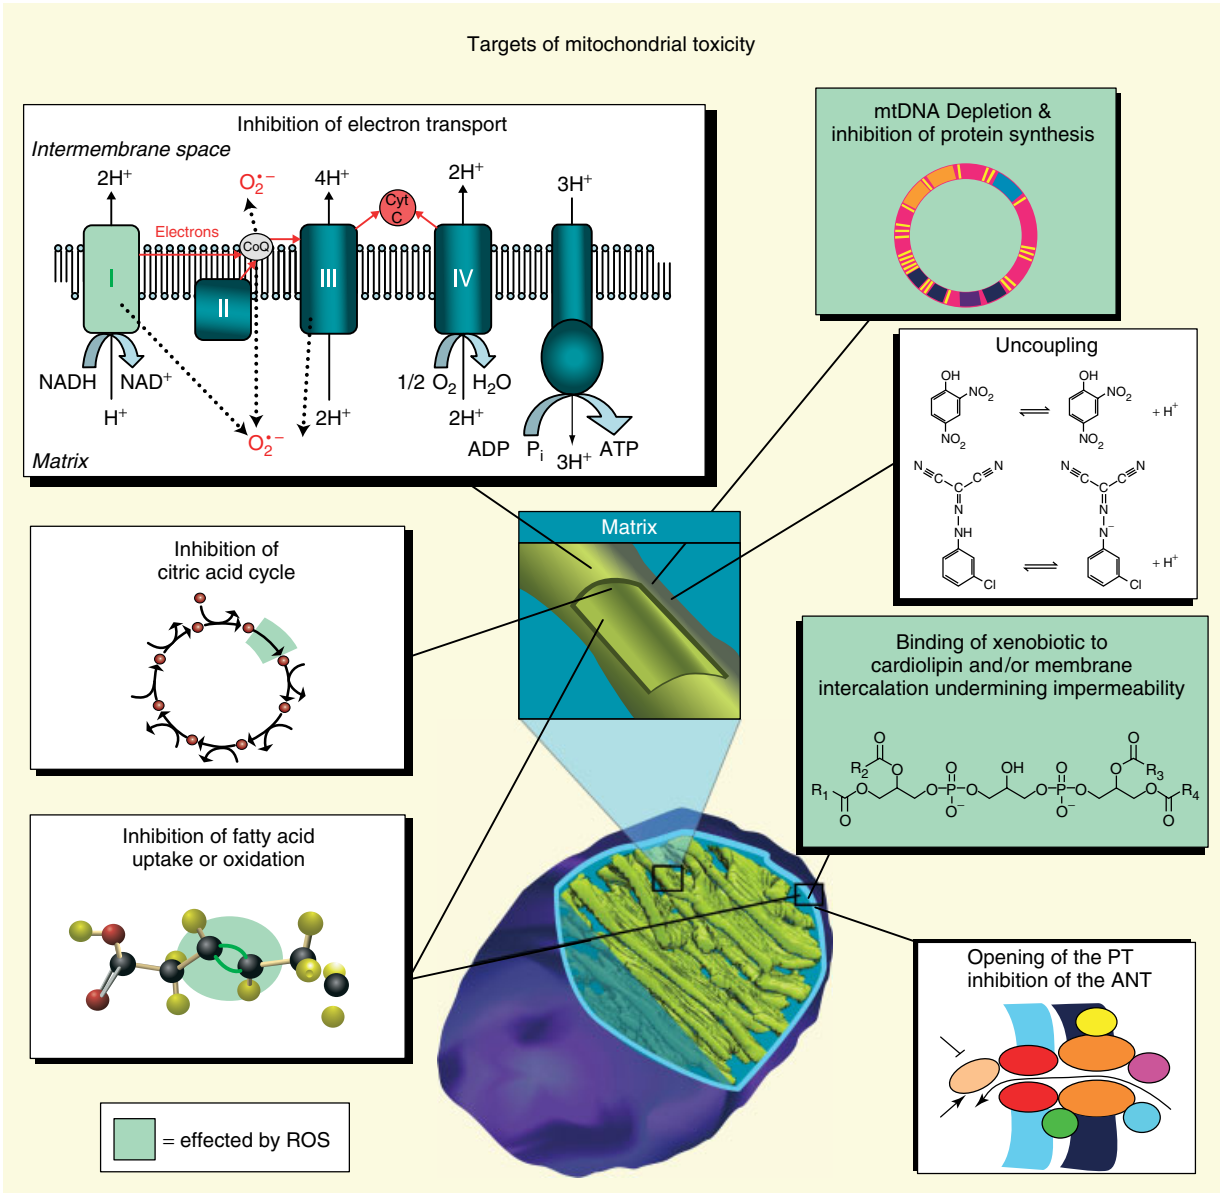

Figure 5 Mitochondrial function can be impaired in many different ways, such as inhibition of ETC proteins, carriers, uncoupling, metabolic-pathway inhibition, mtDNA depletion, inhibition of protein synthesis.

with Parkinson's. MPTP is very lipophilic and therefore can cross the blood–brain barrier. In the brain it is taken up by glial cells. In the astrocytes it is then converted by monoamine oxidase B (MAO-B), which is a mitochondrial enzyme, to MPDP+ (l-methyl-4-phenyl-2,3-dihydropyridinium). MPDP+ autoxidizes to MPP+ (1-methyl-4-phenylpyridinium). MPP+ is then taken up through the dominergic receptor and accumulates in the mitochondria where it inhibits Complex I, causes ROS formation and leads to mitochondrial damage and an energy crisis for the neuron (Ramsay *et al.*, 1987).

There are a variety of other antipsychotic neuroleptic drugs that also inhibit Complex I such as haloperidol, chlorpromazine, fluphenazine and risperidone. Like rotenone and MPTP, these drugs also cause Parkinson-like syndromes, as well as tardive dyskinesia. The rank order of potency for inhibiting Complex I activity in rat brain cortex was haloperidol > chlorpromazine > fluphenazine > risperidone. Similar results were found in human brain cortex (Balijepalli *et al.*, 1999; Maurer and Möller, 1997). Fibrates, such as clofibrate, ciprofibrate and fenofibrate are used therapeutically to decrease hyperlipidaemia. They are agonists of PPARα (peroxisome proliferator-activated receptor α), whose activation induces peroxisomes containing high palmitoyl–CoA ligase activity, which metabolizes fatty acids and lowers blood triglycerides, low-density lipoprotein (LDL) cholesterol and increases high-density

Table 1 Examples of drugs that cause mitochondrial impairment and their proposed mechanisms

Effect on mitochondria	Compound	Reference
Complex I	Neuroleptics (haloperidol, chlorpromazine, fluphenazine, risperidone, zotepine)	Balijepalli *et al*. (1999) Maurer and Möller (1997)
	Classical inhibitors (rotenone)	Horgan *et al*. (1968)
	Model compound (MPP+)	Ramsay *et al*. (1987)
	Antidiabetics and antihyperlipaedimics: fibrates (clofibrate, ciprofibrate, fenofibrate), thiazolidinediones (rosiglitazone, troglitazone) and biguanides (phenformin, buformin, metformin)	Dykens *et al*. (2008a) Nadanaciva *et al*. (2007) Brunmair *et al*. (2004a) Brunmair *et al*. (2004b) El-Mir *et al*. (2000)
	Antiandrogen (flutamide)	Coe *et al*. (2007)
	Antidepressant (nefazodone)	Dykens *et al*. (2008b)
	Anticancer (sorafenib)	Will *et al*. (2008)
Complex II/III	Cancer and autoimmune (cyclophosphamide) and antifungal (ketoconazole)	Souid *et al*. (2003)
	Classical inhibitors (antimycin)	Schagger *et al*. (1995)
	Anticancer (tamoxifen, sorafenib)	Will *et al*. (2008) Tuquet *et al*. (2000)
Complex IV	Thiazolidinediones (darglitazone, troglitazone)	Nadanaciva *et al*. (2007)
	Anticancer (tamoxifen, sorafenib)	Will *et al*. (2008) Tuquet *et al*. (2000)
Complex V	Classical inhibitor (oligomycin)	Walker *et al*. (1995)
	Dietary supplement (resveratrol)	Gledhill *et al*. (2007)
Uncouplers	Classical uncouplers (FCCP, DNP)	Cunarro and Weiner (1975)
	NSAIDs (flufenamic acid, diflunisal, tolfenamic acid, mefenamic acid, indomethacin, benoxaprofen, naproxen, fenoprofen, nimesulide, diclofenac)	Ong *et al*. (2006) Boelsterli (2003) Masubuchi *et al*. (1999)
	Anaesthetics (bupivacaine, etidocaine, lidocaine)	Sztark *et al*. (1998)
	Parkinsons (tolcapone)	Haasio *et al*. (2002)
	Anticancer (tamoxifen)	Tuquet *et al*. (2000)
	Antidiabetic (WY-14643, fenofibrate)	Zungu *et al*. (2006)
	Antidepressant (fluoxetine)	Souza *et al*. (1994)
Inhibitors of mtDNA replication	Antivirals (ddC > ddI > d4T > AZT)	Zungu *et al*. (2006)
Inhibitors of mt protein synthesis	Antibiotics (chloramphenicol, tetracyclines, aminoglycosides, macrolides, lincosamides, oxazolidinones (linezolid)).	Duewelhenke *et al*. (2007) McKee *et al*. (2006)
Inhibitors of Krebs cycle enzymes and fatty acid metabolism	Anticonvulsant (valproic acid)	Nulton-Persson *et al*. (2004)
	Antidepressant (amineptine, tianeptine)	Pessayre *et al*. (1999)
	Antibiotics (tetracycline derivatives)	Fromenty and Pessayre (1997)
	Salicylates (aspirin, ibuprofen)	
Oxidative stress	Analgesic (acetaminophen)	Jaeschke *et al*. (2003)
	Anticancer (doxorubicin, danunorubicin)	Berthiaume and Wallace (2007)
	Antidiabetic (chlofibrate, ciprofibrate)	Qu *et al*. (2001)
	Antianginal (amiodarone, perhexillin)	Ribeiro *et al*. (1997)
Induction of the mitochondrial permeability transition	Anticancer (lamellarin D)	
	NSAIDs (ibuprofen, nimesulide)	Berson *et al*. (2006)
	Analgesic (acetaminophen)	Kon *et al*. (2004)
	Antidiabetic (gemfibrozyl, WY-14643, troglitazone)	Zhou and Wallace (1999)

lipoprotein (HDL). Fibrates can cause liver toxicity, hepatomegaly and muscle toxicity in some patients. All fibrates inhibit Complex I (Brunmair *et al*., 2004b; Nadanaciva *et al*., 2007).

The biguanide agents, phenformin, buformin and metformin act as antidiabetic drugs by inhibiting hepatic glucose release, gluconeogenesis and β-oxidation of fatty acids. Phenformin and buformin both were discontinued in 1977 and 1978, whereas metformin is still available due to its 20-fold less potency for lactic acidosis. All three compounds inhibit Complex I of the OXPHOS. Using immunocapture, the IC50 (half maximal inhibitory concentration) for Complex I inhibition was 1.2, 11.3 and 66 mM for phenformin, buformin and metformin, respectively (Dykens *et al*., 2008b). Phenformin was shown to have an IC50 of 4.97 $\pm$ 0.87 μM for lactic acidosis and also was shown to significantly inhibit mitochondrial respiration after 40 minutes preincubation (Dykens *et al*., 2008b). In contrast, buformin was much less potent in inhibiting the oxygen consumption and its reported IC50 for lactic acidosis is 119 $\pm$ 18 μM. The least toxic compound, which is the only one of the three still on the market is metformin, where the IC50 for lactic acidosis is close to mM concentrations (734 $\pm$ 168 μM). It is thought that these compounds bioaccumulate in the mitochondria, a fact that is supported by our findings that 30 minutes preincubation was required to achieve inhibition of glutamate/malate-driven respiration (Dykens *et al*., 2008b).

Thiazolidinediones are antihyperglycemic drugs used for Type 2 diabetes. The effectiveness of thiazolidinediones for inhibiting Complex I or causing lactate release in skeletal muscle or rat liver homogenates was found to be in the order: rosiglitazone > troglitazone $\gg$ metformin (Brunmair *et al*., 2004b). In addition, a recent study reported that the major targets for thiazolidinediones are Complexes IV and V of the OXPHOS (Nadanaciva *et al*., 2007). Results from this study showed the rank order of potency on mitochondrial respiration to be: rosiglitazone, pioglitazone > darglitazone, muraglitazar > troglitazone. Troglitazone was withdrawn form the market in 1997, due to idiosyncratic hepatotoxicity. Darglitazone and muraglitazar were discontinued in development. Rosiglitazone and pioglitazone recently received a black box label[a] for potential cardiotoxicity. The link between mitochondrial toxicity and the potential contribution to cardiotoxicity remains to be established.

Flutamide also inhibits Complex I (Coe *et al*., 2007) and causes hepatotoxicity. It is thought to mainly inhibit Complex I even though inhibition of succinate-driven respiration has also been shown to occur. Flutamide decreases ATP in hepatocytes and leads to GSH depletion. This might result in inhibition of succinate dehydrogenase, an enzyme containing SH groups in its catalytic site.

Recently, nefazodone was also found to inhibit Complex I, which potentially could contribute to the idiosyncratic hepatotoxicity that led to its withdrawal in 2004 (Dykens *et al*., 2008a).

4.1.2 Complex II/III Inhibitors

Only very few drugs are known to inhibit Complexes II and III of the OXPHOS. Oxaloacetate and malonate are competitive inhibitors of Complex II. Cyclophosphamide or ketoconazole, and hydrazine also inhibit succinate dehydrogenase. 3-Nitropropionic acid inhibits Complex II and is used to mimic Huntington's disease (Souid *et al*., 2003).

The classical inhibitor for Complex III is antimycin. Its binding will cause ROS formation in the OXPHOS chain (Schagger *et al*., 1995). Another Complex III inhibitor is stigmatellin.

Tamoxifen has also been shown to inhibit Complex III (Tuquet *et al*., 2000).

4.1.3 Complex IV Inhibitors

As mentioned above, it has been shown that the main targets of OXPHOS inhibition for the thiazolidinediones are Complexes IV and V (Nadanaciva *et al*., 2007).

Many local anaesthetics inhibit cytochrome c oxidase following order of potency: quinisocaine > butacaine > pramocaine > bupivacaine > carticaine > lidocaine, procaine > prilocaine. This inhibition is in accord with their potency as anaesthetics, and correlates with their lipophilicity (log P) (Casanovas *et al*., 1983; Stringer and Harmon, 1990).

4.1.4 Complex V Inhibitors

The classical Complex V inhibitor is oligomycin (Walker *et al*., 1995). Resveratrol also inhibits Complex V (Gledhill *et al*., 2007), but *in vivo* translation has not been established.

4.2 Drugs Uncoupling OXPHOS

The most well-known mitochondrial uncoupler is dinitrophenol (DNP), which was widely used as a wood preserver. In the 1930s it was used as a diet pill. It caused dramatic weight loss. However, no feedback mechanism exists *in vivo* to regulate the upper limit of body temperature and so people died with overdose. DNP is still illegally used by body builders (Cunarro and Weiner, 1975).

Many members of the NSAIDs are uncouplers. They contain a carboxyl (weak) acid group which can bind to the arachinonate binding sites for COXI and COXII (cyclo-oxygenases I and II). The lipid-soluble nature of the NSAIDs and also the acid group allows the NSAIDs

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat021
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to interact with the inner mitochondrial membrane of enterocytes, binding to phospholipids. They act as protonophores, leading to an increase in oxygen consumption causing ATP depletion and subsequent cell injury and cell death. There are different classes of NSAIDs, such as salicylic acids (aspirin), phenylacetic acids (diclofenac), carbo and heterocyclic acids (indomethacin, sulindac), profionic acids (ibuprofen, fenoprofen, ketoprofen) and fenamic acids (flufenamic acid). NSAIDs potency for increasing basal respiration and inhibiting ADP-stimulated respiration was found to be in the order: flufenamic acid, diflunisal > tolfenamic acid > mefenamic acid > diclofenac > indomethacin > benoxaprofen, naproxen, fenoprofen (Masubuchi *et al*., 1999).

The nitroaromatic compound, nimesulide, also uncouples mitochondrial respiration. Unlike the NSAIDs described above, nimesulide causes less gastroinsestinal toxicity, but rare and serious hepatic dysfunction (Ong *et al*., 2006).

Diclofenac also can cause rare, but serious hepatotoxicity. Diclofenac is taken up by the mitochondrial anion carrier. It uncouples and also induces the MPT (Boelsterli, 2003).

Several long-acting anaesthetics (bupivacaine and etidocaine) have caused severe cardio and myotoxicity. These compounds are lipophilic amphiphilic amines, which can act as true protonophores. Lidocaine also uncouples mitochondria, but to much less extent (Sztark *et al*., 1998).

Tolcapone was withdrawn after only being on the market for six months due to several deaths through hepatic failures. Tolcapone uncouples rat liver mitochondria at 10 μm whereas 50 μM of DNP or 200 μM of entacapone is needed for the same amount of uncoupling (Haasio *et al*., 2002).

The last compound to be discussed is tamoxifen, one of the most widely used agents to treat breast cancer. Tamoxifen may induce fatty liver and nonalcoholic steatohepatitis (NASH) in patients. Tamoxifen has been shown to uncouple mitochondria at 10 nmol mg^{-1} protein, whereas at a dose of 40 nmol mg^{-1} protein, ATP-dependent respiration is inhibited (Tuquet *et al*., 2000).

4.3 Drugs Causing Oxidative Stress

Doxorubicin, an anthracycline, is used for the treatment of various solid tumours and also lymphomas. Its use is somewhat compromised by the fact that it causes cumulative and dose-dependent nonreversible damage to the heart. An increased incidence of arrhythmias has been reported, as well as degeneration of the cardiac muscle. Much work has been done in trying to understand the mechanism leading to the cardiac-specific injury. It is now understood that doxorubicin selectively redox cycles on Complex I of the OXPHOS (see **Figure 4**). The consequences of this are GSH depletion and induction of the MPTP, as well as oxidation of mtDNA. Progress also has been made in trying to understand the cardio-specificity of doxorubicin. Several hypotheses have been postulated: (i) the heart has a high energy demand and therefore relies on continuous ATP production; (ii) the heart has low antioxidant capacity and therefore is prone to oxidative stress and its consequences; (iii) doxorubicin alters cardiac-specific gene transcription; (iv) doxorubicin causes alterations in sarcomeric protein organization and potentially targets nuclear lamina proteins (Berthiaume and Wallace, 2007).

4.4 Drugs Effecting Mitochondrial DNA Synthesis

The adverse effects that are predominantly attributed to NRTIs include peripheral neuropathy, cardiomyopathy, hepatic steatosis and hepatotoxicity, hyperlactataemia and lactic acidosis, Type 2 diabetes or insulin resistance, and lipodystrophy. *In vitro* inhibition of mtDNA transcription shows the following rank order of toxicity: ddC > ddI > d4T > AZT > ABC = 3TC = TDF. The *in vitro* findings correlate well with the observed clinical adverse events related to mitochondrial toxicity (Zungu *et al*., 2006); specifically, ddC and d4T are known to be highly toxic. The European Medicines Evaluation Agency actually issued a guidance document that requires testing of all newly submitted antivirals for mitochondrial DNA depletion (EMEA, 2005). In the USA, there is also guidance for industry (CDER, 2006).

4.5 Drugs Effecting Mitochondrial Protein Synthesis

Classes of antibiotics that bind to the bacterial ribosome and inhibit bacterial protein synthesis include: chloramphenicol, tetracyclines, aminoglycosides, macrolides, lincosamides and most recently the oxazolidinones. IC50 values obtained *in vitro* for inhibition of mitochondrial protein synthesis are well in accord with therapeutic doses. Toxicities observed are different for different antibiotics. For example, chloramphenicol causes a dose-dependent and reversible bone-marrow depression and fatal aplastic anaemia in certain genetically sensitive individuals. Tetracyclines can cause anaemia, thrombocytopenia, central nervous system effects, endocrine and metabolic effects, tooth discolouration, skin photosensitivity, and renal and liver toxicity, especially liver steatosis and myopathy. Members of the aminoglycosides are known to concentrate and persist in the endolymph

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat021
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and perilymph of the inner ear, causing ototoxicity when given at high concentrations.

Linezolid, which belongs to the newer class of the oxazolidinones, causes dose-dependent and reversible bone-marrow suppression (McKee *et al*., 2006; Duewelhenke *et al*., 2007) (**Table 1**).

4.6 Methods to Investigate Mitochondrial Dysfunction

4.6.1 Oxygen Consumption/pH

The traditional way to measure mitochondrial function/dysfunction is by measuring oxygen consumption (oxygraph). Most used for this purpose is still the Clark electrode which is connected to a small glass chamber holding 0.5–3 ml buffer, substrates and mitochondria (Examples of suppliers are *www.oroboros.at* and *www.hansatech-instruments.com*; Hansatech and Orosboros). The chamber is sealed with a plunger to avoid exchange of oxygen with the environment. A chart recorder or computer programmes can be used to monitor oxygen consumption over time. By comparing basal respiration (state 2/4) with ADP-stimulated respiration, one gains understanding on how functional/dysfunctional the mitochondria are.

Figure 6 shows a typical respiration measurement. First mitochondria (usually at 0.5–1 mg ml^{-1}) are added to the chamber. Respiration should be zero if mitochondria have been isolated intact. Upon addition of the substrate, basal respiration is measurable as State 2, which should be low, as no phosphorylation occurs. Upon addition of a small amount of ADP, respiration rapidly increases (State 3). Upon complete phosphorylation of ADP, mitochondria will return to basal respiration (State 4). Often respiratory ratios are calculated by dividing the rate at State 3 by the rate at State 4. In isolated rat-liver mitochondria, this rate would be approximately 6–8 if glutamate/malate is used to fuel OXPHOS Complex I and approximately 4–5 when succinate is used as a substrate.

Naturally, respiratory control ratios (RCRs) are higher for heart and muscle mitochondria with glutamate/malate and can easily reach values of 8–10. An excellent method for oxygraph measurements is described by Heisler (1991).

As mentioned above, drugs can have different effects on respiration, which is illustrated in the figure. For example, if a drug is added to the mitochondria and, after addition of glutamate/malate, no change in oxygen consumption is observed, this compound is a Complex I inhibitor. The block could be bypassed by addition of succinate. If a drug increases basal respiration, it is an uncoupler. Several different degrees of inhibition and uncoupling can be observed, depending on the potency of the compound/drug.

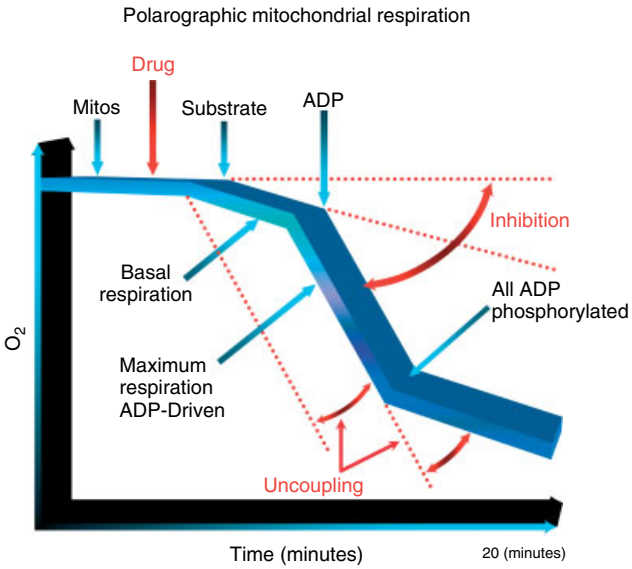

Figure 6 Polarographic measurement of oxygen consumption.

Whereas the oxygraph is the main work horse for students and academics, the method is not applicable to the industrial setting. Here, many compounds will have to be screened to avoid mitochondrial liabilities. Static and soluble sensor technology has allowed much higher throughput (Seahorse and Luxcel). Oxygen consumption can be measured in isolated mitochondria after *in vivo* treatment with drugs or *in vitro* by adding drugs of interest to isolated mitochondria.

Oxygen consumption can also be measured in cells. Whereas the oxygraph will require a larger amount of cells and low throughput, the sensors allow measurement at higher throughput. Oxygen-consumption measurement in cells becomes even more meaningful when paired with pH measurement. A true mitochondrial toxicant would cause an increase in oxygen consumption with a subsequent increase in acidification as compensation through glycolysis, whereas drugs not acting through the mitochondria will lead to a decline in oxygen consumption without a concomitant increase in acidification. pH measurements can also be made using solid and soluble sensor technologies.

4.7 OXPHOS Activities

Often it is also important to understand the possible mechanisms of mitochondrial toxicity as described in **Figure 5**. Activities of the OXPHOS complexes can be measured by spectrophotometry, either in isolated mitochondria, cells or tissues. After careful solubilization with an appropriate detergent, substrates are added, the reaction is monitored over time and rate constants are calculated (Birch-Machin *et al*., 1993). By combining the measurements of amount and activity

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat021
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

through immunocapture, sensitivity can be increased even more (Nadanaciva *et al*., 2007).

5 MITOCHONDRIAL PERMEABILITY TRANSITION

Induction of MPT can be monitored in isolated mitochondria and cells, where it can be measured as swelling, which manifests itself in a decrease in absorbance, monitored at 680 nm spectrophotometrically. Compounds are usually tested in the presence of calcium, which in itself can induce MPT at high concentrations. The classical inhibitors of MPT are cyclosporin A, bongrecic acid and ATP. In cells, MPT is much more difficult to demonstrate. It is measured using calcium and membrane-potential dyes in combination using confocal imaging or other live cell imaging. (Nieminen *et al*., 1995; Qian *et al*., 1997; Trollinger *et al*., 1997; Kim *et al*., 2006).

5.1 Oxidative Stress (ROS)

Oxidative stress (ROS) generation can also be measured in both isolated mitochondria and cells, using specific dyes for superoxide formation such as dihydroethidium (Tay *et al*., 2005), mitosox (Fauconnier *et al*., 2007) and amplex red (Starkov and Fiskum, 2003).

5.2 Cell-Based Assays

Modern drug-discovery and development programmes rely heavily on cell-culture models to assess drug activity and toxicity. The organ toxicities of the drugs discussed in this chapter were not predicted by such culture models, and so drug-induced mitochondrial dysfunction is only now becoming more widely recognized as an important aspect of drug toxicity. Even potent mitotoxicants failed to kill cells in culture, or cause organ toxicity in animal models designed to detect it. Now that we know more about mitochondrial failure, we understand why the standard cell-based assays did not reveal off-target mitochondrial impairment. Indeed, many cells in culture are resistant to canonical mitotoxins such as cyanide, antimycin, rotenone and oligomycin, let alone to less potent xenobiotics being developed as therapeutics. This is because cells grown in culture are almost always provided with abundant glucose as oxidizable substrate, typically 25 mM, which is fivefold higher than physiological. Because of this excess glucose, the medium does not have to be changed as frequently. However, under these high-glucose conditions, the cells are almost completely glycolytically poised, that is, relying on glycolysis for all their ATP needs.

This condition was noted as early as 1929 when Crabtree and Warburg independently found that under high glucose conditions respiration mitochondrial OXPHOS is repressed (Crabtree effect), and that lactate is produced despite the presence of competent mitochondria (Warburg effect). Although there are differences between these two effects, they are essentially variations on a metabolic theme that has generally been attributed to the fundamental glycolytic nature of cancer cells. However, the notion that cancer cells are glycolytic by disposition does not necessarily hold. In a metanalysis of studies where both oxygen consumption and lactate efflux were concomitantly monitored, Zu and Guppy (2004) concluded from 16 studies of normal, freshly isolated cells, that glycolysis contributes anywhere from less than 1% to almost 60% of the total ATP, with an average of 20%, but with a standard deviation that exceeds the mean (SD = 21). A similar analysis of more than 30 cancer cell lines revealed that, on average, these transformed cells derive 18% of their ATP from glycolysis, with an SD that also exceeds the mean (SD = 19). Zu and Guppy (2004) concluded that solid tumours are glycolytically poised because they are hypoxic *in vivo*, not because of fundamental reorganization of metabolic poise. Interestingly, glycolysis increases 34-fold when rabbit thymocytes shift from a resting to a proliferating state, which increases the percentage of glycolytic ATP by an order of magnitude. In this way, the susceptibility of cells to metabolic impairment also depends on what growth phase or state of stimulation the cells are in. Debate continues, no doubt confounded by the nature of these moving targets, but it is clear that we still do not fully understand regulation of metabolic poise.

To render glycolytic cells susceptible to mitotoxicants and hence useful for prediction *in vivo*, glucose in the medium can be replaced by galactose, a sugar that, together with glucose, forms the disaccharide lactose. The net ATP yield from glycolysis with glucose as substrate is 2 mol per mol of fuel. However, for galactose to enter glycolysis, two ATP equivalents have to be invested, so that the net yield from glycolysis to lactate is zero ATP. Under these conditions, the cells are compelled to generate ATP via OXPHOS, and as such become susceptible to mitotoxins (Marroquin *et al*., 2007). Indeed, 100% of HepG2 cells grown in galactose are killed by concentrations of oligomycin in which more than 80% of the glucose-grown cells remain viable (Marroquin *et al*., 2007). The facility with which various cell lines can accomplish this switch is a characteristic of the line. In our hands, hepatoma cells (e.g. HepG2) show immediate and spontaneous increases in respiration and dimunition of extracellular acidification rates, indicating that fully functional mitochondria are present, but not being used much for ATP production. However, other cell lines, such as neuroblastoma (SH SY-5Y) die when acutely transferred into galactose media, so that these

cells require gradual replacement of glucose by galactose over numerous passages. No doubt clonal selection results form the imposed metabolic bottleneck in addition to upregulation of organelle biosynthesis. The use of galactose-grown cells for drug-toxicity screening is just now becoming more widely appreciated, but we suspect the model will gain wide acceptance once its utility for predicting drug safety in *in vivo* models is confirmed. This raises the question of why the standard preclinical *in vivo* models used to evaluate drug safety also fail to predict organ toxicity of many mitotoxins, not to mention many drugs without mitochondrial liabilities. It should be noted in this context that almost all such *in vivo* evaluations are conducted in young, perfectly healthy and drug-naïve animals, precisely the circumstances where drug-induced mitochondrial impairment (DIMI) is least likely to be detected.

The model whereby DIMI yields cell and organ pathology is based on threshold effects and physiological scope, which is the spare capacity inherent in any metabolic pathway. This model also incorporates nonclassical pharmacokinetics, where selective tissue bioaccumulation of the drug can yield cytosolic and mitochondrial concentrations that far exceed plasma levels, which are the primary measures of drug exposure in most current drug-development programmes. In this way, a drug at plasma concentrations insufficient to yield mitochondrial impairment in one cell type can selectively accumulate to injurious levels in another, resulting in toxicity to that organ.

The threshold at which DIMI emerges is likely to be relatively fixed and varies among different cell types. For example, an unstressed hepatocyte needs some finite amount of ATP to conduct normal business, which includes albumin secretion, xenobiotic detoxification, glucose homoeostasis and a host of other processes. This is also the case for more aerobically demanding cells, such as myocardiocytes and neurons that have higher ATP turnover, but also a minimum requirement for homoeostasis. So, although the basal energetic demands varies in different cell types, in a given cell type it is likely to be relatively constant across the population, and therefore unlikely to underlie the idiosyncratic nature of many toxic drug responses. Rather, it is more likely that the aerobic reserve capacity above the threshold needed to maintain basal function varies more widely among individuals. For example, the mitochondrial capacity in a hepatocyte from an alcoholic is substantially less than that found in a drug-naive person in liver disease, so that the impaired hepatocyte will tolerate loss of mitochondrial capacity via drug exposure less well than a cell with robust reserve capacity, and so will show organ toxicity sooner, that is, idiosyncratically (Sastre *et al*., 2007).

6 MITOCHONDRIAL IMPAIRMENT IN IDIOSYNCRATIC DRUG TOXICITY

In an elegant review, Roger Ulrich (2007) points out those idiosyncratic drug reactions, that is, rare toxicity not predicted by preclinical data and unrelated to dose, result from the convergence of several variables that are characteristic for individuals, but that vary across the population. As several of these risk factors converge, the probability of drug-induced organ toxicity increases. The most important factor, that is, the one which accounts for the largest fraction of variance, is increasing age. But Ulrich also identified inhibition of key cellular function, physical activity, genetics and inherited metabolic defects, concurrent exposures, heterogeneity in drug metabolism and bioactivation, underlying disease, nutrition and innate immune response, as other risk factors.

It is telling that all of these risk factors are also unambiguously implicated in idiosyncratic toxicity caused by mitochondrial impairment. In light of the preceding discussion of threshold effects, the mitochondrial capacity declines as we age, reducing the physiological scope and lowering the bioenergetic threshold for cell death. Going through the list of risk factors, almost all have direct mitochondrial counterparts. For example, with inhibition of key cellular function, under normoxic physiological circumstances mitochondrial OXPHOS generates >90% of cellular ATP and, depending on the tissue, energy demand and physiological scope, even modest impairment could prove injurious. Mitochondrial biomass is directly related to physical activity; depending on the timing and type of exercise, the more we exercise, the greater the mitochondrial capacity. As such, a well-trained athlete has greater mitochondrial reserves, and hence can tolerate more DIMI before pathology emerges. This is particularly true for tissues where the bioenergetic capacity is subject to conditioning, such as skeletal muscle and heart, but less so for an organ such as the liver, where bioenergetic capacity reflects organ history more than condition.

Earlier we mentioned that mutations or deletions in mtDNA cause a host of pathologies, and exposure to drugs with mitochondrial toxicity is reported to reveal a previously silent mtDNA disorder, or to exacerbate already frank pathology (Schon *et al*., 2008). In addition, polypharmacy with several mitochondrial toxicants is at least additive (Dykens *et al*., 2007). Heterogeneity in drug metabolism is also an important factor; for example, there are at least six metabolites of troglitazone that have been identified, and the complement of the various cytochrome P450s and other drug-metabolizing systems is thought to contribute to idiosyncratic responses in the population. Not every individual will metabolize the drug in the same way. However, the parent molecule without any such metabolism is a potent mitotoxin, so

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

that we need not invoke a reactive metabolite to explain its toxicity (Dykens *et al*., 2007). However, we may find that such metabolism reduces its toxicity, and in this way heterogeneity in the population would still serve to render some individuals more susceptible to the drug than others. Also, mitochondria may well be capable of catalysing some drug-metabolizing reactions, particularly hydroxylations.

In this light, idiosyncratic drug reactions, and hence organ toxicity due to idiosyncratic mitochondrial reactions, depend on age, organ history and genetics, among others, as noted. However, the animals used in almost all preclinical studies for drug toxicity are young, with abundant mitochondrial capacity not yet diminished by age or drug exposure, and hence possessing maximum bioenergetic scope. As noted above, these are exactly the wrong circumstances to detect drug-induced mitochondrial dysfunction. For example, hepatotoxicity by troglitazone is not detected preclinically in such healthy animals until the activity of the mitochondrial form of the antioxidant enzyme superoxide dismutase is reduced by 50% (Ong *et al*., 2007). In these animals, with artificially repressed reserve antioxidant capacity, troglitazone yields frank hepatic lesions. It remains to be determined whether such pathology is precipitated by the increased oxidative stress resulting from loss of antioxidant capacity *per se,* or to secondary mitochondrial impairment resulting from oxidative inactivation of OXPHOS Fe–S centres. Given that both pathological processes are so functionally intertwined, it seems likely that both contribute to the aetiology of the lesion.

Toxicity of Peroxisome Proliferators

John P. Vanden Heuvel

CONTENTS

1 PEROXISOMES: HISTORY AND FUNCTION

Peroxisomes were first described in mouse kidney cells as 'microbodies' characterized as subcellular organelles with single lipid membranes surrounding a granular matrix of soluble proteins (de Duve, 1969). Subsequently, peroxisomes were shown to be present in many cell types in numerous organisms including plants and mammalian cells. The distribution and relative size of peroxisomes in mammals is variable. Cells containing considerable amounts of peroxisomes include liver, kidney, adrenal cortex and sebaceous cells, while peroxisomes are rarely found in smooth muscle or fibroblasts. In rat liver, peroxisomes account for approximately 2.5% of total protein and are approximately 1.5% of the cell volume (Weibel *et al.*, 1969).

Urate oxidase, D-amino acid oxidase and catalase were some of the first enzymes identified that were localized in peroxisomes (de Duve, 1969). The term 'peroxisome' was first used to describe these organelles, based on the biochemical property of peroxide formation by the enzymes associated with peroxisomes. Since this time, numerous enzymes have been localized within peroxisomes and include many that catalyze reactions central to lipid metabolism. Among the general groups of enzymes are those involved in fatty acid activation (acyl-CoA synthases), β-oxidation, carnitine acyltransferase, bile acid synthesis, glycerolipid synthesis, cholesterol synthesis, fatty acid elongation, metabolism of oxygen or reactive oxygen species and nucleotide binding proteins (see Osmundsen *et al.* (1991) for review).

Biological roles of peroxisomes in respiration, gluconeogenesis, thermogenesis, purine catabolism and lipid metabolism have all been described. There are similar enzymes to those found in peroxisomes in other cellular compartments, including the cytoplasm and mitochondria. This is particularly true for the fatty acid metabolizing enzymes, where similar steps in β-oxidation occur in both peroxisomes and mitochondria (see **Figure 1**). Peroxisomes preferentially oxidize long-chain fatty acids prior to further mitochondrial oxidation to modulate energy production, since peroxisomal oxidation yields H_2O_2 and heat, rather than mitochondrial oxidation which produces energy in the form of NADH or $FADH_2$. A key component of the peroxisome is the enzyme catalase. This enzyme detoxifies hydrogen peroxide generated from the first and rate-limiting enzyme in the peroxisomal β-oxidation pathway, acyl-CoA oxidase (ACO). The relationship between catalase, ACO and cancer will be discussed below under the auspices of oxidative stress.

2 PEROXISOME PROLIFERATION

The phenomenon of peroxisome proliferation was first reported by several groups in the mid-1960s (Hess *et al.*, 1965). These investigators demonstrated significant increases of hepatic peroxisomes in both size and

number in response to administration of the hypolipidaemic drug clofibrate in rats. This peroxisome proliferation accompanied hepatomegaly in these animals. Peroxisomes typically occupy less than 2% of the cytoplasmic volume, while treatment with fibrate drugs increases this volume to as much as 25%. In addition to

peroxisome proliferation and hepatomegaly, peroxisomal fatty acid oxidation is induced, and long-term administration of hypolipidaemic drugs causes hepatocarcinogenesis (Reddy *et al.*, 1976), as will be discussed in more detail below. A number of structurally diverse compounds were later identified that share the morphological and biochemical response of clofibrate and deemed 'peroxisome proliferators'. Peroxisome proliferators (PPs) are a diverse class of chemicals and include the fibrate class of hypolipidaemic drugs (clofibrate, ciprofibrate), Wy-14,643 (often used as the prototypical PP), commercially used plasticizers (phthalates), steroids (dehydroepiandrosterone (DHEA)), and dietary fatty acids or derivatives (**Figure 2**). Further, starvation or feeding high levels of fatty acid can induce peroxisome proliferation, although the magnitude of the effect is substantially lower than that found with treatment with xenobiotics.

During the mid-1980s, it was suggested that the biological effects induced by PPs were mediated by an unidentified cytosolic receptor that modulated gene expression to cause the pleiotropic effect of these chemicals (Reddy and Lalwai, 1983). There were several reasons for this hypothesis. First, the peroxisome proliferation response was tissue-, species- and sex-dependent. Second, although PPs are structurally diverse, structure–activity relationships were identified, and most chemicals able to cause peroxisome proliferation were found to share a fatty acid-like structure. Last, PPs regulate a battery of genes involved in fatty acid metabolism with a similar dose–response relationship. Based on the hydrophobic nature of PPs, it was hypothesized that the heretofore-unidentified receptor would be a nuclear hormone receptor. In 1990, a receptor termed peroxisome proliferator-activated receptor (PPAR) was cloned from mouse liver using the oestrogen receptor DNA binding domain as a probe (Issemann and Green, 1990). Discovery of PPAR has proven to be pivotal to the understanding of how PPs regulate gene expression and ultimately result in toxicity.

3 PEROXISOME PROLIFERATOR-ACTIVATED RECEPTORS (PPARs)

3.1 Introduction

PPARs are members of the nuclear receptor (NR) superfamily of transcription factors, similar in both structure and function to the steroid, thyroid and retinoid receptors. The NR superfamily of proteins is subdivided into six sub-families, based on their amino acid sequence similarities (Nuclear Receptors Nomenclature Committee, 1999). In the systematic nomenclature for NRs, PPARs comprise the group C of subfamily 1 (Nuclear Receptors Nomenclature Committee, 1999). The multifaceted responses of PPARs are mediated by three subtypes expressed in different tissues and at different times in development. The subfamily has been defined as PPARα (NR1C1), PPARβ (also called PPARδ and NUC1, NR1C2) and PPARγ (NR1C3), each with a possibility of different ligands, target genes and biological role (**Figure 3**).

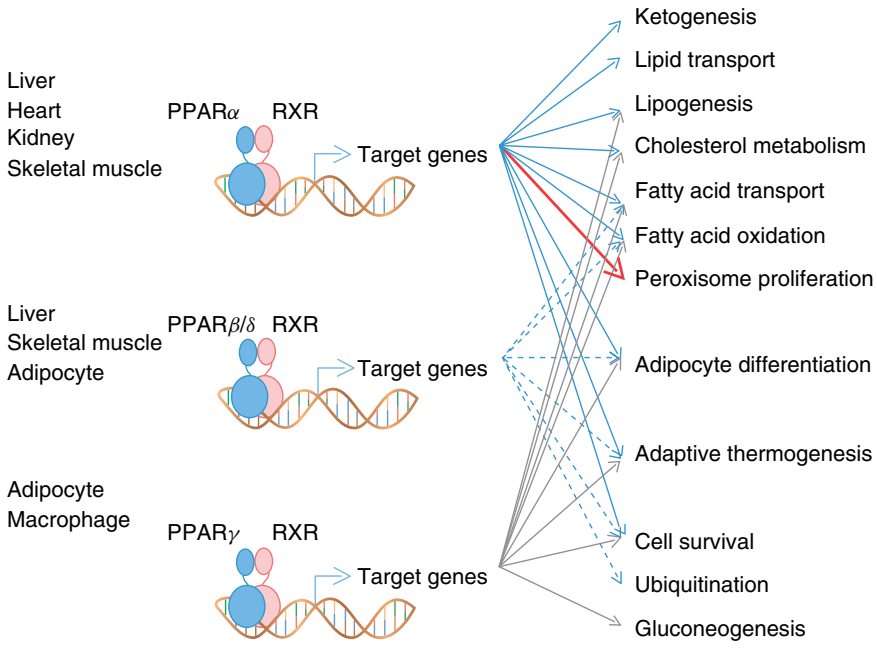

Figure 3 Basic mechanism of action of peroxisome proliferator-activated receptors. (Summarized from KEGG Pathways, http://www.genome.ad.jp/kegg/pathway/hsa/hsa03320.html).

3.2 Mechanism of Action

The structure and mechanism of action of all NRs is very similar. In general, there are three functional domains: (i) a ligand-binding/dimerization domain, (ii) a DNA-binding/weak dimerization domain, and (iii) transactivation domains activation function 1 (AF-1) and activation function 2 (AF-2). The ligand-binding domain at the carboxy terminus of the receptor is where endogenous or xenobiotic ligands bind, resulting in a conformational change of the receptor that alters its biophysical properties. Many receptors, including PPARs, require heterodimerization with retinoid X receptor (RXR) (Mangelsdorf and Evans, 1995) for DNA binding. The DNA binding domain of the receptor is responsible for recognition of a receptor-specific response element consisting of a sequence of nucleotides in the promoter region of the target gene. The transactivation domains consist of a ligand-independent AF-1 domain in the amino terminus and a ligand-dependent transcription AF-2 found in the ligand-binding domain. These domains are protein–protein interface domains that direct recruitment of transcriptional coactivators to the target gene (Glass and Rosenfeld, 2000). In short, NRs are ligand-activated transcription factors that result in their pleiotropic responses by directing target gene expression.

3.3 Target Gene Expression

The PPAR/RXR complex controls gene expression by interacting with specific DNA response elements (peroxisome proliferator response elements, PPREs) located upstream of target genes (Tugwood *et al.*, 1992). Genes containing PPRE motifs include ACO (Tugwood *et al.*, 1992), peroxisomal bifunctional enzyme (PBE or BIF (Zhang *et al.*, 1992)), liver fatty acid-binding protein (L-FABP (Issemann *et al.*, 1992)) and microsomal CYP4A (Muerhoff *et al.*, 1992), although many more have been described (Juge-Aubry *et al.*, 1997). Members of the RXR-interacting subgroup of NRs typically bind to DNA elements containing two copies of direct repeat arrays spaced by 1–6 nucleotides (DR1–DR6). The idealized consensus binding site (AGGTCA) is similar for most members of this class of NR, with the specificity dictated by the number of nucleotides between half-sites as well as the 5′ flanking elements (Juge-Aubry *et al.*, 1997). In the case of PPAR, a DR1 motif is preferred, with PPAR interacting with the 5′ repeat and RXR (α, β or γ) binding to the 3′ motif (Ijpenberg *et al.*, 1997). PPREs are similar for all three PPAR subtypes (Ijpenberg *et al.*, 1997; Juge-Aubry *et al.*, 1997).

In addition to regulating PPRE-target genes, PPARα can affect gene expression in a non-DNA binding mechanism via protein–protein interactions. Including its heterodimerization partner RXRα, PPARα associates with heat shock protein 70 (hsp70 (Huang *et al.*, 1994)), hsp90 (Sumanasekera *et al.*, 2003a; 2003b), hepatitis X-associated protein (XAP2) (Sumanasekera *et al.*, 2003b), liver X receptor (LXR) (Miyata *et al.*, 1996), C/EBPα (Hollenberg *et al.*, 1997) and NF-κB subunits (Fruchart *et al.*, 1999). These interactions may influence the activity of numerous transcription factors and hence regulate genes that do not contain PPREs. A good example of such a gene is prolactin, which is regulated by PPs independent of PPARα's DNA binding (Tolón *et al.*, 1998).

3.4 PPARα and Gene Expression

The PP response (hepatomegaly, increased peroxisome enzymes) is due almost exclusively to the PPARα subtype and will be the focus of the subsequent discussion. **Figure 4** provides a summary of mRNAs that are altered as a result of treatment with PPs. As noted, administration of PPs causes changes in numerous mRNAs, and many of these genes are central to lipid metabolism. For example, mRNAs encoding peroxisomal, mitochondrial and microsomal fatty acid metabolizing enzymes are all increased by PPs. Further, liver mRNAs encoding proteins involved in lipid transport including fatty acid binding protein, fatty acid transporters, lipoprotein lipase and apolipoproteins are also regulated by these chemicals. Expression of mRNAs encoding other lipid-related proteins that are altered as a result of PPs includes HMG CoA synthase, lecithin:cholesterol acyl transferase, stearoyl-CoA desaturase 1, fatty acid synthase, S14 and malic enzyme, which are involved in cholesterol metabolism and lipogenesis. In addition to modifying gene expression essential to lipid metabolism, PPs can also influence mRNAs encoding proteins that regulate cell proliferation or the acute phase response. Lastly, PPARα can mediate alterations in mRNAs associated with steroid metabolism (17β-HSD), prostaglandin synthesis (COX-2), iron metabolism (transferrin), nitrogen metabolism (GOT, GPT) and hepatitis B viral replication. While it is clear that PPARα is critical in the regulation of lipid metabolism, and that this receptor likely regulates cell proliferation/apoptosis underlying PP-induced hepatocarcinogenesis, the precise role for some of these alterations in gene expression is not understood. For many of the target genes that regulate lipid metabolism, functional PPREs have been identified in their respective promoter region, including peroxisomal fatty acid metabolizing enzymes, fatty acid transporter, apolipoproteins and lipoprotein lipase.

Gene expression profiling has been performed on a wide variety of PPs including monoethyhexylphthalate (MEHP), clofibrate, Wy-14,643 and perfluorooctanoic acid (PFOA), to name a few (reviewed in Woods *et al.*, 2007). Toxicogenomic analysis has been used to discriminate between transcriptional responses to

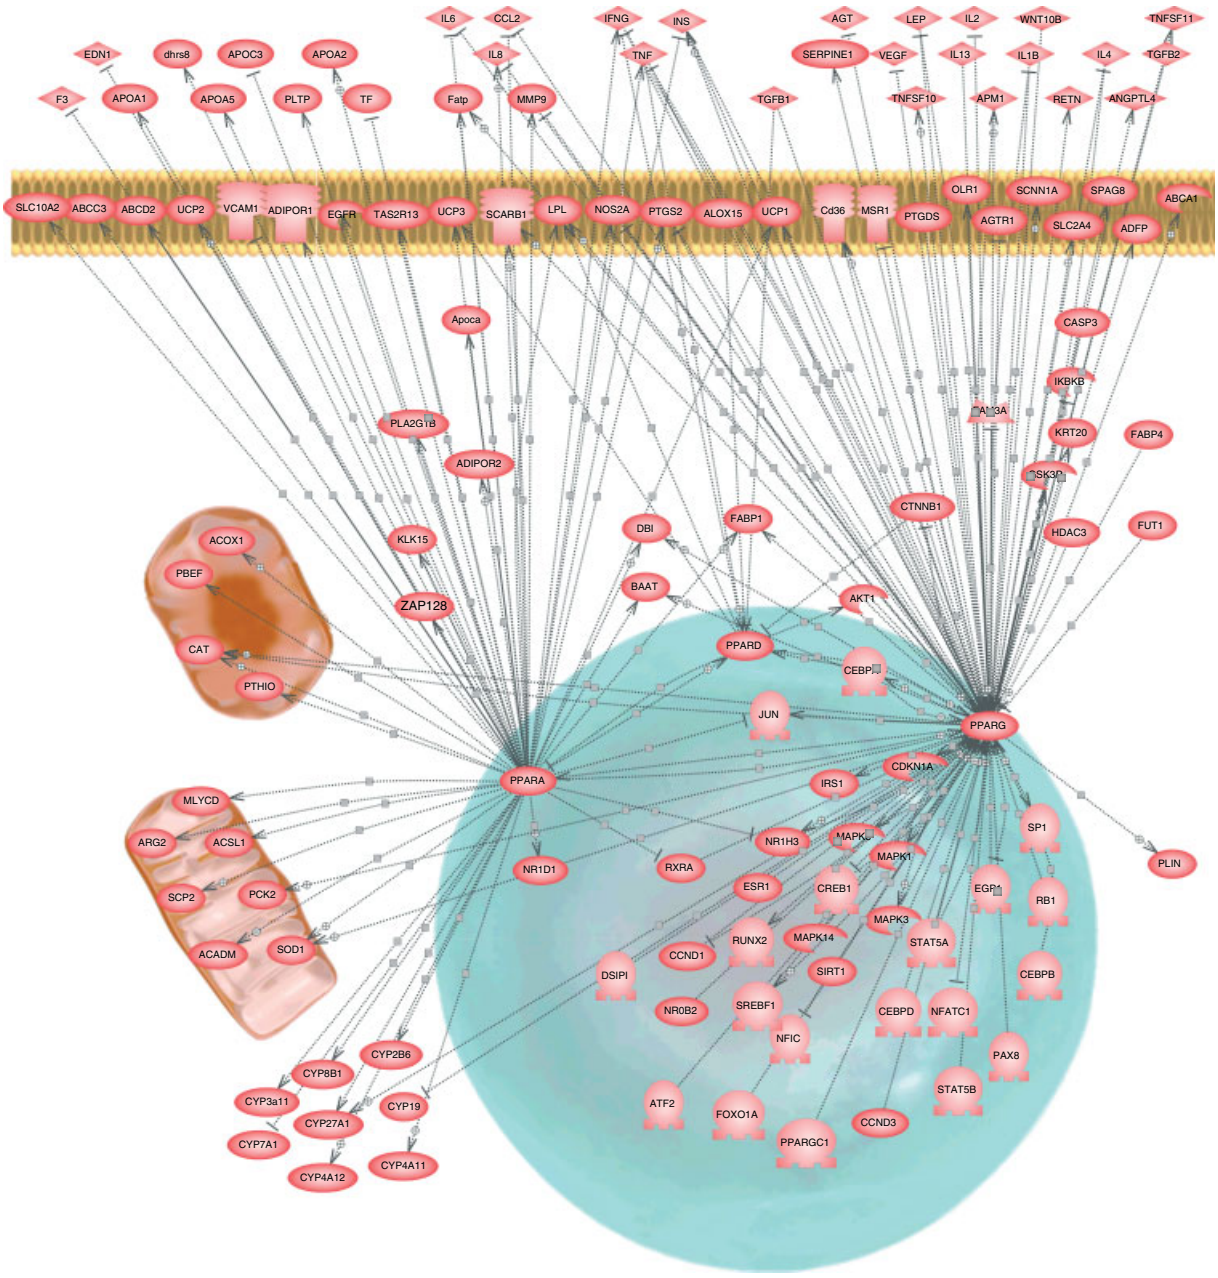

Figure 4 Regulatory network of genes regulated by peroxisome proliferators via PPARα. (Prepared using PathwayStudio® 4.0 software (Ariadne Genomics, Rockville, MD). Using Medscan natural language processing, information from all abstracts on PubMed and other public data sources was extracted to assemble molecular networks.)

chemicals of different classes. For example, in mouse liver the transcript profiles of activators of PPARα (Wy-14,643, clofibrate or gemfibrozil) were much more similar to each other than to that of a constitutive androstane receptor (CAR) agonist phenobarbital (PB) (Hamadeh *et al.*, 2002). All compounds caused an induction of genes involved in fatty acid metabolism, cell proliferation and acute phase proteins and a suppression of genes associated with gluconeogenesis. However, PPARα agonists produced a significantly greater increase in β-oxidation pathways, whereas PB caused a large response of genes encoding for detoxification and microsomal enzymes. It is generally believed that the similar responses of the PPs are those that are regulated via PPARα, although each chemical may have specific, off-target effects.

4 PPARα-DEPENDENT TOXICITY

PPARα agonists are collectively referred to as PPs because of the hyperplastic effects on liver peroxisomes following exposure in rodents (Reddy and Krishnakantha, 1975). In addition to peroxisomal proliferation, the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

size and number of hepatocytes also increases, causing significant liver enlargement. Chronic administration of PPs in rodents leads to liver tumourigenesis by a nongenotoxic mechanism (Marsman and Popp, 1994). These two phenomena (hepatic peroxisome proliferation/hepatomegaly and hepatocarcinogenesis in rodents) are seen with this class of compound and are dependent on the presence of PPARα (Klaunig *et al.*, 2003). Other toxic responses have been reported for PPs (see **Table 1**). For example, male reproductive and developmental toxicity and carcinogenic effects in testis, pancreas and kidney have also been associated with chronic administration of several PPARα agonists (Biegel *et al.*, 2001; Kurokawa *et al.*, 1988). However, this is not seen with all PPs and there is either lacking or conflicting evidence of whether PPARα is the key mediator (reviewed in Peraza *et al.*, 2006). In the subsequent discussion we will focus on the accepted PPARα-dependent responses, how they have been definitively studied and what this may mean to human health risk.

4.1 PPARα-Null Mouse

In 1995, the PPARα-null mouse was first described (Lee *et al.*, 1995). Targeted disruption of the murine PPARα gene was not developmentally lethal, thus providing an excellent model to examine the role of PPARs in homeostasis, toxicity and cancer. In the initial report, PPARα-null mice were described as refractory to peroxisome proliferation, hepatomegaly, and increased expression of mRNAs encoding peroxisomal and microsomal fatty acid metabolizing enzymes. Subsequently, this mouse model has been used extensively to examine the role of the PPARα in PP hepatocarcinogenesis, lipid homeostasis and alterations in gene expression elicited from a variety of stimuli, such as feeding experimental diets, fasting and cold acclimation (Klaunig *et al.*, 2003; Gonzalez and Shah, 2008). Combined, these data have provided definitive *in vivo* evidence that the PPARα has a critical role in modulating gene expression to maintain lipid homeostasis. Further, these reports conclusively demonstrate that the PPARα is the only member of this receptor subfamily capable of mediating peroxisome proliferation and, most importantly, hepatocarcinogenesis induced by PPs. Hence, the term peroxisome proliferator-activated receptor best describes the PPARα, yet will continue to be used for the other two PPAR isoforms due to significant sequence homology.

Table 1 Toxicity of peroxisome proliferators in laboratory animals

Toxic response	PPARα dependence
Hepatocarcinogenesis	Yes
Other tumours (Leydig, pancreatic acinar, kidney)	Questionable
Hepatotoxicity	Questionable
Cardiotoxicity/lipotoxicity	Yes
Reproductive/developmental	Questionable
Muscle toxicity	Questionable

4.2 Peroxisome Proliferator Hepatocarcinogenesis

Long-term administration of PPs causes hepatocarcinogenesis in rodent models (Klaunig *et al.*, 2003). The carcinogenic effect of these chemicals is only seen when there is significant peroxisome proliferation (i.e. greater than four-fold increase in peroxisomal ACO activity) (Ashby *et al.*, 1994). Due to limited peroxisome proliferation, hepatocarcinogenesis is not likely to occur in response to physiological activation of PPARα-dependent transcription such as that observed with fasting or feeding a diet rich in fatty acids. PPs that cause hepatocarcinogenesis include the fibrate class of hypolipidaemic drugs, Wy-14,643, DHEA, di(2-ethylhexyl) phthalate (DEHP) and trichloroethylene (reviewed in Gonzalez and Shah, 2008). The incidence of hepatocarcinogenesis in wild-type mice fed the potent PP Wy-14,643 for 11 months is 100%, while PPARα-null mice are refractory to this effect (Peters *et al.*, 1997). Microscopic examination of livers from PPARα-null mice fed Wy-14,643 also failed to identify any preneoplastic lesions. Thus, it is clear that the carcinogenic effect of these chemicals is mediated by PPARα; however the specific mechanisms underlying this effect have not been fully elucidated. Further, it is likely that a species difference in sensitivity to PPs exists, and this will be discussed later. A number of possible mechanisms for PP-induced hepatocarcinogenesis have been hypothesized, including: (**i**) increased oxidative damage to intracellular macromolecules (DNA, protein, lipids) that contribute to gene mutations indirectly; (**ii**) increased cell replication in the presence of damaged cells; and (**iii**) inhibition of apoptosis, resulting in the persistence of damaged cells.

4.2.1 Oxidative Stress

One of the first hypotheses to explain the carcinogenic effect of these chemicals is that peroxisome proliferation causes oxidative damage, resulting from increased intracellular concentration of H_2O_2 produced by peroxisomal ACO (Reddy and Rao, 1989). Hydrogen peroxide in the presence of metals facilitates free radical formation, which may in turn damage macromolecules. Oxidative stress may occur as a result of the large induction of ACO caused by PPs in the absence of significant increases of catalase (Nemali *et al.*, 1988). Evidence demonstrating intracellular oxidative damage resulting from PPs is inconsistent. Peroxide-modified lipids have been detected in hepatocytes from rats treated with either Wy-14,643, clofibrate or DEHP (Conway *et al.*,

1989; Marsman *et al.*, 1992). However, more sensitive measures of oxidative damage, including ethane exhalation and hepatic levels of esterified F2-isoprostanes, are not markedly influenced by administration of Wy-14,643 (Conway and Popp, 1995; Soliman *et al.*, 1997). Evidence showing oxidative damage to DNA resulting from PPs is also inconsistent. DNA damage in the form of 8-hydroxydeoxyguanosine (8-OH-dG) has been reported in liver from rats after long-term treatment with PPs, including DEHP (Takagi *et al.*, 1990). However, the increase in 8-OH-dG residues is small (less than two-fold), not sustained with chronic DEHP treatment, and the correlation between 8-OH-dG levels and tumour multiplicity is weak (Marsman *et al.*, 1988). In contrast to the studies demonstrating oxidative damage to DNA, no measurable increase in 8-OH-dG or thymidine glycol was reported in rat liver after administration of nafenopin (Hegi *et al.*, 1990).

Despite evidence that PPs cause intracellular oxidative damage to lipids or DNA, most investigations support the idea that PPs are nongenotoxic carcinogens (Klaunig *et al.*, 2003). Numerous assays designed to determine the genotoxicity of chemicals have been utilized to assess the effect of PPs, including mutation, genotoxicity, DNA damage, chromosomal damage and cell transformation assays. Nonetheless, there is one report suggesting that H_2O_2 produced from overexpression of ACO in NIH3T3 cells causes cell transformation (Chu *et al.*, 1995). While this suggests that oxidative damage can lead to cell transformation *in vitro*, this has not been clearly demonstrated *in vivo*.

Interestingly, spontaneous peroxisome proliferation, induction of many PPARα target genes and hepatocarcinogenesis are all found in ACO-null mice after one year of age (Fan *et al.*, 1996). This phenotype is remarkably similar to that of rodents fed PPs, suggesting that in the absence of fatty acid oxidation by peroxisomal acyl-CoA oxidase, a fatty acid metabolite accumulates and increases PPARα-dependent transcription. Thus, ACO may function to metabolize this unidentified fatty acid metabolite to prevent accumulation that ultimately would result in peroxisome proliferation and hepatocarcinogenesis.

4.2.2 Cell Cycle Control

Alterations in cell cycle control constitute another postulated mechanism of PP-induced carcinogenesis. A significant increase in liver weight is always found in rodents fed PPs, and this is due in large part to increased cell proliferation as measured by ^{3}H-thymidine or bromodeoxyuridine incorporation in hepatocytes (Plant *et al.*, 1998; Anderson *et al.*, 2001). Since hepatomegaly and increased expression of cell cycle control proteins are not found in PPARα-null mice treated with PPs (Peters *et al.*, 1997; 1998), the mitogenic effect of these chemicals clearly requires this receptor. Perhaps PPs, acting through PPARα, alter the expression of a particular subset of genes that in turn affects the rate of proliferation of cells. Several early studies indicated that the degree of peroxisome proliferation correlated poorly with the relative hepatocarcinogenicity of PPs. However, a strong correlation was observed between the relative tumour promoting activity of the PPs DEHP and Wy-14,643, with the ability to induce a persistent increase in replicative DNA synthesis (Marsman *et al.*, 1988).

Although most genes known to be regulated by these chemicals are involved in fatty acid metabolism (reviewed in Desvergne *et al.*, 1998; Desvergne and Wahli, 1999), there are several PP-responsive genes with a link to cell cycle control. Induction of the oncogenes c-Ha-ras, jun and c-myc by PPs has been reported, and the ability to induce these genes correlates well with tumour promoting potential (Vanden Heuvel, 1999). For example, the tumour promoters Wy-14,643, clofibrate, ciprofibrate and DEHP were inducers of c-fos, c-jun, junB egr-1 and NUP475, whereas the noncarcinogenic peroxisome proliferator DHEA was ineffective (Ledwith *et al.*, 1996). In addition, an immediate early gene (IEG) critically involved in lipid metabolism, tumour promotion and inflammation, COX-2, is also regulated by PPs (Ledwith *et al.*, 1997). A novel IEG involved in neuronal differentiation, rZFP-37, is a PP-regulated gene in rodent liver (Vanden Heuvel *et al.*, 1998). Both rZFP-37 and c-myc have been demonstrated to be controlled by PPARα (Vanden Heuvel *et al.*, 1998; Belury *et al.*, 1998), using the null mouse model. Many of the genes described above are critical in the progression of the cell cycle, in particular the G_1 to S transition. PP-induced expression of growth regulatory genes precedes entry of the cell into S phase (Ledwith *et al.*, 1997). Also, expression of cell cycle control proteins associated with cell replication (cyclins, cyclin-dependent kinases) are increased as a result of treatment with PPs (Rininger *et al.*, 1996; Ma *et al.*, 1997).

A genomics study in immortalized hepatocytes from PPARα wild-type and knockout mice treated with Wy-14,643 demonstrated a PPARα-dependent induction of ACO and genes regulating cell cycle, along with changes in other genes implicated in cancer, such as JunB, and retinoblastoma protein 1 (Rb1) (Tien *et al.*, 2003). Also, the Wy-14,643-induced increase in growth rate was PPARα dependent, but this response has not been observed in other pure cell cultures. Previous studies conducted *in vitro* using primary cells have demonstrated that hepatocytes, in absence of Kupffer cells or Tumor necrosis factor (TNF)α, do not exhibit Wy-14,643-induced cell proliferation (Parzefall *et al.*, 2001). One major difference between primary and permanent cultures is the capacity for proliferation, with permanent cultures exhibiting higher cell turnover, which likely explains the difference between the observations in this study and historical data.

Hepatocyte growth factor (HGF) is altered as a result of PP treatment and thus could influence hepatocyte cell

proliferation. Administration of PPs to rats decreases hepatic HGF mRNA after short-term feeding with Wy-14,643 (Motoki *et al.*, 1997; 1999), with a continuing decline to less than 50% of control levels after 40 weeks of feeding (Motoki *et al.*, 1997). The reduction in liver HGF mRNA levels is found in nontumour portions of cancerous livers in PP-treated rats, although a more striking decrease is found in the tumour regions of the same livers (Motoki *et al.*, 1997; 1999). Since HGF can also inhibit colony formation in soft agar of neoplastic or preneoplastic liver cells from Wy-14,643-fed rats, this suggests that decreased HGF expression resulting from PP treatment could contribute to the mechanisms underlying PP-induced hepatocarcinogenesis. Importantly, PP-induced reduction of HGF requires a functional PPARα (Kiss *et al.*, 2001). However, these studies also showed that hepatomegaly and expression of mRNAs encoding cell cycle control proteins resulting from PP feeding are not prevented in two different lines of transgenic mice overexpressing liver HGF at substantially high levels. Thus, the precise role of reduced HGF expression in the pleiotropic response resulting from PP treatment is unclear.

Consistent with peroxisome proliferators' role as hepatic tumour promoters, these chemicals decrease the rate of programmed cell death, thereby altering the balance between mitosis/apoptosis, a key mechanism in carcinogenesis (Bayly *et al.*, 1993; James and Roberts, 1994; Roberts *et al.*, 1995). A proteomics study was conducted with clofibrate-treated rats (Léonard *et al.*, 2006). As expected, the altered proteins were involved in lipid metabolism, fatty acid metabolism, amino acid metabolism, protein metabolism, citric acid cycle, xenobiotic detoxification and oxidative stress. However, several proteins were implicated in apoptosis, such as prohibitin, 10-formyl tetrahydrofolate dehydrogenase, senescence marker protein-30, pyridoxine 5′-phosphate oxidase and vimentin. PPARα is an essential component of PP repression of cell death as determined with the null mouse model (Hasmall *et al.*, 2000). In addition, overexpression of a dominant negative PPARα, (thereby abolishing PPARα activity) abrogates the suppression of apoptosis by PPs (Roberts *et al.*, 1998). Additionally, hepatocytes from PPARα-null mice are refractory to suppression of apoptosis caused by PPs (Hasmall *et al.*, 2000). Combined, there is evidence that PPARα can regulate the response to PPs by preventing programmed cell death that potentially results in cell proliferation of 'damaged' cells which would normally undergo apoptosis.

Microarray studies in mouse liver following two weeks of dietary treatment of potent PP, 4-chloro-6-(2,3-xylidino)-2-pyrimidinylthioacetic acid (Wy-14,643) revealed similar results with altered expression of genes involved in lipid and glucose metabolism, transcription, apoptosis and cell cycle (Cherkaoui-Malki *et al.*, 2001). A novel set of 27 PP-regulated genes were identified and included cell death inducing DNA fragmentation factor α, retinoic acid early transcript γ, cell surface receptors Cd39, Cd24, pyruvate dehydrogenase-kinase-4 (Pdk-4), Cyp2b9 and Cyp2b10. Furthermore, PPARα dependency was demonstrated for many of these genes, as no increase in expression was observed in PPARα knockout mice.

Another possible mechanism by which PPs could effect gene expression and hepatocarcinogenesis is through influencing the expression of microRNAs (miRNAs) that in turn could alter gene expression or levels of specfic mRNAs. Indeed, miRNA arrays revealed a marked change in the expression of several miRNAs after a four-hour short-term Wy-14,643 treatment (Gonzalez and Shah, 2008). The mechanism of hepatocellular proliferation involves downregulation of the miRNA let-7c gene by PPARα. Let-7c controls levels of c-myc by destabilizing its mRNA. Thus, upon suppression of let-7c, c-myc mRNA and protein are elevated, resulting in enhanced hepatocellular proliferation.

4.2.3 Species Differences

There is considerable debate concerning the mechanisms by which PPs cause liver tumours in rodent models and whether these chemicals represent a human cancer risk. It is well established that long-term administration of PPs results in hepatocarcinogenesis in rats and mice (reviewed in Klaunig *et al.*, 2003). In contrast, liver tumours are not found in Syrian hamsters after long-term administration of PPs. Similar investigations in nonhuman primates indicate that these species are also refractory to the PP-induced liver cancer, although these experiments were not carried out over the lifespan of the animals. Consistent with this idea, hepatic peroxisome proliferation is not found in nonhuman primates treated with these chemicals. Liver biopsies from humans treated with gemfibrozil, clofibrate or fenofibrate for periods ranging from 27 to 94 months did not reveal convincing evidence of peroxisome proliferation, supporting the hypothesis that humans are less responsive to PPs. Further support of this idea is provided by two limited epidemiological studies that showed no evidence of increased cancer risk as a result of fibrate therapy. While these observations suggest that a significant species difference in the response to PPs exists, it is critical to delineate the mechanisms of this putative difference in order to increase the confidence of risk assessments made for this class of chemicals.

An important advance in understanding the human relevance of PP hepatocarcinogenesis came with the development of the 'humanized' PPARα mouse (Cheung *et al.*, 2004). This line expresses the human receptor in liver in a PPARα null background by placing the human peroxisome proliferator-activated receptor alpha (hPPARα) cDNA under control of the Tet-Off system of doxycycline control with the liver-specific LAP1 (C/EBPβ) promoter (reviewed in Gonzalez and Shah,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat023
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2008). In the absence of doxycycline, hPPARα is constitutively expressed and after administration of a PP, target genes are affected specifically in the liver. For example, treatment of humanized mice with Wy-14,643 resulted in increased expression of ACO, bifunctional enzyme (BIEN) and thiolase (THIOL) and the fatty acid transporter CD36. Upon treatment with Wy-14,643, hPPARα mice had lower levels of fasting serum total triglycerides similar to wild-type mice expressing native mPPARα. Importantly for this discussion, hPPARα mice do not show any significant hepatocellular proliferation, nor did they have an induction of cell cycle control genes (PCNA, c-myc, c-jun, Cdk1, Cdk4 and several cyclins) upon treatment with Wy-14,643, unlike the wild-type mice. Humanized PPARα mice were resistant to Wy-14,643-induced hepatocarcinogenesis after 11 months of Wy-14,643 feeding in contrast to a 100% incidence in the wild-type mouse group (Morimura *et al.*, 2006) (**Table 2**). These findings suggest that the species-specific effects of fibrates are likely due to differences in the profile of genes activated by mPPARα versus hPPARα following fibrate treatment (Gonzalez and Shah, 2008).

4.3 Cardiotoxicity/Lipotoxicity

Activation of PPARα and to some extent PPARβ/δ plays a major role in heart metabolism. The postnatal mammalian heart uses mitochondrial fatty acid oxidation as the chief source of energy, and PPARα regulates the expression of several key enzymes involved in cardiac mitochondrial fatty acid oxidation. In cardiac hypertrophy and heart failure, myocardial energy utilization reverts to the foetal pattern, and metabolic substrate switches from fatty acid to glucose with a decrease of PPARα expression. Overexpression of PPARα in heart in mice increases myocardial fatty acid oxidation and decreases myocardial glucose uptake and oxidation (Hopkins *et al.*, 2003), a metabolic phenotype strikingly similar to that of the diabetic heart (Snyder, 1991). The hearts of these mice exhibited signs of diabetic cardiomyopathy including ventricular hypertrophy, activation of gene markers of pathologic hypertrophic growth, and transgene expression-dependent alteration in systolic ventricular dysfunction. In addition, the recovery from ischaemic injury is affected in the mice with overexpressed PPARα (Sambandam *et al.*, 2006). Insulin-resistant mice crossed into a PPARα-null background did not exhibit evidence of mitochondrial biogenesis or induction of mitochondrial gene expression indicative of the insulin resistant heart (Duncan *et al.*, 2007). Conversely, transgenic mice with cardiac-specific overexpression of PPARα exhibited signatures of cardiac mitochondrial biogenesis. Uptake of fatty acids by the heart is crucial in the development of lipotoxicity in the transgenic PPARα animals (Yang *et al.*, 2007). There is no report indicating that available PPARα activators (fibrates) induce either deleterious or beneficial effects on cardiac function in patients with heart failure. Nevertheless, it has been reported that PPARα and PPARγ agonists prevent left ventricular diastolic dysfunction in diabetic rats (Kim *et al.*, 2003), possibly through an improvement of the hyperglycaemia and/or hyperlipidaemia. Thus, the physiological importance of PPARα in cardiac tissue is evident and there is evidence of unfavourable effects of PPARα activation in lipid metabolism (lipotoxicity) in cardiomyocytes. Whether exogenous PPARα ligands can exacerbate pathologic cardiac hypertrophy in individuals with diabetes type 2, metabolic syndrome or obesity needs to be further studied.

Table 2 Incidences of liver tumours in hPPARα and wild-type (mPPARα) mice treated with Wy-14,643[(a)]

Genotype	Treatment	Tumours (%)
hPPARα	Control	0
hPPARα	Wy-14,643	5
mPPARα	Control	0
mPPARα	Wy-14,643	71

[(a)] Mice were fed with 0.1% Wy-14,643 for up to 44 weeks. Adapted from (Gonzalez and Shah, 2008).

5 SUMMARY AND CONCLUSION

In summary, PPs are a diverse class of chemicals that are capable of producing a consistent pleiotropic response. The effects observed in rodent liver include peroxisome proliferation, hepatomegaly, regulation of gene expression, cell cycle control and, ultimately, carcinogenesis. The majority of biological effects induced by PPs are mediated by the PPARα, and include physiological, toxicological and carcinogenic pathways. Acting as transcription factors, PPARα functions in classic NR fashion by ligand binding, heterodimerization, recruitment/dissociation of coactivators/co-repressors, and modulation of transcription after binding to specific responsive elements of target genes. Definitive evidence of the biological and toxicological role of this receptor has been provided by extensive analysis of PPARα-null mice. The mechanisms underlying PP-induced hepatocarcinogenesis are not clear, although oxidative stress, increased cell proliferation and/or repressed apoptosis are likely to have roles in this process. Whether or not the hepatocarcinogenic effect of PPs routinely observed in rodent models is relevant to humans is a controversial issue and requires ongoing molecular and cellular research.

Reactive Oxygen Species in the Induction of Toxicity

Giorgio Lenaz and Paola Strocchi

CONTENTS

1 INTRODUCTION

Reactive oxygen species (ROS), although recognized to be physiologically involved in cell signalling by affecting the oxidoreductive (redox) state of signalling proteins, are among the major determinants of toxicity in cells and organisms. These aggressive derivatives of partial oxygen reduction exert their damaging effects in mainly two ways: (i) by direct modification of cellular or extracellular macromolecules that are in this way altered in their function, leading to pathological effects; (ii) by alterations of their physiological action on the redox state of factors involved in signal transduction, thus leading to hyper- or hypo-functionality of the signalling pathways.

ROS is a collective term including oxygen derivatives, either radical or nonradical, that are oxidizing agents and/or are easily converted into radicals (Halliwell, 2006). A free radical is a species containing one or more unpaired electrons. Diatomic oxygen O_2 is a radical because it has two unpaired electrons each located in a different π^* antibonding orbital, but both with the same spin quantum number: this parallel spin is the reason for its low reactivity with nonradical molecules. However, inverting the spin of one of the unpaired electrons by an energy input converts O_2 into the much more reactive singlet oxygen O_2 in which both unpaired electrons have been moved to the same π^* orbital. Transition metals such as iron and copper, when in a free state, have a strong capacity to reduce O_2, thus generating radical species.

If a single electron is supplied to O_2, it enters one of the π^* orbitals to form an electron pair there, thus leaving only one unpaired electron in the superoxide radical anion $O_2^{\bullet -}$; addition of another electron gives the peroxide ion, which is a weaker acid and is protonated to hydrogen peroxide H_2O_2; addition of two more electrons breaks the molecule producing water H_2O. If one single electron is added to H_2O_2 by a reduced metal ion (e.g. Fe^{2+}), the hydroxyl radical $OH^{\bullet}$ is produced by the Fenton reaction. The hydroxyl radical is extremely reactive with a half-life of less than 1 ns, thus it reacts

close to its site of formation.

$$O_2 + 1e^- \longrightarrow O_2^{\bullet -} \quad (1)$$

$$O_2^{\bullet -} + 1e^- + 2H^+ \longrightarrow H_2O_2 \quad (2)$$

$$H_2O_2 + 2e^- + 2H^+ \longrightarrow 2H_2O \quad (3)$$

$$Fe^{2+} + H_2O_2 \longrightarrow Fe^{3+} + OH^{\bullet} + OH^- \quad \text{(Fenton reaction)} \quad (4)$$

Reaction 1 is catalysed in cells by several systems described in Section 15.2. Hydrogen peroxide can also be formed *in vivo* by two-electron reduction of O_2 catalysed by a number of oxidases. Reaction 2 is catalysed by superoxide dismutases (SODs) and Reaction 3 by catalase, glutathione peroxidases (GPxs) and other peroxidases (Section 15.5).

Since there are other reactive species besides those of oxygen, the term reactive species (RS) has been expanded to include reactive nitrogen species (RNS), reactive chlorine species (RCS), and so on. Among RNS is nitric oxide $NO^{\bullet}$, a not very reactive radical well known as a signalling molecule (Rubio and Morales-Segura, 2004; Schlossmann and Hofmann, 2005). If $NO^{\bullet}$ reacts with $O_2^{\bullet -}$ the nonradical product peroxynitrite is formed and rapidly protonated at neutral pH to the aggressive peroxynitrous acid, which can further undergo homolytic fission to hydroxyl radical and nitrogen dioxide radical.

$$NO^{\bullet} + O_2^{\bullet -} + H^+ \longrightarrow ONOOH \quad (5)$$

$$ONOOH \longrightarrow NO_2^{\bullet -} + OH^{\bullet} \quad (6)$$

Hypochlorous acid HOCl is a RCS that can also generate the hydroxyl radical by reacting with Fe^{2+}

$$Fe^{2+} + HOCl \longrightarrow Fe^{3+} + OH^{\bullet} + Cl^- \quad (7)$$

Several other radicals are produced by reaction of RS with organic compounds and macromolecules, as we shall see in Section 15.3.

2 SOURCES OF ROS IN THE CELL

ROS arise in cells from exogenous and endogenous sources. Exogenous sources of ROS include ultraviolet (UV) and visible light, ionizing radiation, drugs and environmental toxins. Among endogenous sources there are xanthine oxidase (XO), cytochrome P-450 enzymes in the endoplasmic reticulum, peroxisomal flavin oxidases, plasma membrane nicotinamide adenine dinucleotide phosphate (NADPH) oxidases; nevertheless, the major source of ROS is usually considered to be the mitochondrial respiratory chain in the inner mitochondrial membrane, although other enzyme systems in mitochondria can be important contributors to ROS generation.

In healthy cells, the continuous production of ROS is balanced by various detoxification reactions by a number of antioxidant systems. Only excessive ROS production or defects in protective systems lead to oxidative stress and pathological conditions. Under normal conditions, ROS are maintained within narrow boundaries and contribute to the redox balance in the cell (Linnane and Eastwood, 2006): redox balance, the ratio between oxidizing and reducing species, is involved in regulation of signalling pathways, including protein kinase and phosphatase activity and gene expression through modulation of transcription factor function (Fruehauf and Meyskens, 2007) (Section 15.4); glutathione redox state plays a central role in maintaining such redox homeostasis and the GSH/GSSG ratio is an estimate of cellular redox buffering capacity (Schafer and Buettner, 2001).

2.1 Mitochondria as Sources of ROS

Within a cell, mitochondria largely contribute to the production of ROS via the respiratory chain (Lenaz, 1998; 2001). The relevance of mitochondrial production of ROS within a cell is indirectly revealed by the results of deficiency of mitochondrial antioxidant enzymes. Mitochondria contain an isozyme of SOD (SOD-2) and GPx (see Section 15.5). The lack of SOD-2 (Melov *et al.*, 1999) and of mitochondrial GPx (Esposito *et al.*, 2000) is deleterious to cells.

2.1.1 Overview of the Mitochondrial Respiratory Chain

The electron transfer chain or respiratory chain consists of four major multisubunit complexes designated as NADH-coenzyme Q (CoQ) reductase (Complex I), succinate-CoQ reductase (SQR) (Complex II), ubiquinol-cytochrome c reductase (Complex III) and cytochrome c oxidase (Complex IV). The best fit unit stoichiometry between complexes in beef heart mitochondria is 1 Complex I : 1.3 Complex II : 3 Complex III : 6.7 Complex IV (Schägger and Pfeiffer, 2001). In addition there are 0.5 adenosine triphosphate (ATP) synthase (also called Complex V) and three to five units of the ADP/ATP translocase (catalysing the equimolar exchange of adenosine diphosphate (ADP) and ATP across the inner membrane) for each cytochrome oxidase, and there is one NADH/$NADP^+$ transhydrogenase per Complex I.

The respiratory chain collects reducing equivalents (hydrogen atoms) from mitochondrial oxidations of the tricarboxylic acid cycle, from pyruvate oxidation, fatty acid and amino acid catabolism and other oxidative reactions, and conveys them to molecular oxygen that is reduced to water (four electron reduction). The free energy decrease accompanying electron transfer is exploited to create an electrochemical proton gradient ($\Delta\mu_{H^+}$) by proton translocation from the mitochondrial inner space, the matrix, to the space between

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the inner and outer mitochondrial membranes (Nicholls and Ferguson, 2002). The proton gradient is then used as a source of energy to synthesize ATP from ADP and inorganic phosphate (Pi) by the ATP synthase complex (oxidative phosphorylation (OXPHOS)), or alternatively to drive other energy-linked reactions such as NADH/$NADP^+$ transhydrogenation and up-hill ion movements across the inner membrane. The ATP synthesized is moved to the cytoplasm in exchange with ADP by the ATP/ADP translocase.

The inner membrane contains several other proteins having electron transfer activity in smaller amounts (Ernster and Schatz, 1981); among these there are electron transfer flavoproteins (ETFs) capable of feeding electrons to the respiratory chain by pathways not involving Complex I and/or NAD, that is, glycerol-3-phosphate dehydrogenase, ETF-ubiquinone oxidoreductase, dihydroorotate dehydrogenase, choline dehydrogenase, besides alternative NADH dehydrogenases in mitochondria from several organisms, especially plants and fungi.

2.1.2 The Respiratory Chain as Source of ROS

The major sites of superoxide formation in the respiratory chain are within respiratory Complexes I and III. Further sites, however, may have importance and physiological relevance. It is worth noting that mitochondria from different tissues may vary conspicuously in their capacity to produce ROS using different substrates (Kwong and Sohal, 1998), and this capacity is also related to animal species and age.

2.1.2.1 Complex III

Complex III (ubiquinoe-cytochrome c reductase) represents a confluence point for reducing equivalents from various dehydrogenases: it catalyses the transfer of electrons from ubiquinol ($CoQH_2$) to water-soluble cytochrome c and concomitantly links this redox reaction to translocation of protons across the membrane, converting the energy associated with electron flow into an electrochemical proton gradient.

$$CoQH_2 + 2\ \text{cyt.c}\ Fe^{3+} + 2H^+\ (\text{in}) \longrightarrow CoQ + 2\ \text{cyt.c}\ Fe^{2+} + 4H^+\ (\text{out}) \quad (8)$$

The formation of superoxide in Complex III depends on the peculiar mechanism of electron transfer, the so-called Q-cycle (Crofts, 2004) (**Figure 1**).

Since the electron transfer from cytochrome b_L to b_H occurs against the electrical gradient (from the positive to the negative side), it is strongly retarded when the electrochemical potential is high, as in the controlled state (State 4); this retardation prolongs the lifetime of Qo and allows reaction of the semiquinone with O_2 forming superoxide (Jezek and Hlavata, 2005).

Antimycin A (AA) is known not to completely inhibit electron flow from ubiquinol to cytochrome c: the AA-insensitive reduction of cytochrome c is mediated by superoxide radicals. According to the Q-cycle, AA blocks ubiquinone reduction by cytochrome b_H at centre i, at the inner or negative side of the membrane. The antimycin-stimulated production of ROS is inhibited by the inhibitors acting at centre o (at the outer or positive side), where ubiquinol reduces both the Rieske iron–sulphur cluster and cytochrome b_L. Thus, we may locate the site of one-electron reduction of oxygen in the presence of antimycin at a component located at centre o, presumably ubisemiquinone (Casteilla *et al.*, 2001).

Myxothiazol was found to enhance ROS production using different respiratory substrates in the absence of antimycin, and the effect was reversed by stigmatellin (Starkov and Fiskum, 2001). Muller *et al.* (2003) found that proximal Qo site inhibitors, acting close to the b_L niche induce superoxide formation in yeast submitochondrial particles (SMPs) supplemented with decylubiquinol; the effect is not modified by antimycin, showing that the source of radicals is not at the Qi site. Muller *et al.* (2003) suggested that oxidation of ubiquinol at centre o is biphasic, with delivery of the first electron to the Rieske iron–sulphur cluster, leaving a semiquinone that in absence of further oxidation by cytochrome b_L would interact with oxygen, forming superoxide.

Ubisemiquinone is relatively stable only when protein-bound, therefore the CoQ pool in the lipid bilayer should not be a source of ROS. Exogenously administered CoQ has not been found to exert pro-oxidant effects *in vivo*: thus, the pro-oxidant species deriving from its antioxidant action (Nohl *et al.*, 1998) would not seem to be operative in *in vivo* supplementation.

2.1.2.2 Complex I

Complex I (NADH CoQ reductase) oxidizes NADH in the mitochondrial matrix and reduces CoQ in the lipid bilayer of the inner mitochondrial membrane.

$$NADH + H^+ + CoQ + 4H^+\ (\text{in}) \longrightarrow NAD^+ + CoQH_2 + 4H^+\ (\text{out}) \quad (9)$$

Several prosthetic groups contribute to electron transfer within the enzyme: flavin mononucleotide (FMN) is the entry point for electrons, that are then transferred to a series of iron–sulphur clusters (Ohnishi *et al.*, 1998). Enzymes from different sources have different numbers of iron–sulphur clusters, most of which share the same midpoint potential. The N2 iron–sulphur cluster, which is of the kind Fe_4S_4, has the highest midpoint potential (E_m between -150 and -50 mV) and is considered to be the direct electron donor to ubiquinone. N2 is most likely located in the connection between the peripheral and the membrane arms. The magnetic interaction with the semiquinone radical, corresponding to a distance of about 10 Å (Ohnishi and Salerno, 2005), suggests that

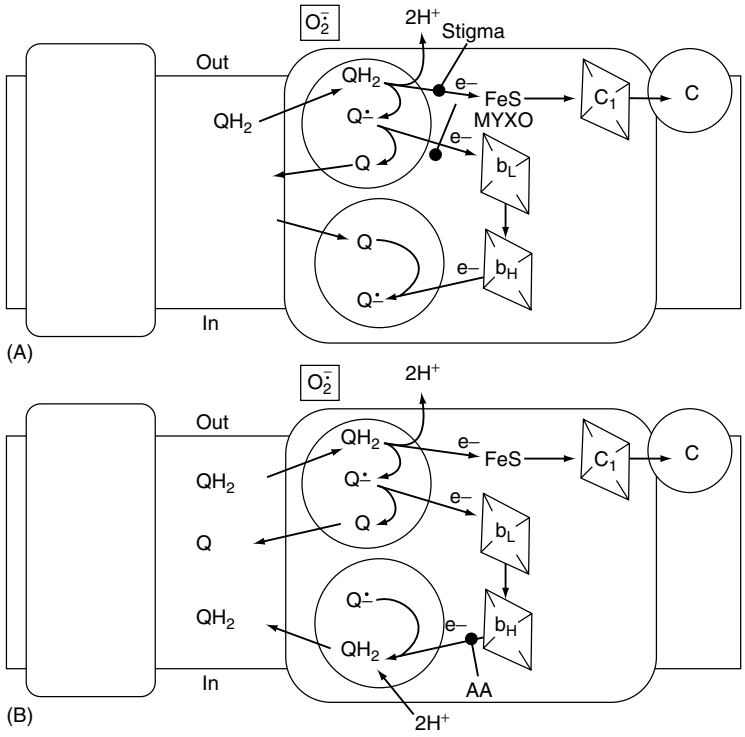

Figure 1 The Q-cycle in Complex III as a source of superoxide. In the Q-cycle, QH_2 delivers the first electron at the outer positive site (thus called site o or P) of the inner membrane to the Rieske iron–sulphur protein and hence to cytochromes c_1 and c; the result is release of two H^+ in the intermembrane space and formation of an unstable semiquinone anion $Q^{\bullet-}$ at the Qo site, which is immediately oxidized to Q by the low-potential cytochrome b_{566} (or b_L) at the cytosolic side; the electron is then delivered to the high-potential cytochrome b_{562} (or b_H) at the internal negative side (thus called site i or N); b_H is then reoxidized by CoQ at site i (Q_i) forming another semiquinone. The cycle is completed by oxidation of a second molecule of QH_2. Superoxide is thought to arise mainly from the CoQ semiquinone at centre o under conditions stabilizing this intermediate, and is released in the intermembrane space. STIGMA, stigmatellin; MYXO, myxothiazol; AA, antimycin A.

the ubiquinone headgroup could somehow reach up into the peripheral arm, as recently assumed by Brandt *et al.* (2003), who have hypothesized an amphipathic 'ramp' guiding ubiquinone into the catalytic site. Recently, the arrangement of iron–sulphur clusters in the hydrophilic domain of Complex I from *T. thermophilus* has been determined by X-ray crystallography, showing a linear chain of all clusters except N1a and N7 (Hinchliffe and Sazanov, 2005).

Early experiments proved the involvement of Complex I in ROS production (Takeshige and Minakami, 1979); addition of NADH at low concentration led to copious ROS production detected by lipid peroxidation; addition of NADH at high concentration, but in presence of rotenone, also induced peroxidation. Water-soluble CoQ homologues used as electron acceptors from isolated Complex I stimulated H_2O_2 production, whereas CoQ_6 and CoQ_{10} were inactive (Cadenas *et al.*, 1977). More recent studies confirmed that Complex I is a major source of superoxide production in several types of mitochondria. The superoxide production by Complex I is higher during the reverse electron transport from succinate to NAD^+ (Korshunov *et al.*, 1997; Turrens, 2003; Jezek and Hlavata, 2005), whereas during the forward electron transport it is much lower. Reverse electron transfer-supported ROS production requires high membrane potential and is inhibited by uncouplers and by processes dissipating membrane potential (Kushnareva *et al.*, 2002; Starkov and Fiskum, 2003). Rotenone enhances ROS formation during forward electron transfer (Herrero and Barja, 2000; Genova *et al.*, 2001) and inhibits it during reverse electron transfer (Lambert and Brand, 2004; Ohnishi *et al.*, 2005; Vinogradov and Grivennikova, 2005).

The identification of the oxygen reducing site has been the subject of extensive investigation, and several prosthetic groups in the enzyme have been suggested to be the direct reductants of oxygen. These include FMN, ubisemiquinone and iron–sulphur cluster N2 (Lenaz *et al.*, 2006a; 2007a). In isolated Complex I, FMN is considered the major electron donor to oxygen to form the superoxide anion. In mitochondrial membranes, however, the identification of flavin as the site of oxygen reduction is incompatible with the finding that two classes of inhibitors both acting downstream of the iron–sulphur clusters in the enzyme have opposite

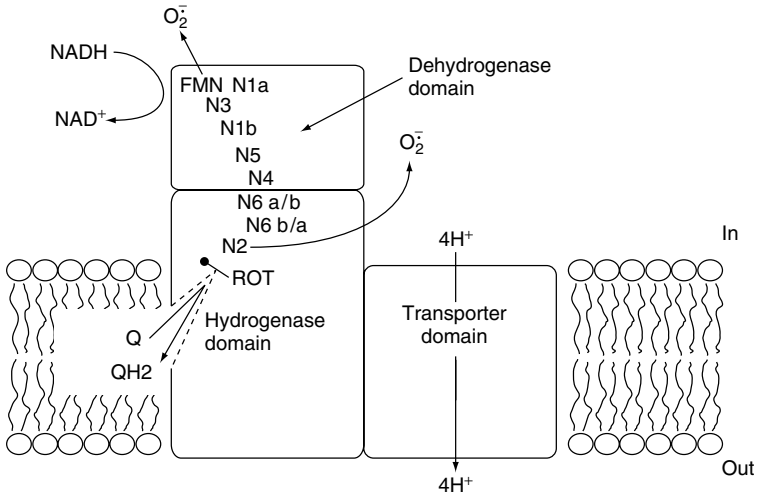

Figure 2 Schematic representation of Complex I formed by the apposition of three different modules: a dehydrogenase domain where NADH is oxidized, containing FMN and iron–sulphur clusters N1a, N1b, N3, N4, and N5; a hydrogenase domain where CoQ is reduced, containing FeS clusters N6a, N6b and N2; and a transporter domain containing no prosthetic groups and involved in proton translocation. Superoxide formation presumably occurs at both FMN and N2 (see text) and is released in the mitochondrial matrix. ROT, rotenone.

effects, in that rotenone enhances superoxide production, whereas stigmatellin inhibits it (Lenaz *et al.*, 2006a). A possible explanation is that two sites for oxygen reduction exist in the complex, represented by flavin and an iron–sulphur cluster; the latter site would be predominant in membrane particles, whereas the former might be available after Complex I isolation.

The electron donor to the first molecule of bound ubiquinone in the complex is most probably iron–sulphur cluster N2 (Ohnishi *et al.*, 1998). It is likely that this centre is also the electron donor to oxygen both directly and via one-electron reduction of several exogenous quinones (**Figure 2**). Studies in CoQ-depleted and reconstituted mitochondria indicated that endogenous CoQ is not required for superoxide generation (Genova *et al.*, 2001). It is worth noting that reconstituted mitochondria, containing a large excess of CoQ_{10}, produce the same amount of superoxide as CoQ-depleted mitochondria, indicating that endogenous CoQ_{10} is not a source of ROS.

2.1.2.3 Complex II

The enzyme is also a component of the Krebs cycle (succinate dehydrogenase) and catalyses the reduction of CoQ by succinate, without formation of a proton gradient.

$$\text{succinate} + \text{CoQ} \longrightarrow \text{fumarate} + \text{CoQH}_2 \qquad (10)$$

The indirect evidence that often ROS production is higher when electrons are channelled through Complex II than through Complex I, while in both cases reaching Complex III, would be in line with the idea that Complex II may be a source of ROS (McLennan and Degli Esposti, 2000).

Ishii *et al.* (1998), in a study on *C. elegans*, produced evidence that a mutation in succinate dehydrogenase cytochrome b induces oxidative stress and ageing. In *E. coli*, fumarate reductase (QFR), active under anaerobic conditions, is structurally analogous to Complex II (SQR), active under aerobic conditions; in contrast with Complex II, however, *E. coli* QFR has no *b* haeme. Significantly, *E. coli* QFR is a potent source of H_2O_2, whereas SQR is not (Messner and Imlay, 2002). The source of electrons to oxygen is fully reduced flavin adenine dinucleotide (FAD). The difference between SQR and QFR has been ascribed to the electron attracting capacity of cytochrome *b*, due to its high redox potential (Yankovskaya *et al.*, 2003): thus, in the absence of cytochrome *b*, the electrons would be held preferentially on the flavin, favouring leak to oxygen.

Direct demonstration of ROS production by Complex II was obtained by Zhang *et al.* (1998) in purified SQR and succinate dehydrogenase; auto-oxidation of flavin was the source of the superoxide; reconstitution with the bc1 complex, to yield an active succinate cytochrome c reductase, inhibited superoxide formation.

2.1.2.4 Glycerol-3-Phosphate Dehydrogenase

This enzyme catalyses the oxidation of glycerol-3-phosphate by CoQ:

$$\text{glycerol-3-P} + \text{CoQ} \longrightarrow \text{dioxyacetone-P} + \text{CoQH}_2 \qquad (11)$$

A high rate of ROS production was detected in insect flight muscle mitochondria (Bolter and Chefurka, 1990) and in brown adipose tissue mitochondria (Sekhar

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 1987) when glycerol-3-phosphate was used as the respiratory substrate. This suggested that mitochondrial glycerophosphate dehydrogenase (mGPDH) could be the source of ROS. Drahota *et al.* (2002) demonstrated that mGPDH in the presence of antimycin is a powerful source of hydrogen peroxide, that was strongly stimulated by addition of the one-electron acceptor ferricyanide. The ferricyanide-induced H_2O_2 production is a specific feature of mGPDH: it is completely inhibited by mGPDH inhibitors, and is negligible using NADH or succinate as substrates. It is reasonable that ferricyanide takes up one electron and the other is used to reduce oxygen.

In a study on *Drosophila* mitochondria (Miwa *et al.*, 2003) ROS production by mGPDH and the relative contributions of Complex I by reverse electron transfer of centre o of Complex III and of mGPDH were assessed by use of specific inhibitors, demonstrating that mGPDH was the major source of superoxide.

2.1.2.5 Dihydroorotate Dehydrogenase

This essential enzyme of pyrimidine biosynthesis catalyses the oxidation of dihydroorotate to orotate:

$$\text{dihydroorotate} + \text{CoQ} \longrightarrow \text{orotate} + \text{CoQH}_2 \qquad (12)$$

The enzyme was found to be involved in the production of superoxide in liver mitochondria (Forman and Kennedy, 1975) and in malarial parasite cells (Krungkrai, 1991). It is worth noting that the major domain of the enzyme, carrying the carboxyl terminal, protrudes in the intermembrane space, so that it is likely that superoxide is released in this space similarly to glycerol-3-phosphate dehydrogenase.

2.1.2.6 ETF and ETF Dehydrogenase

ETF is a small flavoprotein that accepts electrons from fatty acyl coenzyme As (CoAs) and other lipid compounds and is then reoxidized by CoQ in the respiratory chain:

$$\text{ETF}(\text{FADH}_2) + \text{CoQ} \longrightarrow \text{ETF}(\text{FAD}) + \text{CoQH}_2 \qquad (13)$$

It was observed that the oxidation of palmitoyl carnitine by mitochondria leads to production of H_2O_2 (Boveris *et al.*, 1972). More recently, in a study on the topology of ROS production by the respiratory chain, St-Pierre *et al.* (2002) observed copious production of H_2O_2 by rat muscle and heart, but not liver, mitochondria when oxidizing palmitoyl carnitine; since the rate was only slightly enhanced by exogenous SOD, it was suggested that superoxide production occurred at the matrix side, therefore it was generated at a site different from centre o of Complex III. The authors considered it likely that the flavoproteins ETF and ETF dehydrogenase, involved in fatty acid oxidation, were the sites for generation of superoxide.

(**Figure 3**) summarizes the superoxide production sites of the respiratory chain.

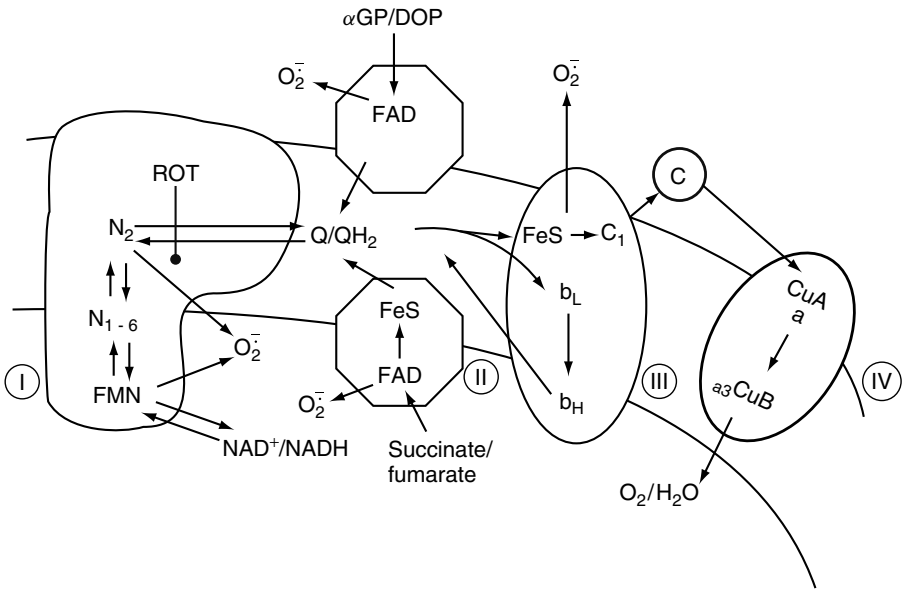

Figure 3 Overall cartoon showing the main sites of generation of superoxide in the mitochondrial respiratory chain. The scheme shows $O_2^{\bullet-}$ formation by Complex I, with release in the matrix during forward and reverse electron transfer, by Complex III during the Q-cycle, with release in the intermembrane space, and by Complex II in the matrix and glycerol-3-phosphate dehydrogenase in the intermembrane space. ETF dehydrogenase behaves as Complex II, while dihydroorotate dehydrogenase behaves as glycerol-phosphate dehydrogenase. ROT, rotenone; α-GP, glycerol-3-phosphate; DOP, dioxyacetone phosphate.

2.1.3 Modulation of Mitochondrial ROS Production

Are free radicals produced by mitochondria physiologically released to the cytosol? Staniek and Nohl (2000) applied a noninvasive detecting system for hydrogen peroxide and found that isolated intact rat heart mitochondria do not produce detectable H_2O_2, unless using succinate in the presence of antimycin. Korshunov *et al.* (1997) also found no hydrogen peroxide formation by intact rat heart mitochondria, unless pretreated in such a way as to deplete them of endogenous antioxidants. It may be inferred that under normal conditions ROS are not exported out of mitochondria. There is, however, overwhelming evidence that ROS production detected in different cells under pathological conditions has a mitochondrial origin.

Although the first product of oxygen reduction by the respiratory chain is superoxide, this radical has a short life and is rapidly converted into hydrogen peroxide by mitochondrial SOD or can attack other molecules, such as lipids, before being able to escape the mitochondrion. Although hydrogen peroxide is also removed by GPx, it is much more stable than superoxide, so that some molecules can escape the organelle and be detected outside. Most of superoxide is generated at the matrix side of the inner membrane, as appears from the observation that superoxide is detected in SMPs which are inside-out with respect to mitochondria. A study with suitable spin traps, however, demonstrated the formation of superoxide radical in mitoplasts (Han *et al.*, 2001) indicating that a significant aliquot of this species is released at the outer face of the inner membrane (St-Pierre *et al.*, 2002). It is likely that Complex I releases ROS in the matrix while Complex III releases them in the intermembrane space. The superoxide anion released in the intermembrane space may be exported to the cytoplasm through an anion channel related to a voltage-dependent anion channel (VDAC) (Han *et al.*, 2003).

It is not easy to demonstrate that ROS detected in cells are produced by mitochondria; the effect of respiratory inhibitors appears to be the best way to discriminate between mitochondrial and nonmitochondrial ROS. However, the effect of inhibitors is ambiguous. Although antimycin is usually found to stimulate ROS production (Boveris *et al.*, 1972) in intact cells, as it does in mitochondria, the effect of rotenone is contradictory (Lenaz, 2001). Some studies showed that rotenone enhances ROS production in intact cells, whereas others showed inhibition of cellular ROS production by the same inhibitor. Since rotenone decreases ROS production by Complex III while enhancing ROS production by Complex I, the relative contribution of the two complexes to ROS production may vary in different cells. Since ROS production by reverse flux of electrons is decreased by rotenone (Kushnareva *et al.*, 2002), another critical point is represented by membrane potential and the contribution of reverse electron transfer in Complex I.

Mitochondrial ROS production is enhanced in State 4 and when the rate of electron transfer is lowered (Skulachev, 1996). The rationale is in a more reduced state of the respiratory carriers capable of donating electrons to oxygen. To this purpose, uncoupling and release of excessive membrane proton potential may protect mitochondria from damage due to excessive free-radical production. In rat hepatocytes the futile cycle of proton pumping and proton leak may be responsible for 20–25% of respiration (Brand, 2000); in perfused rat muscle the value is even greater. Uncoupling may be obtained by activating proton leak through uncoupling proteins (Casteilla *et al.*, 2001). In this way a tissue may dissipate a conspicuous part of the energy conserved by its mitochondria, however it keeps the mitochondrial respiratory chain under more oxidized conditions preventing the formation of damaging free radicals (**Figure 4**).

The ROS production by the respiratory chain complexes may be under physiological control; this is particularly evident for Complex I. Events leading to decrease of the rate of electron flow in the complex also lead to overproduction of ROS; physiological states, such as subunit phosphorylation, which inhibits Complex I activity, may modify its ROS-generating capacity (Raha *et al.*, 2002; Maj *et al.*, 2004; Scacco *et al.*, 2006). It is therefore tempting to speculate that endocrine alterations may affect the capacity of ROS formation by hyper- or hypophosphorylation of the complex.

There is increasing evidence that pathological states in which Complex I activity is impaired also lead to ROS overproduction (Fato *et al.*, 2008); in cell lines from patients with Complex I deficiency, an inverse relationship was found between superoxide production and residual enzyme activity (Verkaart *et al.*, 2007).

2.1.4 Other Mitochondrial Enzymes

2.1.4.1 $p66^{Shc}$

Recently, an additional source of ROS in mitochondria (directly in the form of hydrogen peroxide) was demonstrated in the $p66^{Shc}$ protein (Migliaccio *et al.*, 2006); $p66^{Shc}$ is a splice variant of $p46^{Shc}$/$p52^{Shc}$, two cytoplasmic proteins involved in signal transduction from tyrosine kinases to Ras. $p66^{Shc}$ has the same modular structure of the former proteins, but contains a unique N-terminal region and is not involved in Ras regulation. Its function has been recently discovered to be in the regulation of ROS metabolism and apoptosis (Migliaccio *et al.*, 1999). $p66^{Shc-/-}$ cells are resistant to apoptosis induced by a variety of different signals (Migliaccio *et al.*, 1999); expression of the protein is required for mitochondrial depolarization and release of cytochrome c after a variety of proapoptotic signals (Trinei *et al.*, 2002). $P66^{Shc}$ deletion in mice decreases the incidence of ageing-associated diseases (Napoli *et al.*, 2003; Menini *et al.*, 2006; Rota

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

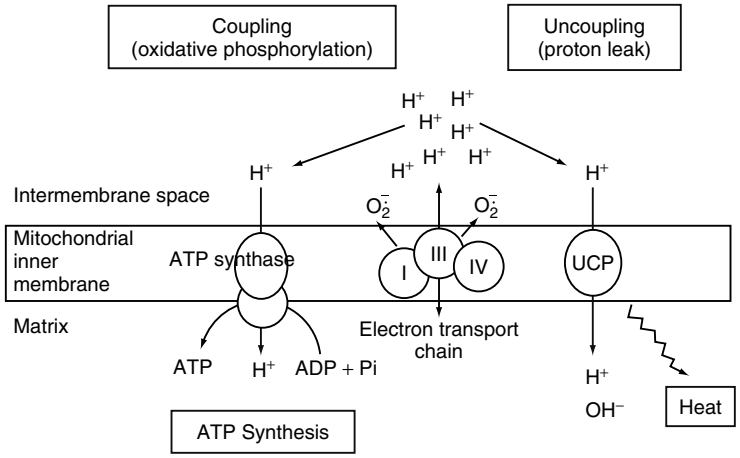

Figure 4 Scheme showing the competition of ATP synthase and uncoupling proteins (UCPs) for the proton gradient. Both systems utilize protons from the intermembrane space and release them in the matrix, determining an increase of the rate of electron transfer in the respiratory chain. Under both these conditions (State 3 and uncoupled state respectively) the membrane potential is decreased and ROS production is low. When ATP is not synthesized and UCPs are not expressed, the membrane potential is high, electron transfer is slow and the chain is more reduced, allowing abundant ROS formation.

et al., 2006) and prolongs lifespan of animals (Migliaccio *et al.*, 1999).

Pathways leading to increase of $p66^{Shc}$ expression in oxidative stress involve p53 (Trinei *et al.*, 2002) and protein kinase C (PKC)-β isoform (Pinton *et al.*, 2007); moreover $p66^{Shc}$ expression and phosphorylation is involved in stabilization of the hypoxia-inducible factor (HIF)1α (Bianchi *et al.*, 2006; Carraro *et al.*, 2007) (cf. Section 15.5).

A fraction of $p66^{Shc}$ has a mitochondrial localization in the intermembrane space, where it is bound in an inactive form in a high-molecular-weight complex including the inner membrane transporter (TIM)/outer membrane transporter (TOM) protein import system (Giorgio *et al.*, 2005); proapoptotic signals dissociate the protein from the complex and activate it to a form inducing a permeability transition by opening a high-conductance channel in the inner membrane, the permeability transition pore (Bernardi *et al.*, 2001) involved in the events leading to apoptosis. This effect is due to the intrinsic property of $p66^{Shc}$ to act as a redox protein accepting electrons from cytochrome c and directly producing hydrogen peroxide (Giorgio *et al.*, 2005) (**Figure 5**). Since the reaction equilibrium of cytochrome c oxidation by $p66^{Shc}$ is low ($K_{eq} = 0.1$), the reaction is thermodynamically favoured when the level of cytochrome c reduction is high (Giorgio *et al.*, 2005).

This means that H_2O_2 production by this mechanism should be enhanced when cytochrome c oxidase (the enzyme catalysing cytochrome c reoxidation by oxygen)

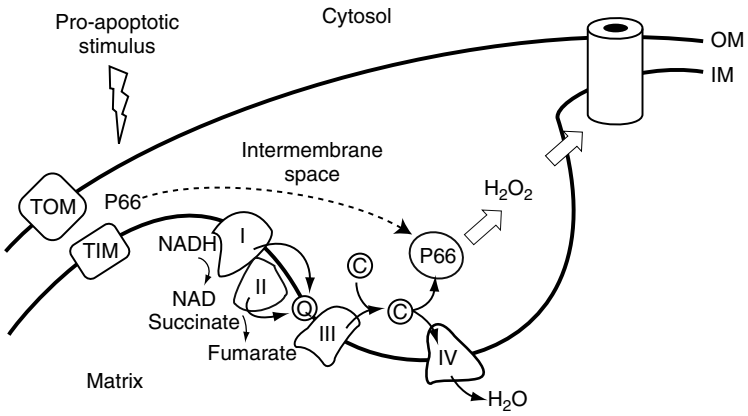

Figure 5 Role of $p66^{Shc}$ in H_2O_2 production in mitochondria. In the presence of proapoptotic stimuli, p66 is released from the protein transport complex (TOM, outer membrane transporter, TIM, inner membrane transporter) and becomes free in the intermembrane space, where it may receive electrons from cytochrome c, with production of H_2O_2. The generation of H_2O_2 would be favoured by conditions where cytochrome oxidase (IV) is inhibited. OM, outer membrane; IM, inner membrane. (Reproduced by Giorgio *et al.*, 2005. © Elsevier.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is inhibited. The K_m of cytochrome oxidase for oxygen is very low (<1 μM), thus allowing its activity, even at low oxygen tensions; however, low oxygen tensions promote the activation of HIF by a still controversial mechanism (Taylor, 2008) that triggers a series of metabolic changes, among which is the alteration of cytochrome oxidase subunits and activity. The activation of the $p66^{Shc}$ pathway may in part explain the paradoxical enhancement of ROS production during hypoxia (Guzy and Schumacker, 2006).

Another factor leading to decrease of cytochrome oxidase activity is nitric oxide $NO^{\bullet}$, which inhibits the enzyme competitively with oxygen (Sarti *et al.*, 2000), thus elevating the K_m. The $NO^{\bullet}$ inhibition may not be relevant at normal oxygen tensions (about 30 μM), but may become important when the oxygen tension is lowered, for example during ischaemia.

2.1.4.2 Dihydrolipoamide Dehydrogenase

Dihydrolipoamide dehydrogenase (DLD) is a flavoprotein subunit of the α-ketoglutarate dehydrogenase and pyruvate dehydrogenase complexes situated in the mitochondrial matrix, catalysing the reoxidation of protein-bound lipoate (lipoamide) by NAD^+.

$$\text{lipoamide (SH)}_2 + \text{NAD}^+ \longrightarrow \text{lipoamide (S-S)} + \text{NADH} + \text{H}^+ \quad (14)$$

This subunit of α-ketoglutarate dehydrogenase has been shown to be a source of superoxide by electron leak from the flavin (Starkov *et al.*, 2004; Tretter and Adam-Vizi, 2004) under State 4 conditions, when the enzyme is more reduced; the contribution of the pyruvate dehydrogenase analogous subunit to superoxide formation was found to be 50% of that of α-ketoglutarate dehydrogenase. In *S. cerevisiae* under conditions of NAD depletion or at high $NADH/NAD^+$ ratios, the contribution of α-ketoglutarate dehydrogenase to ROS formation was higher than that of the respiratory chain (Tahara *et al.*, 2007) as demonstrated by strong ROS formation by adding α-ketoglutarate or pyruvate, but not malate, to wild-type permeabilized mitochondria, and by prevention of oxidative stress in deletion mutants of the DLD gene; the oxidative stress was also prevented by calorie restriction, which is known to keep the $NADH/NAD^+$ ratio low (Lin *et al.*, 2004).

2.1.4.3 Monoamine Oxidase

Amine oxidases are a class of enzymes catalysing the oxidation of amines by O_2 forming the respective aldehydes and H_2O_2; they are subdivided into FAD-dependent oxidases (monoamine oxidases (MAOs), polyamine oxidases) and copper and topaquinone-dependent oxidases (Strolin Benedetti *et al.*, 2007). Amine oxidases are involved in the oxidation of endogenous amines, such as dopamine (DA), serotonin and so on, but also of xenobiotic amines, such as tyramine and several drugs (Strolin Benedetti *et al.*, 2006).

$$\text{R-CH}_2\text{NH}_2 + \text{O}_2 \longrightarrow \text{R-CH=NH} + \text{H}_2\text{O}_2 \quad (15a)$$

$$\text{R-CH=NH} + \text{H}_2\text{O} \longrightarrow \text{R-CHO} + \text{NH}_3 \quad (15b)$$

MAO exists in two isoforms bound to the outer mitochondrial membrane, MAO-A and MAO-B; it is a flavoprotein (Cadenas and Davies, 2000) (for a review on the molecular mechanism see Edmondson *et al.*, 2007). MAO-A has been shown to represent an important source of ROS in rat heart (Maurel *et al.*, 2003); oxidative stress mediated by MAO-A results in cardiomyocyte apoptosis and MAO-A inhibition reduces myocardial damage induced by ischaemia-reperfusion (Bianchi *et al.*, 2005). The increase of MAO-A activity in a heart subjected to ischaemia-reperfusion has been attributed to increased availability of its substrate serotonin. Use of specific MAO inhibitors may represent a tool for cardioprotection (Di Lisa *et al.*, 2007).

Table 1 summarizes the sites of ROS formation in mitochondria.

2.2 Other Cellular Sources of ROS

Besides mitochondria, other systems in the cell may significantly contribute to ROS generation and sometimes

Table 1 Summary of the known sites for ROS production in mitochondria

Respiratory chain	Comments
Complex I	Forward and reverse e-transfer; $O_2^{\bullet -}$ in the matrix
Complex III	High membrane potential, $O_2^{\bullet -}$ in the IMS
Complex II	$O_2^{\bullet -}$ in the matrix
α-GP-DH	$O_2^{\bullet -}$ in the IMS
ETF-DH	$O_2^{\bullet -}$ in the matrix
Dihydroorotate DH	$O_2^{\bullet -}$ in the IMS
P66	H_2O_2 from cyt c, in the IMS
α- ketoglutarate DH complex	From the E_3, DLD subunit- $O_2^{\bullet -}$ in matrix
Pyruvate DH complex	From the E_3, DLD subunit- $O_2^{\bullet -}$ in matrix
Monoaminooxidase (MAO)	Outer membrane

α-GP-DH = α-glycerophosphate dehydrogenase; ETF-DH = electron transfer flavoprotein dehydrogenase; DLD = dihydrolipoate dehydrogenase; IMS = intermembrane space.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

become the overwhelming source of such species. This is particularly true in cells where mitochondria are not a substantial mass percentage or in specialized systems such as the phagocytic cells. Nevertheless some authors consider extramitochondrial sources of ROS as prevalent and endowed of higher damaging potential for the cell.

2.2.1 Xanthine Oxidase

This enzyme catalyses the oxidation of hypoxanthine to xanthine and in turn the oxidation of xanthine to urate and is involved in the degradation of purine nucleotides. The enzyme in healthy tissues exists mainly in the form of NAD-dependent xanthine dehydrogenase (XDH), but under ischaemic conditions is converted by a protease into XO, which reduces oxygen to both superoxide and hydrogen peroxide.

$$\text{hypoxanthine} + \text{NAD}^+ \longrightarrow \text{xanthine} + \text{NADH} + \text{H}^+ \text{ (xanthine dehydrogenase)} \quad (16)$$

$$\text{hypoxanthine} + \text{O}_2 \longrightarrow \text{xanthine} + \text{H}_2\text{O}_2 \text{ (xanthine oxidase)} \quad (17)$$

$$\text{hypoxanthine} + 2\text{O}_2 \longrightarrow \text{xanthine} + 2\text{O}_2^{\bullet -} \text{ (xanthine oxidase)} \quad (18)$$

The enzyme from animal sources is a homodimer with a molecular weight of 300 kDa; each subunit binds a molybdopterin cofactor, two nonidentical iron–sulphur centres and one FAD (Nishino *et al.*, 2008). The enzyme is largely localized in peroxisomes, but is also found in the cytoplasm of hepatic endothelial cells.

Stirpe and Della Corte (1969) first reported that the enzyme originally exists in the XDH form, but is converted to XO by proteolysis or by oxidation of cysteine residues to form S-S bridges. The difference between XDH and XO is the changed reactivity of reduced FAD towards NAD and O_2. Indeed FAD is the only redox centre in the enzyme undergoing significant changes in redox properties when XDH is converted into XO, so that the flavin semiquinone $FADH^{\bullet}$ is thermodynamically stable in XDH, but not in XO (Nishino *et al.*, 2008).

Under ischaemic conditions XDH rapidly converts to XO generating both $O_2^{\bullet -}$ and H_2O_2: ATP depletion results in loss of ATP-dependent Ca^{2+} homeostasis increasing its concentration in the cell; one important consequence of Ca^{2+} increase is the activation of a Ca-dependent protease that cleaves XDH to XO, thus inducing massive production of ROS by oxidation of hypoxanthine generated by cleavage of AMP, the major nucleotide present in the cell under ischaemic conditions. The protective effect of the XO inhibitors oxypurinol or allopurinol against ischaemia-reperfusion injury in several tissues (e.g. Viňa *et al.*, 2000; Rieger *et al.*, 2002) is an indirect demonstration of the important role of XO in ROS generation under ischaemic conditions.

2.2.2 Cytochrome P450

Cytochrome P450 (CYP) constitutes a superfamily of enzymes acting as mono-oxygenases inserting one oxygen atom from O_2 into a variety of endogenous and exogenous compounds (Zangar *et al.*, 2004).

$$\text{RH} + \text{NADPH} + \text{H}^+ + \text{O}_2 \longrightarrow \text{R-OH} + \text{NADP}^+ + \text{H}_2\text{O} \quad (19)$$

These include physiological molecules such as fatty acids, sterols, eicosanoids, amino acids and so on, or xenobiotic molecules such as drugs, procarcinogens, antioxidants, organic solvents, plant products and so on. CYPs are haeme proteins defined by an absorption spectrum, where the $Fe^{2+}(CO)$ complex has a characteristic Soret band near 450 nm. The CYP enzymes are membrane-bound (mostly to the endoplasmic reticulum) existing in a multienzyme system including a flavin-containing NADPH-CYP reductase. The microsomal complex also contains an alternative system of cytochrome b_5 and the flavoprotein NADH-cytochrome b_5 reductase; the role of cytochrome b_5 in P450 function is unclear.

There are many different CYP isoforms, and there can be over 30 CYP genes expressing their products in the same organism, many of them in the same tissue (Nebert *et al.*, 1991). Some CYP isoforms are specific in their choice of substrates, but many, particularly those in the endoplasmic reticulum, can react with a wide number of endogenous and exogenous compounds. The vast majority of CYPs are expressed in the liver, but some are specifically detected in other tissues, including heart (Gottlieb, 2003).

The efficiency of electron transfer from NADPH through the reductase to P450 for oxygenation reactions is called the degree of coupling (Yasui *et al.*, 2005); in microsomal P450 the degree of coupling is poor, less than 50% and often much lower. For this reason the rate of NADPH and oxygen consumption by P450 is weakly dependent on the presence of substrates, and then the microsomal P450 generates ROS, including superoxide, hydrogen peroxide, hydroxyl radical and singlet oxygen (Yasui *et al.*, 2005).

The mechanism of mono-oxygenation involves several steps (Sono *et al.*, 1996) (**Figure 6**).

Besides producing radicals, P450 may also inactivate fatty acid hydroperoxides (Zangar *et al.*, 2004). Fatty acid hydroperoxides (cf. Section 15.3.1) may act as direct oxidizing agents to P450 leading to substrate oxidation and monohydroxylated fatty acids; in the absence of substrate co-metabolism, P450 can catalyse the isomerization of fatty acid hydroperoxides to the dihydroxylated fatty acids.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

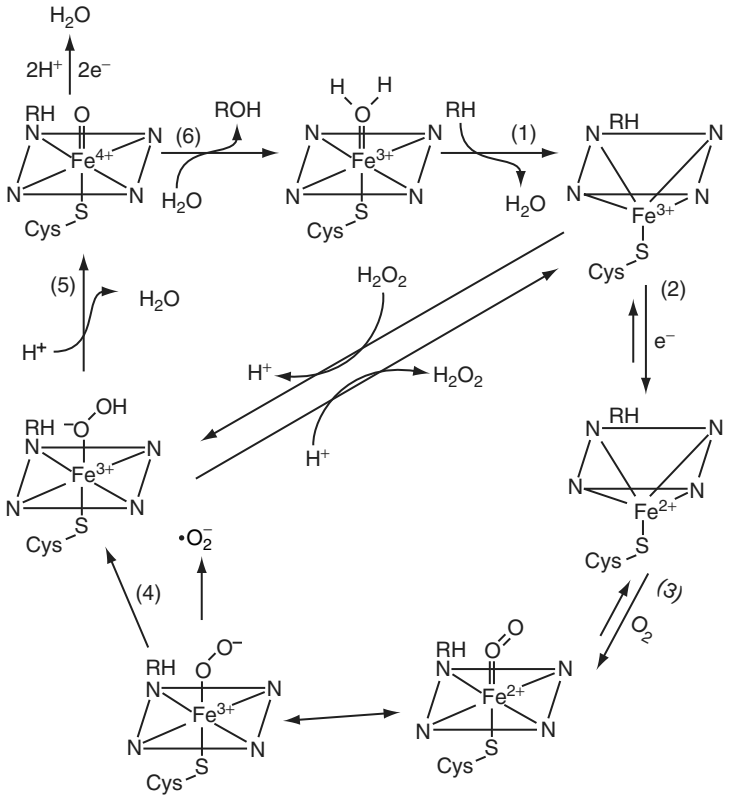

Figure 6 The catalytic cycle of cytochrome P450 and the sites of ROS production. The release of superoxide would occur after transfer of one electron to the haeme iron and binding of oxygen, producing a six-coordinate haeme–Fe^{3+}–$O_2^{\bullet -}$ intermediate (step 3) that can release $O_2^{\bullet -}$; after addition of a second electron and protonation (step 4), the hydroperoxo-Fe^{3+} intermediate may dissociate H_2O_2, regenerating the free Fe^{3+}-haeme (peroxide shunt). (Reproduced by Sono *et al.*, 1996. © American Chemical Society.)

P450 appears to contribute significantly to the overall ROS formation in the cell, even in the absence of xenobiotics induction, in some tissues, such as the liver.

2.2.3 Nitric Oxide Synthase

Nitric oxide synthases (NOS) are a family of enzymes including endothelial nitric oxide synthase (eNOS), neuronal nitric oxide synthase (nNOS) and inducible nitric oxide synthase (iNOS); NOS is a CYP reductase-like enzyme that catalyses flavin-mediated electron transfer from NADPH to a prosthetic haeme group; the enzyme also requires tetrahydrobiopterin (BH_4) to transfer electrons to arginine to release $NO^{\bullet}$ (Bredt, 1999). Although NOS is mostly a cytoplasmic enzyme, a mitochondrial isoform has been described (Ghafourifar and Sen, 2007), but its existence is still debated (Burwell and Brookes, 2008).

The reaction catalysed by NOS is still little understood; the reaction occurs in two steps with formation of *N*-hydroxyarginine, but the detailed mechanism is uncertain:

$$\text{arginine} + 2O_2 + \text{NADPH} + H^+ \longrightarrow \text{citrulline} + NO^{\bullet} + \text{NADP}^+ \quad (20)$$

$NO^{\bullet}$ is a relatively stable radical with a half-life of 1–10 s (Brown and Borutaite, 2004).

In the absence of either BH_4 or arginine, NOS uncouples, that is, it reacts with oxygen, generating $O_2^{\bullet -}$ instead of $NO^{\bullet}$ (Pou *et al.*, 1999); ROS generated by other sources are involved in a feed-forward mechanism inactivating BH_4 and leading to NOS uncoupling (Alp and Channon, 2004). Simultaneous formation of $NO^{\bullet}$ and $O_2^{\bullet -}$ would favour the production of peroxynitrite.

2.2.4 Peroxisomal Enzymes

Peroxisomes are cellular organelles which oxidize a number of substrates, consuming oxygen, the latter being reduced to H_2O_2. In rat liver, peroxisomal oxidations account for about 20% of total O_2 consumption (Reddy and Mannaerts, 1994). Peroxisomes play a key role in both the production and scavenging of ROS in the cell (Schrader and Fahimi, 2006). Besides H_2O_2, peroxisomal enzymes also generate $O_2^{\bullet -}$ and $OH^{\bullet}$ radicals; it was also found that the inducible isoform of NOS is localized in the peroxisomes in its monomeric inactive state, and in the cytoplasm in its dimeric active state (Loughran *et al.*, 2005).

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The main pathway of peroxisomes involved in H_2O_2 production is fatty acid β-oxidation (Hiltunen and Poirier, 2006) via three different acyl-CoA oxidases specific for fatty acyl chains of different lengths and bile acid intermediates. Other enzymes contained in peroxisomes and contributing to hydrogen peroxide generation are D-amino acid oxidases, sarcosine oxidase, L-α-hydroxy acid oxidase, polyamine oxidase (Schrader and Fahimi, 2006), and, most important, XO described in Section 15.2.2.1.

Peroxisomes also contain enzymes that scavenge these reactive species (Schrader and Fahimi, 2006): catalase is the typical marker enzyme of peroxisomes that removes with high efficiency peroxides formed by peroxisomal enzymes; in addition these organelles also contain GPx, Mn-superoxide dismutase (SOD-2) (more typically present in mitochondria), Cu, Zn-superoxide dismutase (SOD-1), peroxiredoxin (Prdx) I, and others (cf. Section 15.5). **Table 2** shows the major ROS-generating and ROS-scavenging enzymes of peroxisomes.

An elevation of oxygen concentration induces a moderate proliferation of peroxisomes, but a more pronounced proliferation, with a many-fold induction of H_2O_2-generating enzymes, occurs after treatment with peroxisome-proliferating chemicals such as hypolipidaemic drugs, industrial compounds and agrochemicals (Beier and Fahimi, 1991); this effect is due to the nuclear transcription factor peroxisome proliferator-activated receptor (PPAR) α and its coactivators (Reddy, 2004). On then other hand, the regulation of peroxisomal proliferation and enzyme induction by oxygen and ROS is not yet well understood (Schrader and Fahimi, 2006). The exposure of cultured cells to UV light and oxidizing agents induces peroxisomal proliferation; the massive proliferation induced by a variety of xenobiotics and the subsequent tumour formation in rats is due to an imbalance in the formation and scavenging of ROS and is mediated by PPARα (Yu *et al.*, 2003).

Studies of knockout (KO) mice in which the PEX genes required for peroxisomal biogenesis and protein import have been deleted (Baes and Veldhoven, 2006) showed absence of functional peroxisomes, mitochondrial alterations, but no evidence of oxidative damage nor increased peroxide production.

Table 2 Peroxisomal enzymes involved in ROS formation and detoxification in mammals

ROS generation	ROS degradation
Acyl-CoA oxidases	Catalase
Palmitoyl-CoA oxidase	Glutathione peroxidase
Pristanoyl-CoA oxidase	Mn-SOD
Trihydroxycoprostanoyl-CoA oxidase	Cu, Zn-SOD
Urate oxidase	PMP20
Xanthine oxidase	Epoxide hydrolase
D-Amino acid oxidase	Peroxiredoxin-1
Pipecolic acid oxidase	—
D-Aspartate oxidase	—
Sarcosine oxidase	—
L-α-Hydroxy acid oxidase	—
Polyamine oxidase	—
NO synthase	

SOD, superoxide dismutase; PMP, peroxisomal membrane protein.

2.2.5 Plasma Membrane NADPH Oxidase

A phagocyte NADPH oxidase, later called NOX-2, was found to be responsible for the respiratory burst accompanying phagocytosis (Rossi and Zatti, 1964) and producing superoxide. Much later it was found that NOX isozymes are present in many other cell types (Bedard *et al.*, 2007; Lambeth, 2007; Sumimoto, 2008). All NOX family members are transmembrane proteins that transport electrons across biological membranes to reduce O_2 to superoxide; all have a strong preference for NADPH over NADH as the donor substrate.

$$\mathrm{NADPH} + 2\mathrm{O}_2 \longrightarrow \mathrm{NADP}^+ + 2\mathrm{O}_2^{\bullet -} + \mathrm{H}^+ \qquad (21)$$

Much of what is known about the topography and structure of NOX isoforms is derived from studies of NOX-2 (**Figure 7**); the protein has six transmembrane domains and contains FAD in the cytoplasmic domain and two asymmetrical haeme groups embedded in the membrane domain, so that electrons are transferred from

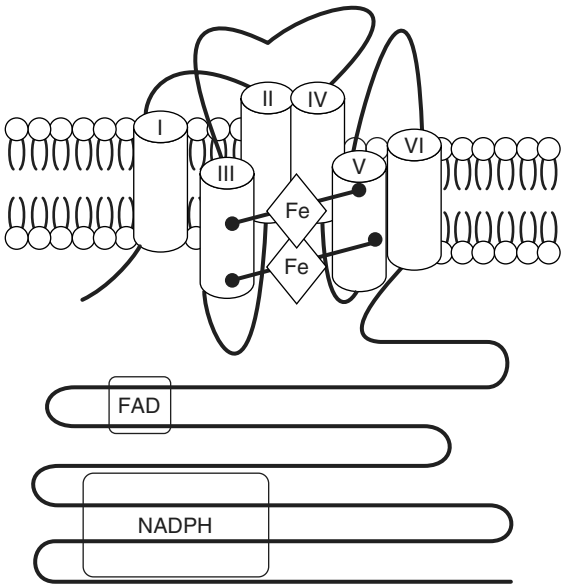

Figure 7 Structure of NOX-2 (gp91^{phox}). The six cylinders I-VI are transmembrane α-helices; the two rhombs connecting helices III and V are the haeme groups, while FAD and the NADPH binding region are in the cytoplasmic domain. NOX-2 is constitutively linked to membrane-bound p22^{phox} (not shown).

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

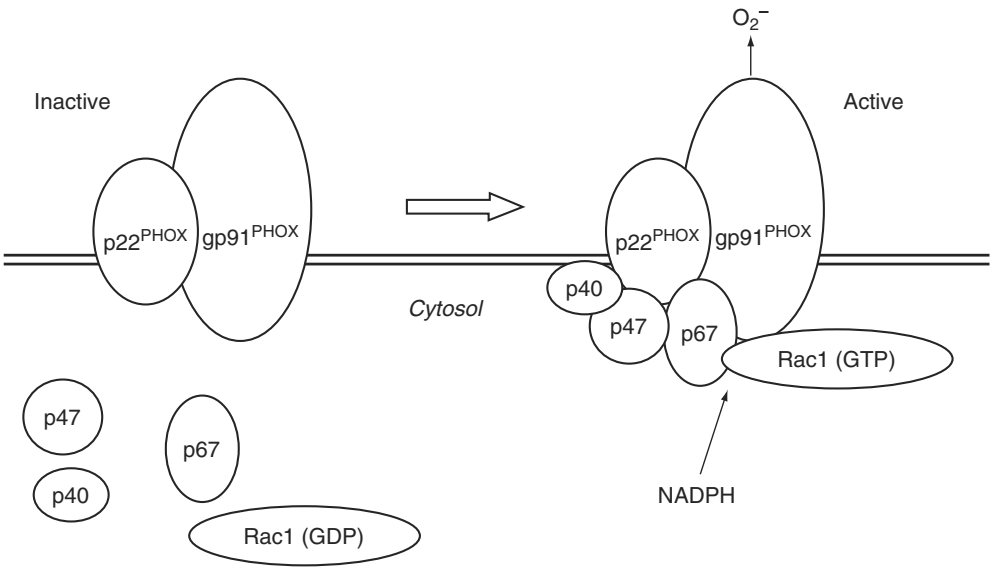

Figure 8 Activation of NOX-2 by cytoplasmic factors. Upon cellular stimulation, the p40, p47, p67 and the GTPase Rac1 associate from forms free in the cytoplasm to a supramolecular complex with the gp91-p22^{phox} complex. This activated complex is able to transfer electrons from cytoplasmic NADPH to extracellular oxygen to form superoxide.

NADPH to FAD in the cytoplasm and translocated to oxygen on the exterior of the cell.

The activation of NOX-2 occurs through a complex series of protein–protein interactions; NOX-2 (gp91^{phox}) forms a constitutive complex with p22^{phox}; phosphorylation of p47^{phox} allows its interaction with the NOX2-p22^{phox}; p47^{phox} is an organizer subunit allowing the translocation of other cytosolic subunits (the activator subunit p67^{phox}, the smaller p40^{phox} and then finally the guanosine triphosphate (GTP)ase Rac) (**Figure 8**); once assembled, the complex is active in catalysing the reaction of NADPH with oxygen.

Although NOX-2 is regarded as the typical phagocyte-specific NADPH oxidase, widely expressed in neutrophils and macrophages, nevertheless it is found in a number of tissues. In phagocytes, NOX-2 localizes in both plasma membranes and in intracellular granules; upon phagocyte stimulation, NOX-2 translocates to the surface by fusion of the granules with the plasma membrane.

Once superoxide is formed (Reaction 21), this is converted to H_2O_2 by SOD and then to hypochlorous acid by myeloperoxidase:

$$2O_2^{\bullet -} + 2H^+ \longrightarrow H_2O_2 + O_2 \qquad (22)$$

$$H_2O_2 + Cl^- + H^+ \longrightarrow HOCl + H_2O \qquad (23)$$

It is not clear how much the bacterial killing activity is due to superoxide, to H_2O_2 or to hypochlorous acid, or even to hydroxyl radical, singlet oxygen or peroxynitrite (Bedard and Krause, 2007); probably the combination of all of these factors is active *in vivo*.

More recently, several homologues of NOX-2 were discovered, each present in major amounts in a specific tissue, but all expressed in a wide variety of tissues (Bedard and Krause, 2007) (cf. **Table 3**). All the NOX homologues, except NOX-5, require p22^{phox} for activity, while the requirement for cytosolic subunits is clear only for NOX-1.

Two additional enzymes resembling NOX, called dual oxidase (DUOX)-1 and -2, were identified in the thyroid gland (Dupuy *et al.*, 1999). The first product of these enzymes is likely to be superoxide, which is, however, very rapidly dismutated to hydrogen peroxide (Ameziane-el-Hassani *et al.*, 2005); DUOX enzymes do not appear to require cytosolic factors.

Besides the well-understood role of NOX-2 in bacterial killing, the function of NOX from other sources is essentially cell regulation; this function occurs through oxidation of redox-sensitive cysteine residues in signal transduction proteins (Hunter, 2000). Nevertheless, the

Table 3 Human NOX isoforms

Enzyme	Location	Regulatory factors
NOX-1	Inducible (colon and smooth muscle)	NOX01, NOXA1, P22^{phox}
NOX-2	Phagocytes	P22^{phox}, P47^{phox}, P67^{phox}, P40^{phox}, Rac1
NOX-3	Foetal kidney	P22^{phox}
NOX-4	Widespread	—

biochemical and physiological properties of NOX enzymes *in situ* are not yet fully clarified (Nauseef, 2008).

NOX-derived ROS have been implicated in a wide variety of pathological dysfunctions, including cardiovascular diseases, neurodegenerative diseases, hyperinflammatory response to *Helicobacter* infection, inflammatory colon disease and colon cancer, liver cirrhosis, diabetic nephropathy, asthma, chronic obstructive pulmonary disease and others (Bedard and Krause, 2007; Lambeth, 2007).

In addition to the NADPH oxidases described above, Morré's group has described a family of cell surface hydroquinone and NADH oxidases with protein disulfide thiol exchange activity, referred to as ECTO-NOX (Morré and Morré, 2003); one member of this family, designated tNOX, is specific for cancer cells and for cells in early developmental stages (Cho and Morré, 2008). These enzymes react with O_2, generating superoxide, and are characterized by the requirement for ubiquinone in the membrane as a redox mediator between quinone reductase and NOX proper.

2.2.6 Lipoxygenases

Lipoxygenases catalyse the conversion of arachidonic acid into a broad class of signalling molecules, such as leukotrienes, hydroxyeicosatetraenoic acid and lipoxins (Schewe, 2002). The enzymatic cycle involves formation of enzyme-bound radicals and lipid hydroperoxides that, under certain conditions, escape the active site and attack surrounding molecules. Lipid hydroperoxides can also be formed by nonenzymatic oxidation of polyunsaturated fatty acids (PUFAs) and further modified by lipoxygenases.

2.2.7 Metal-induced Oxidative Stress

The generation of ROS is closely linked to the participation of redox-active metals (Valko *et al.*, 2005; 2006). The redox state of the cell is largely linked to an iron redox couple; it has been shown that an excess of superoxide releases free iron from iron proteins (Liochev and Fridovitch, 2002); the released Fe^{2+} can participate in the Fenton reaction, generating the highly reactive hydroxyl radical (Reaction 4). Since superoxide is able to reduce Fe^{3+} to Fe^{2+}, it participates in the Haber–Weiss reaction, which combines the Fenton reaction and the reduction of Fe^{3+} by superoxide (Reaction 24 + 4):

$$Fe^{3+} + O_2^{\bullet -} \longrightarrow Fe^{2+} + O_2 \quad (24)$$

$$O_2^{\bullet -} + H_2O_2 \longrightarrow O_2 + OH^{\bullet} + OH^{-}$$

(Haber–Weiss reaction) (25)

The most realistic *in vivo* production of $OH^{\bullet}$, according to the Fenton reaction, occurs when the reduced metal is iron, copper, chromium or cobalt; the pathophysiological significance of Fenton chemistry is however still debated, due to the effective sequestration of metals, namely iron, by metal-binding proteins (Kakhlon and Cabantchik, 2002); however, organisms overloaded with iron contain large amounts of free iron; free iron is transported into an intermediate pool of exchangeable and easily chelated iron.

The role of metal ions in enhancing ROS formation is considered the main basis of their toxicity and carcinogenicity (Valko *et al.*, 2006). Besides the well-characterized carcinogenic action of arsenic, cadmium, chromium and nickel (Durham and Snow, 2006), iron in excess may also be carcinogenic due to direct action on DNA (Goetz and Luch, 2008).

ROS are continuously produced in erythrocytes due to the high O_2 tension and their high iron content (Cimen, 2008); the source of ROS in erythrocytes is haemoglobin (Hb), which undergoes auto-oxidation to produce $O_2^{\bullet -}$ and meta-Hb having a ferric iron. Oxidative stress may damage the red cell itself, but ROS may also leave the cell and damage other components of the circulation (Johnson *et al.*, 2005).

2.2.8 Role of Electron Mediators and Xenobiotics: Redox Cycling

Many physiologically active substances and xenobiotics have electron transfer functionalities, either per se, or more usually in their metabolites. These main groups include quinones (or phenolic precursors), metal complexes (or complexors), aromatic nitro compounds (or reduced derivatives), and conjugated imines or iminium species (Kovacic and Cooksy, 2005). *In vivo* redox cycling with oxygen can occur in a catalytic fashion giving rise to a futile cycle that regenerates the parent compound and releases ROS. Redox cycling has been suggested for several drugs, like cocaine, other abused drugs, catecholamines and several other compounds (Halliwell and Gutteridge, 1999). Electron transfer with redox cycling occurs through interference with physiological electron transfer reactions such as microsomal CYP, XO and the mitochondrial respiratory chain.

A typical example is the anticancer agent, adriamycin, which exhibits severe cardiotoxicity; the toxic effect is distinct from the anticancer mechanism, and involves ROS formation, as also suggested by the protective effect of overexpressing antioxidant enzymes in transgenic animals (Sun *et al.*, 2001).

Studies in perfused rat hearts showed that adriamycin largely localizes to mitochondria. Thus, although the drug can be reduced univalently by a variety of systems, such as CYP, XO and mitochondrial Complex I, the oxidative activation in the heart appears to involve mainly mitochondria (Berthiaume and Wallace, 2007). Conversely, in the liver CYP appears to account for a substantial portion of activation (Cribb *et al.*, 2005). The mechanism of redox cycling is shown in (**Figure 9**): the

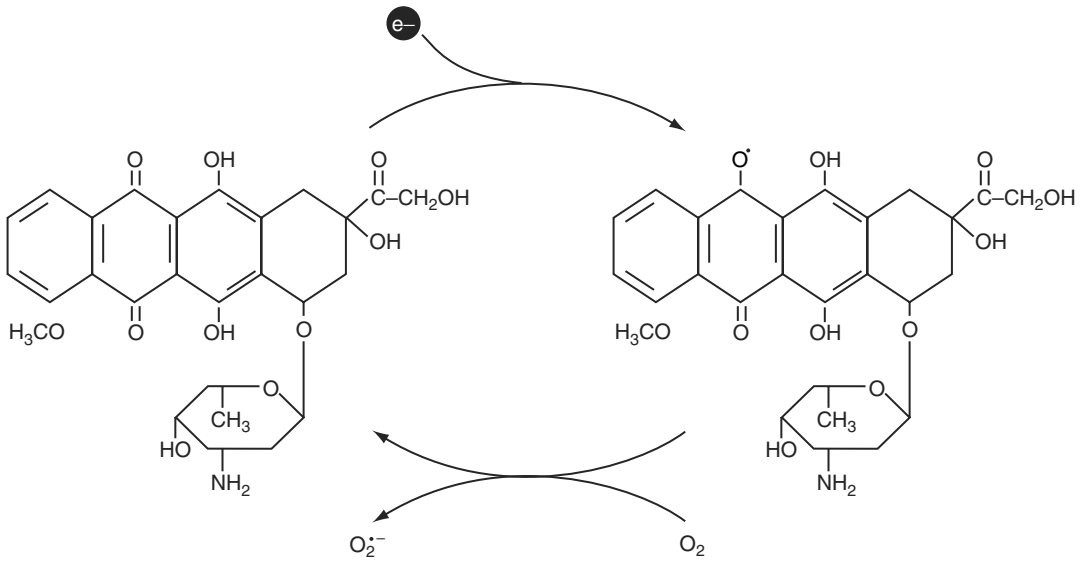

Figure 9 Redox cycle of adriamycin. The drug is reduced by one electron (from CYP or mitochondrial Complex I) to its semiquinone radical, which reacts with oxygen, producing superoxide.

drug is first reduced to a semiquinone radical by a one-electron transfer, and then reacts with oxygen, releasing superoxide and regenerating adriamycin.

Recent studies with physiological doses confirm that adriamycin induces acute ROS generation that occurs mainly at the level of Complex I (Salvatorelli *et al.*, 2006). The mechanism of cardiotoxicity, however, implies long-term exposure, indicating that acute oxidative stress per se is not sufficient to explain cardiac failure. The major mechanisms involved in chronic toxicity also appear to involve mitochondria and are ascribed to secondary damage induced by ROS to Complex I and other mitochondrial complexes, with loss of OXPHOS efficiency, and to oxidative damage to mitochondrial DNA leading to permanent loss of the OXPHOS machinery (Berthiaume and Wallace, 2007).

The activation pathway followed by carcinogenic polycyclic aromatic hydrocarbons is more complex (Luch, 2005) (**Figure 10**); mono-oxygenation by CYP generates *trans*-dihydrodiols with the subsequent formation of dihydrodiol epoxides, which form adducts with DNA, thus initiating carcinogenesis. Alternatively, *trans*-dihydrodiols may be converted by enzymatic oxidation into cathecols, which undergo spontaneous auto-oxidation with O_2 to the corresponding *o*-quinones, by two one-electron steps, with intermediate formation of the semiquinone anion radicals and reduction of O_2 to either $O_2^{\bullet -}$ or H_2O_2; both the semiquinone and the quinone forms can undergo catalytic one-electron redox cycling, being reduced by either microsomal CYP and cytochrome b_5 reductase or mitochondrial Complex I (Luch, 2005). One-electron reduction and auto-oxidation steps establish futile redox cycles in which ROS generation is amplified multiple times (Goetz and Luch, 2008). Biotransformation of polycyclic hydrocarbons also leads to formation of polynuclear quinones, which may also undergo redox cycling with the corresponding quinols.

A similar mechanism has been suggested for benzene: initial metabolism occurs in the liver by CYP, with resulting formation of, among other compounds, benzene dihydrodiol, which is oxidized to cathecol and then

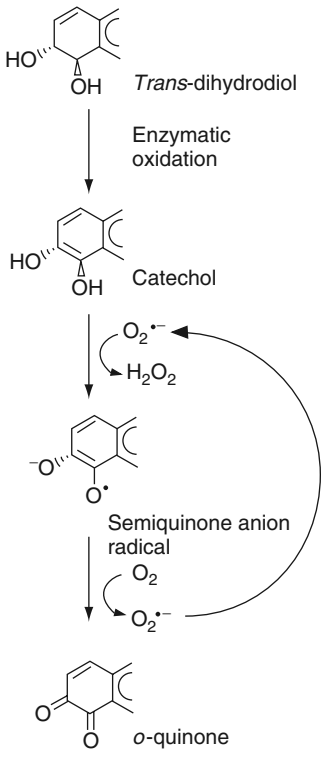

Figure 10 Redox cycling of aromatic polycyclic hydrocarbons. The *trans*-dihydrodiols are oxidized to cathecols that undergo redox cycling as described in the text.

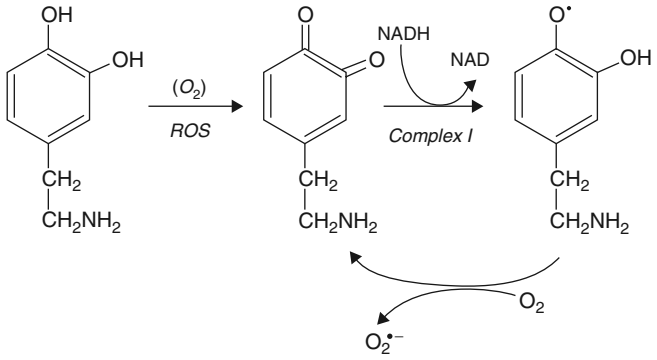

Figure 11 Redox cycling of cathecolamines: the example of dopamine is shown in the figure. Dopamine is first oxidized to dopaminochrome, which is reduced by Complex I by one-electron transfer to the semiquinone, which then auto-oxidizes generating superoxide and perpetuating the cycle.

to benzoquinone (Shen *et al.*, 1996), which undergoes redox cycling with ROS production. To this purpose, *p*-benzoquinone derivatives, such as short-chain CoQ homologues and analogues undergo redox cycling with oxygen at the level of mitochondrial Complex I (Genova *et al.*, 2001); the mechanism of activation involves a site close to the CoQ physiological reduction site, but situated upstream of the rotenone block, presumably the iron–sulfur centre N2 (Lenaz *et al.*, 2006a). When, however, the quinones are added in the absence of a Complex I inhibitor, but in presence of a Complex III inhibitor, thus allowing their reduction, they behave as potent antioxidants preventing ROS formation (Fato *et al.*, 2008).

Adrenaline may undergo oxidation and cyclization to adrenochrome in a multistep process in which the main oxidant under physiological conditions is the superoxide anion (Bindoli *et al.*, 1992). On the other hand adrenochrome can be reduced to the corresponding semiquinone by NADPH in liver microsomes and by mitochondrial Complex I in bovine heart (Bindoli *et al.*, 1990). A redox cycle is then established in which the semiquinone reacts with O_2, producing superoxide and regenerating adrenochrome (Genova *et al.*, 2006).

Since adrenochrome reduction to the semiquinone is totally insensitive to both rotenone (which acts at the level of iron–sulphur centre N2) and *p*-hydroxymercuribenzoate (which inhibits at the start of the iron–sulfur chain), the site of electron delivery to adrenochrome is presumably FMN. Similar events may also occur with other catecholamines such as DA and noradrenaline (**Figure 11**).

2.2.9 UV and Ionizing Radiation

The UV light region occurs between 100 and 400 nm and is subdivided into thee main categories: UVA (315–400 nm), UVB (280–315 nm) and UVC (100–280 nm). The ozone layer absorbs all UVC and most UVB, but the damage to the protective ozone layer now allows an increased amount of UVB to reach the ground (De Gruijl and van der Leun, 2000). UVA is totally absorbed by the skin and penetrates deep into the epidermis and dermis, whereas UVB is less penetrating, but much more active. The UVC light is the most energetic, but is completely absorbed by the Earth's atmosphere.

To exert its biological effects UV light must be transmitted across skin layers and be absorbed by cellular molecules. Damage is induced via two different mechanisms (Pattison and Davies, 2006): one is direct absorption of photons by cellular chromophores leading to photoinduced reactions; the second is indirect and involves photosensitization processes where endogenous and exogenous photosensitizers absorb UV light and induce damage, either by direct interaction of the excited photosensitizer with other molecules, with free radical formation, or by energy transfer to molecular oxygen, with production of ROS, mostly singlet oxygen, but also superoxide (**Figure 12**).

The formation of ROS as mediators of photooxidative stress in UV-irradiated skin depends on a number

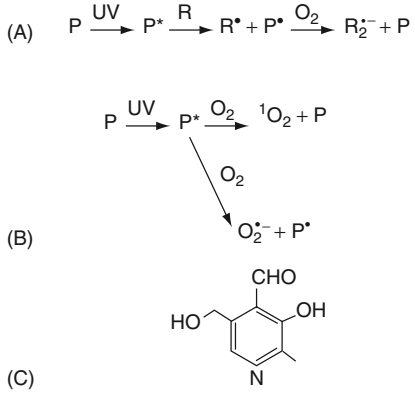

Figure 12 Mechanism of photosensitizers in ROS formation: (A) direct interaction of the excited photosensitizer (P*) with another compound R, with radical formation and secondary autooxidation; (B) interaction of P* with oxygen, with formation of either singlet oxygen or superoxide; (C) an example of endogenous photosensitizer: pyridoxal.

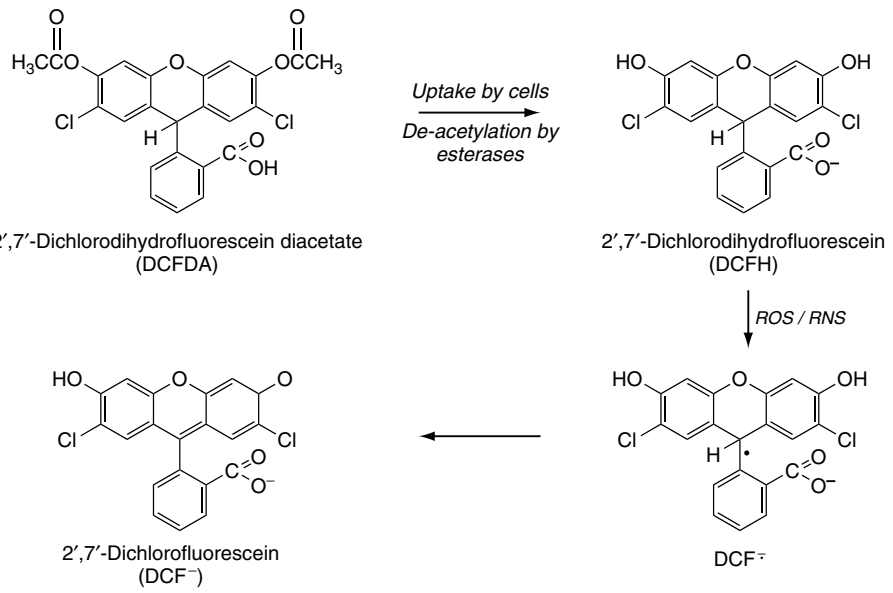

Figure 13 Mechanism of dichlorofluorescein diacetate (DCFDA) as a probe for ROS. DCFDA is taken up by cells, deacetylated to DCFH and oxidized by ROS to DCF via an intermediate radical DCF•.

of photosensitizers present in the skin, such as urocanic acid, riboflavin, melanin precursors, advanced glycation end products (AGE, see Section 15.3.3) and also endogenous 3-hydroxypyridine derivatives (Wondrack *et al.*, 2004); the latter derivatives may arise from various sources, such as B_6 vitamins, the extracellular matrix-associated crosslinks pyridinoline and deoxypyridinoline, and various AGE that accumulate during aging.

The cellular damage induced by ionizing radiation initiates with radiolysis of water, producing radicals, mostly OH•. The direct effect of radiation on ROS production is rather modest and much inferior to the amount of radicals produced by normal metabolic processes ($1\,\mu M\ Gray^{-1}$ compared with hundreds of $mmol\ day^{-1}$ produced by mitochondria). Thus the few primary ionization events must be amplified to account for the rapid and robust activation of signal transduction pathways (Mikkelsen and Wardman, 2003); amplification mechanisms may involve stimulation and uncoupling of NOS with formation of peroxynitrite, release of metal ions and ROS-induced opening of the mitochondrial permeability transition pore (MPTP). This latter mechanism is of major importance since rho^0 cells deficient in mitochondrial DNA (mtDNA) and mitochondrial electron transfer do not show amplification. It has been proposed that radiation damage in a few mitochondria is transmitted via a wave of Ca^{2+}-dependent permeability transitions to adjacent mitochondria, with enhanced ROS/RNS formation.

2.3 Measuring ROS in Cells

Most ROS persist for very short times *in vivo* and cannot be measured directly; there are two approaches to detect transient ROS (Halliwell and Whiteman, 2004): (i) attempt to trap these species and measure the levels of the trapped molecules; (ii) measure the amount of oxidative damage done by ROS. In addition, sometimes the antioxidant activity of body fluids or cells is taken as an index of oxidative stress.

The only technique that can detect free radicals directly is electron spin resonance (ESR). Since reactive radicals are transient, one solution is to add probes that act as 'traps' that intercept them, forming stable radicals detectable by ESR; a wide range of traps has been used in animals and cells in culture, mostly nitroxides. Measuring the amount of oxidative damage (see Section 15.3) by selecting appropriate biomarkers is widely used, but there is often little correlation between the extent of oxidative stress and the enhancement of a biomarker, and often different biomarkers behave differently.

The most widely used methods to detect ROS in cells are based on the use of probes, mainly fluorescence probes. The most popular is 2′-7′-dichlorofluorescein diacetate (DCFDA) (**Figure 13**); DCFDA enters cells and accumulates, then is deacetylated by endogenous esterases to yield the non-fluorescent 2′-7′-dichlorohydrofluoroscein (DCFH) which is oxidized by endogenous ROS to the strongly fluorescent 2′-7′-dichlorofluoroscein DCF: although DCF is usually considered a probe for peroxides, it reacts slowly with H_2O_2, and also with superoxide, while reacting mostly with OH• and peroxynitrite. Other widely used probes are listed in **Table 4**.

The fluorescence can be measured by putting the cells in a plate reader or better by flow cytometry, which measures only intracellular fluorescence. It has to be borne in mind that all studies with probes are amenable

3 EFFECTS OF ROS ON CELLULAR MOLECULES AND CELLULAR STRUCTURES

All biomolecules in the cell are targets of ROS and undergo chemical modifications that accumulate with age (Diplock, 1994; Lenaz, 1998): protein carbonylation and methionine oxidation, AGE, lipid peroxidation and nucleotide modifications. However, it is not completely understood which species are responsible for the damage *in vivo* and how the increased availability of ROS translates into the accumulation of specific oxidative damage (Schoneich, 1999); for instance, some proteins are better targets than others for oxidative damage.

The damage induced by ROS depends on the extent and specificity of their reactivity (Halliwell, 2006). If two free radicals meet, they can join their unpaired electrons to form nonradical products; this may lead to loss of reactivity, but in some cases the products may be even more dangerous than the reactants, for example, the reaction of $O_2^{\bullet -}$ and $NO^{\bullet}$ generates the toxic peroxynitrite (Reaction 5).

When a radical meets a nonradical species, several options are possible (Halliwell, 2006). If the radical is reactive enough it attacks the nonradical, generating a new radical and initiating a chain reaction. There are several types of reaction: (i) the radical can add to the nonradical, forming an adduct still having an unpaired electron; (ii) the radical may behave as a reductant, donating a single electron to the nonradical; (iii) the radical may be an oxidant, taking a single electron from the nonradical; (iv) a radical may abstract a hydrogen atom from a –CH bond, for example, $OH^{\bullet}$ can abstract $H^{\bullet}$ from a hydrocarbon, forming water and a carbon-centred radical.

3.1 Lipid Peroxidation

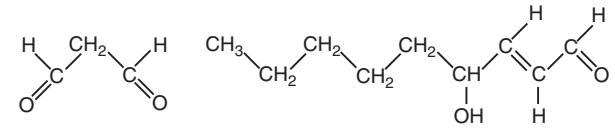
The polyunsaturated fatty acyl chains of phospholipids are very sensitive to oxidation by ROS (Balazy and Nigam, 2003). Since subcellular membranes contain high amounts of polyunsaturated fatty acids (PUFAs), formation of carbon-centred radicals within membranes results in peroxidation of fatty acids.

The overall process of lipid peroxidation can be divided into three stages:

(i) Initiation, that is, extraction of hydrogen from allylic or bis-allylic positions of PUFAs: carbon radicals in the presence of O_2 generate peroxyl radicals ($LOO^{\bullet}$) and random mixtures of cyclic peroxides and hydroperoxides. The initiating species may be the $OH^{\bullet}$ radical, but also a $Fe^{2+}–O_2–Fe^{3+}$ complex or a $ADP–Fe^{2+}$ complex (Valko *et al.*, 2006).

(ii) Radical chain propagation (**Figure 14**): peroxyl radicals may react with side chains of PUFA, yielding hydroperoxides ROOH and other carbon radicals, thus initiating a chain reaction. Phospholipid hydroperoxides may be cleaved by phospholipase A_2 to yield the free fatty acid hydroperoxides (Williams and Gottlieb, 2002). In addition, hydroperoxides can further degrade to alkoxyl ($LO^{\bullet}$), alkyl ($L^{\bullet}$) or $OH^{\bullet}$ radicals, thereby initiating another cycle of chain reactions.

(iii) Termination: when a radical meets another radical or an antioxidant, the chain reaction is terminated. However, peroxyl radicals can react with O_2 by cyclization to produce a cyclic peroxide, which can undergo a second cyclization to form a bicyclic peroxide and then an endoperoxide; the latter is cleaved to produce aldehyde products, the major being malondialdehyde (MDA) and 4-hydroxy-2-nonenal (4-HNE), but including also alkadienals, crotonaldehyde, acrolein and so on, all cumulatively designated as advanced lipid peroxidation end products (ALE) (Negre-Salvayre *et al.*, 2008). Oxidation of ω-6 PUFA yields 4-HNE, while oxidation of ω-3 PUFA yields 4-hydroxy-2-hexanal.



MDA is a volatile molecule that reacts via Schiff base formation with amino groups of protein, lipid and DNA. In addition MDA also reacts with DNA bases forming adducts that are mutagenic (Marnett, 1999). 4-HNE is more reactive than MDA with proteins; in addition the modified proteins are not degraded efficiently by the proteasome (Friguet and Szweda, 1997).

Other nonenzymatic products of arachidonic acid oxidation are isoprostanes, which are formed *in situ* within phospholipids, and are then removed by action of phospholipase A_2; isoprostanes are similar to prostaglandins, exert numerous biological functions, but also may

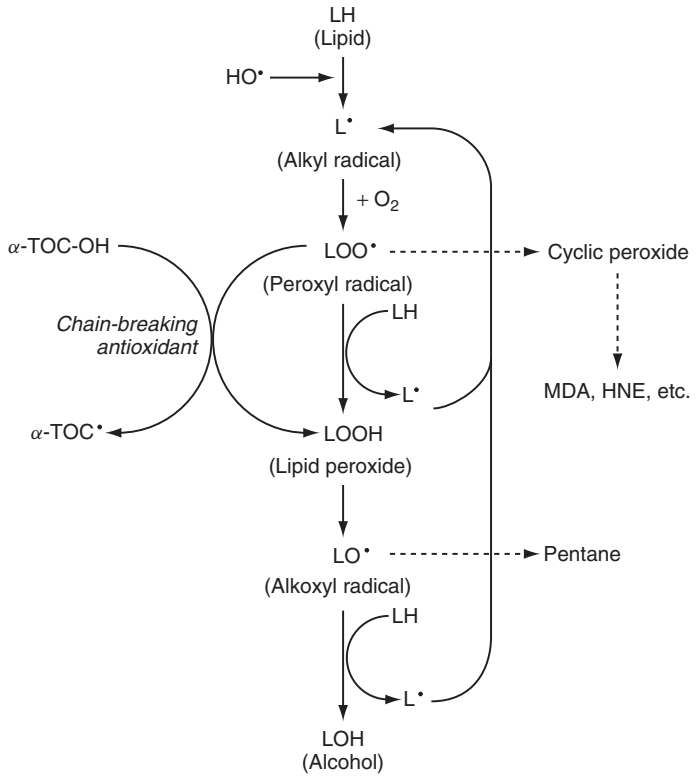

Figure 14 Mechanism of lipid peroxidation. After initiation by attack with an OH•, polyunsaturated fatty acids (LH) form an alkyl radical L• that reacts with oxygen, forming a hydroperoxide radical LOO•. By reacting with other fatty acids LOO• starts a chain reaction with formation of lipid peroxides LOOH; the chain reaction may be interrupted by an antioxidant, a molecule generating more stable radicals, such as α-tocopherol (α-Toc-OH). Alternatively LOOH may react with Fe^{2+}, generating the alkoxyl radical LO•, which may establish a further chain reaction or be degraded to hydrocarbons (pentane). Usually LOOH are degraded to aldehydes such as MDA, 4-HNE, and so on (see text).

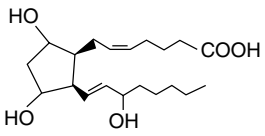
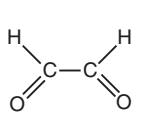
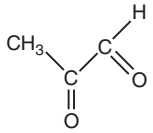
form protein adducts with lysine side chains. Isoprostanes are used as indicators of oxidative stress (Morrow, 2005; Dalle Donne *et al.*, 2006).



Isoprostane



Glyoxal



Methylglyoxal

Another class of reactive ALE precursors is represented by α-oxoaldehydes (methylglyoxal and glyoxal); they are basically derived from sugars in hyperglycaemic conditions, however they are also generated from lipid peroxidation (glyoxal) or the catabolism of glycerol and ketone bodies (methylglyoxal) (Negre-Salvayre *et al.*, 2008). Methylglyoxal metabolism is also linked to ROS production both in the generation and in the degradation of this compound (Kalapos, 2008).

The initial H• abstraction from PUFAs can occur at different points in the carbon chain; thus the peroxidation of arachidonic acid (20 : 4) gives six lipid hydroperoxides, eicosapentaenoic acid (20 : 5) can give eight, and docosahexaenoic acid (22 : 6) can give 10, plus high numbers of cyclic peroxides and isoprostanes (Halliwell, 2006).

Cholesterol can be peroxidized at different positions (5α, 6α, 6β, 7α, 7β) by free radical or singlet oxygen attack. Subsequent breakage of the B ring will produce aldehydes (secosterols), that induce protein misfolding (Bieschke *et al.*, 2006). A common product in atherosclerotic plaques is 27-hydroxy-cholesterol.

Metal ions may split lipid hydroperoxides to produce alkoxyl (LO•) and more peroxyl (LOO•) radicals, that will continue the chain reaction.

$$LOOH + Fe^{2+} \longrightarrow Fe^{3+} + LO^{\bullet} + OH^{-} \quad (26)$$

$$LOOH + Fe^{3+} \longrightarrow Fe^{2+} + LOO^{\bullet} + H^{+} \quad (27)$$

Lipid hydroperoxides have relatively long lifetimes, compared with lipid radicals; for this reason they

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

can easily translocate relatively long distances (Girotti, 2008). A well-known example is the transbilayer movement of peroxidized phosphatidyl serine in cells destined for apoptosis. In addition ROOH can move from one to another membrane within a single cell, or from the plasma membrane of a cell to that of another cell or to a lipoprotein (Girotti, 2008). Movement of peroxides from one membrane to another may greatly expand their range of toxic damage, particularly if they move to a compartment rich in iron and/or poor in antioxidants (Vila *et al.*, 2000).

A distinct lipid modification is the reaction of the *cis* double bonds of arachidonic acid with the nitrogen dioxide radical ($NO_2^{\bullet}$) forming nitroeicosanoid derivatives that can then split to four different *trans* isomers; these compounds have a number of biological effects, including induction of apoptosis, and may be regarded as selective biomarkers of nitro-oxidative stress (Balazy and Chemtob, 2008).

At the cellular level, lipid peroxidation induces changes in cell membranes with modification of their permeability and alterations of lipid-dependent enzymes. This latter effect is well studied in mitochondria where oxidation of cardiolipin induces a decrease in activity of respiratory complexes (Paradies *et al.*, 2000; 2002) and loss of supercomplex organization (Lenaz *et al.*, 2007b).

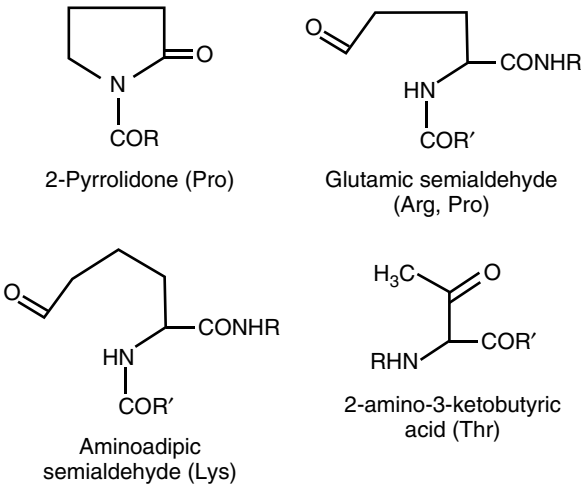

Figure 15 Structures of protein carbonyls arising from oxidation of amino acid side chains. The parent amino acids are indicated in parentheses. R and R′ indicate the remainder of the polypeptide chains.

3.2 Protein Oxidation

Hydroxyl radicals produced by ionizing radiation or by the Fenton reaction are able to attack the polypeptide backbone of proteins to form a carbon-centred radical, which may react with O_2 to form a peroxyl radical (Stadtman, 1992; Stadtman, 2004). The peroxyl radical is then converted to alkyl peroxide by reaction with protonated superoxide $HO_2^{\bullet}$. The alkoxyl derivatives of proteins may then undergo peptide bond cleavage. In the absence of radiation or metal ions, superoxide and H_2O_2 would be inactive.

The side chains of all amino acids in proteins are susceptible to oxidation; however some residues like proline, histidine, arginine, lysine and cysteine are highly sensitive to oxidation by metal ions. Thus it is believed that Fe^{2+} binding to the above residues undergoes the Fenton reaction with H_2O_2 to yield $OH^{\bullet}$ at those specific sites.

The amino acid residues that are most vulnerable to attack by ROS are arginine, glutamate, histidine, tyrosine, valine, cysteine, proline, threonine and methionine (Stadtman, 2004). Cysteine and methionine residues are particularly susceptible to oxidation by ROS. The oxidation of methionine residues by ROS forms methionine sulfoxide (Met-SO). The oxidation of the amino acid residues, as well as the glycation of lysine groups (cf. Section 15.3.3) generates carbonyl groups: protein carbonylation is the most widely used marker of protein oxidation both *in vitro* and in pathological conditions (Dalle Donne *et al.*, 2006) (**Figure 15**).

Peroxynitrite formed by the reaction of $NO^{\bullet}$ with $O_2^{\bullet -}$ may react with cysteine SH groups, oxidizes methionine to methionine sulfoxide and reacts with tyrosine forming 3-nitrotyrosine (another important marker of oxidative protein damage).

Protein oxidation by ROS is associated with the formation of many different kinds of inter- and intraprotein crosslinkages, such as by addition of a lysine amino group to a carbonyl group of the oxidized protein, by interaction of two carbon-centred radicals of polypeptide backbones, by oxidation of cysteine residues to form S-S crosslinks, or by oxidation of tyrosine residues to form tyr-tyr crosslinks. The cysteine S-S crosslinks are reversible, since they can be repaired by disulfide exchange reactions. Oxidation of cysteine residues can also lead to reversible formation of mixed disulfides, particularly with glutathione (GSH) (S-glutathionylation); S-glutathionylated proteins accumulate under conditions of oxidative stress (Dalle Donne *et al.*, 2005).

Besides being altered by direct oxidation by ROS, proteins may be covalently modified by products of lipid peroxidation, such as the reactive aldehydes described in Section 15.3.2.1 (Bieschke *et al.*, 2006).

3.3 Advanced Glycation End Products (AGE)

AGE are a group of heterogeneous compounds that form constantly in the body, but are markedly increased in conditions of hyperglycaemia and oxidative stress (Vlassara, 2005). AGE are the end-products of the Maillard

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024

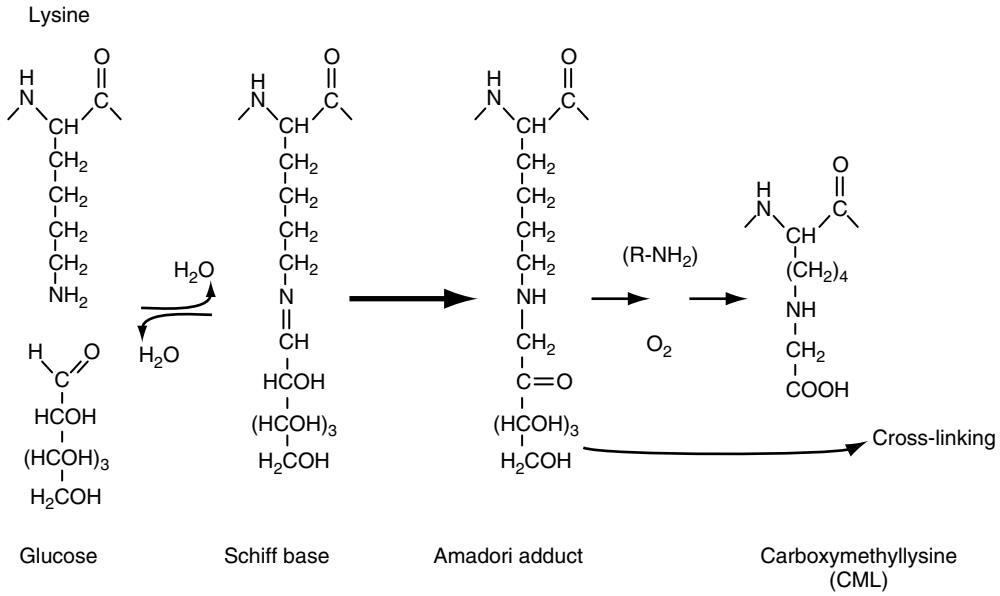

Figure 16 Mechanism of formation of AGE. The example concerns glucose and protein-bound lysine residues. The formation of the Schiff base has a timescale of hours, whereas Amadori products are formed within days. The formation of stable crosslinks takes weeks or months.

reaction between sugars and proteins: a sugar reacts with a protein amino group to form a Schiff base, is then stabilized in the form of an Amadori product and its subsequent rearrangement leads to formation of stable and irreversible AGE compounds (**Figure 16**).

The final step of the Maillard reaction is driven by oxidative stress, and AGE accelerate oxidation, thus favouring their own production. Protein adducts also arise from lipid oxidation and are often included among AGE, although they should be more properly called ALE (Section 15.3.1).

For the process of AGE formation, glucose is the predominant substrate, but other sugars, such as fructose, glucose-6-phosphate, glyceraldehyde-3-phosphate, ascorbate and methylglyoxal, may react with proteins and produce chemically distinct AGE (Bohlender *et al.*, 2005; Soskic *et al.*, 2008). AGE-modified proteins are recognized by specific receptors (RAGE) whose activation is responsible for the cellular effects of AGE and their pathological consequences (Wendt *et al.*, 2003). Binding and activation of RAGE can promote further oxidative stress and AGE formation via the NADPH oxidase pathway (Peppa *et al.*, 2008).

The diet is a major source of AGE and dietary AGE are called glycotoxins; exaggerated intake of thermally treated food may exert oxidative stress and pathological consequences (Vlassara and Striker, 2007).

3.4 DNA Damage

The hydroxyl radical reacts with all components of the DNA molecule damaging the purine and pyrimidine bases and the deoxyribose backbone (Dizdaroglu *et al.*, 2002; Cooke *et al.*, 2003). Permanent modifications of genetic material are the first step involved in mutagenesis, cancerogenesis and ageing. To date more than 100 products have been identified from the oxidation of DNA, including single- or double-stranded DNA breaks, purine, pyrimidine and deoxyribose modifications, and DNA crosslinks (Valko *et al.*, 2006). DNA damage can result in either arrest or induction of transcription, induction of signal transduction pathways, replication errors and genome instability.

The $OH^{\bullet}$ radical is able to add to double bonds of DNA bases and to abstract an H atom from the methyl group of thymine and each of the C atoms of deoxyribose; the formation of 8-hydroxyguanine (8-OH-G) (**Figure 17**) is the most prominent example among over 20 base modifications.

8-OH-G is the most easily formed base alteration, is mutagenic and carcinogenic, and is a good biomarker of oxidative DNA damage. This modification occurs in one in 10^5 G residues in normal cells, but increases in oxidative stress, ageing and a number of diseases (Halliwell and Gutteridge, 1999). mtDNA is more susceptible than nuclear DNA (nDNA) to oxidative damage (Ott *et al.*, 2007) due to the close proximity of the respiratory chain and the lack of protective histones; the incidence of 8-OH-G is 10- to 20-fold higher in mtDNA than in nDNA. The oxidative damage to mtDNA can lead to deletions or other rearrangements (Meissner, 2007). In particular the 4977 base pair deletion ('common deletion') has been studied in many tissues and found to increase with ageing (Lenaz *et al.*, 2006b).

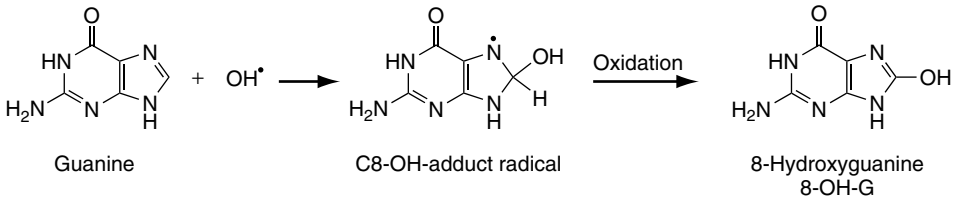

Figure 17 Formation of 8-hydroxy-guanine (8-OH-G) by reaction of $OH^{\bullet}$ with guanine. The reaction occurs via the intermediate formation of an 8-hydroxy adduct radical.

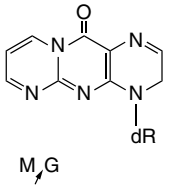
Also, products of lipid peroxidation, such as MDA, can react with DNA bases forming adducts (Marnett, 1999); for example, the M_1G adduct can rise to 1.2 per 10^6 nucleotides and is mutagenic.



4 ROS AND CELL SIGNALLING

It is clear nowadays that ROS (and RNS) act as second messengers (Forman *et al.*, 2008) by interfering with the expression of a number of signal transduction pathways and genes. Because ROS are oxidants, they influence the redox state of signalling proteins. To produce a redox-dependent modification of an enzyme, enzymatic catalysis is usually required to allow the modification under physiological conditions. For the same reason not all ROS are equally suitable for signal transduction; for instance the $OH^{\bullet}$ radical is too unspecific to undergo catalysed reactions, while $O_2^{\bullet -}$, H_2O_2 and lipid peroxidation derivatives like HNE are widely used. Depending on their concentration, ROS can have positive responses (cell proliferation) or negative responses (cell death).

The ROS concentration within cells is largely dependent on the redox state of glutathione (GSH/GSSG) and thioredoxin (Trx), which has two critical cysteine residues (see also Section 15.5). GSH reduces H_2O_2 enzymatically (GPx) generating the oxidized form GSSG, but the GSH/GSSG ratio also depends on disulfide exchange with proteins catalysed by protein disulfide isomerase (PDI).

$$2GSH + H_2O_2 \longrightarrow GSSG + 2H_2O \text{ (GPx)} \quad (28)$$

$$\text{Protein-SH} + GSSG \longrightarrow \text{Protein-SSG} + GSH \text{ (PDI)} \quad (29)$$

Also Trx is involved in disposing of H_2O_2 by Trx peroxidases or Prdxs:

$$\text{Trx (SH)}_2 + H_2O_2 \longrightarrow \text{Trx(S-S)} + 2H_2O \text{ (Prdx)} \quad (30)$$

Proteins may be glutathionylated by ROS by a two-step mechanism:

$$\text{Protein-S}^- + H_2O_2 \longrightarrow \text{Protein-SO}^- + H_2O \quad (31a)$$

$$\text{Protein-SO}^- + GSH \longrightarrow \text{Protein-SSG} + OH^- \quad (31b)$$

Glutathionylation has been proposed to act as a protective mechanism to prevent overoxidation of cysteines in signal transducing proteins.

The protein thiol oxidation by ROS also occurs in the thiolate form ($Cys\text{-}S^-$); signalling proteins thus modified include phosphoprotein phosphatases (PTPs), Ras, large G-proteins, serine/threonine kinases of the mitogen-activated protein kinase (MAPK) families, transcription factors, such as AP-1, NFκB, p53 and others. The effect of oxidants is different with different proteins: PTPs are inhibited, nuclear transcription factors are activated (Valko *et al.*, 2006). Thus for example, activation of ERK1/2, Akt and NFκB promotes cell survival, whereas activation of c-jun N-terminal kinases (JNKs), p38 kinase and p53 would lead to cell cycle arrest and apoptosis. In addition, ROS appear to activate the HIF-1α (Kietzmann and Gorlach, 2005) by inhibiting prolyl-4-hydroxylase (which hydroxylates a critical proline directing the factor to proteolytic digestion), similarly to what happens in anoxia, for lack of O_2 required for HIF hydroxylation. During neoplastic transformation certain signalling pathways bypass the programmes leading to apoptosis and senescence.

Numerous studies have shown that HNE at physiological concentrations stimulates cell proliferation, differentiation and cytoprotective response through affecting multiple signalling pathways: activation of PKC, of the family of MAPK, and of tyrosine kinase receptors, inhibition of Ca-ATPases with consequent accumulation of Ca^{2+} in the cytoplasm, and others (Forman *et al.*, 2008). It is beyond the scope of this chapter to provide a detailed description of the signalling pathways modified by ROS.

A special mention is needed for the role of mitochondria in relation to ROS signalling (Ott *et al.*, 2007). Apoptotic stimuli induce release of protein-bound $p66^{Shc}$ (Section 15.2.1.4) that interacts with cytochrome c,

generating H_2O_2. A key player of ROS signalling is p53, which is stabilized by DNA damage from ROS and activates the apoptotic machinery in mitochondria. Direct action of mitochondrial ROS within mitochondria on the apoptotic cascade can be effected through opening of the permeability transition pore, a large channel of the inner membrane activated by various stimuli and involved in outer membrane permeabilization and release of apoptotic factors, such as cytochrome c, from the intermembrane space (Rasola and Bernardi, 2007). The pore is activated by ROS, presumably via redox-sensitive cysteines (Fruehauf and Meyskens, 2007). The role of oxidative stress in apoptosis is beyond the scope of this chapter; an important reference is Ryter *et al.* (2007). Additional information is provided in **Cell Death and Apoptosis** of this book.

Finally, mitochondrial damage induced by ROS or other agents and resulting in decreased membrane potential may induce a retrograde response in the nucleus to activate nuclear genes involved in compensatory mitochondrial biogenesis via decreased mitochondrial Ca^{2+} uptake and concomitant rise in the cytosol (Butow and Avadhani, 2004).

5 ANTIOXIDANT DEFENCES

ROS production and ROS-mediated damage are counteracted in cells by different mechanisms (Zimniak, 2008) that will be described here only in general terms.

First, cells have devised mechanisms capable of repairing damage once occurred. The best known example is represented by DNA repair, which removes oxidative and other lesions from chromosomal and mitochondrial DNA and restores the original strands (Hazra *et al.*, 2007); the mtDNA-repairing systems are usually considered less efficient than those operating in the nucleus (De Souza-Pinto *et al.*, 2008).

Damaged molecules, in particular proteins, are recognized by degrading systems; oxidatively modified proteins are extensively ubiquitinated and directed to the proteasome where their complete digestion takes place (Grune *et al.*, 1997; Ghazi *et al.*, 2007). Incapability of the proteasome to digest some proteins or accumulation of insoluble protein aggregates may lead to profound alterations in cells. Also, damaged mitochondrial proteins are degraded, presumably by the mitochondrial Lon protease (Bulteau *et al.*, 2006).

Cellular structures and organelles undergo turnover and after a suitable lifetime are directed to autophagy by lysosomal digestion (Bergamini, 2006; Chen and Gibson, 2008). Autophagy systems recognize damaged organelles, such as mitochondria, and preferentially address them to digestion. The term mitoptosis has been suggested (Skulachev, 2006) to define the removal of oxidatively damaged mitochondria.

In a way, apoptosis (see Section 15.4 and also **Cell Death and Apoptosis** of this book) is an extreme device to eliminate cells where extensive damage has taken place, rather than allowing them to propagate the oxidative stress to other cells, for example, by plasma membrane NOX (Section 15.2.2.5). The notion that ROS may activate apoptosis through p53 and the mitochondrial permeability transition (Section 15.4) is in line with this assumption.

Other defence mechanisms operate to reduce ROS production. In mitochondria, uncoupling proteins UCPs have been suggested to fulfil this function, producing mild uncoupling and limiting ROS generation by the respiratory chain (Section 15.2.1.3). Also, substrate supply down-regulation and decrease of pO_2 would limit ROS production (Barja, 2007).

An opposite strategy of defence is biosynthesis of macromolecules resistant to oxidative stress (Pamplona and Barja, 2007). For instance, the presence of less unsaturated fatty acyl chains in membrane lipids represents a powerful defence against lipid peroxidation. Likewise, lowering the amount of components highly susceptible to oxidation, such as methionine in proteins and guanine in nucleic acids, renders them more resistant to alteration. On the other hand, the presence of a nonessential methionine in proteins may represent a sink against ROS damage (Levine *et al.*, 1996). It was shown that a mtDNA polymorphism (mt5178C→A) substituting Leu with Met at position 237 in Complex I subunit ND2 confers a longevity trait (Tanaka *et al.*, 1998) possibly by reducing oxidative damage to other more functional amino acids.

Finally, cells and body fluids contain molecules that neutralize or scavenge ROS, collectively termed antioxidants. Antioxidants may be divided into antioxidant enzymes that neutralize ROS by forming less toxic species, and antioxidant small molecules; the latter may either be endogenous metabolites and biosynthesized cofactors, or exogenous molecules taken up from the diet. Certain antioxidants are able to regenerate other antioxidants establishing an antioxidant network (Sies *et al.*, 2005).

5.1 Enzymatic Antioxidants

SOD catalyses the dismutation of superoxide to H_2O_2 and oxygen (Reaction 2); it exists in three isoforms in humans: cytosolic Cu, Zn-SOD, mitochondrial Mn-SOD and extracellular SOD (Landis and Tower, 2005). SOD must work in concomitance with enzymes removing H_2O_2, otherwise accumulation of the latter in the presence of reduced metal ions would activate the Fenton reaction (Reaction 4).

The systems capable of removing H_2O_2 are represented by catalase and peroxidases. Catalase (Mates *et al.*, 1999) is localized in peroxisomes and is very efficient, having one of the highest turnover numbers known

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for an enzyme.

$$2H_2O_2 \longrightarrow 2H_2O + O_2 \qquad (32)$$

GPx exists in two main forms, one selenium-dependent and the other not (Mates *et al.*, 1999); humans have four different Se-GPx. The enzyme catalyses Reaction 28 using H_2O_2 as an oxidant for GSH, but can also use organic peroxides:

$$2GSH + ROOH \longrightarrow GSSG + ROH + H_2O \qquad (33)$$

GSH must be regenerated by glutathione reductase (GR), using NADPH as the reductant; the major source of NADPH for cytosolic GR is the pentose phosphate pathway, while in mitochondria it is energy linked NADH/$NADP^+$ transhydrogenation.

$$GSSG + NADPH + H^+ \longrightarrow 2\ GSH + NADP^+ \qquad (34)$$

Perhaps Prdxs, catalysing Reaction 30, are the most important peroxide-removing systems (Rhee *et al.*, 2005). Trx reductase is an Se-enzyme that regenerates reduced Trx.

5.2 Nonenzymatic Antioxidants

Some of these are water-soluble and act in the cell's soluble fraction or in plasma, others, being lipid-soluble, act within membranes, while amphipathic molecules can act in both environments.

Vitamin C (ascorbic acid) is water-soluble and cooperates with lipid-soluble vitamin E to regenerate α-tocopherol from the tocopheroxyl radical produced during the vitamin E radical scavenging activity; the product of the reaction is a very stable ascorbate radical ($Asc^{\bullet -}$) (**Figure 18**).

Although excessive doses of ascorbate may be pro-oxidant, physiological amounts have always been proven to be antioxidant even in the presence of metal ions (Valko *et al.*, 2006).

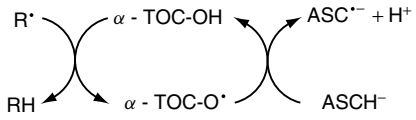

Figure 18 Cooperation between vitamin E (α-tocopherol, α-TOC) and ascorbate ($ASCH^-$ is the partially ionized antioxidant form) in scavenging radical species $R^{\bullet}$.

Vitamin E includes eight different derivatives, of which α-tocopherol is the most potent in humans. It is the most important lipid-soluble antioxidant and mainly prevents lipid peroxidation; its dietary supplementation is beneficial, however high doses may be pro-oxidant (Valko *et al.*, 2006). Its reaction with lipid radicals (mainly peroxyl radicals) generates the α-tocopheroxyl radical, which can be re-reduced to α-tocopherol by ascorbate in the water phase or by reduced Coenzyme Q ($CoQH_2$) in the lipid phase. $CoQH_2$ can also directly scavenge radicals like $LOO^{\bullet}$, generating its semiquinone form (Ernster and Dallner, 1995).

$$QH_2 + LOO^{\bullet} \longrightarrow Q^{\bullet -} + LOOH \qquad (35)$$

Coenzyme Q (ubiquinone, CoQ) is an essential electron carrier in the mitochondrial respiratory chain, but is also present in serum lipoproteins, endomembranes and the plasma membrane (Turunen *et al.*, 2004). Chemically, CoQ is constituted by a benzoquinone ring and a lipid side chain with several isoprenoid units, its number being species specific. Its redox reactions can be driven either by the simultaneous transfer of two electrons in a single step, or by two sequential steps of one-electron transfer through a partially reduced semiquinone intermediate (**Figure 19**). CoQ is the only lipidic antioxidant that is synthesized in mammals, and its biosynthesis is a complex process that involves the participation of at least eight gene products.

Besides the mitochondrial respiratory chain, several enzymes catalyse CoQ reduction to achieve its antioxidant

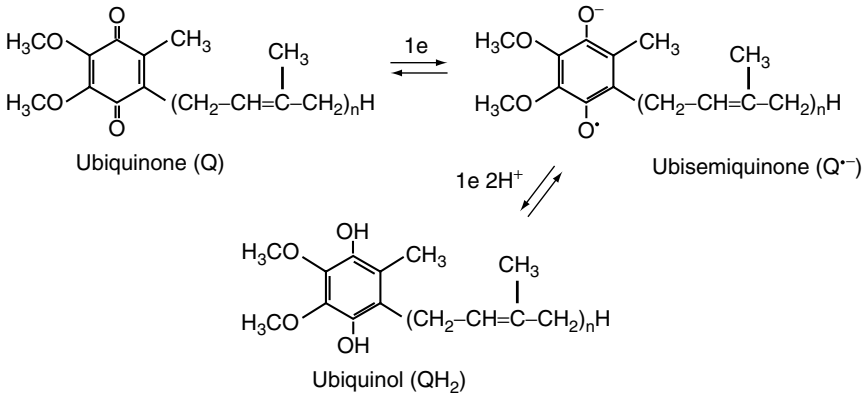

Figure 19 The redox states of Coenzyme Q; n is the number of isoprenoid units.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reduced state in eukaryotic cells. NADH-cytochrome b_5 reductase can reduce CoQ through a one-electron reaction mechanism (Arroyo *et al.*, 1998). The soluble enzyme NAD(P)H:quinone oxidoreductase 1 (NQO1, DT-diaphorase) can reduce quinones by a two-electron reaction and maintains the reduced state of CoQ_{10} *in vitro* (Beyer *et al.*, 1996). A distinct cytosolic NADPH-CoQ reductase different from NQO1 has been also described (Takahashi *et al.*, 1995).

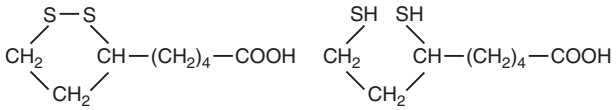
Glutathione GSH, besides scavenging H_2O_2 enzymatically can also scavenge radicals directly, forming thiyl radicals that can dimerize, generating oxidized glutathione GSSG:

$$GSH + R^{\bullet} \longrightarrow GS^{\bullet} + RH \quad (36)$$

$$GS^{\bullet} + GS^{\bullet} \longrightarrow GSSG \quad (37)$$

GSH is also able to regenerate vitamins C and E to their active forms.

Another dithiol antioxidant is lipoic acid in its reduced form dihydrolipoic acid; it is able to quench ROS and to regenerate other antioxidants as described above.



Lipoate Dihydrolipoate

Finally there is a great number of dietary antioxidants contained in fruit and vegetables that are not vitamins or part of coenzymes, such as carotenoids and flavonoids. They may act as quenchers of singlet oxygen and peroxyl radicals forming more stable radicals that do not propagate and may act as chain terminators by reacting with other radicals (Valko *et al.*, 2006).

6 INVOLVEMENT OF ROS IN PATHOLOGY

6.1 ROS and Ageing

The 'mitochondrial theory of ageing' (Linnane *et al.*, 1989) is based on the hypothesis that mitochondrial DNA somatic mutations, caused by accumulation of oxygen radical damage, induce alterations of the OXPHOS machinery culminating in an energetic failure that is at the basis of cellular senescence. Moreover a vicious circle (Ozawa, 1997) can be established since the accumulated damage to the respiratory chain would enhance ROS generation (**Figure 20**). Many reports (reviewed in Lenaz *et al.*, 2006b) demonstrate that the rate of production of ROS from mitochondria increases with age in mammalian tissues and in fibroblasts during replicative

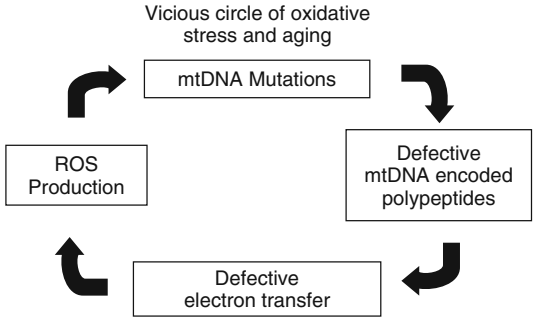


Figure 20 The proposed vicious circle of mtDNA mutations, ROS generation and oxidative phosphorylation decay in ageing.

cell senescence, considered to represent a plausible model of *in vivo* ageing (Hayflick, 2003).

Compelling evidence for the mitochondrial theory of ageing derives from several observations: the strong negative correlation existing between expected lifespan and rate of ROS production of different species (Sohal *et al.*, 1995; Barja and Herrero, 2000), within the same species under different activity conditions (Yan and Sohal, 2000) and between lifespan and membrane lipid unsaturation (Pamplona *et al.*, 2002). Furthermore the demonstration that caloric restriction, while prolonging lifespan in mammals, reduces ROS production (Barja, 2004) provides additional points in favour of the role of ROS in ageing.

A large number of large-scale deletions, point mutations and tandem duplications have been observed in tissues of aged individuals (Lee and Wei, 1997; Ozawa, 1997; Wei and Lee, 2002). Michikawa *et al.* (1999) reported that a T414G transversion in the D-loop of mtDNA is accumulated in skin fibroblasts from old subjects, while two different point mutations (A189G and T408A) accumulate in the D-loop in muscle of old individuals (Wang *et al.*, 2001). These mutations are located in the control region of mtDNA and may impair its replication and transcription.

A minimal threshold level of 50–95% mutated mtDNA is usually necessary to impair respiratory chain function, depending on the type of mutation and the tissue affected (Rossignol *et al.*, 2003). Since the proportions of mutated mtDNA within ageing human tissues rarely exceed 1%, it has been questioned how these levels may cause significant bioenergetic effects. Hayakawa *et al.* (1996), using 180 kinds of polymerase chain reaction (PCR) primers, found that mtDNA in elderly subjects is extensively fragmented into minicircles of different sizes. As a result, the amount of mtDNA mutations may reach such a high level as to cause significant impairment of OXPHOS. Furthermore, mutated mtDNA molecules may be distributed unevenly among the cells of affected tissues in a mosaic pattern of mtDNA segregation (Linnane *et al.*, 1995). Exponential accumulation of mutated mtDNA during life suggests that there is a preferential replication of the mutant genomes.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Are mtDNA mutations the cause of ageing, or do they just accompany the ageing process as interesting biomarkers of senescence? Trifunovic *et al.* (2004) showed that expression of a proof-reading deficient mtDNA polymerase in a homozygous knock-in mouse strain leads to increased levels of somatic mtDNA mutations causing progressive respiratory chain deficiency; the mice develop symptoms strikingly reminiscent of ageing. Even if these mice do not have an enhanced ROS production (Trifunovic, 2006; Trifunovic and Larsson, 2008), it is likely that this effect results from the severe extent of mutation in the mutator mice, while the 'natural' way to induce mutations is ROS attack.

There is overwhelming evidence that the bioenergetic function of mitochondria declines with ageing, specially in postmitotic tissues (Lenaz *et al.*, 2006b). If mtDNA mutations/deletions are at the basis of human ageing, the existence of a biochemical threshold complementing mtDNA mutations is critical, as discussed above. The notion that the respiratory chain is mainly controlled at the level of Complex I suggests that the main alterations due to ageing must be found at the level of this enzyme (Barrientos and Moraes, 1999; Lenaz *et al.*, 2000). Flux control analysis in aerobic respiration in coupled liver mitochondria (Ventura *et al.*, 2002) showed that Complex I has little control in young rats, but very high control in the old animals, meaning that ageing induces a profound alteration of Complex I that is reflected in the entire OXPHOS system.

Recent investigations attempt to relate the mitochondrial changes with the cellular environment. Changes in the redox status of cellular components by oxidative stress during ageing are considered the cause of the increased contents or DNA-binding activities of transcription factors NF-kB, AP-1, HIF-1 and of heat-shock proteins (Calabrese *et al.*, 2001; 2004); their increased activity is considered a compensatory mechanism for cellular protection; caloric restriction, the main known factor recognized to delay ageing, was found to prevent their activation. Available data on redox-responsive transcription factors suggest that their uncontrolled activation in ageing could lead to serious chronic pathogenic conditions characterized by what has been called 'molecular inflammation' (Chung *et al.*, 2002).

The role of oxidative stress in ageing has also been extended to age-related degenerative diseases, such as neurodegenerative diseases (Section 15.6.3) and ocular diseases (Brennan and Kantorow, 2008).

6.2 ROS and Ischaemic Diseases

Atherosclerosis is the major cause of cardiovascular diseases; it is characterized by accumulation of cholesterol deposits in macrophages in arteries with progressive formation of plaques that can rupture and induce thrombi. The hypothesis receiving highest consensus on atherogenesis is that of the oxidative modification of low-density lipoprotein (LDL) (Stocker and Keaney, 2004); oxidized LDL, but not native LDL, is readily internalized by macrophages through the 'scavenger receptors' so that cholesterol esters are accumulated, generating the so-called foam cells and initiating the atherosclerotic process. LDL oxidation is effected by ROS generated by the endothelial cells and affects both lipids and proteins; it is the oxidation of lysine groups in apo-B100 that allows LDL uptake by macrophages.

A major consequence of arterial thrombosis is vessel obstruction with consequent ischaemia. Ischaemia, especially if followed by a reperfusion phase, is involved in most cardiovascular diseases. ROS are involved in tissue lesions due to ischaemia-reperfusion (I/R) in heart, brain and other tissues. A number of mechanisms have been invoked to explain this phenomenon, all involving participation of ROS and oxidative stress (Blomgren *et al.*, 2003; Wang and Lo, 2003; Paradis *et al.*, 2004).

The mitochondria are the primary intracellular source of ROS: when anoxia is followed promptly by reperfusion, the resulting increase in oxygen supply leads to overproduction of ROS. This increase in ROS formation could arise from different patterns of mitochondrial respiration provoked by the ischaemic insult and the reperfusion phase. Mitochondrial respiration is significantly diminished at the level of Complex IV at the early reperfusion phase (Perez-Pinzon *et al.*, 2002), but is exacerbated in Complexes I and II after 24 hours (Piantadosi and Zhang, 1996).

Moreover, during ischaemia, when ATP is progressively depleted, ion pumps cannot function, resulting in a rise in calcium (Ca^{2+}), which further accelerates ATP depletion. The rise in Ca^{2+} during I/R leads to mitochondrial Ca^{2+} accumulation, particularly during reperfusion when oxygen is reintroduced. Mitochondrial Ca^{2+} overload and increased ROS can result in opening of the MPTP, which further compromises cellular energetics. The resulting enhanced permeability of the outer mitochondrial membrane allows the release of proapoptotic proteins such as cytochrome c from the intermembrane space to the cytosol, with activation of caspases and cell death (Szeto, 2008) (**Figure 21**). Another effect of the high cytosolic Ca^{2+} levels is activation of phospholipase A_2, with consequent liberation of arachidonic acid that also would activate the MPTP (Penzo *et al.*, 2004).

Numerous other sources of induced cellular ROS following I/R have been implicated in cell signalling. Among them, XO and myeloperoxidase produce extracellular ROS, as well as associated endothelial cell damage, during the reperfusion injury phase that follows ischaemia (Bulkley, 1993). Finally, NOXs appear also to serve as a source for ROS following I/R (Liu *et al.*, 2004).

6.3 ROS and Neurodegenerative Diseases

Age-related neurodegenerative diseases are characterized by pathological changes in disease-specific areas of the brain; in each disease, these pathological processes lead to degeneration of distinct subsets of neurons. However, despite the differences in the clinical manifestations and selective neuronal vulnerability, the underlying pathological processes on cellular and molecular levels appear similar across different diseases, suggesting common pathways of neurodegeneration. Increasing lines of evidence suggest a key role of oxidative stress, which can modify cellular bioenergetic capacity, further increasing ROS generation resulting in cellular damage and programmed cell death.

6.3.1 Parkinson's Disease

Parkinson's disease (PD) affects approximately 1% of the population at the age of 55 and increases in prevalence to roughly 5% by the age of 85. PD is characterized clinically by bradykinesia, resting tremor and rigidity. The symptoms of PD are predominantly due to a profound reduction in striatal DA content caused by the loss of dopaminergic neurons in the substantial nigra (SN) pars compacta and its projections to the striatum. The pathological lesions of PD are neuronal inclusions known as Lewy bodies (LBs) (Forno, 1996) and dystrophic neurites termed Lewy neurites (Braak *et al.*, 1994); the protein α-synuclein (syn) is the major component of Lewy pathology (Spillantini *et al.*, 1997).

The role of oxidative stress in neuronal degeneration in PD is substantiated by pathological findings and animal models that have provided experimental paradigms to delineate the possible mechanisms (Chinta and Andersen, 2008). Markers of oxidative stress, such as products of lipid peroxidation and oxidation of mtDNA and cytoplasmic RNA, are increased in dopaminergic neurons of PD brains. Increased oxidation in the SN of PD patients also may be partially due to the reported accumulation of iron, which in the form of Fe^{2+} can catalyse the formation of strong oxidants. The presence of AGEs in Lewy pathology and the demonstration that α-syn is a specific target of nitration suggests that oxidative damage may be involved in the formation of these inclusions.

The selective loss of DA neurons in the SN might be due to DA neuron glutathione deficiency (Loeffler *et al.*, 1994) (resulting in a reduced antioxidant capacity), high content of DA, a redox active molecule (Section 15.2.2.8) (Zigmond *et al.*, 2002) or elevated iron concentrations (Section 15.2.2.7) (Zecca *et al.*, 2004). The normal enzymatic metabolism of DA results in the generation of hydrogen peroxide, and the nonenzymatic auto-oxidation of DA results in the formation of reactive quinones and semiquinones that react to generate hydrogen peroxide, superoxide anions and hydroxyl radicals (cf. Section 15.2.2.8) (Fato *et al.*, 2008). These findings have provided further credence to the proposal that DA metabolism results in oxidative stress (Baumgarten and Grozganovic, 2000).

The possible involvement of oxidative stress as an aetiological factor of PD is further supported by studies with specific neurotoxins that are extremely potent inducers of parkinsonism in humans and animals. The best studied of these toxins are 6-hydroxydopamine (6-OHDA) and 1-methyl-4-phenylpyridinium (MPP^+), the active metabolite of 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which selectively destroys catecholaminergic neurons. Both toxins have been shown to generate hydroxyl radicals in the caudate of treated animals (Chiueh *et al.*, 1993). Moreover, administration of rotenone, an inhibitor of mitochondrial Complex I also inducing ROS generation (15.2.1.2.2), recapitulated the

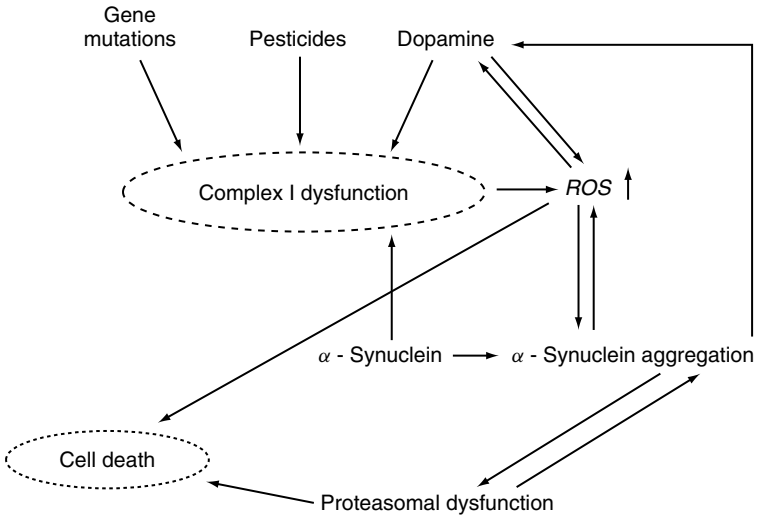

Figure 22 Postulated role of Complex I in Parkinson's disease.

major pathological features of PD, including selective loss of dopaminergic neurons and α-syn-positive LB-like inclusions, indicating that the inhibition of Complex I might be sufficient to trigger PD pathogenesis (Betarbet *et al.*, 2000).

Multiple lines of evidence suggest a pathogenic role of oxidative damage and mitochondrial dysfunction in causing PD (Schapira, 2008). The direct relation between mitochondrial dysfunction and PD came from the post-mortem description of Complex I deficiency in the SN of patients with PD. Subsequently, the deficiency was also seen in the skeletal muscle and platelets. Consistent deficits in the subunits and activity of mitochondrial Complex I of the electron transport chain in blood platelets and SN of PD patients is a prominent phenomenon (Keeney *et al.*, 2006). Reduced Complex I activity is also seen in cytoplasmic hybrid (cybrid) cell lines containing mtDNA from PD patients (Swerdlow *et al.*, 1996). The Complex I deficiency in the substantia nigra and platelets implies that it is a systemic defect in a proportion of cases ($\sim$25% on the basis of platelet activities) and this might be due to genetic or environmental causes. The specificity of the Complex I defect and its relation to oxidative stress have been supported by the recent finding that this is the only respiratory chain protein complex that is affected by endogenous oxidative damage and reduced structural stability (Keeney *et al.*, 2006).

Mutations or polymorphisms in both mtDNA and nDNA were implicated in causing PD or in affecting PD risk (Bogaerts *et al.*, 2008). To this purpose, mtDNA mutations may be involved in the aetiology and predisposition to the idiopathic disease, since cybrids containing mitochondria from patients exhibit a reduced activity of Complex I (Swerdlow *et al.*, 2001) and generate Lewy bodies (Trimmer *et al.*, 2004). However, exhaustive sequencing of mtDNA has not revealed mutations that consistently associate with PD (Pankratz and Foroud, 2007); nevertheless, somatic deletions of mtDNA are found more frequently in SN from PD patients. The possible role of Complex I in PD is shown in (**Figure 22**).

Besides mitochondria, plasma membrane NOX have also been implicated in ROS generation in PD. Activated glial cells are observed at sites of neurodegeneration in PD (Lawson *et al.*, 1990; Kim *et al.*, 2000; Miller *et al.*, 2008). By altering concentrations of intracellular ROS, NADPH oxidase is also reported to prime the microglial response to additional stimuli. For example, neuronal toxins such as MPTP and rotenone are also shown to prime microglia, resulting in synergistic microglial activation and associated neurotoxicity on additional insult with LPS.

6.3.2 Alzheimer's Disease

Alzheimer's disease (AD) is the most common cause of dementia in developed countries. Senile plaques and neurofibrillary tangles (NFTs) are, together with neuronal loss and cortical atrophy, characteristic neuropathological features of the disease. Senile plaques contain β-amyloid (Aβ) peptide, produced by cleavage of the amyloid precursor protein (APP) by β- and γ-secretases. NFTs are twisted helicoidal strands of hyperphosphorylated τ protein, a microtubule-associated protein (Selkoe, 2001; Reynolds *et al.*, 2007).

Oxidative stress is one of the earliest events of AD, with implications as an important mediator in the onset, progression and pathogenesis of the disease. The sources of ROS-mediated damage appear to be multifaceted in AD, with interactions between redox transition metals, mitochondria and other factors. Over the past decade, modification to virtually all classes of biomacromolecules

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

indicative of oxidative stress has been described in association with the susceptible neurons of AD (Smith, 1998; Zhu *et al.*, 2007).

Mitochondrial dysfunction is a consistent hallmark of AD (Moreira *et al.*, 2007): a deficient activity of cytochrome oxidase is a constant feature in AD and has been associated with the presence of pathogenic mtDNA mutations (Cardoso *et al.*, 2004). According to Swerdlow and Khan (2004) mitochondrial dysfunction is the primary event leading to the development of AD. Elson *et al.* (2008), however, failed to find consistent mtDNA differences in 270 AD patients with respect to controls. Recent studies have demonstrated that Aβ progressively accumulates within the mitochondrial matrix, providing a direct link to mitochondrial toxicity. β-amyloid-binding alcohol dehydrogenase (ABAD) is localized to the mitochondrial matrix and binds to mitochondrial Aβ exaggerating Aβ-mediated mitochondrial and neuronal perturbation (Takuma *et al.*, 2005; Devi *et al.*, 2006; Chen and Yan, 2007). It is therefore likely that the initial stress is provided by Aβ deposition and is further enhanced by mitochondrial dysfunction.

In AD, overaccumulation of iron in the hippocampus, cerebral cortex and basal nucleus of Meynert colocalizes with AD lesions. Iron is an important cause of oxidative stress in AD because it accumulates in the brain and is involved in the formation of $OH^{\bullet}$ via the Fenton reaction (Castellani *et al.*, 2007). As with iron, copper concentrations are also highly INCREASED within Aβ plaques, setting up conditions for Fenton-type chemistry through the reduction of Cu(II) by Aβ–H_2O_2 reactions. Recently, it has been shown that RNA-bound iron plays a pivotal role for RNA oxidation in vulnerable neurons in AD (Nunomura *et al.*, 2007; Shan *et al.*, 2007; Moreira *et al.*, 2008).

Growing evidence supports the role of oxidative stress in AD, such as increased levels of lipid peroxidation, glycation and protein oxidation products in AD brains. Modification to sugars is marked by increased glycation and glycoxidation. Accumulated AGE were detected in NFTs, and the glycation of tau has been proposed to play a role in stabilizing paired helical filament aggregation leading to neurofibrillary tangle formation (Takeuchi and Yamagishi, 2008). Furthermore, AGE, by activating RAGE receptors, increase intracellular ROS production.

Oxidative modification of proteins is marked by significantly elevated levels of protein carbonyls and widespread nitration of tyrosine residues (Malinski, 2007; Polidori *et al.*, 2007). Moreover, crosslinking of proteins, by oxidative processes, may lead to the resistance of the lesions to intracellular and extracellular removal, even though they are extensively ubiquitinated, and this resistance of NFTs to proteolysis might play an important role in the progression of AD, as revealed by immunostaining of NFTs for 3-NT (Smith, 1998). Some specifically oxidized proteins have recently been identified by proteomics and it is notable that many are either enzymes related to ATP generation or involved in glycolysis, for example, creatine kinase BB, involved in production of high-energy phosphate used for ATP synthesis. Therefore, oxidative modification may lead to metabolic impairment in AD (Castegna *et al.*, 2003).

Both microglia and astrocytes cluster at sites of Aβ deposition. Several lines of evidence suggest that one of the sources of ROS is the microglial NADPH oxidase. Aβ peptide can directly activate the NADPH oxidase of microglia, which results in a burst of superoxide radicals and increased production of hydrogen peroxide; not surprisingly, microglial expression of NADPH oxidase subunit $p22^{phox}$ is enhanced in AD brain, implicating increased microglial respiratory burst activity (Wilkinson and Landreth, 2006).

6.3.3 Huntington's Disease

Huntington's disease (HD) is an autosomal dominant neurodegenerative disease caused by a CAG trinucleotide repeat expansion encoding an abnormally long polyglutamine tract in the huntingtin protein (Htt). HD is characterized by extensive loss of striatal neurones. There is evidence that oxidative damage occurs in HD brain and in models of the disorder (Browne *et al.*, 1997; Polidori *et al.*, 1999; Browne and Beal, 2004), as also shown by enhanced lipid peroxidation, protein carbonylation and DNA damage. Products of the lipid peroxidation process, such as 4-HNE, facilitate the induction of mitochondrial permeability transition, which could lead to cell death by release of apoptogenic factors (Stavrovskaya and Kristal, 2005). Oxidative stress may be a direct mechanism of huntingtin-linked cellular damage; however, findings that increased oxidative damage to DNA and lipids occurs after symptom onset in the R6/2 transgenic mouse model of HD suggest that it is a downstream event in neuronal dysfunction (Bogdanov *et al.*, 2001). It is therefore possible that oxidative damage is induced by energetic defects (Greenamyre, 2007).

More recent findings provided evidence that mitochondrial dysfunction is central to the pathogenesis of HD. Human 143B cells expressing mutant Htt exhibited a reduced activity of Complex III (Fukui and Moraes, 2007), possibly by interference of Htt aggregates with mitochondrial trafficking and distribution in the cell (Solans *et al.*, 2006). Conversely, treatments that inhibited Complex III activity significantly promoted the formation of Htt aggregates. This effect of Complex III inhibition on the Htt aggregates appeared to be mediated by the inhibition of proteasome activity, but not by ATP depletion or production of ROS. Accordingly, Complex III mutant cells also showed decreased proteasome activity. These results suggest the presence of a feedback system connecting the mitochondrial respiratory Complex III and the production of Htt aggregates. This observation indicates that therapeutic interventions

targeting Complex III and/or proteasome could ameliorate the progress of HD (Fukui and Moraes, 2007).

6.3.4 Friedreich's Ataxia

Friedreich's ataxia (FRDA) is a neurodegenerative disorder arising from a deficit of the mitochondrial iron chaperone, frataxin. In typical FRDA patients the gene has undergone a triplet (GAA) expansion within the first intron (Grabczyk and Usdin, 2000). Reduction of frataxin results in the accumulation of iron and ROS, which leads to oxidative damage, neurodegeneration and a diminished lifespan. FRDA patients display signs of increased oxidative stress, including elevated markers of free radical damage to DNA, lipid peroxidation, reduced plasma levels of glutathione, reduced aconitase activity and elevated iron regulatory protein 1 (Karthikeyan *et al.*, 2003; Lobmayr *et al.*, 2005).

Mouse models expressing low levels of human frataxin show decreased aconitase activity and mild oxidative stress with iron accumulation as a late event (Al Mahdawi *et al.*, 2006). Yeast, *Drosophila*, mouse and cell culture models of frataxin deficiency have revealed important roles for frataxin and its homologues in mitochondrial iron storage, regulation of intracellular iron trafficking, iron–sulphur cluster and haeme biogenesis and reactivation of the labile iron–sulphur cluster of mitochondrial aconitase. A role for frataxin in preventing formation of ROS has been well established (O'Neill *et al.*, 2005), invoking a paradigm of FRDA pathology in which ROS toxicity leads to mitochondrial dysfunction with subsequent cell death (Puccio and Koenig, 2002). The loss of intracellular iron chaperone capacity imposed by frataxin deficiency could elicit a Fenton chemistry-based mechanism of ROS toxicity. In the *Drosophila* model of FRDA, *Dfh* suppression recapitulates the principal biochemical hallmarks of FRDA, including diminished activity of iron–sulphur-containing enzymes, susceptibility to iron toxicity, loss of intracellular iron homeostasis and early-onset adult mortality (Anderson *et al.*, 2005). Overexpression of frataxin in the mitochondria increases resistance to oxidative stress and extends lifespan in *Drosophila*.

6.3.5 Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that primarily affects motor neurons in brain cortex, brainstem and spinal cord. ALS occurs in both sporadic (~80–90% cases) and familial (5–10% cases) forms, which are clinically and pathologically indistinguishable. Among the familial cases, 10–20% can be attributed to point mutations in the gene coding for the antioxidant enzyme Cu/Zn SOD (SOD1) (Rosen *et al.*, 1993).

In human sporadic and familial ALS, markers of oxidative damage of proteins, lipids and DNA are elevated in the brain and spinal cord (Beal *et al.*, 1997). Recently, it has been observed that lipid peroxidation is significantly increased in the erythrocytes of sporadic ALS patients. On the other hand, catalase activity was found to be significantly lower. The activities of glucose-6-phosphate dehydrogenase, glutathione reductase and glutathione levels were also significantly reduced in ALS patients (Babu *et al.*, 2008).

Several potential mechanisms of motor neuron degeneration in ALS have been proposed based on animal model and cell culture system analyses. Markers of oxidative damage have been detected in animal models (Aguirre *et al.*, 2005; Perluigi *et al.*, 2005; Liu *et al.*, 2007). SOD1 mutants expressed in human cell lines directly stimulate NOX by binding to Rac1, with overproduction of damaging ROS. Diminishing ROS by treatment with the NOX inhibitor apocynin or by elimination of NOX extends survival in ALS mice, reviving the proposal that ROS mediate ALS pathogenesis (Boillée and Cleveland, 2008; Harraz *et al.*, 2008).

6.4 ROS and Diabetes

Mitochondrial dysfunction has been considered as a pathogenic factor for both Type 1 and Type 2 diabetes (Stark and Roden, 2007). The development of insulin resistance in obese individuals has been linked to alterations of lipid metabolism in skeletal muscle leading to increase of diacylglycerols, which interfere with the insulin receptor-mediated pathway via PKC stimulation (Petersen and Shulman, 2006). A primary mitochondrial defect with alteration of fatty acid β-oxidation or a secondary deficiency due to elevated malonyl-CoA levels inhibiting carnitine acyl transferase I (CAT I) (Bandyopadhyay *et al.*, 2006) have been involved in the pathogenesis of lipid metabolic dysregulation leading to insulin resistance. Even though a primary mitochondrial defect in skeletal muscle as the cause of insulin resistance has been recently challenged (Asmann *et al.*, 2006), mitochondrial dysfunction in muscle and other tissues has been frequently observed in diabetic individuals (McCarty, 2005).

A substantial body of evidence implicates oxidative stress as an important pathogenic factor in diabetic complications in both Type I and Type II diabetes mellitus; decreased uptake of glucose into muscle and adipose tissue leads to chronic hyperglycaemia, which results in tissue damage and pathophysiological complications. The drivers of this oxidative stress include hyperglycaemia, hyperinsulinaemia and the elevated free fatty acids and lipids that are usually associated with diabetes. ROS such as superoxide, hydroxyl radical and hydrogen peroxide arise from many cellular sources in response to hyperglycaemia. These sources include OXPHOS (Brownlee, 2005), glucose auto-oxidation (Wolff and Dean, 1987; Robertson *et al.*, 2003), activation of NADPH

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat024
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

oxidase (Li and Shah, 2003; Cave *et al.*, 2006) and other enzymes, such as XO, lipoxygenase, CYP monooxygenases and nitric oxide synthase. ROS also arise from the production of AGE and activation of RAGE (Wautier *et al.*, 2001). In addition, shifts in redox balances, decreased tissue concentrations of low molecular weight antioxidants such as reduced glutathione (GSH) and vitamin E, and impaired activities of antioxidant defense enzymes such as SOD and catalase (Baynes and Thorpe, 1999), contribute to oxidative stress in diabetes.

Increased oxidative stress in diabetes is postulated to promote the development of neuropathy (Feldman, 2003), nephropathy (Ha and Kim, 1999; Hinokoi *et al.*, 2002), myocardial injury (Cai and Kang, 2001) and retinopathy (Kowluru, 2006).

A unifying mechanism in the development of diabetic complications has been suggested by Brownlee in a central role of ROS production by mitochondria (**Figure 23**). The increase of NADH together with the increased flux of glucose through glycolysis and of free fatty acids through β-oxidation have been suggested to enhance the pressure of electron donors in the respiratory chain with a rise in the transmembrane electrochemical potential and consequent ROS production. Furthermore, the glucose-induced increase in superoxide induces mutations in mitochondrial DNA resulting in defective subunits of the electron transport complexes eventually causing increased superoxide production at physiological concentrations of glucose (Brownlee, 2001; 2005). After the initial enhancement, a secondary decrease in glycolytic flux is thought to occur through inhibition of glyceraldehyde phosphate dehydrogenase; this key glycolytic enzyme is inhibited by poly-ADP-ribose synthesized by poly-ADP-ribose polymerase (PARP), which is activated by the increase of ROS (Du *et al.*, 2003). The accumulation of glycolytic intermediates upstream of the inhibited step activates major pathways of hyperglycaemic damage: (i) the hexosamine pathway from fructose-6-phosphate, leading to increased glycosylation and activation of proinflammatory factors by uridine diphosphate (UDP)-*N*-acetyl-glucosamine; (ii) PKC from dihydroxyacetone phosphate via diacylglycerol, leading to further activation of NFκB and proinflammatory genes and of plasma membrane NADPH oxidase; (iii) the AGE pathway from glyceraldehyde phosphate via methylglyoxal; (iv) in addition, the polyol pathway from glucose is enhanced with consequent decrease of NADPH (**Figure 23**).

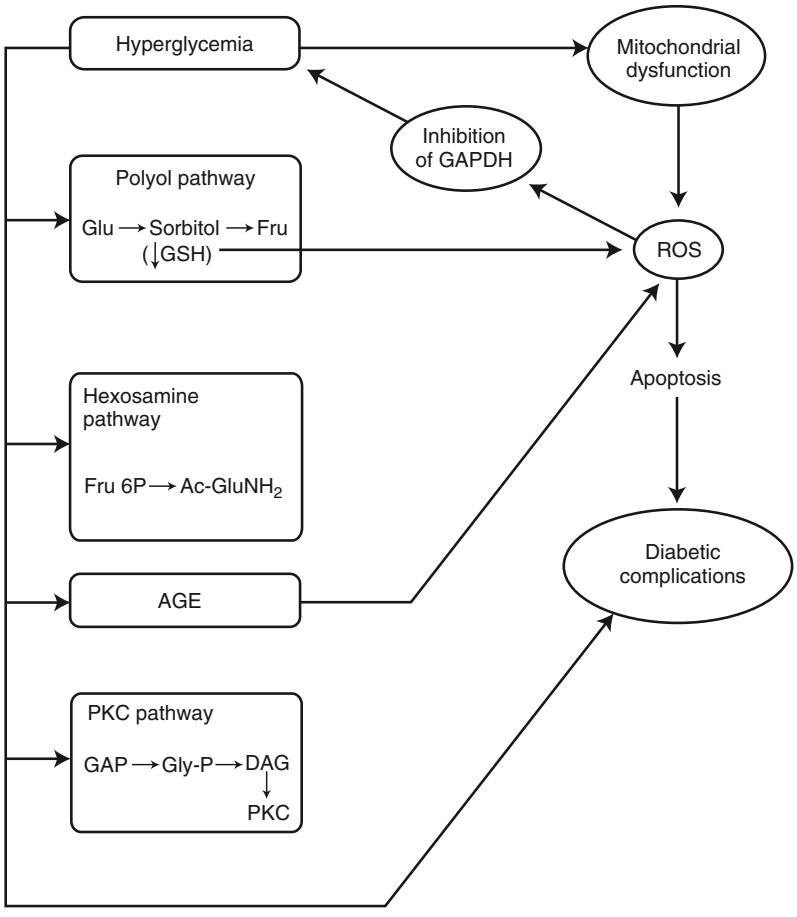

Figure 23 Central role of mitochondrial dysfunction and ROS production in the generation of diabetic complications. (Glu, glucose; Fru, fructose; AC-GluNH$_2$, N-acetylglucosamine; GAP, glyceraldehyde P; Gly-P, glycerol-P).

The modulation of the permeability transition of mitochondrial membrane represents another dysfunction caused by ROS. The inner mitochondrial membrane space contains several soluble proteins including cytochrome c; the release of cytochrome c from mitochondria into the cytoplasm and Bax translocation from the cytosol to mitochondria, which could drive cell apoptosis, are increased in the retina and its capillary cells in diabetes (Kowluru and Abbas, 2003).

6.5 ROS and Cancer

The development of cancer in mammals is a multistep process, the aetiology of which is still largely unknown. Mitochondrial dysfunction and subsequent oxidative stress are suspected to contribute to cancer.

6.5.1 The Warburg Effect

A shift in cellular energy production from aerobic oxidation in mitochondria to anaerobic glycolysis is a fundamental property of cancer cells, also called the Warburg effect (Warburg, 1930; 1956; Garber, 2004). Otto Warburg postulated that damage of the aerobic energy metabolism is a primary and irreversible event in tumour formation (Warburg, 1956).

The early characterization of cancer metabolism by Warburg demonstrated that tumour cells exhibit a two- to threefold increased rate of glycolysis when compared to the tissue from which they have been derived (Andjelkovic *et al.*, 1996). The reasons for this apparent switch away from mitochondrial respiration are still contentious. It has been suggested that mitochondrial inactivation is beneficial for the tumour cell, as it removes the mitochondrial apoptosis pathway; in addition, blockade of the complete oxidation of pyruvate saves precursors for biosynthetic pathways that are required for rapid growth of the tumour (Deberardinis *et al.*, 2007). It has been proposed that the Warburg effect is a consequence of the tumour's hypoxic environment, making glycolysis the more viable metabolic pathway for energy generation (Zu and Guppy, 2004). Hypoxia due to rapid tumour growth stimulates the expression of the transcriptional factor HIF-1α, which induces transcription of glycolytic enzymes; the concomitant decrease in mitochondrial respiration has been thought to be a direct consequence of the HIF-1α increase, since the enhanced expression of pyruvate dehydrogenase kinase inhibits pyruvate dehydrogenase and decreases carbon input into the Krebs cycle (Kim *et al.*, 2006). At the same time HIF-1 causes a switch in the nuclear-encoded subunit 4 of cytochrome oxidase from the isoform COX4-1 to COX4-2 resulting in more efficient electron delivery to oxygen (Fukuda *et al.*, 2007; Semenza, 2007). On the other hand, a decrease of activity of the respiratory chain has been observed in several tumours (Wallace, 2005). This latter observation has brought the postulate of an opposite sequence of events, with reduction of respiration preceding a compensatory increase of glycolysis. In favour of the second interpretation is the observation of a primary mitochondrial dysfunction due to transcriptional deregulation of several mitochondrial proteins (Chiaradonna *et al.*, 2006). In this scenario, p53 mutations, frequently observed in cancer, have been proposed to represent the primary cause of respiration decrease by preventing the correct assembly of cytochrome oxidase (Matoba *et al.*, 2006). Recent studies indicate that mitochondrial dysfunction is one of the more recurrent features of cancer cells (Modica-Napolitano and Singh, 2004; Wallace, 2005), given that substantial differences between mitochondria of normal and cancer cells have been reported at microscopic, molecular, biochemical, metabolic and genetic levels. Tumour cells have long been known to possess an abnormal redox state, characterized by aberrant energy metabolism, down-regulation of antioxidant enzymes and increased production of ROS (Szatrowski and Nathan, 1991). This is advantageous for cancer progression as elevated ROS production increases the basal rate of mutation of the genome (Jackson and Loeb, 2001) and so accelerates the progression of the cancerous phenotype by the acquisition of mutations.

6.5.2 The Mitochondrial Energetics and ROS Biology of Cancer

Mitochondrial DNA mutations, extremely frequent in cancer cells, have also been involved in the generation of mitochondrial abnormalities (Carew and Huang, 2002; Petros *et al.*, 2005).

Only a few reports have been able to identify a strict association between metabolic changes in cancer cells and mitochondrial complex composition and activity; for example, in a cell line derived from a thyroid oncocytoma, Bonora *et al.* (2006) found a decrease of Complex I activity that was ascribed to a specific mutation in the ND1 gene of mitochondrial DNA. Evidence that dysfunction of the respiratory chain, resulting from mutations in mtDNA, plays a role in tumour genesis is based on data of cultured cells, but has not been shown directly in tumour tissues (Petros *et al.*, 2005; Modica-Napolitano *et al.*, 2007). Recently, it has been demonstrated that mutations in the gene encoding subunit ND6 of Complex I produced a deficiency in Complex I activity and were associated with ROS overproduction. Pretreatment of the highly metastatic tumour cells with ROS scavengers suppressed their metastatic potential in mice. These results indicate that mtDNA mutations can contribute to tumour progression by enhancing the metastatic potential of tumour cells (Ishikawa *et al.*, 2008).

Mutations in nDNA or mtDNA OXPHOS genes that impede the flow of electrons through the ETC increase mitochondrial ROS production. The resulting H_2O_2, which is relatively stable, diffuses out of the mitochondrion, through the cytosol, and into the nucleus.

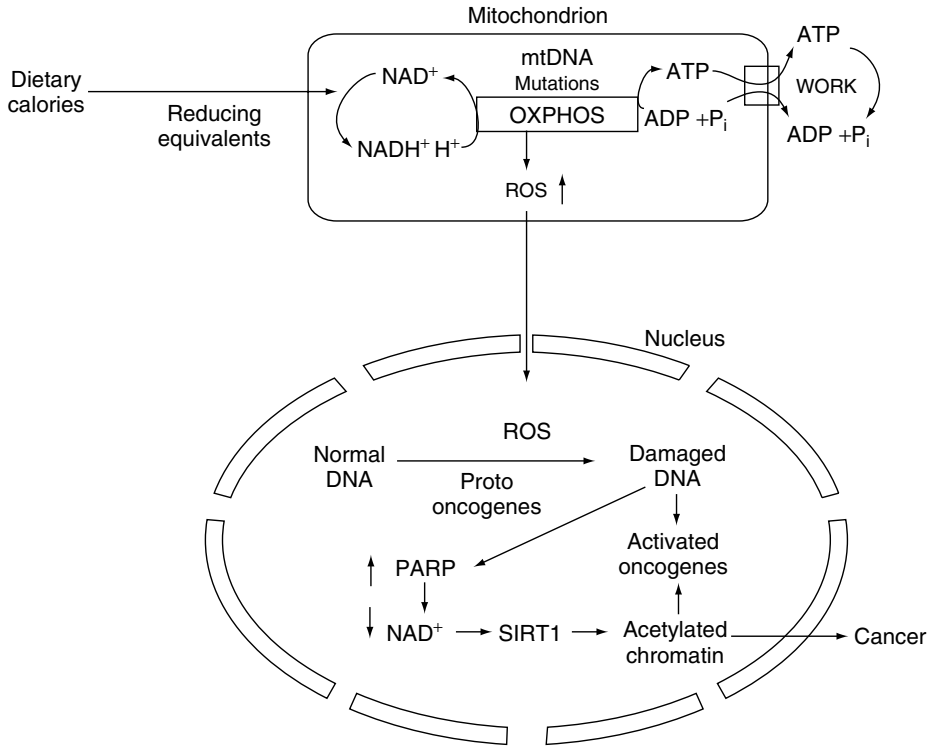

Figure 24 Model for the proposed role for mitochondrial dysfunction in cancer (Wallace, 2005). Caloric overload or inhibition of OXPHOS (mtDNA somatic mutations) perturbs the cellular mitochondrial energetic balance, resulting in increased ROS. The increased ROS also diffuse into the nucleus where they can mutate and activate protooncogenes (initiation) and can interact with NFκB, APE-1 and various kinases to initiate cell division (promotion) leading to neoplastic transformation (cancer). Damaged DNA activates PARP resulting in NAD^+ depletion and consequent inhibition of SIRT-1, a deacetylase of histones and other proteins; the resulting prevalent activity of histone acetylases allows further activation of proto-oncogenes. Figure abbreviations are PARP, poly ADP-ribose polymerase; SIRT1, the mammalian homologue to Sir2.

In the nucleus, it interacts with transition metals and is converted to $OH^\bullet$, which mutagenizes the nDNA. The resulting nDNA damage activates the nDNA repair systems, including the PARP. The activated PARP degrades the nuclear NAD^+ in the process of adding poly ADP-ribose chains to histones and other nuclear proteins (Wallace, 2005) (**Figure 24**). The degradation of the nuclear NAD^+, together with the high $NADH/NAD^+$ ratio, inactivates nuclear SIRT1. SIRT1 is a histone deacetylase, and nuclear transcription is repressed by the deacetylation of histones and activated by histone acetylation. Therefore, inhibition of SIRT1 permits histone acetylation to predominate, turning on the transcription of normally inactive genes. In postmitotic tissues, histone acetylation permits the activation of the genes that regulate cell replication and differentiation, the protooncogenes. The diffusion of H_2O_2 into the nucleus and its conversion to $OH^\bullet$ can then mutate the protooncogenes, converting them into functional oncogenes. Moreover, increased cytosolic and nuclear H_2O_2 activates a variety of cellular signal transduction factors including NFκB, APE-1, *Fos*, *Jun* and tyrosine kinases. This drives the cell into replication. Consequently, mutations in mitochondrial genes that inhibit electron flow through the ETC result in chronically increased mitochondrial ROS production, which can act as both a tumour initiator (mutation of protooncogenes) and tumour promoter (activation of transcription and replication).

Toxicogenomics and the Evolution of Systems Toxicology

Michael D. Waters and B. Alex Merrick

CONTENTS

1 INTRODUCTION

Toxicology, the study of poisons, is focussed on substances and exposures that cause adverse effects in living organisms. Studies in toxicology measure the effects of an agent on an organism's food consumption and digestion, its body and organ weights, microscopic histopathology and cell viability, immortalization, necrosis and apoptosis (Mattes *et al*., 2004). Toxicogenomics combines toxicology with genetics and genomics to provide a comprehensive view of the function of the genetic and biochemical machinery (genes, proteins and metabolites) of the living cell. A critical part of the study of toxicology, and by extension, toxicogenomics, is the empirical and contextual characterization of adverse effects at the various levels of organization of the organism—ranging from animal health and function to organs, tissues, cells and intracellular and intercellular molecular systems. Thus, toxicology and toxicogenomics are rapidly evolving into systems toxicology (Waters and Fostel, 2004).

Toxicology and toxicogenomics are multidisciplinary in nature and both have evolved significantly as relevant technologies have advanced. By analogy, the invention of the microscope in the seventeenth century was the beginning of a long road of technological development to modern histology and pathology, which is an inherent component of toxicology. The intricacies of tissue organization and the complex architecture of organs at a cellular level were made accessible by light microscopy, which then gave way to higher resolution with the advent of electron microscopy and more recently atomic force microscopy (Maunsbach and Afzelium, 1999; Braga and Ricci, 2004). The twentieth century saw the maturing of histology as a refined tool for pathology and in a like manner presages the potential of toxicogenomics for the field of toxicology.

Similarly, the modern achievements of sequencing whole genomes have been quickly followed by

Table 1 Some relevant terms defined[a]

Functional genomics: The development and application of global (genome-wide or system-wide) experimental approaches to assess gene function by making use of information and reagents provided by physical mapping and sequencing of genomes.
Knowledgebase: An archival and computational system that uses data, information and knowledge captured from experts to carry out tasks that create new information and new understanding.
Metabolomics or metabolite profiling: The directed use of quantitative analytical methods for analysing the entire metabolic content of a cell or organism at a given time (the metabolome).
Metabonomics: Techniques that detect changes in the concentration of low molecular weight metabolites present in a cell or organism at a given time (the metabonome) by using nuclear magnetic resonance or mass spectrometry coupled to gas or liquid chromatography.
Proteomics: A collection of techniques used to measure the structural and functional properties of proteins through the use of 2D gel electrophoresis or liquid chromatography, typically followed by protein identification using some form of mass spectrometry.
Systems biology: The integrated study of biological systems (cells, tissues, organs or entire organisms) at the molecular level. It involves perturbing systems, monitoring molecular expression, integrating response data and modelling the molecular structure and network function of the system. See GENE REGULATORY NETWORK.
Systems toxicology: The study of the perturbation of biological systems by chemicals and stressors, monitoring changes in molecular expression and conventional toxicological parameters, and iteratively integrating response data to describe the functioning organism.
Toxicoinformatics: The description of a toxicological stress and the annotation of the dose-dependent molecular responses that are elicited over time.
Transcriptomics: Techniques that measure the full complement of activated genes, mRNAs or transcripts in a particular tissue at a particular time, typically through the use of cDNA or oligonucleotide microarrays.

[a]Waters and Fostel, 2004.

gene expression profiling technologies that allow comprehensive queries of the transcriptome, to the refinement of traditional proteomics, and to the creation of other -omic technologies (see **Table 1** for definitions). Toxicogenomics (Nuwaysir *et al*., 1999) evolved from the desire to characterize how genomes respond to environmental stressors or toxicants by combining genome-wide mRNA expression profiling (transcriptomics) with global protein expression patterns (proteomics) that are interpreted by the use of bioinformatics to understand the role of gene–environment interactions in disease and dysfunction.

The increasing resolution of toxicogenomic analysis with oligonucleotide probe sets is becoming sufficiently refined for the production of single nucleotide polymorphism (SNP) genotyping arrays that can be used for cytochrome P450 (CYP450) genotyping and SNP mapping for identifying relevant gene loci for sensitivities or resistant responses (Mandal *et al*., 2005; Shi, 2002; Wen *et al*., 2003). The inherently reductive nature of toxicogenomic analysis down to the level of DNA, mRNA and protein sequences is also being counterbalanced by a concerted attempt to reassemble these molecular pieces of information into pathways and networks (Jiang *et al*., 2008; Hellerstein, 2008; Grzegorczyk, 2008; Gohlke *et al*., 2008; Ganter *et al*., 2008) that form the new field of systems toxicology (Ideker *et al*., 2001a; 2001b; Ekins *et al*., 2005; Heijne *et al*., 2005; Wetmore and Merrick, 2004; Waters and Fostel, 2004; Waters *et al*., 2003b; Waters and Yauk, 2007; Gant, 2007).

The result of these concurrent reductive and assembly activities in gene expression information is a much greater depth of field now possible for examining toxicant responses. Toxicogenomics is leading the next revolution towards a better understanding of molecular pathology. Expectations are that toxicology and pathology of the future will merge three areas: traditional pathology and toxicology, differential protein and gene expression analysis and systems biology (Lobenhofer *et al*., 2006; Ruepp *et al*., 2005; Boorman *et al*., 2002). The teaming of these technologies will extend the sensitivity of toxicity detection beyond what is currently achievable and may even uncover the earliest beginnings of acute toxicity onset or the molecular signatures of long-term toxicant exposure and disease (Storck *et al*., 2002; Suter *et al*., 2004; Jiang *et al*., 2008).

The ability to discern mechanisms of toxicity as related to health issues is an important challenge facing scientists, public health decision-makers and regulatory authorities, whose aim is to protect humans and the environment from exposures to hazardous drugs, chemicals and environmental stressors (e.g. nonionizing radiation). The problems of performing safety and risk assessments for drugs and chemicals and of identifying environmental factors involved in the aetiology of human disease have long been formidable issues. Genomic technologies offer the potential to change the way in which toxicity and human health risk are assessed.

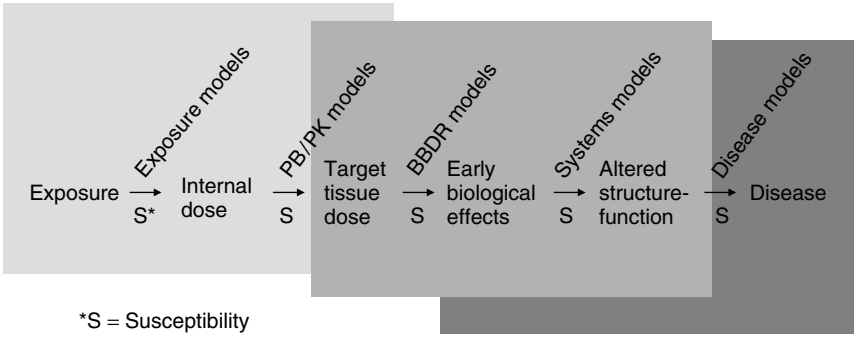

Figure 1 The role of genetic susceptibility and computational modelling on the continuum from exposure to disease outcome. The sequence of events between initial exposure and final disease outcome are shown from left to right. Following exposure, the body's 'ADME' (absorption, distribution, metabolism, excretion) systems control local concentrations of a chemical stressor in various body compartments. The impact of genetics is felt in specific alleles encoding various transporters, xenobiotic metabolizing enzymes, etc. Mathematical models such as exposure models, PB/PK and BBDR models can be used to approximate these processes. PB/PK models are a set of differential equations structured to provide a time course of a chemical's mass-balance disposition (wherein all inputs, outputs and changes in total mass of the chemical are accounted for) in preselected anatomical compartments. BBDR models are dose–response models based on underlying biological processes. Once the target tissue is exposed to a local stressor the cells respond and adapt or undergo a toxic response; this process can be modelled with systems toxicology approaches. Finally, the disease outcome itself can be mimicked by genetic or chemically induced models of particular diseases.

The rapid accumulation of genomic sequence data and associated gene and protein annotation has catalysed the application of gene expression analysis to understand the modes of action of chemicals and other environmental stressors on biological systems (see **Figure 1**). These developments have facilitated the emergence of the field of toxicogenomics, which aims to study the response of a whole genome to toxicants or environmental stressors (Aardema and MacGregor, 2002; Afshari, 2002; Ulrich and Friend, 2002; Fielden and Zacharewski, 2001; Hamadeh *et al*., 2002a; Tennant, 2002; Thomas *et al*., 2001; Olden and Guthrie, 2001; Olden, 2006; Waters *et al*., 2003b; 2003c; Lobenhofer *et al*., 2001; 2006; Burchiel *et al*., 2001). The related field of toxicoproteomics (Merrick and Tomer, 2003; Merrick and Madenspacher, 2005; Petricoin *et al*., 2004; Wilkins *et al*., 1996) is similarly defined with respect to the proteome, the expression of gene products of the genome. The emerging field of toxicometabonomics combines high-throughput intermediary metabolite or pharmaceutical metabolite profiling with computer-assisted pattern recognition approaches (Lindon *et al*., 2006; 2007; Kasper *et al*., 2005; Griffin, 2006). Global technologies, such as oligonucleotide microarrays, protein chips, mass spectrometry (MS) and nuclear magnetic resonance (NMR)-based molecular profiling, for example, can simultaneously measure the expression of numerous genes, proteins and metabolites, respectively, thus providing the potential to accelerate the discovery of toxicant pathways, modes-of-action and specific chemical and drug targets. Toxicogenomics therefore combines toxicology with genetics, global -omics technologies (see Appendix A) and appropriate pharmacological and toxicological models (**Figure 1**) to provide a comprehensive view of the function of the genetic and biochemical machinery of the cell.

This review explores the new field of toxicogenomics, delineates some of its research approaches and success stories, and describes the challenges it faces. It discusses how integrating data derived from transcriptomics, proteomics and metabonomics studies can contribute to the development of a toxicogenomics knowledgebase (**Figure 2**) and to the evolution of systems toxicology as it relates to molecular expression profiling. In many ways, current gene, protein and metabolite expression profiles are simple 'snapshots'; by contrast, systems toxicology, like systems biology (Ideker *et al*., 2001a; Nurse, 2003), attempts to define the interactions of all of the elements in a given biological system, under stress or toxicant perturbation, to achieve a mechanistic understanding of the toxicological response.

2 TOXICOGENOMICS: AIMS AND METHODS

Toxicogenomics has three principal goals: to understand the relationship between environmental stress and human disease susceptibility (**Figure 1**), to identify useful biomarkers of exposure to toxic substances and biomarkers of disease and to elucidate the molecular mechanisms of toxicity. A typical toxicogenomics study

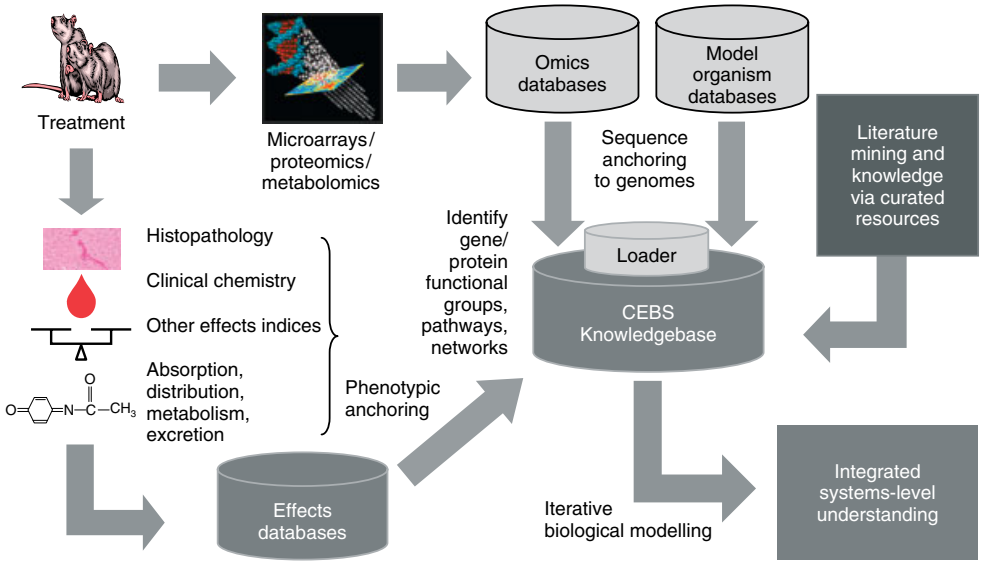

Figure 2 A framework for systems toxicology. The figure indicates the paths from the initial observation (rat in upper left) to an integrated toxicogenomics knowledgebase and thence to systems toxicology. The '-omics datastream' is shown by the clockwise path from rat to knowledgebase, and the 'traditional' toxicology approach is shown in the counterclockwise path. The knowledgebase will integrate both data streams, along with literature knowledge, and by virtue of iterative modelling lead to a systems toxicology understanding. The framework involves 'phenotypic anchoring' (to toxicological endpoints and study design information) and 'sequence anchoring' (to genomes) of multidomain molecular expression datasets in the context of conventional indices of toxicology, and the iterative biological modelling of the resulting data.

might involve an animal experiment with three treatment groups: high- and low-dose treatment groups and a vehicle control group that has received only the solvent used with the test agent. These groups will be observed at two to three points in time, with three to five animal subjects per group. In this respect a toxicogenomics investigation resembles a simple, acute toxicity study. Where the two approaches differ is in the scope of the response they each aim to detect, and in the methods used. The highest dose-regimen is intended to produce an overtly toxic response, which in a toxicogenomics study can be detected using the global measurement techniques described below (see also Appendix A).

In a typical toxicogenomics experiment, lists of significantly differentially expressed genes are created for each biological sample (Hamadeh *et al*., 2002e). Alternatively, profile analysis methods can be applied to dose and time-course studies (Hamadeh *et al*., 2002e) to identify genes and gene profiles of interest. Then, with the aid of the relevant knowledge that is systematically extracted and assembled (Zweiger, 1999) through literature mining, comparative analysis and iterative biological modelling of molecular expression datasets, it is possible to differentiate adaptive responses of biological systems from those changes (or biomarkers) associated with or precedent to clinical or visible adverse effects. Over the past 5–10 years, the field of toxicogenomics has validated the concept of gene expression profiles as 'signatures' of toxicant classes, disease subtypes or other biological end points. These signatures have effectively directed the analytical search for predictive biomarkers of toxicant effects and contributed to the understanding of the dynamic alterations in molecular mechanisms associated with toxic and adaptive responses.

The experimental work involved in a toxicogenomics study and the amount of gene expression data generated are vast. To examine even only one tissue per animal in the study design described above requires 18–45 microarrays (more if technical replicates are used) and the attendant measurement of as many as 30 000 or more transcripts per array. In addition, each animal will typically have treatment-associated data on total body and organ weight measurements, clinical chemistry measurements (often up to 25 parameters) and microscopic histopathology findings for several tissues. The careful collection, management and integration of these data, in the context of the experimental protocol, are essential for interpreting toxicological outcomes. Thus all data must be recorded in terms of dose, time and severity of the toxicological and/or histopathological phenotype(s). The compilation of such experimental data, together with toxicoinformatics tools and computational modelling are important in deriving a new understanding of toxicant-related disease (Tennant, 2002).

Toxicogenomics integrates the multiple data streams derived from transcriptomics, proteomics and metabonomics with traditional toxicological and histopathological end-point evaluation (**Figure 2**). This integration has the potential to synergize our

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

understanding of the relationship between toxicological outcomes and molecular genetics. Furthermore, toxicology and toxicogenomics are progressively developing from studies done predominantly on individual chemicals and stressors into a knowledge-based science (Waters *et al*., 2003a). However, the evolution of a truly 'predictive toxicology'—wherein knowledge of toxicogenomic responses of a prototypic agent in one species and strain is used to predict the mode-of-action of a similar agent in a related strain or another species—will require that the results of numerous toxicogenomics investigations across genotypes and species be assimilated into a multidomain, multigenome, knowledgebase (**Figure 2**). This knowledgebase must be searchable by chemical formula/stressor-type, by gene/protein/metabolite molecular signature, or by phenotypic outcome, among other entities, to find results analogous to those observed with a newly tested agent. It must capture current knowledge of chemical mode-of-action and facilitate the discovery of new modes. Toxicology will then have become an information science, and public health and risk assessment will be the beneficiaries.

3 TOXICOGENOMICS: EVOLUTION OF THE FIELD

Toxicogenomics has evolved from early gene expression studies, which described the response of a biological system to a particular toxicant or panel of reference agents, towards more mature investigations that integrate several -omics domains with toxicology and pathology data (see **Table 2**). Exposure- and outcome-specific patterns of gene, protein and metabolite profiles have been used to identify molecular changes that serve as biomarkers of toxicity (Thomas *et al*., 2001; 2007; 2002; Waring *et al*., 2001b; Mortuza *et al*., 2003; Kramer *et al*., 2004; Heinloth *et al*., 2004; Hamadeh *et al*., 2002c; Bulera *et al*., 2001; Bartosiewicz *et al*., 2001) and provide insights into mechanisms of toxicity (Cutler *et al*., 1999; Coen *et al*., 2004; Donald *et al*., 2002; Fertuck *et al*., 2003; Fountoulakis *et al*., 2002; Hamadeh *et al*., 2002d; Huang *et al*., 2001; Kramer *et al*., 2003; Peterson *et al*., 2004; Ruepp *et al*., 2002; Waring *et al*., 2002) and disease causation (Wagenaar *et al*., 2004; Lu *et al*., 2001; Hamadeh *et al*., 2004; Iida *et al*., 2003; Ellinger-Ziegelbauer *et al*., 2004). Critical to this evolution were extensive and ongoing genome sequencing and annotation efforts (Twigger *et al*., 2002; Higgins *et al*., 2003) and the ability to describe response profiles in genetically and toxicologically important species such as mouse, rat, dog and human. Another important contribution to toxicogenomics has been the formation of collaborative research consortia (Ulrich *et al*., 2004; Pennie *et al*., 2004; Lindon *et al*., 2003), which bring together scientists from regulatory agencies, industrial laboratories and academic and government scientists to identify and address important issues for the field.

3.1 Profiles of Response to Toxicants

Nuwaysir *et al*. popularized the term 'toxicogenomics' to first describe the use of microarrays to measure the responses of toxicologically relevant genes, and to identify selective, sensitive biomarkers of toxicity (Nuwaysir *et al*., 1999). The initial published toxicogenomics study compared the gene expression profiles of human cells responding to the inflammatory agent lipopolysaccharide (LPS) or to mitogenic activation by phorbol myristate acetate (PMA) (Heller *et al*., 1997). RNA samples isolated at various times following exposure showed the expected increases in cytokine, chemokine and matrix metalloproteinase transcripts. Similar expression profiles were seen in synoviocytes and chondrocytes from a patient with rheumatoid arthritis, confirming the ability of the system to mimic the biological changes that occur during inflammatory disease. Subsequent studies extended this type of observation in other tissues and for a wide variety of toxicants, enabling the association of specific molecular profiles with specific toxicities (Merrick and Bruno, 2004).

4 PHENOTYPIC ANCHORING

Conventional toxicology has employed surrogate markers correlated with toxic responses to monitor adverse outcomes in inaccessible tissues. For example, liver enzymes alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are released following hepatic damage, and levels of these enzymes in serum correlate with histopathological changes in the liver (Travlos *et al*., 1996). These serum enzyme markers, in conjunction with histopathology, facilitate the 'phenotypic anchoring' of molecular expression data (Tennant, 2002; Waters *et al*., 2003c; Paules, 2003). 'Phenotypic anchoring' is the process of determining the relationship between a particular expression profile and the pharmacological or toxicological phenotype of the organism for a particular exposure or dose and at a particular time (Tennant, 2002). The dose and time alone are often insufficient to define the toxicity experienced by an individual animal; thus another measure of toxicity is needed for full interpretation of the data obtained during a toxicogenomics study. Conversely, the phenotype alone may be insufficient to anchor the molecular profile, since, for example, an elevated value for serum ALT can be observed both

Table 2 The scope and evolution of toxicogenomics

Study aim	Key references
Toxicogenomics tools and model systems	Toxicogenomics began with 'toxicology-specific' cDNA microarrays designed to measure the levels of acute phase and xenobiotic-metabolizing enzymes such as cytochrome P450s (Nuwaysir *et al*., 1999; Bartosiewicz *et al*., 2000). These were superseded as commercial platforms were developed for toxicologically important species such as rat. The armamentarium of preclinical gene expression platforms was completed with the canine microarray (Higgins *et al*., 2003). It is now possible to use commercial oligonucleotide microarrays to measure expression responses in species ranging from nematode (*Caenorhabditis elegans*), to Daphnia (*Daphnia magna*) (Poynton *et al*., 2007), to frog (*Xenopus laevis*), and zebrafish (*Danio rerio*) (Langheinrich, 2003; Alestrom *et al*., 2006; Hoyt *et al*., 2003; Scholz *et al*., 2008), to rodents (rat and mouse), to nonhuman primates and man. Toxicogenomics tools for sentinel aquatic species have been developed as well (Hogstrand *et al*., 2002). Later experiments began to focus on more challenging subjects such as subcellular organelles (Jiang *et al*., 2004), nonstandard tissue such as saliva (Vitorino *et al*., 2004), less well-characterized species, genetic models of diseases (Talamo *et al*., 2003), and integration of data from different -omics disciplines (Coen *et al*., 2004; Ruepp *et al*., 2002; Iida *et al*., 2003; Hogstrand *et al*., 2002; Juan *et al*., 2002). Additionally, comprehensive studies of yeast have become increasingly important.
Some tissues used in toxicogenomics studies	Many toxicogenomics studies have involved hepatotoxicants (Thomas *et al*., 2002; Hamadeh *et al*., 2002e; Waring *et al*., 2001a; Mortuza *et al*., 2003; Kramer *et al*., 2004; Heinloth *et al*., 2004; Hamadeh *et al*., 2002c; Bulera *et al*., 2001; Bartosiewicz *et al*., 2001; Dong *et al*., 2002; Fountoulakis *et al*., 2002; Hamadeh *et al*., 2002d; Kramer *et al*., 2003; Peterson *et al*., 2004; Ruepp *et al*., 2002; Waring *et al*., 2002; Lu *et al*., 2001; Iida *et al*., 2005; Iida *et al*., 2003; Weiss *et al*., 2004), as the liver is the primary source of xenobiotic metabolism and detoxification, and because liver injury is the principal reason for withdrawal of new drugs from the market (Lee, 2003). However, toxicogenomics studies have also addressed, nephrotoxicity (Cutler *et al*., 1999; Bartosiewicz *et al*., 2001; Huang *et al*., 2001), neurotoxicity (Xie *et al*., 2002; Dam *et al*., 2003) and reproductive toxicity (Fertuck *et al*., 2003), for example, as well as lung toxicity (Mortuza *et al*., 2003; Wagenaar *et al*., 2004), skin toxicity (Hamadeh *et al*., 2002f) and cardiotoxicity (Hu *et al*., 2002).
Phenotypic anchoring	Phenotypic anchoring relates expression profiles to specific adverse effects defined by conventional measures of toxicity such as histopathology or clinical chemistry (Beyer *et al*., 2007; Daston, 2008; Moggs *et al*., 2004; Moggs, 2005; Paules, 2003; Powell *et al*., 2006). Experiments have been designed to correlate expression patterns with disease pathologies such as necrosis, apoptosis, fibrosis or inflammation (Hamadeh *et al*., 2002e; Waring *et al*., 2001b; Wagenaar *et al*., 2004; Higgins *et al*., 2003; Waring *et al*., 2001a). Additionally, phenotypic anchoring can be used to provide biological context for toxicogenomics observations made at subtoxic doses (Heinloth *et al*., 2004; Peterson *et al*., 2004).
Some classes of toxicants characterized	Studies have examined responses to toxicants with established mechanisms of toxicity (Waring *et al*., 2001b; Bulera *et al*., 2001; Bartosiewicz *et al*., 2001; Fountoulakis *et al*., 2002; Hamadeh *et al*., 2002d; Kramer *et al*., 2003; Ellinger-Ziegelbauer *et al*., 2004; Hamadeh *et al*., 2001), environmental toxicants (Lu *et al*., 2001; Hogstrand *et al*., 2002; Hamadeh *et al*., 2002f; Witzmann *et al*., 2003), or exposures to suprapharmacological levels of drugs (Mortuza *et al*., 2003; Heinloth *et al*., 2004; Coen *et al*., 2004; Donald *et al*., 2002; Peterson *et al*., 2004; Ruepp *et al*., 2002; Iida *et al*., 2003; Fountoulakis *et al*., 2000; Hu *et al*., 2002).
Examples of toxicant or stressor mechanisms	Acetaminophen or paracetamol (Heinloth *et al*., 2004; Coen *et al*., 2004; Fountoulakis *et al*., 2000; Ruepp *et al*., 2002; Huang *et al*., 2004; Beyer *et al*., 2007) Arsenic (Ghosh *et al*., 2008; Liu *et al*., 2006; Liu *et al*., 2004), arsenite (Nohara *et al*., 2008) Endocrine disruptors (Phillips and Foster, 2008; Phillips *et al*., 2008; Iguchi *et al*., 2007; Villeneuve *et al*., 2007) Oestrogenic agents (Fertuck *et al*., 2003; Adachi *et al*., 2004) Oxidant stress (Nadadur *et al*., 2000; Weiss *et al*., 2004)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat026

Table 2 (*continued*)

Study aim	Key references
	Peroxisome proliferators[a] (Thomas *et al*., 2001; Hamadeh *et al*., 2002c; Bartosiewicz *et al*., 2001; Hamadeh *et al*., 2002d; Kramer *et al*., 2003)
Importance of reporting husbandry and other technical details	Expression profiles are altered by experimental conditions including harvest method, *in vitro* culture method, vehicle used to deliver an agent, time of day of sacrifice and diet. Up to 9% of the transcripts in mouse liver fluctuated with circadian cycling (Akhtar *et al*., 2002). These included genes controlling glucose metabolism and vesicle trafficking or cytoskeleton, as might be anticipated from changes in the diet of animals during the day and night. In addition, however, transcript levels of Cyp17 and Cyp2a4, which are important for steroid synthesis, and Cyp2e1, which is important for detoxification of xenobiotics, also fluctuated. These changes might be expected to impact the response to test agents, and reflect a requirement to report the time of day of dosing and sacrifice, along with the diet, vehicle and harvest and culture methods when summarizing or publishing results of toxicogenomics studies.
Commercial database resource for toxicogenomics	Toxicogenomics studies for the purpose of developing a commercial database have been performed by GeneLogic (*http://www.genelogic.com/*). This company has gathered data from several hundreds of samples produced from short-term exposures of agents at pharmacological and toxicological dose levels. Customers of the company can access the database to classify the mode-of-action of novel agents of interest.
Integration	*Of toxicogenomics efforts:* ILSI Committee on the Application of Toxicogenomics to Risk Assessment (Ulrich *et al*., 2004; Pennie *et al*., 2004), Toxicogenomics Research Consortium (TRC), Consortium on Metabonomics and Toxicology (COMET) (Lindon *et al*., 2003). Through such Consortia the technical factors affecting data can be identified and overcome, approaches to data analysis and interpretation can be agreed upon, and high-quality public datasets prepared. The field of toxicoproteomics is currently not represented by a consortium, while the ILSI Genomics Committee and the TRC are working toxicogenomics consortia in transcriptomics, and COMET is a working toxicogenomics consortium in metabonomics.
	Of data domains: (Coen *et al*., 2004; Ruepp *et al*., 2002; Hogstrand *et al*., 2002; Juan, 2002; Heijne *et al*., 2004). Integration of data can provide a more complete picture of the expression profiles associated with a particular treatment, shedding light not only on what the cell is planning (transcriptomics), but also what occurred in the proteome and metabonome.

[a]Peroxisome proliferators are compounds that induce increased numbers of peroxisomes—single-membrane cytoplasmic organelles that metabolize long-chain fatty acids.

before peak toxicity (as it rises) and after peak toxicity (as it returns to baseline). Thus, anchoring the molecular expression profile in phenotype, dose and time helps to define the sequence of key molecular events in the mode-of-action of a toxicant.

Phenotypic anchoring can also be used in conjunction with lower doses to classify agents and to explore the mechanisms of toxicity that occur before histopathological changes are seen. For example, transcriptional changes that occur following both low- and high-dose exposures of acetaminophen (paracetamol) were identified, indicating that biological responses can be detected using transcriptome measurements before histopathological changes are easily detected (Heinloth *et al*., 2004; Beyer *et al*., 2007). Follow-up work shows the accumulation of nitrotyrosine and 8-hydroxy-deoxyguanosine adducts phenotypically anchors an oxidative stress gene expression signature observed with a subtoxic dose of acetaminophen (paracetamol), lending support to the validity of gene expression studies as a sensitive and biologically meaningful end point in toxicology (Powell *et al*., 2006). Additionally, phenotypic anchoring can help to elucidate a toxicant's mechanism of action. For example, the transcriptional responses in a rat model to superpharmaceutical doses of WAY-144122 (a negative regulator of insulin) were observed before histopathological changes were seen in either liver or ovary, and reflected different mechanisms of toxicity in the two organs (Peterson *et al*., 2004).

5 BIOMARKERS AND SIGNATURES

A biomarker is an objective measure that can indicate health, disease, pharmacologic response to therapy, or adverse response to toxicants (Guerreiro *et al*., 2003; Frank and Hargreaves, 2003). Several reviews have been written about expression profiling and biomarker discovery (Frank and Hargreaves, 2003; Kennedy, 2002; Gunn and Smith, 2004; Hanash, 2003; Walgren and Thompson, 2004; Wallace *et al*., 2004; Roberts *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat026
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2003). Many classic biomarkers, such as serum ALT, sorbitol dehydrogenase, ornithine carbamyltransferase and others, can almost function as singular indicators of specific types of liver pathology and dysfunction (Amacher, 2002). But at the current level of understanding for complex diseases and toxicities, it is unlikely that any single readout may be a sufficient indicator. Instead, multiple markers that function as a 'molecular signature' or 'metabolic fingerprint' appear needed for classifying and better describing toxicant mechanisms of action (Guerreiro *et al*., 2003; Lindon, 2003; Bailey and Ulrich, 2004).

To some degree, the wide use of cluster analysis in classifying toxicity and disease (Bergmann *et al*., 2003; Abe *et al*., 2003) favours toxicity or disease characterization by transcript signature profile over a single biomarker. However, one appraisal of toxicogenomic studies outlined the following challenges that exist in developing such a profile: (i) it is difficult to generate a transcriptional profile that is truly predictive rather than diagnostic of an expected outcome; (ii) few of the studied toxicants have a specific molecular target and unique mechanism of action that could provide a well-defined response and (iii) it remains a challenge to distinguish between primary and secondary (cause or consequence) transcriptomic changes in toxicity vs adaptive responses unrelated to toxicity (Bailey and Ulrich, 2004). In addition, some of the other major factors that detract from robust DNA microarray toxicity signatures are variation in signal generation, use of different transcriptomic platforms, variation in the number of arrayed genes and sequences and interindividual animal differences due to genetic or microenvironmental factors (Bailey and Ulrich, 2004). Such difficulties encountered in transcript profiling of toxicants in both experimental and preclinical studies will undoubtedly be a shared experience for proteomic analysis in similar settings. Alternatively, part of the challenge in defining predictive signatures are frequent internal redundancies in biochemical pathways and dilution effects by nonresponding cells in complex multicellular tissues that might combine to either mask or dampen the expression of key, singular gene transcripts and proteins in target cells that are the rate-limiting step for toxicity during profiling studies.

Biomarker discovery studies using proteomic profiling methods in toxicological settings are reflected in the fewer numbers of citations in proteomics and toxicology compared to toxicogenomic studies to date. However, a survey of the toxicoproteomic literature reveals keen research and commercial interests for how to best use proteomic technologies for biomarker discovery. The terminology used in biomarker research as a result of toxicogenomic and toxicoproteomic studies is also likely to continue expanding from the conventional terms, 'biomarkers', 'signatures' and 'profiles' to other terms like 'barcode' (Choe *et al*., 2002) for simultaneous detection of multiple bioanalytes for a specific disease or 'footprint' (Bratton and Cohen, 2003) from the signal transduction community to indicate proteins held in a partially activated state. Once a more sophisticated integration of proteomics and toxicogenomic technologies with toxicology occurs and biological responses brought on by subtle changes in activation status or posttranslational modifications are more readily determined, the use of these terms will likely become more widespread. The use of transcriptomics in combination with proteomics for discovering individual biomarkers can accelerate the discovery process, particularly when conventional biomarkers are lacking. As an example, a class of lead compounds identified in a discovery programme based on gamma secretase inhibition as therapy for Alzheimer's disease also had an undesirable effect of inhibiting cleavage by Notch1 of the Hes1 gene product, a process important for differentiation of intestinal epithelial cells. Through the use of gene expression profiling and subsequent protein analysis, Searfoss *et al*., 2003 identified adipsin as a novel biomarker for this toxicity.

Carcinogenic potential is conventionally measured using a two-year study, incurring significant expense in both animals and human resources. It is therefore of great interest to identify biomarkers of carcinogenicity that can be detected in acute, short-term studies and efforts towards this have been reported (Hamadeh *et al*., 2002e; 2004; Kramer *et al*., 2004; Iida *et al*., 2003; Ellinger-Ziegelbauer *et al*., 2004; Newton *et al*., 2004). Biomarkers with clinical relevance have also been found using toxicogenomics approaches. For example, (Petricoin *et al*., 2002) found a set of protein markers that distinguished patients with high levels of prostate specific antigen (PSA), a clinical marker correlated with prostate cancer, from those with low PSA levels and thus presumed to be healthy. In addition, the marker set also correctly predicted 71% of patients with intermediate PSA levels. In a second example (Zhang and Gant, 2004), three plasma biomarkers were discovered and then independently validated to detect early stage invasive epithelial ovarian cancer from healthy controls with high sensitivity and specificity compared to the traditional marker CA125 alone. These biomarkers demonstrate the potential to improve the detection of early stage ovarian cancer using toxicoproteomics technologies.

Doubtless, the sequencing of the human genome has brought about a systematic means of viewing the molecular basis of disease through genes and their many levels of regulation. Genomics-based tools will be developed for diagnosis and prediction of disease onset or recurrence, personalized medicine and assess treatment response (Ginsburg and Haga, 2006). Although in its beginnings, genomic biomarker research has the capability of providing high definition viewing into pathophysiological processes and providing more precise predictors of outcome not previously possible with traditional biomarkers. Before genomic biomarkers can be regularly integrated into clinical practice, however, the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

necessary levels of evidence must be brought to bear to demonstrate analytical and clinical validity and ultimately their utility in improving patient care. Similar caveats apply prior to being embraced by the pharmaceutical and regulatory sectors for preclinical safety assessment.

6 PROTEOMIC ANALYSIS OF TOXIC SUBSTANCES

Toxicoproteomics has been considered by Merrick and colleagues (Wetmore and Merrick, 2004; Merrick and Madenspacher, 2005) as a new field involving a distinct relationship of toxicologic pathology with toxicogenomic disciplines. Other reviews explore its importance in serum protein pattern diagnostics (Petricoin and Liotta, 2004), delineate new biomarkers of toxicity and toxicity signatures (Merrick and Bruno, 2004), highlight the field's achievements and limitations in the development of biomarkers (Sinha *et al*., 2007), and trace discovery of early markers of drug toxicity (Collins *et al*., 2007). Data in these reviews resulting from toxicoproteomic studies were categorized by: (i) pharmaceutical or chemical toxicant under study; (ii) the model organism or clinical subjects involved; (iii) target organs analysed, such as liver, kidney, brain and heart; (iv) biofluids analysed, such as serum, plasma, urine or cerebrospinal fluid; (v) proteomic method of analysis that was conducted, such as 2D gel, differential gel electrophoresis (DIGE), isotope coded affinity tags (ICATs), antibody array; (vi) the use of *in vivo* or *in vitro* model systems and (vii) the number of differentially expressed and identified proteins. While specific proteins were identified as differentially expressed in each of the cited investigations, these reviews noted that validation and follow-up studies to confirm either individual proteins or sets of proteins as 'biomarkers' were extremely limited. There was a general consensus among reviews of toxicoproteomics studies (Collins *et al*., 2007; Merrick and Bruno, 2004; Merrick and Madenspacher, 2005; Petricoin *et al*., 2004; Wetmore and Merrick, 2004) about common aims of the field. First, the discovery potential of proteomics technologies can be exploited to find new biomarkers or toxicity signatures during preclinical safety assessment or hazard evaluation and in diagnosing and treating human disease. Second, toxicoproteomics can be used to achieve a better understanding of molecular mechanisms underlying chemically induced toxicity in preclinical and experimental settings. Third, toxicoproteomics can integrate with data from other -omics technologies, bioinformatics, imaging and computation tools and toxicogenomics databases for a systems biology approach to predictive mechanistic toxicology. These collective aims represent a practical stratification of the discovery to knowledge process that often begins with biomarker(s) development that leads to an improved understanding of toxicity mechanisms.

As multiple consequences of mechanistic research mature and expand into a larger context of systems biology, initial molecular toxic insults will eventually be translated into a predictable series of downstream events that form a visible phenotype of toxicity. The range of toxicant effects analysed by proteomics from tissues, biofluids, subcellular fractions and modified proteins by adduction or other posttranslational effects is impressively broad and promising for toxicology and pathology evaluations. The application of new proteomic platforms and an integration of proteomics with transcriptomic and metabolomic analysis in databases promises to greatly enhance the biomarker discovery capability for toxicoproteomics (Patterson, 2003).

7 SERUM AND PLASMA PROTEOMES AND ACCESSIBLE BIOFLUIDS

Complete proteomic mapping of the human serum and plasma and specialized blood components is being undertaken in healthy individuals and in patients with disease. Serum and plasma are arguably the most informative, accessible biofluids of the body for biomarker development. The reason is that almost all cells of the body are in contact with blood and, as such, the cells and the tissues they make up very often communicate through active endocrine secretion or passive release of peptides and proteins into the circulation (**Figure 3**). Further, analysis of low concentration, bioinformative proteins can be greatly improved after immunoaffinity removal of abundant (but less informative proteins) that make up 85–90% of plasma. Such abundant plasma proteins include albumin, IgG, IgA, transferrin, haptoglobin, α-1-antitrypsin, hemopexin, transthyretin, α-2-HS glycoprotein, α-1-acid glycoprotein, α-2-macroglobulin and fibrinogen from human plasma (Pieper *et al*., 2003a; 2003b). Although any process of abundant protein depletion by affinity chromatography may inadvertently remove some desirable proteins, the gain for detecting low-level protein markers during subsequent proteomic analysis is greatly worthwhile and is in part due to a 10–20-fold enrichment over untreated plasma or serum.

Why has there been such interest in biomarker development from clinical blood samples? One reason is that despite the enormous utility of clinical chemistry in diagnostics and medicine, remarkably few novel biomarkers have been discovered over the last decade (Anderson *et al*., 2002; Anderson and Anderson, 2002). Newer mass spectrometry-based methodologies in the last 8–10 years have transformed proteomics. While this has led to a dramatic increase in biomarker research, the discovery of new biomarkers has been slow to realize. Current

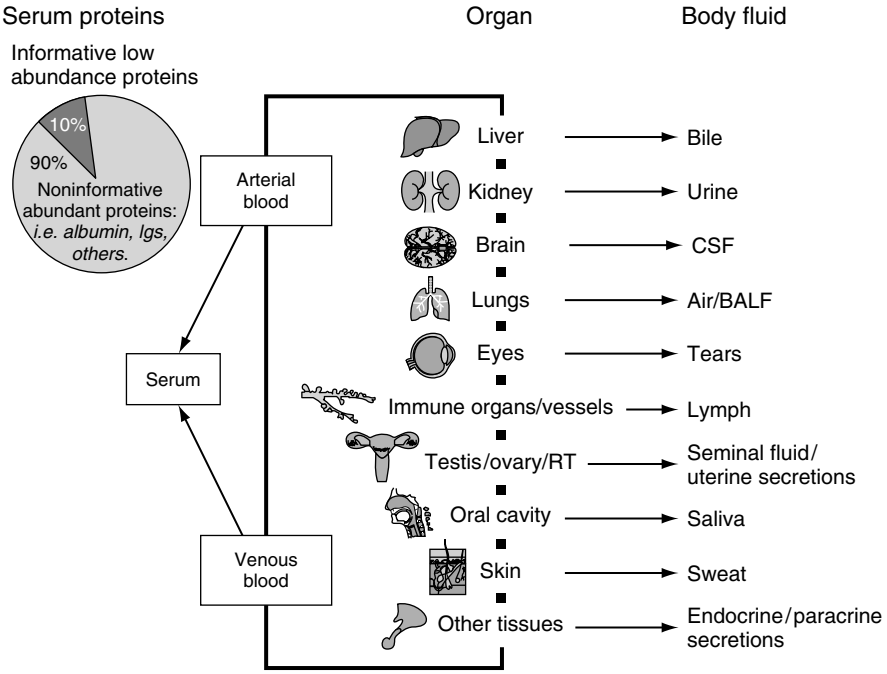

Figure 3 Protein profiling of serum and target organs: systems toxicology and pathology. Blood circulation in organs and tissues makes it an ideal body fluid to assess early, overt injury and recovery periods of acute toxicity. More comprehensive profiling of the serum proteome could lead to improved markers of toxicity and disease, a better understanding of recovery and repair processes, interorgan and intertissue communication, and a more unified, systems toxicology and pathology approach to temporal changes in the serum proteome and its relationship to human health in development, maturity, reproduction and ageing. Similar advances should occur in biomarker development after mapping the proteomes of tissue-specific biofluids and monitoring changes during toxicity and disease. (CSF = cerebrospinal fluid; BALF = bronchoalveolar fluid; RT = reproductive tract).

proteomic technologies can analyse extremely small amounts of proteins. However, a consistent problem has been in detecting and quantifying proteins that are present at 2–3 orders of magnitude lower than the more abundant proteins. The commercial availability of 'immunosubtraction' materials available for human sera and soon for rodent serum, and recent studies that survey the human serum and plasma proteomes (described below) will have major impacts on biomarker research. Three studies published over the past few years have attempted to comprehensively map the human plasma and serum proteomes defining them to 490 (Adkins *et al*., 2002), 325 (Pieper *et al*., 2003a) and 341 (Tirumalai *et al*., 2003) unique proteins with almost 3700 electrophoretically separable features (Pieper *et al*., 2003a). However, the number of serum and plasma proteins is thought to be much higher than 1000 unique proteins, but an exact number is unknown. The detection of nuclear, DNA binding, cytoplasmic and kinesin complex proteins in serum poses exciting possibilities about how the serum proteome reacts and adjusts during the course of disease and toxicity (Merrick and Tomer, 2003). The complete mapping of the human proteome has taken on international importance since this is one of the prime goals of an international consortium called the Human Proteome Organization (HUPO) (Merrick, 2003). Cataloguing of the many other biofluids from various organs (**Figure 3**), such as saliva (Vitorino *et al*., 2004), urine (Pieper *et al*., 2004), cerebrospinal fluid (Puchades *et al*., 2003; Jiang *et al*., 2003) and others (Kennedy, 2001) should lead to important advances in biomarker development. While there are no corresponding organizations dedicated to the proteomes of primates, mice, rats and other experimental animals, such interests will evolve in time either as an outgrowth of HUPO or as separate entities.

One other area in plasma proteome research deserves mention. While most proteins isolated from blood are generally soluble, there are solid protein substances or 'microparticles' in blood that are found at low levels. Microparticles are intact vesicles derived from cell membranes of 0.2–2 μM in size that are shed or secreted from tissues into blood (Piccin *et al*., 2007). Microparticles constitute a 'subproteome' of plasma which has a high likelihood of containing specialized proteins associated with injury and disease (Smalley and Ley, 2008; Merrick, 2008). While this subproteome makes up less than 0.01% of the total plasma proteome, it is rich in proteins altered under a variety of pathological conditions. Membrane activation processes and apoptosis can create microparticles from cell types as diverse

as platelets, endothelial cells, monocytes and granulocytes. Many normal cell types, including tumour cells (Ginestra *et al*., 1997), release vesicles by ectocytosis either spontaneously or in response to various stimuli (MacKenzie *et al*., 2001; Gasser and Schifferli, 2004). Review of various methods for microparticle isolation shows that flow cytometry has been widely adopted, while ultracentrifugation in less than 2 hours provides sufficient amounts for proteomic analysis (Piccin *et al*., 2007). Detection of these emitted membrane vesicles have wide application in immune and cancer diseases and have physiologic roles in coagulation, vascular function, angiogenesis, wound healing, inflammation and development (Pilzer *et al*., 2005; Ardoin *et al*., 2007). The proteome of human platelet microparticles has recently been mapped (Garcia *et al*., 2005) and the likelihood seems high that microparticle changes in response to chemical exposure and injury represent a prime opportunity for facile enrichment and discovery of new biomarkers during toxicoproteomic studies.

8 TRANSCRIPTOMICS AND PROTEOMICS: DISAGREEMENT OR COMPLEMENTARITY?

An important issue that continues to arise in gene expression studies is the reportedly poor correlation between mRNA and protein levels reported for some studies that compared transcriptomic and proteomic datasets from the same experiment (Ideker *et al*., 2001a; Gygi *et al*., 1999). The correlation issue factors into how -omic integration efforts proceed at an experimental design level, at a database level and eventually would affect choices of candidate protein biomarkers predicted from transcript changes in DNA microarrays and vice versa.

Several studies have reported variable correlations between protein and transcript expression in different studies that range from poor to very positive. For example, earlier studies reported relatively poor correlation between changes in transcript and protein levels in yeast, *Saccharomyces cerevisiae* (Gygi *et al*., 1999; Duan *et al*., 2002; Griffin *et al*., 2002) and also in lung adenocarcinoma (Duan *et al*., 2002), while yet another study in yeast reported a weakly positive correlation (Washburn *et al*., 2003). In the latter study (Washburn *et al*., 2003), a clustering approach took into account transcription and posttranscriptional control of expression for several proteins and arrived at a more positive correlation than previous reports. A positive correlation was noted for a limited set of proteins and transcripts in neuroblastoma cells during apoptosis (Weinreb *et al*., 2003) and a high correlation was noted for mRNAs and the corresponding 39 leukaemia-relevant (AML and ALL) proteins in 113 patients (Kern *et al*., 2003). In a recent study, expression of 82 proteins identified from platelets were closely mirrored in the transcriptome (McRedmond *et al*., 2004). In a study from chromium (VI)-treated rats, results from a 380-antibody array probing lung tissue suggested an uncoupling of transcriptome and proteome data under normal homeostatic conditions, but an establishment of parallel mRNA and protein expression when lung cells responded to acute genotoxic damage (Izzotti *et al*., 2004). An interesting computational approach compared published literature knowledge with DNA microarray data of normal and malignant breast tissue and found correlation only among gene expression changes with a >10-fold difference (Hu *et al*., 2003). A recent high impact study with the NCI-60 (60 human cancer cell lines) and controls demonstrated a high correlation of cell-structure-related proteins between mRNA and protein levels across the NCI-60 cell line set, whereas non-cell-structure-related proteins were poorly correlated. The latter two studies suggest that highly expressed, abundant structural proteins appear to be most highly correlated at the transcript and protein levels. One other important study for consideration reports that proteomic mapping of mitochondria in the mouse produced a list of 591 mitochondrial proteins, including 163 proteins not previously associated with this organelle (Mootha *et al*., 2003). These researchers found protein expression data were largely concordant with large-scale surveys of RNA abundance and both measures indicated tissue-specific (brain, heart, kidney and liver) differences in organelle composition. These researchers concluded that the combined proteomic and transcript analysis identified specific genes of biological interest, such as candidates for mtDNA repair enzymes, offered new insight into the biogenesis and ancestry of mammalian mitochondria, and provided a framework for understanding the organelle's contribution to human disease (Mootha *et al*., 2003).

The preceding studies suggest that some of the variability in correlating protein and transcript levels involves: (i) sampling time after treatments (mRNA changes precede protein expression), (ii) the high information density of DNA arrays and proteomic platform capacity for identified proteins (many transcripts compared to few proteins), (iii) very different bioinformatic methods among studies for comparing correlated expression of protein and transcripts and (iv) differences among these studies in the particular cell or tissue sample, time of specific toxicant exposure and experimental design. It is expected that levels of low concentration, short half-life, cell-specific regulatory proteins, such as transcription factors or phosphorylated signalling intermediates, would be highly variable in their transcript and protein isoform levels at any one point in time and cellular spatial compartment. The difficulty in correlating protein and transcript levels appears to escalate when considering entire transcriptomes and proteomes as encountered in reviewing

published studies. Since each -omic discipline has developed with distinct technical platforms and bioinformatic approaches, the challenge of integration should not be unexpected. However, the complementarity and sizeable insight gained by performing proteomic and transcriptomic analysis as illustrated by gene expression studies of mouse mitochondria (Mootha *et al*., 2003) seem highly justified by new knowledge gained. Further, it is essential to eventually acquire transcriptomics, proteomics and metabolomics data to construct a systems biology framework for toxicology and pathology. The variable nature of each experiment emphasizes the need to capture all pertinent experimental details in expression databases designed to accommodate and inter-relate proteomics, transcriptomic and metabolomic data.

9 INTEGRATION OF DATA

A key objective in toxicogenomics is to integrate data from different studies and analytical platforms to produce a richer and biologically more refined understanding of the toxicological response of a cell, organ or organism. For example, one would like to describe the interplay between protein function and gene expression, or between the activity of certain metabolizing enzymes and the excretion into serum or urine of populations of small metabolites. The integration of data from different domains such as proteomics and transcriptomics (Ruepp *et al*., 2002; Hogstrand *et al*., 2002; Juan *et al*., 2002), or transcriptomics and metabonomics (Coen *et al*., 2004) has been reported. In these experiments, tissue samples using different technologies derived from the same individual animals or from comparably treated animals were analysed in parallel using different technologies. However, the data from different studies were integrated only after a short list of differentially responsive transcripts or protein spots had been derived.

The experience gained from integrating global proteomics or metabonomics data, such as spot intensities from 2D gels or metabonomics fingerprint data from NMR, tells us that cluster or principle component analysis may be performed to derive global signatures of molecular expression in much the same way as in transcriptomics analyses. If biological samples segregate into unique clusters that show similar expression characteristics, additional efforts can be undertaken to discern the novel proteins or metabolites that are expressed in these samples. Further steps can also be taken to evaluate these proteins or metabolites as potential biomarkers and as a means to determine the underlying toxicological response.

Although software is plentiful for managing expression profiling data at the laboratory level, there is a compelling need for public databases that combine profile data with associated biological, chemical and toxicological end points (Mattes *et al*., 2004). Comparisons of gene, protein and metabolite data within public databases will be valuable for promoting a global understanding of how biological systems function and respond to environmental stressors (Lindon *et al*., 2003; Amin *et al*., 2002). As these repositories are developed, experiments will be deposited from disparate sources, using different experimental designs, yet targeting the same toxicity end point or a similar class of toxicant. In these cases, it will be important that the databases integrate data from related studies before performing data mining. To maximize the value of deposited datasets, the repositories must also be able to integrate data from different technological domains (see Appendix A). Members of regulatory bodies are working with scientists from industry, academic and government laboratories participating in the International Life Sciences Institute (ILSI) Genomics Committee and Clinical Data Interchange Standards Consortium/Standards for Exchange of Nonclinical Data (CDISC/SEND) consortia to develop standards for the exchange, analysis and interpretation of transcriptomics data.

A proposal has been made to extend toxicogenomics and combine it with computational approaches such as physiologically based pharmacokinetic (PBPK) and pharmacodynamic (PD) modelling (Waters *et al*., 2003b). PBPK modelling can be used to derive quantitative estimates of the dose of the test agent or its metabolites that are present in the target tissue at any time after treatment, thereby allowing molecular expression profiles to be anchored to internal dose, as well as to the time of exposure and to the toxicant-induced phenotype. Relationships among gene, protein and metabolite expression can then be described both as a function of the applied dose of an agent, and the ensuing kinetic and dynamic dose–response behaviours that occur in various tissue compartments. Such models also must take into account the fact that the transcriptome, proteome and metabolome are themselves dynamic systems, and are therefore subject to significant environmental influences, such as time of day and diet (Kita *et al*., 2002).

Despite the numerous successes of toxicogenomics in the context of toxicology, a poorly addressed, but confounding issue pertinent to drug safety and human risk assessment is the impact of the individual genetic background on the response of the individual animal or human patient. The PharmGKB pharmacogenetics knowledgebase (Klein and Altman, 2004) catalogues the relationship between different human genetic backgrounds and susceptibility to drug therapy. In addition, the National Institute of Environmental Health Sciences (NIEHS) Environmental Genome Project (EGP) (Olden and Guthrie, 2001) is identifying SNPs in genes that are important in environmental disease, detoxification and repair. Linking toxicogenomics knowledgebases with those containing information about SNPs and human susceptibility will gradually lead to a more complete

picture of the relevance of the responses and genotypes of surrogate animal species to human risk assessment.

10 CHALLENGES AND TECHNICAL CONSIDERATIONS

Predicting potential human health risks from chemical stressors raises three general challenges. These are: the diverse properties of thousands of chemicals and other stressors that are present in the environment; the time and dose parameters that define the relationship between exposure to a chemical and disease; and the genetic diversity of human populations and of organisms used as surrogates to determine the adverse effects of a toxicant. **Figure 1** illustrates the effect of genetic susceptibility on the continuum from toxic exposure to disease outcome. Knowledge of this continuum, and the role that genetics has in it, can help us to understand environmentally induced diseases, assess risk and make public health decisions. Associated with these challenges are others of a more technical nature; these pertain specifically to toxicogenomics studies and are described below.

Although genome-wide alterations in mRNA, protein or metabolite levels in tissue extracts clearly are useful in identifying 'signature' gene changes, verifying that one or more gene products are involved in a toxic process depends on knowing the specific cell types in which the target-gene transcripts and products are located. Experimental methods, such as Northern or Western blotting, or real-time polymerase chain reaction (PCR), are typically used to verify the expression profile of a gene or to selectively analyse its expression as a function of toxicant dose or time of exposure. *In situ* hybridization, immunohistochemistry and other techniques can be used to identify the specific cell types that express the gene(s).

The ability to focus molecular expression analysis on only a limited number of cell types depends upon cell separation methods that minimize the opportunity for other cell types to contribute to gene expression *in situ*. Even the most carefully gathered biological samples contain many cell types, especially if the sample is from inflamed or necrotic tissue. More homogeneous samples are provided by laser capture microdissection (LCM), a method that isolates individual cells or sections of tissue from a fixed sample (Kabanov, 2006; Karsten *et al*., 2002; Bonner *et al*., 1997; Emmert-Buck *et al*., 1996; Jain, 2002; Wittliff and Erlander, 2002). The use of LCM minimizes contributions by nontarget cell populations in comparisons of diseased and normal tissues, but also introduces handling and preparation steps that can affect detection accuracy.

Simultaneously with new technology that selectively samples cell populations must come the ability to reliably detect signals from increasingly smaller samples. For example, it will frequently be necessary to amplify mRNA from the same biological sample that was used for transcriptomics analysis. The need to detect weak signals or small, but biologically important, changes in expression levels remains, as toxicologists explore the initial steps in biological signalling cascades and compensatory processes. At present, complimentary DNA (cDNA) microarray hybridization can detect strong signals within a mixed cell population in samples that are diluted by up to 20-fold (Hamadeh *et al*., 2002b). Thus, this technology is likely able to detect a strong signal from a population comprising 5–10% of the total tissue, but might miss more subtle changes associated with signalling or other initial responses to a stressor. With LCM a relatively pure cell population could be sampled, thus the technology would be expected to detect much more subtle changes, for instance responses seen only in a subpopulation, or asynchronous responses occurring in 10% of the cells at the time of sampling. The ultimate goal would be the ability to quantify genomic changes occurring in a single cell.

Although mRNA analysis is a powerful tool for recognizing toxicant induced effects, analysis of protein structure and modification and, more importantly, of global protein expression provides distinct advantages for understanding the functional state of the cell or tissue. Promising new methods are emerging, including the capacity to profile proteins with antibody arrays (Huang, 2001) and surface-enhanced laser desorption/ionization MS (SELDI; see Appendix A) (Merchant and Weinberger, 2000; Liotta and Petricoin, 2000). Alterations in patterns of mRNA and protein expression in accessible tissues such as serum (Petricoin *et al*., 2004) may offer new insights into the function of genes in the context of toxicity and guide the search for protein biomarkers of toxicant exposure or predictive toxicity.

Whole genome queries by DNA array platforms are starting to address the complexity of gene expression in mammalian systems by incorporating experiments that include RNA splicing, inhibition and editing and transcriptional silencing and modulation (Herbert, 2004). The perspective for quantifying and cataloguing the human genome has changed markedly since the first maps were published (Venter *et al*., 2001; McPherson *et al*., 2001). Estimates have been placed for those portions of the human genome derived from alternative splicing of multiexon genes at 41–60%, for retrotransposition at 45%, for antisense transcription at 10–20% of genes, and for non-protein-coding RNA at approximately 7% of full-length cDNAs (Herbert, 2004).

Complete transcriptomic analysis with existing DNA array technology, although not routine, is becoming more practical with the use of tiled oligonucleotide microarrays (Mandal *et al*., 2005). However, generation of tissue-specific, normalized and subtracted cDNA libraries has the potential to characterize the expression of rare transcriptional units not represented on available oligonucleotide DNA microarray gene chips. A

detailed study that compared expressed sequence tag (EST) sequences of a subtracted library generated from mouse retina to those MG-430 consensus sequences was undertaken, using UniGene build 124 as the common reference. A set of 1111 nonredundant transcript regions, not represented on the commercial array, was identified from murine cDNA clone collections and subtracted cDNA libraries selected for expression of rare transcriptal units, including seven transcripts and splice variants with retina-specific expression (Shearstone *et al*., 2005).

The challenge can also be exemplified by the p53 gene family. The p53 tumour suppressor protein generally fits a linear expression pattern from gene, to transcript, to single protein; however, its two homologous family members, p63 and p73, have the peculiarity of sharing many splice variants that give rise to at least six major transcripts and subsequent proteins including TAp63/p73 α, β and γ isoforms and ΔNTAp63/p73 α, β and γ isoforms (Benard *et al*., 2003; Courtois *et al*., 2004; Demonacos and La Thangue, 2003). Even p53 splice variants and proteolytic cleavage products have been frequently observed in many different malignancies as well as developmental processes (Courtois *et al*., 2004). Despite the complex expression pattern of some genes and difficulties in distinguishing their variants with current microarray technologies, the current DNA microarray platforms for transcriptome assessments now provide an ever-improving coverage of gene expression.

Proteomic platforms do not yet deliver the same quantity or type of information as the transcriptome. Indeed, for the human genome, the relationship between gene number and proteome size is far from simple when taking into account splice variants and pseudogenes (Harrison *et al*., 2003). One estimate has the number of protein-coding transcripts at about 100 000, but that number might be higher (Harrison *et al*., 2003). Also, accounting for posttranslational modifications of each protein would create many more structurally unique variants and hints at the enormous complexity of the human protein expression. Despite the vastness of the proteome, proteomics is creating revolutionary insights into protein expression of unicellular and higher-order species that will reshape pathology, toxicology and many other disciplines.

First, the composition of subcellular structures such as the nucleolus (Andersen *et al*., 2002), mitochondria (Mootha *et al*., 2003), Golgi (Wu *et al*., 2004) and others are being comprehensively catalogued by new methods in proteomic analysis at a rapid rate and in a manner that will eventually apply to protein dysfunction underlying disease. Second, proteomes of important biological fluids such as serum and plasma, are planned for complete mapping, which will be crucial for biomarker development (Anderson and Anderson, 2002). Third, development of global analysis methods for posttranslational modifications, such as phosphorylation, glycosylation, ubiquitination and others, will help elucidate the active forms of protein during homeostasis and disease. Fourth, identification of specific xenobiotic–protein adducts by proteomics will provide insights, not only into acute cellular injury and necrosis (Liu and Kaplowitz, 2002), but also into immune system activation (Ju and Pohl, 2001) and idiosyncratic responses to therapeutics and environmental chemicals (Ju and Uetrecht, 2002). Fifth, rapid, parallel and nanovolume protein analysis of biofluids will be entering research and clinical realms ranging from therapeutic target discovery to diagnosis and to epidemiological investigations. These contributions of proteomics to toxicology and pathology represent a technological exploitation of the complex properties of proteins, such as posttranslational modifications (i.e. signal transduction) spatial location and structure (i.e. subcellular organelles), and functions (enzyme activities).

One of the great challenges in metabolomics, whether one is using NMR spectroscopy, MS, electrochemical detection or other methods, is poor annotation (metabolite identification) of the observed signals. In a typical NMR study, fewer than 30 metabolites of the estimated few hundred compounds within a spectrum will be unambiguously identified. This limits the metabolic information that can be extracted from the spectral data and restricts the mechanistic insight that could potentially be gained of the biological system under study. Furthermore, peak annotation is a prerequisite for instrument-independent metabolic data, which is both the desired format for the construction of metabolic databases and facilitates the comparison of datasets regardless of the instrument on which they were measured. This problem must be addressed urgently if metabolomics is to fulfill its potential.

11 BIOINFORMATICS CHALLENGES

Full realization of the potential of molecular profiling in toxicogenomics requires a very substantial investment in bioinformatics in order to extract biological sense from the myriad of interrelated numerical molecular identifiers and their associated annotations. Advances in bioinformatics and mathematical modelling provide powerful approaches for identifying the patterns of biological response that are imbedded in genomic datasets (**Figure 4**). However, facile interpretation of global molecular datasets derived from -omics technologies is currently constrained by the 'bioinformatics bottleneck'. Bioinformatics and -omics technologies themselves must improve in gene, protein and metabolite identification and annotation to open the field of toxicogenomics to high-throughput applications in drug development and toxicant evaluation. Several useful resources address the annotation problem by linking identifiers used in genomic databases at the National Center for Biotechnology Information (NCBI), European

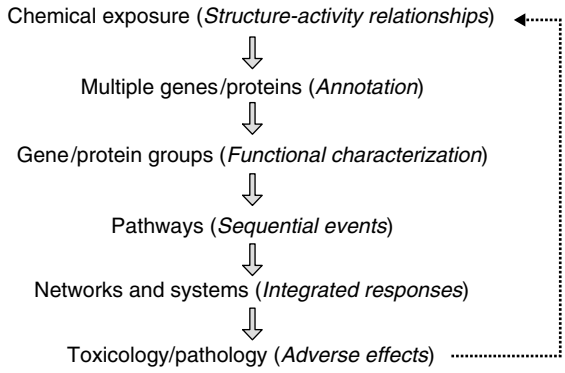

Figure 4 Bioinformatics challenges and biological complexity. The focus of bioinformatics in interpreting molecular expression data depends on the level of biological complexity—here shown progressing from genes/proteins/metabolites to networks and systems. For toxicology/pathology the focus is on phenotypic anchors—observed biological responses that can be related to the chemical structure of the test agent or exposure.

Molecular Biology Laboratory (EMBL) and DNA Data Bank of Japan (DDBJ) to other annotation resources. Critical to resolving annotation inconsistencies is the knowledge of the sequence of the actual nucleotide or protein that is used to query the genome.

The use of advanced bioinformatics tools to extract information from microarray results (Quackenbush, 2001) is valuable only if the data employed by these tools have a high degree of internal specificity and accuracy (Mattes *et al*., 2004). Additionally, the interpretation of molecular expression profiles must emphasize biological coherence as well as statistical validity when deriving knowledge from toxicogenomics experiments. This means that once a set of genes with altered expression is identified, their biological functions must be ascertained. Mechanistic interpretation of transcript changes may be impeded by the nonstandard or imprecise annotation of a sequence element (i.e. gene). Without appropriate synonyms for gene names, the effectiveness of a literature search may be limited. Differences in annotation within and among different microarray platforms may hamper the comparison of results. Such inconsistency frequently arises from annotation resources using different lexicons, or from annotation information being compiled at different times.

Additional bioinformatics and interpretive challenges arise at many levels of biological organization (**Figure 5**). Our current focus and level of understanding of the global molecular landscape encompasses only the lower levels of complexity (genes/proteins, gene/protein groups, functional pathways). The resolution of this knowledge might be termed linear toxicoinformatics, that is, the description of environmental stimuli and responses over dose and time following a toxicological stress. Toxicologists and risk assessors typically define a sequence of key events and linear modes-of-action for environmental chemicals and drugs (Farland, 1992; 1996; Larsen *et al*., 2000). By contrast, the networks and systems level of biological organization may demonstrate highly nonlinear cellular expression state changes in response to environmental stimuli (Hughes *et al*., 2000; Begley *et al*., 2002). Thus, the statistical and bioinformatics-based separation of the complex adaptive, pharmacological and toxicological responses of drugs, chemicals and even dietary constituents will probably very much be a matter of degree. This reflects the kinetic and dynamic responses of specific tissues to toxicants as directed by the genome, the genetic heritage of the individual, and that individual's current and prior exposures.

12 SYSTEMS TOXICOLOGY

Ideker *et al*. (2001a) used the phrase 'systems biology' to describe the integrated study of biological systems at the molecular level—involving perturbation of systems, monitoring molecular expression, integrating response data and modelling the systems molecular structure and network function. Here we similarly use the phrase 'systems toxicology' to describe the toxicogenomic evaluation of biological systems, involving perturbation by toxicants and stressors, monitoring molecular expression and conventional toxicological parameters, and iteratively integrating response data to model the toxicological system (Waters *et al*., 2003a).

A number of approaches are being developed to model network behaviour, with different assumptions, data requirements and goals. However, it is not likely that toxicogenomics and systems toxicology models will be assembled exclusively from knowledge of cellular components, without equivalent knowledge of the response of these components to toxicants (Begley *et al*., 2002). Thus the 'stress testing' of the structural biology of the system and the capture of that data in the context of the functioning organism adapting, surviving or succumbing to the stress will be required.

Development of a knowledgebase to accurately reflect network-level molecular expression and to facilitate a systems-level biological interpretation requires a new paradigm of data management, data integration and computational modelling. A knowledgebase that fully embraces systems toxicology (Waters *et al*., 2003a; 2008) will use precise sequence data to define macromolecules, interaction data based experimentally on colocalization, coexpression and analyses of protein–protein interactions; and functional and phenotypic data based on gene knockouts, knockins and RNA-interference studies, in addition to studies of responses to chemical, physical and biological stressors. These data will allow specific molecules to be accurately

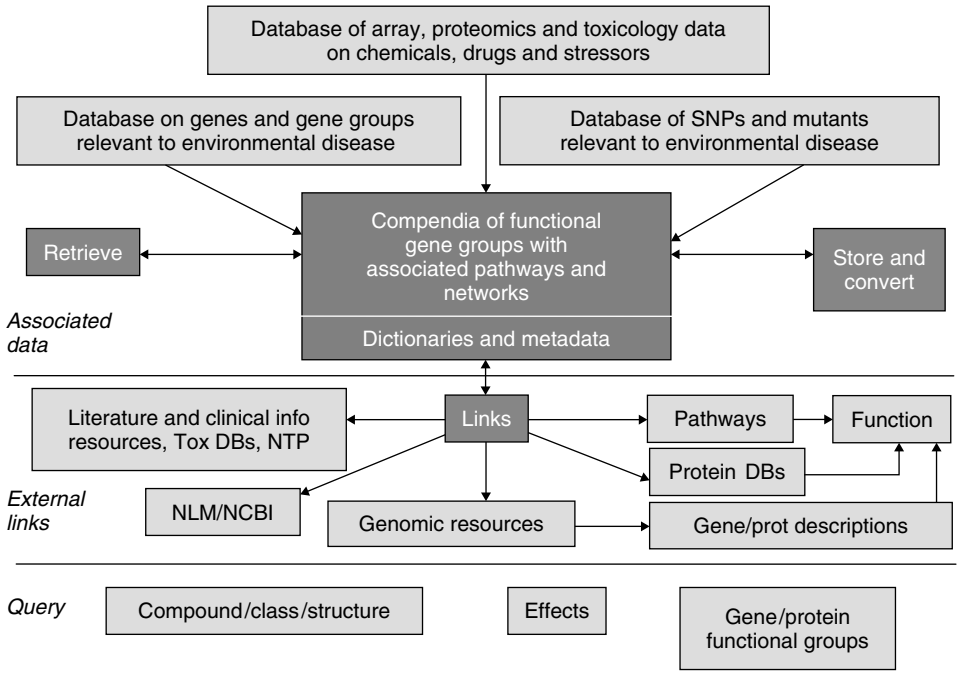

Figure 5 Conceptual framework for the development of the chemical effects in biological systems (CEBS) knowledgebase. CEBS knowledgebase is a cross-species reference toxicogenomics information system on chemicals/stressors and their effects. The figure has three sections—the upper section, indicating data associated in CEBS, the centre section, indicating external links from CEBS, and the lower section, indicating example query types that CEBS will support. The boxes in the upper section include primary data, important genetic loci and genetic markers such as SNPs. In the central section, links to databases and unstructured data are shown. SNPs, Single Nucleotide Polymorphisms; Tox, toxicology; DBs, databases; NTP, National Toxicology Program; NTP, National Library of Medicine; NCBI, National Center for Biotechnology Information; Prot, protein.

related to biological phenomena that reflect the normal as well as the stressed cell, tissue, organ and organism. In the best of circumstances, a systems toxicology approach will build a toxicogenomic understanding from global molecular expression changes that are informed by PBPK/PD modelling and biologically based dose–response (BBDR) modelling. The challenge in constructing a robust systems toxicology knowledgebase is formidable.

13 THE FUTURE OF TOXICOGENOMICS

New toxicogenomics methods have the power and potential to revolutionize toxicology. Technological innovations that are already in use permit RNA profiling of formalin-fixed tissues (Lewis *et al*., 2001), potentially making archived tissues from generations of toxicological studies accessible to gene expression analysis. Methods to array hundreds of toxicologically relevant protein antibodies, and to profile hundreds of small molecules in high-throughput mode using gas chromatography (GC)/liquid chromatography (LC)/MS are in development.

Toxicoproteomics research is anticipated to lead to the identification, measurement and evaluation of proteins and other biomarkers that are more accurate, sensitive and specific than those available now, and which might be targeted to particular human genetic subpopulations. Metabonomics research will help to identify small endogenous molecules as important in a sequence of key metabolic events; such 'metabolite fingerprints' might then help to diagnose and define the ways in which specific chemicals, environmental exposures or stressors cause disease. This, coupled with the ability to detect damage to particular organs by observing alterations in serum and urine components, is expected to lead to the more sensitive detection of exposure or risk factors (Wetmore and Merrick, 2004). Additional considerations in assessing the toxicogenomic response to environmental exposures are the individual genotype, lifestyle, age and exposure history (Kaput and Rodriguez, 2004). Toxicogenomics will help to ascertain the degree to which these factors influence the balance between healthy and disease states.

Toxicogenomics will increase the relevance of toxicology through the global observation of genomic responses with therapeutically and environmentally realistic dose regimens. It will help to delineate

the mode-of-action of various classes of agents and the unique genetic attributes of certain species and population subgroups that render them susceptible to toxicants (Farland, 1996; Waters *et al*., 2003b). Studies on strains within a species that are sensitive or resistant to the chemical induction of specific disease phenotypes will be particularly valuable. Extending this thinking to the phylogenetic analysis of both core conserved biological processes (Stuart and Berry, 2003) and to the toxicological responses seen in different species will provide additional comparative insight on genetic susceptibility and on probable disease outcomes.

The combined application of the -omics technologies will improve our overall understanding of mechanisms of toxicity and disease aetiology as integrated toxicogenomics databases are developed more fully (Waters *et al*., 2003b). Data on gene/protein/metabolite changes collected in the context of dose, time, target tissue and phenotypic severity across species from yeast to nematode to man will provide the comparative information needed to assess the genetic and molecular basis of gene–environment interactions. Toxicology will emerge as an information science that will facilitate scientific discovery across biological species, chemical classes and disease outcomes (Tennant, 2002). Although there are large challenges in developing public toxicogenomic data repositories, the nucleotide sequence databases—GenBank, EMBL and DDBJ—provide an excellent example of the benefit to the larger scientific and medical community of sharing data.

Concomitant with development of toxicogenomics databases must be the evolution of bioinformatics methods and data-mining tools, and individuals trained to apply them (Quackenbush, 2001). We believe that a predictive systems toxicology will gradually evolve, aided by knowledge that is systematically generated (Zweiger, 1999) through literature mining (Chaussabel and Sher, 2002; Sluka, 2002), comparative analysis and iterative biological modelling of molecular expression datasets over time. Given the vast numbers and diversity of drugs, chemicals and environmental agents, and the diversity of species in which they act, we believe, however, that it is only through the development of a comprehensive and public knowledgebase that toxicology and environmental health can rapidly advance. The ultimate goal of the National Center for Toxicogenomics (NCT) is to create the Chemical Effects in Biological Systems (CEBS) knowledgebase (Waters *et al*., 2003a; Waters *et al*., 2008), a public resource that will enable health scientists and practitioners to understand and mitigate or prevent adverse environmental exposures and related diseases.

ACKNOWLEDGEMENTS

We are indebted to the staff of the National Center for Toxicogenomics for their support and involvement with this work. This chapter was derived from prior publications by the authors in *Nature Reviews Genetics* and *Toxicological Pathology*. This work was supported by the Intramural Research Program of the National Institutes of Health (NIH), National Institute of Environmental Health Sciences (NIEHS) and NIEHS contract number 273-02-C-0027.

APPENDIX A: DESCRIPTIONS OF SELECTED -OMICS TECHNOLOGIES

The terms transcriptomics, proteomics and metabonomics or metabolomics refer to highly parallel analytical technologies wherein simultaneous measurements are made of expressed genes, proteins or metabolites, respectively. These technologies are used to ascertain the function of the genome. Toxicogenomics makes use of all of these functional genomics technologies in the study of toxicology. The terms toxicoproteomics and toxicometabolomics are sometimes used in a technology-centric sense to discuss the response of the proteome or metabolome to toxicants. Toxicoproteomics, as part of the larger field of toxicogenomics, seeks to identify critical proteins and pathways in biological systems that are affected by and respond to adverse chemical and environmental exposures using global protein expression technologies.

A.1 Transcriptomics—DNA Microarray Hybridization and Analysis

Early gene-expression profiling experiments that were carried out for toxicogenomics studies employed cDNA microarrays (Nuwaysir *et al*., 1999). Although this cDNA technology has been supplanted by synthetic short and long oligonucleotide microarrays, the technological concepts underlying the two approaches are largely analogous: cDNAs are derived from sequence-verified clones representing the 3′ ends of the genes, which are either spotted onto glass slides using a robotic arrayer or synthesized *in situ*. Each RNA sample is labelled with dye-conjugated 2′-deoxyuridine 5′-triphosphate (dUTP) by reverse transcription from an oligo deoxythymine (dT) primer. The fluorescently labelled cDNAs are then hybridized to the microarray and the microarray is scanned using laser excitation of the fluorophores (Hamadeh *et al*., 2002e). Raw pixel intensity images derived from the scanner are analysed to locate targets

on the array, measure local background for each target, and subtract it from the target intensity value. Prime discovery features of cDNA and oligonucleotide microarrays are the sequences representing ESTs, hypothetical proteins, homologues, orthologues or genes of unknown function. ESTs or similar features are not currently represented on antibody arrays. When examining differential transcript profiles, however, many researchers focus more upon annotated genes of known or homologous function that currently account for less than half the genes predicted for the human genome. Changes in expression of ESTs might be tracked in transcriptomic studies, but they are often not followed up in many gene expression experiments (except when used as part of discriminating signatures to classify disease of toxicity).

A.2 Proteomics

Global measurement of proteins and their many attributes in tissues and biofluids defines the field of proteomics. An established proteomics strategy (Patterson and Aebersold, 2003) uses global protein stratification systems, such as polyacrylamide gel electrophoresis (PAGE), followed by protein identification by MS. 2D PAGE separation, by charge and by mass, can resolve thousands of proteins to near homogeneity. This separation is a necessary prerequisite to enzymatic digestion and MS identification, which requires unique peptide fingerprint masses or amino-acid sequence tags. Where proteins are separated by LC instead of PAGE, a new and promising platform involving multidimensional LC can be used to fractionate and reduce the complexity of the protein mixture before peptide sequencing by MS or tandem MS (LC/MS/MS). This approach is being augmented by SELDI-TOF MS (surface-enhanced laser desorption/ionization time-of-flight mass spectrometry), a method that results in the isolation of tens- to hundreds-of-thousands of low molecular weight fragments representing a proteome.

The focus of proteomics can range from global protein analysis (Davis, 2004; Zhu *et al*., 2003) via approaches such as 'shotgun proteomics' (Wolters *et al*., 2001; MacCoss *et al*., 2002) where researchers strive for the maximum number of protein identifications, to a more discrete level of protein analysis often termed 'targeted proteomics' (Dongre *et al*., 2001). In targeted proteomics, protein groupings or subproteomes (Cordwell *et al*., 2000) may be organelles (Dreger, 2003), portions of structures like nuclear membrane proteins (Schirmer *et al*., 2003), signalling pathways (Ping, 2003) and protein complexes or protein families (Lee *et al*., 2003). Inherent in this range of different biochemical perspectives is the assumption that protein structure and spatial location within cell(s) or tissue remain critical features in proteomic analysis. Other characteristics of proteins, such as function, protein–protein interactions, 3D structure or specific posttranslational modifications, have also helped define various subdisciplines of proteomics.

A.3 Metabolomics and Metabonomics

Quantitative analytical methods have been developed to identify metabolites in pathways or classes of compounds. This collective directed approach has been called metabolite profiling or metabolomics. Semiquantitative, NMR-based metabolic fingerprinting has also been applied to high abundance metabolites and has been termed 'metabonomics' (Nicholson *et al*., 2002). Peaks detected in NMR spectra carry information regarding the structure of the metabolites, whereas peaks detected by MS have associated molecular weights. In addition, specific MS methods can be established to fragment the parent molecule, allowing metabolites to be identified through investigation of fragmentation patterns.

Environmental and Endogenous Factors Determining the Expression of Toxicity

Karen E. Stine

CONTENTS

1 INTRODUCTION

One of the basic principles of toxicology is the concept of the molecular site of action, or molecular lesion. This interaction of a toxicant with a target, typically a cellular macromolecule or macromolecules, leads to cellular dysfunction with consequences that are often expressed at the physiological or organismal level. The focus of this chapter, however, is not on the nature of the molecular lesion itself, but rather on the environmental and endogenous factors that influence its expression. Relevant factors that will be discussed are illustrated in **Figure 1**, and include exposure to environmental stressors (including other chemical exposures), as well as intrinsic characteristics of the organism (such as species, sex, age, physiologic parameters or genetic variation), which may either influence delivery and binding of the toxicant to the target molecule or alter the ultimate physiological consequences of that binding.

2 ENVIRONMENTAL FACTORS

2.1 Interactions between Chemical Toxicants

There are a number of environmental factors that may have a significant influence on expression of toxicity relating to a given chemical exposure. Perhaps chief among these, however, would be coexposures to other chemicals in the environment. Interaction between chemical toxicants can be complex, and may be mediated through a number of different mechanisms, including impacts on toxicokinetics, metabolism or binding at the target site. Identifying and assessing these interactions between biologically active compounds, however complex, is critical to the accurate prediction of both human health and environmental risks (Robinson and MacDonell, 2004; McCarty and Borgert, 2006; Pomati *et al.*, 2008).

2.1.1 Impact of Coexposures on Toxicokinetic Parameters

There are several mechanisms by which one toxicant has been reported to impact the absorption and distribution of another in an organism. These would include modification of properties of the epidermis, including changes which may enhance or reduce the ability of other compounds to undergo absorption through the skin. For example, in one study, parathion absorption was significantly altered by coadministration of sodium lauryl sulfate (which enhanced absorption) and stannous chloride (which reduced absorption) (Qiao and Riviere, 1995).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat028

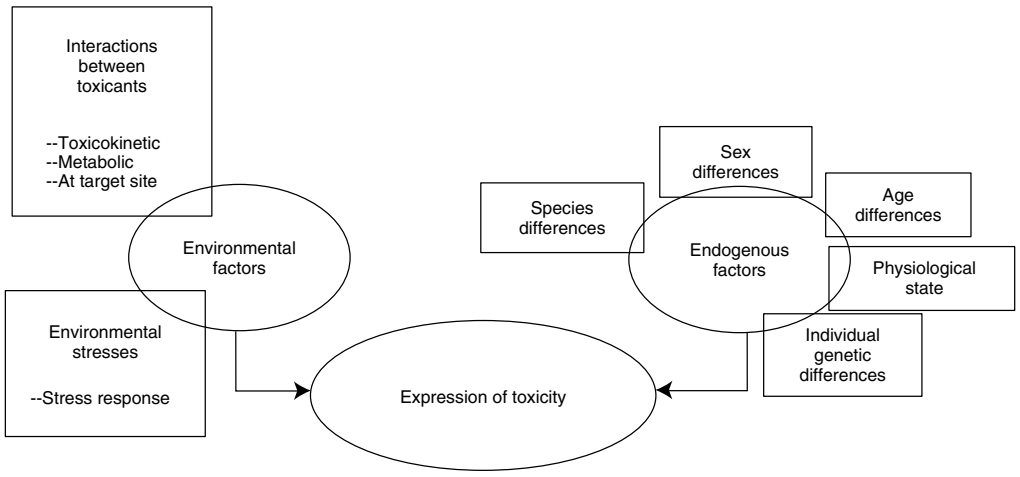

Figure 1 A schematic showing the types of environmental and endogenous factors that may influence expression of toxicity.

Likewise, compounds that affect conditions in the gastrointestinal tract may alter absorption of other compounds. For toxicants absorbed by simple diffusion, an increase in epithelial permeability such as that produced by polyamines, for example (Gao *et al.*, 2008), may enhance absorption of other compounds. On the other hand, competition for carrier-dependent transport (such as occurs between cadmium, calcium, zinc and other ions) can potentially decrease toxicant absorption (Glover and Hogstrand, 2003). Toxicant absorption can also be decreased by direct modulation of the activity of a transporter molecule, as in the case of the effects of acetaldehyde, a metabolite of ethanol, on the PEPT1 drug transporter (Fisher *et al.*, 2008). Of course, gastrointestinal coexposures may certainly include compounds found in foods, making diet an important source of variation in absorption. For example, plant flavonoids, found both in food and in dietary supplements, have been shown to interact with and alter transport of drugs such as vinblastine, doxorubicin and digoxin (Cermak and Wolffram, 2006). These effects are mediated through action on intestinal drug transporters including MRP2 and a P-glycoprotein transporter. The P-glycoproteins (two of which are found in humans) belong to the family of adenosine triphosphate (ATP)-binding cassette (ABC) transporters (Hennessy and Spiers, 2007). The genes coding for these proteins are expressed in many tissues, and play a critical role in blocking uptake of toxicants into those tissues. P-glycoproteins have been shown to be inducible and while the mechanism has yet to be completely elucidated, it appears to involve multiple signalling pathways and may possibly involve nuclear receptors such as pregnane X (PXR) (Callaghan *et al.*, 2008). Unfortunately, however, P-glycoprotein is frequently expressed in cells with a neoplastic phenotype, where its protective effects provide a daunting barrier to the success of chemotherapy (Cordon-Cardo *et al.*, 1990).

Compounds that affect general gastrointestinal motility can also affect absorption of toxicants through altering the time available for absorption to take place (DeSesso and Jacobson, 2001). Similarly, respiratory absorption of toxicants can be affected by a number of factors that affect rate and depth of respiration, including both exercise and chemical exposures (Mautz, 2003).

Once absorbed into the blood stream, toxicants are then delivered to the various body tissues. The rate of this delivery is dependent on a number of factors, including the binding affinity of the toxicant for binding to plasma proteins such as albumin. Competition for binding to albumin and other proteins can lead to displacement of toxicants from binding, which may lead to increased tissue toxicant levels, and, thus, increased potential toxicity. For example, acetylsalicylic acid has been shown to reduce binding of both propranolol (Rezaei *et al.*, 2007) and imipramine (Juarez-Olguin *et al.*, 2002) to human serum albumin, an action which led to a significant increase in the incidence of side effects in patients receiving the imipramine.

Finally, a special factor influencing distribution of toxicants is the blood–brain barrier. The blood–brain barrier is a set of anatomical and physiological modifications that result in a reduced passage of toxicants from the bloodstream into central nervous system tissues. This complex combination of tight junctions between capillary endothelial cells, transporters (such as the P-glycoprotein pump, Cordon-Cardo *et al.*, 1989), and additional layers of glial cell membrane and cytoplasm to cross renders many toxicants incapable of entry into the central nervous system (Zlokovic, 2008). However, chemical compounds that reduce the effectiveness of the barrier may lead to enhanced central nervous system toxicity of other compounds. This would be a concern, for example, with the usage of potential P-glycoprotein inhibitors such as verapamil for cancer chemotherapy (Kars *et al.*, 2008).

2.1.2 Impact of Coexposures on Metabolism of Toxicants

One of the most well-characterized ways in which multiple toxicants interact is through impact on xenobiotic metabolism. Xenobiotic metabolism has been generally subdivided into two phases: Phase I, involving oxidation, hydrolysis and occasionally reduction; and Phase II, involving conjugation of either the parent compound or a Phase I metabolite with glucuronic acid, glutathione or another compound, which typically confers increased size and hydrophilicity to the substrate. Many of the enzymes involved in these processes are inducible, and the process is thus subject to alteration based on the chemical environment within the cell. For example, one of the major enzyme families involved in Phase I metabolism, the cytochrome P450 family, contains a number of isozymes that can be both induced and inhibited by substrates. This, of course, would affect not only the metabolism of those specific substrates, but also any other toxicants which are substrates for metabolism by that isozyme.

Specific examples of P450 inducers include polycyclic aromatic hydrocarbons (PAHs) such as 3-methylcholanthrene, which are inducers of the cytochrome P450 CYP1A1 and CYP1A2 isozymes. This induction is mediated through PAH binding to and activation of a cytosolic receptor known as the aryl hydrocarbon (Ah) receptor. This receptor, when activated, stimulates gene transcription through its interaction with DNA regulatory sequences such as the dioxin-responsive elements (DRE) or xenobiotic responsive elements (XRE) (Beischlag *et al.*, 2008). Also among the inducible members of the cytochrome P450 family is the most abundant human cytochrome, CYP3A4. This isozyme can be induced by rifampin and phenytoin, through a mechanism involving the PXR nuclear receptor (Zhou, 2008). Inducers of other P450 isozymes include barbiturates, pregnenolone-16α-carbonitrile (PCN), clofibrate and isoniazid (Runge *et al.*, 2000). Again, induction of a P450 isozyme through exposure to an inducing agent is significant not only because of effects on the metabolism of the inducer, but also because of effects on the metabolism of any other compounds metabolized by that isozyme. Interestingly, many of the same compounds that induce P450 isozymes are also inducers of P-glycoprotein (Callaghan *et al.*, 2008).

Inhibition of cytochrome P450 isozymes can also play a significant role in impacting toxicity. For example, members of a class of compounds known as mechanism-based inactivators are activated by P450, only to then bind to and irreversibly inhibit the enzyme itself. These compounds tend to be specific for particular P450 isozymes, and include compounds with terminal acetylenes that alkylate the P450 haem group, alkyl and aromatic amines, furans, and sulphur-containing compounds (Masubuchi and Horie, 2007) For example, 17α-ethinylestradiol and mifepristone (also known as RU-486), as well as erythromycin and the calcium-channel blocker verapamil are all inhibitors of CYP3A4 (Guengerich, 1990; He *et al.*, 1999; Ma *et al.*, 2000), leading to significant potential impact on other drugs being administered to a patient simultaneously.

One additional group of compounds that can impact expression of toxicity are compounds that lead to depletion of glutathione. Glutathione, a small peptide consisting of a glycine, a cysteine and a glutamic acid residue, undergoes conjugation with hydrophobic, electrophilic xenobiotics through the action of a family of enzymes known as glutathione S-transferases (GSTs). Because of the reactive nature of the substrates for this reaction, glutathione conjugation is one of the body's major detoxification reactions. Exposure to compounds, such as ethanol, that deplete glutathione, has been shown to potentiate toxicity of other compounds, such as acetaminophen (paracetamol), which depend on conjugation to glutathione for effective detoxification (Zhao and Slattery, 2002). Levels of glutathione also vary significantly with levels of food consumption, making diet yet another factor that can impact toxicity (Qin *et al.*, 2007).

2.1.3 Impact of Coexposures on Physiological Effects of Toxicants

Another level at which one compound may affect the toxicity of another is through interactions mediated at or near the site of the molecular lesion. Sites where these effects may be seen would include cellular targets such as enzymes and receptors. Interactions between chemicals have often been described as additive, synergistic (when the combined effect is greater than that predicted on the basis of either alone) or antagonistic. Another category, potentiation, is used to refer to a chemical that may be inactive at a receptor itself, but which acts to enhance the activity of a second chemical at that site (Eaton and Klaassen, 2001). However, the situation is complicated by the existence of partial agonists, which produce effects upon binding that are nonetheless reduced from those produced by a full agonist, as well as inverse agonists, which actually reverse receptor activity. For example, naloxone, long categorized as an opioid antagonist, has actually proven to be an inverse agonist at the mu receptor (Sadee *et al.*, 2005). Antagonistic effects have also been reported in binding of halogenated aromatic compounds to the Ah receptor, leading to varying responses in CYP1A1 induction (Petrulis and Bunce, 2000).

It should be noted, however, that physiological antagonism between two drugs or toxicants may exist without necessarily implying that the two compounds share a single molecular site of action. Atropine, for example, is an antidote to all organophosphates (OPs) such as sarin exposure: sarin targets acetylcholinesterase, leading to an increase of acetylcholine in the synapse; atropine

counters that effect through blocking the muscarinic acetylcholine receptor (Cannard, 2006) (see **Toxicology of Chemical Warfare Agents**).

The mechanism of action of some toxicants relates to the ability of the toxicant, or often a metabolite, to initiate oxidative damage through the mechanism of lipid peroxidation. This is particularly true of toxicants such as chlorinated hydrocarbons, which are metabolized to form free radicals, species whose unpaired electrons render them highly reactive. These reactive molecules can, and will, bind to cellular macromolecules such as lipids, initiating degradation of the fatty acid components and resulting in both membrane damage and production of additional reactive molecules that can damage other cellular components. Interaction of free radicals with cellular macromolecules can, however, be reduced or blocked by the presence of other molecules that act as antioxidants. For example, in one study, the antioxidants α-tocopherol and selenium were shown to reduce hepatic damage by malathion in chicks, through inhibition of lipid peroxidation (Sodhi *et al.*, 2008).

2.2 Effects of Environmental Stressors on Toxicity

2.2.1 Basics of the Heat Shock or Stress Response

The response of organisms to environmental stressors has been documented in multiple biological systems (Moseley, 1997). A common feature of this response is the induction of a group of proteins which were first termed heat shock proteins (hsps) due to their initial discovery in cells exposed to hyperthermia (Tissieres *et al.*, 1974). An entire family of these proteins, now also more generally known as stress proteins, has since been identified (Morimoto *et al.*, 1997; Horvath *et al.*, 2008). Ranging in size from approximately 15 to 110 kDa in molecular weight, some of these proteins are constitutive, while others have been found to be induced in response to a variety of cellular stresses, including heavy metals (Bauman *et al.*, 1993), oxidative stress (Drummond and Steinhardt, 1987) and ischaemia (Myrmel *et al.*, 1994). This seems to be an adaptive response, as the presence of stress proteins was shown early on to confer resistance to further stresses, such as additional hyperthermia (Li and Werb, 1982). In fact, the existence of stress proteins in so many diverse species certainly argues strongly for a central role for these proteins in basic cellular processes.

Stress proteins play a variety of roles in the cell. Many stress proteins seem to function as molecular chaperones by regulating protein folding (Hendrick and Hartl, 1993; Roth *et al.*, 2008). This seems to be the major function of many hsps including the hsp60, hsp70 and hsp100 families (Saibil, 2008). Other hsps play a variety of roles, including regulation of the function of receptors such as the glucocorticoid receptor (Pratt *et al.*, 1992), regulation of membrane structure and function (Horvath *et al.*, 2008) and control of apoptosis (Lanneau *et al.*, 2008). Hsp90, for example, is a eukaryotic cytosolic protein that occurs in two isoforms (α and β). In humans, it is primarily the hsp90-α gene that is inducible. One of the best known interactions of hsp90 is with glucocorticoid, progesterone and oestrogen receptors. The protein binds to the hormone-binding domain of these receptors, keeping them partially unfolded in the configuration that binds the hormonal ligand with the highest affinity (Pratt, 1997). The presence of hsp90 on the cell surface may indicate a role in presenting proteins to immune cells. In fact, geldanamycin (a specific inhibitor of hsp90 activity which binds to the N-terminal chaperone site) blocks the CD28 costimulation signal for T lymphocytes (Schnaider *et al.*, 1998). Intriguing evidence also implicates hsp90 in the stabilization of mutant proteins in *Drosophila*, allowing mutations to accumulate in the genome (Tomala and Korona, 2008). A final group, the so-called small hsps with molecular weights ranging from around 15 to 30 kDa, have divergent structures, but with a common α-crystalline domain with several highly conserved segments. Most are strongly inducible, some are also constitutively expressed (Arrigo and Landry, 1994; Shemetov *et al.*, 2008).

The mechanism of how induction of the stress response occurs in eukaryotes is relatively well understood and involves binding of an activated heat shock factor (HSF) protein to a responsive heat shock element (HSE) in the genome, which initiates the processes of transcription and translation for these proteins (Shamovsky and Nudler, 2008). There is some evidence, also, that protein kinase A (PKA) and protein kinase C (PKC) may play a role in regulation of promoter activity, as the binding of HSF to DNA in a glioblastoma cell line was suppressed by PKC and PKA inhibitors and the accumulation of hsp72 was induced by PKC and PKA activators (Ohnishi *et al.*, 1998).

The stress response can be triggered by a number of factors besides the classic exposure to elevated temperatures. Numerous chemicals have been reported to induce various hsps, including heavy metals (Ivanina *et al.*, 2008), pesticides (Sharma *et al.*, 2008) and other environmental toxicants (Ait-Aissa *et al.*, 2000).

2.2.2 The Relevance of the Stress Response to Toxicology

Obviously, induction of stress proteins in response to one chemical exposure has the potential to alter the impact of a second exposure to the same or different chemical. For example, exposure to oxalate has been shown not only to lead to elevated levels of hsp70 in LLC-PK1 (renal epithelial) cells, but also to protect against subsequent exposure to oxalate (Koul *et al.*, 2008). And

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat028
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

not only can prior exposure to heat protect against later chemical exposure (Venkatakrishnan *et al.*, 2006), but chemical exposure (in this case, to sodium azide) can also induce thermotolerance (Massie *et al.*, 2003). However, some toxicants may actually reduce stress protein expression (either specifically or through general inhibition of protein synthesis) and might thus contribute to an increase in vulnerability of the cells (Skandrani *et al.*, 2006).

There are other reasons, as well, to be interested in the impact of stress protein induction on cell survival. Stress proteins are not only certain to play a role in cell death, but also possibly in oncogenic transformation and expression of neoplastic phenotypes (Romanucci *et al.*, 2008). For example, hsp70 has been reported to confer some degree of resistance to apoptosis in lymphoid and myeloid cell lines (Lasunskaia *et al.*, 1997) and expression of hsp27 in tumorigenic mouse fibroblasts reduced the cytotoxicity of TNF-α to these cells (Mehlen *et al.*, 1995). In addition, hsp90 has been shown to form complexes with members of the cellular src family of tyrosine kinases, and may be a participant in src-mediated oncogenic transformation (Whitesell *et al.*, 1994). A member of the hsp90 family has also been shown to be constitutively expressed in drug-resistant cancer cells, and may be involved in stabilization of the function of the P-glycoprotein molecule involved in multidrug resistance (Bertram *et al.*, 1996). The relationship between expression of small hsps in cancer cells and prognosis has been studied, but is not entirely clear. Hsp27 has been detected in several, but not all types of brain tumours, with expression roughly correlating with degree of malignancy (Khalid *et al.*, 1995), and overexpression of hsp27 in breast cancers has been associated with increased risk of relapse, although it may, in fact, render those cells more susceptible to being targeted by some immune system cells (Mahvi *et al.*, 1993). Stress proteins may also play a role in neurodegenerative diseases (Morimoto, 2008).

There are, of course, other cytoprotective molecules besides the stress proteins which may also be induced and which may then protect against subsequent toxic exposures. These would include the P-glycoprotein pump (the ABC transporter mentioned earlier), which, again, is often found overexpressed in neoplastic cells. The mechanism for this overexpression is not clear, but may well result at least in part from response to cell stress (Callaghan *et al.*, 2008). Also in this grouping would be the metallothioneins, low molecular weight metal-binding proteins rich in cysteine residues. Ubiquitous in all kingdoms of life, in mammals these inducible proteins are found primarily in liver and kidney, where they seem to serve primarily as protection against heavy metal toxicity (Coyle *et al.*, 2002). Metallothioneins also appear to play a role in apoptosis (Dutsch-Wicherek *et al.*, 2008).

2.3 New Techniques for Sorting Out Complex Mechanistic Questions

Whether one is discussing sorting out complex effects of multiple toxicants, or a complex physiological reaction to environmental stressors, the number of variables involved in both cause and effect can be daunting. A few new molecular techniques, however, have been developed that show promise in helping sort out these complex relationships. One of these is the microarray technique, which can be used to compare the effects of chemical toxicants individually and in mixtures as well as to identify the complex responses of inducible genes to environmental stressors. Briefly, a microarray consists of a glass chip covered by a chemical matrix to which pieces of DNA (generally a short segment of a gene of interest) are attached. A typical microarray may contain tens of thousands of these DNA segments. Typically, fluorescently labelled mRNA is prepared from the tissues of interest, and allowed to react with the chip, where binding of the labelled mRNA to complementary DNA on the chip can be quantified by measuring fluorescence at each location. A virtual snapshot of gene activity at that point in time is thus produced (Jaluria *et al.*, 2007).

This technique and others have led to the development of the new field of toxicogenomics, a field which focuses on the response of the genome to toxicants and stressors (Thomas *et al.*, 2002; Gomase and Tagore, 2008). In one example of a toxicological application of this technology, Sen, *et al.* employed DNA microarrays to examine the effects of cigarette smoke (a complex mixture) on mouse fibroblast cells (Sen *et al.*, 2007), demonstrating upregulation of genes coding for metallothioneins, heat shock proteins and other stress and growth-related proteins. They were also able to demonstrate upregulation of a number of CYP isozymes in human bronchial cells, including CYP1A1 and CYP1B1. Microarrays have also been utilized in ecotoxicological studies (Nesatyy and Suter, 2007). Hook, *et al.*, examined the gene expression profile in rainbow trout liver following exposure to three individual chemicals and then a mixture of the three. Underscoring the complexity involved in mixture toxicology, they found that although the patterns of the individual exposures could be seen in the mixture results, they were not simply additive (Hook *et al.*, 2008).

3 ENDOGENOUS FACTORS

3.1 Species Differences

3.1.1 Species Differences in Toxicokinetics and Metabolism

It is well known that there are significant species differences in terms of response to toxicants, particularly as concerns xenobiotic metabolism. Differences

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat028
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in metabolism between species can be characterized as either qualitative (different enzymes and pathways) or quantitative (same pathways, but different relative activity levels). In Phase I metabolism, differences in structure and function have been identified between mouse, rat, dog, monkey and human P450 isozymes, with the fewest differences between species seen for CYP2E1, and greater differences seen between species for CYP1A, CYP2C, CYP2D and CYP3A (Martignoni *et al.*, 2006). These differences may prove significant in choosing animal models for assessment of first-pass metabolism, as CYP3A is a major factor in bioavailability of the many drugs that are substrates of this isozyme (Komura and Iwaki, 2008). One focussed comparison between CYP3A gene structure and expression in human and chimpanzee tissues has indicated that CYP3A metabolism in adult humans and chimpanzees most likely does not differ significantly (Williams *et al.*, 2007). Other studies have also examined CYP3A activities, indicating that mouse, monkey, minipig and dog CYP3A activities are all more similar to human activities than is rat CYP3A (Turpeinen *et al.*, 2007).

Enzymes involved in Phase II metabolism also show interspecies differences. For example, differences have been identified between humans, monkey, dogs and rats in glucuronidation and sulfation reactions (Wang *et al.*, 2005; 2006) as well as between dogs and humans in *N*-acetylation reactions (Gao *et al.*, 2006).

3.2 Sex Differences

3.2.1 Sex Differences in Toxicokinetics and Metabolism

Sex differences with the potential to impact toxicology have been characterized in humans as well as in other organisms (Gochfeld, 2007). In looking at humans, for example, differences in gender roles may lead to differences in exposure levels to toxicants. This observation holds true both on and off the job, but may be particularly significant in the work environment (Kennedy and Koehoorn, 2003). Physiological factors such as differences in respiratory rates between the sexes may also affect the toxicokinetics of absorption, although the actual impact of this in humans is not well established (Ernstgard *et al.*, 2003a; 2003b). Few, if any, studies have identified sex differences in dermal absorption. And whereas some studies (Schwartz, 2003) have indicated differences in gastrointestinal absorption, this observation may, in fact, be complicated by differences in metabolism. Differences between sexes may also exist in toxicokinetics of elimination. For example, sex differences have been reported in the handling of organic anions in rat liver (Wang *et al.*, 2008), and multiple studies have addressed the impact of possible sex differences in transporter proteins such P-glycoprotein and breast cancer resistance protein (BCRP) in humans (Modjtahedi *et al.*, 2006).

While many gender-related studies have focussed on pharmaceuticals, some have also examined the role of sex in toxicant handling. Twenty years after the industrial accident at Seveso in 1976 (which led to the release of 2,3,7,8-tetrachlorodibenzodioxin (TCDD) over a wide area), women in the area were found to have higher plasma levels of TCDD than men, a difference potentially due to differences in metabolism or elimination (Landi *et al.*, 1998). Cadmium, also, has been found to accumulate to significantly higher levels in retinal tissues in older women as opposed to older men (Wills *et al.*, 2008).

Differences between sexes are almost certainly present in the metabolism of many compounds in several species. Not only have differences in cytochrome P450 metabolism of xenobiotics been detected in rodents and other laboratory animals (Ramesh *et al.*, 2000; Visalli *et al.*, 2005); but studies in humans have also indicated the existence of sex-related differences (Tanaka, 1999). While there may be at least approximate equivalence between many human male and female P450 activities for a variety of substrates (Schwartz, 2003), differences in P450 induction and activity in humans have been reported in the cases of CYP3A which may show higher activity in women (Schwartz, 2003; Wolbold *et al.*, 2003; Gorski *et al.*, 2004; Wenk *et al.*, 2004) and some of the CYP2 subfamilies, which may show higher activities in men (Tanaka, 1999). Some differences have also been seen in Phase II metabolism in humans, although the significance of these are not yet clear (Tanaka, 1999; Schwartz, 2003).

In wildlife toxicology, as well, increasing attention is being given to the potential impact of sex differences on exposure, metabolism and elimination of toxicants (Burger *et al.*, 2007). Exposure may vary with sex, for example, due to different feeding patterns, leading to differences in tissue levels of environmental contaminants.

3.2.2 Sex-related Differences in Molecular Targets

Of course, the physiological differences between males and females also present the possibility for differential toxicity through interaction of a toxicant with different molecular targets. While the most obvious example of this would involve toxicants that exclusively target male or female reproductive structures and functions (the impact of dibromochloropropane (DBCP) on spermatogenesis, for example) a more subtle variation would involve toxicants which may impact either reproductive system, but in different ways. A candidate for this category would be the environmental oestrogens, or endocrine disrupting chemicals (EDCs). These compounds interact with steroid receptors and have been postulated to be linked to a variety of human health problems, including breast cancer in women, reproductive

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tract problems in men and fertility in both sexes (Caserta *et al.*, 2008). They have also been linked to changes in sexual structure and function in wildlife (Goksoyr, 2006; Sonne *et al.*, 2006; Fossi *et al.*, 2007). There are conflicting viewpoints, however, and the issue of links between EDC exposures and human diseases, in particular, remains controversial (Safe, 2005).

Endocrine disrupters almost certainly exert their effects through interaction with receptors, including not only oestrogen receptors, but also receptors such as the PXR and constitutive androstane receptor (CAR) (Kretschmer and Baldwin, 2005). In fact, the mechanism through which toxicants display gender differences in effects may well involve variation in expression of receptors. Differences in kidney toxicity between male and female rats has been linked to differences in expression levels of genes coding for the peroxisome proliferator-activated receptor α (PPAR-α), Ah receptor and oestrogen receptor α, among others (Lu *et al.*, 2006). Another possible mechanism is disruption of steroid hormone biosynthesis (Sanderson, 2006).

3.3 Age Differences

Obviously, the fundamental effects of toxicants on developing organisms may be entirely different than the effects on adults due to the complex developmental processes taking place at that stage in the life cycle. Addressing these differences is a task that is clearly beyond the scope of this review. However, the impact of age on the other factors that influence toxicity, such as toxicokinetics, can be examined. There are many toxicokinetic differences between adults and children including increased gastrointestinal absorption rates and reduced gastrointestinal motility in children, as well as increased deposition of particles in the lungs (Oskarsson *et al.*, 1998; Alcorn and McNamara, 2003; Ginsberg *et al.*, 2004). On the other side of the coin, alterations in gastrointestinal function such as decreased motility with ageing (Salles, 2007) may also impact absorption of toxicants in older adults.

In terms of distributional factors, incomplete development of the blood brain barrier in infants (Saunders *et al.*, 2000) as well as differences in relative lipid content in younger children (Clewell *et al.*, 2002) may lead to age-related differences in distribution of toxicants. There is also evidence that plasma protein levels are lower in neonates than in adults (McNamara and Alcorn, 2002), a factor that also has the potential to affect distribution of toxicants to tissues.

Biotransformation is also significantly affected by age. Levels of many Phase I enzymes including CYP1A2 and CYP3A4 are markedly reduced in neonates while other activities such as CYP3A7 are at high levels at birth and decline with age (Alcorn and McNamara, 2003; Ginsberg *et al.*, 2004; Hines, 2008). The substrate profile of CYP3A7 has not been completely determined, but evidence indicates that its metabolic capacity is most likely reduced when compared to CYP3A4 (Williams *et al.*, 2002). For Phase II reactions, glucuronidation capacity is reduced at least through two months of age, (Ginsberg *et al.*, 2002), and neonates appear to be slow acetylators (Parientekhayat *et al.*, 1991). On the other hand, sulphation in neonates seems to approach adult levels (Richard *et al.*, 2001). There is a neonatal GST isozyme, GST-pi, although it may not be as effective at detoxification as adult GST for at least some substrates (Pacifici *et al.*, 1988). In the elderly, on the other hand, evidence indicates that reduced drug and toxicant clearance may be primarily attributed to reduced blood flow and liver volume, rather than decline in P450 activities (Schmucker, 2001).

Any discussion of the impact of age on toxicokinetics must also address kidney function. Glomerular filtration rate (GFR) and renal blood flow are reduced in neonates, and the processes of secretion and reabsorption are significantly reduced as well (Alcorn and McNamara, 2003). The functional capabilities of the kidneys are reduced with age, as well, making the elderly also at increased risk for drug and toxicant-related toxic effects (Zhou *et al.*, 2008).

3.4 Physiological States

Another factor that must be considered in expression of toxicity is the physiological state of the organism in question. Variations here can range from physiological changes imposed by exercise (alterations in cardiovascular or respiratory parameters, for example) to physiological changes accompanying disease states. One area of interest has been in the effects of exercise on absorption of air pollutants. Lower amounts of benzene, for example, have been shown to be absorbed by individuals breathing at a higher rate over a shorter duration of time than by individuals breathing at a slower rate over a longer period of time (McNabola *et al.*, 2007). For smokers, as well, lung retention of particles depends on depth of inhalation and other respiratory factors; interestingly, rates of nicotine absorption are much less dependent on these parameters (Baker and Dixon, 2006). Physical activity has also been shown to impact absorption of organic solvents (Lof and Johanson, 1998).

More attention is now being shown to potential interactions between microbes and toxicants, both as regards normal gut flora and disease-causing pathogens (Ilback and Friman, 2007). Evidence indicates that the composition of gastrointestinal flora can affect xenobiotic absorption either through microbial production of metabolites that are absorbed to a greater or lesser extent than the parent compound, or through reversal of detoxification processes such as conjugations (Humblot *et al.*, 2007). In general, impact of nutritional state on effect of toxicants

DOI: 10.1002/9780470744307.gat028
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

must also be considered. This is of particular concern, since in developing countries undernutrition and toxicant exposure may go hand in hand (Ahamed *et al.*, 2007; Wasserman *et al.*, 2008).

3.5 Individual Differences: Another Role for Genomics in Toxicology

Along with their usefulness in sorting out complex environmental interactions, genomic techniques can also help elucidate the elusive biochemical differences between individuals of the same species. The question of individual susceptibility to toxicants can then be addressed through examination of genetic variation within key enzymes involved in the toxicologic process. One major area of research has been in characterization of individual variations in the enzymes involved in xenobiotic metabolism.

There are many well-characterized genetic polymorphisms in human cytochrome P450 genes (Thier *et al.*, 2003). One recent review (Ingelman-Sundberg *et al.*, 2007) estimates over 350 different P450 alleles, with the highest number of variations described for CYP2D6, CYP2B6, CYP1B1 and CYP2A6. Some of these variations show ethnic differences. For CYP2A6, for example, one common allele which results in inactivity occurs at much higher frequencies in Asian than in Caucasian populations (Ingelman-Sundberg *et al.*, 2007). On the other hand, CYP2C9*2, a variant with reduced activity is present mainly in Caucasians (Schwarz, 2003). Many of these polymorphisms have been shown to modify metabolism of several drugs and toxicants, and several have been associated with increased risk for diseases such as cancer (Kamataki *et al.*, 2005; Shimada, 2006), as well as reduced responsiveness to drugs due to increased metabolism (Kawanishi *et al.*, 2004). Molecular modifications underlying these P450 polymorphisms include deletions, duplications and copy number variations (Ingelman-Sundberg *et al.*, 2007). There are also genetic polymorphisms in the gene for cytochrome P450 oxidoreductase, the electron donor for CYP-catalysed oxidations (Hart and Zhong, 2008).

GSTs are the enzymes responsible for glutathione conjugation, an important Phase II reaction. Two isozymes, GSTT1-1 and GSTM1-1 (which participates in metabolism of PAHs) are actually deleted in a segment of the human population (Bolt and Thier, 2006). Affected individuals are homozygous for the *GSTM1*0* or *GSTT1*0* deletion polymorphism, and the frequency of the deletion varies between different ethnic groups (Bolt and Thier, 2006). The functional significance of this deletion in terms of susceptibility to toxicants and/or disease is not entirely clear; however, one study has found the *GSTM1*0* and *GSTT1*0* polymorphisms to be positively associated with an increased risk for heavy metal (mercury) accumulation (Gundacker *et al.*, 2007). *GSTM1*0* has also been found to be associated with increased risk of cirrhosis (Ghobadloo *et al.*, 2004), increased cataract risk in the indoor workplace (Saadat and Farvardin-Jahromi, 2006), increased risk for tobacco-induced DNA damage (Palma *et al.*, 2007) and increased risk of smoking-related coronary artery disease (Manfredi *et al.*, 2007). Individual differences in expression of these and other GST isozymes may also play a role in individual susceptibility to a number of cancers (Hayes and Pulford, 1995). Also involved in Phase II, the *N*-acetyltransferases NAT1 and NAT2 show polymorphisms, as well, with a percentage of the population characterized as 'slow acetylators' (Thier *et al.*, 2003).

Genetic variability is best characterized in mammals, but it is certainly recognized that genetic polymorphisms in other species may be of critical importance in ecotoxicology. Reductions in genetic variation due, for example, to population bottlenecks may affect the ability of populations to tolerate exposure to environmental chemicals. One organism in which this has been demonstrated is the midge *Chironomus riparius* (Nowak *et al.*, 2007). In addition, genetic variations between strains chosen for laboratory testing may significantly impact results of ecotoxicological testing (Picado *et al.*, 2007).

3.6 Epigenomics

Perhaps the final word in assessing the factors that influence expression of toxicity is epigenomics. Epigenomics focuses on regulation of gene expression rather than the structure of the genes themselves, and involves mechanisms such as modification of chromatin structure through histone modification and methylation of DNA, as well as control of gene expression through microRNAs (miRNAs) (Ingelman-Sundberg *et al.*, 2007; Szyf, 2007). While the specific impact of these mechanisms on expression of toxicity is not yet well understood, preliminary indications are that they do play an important role. One study, for example, has implicated alterations in the methylation of promoter and enhancer regions of the CYP1B1 gene in prostate cancer (Tokizane *et al.*, 2005). MicroRNAs also appear to be involved in regulation of this gene (Tsuchiya *et al.*, 2006).

Chronotoxicology

Karam F. Soliman and Elizabeth A. Mazzio

CONTENTS

1 INTRODUCTION

The study of kinetics, dynamics, toxicological responses and side effects of drugs, poisons or toxic substances relative to temporal rhythms occurring in living organisms is referred to as 'chronotoxicology'. Temporal rhythms are dynamic changes in the body guided by environmental time cycles with variation in frequency (i.e. day: circadian, week: circaseptan, month: circalunar, annual: circannual or seasonal) which are governed by the momentum of the earth's rotation about its central axis (rotation speed: 467 m s^{-1}) and its elliptical orbit around the sun (a 365.25 day cycle). Each day the earth's single rotation about its central axis completes a full day/night 24 hour cycle, where the earth is further split into day and night by a dividing edge called the 'circle of illumination'. Temporal rhythms are also contingent upon the earthly position of an organism in terms of its location–degrees latitude/longitude.

Temporal rhythmic patterns in living organisms have been documented throughout history often describing observable photoperiodicities in almost all terrestrial life forms, including plants, single-celled organisms, insects, cells, yeasts and mammals (Pierre *et al*., 1985; Lloyd and Stupfel, 1991; Egan *et al*., 1999; Herzog *et al*., 2004; Chen and McKnight, 2007; Michael *et al*., 2008). In mammals, the main metronomes to which temporal biorhythms align themselves are photoperiodic stimuli derived from natural sunlight (photophase) or lack of illumination (scotophase) throughout the 24 hour period. An endogenous rhythmic flow is further influenced by local external time cues in the environment such as the daily sound of an alarm clock, a daily routine, social schedules, exercise, feeding patterns or routine noises which in the absence of photoperiodic stimuli create '*zeitgebers*' (German for 'time giver', synchronizer) (Lax *et al*., 1999; Carney *et al*., 2006; Kosobud *et al*., 2007; Korczak *et al*., 2008; Ni *et al*., 2008).

There is a vast complexity in understanding biological rhythms because of the number of variables that alter timing systems such as disease states, drugs, lifestyles or the very process of ageing (Van Someren and Riemersma-Van Der Lek, 2007). While biological circadian rhythms are in essence endogenous free-running systems, they are also entrained (synchronized) to the world around them and adapt to ensure survival of life, acclimatization to environmental or seasonal conditions, and to ensure productivity and species reproduction. Units of measurement most often used to quantify biological temporal rhythms are 'periods' (length of time to complete a single cycle), 'oscillations' (the repetitive

motion of a cycle), 'amplitude' (magnitude of a biological response) and 'phase' (a representative peak or valley of an amplitude).

1.1 Entrainment of SCN by Photoreceptive Retinal Ganglion Cells

In humans, the anatomical 'biological clock' is the suprachiasmatic nucleus (SCN), which is housed within the anterior hypothalamus proximal to the optic chiasm. The SCN receives information from intrinsically photosensitive retinal ganglion cells (ipRGCs) through a monosynaptic retinohypothalamic tract (RHT), which detects illumination through a blue-light sensitive photopigment called melanopsin (Turner and Mainster, 2008; Ruggiero *et al*., 2009). The blue spectral absorbance of melanopsin in ipRGCs peaks between 460 and 480 nm making it excitable by direct sunlight, which has a wavelength of approximately 477 nm (Stevens *et al*., 2007; Turner and Mainster, 2008). The photic receptivity of ipRGCs differs vastly from parts of the eye required for vision such as the basic rod-mediated scotopic response to light (night vision) and cone-mediated photopic response to light (day vision). Melanopsin in ipRGCs is responsible for the non-image-forming photosensitive system that regulates circadian timing, where rods and cones relay visual information such as colours, images, shapes and patterns to the brain (Ruggiero *et al*., 2009). For this reason, therapeutic use of short wavelength blue monochromatic light is more effective in evoking circadian phase shifts, suppressing melatonin, enhancing alertness and treating disorders associated with disruption of circadian rhythms (Stevens *et al*., 2007) (**Figure 1**). Any degenerative loss of ipRGCs as in the case with glaucoma can adversely affect entrainment and circadian rhythmicity (Drouyer *et al*., 2008), whereas visually impaired/blind animals continue to be entrained by the light/dark cycle, provided ipRGCs are still functional (Silva *et al*., 2005).

SCN entrainment is necessary to establish physiological temporal rhythms that promote the optimization of health. In brief, darkness to the back of the retina signals adrenergic innervation to the pineal gland through the superior cervical ganglia functioning to regulate the production of melatonin and its release into the bloodstream to regulate sleep (Cardinali and Vacas, 1987). Exposure to natural or artificial daylight entrains the SCN, initiates suppression of melatonin during the day and improves quality of sleep (Adler *et al*., 1992; Murphy *et al*., 1993; Park *et al*., 2007). However, for daylight exposure to properly synchronize the clock, it must be applied during the actual solar day because exposure to artificial daylight during dark phase (night) can counter proper phase adjustment leading to disturbed sleep patterns and impaired cognitive function.

The amount of daylight required to entrain the SCN should reach a certain light intensity and duration each day with varying requirements set forth for varying species. However, in mammals, SCN entrainment generally requires light intensities of >1000 lux for several hours (Sack *et al*., 2007a; 2007b) consisting of monochromatic light at 460 nm rather than photopic

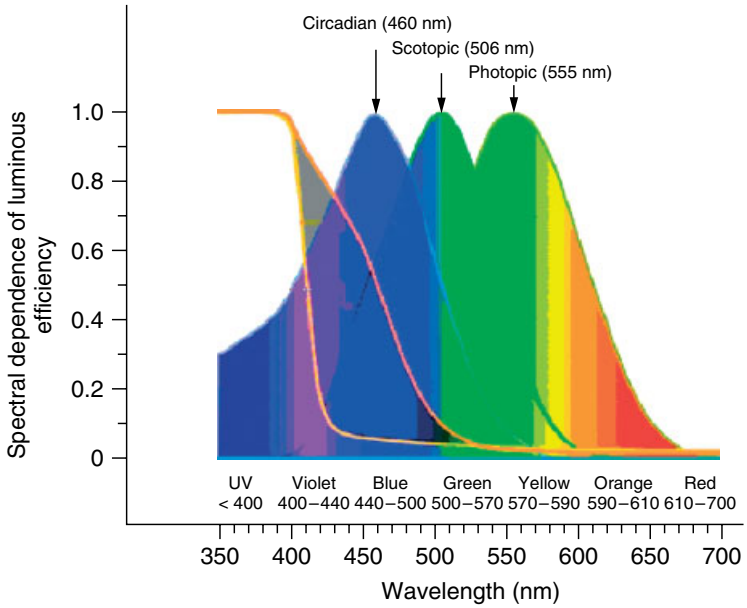

Figure 1 Spectral sensitivity peaks of photopic, scotopic and circadian (melatonin suppression) photoreception. Peak sensitivities of circadian, scotopic and photopic photoreception are 460 nm (blue), 506 nm (green) and 555 nm (green-yellow). (Reproduced from Turner and Mainster, 2008. © BMJ Group.)

light at 555 nm (Lockley *et al*., 2003). And light exposure must be directed and received by the eye, because sunlight directed at the skin does not entrain human circadian rhythms (Lindblom *et al*., 2000).

1.2 Entrainment of Nonphotoreceptive Peripheral Oscillators

The SCN sets its tempo to environmental light/dark cycles as a self-sustained clock in response to light. It also serves to orchestrate rhythms in thousands, if not millions, of concurrent biological clocks located within cells, tissues and organs that are not responsive to light but respond through neural and humoral SCN outputs, which then regulate peripheral oscillatory rhythmicity (Yamazaki *et al*., 2000) (**Figure 2**).

Secondary peripheral oscillators entrain to various frequency rhythms that regulate life by maintaining a plethora of basic physiological functions occurring in major organs such as the heart, liver kidney and so on, that serve to regulate body temperature, blood pressure, appetite and health of the cardiovascular, nervous, digestive, immune, reproductive, endocrine and neuromuscular systems. These peripheral clocks respond both to the SCN and zeitgebers, allowing for coordination of precisely timed events to sustain biological life (Prasai *et al*., 2008).

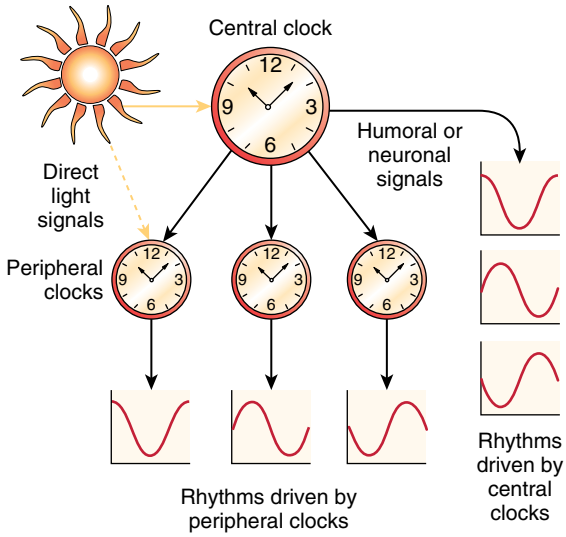

Figure 2 Circadian rhythms are generated by the central clock, which is under the influence of light. Peripheral clocks are under the direct control of the central clock, although they may also be regulated by other stimuli. Peripheral clocks receive input from the central clock, which can be neural, diffusible or hormonal. So the SCN directly induces a variety of physiological rhythms, while synchronizing or directing peripheral clocks, which may have distinctive characteristics. (Reproduced from Cermakian and Sassone-Corsi, 2000. © Nature Publishing Group.)

1.3 Desynchronization of the SCN from Peripheral Oscillators

A dissociation of the SCN main clock from peripheral oscillators is thought to lead to disorders of circadian rhythm and disease. Experimentally, lesions to the SCN in rats can lead to a functional loss of peripheral neuroendocrine cycles and desynchronized circadian rhythms (Eastman *et al*., 1984; Nagai *et al*., 1994; Filipski *et al*., 2004), which can occur even when peripheral oscillators continue to display rhythms in a self-sustaining manner (Yoo *et al*., 2004). In other words, peripheral oscillators not communicating properly with the SCN in essence have lost sight of the 'orchestra conductor', but continue to play their instruments without working in concert to perform a symphony. The result is an undesirable disjointed and nonharmonious sound.

In humans, a disruption of peripheral oscillators to the SCN leads to desynchronization or internal rhythms being jolted out of alignment. This is often the case in instances such as abnormal eating patterns which alter food-entrainable oscillators (Bechtold, 2008), jet lag where the body is rapidly transported through different time zones given no chance to acclimatize (Reilly *et al*., 2008; Srinivasan *et al*., 2008; Locke *et al*., 2008), or night-shift work which can lead to chronically impaired sleep, cardiovascular disease, peptic ulcers, glucose intolerance, mood/cognitive deficits, reproductive problems, accidents and increased risk for breast cancer (Yoon and Song, 2002; Van Dongen, 2006; Biggi *et al*., 2008; Mosendane *et al*., 2008; Kolstad, 2008). A lack of sunlight can also adversely affect circadian rhythms leading to winter depression (seasonal affective disorder) (Monteleone and Maj, 2008), major depressive disorder or exacerbate conditions such as Alzheimer's disease, schizophrenia and bipolar disorder (Lamont *et al*., 2007; Kaladchibachi *et al*., 2007). Other common conditions of desynchronization are classified as circadian-rhythm sleep disorders and include advanced sleep-phase disorder, delayed sleep-phase disorder, free-running disorder, irregular sleep–wake rhythm and premenstrual dysphoric disorder (Sack *et al*., 2007b).

When peripheral oscillators dissociate from the main SCN clock, phase adaptation and time would be required before entrainment to the central clock could be re-established. This process can be expedited by various therapeutic regimes such as bright light therapy, hypnosis, oral administration of melatonin, vitamin B_{12}, stimulants, melatonin MT_1 and MT_2 receptor agonists or implementing structured sleeping patterns (Brunner and Wirz-Justice, 1993; Morgenthaler *et al*., 2007;

Pandi-Perumal *et al*., 2008; Santhi *et al*., 2008; Lieverse *et al*., 2008). Physical activity or exercise can also assist in phase shift of the circadian clock (Sack *et al*., 2007a; 2007b) in addition to manipulating the timing of nonphotic stimuli such as establishing routine eating patterns (Mendoza *et al*., 2005; Bechtold, 2008).

2 THE ANATOMY OF THE SCN

Understanding the anatomy of the SCN is a critical foundation for the study of any physiological process as it is affected by universal planetary time cycles. A closer look at the SCN main clock reveals it to be a small population of approximately 10 000 γ-aminobutyric acid (GABA)-ergic neurons further comprised of an inner core (ventrolateral) containing vasoactive intestinal polypeptide (VIP), somatostatin, gastrin-releasing peptide (GRP) and androgen receptors (ARs) where the outer 'shell' (dorsomedial) contains arginine vasopressin (AVP)-positive neurons (Moore *et al*., 2002; Karatsoreos and Silver, 2007). The SCN shell displays rhythmic oscillation patterns associated with neuronal firing, whereas the core displays relatively lower rhythmic amplitude. Destruction of the SNC core results in loss of all circadian controls indictating that the unit functions as a whole self-sustaining rhythmic entity. Incoming information travels through afferent pathways which intervene on various parts of the SCN resulting in neuronal firing and circadian biological timekeeping (Karatsoreos and Silver, 2007; Locke *et al*., 2008; Kent and Meredith, 2008). **Figure 3** shows the core and shell through caudal to rostral sectioning, as determined by immunocytochemistry.

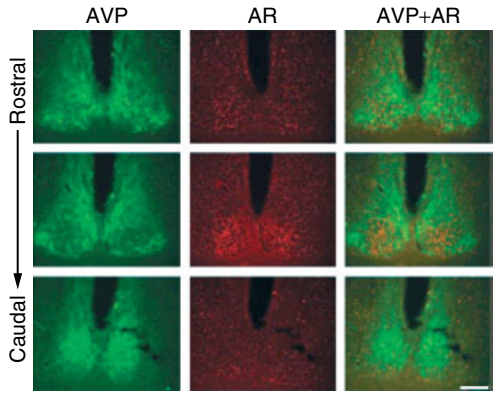

Figure 3 Photomicrographs depict double-label immunocytochemistry for arginine vasopressin (AVP) (green) and androgen receptor (AR) (red) from the rostral to caudal SCN in a male mouse. AVP delineates the shell region of the SCN, where as AR is largely restricted to the core region. Scale bar 150 μm. The core marker ARs are involved with circadian rhythms of the neuroendocrine system that regulate male and female reproductive physiology. 2.1 SCN: Major Afferent Pathways

The SCN receives major afferent input via three main pathways. The main zeitgeber (light intensity) establishes the foremost afferent pathway, which receives photic information about the position of the sun and its rotation around the earth.

Retinal ganglion cells containing melanopsin connect through the RHT, which is a glutaminergic innervation also containing pituitary adenylate cyclase activating polypeptide (PACAP), which junctions at a VPAC 2 receptor/VIP-positive SCN core (Hannibal *et al*., 1997; 2000; Fukuhara *et al*., 1997; Itri and Colwell, 2003). Animals that lack VIP or VIP-PACAP Type 2 (VPAC2) receptors show reduced amplitude of circadian gene expression with loss of rhythmicity or electrical firing within the SCN (Maywood *et al*., 2007). This is because SCN firing is synchronized by VIP acting on VPAC2, which is required for circadian rhythmicity and coupling of the SCN core to the shell (Kalló *et al*., 2004), which then regulates genes in peripheral tissue through neural or hormonal pathways (Toh, 2008). Both light and glutamate are capable of stimulating the SCN core via glutamatergic *N*-methyl-D-aspartate (NMDA)/non-NMDA retinal terminals which then can trigger oscillatory changes in $[Ca^{2+}]_I$, via calcium-dependent cascades involving mitogen-activated protein kinases (MAPKs)/extracellular signal-regulated kinase (ERK), protein kinase G, phosphorylation, nitric oxide, c-fos and calcium/cyclic adenosine monophosphate (AMP) response elementcyclic AMP (cAMP) response-element-binding protein (CREB) control of SCN circadian clock gene expression and thus circadian rhythms (Hastings *et al*., 2007; Pulivarthy *et al*., 2007; Irwin and Allen, 2007; Akashi *et al*., 2008) (*see* Section 3).

Both photic (light) and nonphotic stimuli (i.e. physical activity, brain stimulation reward and foot shock) can act on a second branch of the RHT, directing information to the intergeniculate leaflet (IGL), enkephalin and neuropeptide Y (NPY)-positive cells, which via the geniculohypothalamic tract (GHT) terminate in areas that overlap the direct RHT–SCN projections (Pickard *et al*., 1987; Kumar and Rani, 1999; Cain *et al*., 2007; Kim and Harrington, 2008; Toh, 2008). Lesions to the IGL impair light-induced periodicities (Harrington and Rusak, 1986) and block phase-shifting responses to triazolam, indicating that both light and benzodiazepine GABA receptors relay information to establish rhythm and entrainment through the IGL (Johnson *et al*., 1988).

Nature Reviews | Molecular Cell Biology

Figure 4 The SCN circadian clock is affected by light (photic cues) through the RHT leading to use of glutamate (Glu) as a neurotransmitter. Glutamate receptor triggering induces various intracellular responses, leading ultimately to gene expression and phase shifts. Nonphotic cues involve a variety of other neurotransmitter and signalling pathways (three of which are shown here). The photic and nonphotic pathways can crossregulate each other pre- and postsynaptically. AC, adenylate cyclase; CRE, cAMP response element; ER, endoplasmic reticulum; ERK, extracellular signal-regulated kinase; GC, guanylyl cyclase; H, histone; for example immediate early genes (e.g. c-*fos*); IGL, nerve terminus from the intergeniculate leaflet (thalamus); NMDA, *N*-methyl-D-aspartate; NOS, nitric oxide synthase; NPY, neuropeptide Y; PKA, cAMP-dependent protein kinase; PKC, protein kinase C; PKG, cyclic guanosine monophosphate (cGMP)-dependent protein kinase. This diagram shows the multilevel regulation of the circadian clock. (Reproduced from Cermakian and Sassone-Corsi, 2000. © Nature Publishing Group.)

The third major afferent to the SCN comprises serotonergic neurons, which stem from the median raphe nucleus (Meyer-Bernstein and Morin, 1996). Light or serotonin-altering drugs may affect circadian rhythms due to both the SCN and the IGL receiving serotonergic input from the midbrain raphe nucleus (Ying *et al*., 1993). Lesions to the median raphe will render animals more sensitive to light at high intensity, indicating serotonin to be an inhibitory modulator of circadian rhythmicity (Muscat *et al*., 2005). IGL innervation from the dorsal raphe is also modulated by inhibitory effects of serotonin, which regulate circadian and sleep/arousal systems (Blasiak *et al*., 2006). **Figure 4** is an illustrative showing the three primary afferent projections extending to the SCN, which ultimately control transcription of clock genes.

2.2 SCN: Major Efferent Pathways

SCN efferent pathways are quite numerous and include those that extend to many areas of the brain, including the caudal projections to the subparaventricular zone and hypothalamic arousal systems in the posterior/lateral hypothalamic areas (regulate rest activity) (De la Iglesia

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat030
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and Schwartz, 2002; Moore and Danchenko, 2002), the ventrolateral preoptic nucleus, via GABAergic neuron projections targeting the medial preoptic area and the dorsomedial hypothalamic nucleus (regulate sleep wake cycle) (Deurveilher *et al*., 2002), ipsilateral neural efferents from the SCN to leutinizing hormone (LH)-containing neurons in the preoptic area (regulating LH cycles) (De la Iglesia and Schwartz, 2002), and efferents from the SCN to the paraventricular nucleus (PVN), the preoptic area and the mediobasal nuclei to (regulate daily rhythms of adrenocorticotrophins, gonadotrophins and metabolic hormones, respectively) (De la Iglesia and Schwartz, 2002; Kalsbeek *et al*., 2007). The hypothalamic PVN is an important target area of biological clock output and harbours the preautonomic neurons that control peripheral sympathetic and parasympathetic activity which in turn regulate plasma glucose and insulin concentrations (Kalsbeek *et al*., 2008).

Secondary projections from the SCN involve those that project to the neocortex, limbic system, hippocampus, anterior pituitary and reticular activating system to provide temporal information required for thermoregulation, feeding, memory and learning, mental performance and endocrine function. And, one of the main SCN efferents is to the upper thoracic intermediolateral cell column which extends to the superior cervical ganglion sympathetic neurons, which in turn innervate the pineal gland. Via this pathway, the SCN regulates the circadian rhythm by pineal secretion of melatonin, the compound responsible for sleep onset (Toh, 2008).

Secretion of melatonin is mediated by sympathetic efferents to the pineal gland and is the primary regulator of circadian sleep patterns. Melatonin released from the pineal gland is highest in the evening and suppressed by sunlight, therefore the term dim-light melatonin onset 'DLMO' is used as a diagnostic position marker to assess physiological parameters of circadian rhythm that occur under dim light, which include plasma or saliva melatonin, as well as cortisol, sleep onset, core body temperature or urinary 6-sulfatoximelatonin concentrations (Sarabia *et al*., 2008; Hofstra and de Weerd, 2008). In the absence of light, pineal melatonin secretion is at it highest (3–10×) (Touitou, 1998; Thapan *et al*., 2001), whereas SCN clock genes up-regulate the transcription of N-acetyl transferase (NAT) and hydroxy indole-O-methyl transferase to maximize melatonin synthesized from tryptophan (Touitou, 2005; Ravindra *et al*., 2006). Nocturnal melatonin synthesis is critical in regulating sleep, and individuals with polymorphisms in the promoter region of the NAT gene are at greater risk for developing late-sleep-onset/short-duration circadian-rhythm disorder (Wang *et al*., 2004). In contrast, sunlight suppresses melatonin synthesis via photic non-vision-related retinal ganglion cells, the SCN, the PVN and the superior cervical ganglion through down-regulating NAT (Thapan *et al*., 2001; Stevens *et al*., 2007). Exposure to bright light marks a new day corresponding to elevation of heart rate, circulating cortisol, core body temperature, mental alertness (Rüger *et al*., 2006) and a rise in dopamine (DA) which inhibits melatonin synthesis through acting on D_2-like DA receptors (Tosini *et al*., 2008).

The circadian cyclic amplitude of melatonin is often dampened during the process of ageing, limited exposure to daylight, seasonal variation or night-shift work—factors which correlate to greater incidence of coronary heart disease, orthostatic hypotension, Alzheimer's disease and a diverse range of human cancers (Ravindra *et al*., 2006). For this reason, oral or sublingual melatonin supplementation holds considerable promise in the amelioration of altered sleep/wake cycles in the elderly, patients with circadian-rhythm sleep disorders and for the treatment of cancer (Ravindra *et al*., 2006). In addition, melatonin also provides additional health benefits such as its inherent immunostimulant, antioxidant, oncostatic, thermoregulatory, antidepressive, anti-inflammatory and cytoprotective properties (Karasek, 2004; 2007; Touitou, 2005; Ravindra *et al*., 2006).

3 REGULATION OF CLOCK GENES

Biological clocks are regulated by genetic transcriptional-translation feedback loops that respond to the day/night cycle and information received by the SCN. In brief, retinal stimulation via glutaminergic activation of VIP in the SCN core then extends through GABA/GRP signalling to the shell which then influences clock genes through signalling systems involving calcium calmodulin kinase, the p42/44 MAPK pathway, nitric oxide, protein kinase G and ERK, which activates CREB, thereby controlling rapid or slow genetic transcription of SCN clock-related proteins. The major SCN elements controlling circadian oscillation transcriptional feedback loops are period (Per 1–3), cryptochrome (Cry 1, 2), the nuclear orphan receptors: reverse erythroblastic leukaemia viral oncogene homologs (Rev-erbα, Rev-erbß), retinoic acid-related orphan receptors (RORs) (Rorα, Rorß) and the CLOCK (circadian locomotor output cycles kaput)/BMAL1 (brain and muscle ARNT-like protein 1) heterodimers (Challet, 2007).

CLOCK and BMAL1 contain basic helix–loop–helix motifs for DNA binding at the NPAS2 domain which heterodimerize and translocate from the cytosol to the nucleus, where the positive (+) molecular feedback loop consists of CLOCK-BMAL1 binding to the E-box promoter element sequence upstream of *Per* (1,2,3 genes)/*Cry* (1,2 genes) and nuclear receptors Ror and Rev-erbβ. CLOCK also acts as a histone acetyltransferase involved with the activation of *Per* and *Cry*

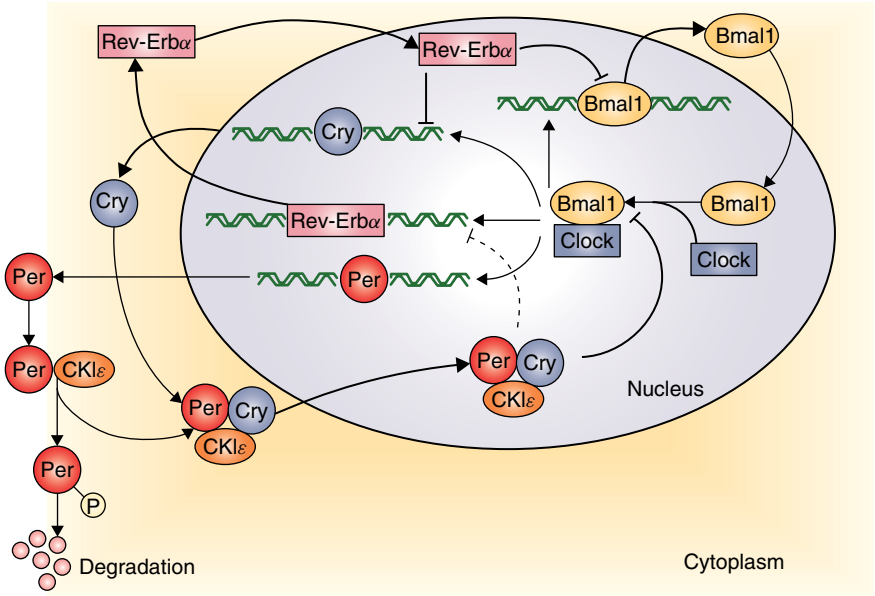
General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat030
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

genes (Doi *et al*., 2006; Zhu *et al*., 2008). The negative (−) molecular feedback loop occurs when attainment of critical concentrations of Per accumulate in the cytoplasm, which then complex with Cry, enter the nucleus and down-regulate the nuclear transcriptional activator CLOCK-BMAL1 and thus downregulate further transcription of the *Cry* and *Per* genes and other clock-related genes. This negative feedback cycle largely regulates the oscillation of the circadian clock.

More specifically, the cycle starts with heteromeric proteins CLOCK and BMAL1 activating clock genes by acting on the m*Per*1 promoter. Per then enters the cytoplasm where it is phosphorylated by casein kinase I ε (CKI-ε, CKI-δ), protein kinase A, protein kinase C (PKC) and other kinases that regulate its stability, where phosphorylation delays nuclear entry and that of Cry. Post-translational modification of Per by CKI is also genetically regulated, where a peak in CKI in the SCN is observed at the start of a subjective night (Agostino *et al*., 2008). When Per and Cry proteins attain critical mass, they dimerize and translocate to the nucleus where they suppresses CLOCK-BMAL1 transcription of *Per, Cry, Ror and Rev-erb*β in a negative feedback loop. The existing Per and Cry complexes are degraded by the end of circadian night, where a surge of BMAL1 expression emerges initiating a new cycle of *Per* and *Cry* gene expression to start a new day (Preitner *et al*., 2002; Sato *et al*., 2004; Hastings *et al*., 2007).

As demonstrated in **Figure 5**, the core loop is stabilized by feedback pathways involving the transcription of *Rev-erb* (α,β) and *ROR* (α,β), which translocate to the nucleus and compete for binding to a nuclear target sequence called retinoic acid-related orphan receptor response elements (RORE) in the BMAL1 promoter.



Nature reviews | Cancer

Figure 5 Circadian rhythms are generated by the feedback loops of the core circadian genes. In the SCN neurons, the intracellular levels of CLOCK remain steady throughout the 24 hour period, whereas BMAL1 expression levels are high at the beginning of a subjective day and low at the beginning of a subjective night. The high level of BMAL1 promotes the formation of BMAL1–CLOCK heterodimers. These bind to E-box sequences in the promoters of the *Cry, Per* and *Rev-erb* genes to activate transcription at the beginning of a circadian day. The BMAL1–CLOCK heterodimer can also inhibit *Bmal1* transcription. After transcription and translation, the Rev-erb protein enters the nucleus to suppress the transcription of *Bmal1* and *Cry* genes. As the Per proteins, such as Per2, accumulate in the cytoplasm, they become phosphorylated (P) by CKI. The phosphorylated forms of Per are unstable and are degraded by ubiquitylation. Late in the subjective day, however, Cry accumulates in the cytoplasm, promoting the formation of stable CKI/Per/Cry complexes, which enter the nucleus at the beginning of a subjective night. Once in the nucleus, Cry1 disrupts the CLOCK/BMAL1-associated transcriptional complex, resulting in the inhibition of *Cry, Per* and *Rev-erb* transcription, and depression of *Bmal1* transcription. It is not clear whether Per and Cry must dissociate from the CKI/Per/Cry complex to inhibit the activity of the CLOCK/BMAL1 heterodimer and to stimulate *Bmal1* transcription in the nucleus. The interacting positive and negative feedback loops of circadian genes ensure low levels of Per and Cry, and a high level of BMAL1 at the beginning of a new circadian day. Solid lines indicate direct regulation, and dashed lines indicate indirect regulation (Fu and Lee, 2003). (Reproduced from Loning and Cheng, 2003. © Nature Publishing Group.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat030
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The *Rev-erbα* promoter contains E boxes and its transcription is activated by CLOCK-BMAL1 heterodimer and repressed by Per/Cry1 resulting in the oscillations of Rev-erbα. In turn Rev-erbα can repress *BMAL1* and *CLOCK* transcription through RORE, which occurs during the day cycle, ending early in the evening (Preitner *et al*., 2002; Sato *et al*., 2004). Their antagonistic effects generate a rhythmic level of BMAL1 and thus CLOCK-BMAL1. Additionally, Per2 activates *BMAL1* transcription in a positive feedback loop. ROR-*α* competes with Rev-erbα for the binding of shared DNA response elements, and genes containing RORE in their promoter are repressed by Rev-erbα, whereas RORα activates their transcription (Duez and Staels, 2008) and RORs tend to activate transcription of *BMAL1* mRNA (Hasting *et al*., 2007; Maywood *et al*., 2007). The amplitude of Rev-erb dwindles by early morning and it acts as a repressor of BMAL1 in tandem with the actions of Per and Cry.

There are many other SCN transcription factors capable of binding to E-Box cis-elements in response to photic light stimuli that contribute to temporal circadian oscillations, the scope of which exceeds this review (Honma *et al*., 2002; Porterfield *et al*., 2007; Rossner *et al*., 2008). In brief, SCN clock genes ultimately regulate humoral or neuronal output signalling that subsequently drive peripheral oscillations (i.e. liver, adipose, skeletal, muscular, vascular, etc.) in cells containing genes that have E boxes in their promoter and/or RORE sites in their regulatory regions (Duez and Staels, 2008).

4 CHRONOTOXICOLOGY

Biological rhythms established by the SCN/peripheral oscillators influence most all biological processes ('chronobiology'), where anomalies can predicate disease onset ('chronopathology'), which can influence time-dependent exacerbation/reduction of toxic effects of drugs and poisons ('chronotoxicology') and alter the responsiveness to drugs ('chronopharmacology'), which then may require time-wise delivery of medications ('chronotherapeutics'). These terminologies basically describe the means by which SCN/peripheral rhythmic oscillation patterns regulate physiological function, eating patterns, drug delivery, metabolism, detoxification, nutrient drug/utilization or excretion.

The term 'chronotoxicology' in some cases is not independent of chronotherapeutics, which is dependent upon the study of chronopathology. For example, rhythmic patterns of disease onset or symptoms can peak and trough at certain hours or seasons, thereby opening an avenue by which chronotherapeutic application can be applied to optimize drug efficacy and reduce unwanted toxic side effects (Halberg *et al*., 2006). In discussing the term chronotoxicology, we will use as an example a disease most impacted by circadian rhythms: cancer. The study approach to chronotoxicology in general involves various separate segments: (i) chronopathology of cancer—the study of how various clock genes regulate circadian rhythms that create risk factors for developing cancer, (ii) the extent to which clock genes control cancer specific genes: cell proliferation, DNA repair and angiogenesis and (iii) assessing the chronotoxicology of various chemotherapy agents to assess optimal drug-delivery times and reduce unwanted side effects.

4.1 SCN Clock Desynchronization and Cancer Risk

A higher incidence of cancer is associated with aberrant circadian rhythms brought about by night-shift work, jet lag or inherent mutations in clock genes (Hansen, 2001; Stevens, 2005; Zhu *et al*., 2006; 2008; Wood *et al*., 2008; Tokunaga *et al*., 2008). It has been hypothesized that cancer may develop from desynchronization as a result of night-time light exposure during the normal nocturnal sleep phase, creating hormonal fluctuations and suppressing melatonin production (Reiter *et al*., 2007; Kloog *et al*., 2009). Once a malignant tumour is established, circadian patterns then govern tumour growth, as described by Filipski *et al*. (2002). In the following study, desynchronization established by SCN bilateral electrolytic lesions in animals with Glasgow osteosarcoma or pancreatic adenocarcinoma resulted in a loss of circadian rhythmic patterns (**Figure 6A**) parallel to acceleration of tumour growth (**Figure 6B**).

4.2 Clock-Gene Coupling to Cell Division/Proliferation

The undisputable link between the cancer and circadian rhythms may be deep-rooted in evolution, where the process of cell division, proliferation, DNA repair and cell cycling was timed in order to prevent DNA damage from the mutagenic effects of ultraviolet light during the day (Chen and McKnight, 2007). As mentioned previously, the circadian oscillation transcriptional feedback loop is under the control of Per 1–3, Cry 1,2 (stabilized by the casein kinases), Rev-erbα, Rev-erbß, Rorα, Rorß, CREB and the CLOCK/BMAL1 heterodimers (Challet, 2007) many of which regulate cell division, cell-cycle gene transcription or DNA repair (Arjona and Sarkar, 2005; Chen and Mcknight, 2007) such as Wee1, the cyclins and c-Myc that in turn modulate the expression of active cyclin B1-Cdc2 kinase, a regulator of mitosis (Matsuo *et al*., 2003; Chen-Goodspeed and Lee, 2007).

Cell-cycle and circadian rhythms, both controlled by clock genes, can lead to varying therapeutic efficacy

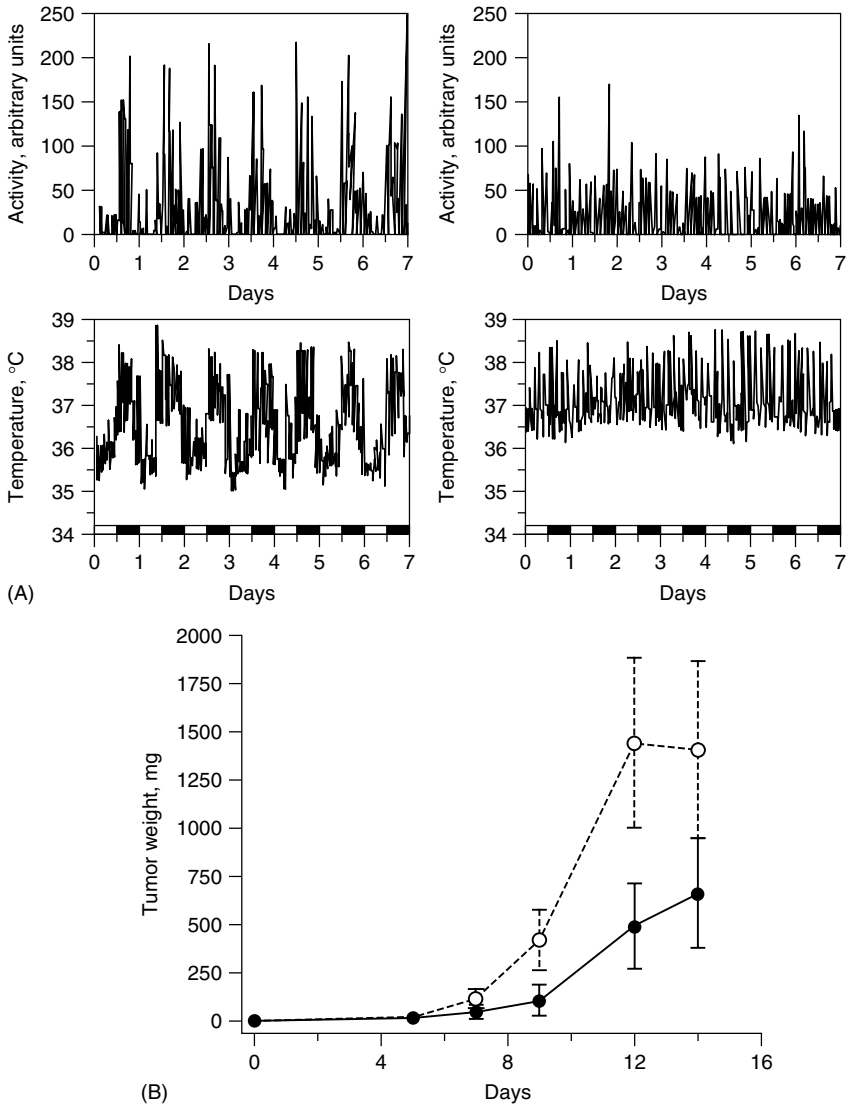

Figure 6 (A) Representative sample: loss of circadian rhythms in SCN lesioned tumour bearing animals evidenced by quantification of changes in core body temperature or rest activity. Pattern of rest activity (top) and temperature (bottom) in a sham-operated mouse (left) and in a mouse with lesions in SCN (right). A rhythmic pattern was clearly recognizable in the sham-operated mouse, with no rhythm obvious in the mouse with SCN lesions, and no 24 hour period stood out in Fourier analysis. The rest-activity cycle was suppressed in 79 of 110 mice with SCN lesions and body-temperature rhythm was suppressed in 60 of the 75 mice with SCN lesions (Filipski *et al*., 2002). (B) The effect of SCN lesion on Glasgow osteosarcoma tumour growth in sham-operated (o) and mice with lesions in the SCN (•). Mean tumour weights are shown with their respective 95% confidence intervals. Accelerated growth of tumours in mice with SCN lesions was statistically validated with ANOVA (analysis of variance), $p < 0.001$. Tumour size was measured three times a week using a calliper. Tumour weight (mg) was estimated from two perpendicular measurements (mm): tumour weight = (length × width)/2. (Reproduced from Filipski *et al*., 2002. © Oxford University Press.)

of chemotherapy drugs (as measured by suppressed proliferation of tumour cells) with drug dosing at various time points throughout the day (**Figure 7**). Iurisci *et al*. (2006) investigated osteosarcoma tumour growth in mice with administration of Seliciclib (which down-regulates casein kinases, ERK2 and cyclin-dependent kinase) administered at three time points ZT (zeitgeber time = lights on) 3, 11, 19 for five days using a 12/12 light/dark cycle.

The results from this study show that administration of the drug during the early morning phase or ZT3, 11 resulted in greater tumour suppression, which also corresponded to changes in tumour mRNA for the clock genes (*Per2, Rev-erbα* and *BMAL1*) and clock-controlled cell-cycle genes as well (*c-Myc, Wee1, cyclin B1* and *Cdk1*) (Iurisci *et al*., 2006).

Many studies have attempted to define the nature of the relationship between clock genes and cell-cycle genes,

with the most consistently reported clock gene to control cell growth being Per 1 ± 2 proteins. High levels of Per 1,2 are potent tumour suppressors that regulate ataxia telangiectasia mutated (ATM)/ATM and Rad3 related (ATR) protein kinase phosphorylation of Chk1/Chk2 which halt the cell cycle through G1-S/G2-M (Yu, 2007) and facilitate the DNA repair pathway (Chen-Goodspeed and Lee, 2007; Chen and Mcknight, 2007). The phosphorylation/stabilization of Per2 by CK1-ε) and both Per 1,2 potentiates the expression of several tumour suppressor proteins such as Cyclin D1, Cyclin A, Mdm-2 and Gadd45α (Fu *et al*., 2002).

The overexpression of Per 1,2 leads to greater vulnerability for cancer cells to undergo apoptosis due to suppressed expression of anti-apoptotic c-Myc, Bcl-X and Bcl-2 and elevating expression of proapoptotic p53 and Bax (Hua *et al*., 2006). In contrast, a deficiency or inhibition of Per 1,2 led to aggressive tumour proliferation, a stronger cell survival response, resistance to apoptosis and a reduction in tumour suppressor proteins, including the cyclins (Fu *et al*., 2002; Gery *et al*., 2006; Chen-Goodspeed and Lee, 2007). Low levels of Per 1, 2 are found in samples taken from patients with non-small-cell lung cancer (Gery *et al*., 2007), sporatic and familial primary breast cancer (Winter *et al*., 2007) and aggressive colorectal tumours (Krugluger *et al*., 2007). **Figure 8** shows the results of realtime reverse-transcription polymerase chain reaction (RT-PCR) for quantification of *Per 1,2, CLOCK* and dihydropyrimidine dehydrogenase (5-fluorouracil-metabolizing enzyme) in Grade 2 or Grade 3 primary colorectal tumours vs. normal colon mucosa from the same patients.

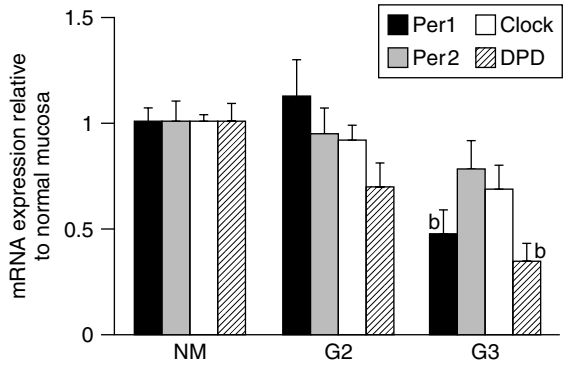

Figure 8 Relative change of Per1, Per2 and DPD mRNA levels in call patients with colorectal tumours grade 2 (G2) or grade 3 (G3) compared with normal mucosa (NM). Data represent fold change ±SD of specific mRNA levels in tumour specimen as compared with specimen of NM. a, $P < 0.05$; b, $P < 0.01$; c, $P < 0.001$ (Reproduced with permission from Krugluger *et al*., 2007. © American Association for Cancer Research.)

The results show attenuation of clock genes in the order of *Per 1 > CLOCK > Per 2* in Grade 3 tumours derived from 30 cancer patients.

While Per 1 appears to be a primary regulator of tumour growth, a less pronounced association has been reported for other clock genes including Cry (Gauger and Sancar, 2005; Chen and McKnight, 2007) or Clock

(Antoch *et al*., 2008). However, mutations in genes that encode factors which regulate clock genes *Per* and *Cry* contribute to a predisposition or risk for developing cancer. This is the case for mutations in the *CSNK1E* gene which encodes for CK1-ε which can adversely affect phosphorylation of clock-gene products and p53 tumour suppressor proteins thereby altering tumour growth and circadian rhythmic patterns (Knippschild *et al*., 1997; 2005) or mutations in NPAS2 which forms heterodimers with BMAL1 to regulate the clock genes *Per* and *Cry* (Zhu *et al*., 2008). Lastly, the direct administration of melatonin (as a chronobiotic agent to induce phase shift or establish synchronization) inhibits tumour growth, angiogenesis, proliferation and metastasis (Ravindra *et al*., 2006) possibly through attenuating fatty-acid growth-factor-uptake, telomerase, endothelin-1 synthesis (angiogenic factor) and activating the tumour suppressor p53 gene (Blask *et al*., 2005; Stevens *et al*., 2007).

4.3 Clock-Gene Coupling to DNA Repair

DNA repair enzymes are closely linked to the circadian clock and regulated by daily variations in exposure to UV radiation or genotoxins (Shadan, 2007). It is important to note that SCN clock genes are not necessarily aligned to the timing of peripheral clock genes, where the fluctuation of Cyr/Per that drive the motor could be different for diverse tissues based on need. However, as an example, the following study (Kang *et al*., 2009) assesses the activity of DNA repair enzymes monitored in reference to changes in clock genes: *Clock, Bmal1, Per* and *Cry* in cerebrum tissue derived from mice which were exposed to a 12 hour light/dark cycle: ZT0 = (lights on) and a 24 hour dark cycle where CT0 = (subjective time point zero, corresponding to ZT0 for the 12 hour light/dark cycle). **Figure 9A** represents the excision rate as assessed by protein A/+ substrate of 140 bp duplex with a 6–4 photoproduct in the centre and a ^{32}P label at the fifth phosphodiester bond 5′ to the damage; **Figure 9B** represents quantified excision activity.

These findings show that peak hours of DNA repair (**Figure 9A,B**) correspond to a reduction in Per2/Cry1 (**Figure 9C**) which occurs simultaneously at approximately 10–14 hours CT/ZT.

4.4 Clock-Gene Controls and Angiogenesis

Cyclical oscillation of Per 2/Cry 1 also regulate diurnal fluctuations in vascular endothelial growth factor (VEGF) promoter activity, where the efficacy of antiangiogenic agents can be optimized by administering drugs when VEGF production increases (Ohdo, 2007). In the following study (Shimizu *et al*., 2008) the effect of circadian rhythms on VEGF/tumour growth using antineovascular therapy (ANET), an Ala-Pro-Arg-Pro-Glyc peptide in a liposome were assessed in Colon 26 NL-17 tumour-bearing mice. The results demonstrate variable effects of tumour suppression at various hours after circadian light onset expressed as 'ZT = 0' on a 12 hour light/dark cycle, where tumour suppression peaked at ZT 14 (♦) (**Figure 10A**), also corresponding to lower plasma VEGF concentrations and greater tumour suppression (**Figure 10B**) (Shimizu *et al*., 2008).

Similar results were reported by Koyanagi *et al*. (2003), where a drop in VEGF gene transcription in hypoxic tumour cells implanted in mice occurred between ZT 10 and 14, near the early dark phase correlating to/or subsequent to a rise in Cry 2 or Per 1,2 which were in antiphase to BMAL1 and CLOCK (**Figure 11**).

Here, circadian fluctuation in VEGF protein levels in tumour-bearing mice (tumour mass and liver) showed similar temporal profiles as that reported by Shimizu *et al*. (2008) also providing information that fluctuating levels appear to be linked to the time clock genes *Per 1,2* .

4.5 Chronotherapeutic Applications and Chronotoxicology

In establishing effective time-wise delivery of chemotherapy drugs, it is important to ascertain how each drug works and to determine the circadian rhythms of the particular drug targets (Altinok *et al*., 2009), drug detoxification systems (Lévi, 2008) and fluctuations in hormonal or immunological variables (Lissoni *et al*., 2008). Applied chronotoxicology can render fewer side effects and greater efficacy, which is often obtained following treatment delivery at which side effects are least observed (Lévi, 1999; 2001; 2008), and achieved with drugs which are formulated to release drug concentrations to accommodate these patterns (Ohdo, 2007). Some applications include peak infusions of 5-fluorouracil at 04:00, folinic acid at 04:00, doxorubicin at 06:00, oxaliplatin at 16:00 and cisplatin at 16:00–20:00 hours (Ohdo, 2007). **Figure 12** reflects circadian rhythms in anticancer drug tolerability in laboratory mice or rats, as presented by Mormont and Levi (2003).

While time-guided administration of drugs continues to be a valuable tool in reducing side effects and improving therapeutic response rates, future research will be required to assess the efficacy of chronotoxicology

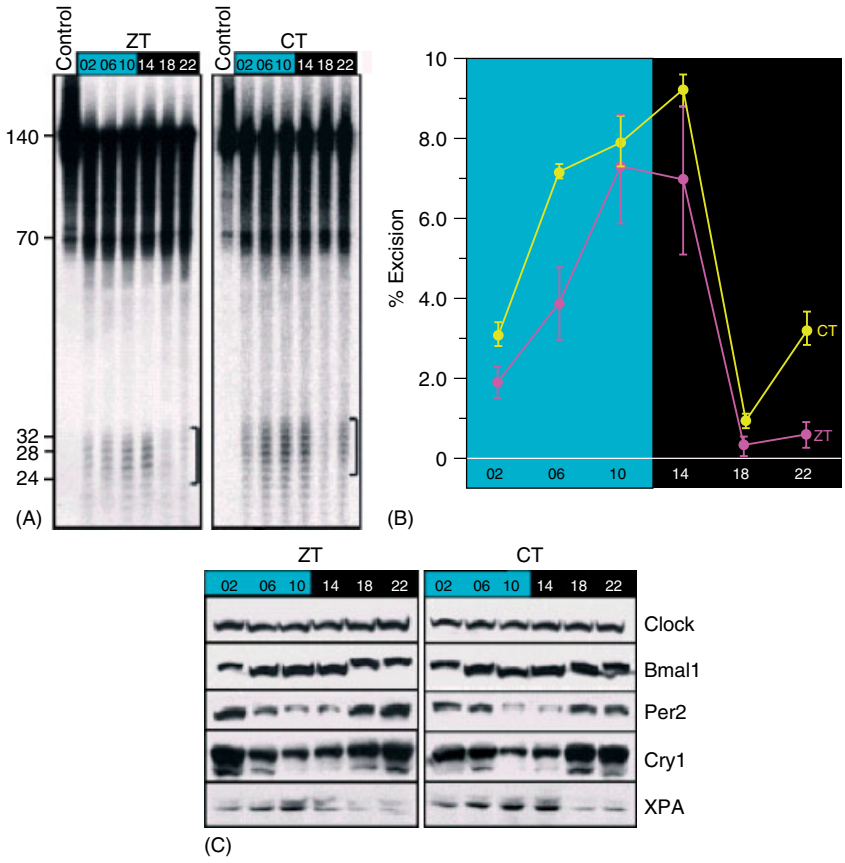

Figure 9 Circadian oscillations of nucleotide excision repair activity in the mouse brain. (A) Excision assays with mice cerebrum extracts prepared from brains harvested at the indicated ZT and CT times. Ten femtomoles of substrates were loaded as a control. (B) Quantitative analysis of the excision activity as a function of ZT or CT. For ZT, each data point represents the average of excision activity from the cerebrums of three mice, and the bars represent the SE. For CT, the data points represent the averages of duplicate experiments conducted with extracts from a single mouse for each data point. Bars indicate SD. (C) The effect of circadian clock on 'day/night' expression patterns of the clock genes and excision repair. Extracts from brains were harvested at ZT18 (night) and ZT06 (day) and were analysed by immunoblotting. Circadian oscillations of xeroderma pigmentosum A (XPA) determined by immunoblotting with the four core clock proteins. XPA peaks in the afternoon/evening hours and is in phase with BMAL1 and antiphase with *Cry* 1 and *Per* 2 indicating they are controlled by clock genes. on long-term survival rates, in order to establish the relative impact of this science on tactical advantage in the treatment of cancer.

4.6 Chronokinetics and Chronotoxicology

While chronotherapeutics is synonymous to chronotoxicology in the study of cancer treatment or chemotherapy drugs to selectively kill tumour cells, the term chronotoxicology also describes the toxic effects of drugs or poisons relative to circadian rhythmic patterns. This requires an in-depth review of how each individual toxin is processed, metabolized and excreted in the human body ('chronokinetics'), the directed target or means by which it exerts its lethal effects ('chronodynamics') and the extent of toxicological damage (chronotoxicity) relative to 24 hour time points. Chronokinetics is further defined as a dosing time-dependent and predictable (rhythmic) change used to characterize the pharmacokinetics (or the bioavailability) of a drug, chemical or toxic substance which is often dependent on the solubility/physical properties (i.e. lipophilicity, hydrophilicity) of a compound (Reinberg, 1992). The distribution of poisonous substances throughout the body is governed by circadian rhythms inherent to peripheral tissues and organs that regulate absorption (dermal, digestive or pulmonary), distribution (delivery from the blood or lymph to tissue dependent upon circulation/binding capacity of plasma proteins), metabolic rate,

tissue storage capacity, liver function and excretion (i.e. glomerular filtration, tubular reabsorption and urinary pH), all of which establish a unique chronokinetic profile that varies from substance to substance (Reinberg, 1992).

The diurnal fluctuation in observed adverse effects of toxic substances is highly reliant on circadian rhythms that occur in liver detoxification processes. The liver is the major processing centre for drug metabolism, biotransformation and detoxification of lipid and soluble drugs/poisons involving oxidative Phase I (NADPH-cytochrome P450 reductase/cytochrome P450 electron transfer systems) or conjugative Phase II (uridine-5′-diphospho-glucuronosyltransferase) reactions, which regulate the rate and capability to eliminate toxic substances from the body through excretion. The cytochrome P450s (CYPs) involved with Phase I make the field of chronotoxicology extremely broad because there are >2500 cytochrome P450 sequences known and, in humans alone, there are 18 families of genes and 43 subfamilies which in large part control many aspects of steroid, drug and fatty-acid metabolism (Nelson, 1999; Nelson, 2003). The CYP (1–3) families and their 17 subfamilies play the most critical role in the metabolism of drugs and, just for one example alone, the CYP 2D6 family processes a large classification and number of drugs, including several of the antiarrhythmics (flecainide, mexiletine, propafenone); antidepressants (amitriptyline, paroxetine, venlafaxine, fluoxetine (Prozac), trazadone); antipsychotics (chlorpromazine, haloperidol, thoridazine); β-blockers (labetalol, timolol, propanolol, pindolol, metoprolol) and analgesics (codeine, fentanyl, meperidine, oxycodone, propoxyphene) (Nelson, 1999; Nelson, 2003). Other individual CYPs such as CYP 2E or CYP 1A2 are responsible for the metabolism of ethanol (Diaz Gómez *et al.*, 2006) and caffeine (Kot and Daniel, 2008), respectively.

Further, some drugs/substances can alter their own rate of detoxification by acting on hepatic tissue, as in the case with CYP inhibitors (blocking the detoxification of a drugs), that is, (−) CYP 3A4, CYP 2D6, CYP 2 C9 (grapefruit juice) (Girennavar *et al.*, 2007), CYP potentiators (enhancing detoxification of the drug), agents that alter the catalytic biotransformation of drugs, that is CYP 2 C8, CYP 3A4 (taxol) (Spratlin and Sawyer, 2007), induce drug interactions (Darwish *et al.*, 2008) or even gene mutations linked to disease predisposition, that is CYP 1B1 (congenital glaucoma) each which contribute confounding variables to a chronotoxicological profile (Firasat *et al.*, 2008).

Circadian rhythms in the liver are governed by clock genes which regulate the diurnal transcription of Phase I/Phase II enzymes, detoxification and transport of xenobiotics (Akhtar *et al.*, 2002; Storch *et al.*, 2002; Lim *et al.*, 2006). For example, the clock nuclear orphan receptors: RORα and RORγ are highly expressed in liver tissue and, in mice, a concentration peak is observed at approximately 16–24 HALO 'hours after light onset', also governing the transcription of genes encoding Phase I/Phase II metabolic enzymes (Kang *et al.*, 2007). Kang *et al.*, examined gene alterations in RORα and RORγ double knockout mice (DKO), where results show induction of genes (corroborating

proliferator-activated receptor α (PPARα), which serves as a transcription factor regulating the expression of genes (Lemberger *et al*., 1996; Oishi *et al*., 2005). PPARα is highly expressed in liver tissue (Desvergne *et al*., 2006) and regulates circadian output expression of Phase I/Phase II proteins, such as Cyp4a-UGT (Johnson *et al*., 2002; Barbier *et al*., 2003; Teboul *et al*., 2008). Briefly, PPARs heterodimerize with the retinoid X receptor (RXR) and bind to DNA sequences (peroxisome proliferator hormone response elements) that turn on/off gene transcription. However, similar to ROR/Rev-erb, the PPARα/RXRα can also modulate CLOCK/BMAL1-mediated transcription of *Per* and *Cyr* (Nakamura *et al*., 2008) and for this reason, PPARα agonists are capable of entraining both liver and systemic circadian rhythms (Canaple *et al*., 2006; Shirai *et al*., 2007). These findings suggest that circadian expression of proteins involved in xenobiotic detoxification are largely regulated by ligand-dependent transcription factor nuclear receptors, which appear to be responsible for the daily fluctuation in drug metabolism and changes of drug effectiveness and toxicity.

Experimental analysis of daily fluctuations in toxicity requires routine chronotoxicological assessment, often carried out by determination of an LD_{50} (median lethal dose) in mice synchronized to a 12 hour light/dark cycle, with varying administration times measured by 'HALO'. Many studies show that the time of administration plays an enormous role in the variability of the toxicity/lethal effects of drugs. Examples of this would include that observed for ondansetron (a chemotherapy adjunct antinausea agent) in mice; where dosing at 1 HALO corresponded to an absence of mortality vs. dosing at 19 HALO, which dropped the survival rate by approximately 50% (Khedhaier *et al*., 2003). Similarly, florfenicol shows 2.5 times greater toxicity at 16 HALO compared to 4 HALO in mice (Picco *et al*., 2001). Opposite diurnal patterns are also observed for drugs such as cetirizine (histamine H1 receptor antagonist), where drug dosing at 17 HALO was associated with greater survival rate than at 5 HALO (Dridi *et al*., 2005). The chrontoxicological profile obtained for a chemical/drug or foreign substance has in its foundation a rationale for the observed effects, which are dependent upon how clock genes affect the specific drug target, such as receptors, ion channels, signalling systems and so on (chronodynamics) or specific enzymes in the liver responsible for its metabolism or detoxification (chronokinetics).

In summary, the chronotoxicological effects of poisons or toxic substances are highly dependent upon chronopharmacokinetics, which render a variation in biodistributions or absorption patterns, or chronodynamics, rhythmic variation in toxin target proteins or processes. The study of time and life processes are complex due to the many multifactorial interfering variables comprising oscillations, patterns governed by the reception and transmittance of all types of information occurring simultaneously in many tissues, organs and cells. Future investigations should aim to compile data between inter- and intraspecies variability for all types of chronological studies in tissues, organs and cells, to determine if there is a potential means by which to assess the probability of an outcome.

ACKNOWLEDGEMENTS

Dedicated to the memory of Dr. Charles A. Walker who pioneered Chronotoxicology.

Effects of Chirality on Toxicity

Mae Grace Nilos, Jay Gan and Daniel Schlenk

CONTENTS

1 INTRODUCTION

We live in an asymmetric world where life is neither fair nor even-handed—sociologically and physically.
David Triggle (2002)

Louis Pasteur was the first to describe 'chirality' as an inherent property of compounds which are products of biological processes (Tombo and Bellus, 1991; Kurihara and Miyamoto, 1998; Ali *et al*., 2003). His pioneering work on the resolution of tartaric acid in the middle of the nineteenth century allowed chemists to realize that optical activity results from molecular dissymmetry of the individual molecules of (+)- and (−)-stereoisomers, related as nonsuperimposable mirror-image forms (Mason, 1986). Following Pasteur's resolution of the tartaric acid racemate, J. H. van't Hoff and J. A. Le Bel, developed the concept of molecular asymmetry (Kurihara and Miyamoto, 1998). Pasteur's term, 'dissymétrie', for enantiomorphism (from the Greek enantios morphe which means opposite shape), was later replaced by 'chirality', from the familiar correlation to the mirror-image relationship between the left and the right hands (Mason, 1986). The significance of stereoisomerism, not only in relation to physicochemical, but also to biological properties, has since been recognized by scientists (Mason, 1986; Tombo and Bellus, 1991).

The first definitive example of differential bioactivity of a pair of drug enantiomers was that of British pharmacologist Arthur Cushny almost 100 years ago (Waldeck, 2003; Patel and Hutt, 2004). He demonstrated the higher potency of the natural, levorotatory alkaloid (−)-hyoscyamine over its racemate, atropine ((±)-hyoscyamine), in antagonizing cholinergic stimuli. He showed that endogenous adrenaline, which is also levorotatory, is twofold more potent than synthetic adrenaline, which is racemic (Waldeck, 2003). This was followed in 1933 by Easson and Steadman's postulate of a three-point interaction between a drug and its receptor, explaining stereoselectivity in the action of chiral drugs (Waldeck, 2003; Patel and Hutt, 2004).

However, apart from relatively few instances, stereoselectivity was essentially ignored after it was first described in the early years of the last century (Maher and Johnson, 1991; Patel and Hutt, 2004; Garrison, 2006). Following decades of essentially 'limited dimensionality' in pharmacology and therapeutics, in which racemates dominated the pharmacopoeia, the significance of stereochemistry is only beginning to be rediscovered, first in pharmaceuticals, and more recently in agrochemicals (Tombo and Bellus, 1991; Crossley, 1992; Shah *et al*., 1998; Agranat *et al*., 2002; Brocks *et al*., 2004; Patel and Hutt, 2004; Garrison, 2006). Several factors need to be considered when addressing the need for enantiomer-specific toxicological data for bioactive agents, including availability of suitable analytical techniques and appropriate assay methods (Waldeck, 2003). It is therefore not so much the lack of interest, but rather the challenges and the lack of necessary technology that kept scientists from looking into the importance of chirality in chemical toxicity.

The separation and quantification of enantiomers is probably the greatest challenge in chiral chemical analysis (Gorog, 2007). Separation of enantiomers can only be achieved in chiral environments, mostly on chiral chromatographic columns containing chiral derivatives (e.g. β-cyclodextrin and α_1-acid glycoprotein (AGP)). In addition, enantiomeric separation of chemicals with two or three stereogenic centres can be challenging, since they consist of up to four to eight enantiomers. The difficulty in chiral analysis was further complicated by the lack of enantiomer standards, which are hard to synthesize and purify. Also, for compounds with labile chiral centres, enantiomers may undergo isomer inversion or racemization, which further complicates quantitative analysis of enantiomers (Testa *et al*., 1993; Lamzin *et al*., 1995; Reist *et al*., 1998; Wsol *et al*., 2004). The past 30 years saw significant advances in chiral separation and synthesis techniques, which helped facilitate the routine separation of enantiomers of a significant number of chiral compounds for stereoselective toxicity assessment (Tombo and Bellus, 1991; Wong, 2006; Agranat *et al*., 2002).

This chapter is not intended as an exhaustive compilation of enantioselective properties of chiral bioactive agents, but rather to provide an overview of the complexities that may result from chirality in order to underscore the importance of stereochemical considerations in both human and ecotoxicology. Discussions will focus on toxicological processes that might be subject to stereoselectivity. Because the nomenclature for stereoisomers in the literature is not uniform, optical activity, whenever possible, will be noted as (−)- and (+)- for the levo- and dextrorotatory enantiomers, respectively. When the absolute configuration is known, the designations (*R*) and (*S*) will be used.

2 DEFINITIONS AND NOMENCLATURE

A considerable number of organic chemicals exist in a number of isomeric forms, which can be classified as either structural isomers or stereoisomers (**Figure 1**). Stereoisomers have the same chemical groups connected in the same sequence of bonds and only differ in their 3D structures. Stereoisomers are comprised of nonsuperimposable mirror-image enantiomers and the non-mirror-image stereoisomers (comprising multiple chiral centres) diastereomers (McMurry, 2004; Brocks, 2006; Ulrich, 2007). Geometric isomers, which have as their basis for asymmetry restricted bond movement about a plane, are also possible, but are not common as pharmaceutical or agrochemical agents (Brocks, 2006).

The term 'chiral', as used to describe the molecular asymmetry of carbon-containing compounds was first coined by Lord Kelvin in his Baltimore Lectures on molecular dynamics (Lamzin *et al*., 1995; Ali *et al*., 2003). The term is derived from the Greek word 'cheir', which means 'hand'. Thus, chirality, in very simple terms is 'handedness' (i.e. the existence of left/right opposition) (Lamzin *et al*., 1995).

Chirality results from the asymmetric positions in the structure of a molecule (Davies and Teng, 2003). The occurrence of asymmetry in organic compounds results from a tetrahedral sp^3 hybridized atom (the 'chiral centre', which is usually carbon, but also phosphorus, sulphur and other tetrahedral-substituted atoms) on which are attached four different constituent atoms or groups (**Figure 2**) (Lamzin *et al*., 1995; Davies and Teng, 2003; Brocks, 2006; Sasaki, 2008). The presence of a carbon–carbon double bond that renders the molecule rigid may also result in a chiral structure. Steric hindrance arising from ring structures that prevents free rotation about a bond allows enantiomeric atropisomers to exist. For many of the polychlorinated biphenyl (PCB) congeners with three or four *ortho* chlorine substituents and PCB metabolites (e.g. PCB methyl sulphones), the restricted rotation around the biphenyl bond provides molecular stability, allowing for the formation of two stable rotational isomers that are nonsuperimposable mirror images of each other (Kania-Korwell *et al*., 2006; Wong, 2006).

The presence of a chiral centre in a molecule is associated with its ability to rotate plane-polarized light. Optical activity by a chiral compound is typically described by the direction of optical rotation. A clockwise rotation is generated by the dextrorotatory (*d*) or (+)-enantiomer, while a levorotatory (*l*) or (−)-enantiomer will rotate the plane-polarized light counterclockwise. It should be noted that this property has no influence on biological activity, but serves as a useful marker in the analysis of enantiomers (Maher and Johnson, 1991; Karim, 1996; Davies and Teng, 2003; Patocka *et al*., 2004; Brocks, 2006).

Another method of describing chiral compounds, as proposed by the International Union of Pure and Applied Chemistry (IUPAC), is the 'Cahn–Ingold–Prelog (CIP) (sequence) rule' or the '*R*–*S* convention' which indicates the absolute configuration and stereochemical description of a chiral entity (Sewell *et al*., 1998; Tucker, 2000; Agranat *et al*., 2002; Davies and Teng, 2003). It defines a chiral centre as being *R* (derived from the Latin rectus or clockwise) or *S* (sinister or counterclockwise), in reference to the spatial arrangement of the constituents around the chiral centre (van der Goot and Timmerman, 1988; Davies and Teng, 2003). If a chemical has more than one chiral centre, it is necessary to assign absolute configuration to each chiral centre.

The spatial orientation of the constituents surrounding the chiral carbon atom in amino acids and sugars is often identified by the prefix D or L (in small uppercase letters), referring to the absolute configuration of the compound's α-carbon (the chiral carbon of D- and

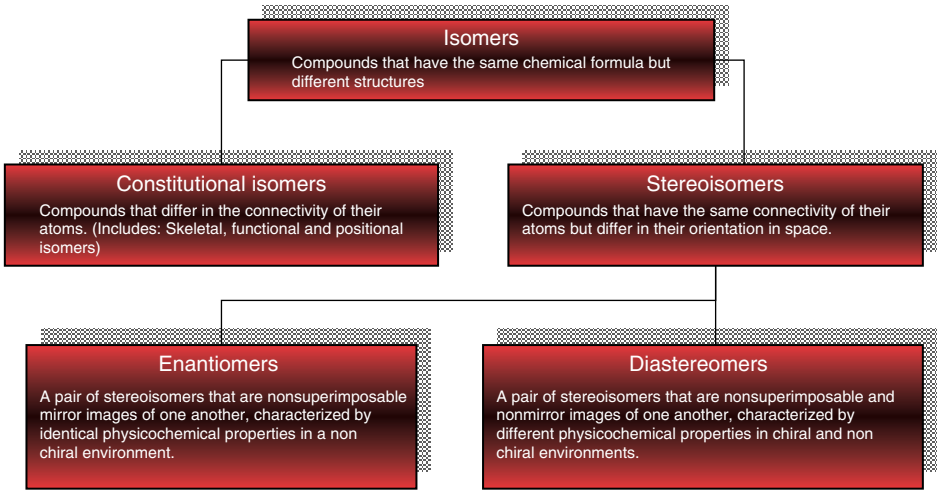

Figure 1 Basic terms in stereochemistry.

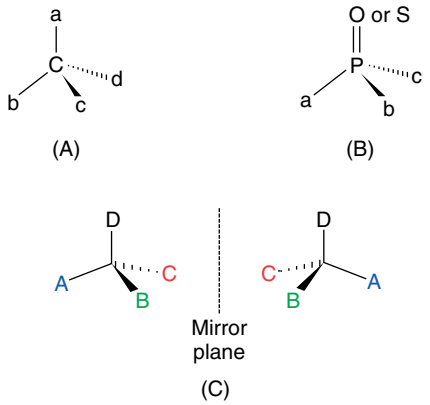

Figure 2 Structural representation of a chiral carbon (A); a chiral phosphorus (B) and pair of mirror image enantiomers (C) where A, B, C and D are different chemical groups attached to the chiral (asymmetric or stereogenic) centre.

L-glyceraldehyde) (van der Goot and Timmerman, 1988; Maher and Johnson, 1991; Lamzin *et al*., 1995).

The number of possible enantiomers increases with the number of asymmetric centres in a chiral molecule and so does the complexity of the required nomenclature. The number of enantiomers in a chiral compound is determined by the asymmetric (chiral) centres, which is given by the relationship 2^n, where n is the number of asymmetric positions (Maher and Johnson, 1991; Karim, 1996; Daniels *et al*., 1997). The term racemate generally denotes an optically-inactive equimolar (50 : 50) mixture of optical enantiomers (Mason, 1986). With the exception of optical activity, individual enantiomers possess the same physical and chemical properties when placed in an achiral environment. Biologically, however, enantiomers can be regarded as different compounds (Ariens, 1986; Agranat *et al*., 2002).

For a particular action (e.g. therapeutic or pesticidal), enantiomers are sometimes described based on their relative activity. The terms 'eutomer' and 'distomer' refer to the more active and less active enantiomer, respectively (Lehmann *et al*., 1976; Ariens, 1986; Maher and Johnson, 1991; Karim, 1996). The degree of selectivity for any given activity, is given by the 'eudismic ratio', or the potency ratio between the eutomer and distomer (Waldeck, 2003; Patel and Hutt, 2004). These terminologies and designations refer to a particular single activity (desired or adverse) of a chiral agent, so that the eutomer for one activity may be the distomer for another.

Table 1 provides a summary of the nomenclatures and their definitions commonly encountered in chiral chemistry.

3 CHIRAL RECOGNITION IN BIOLOGICAL SYSTEMS

Having observed that the mold, *Penicillium glaucum*, metabolized (+)-tartrate more rapidly than (−)-tartrate, Pasteur in 1858 commented, 'There cannot be the slightest doubt that the only and exclusive cause of this difference in the fermentation of the two tartaric acids is caused by the opposite molecular arrangements of the tartaric acids. In this way, the idea of the influence of molecular asymmetry of natural organic products is introduced into physiological studies, this important characteristic being perhaps the only distinct line of demarcation between dead and living matter.' (Booth *et al*., 1997; Triggle, 2002; Patel and Hutt, 2004).

The significance of chirality has long been recognized in relation to the biological activity of natural compounds and synthetic drugs (Caldwell, 1995; Karim, 1996; Kurihara *et al*., 1997; Ladik and Szekeres, 2006). At the molecular level, chirality is ubiquitous in proteins, carbohydrates, nucleic acids, lipids and steroids (Lamzin *et al*., 1995; Greer and Wainer, 2002;

Table 1 Commonly used nomenclature in chiral chemistry and their definitions

Notation	Identification	Comments
	Optical activity	
(−) or *l*	Levorotatory—rotates plane-polarized light in a counterclockwise direction.	Optical activity is a property of an enantiomer that has no influence on its biological activity. However, it serves as a useful analytical marker in the identification of enantiomers in the laboratory.
(+) or *d*	Dextrorotatory—rotates plane-polarized light in a clockwise direction.	
	Absolute configuration	
R	Rectus (right)—if a curve arrow is drawn from the highest to the lowest priority substituent, the direction of rotation is clockwise.	Based on the Cahn–Ingold–Prelog (CIP) sequence rule, the *RS* convention indicates the absolute configuration of the molecule based on priorities assigned to atoms directly bonded to the chiral centre. Priorities are assigned in order of decreasing atomic numbers. *R* and *S* are italicized and connected with a hyphen only when used as a prefix. If a chemical has more than one chiral centre, it is necessary to assign absolute configuration to each chiral centre.
S	Sinister (left)—if a curve arrow is drawn from the highest to the lowest priority substituent, the direction of rotation is counterclockwise.	
	Amino acids and sugars	
D	In α-amino acids, the configuration is D if the amino group is on the right of the Fisher projection formula with the carboxylate written on top. In sugars, the configuration is D when the −OH is on the right of the Fisher projection formula with the C=O written on top and CH_2OH on the bottom.	The DL system is currently used only in amino acids and carbohydrates. Configuration at the chiral centre is assigned based on the planar (Fischer) projection rather than 3D formulas. The descriptors used are small capital D and L.
L	In α-amino acids, the configuration is L if the amino group is on the left of the Fisher projection formula with the carboxylate written on top. In sugars, the configuration is L when the −OH is on the left of the Fisher projection formula with the C=O written on top and CH_2OH on the bottom.	

McConathy and Owens, 2003; Inoue, 2005). These biomolecules are made up of units that have the same sense of chirality, so that any polymer chain folded into a three-dimensional structure generally adopts one of the two stereochemical configuration. This determines the fit of the enantiomer with biomolecular targets (Simonyi *et al*., 1986; Garrison, 2006).

Most carbohydrates have the D-configuration (Agranat *et al*., 2002). The 21 essential amino acids are L-enantiomers (with very few exceptions) (Lamzin *et al*., 1995). Moreover, many of the natural substrates and ligands for these systems are single stereoisomer chiral molecules (e.g. neurotransmitters, endogenous opioids and hormones) (Lamzin *et al*., 1995; Patel and Hutt, 2004). Therefore, when an exogenous chiral compound is introduced into the body, it is not surprising to see markedly different effects of enantiomers as a consequence of their differential interaction with receptors, enzymes and ion channels (Crossley, 1992; Triggle, 1994; Agranat *et al*., 2002; Hegeman and Laane, 2002; Brocks, 2006; Ladik and Szekeres, 2006). The interaction between chiral chemicals and receptor molecules may result in a number of possibilities, including: (i) equal activities of enantiomers, (ii) one enantiomer possessing all the expected activity, (iii) quantitatively different activities between enantiomers and (iv) qualitatively different activities of enantiomers (Triggle, 1994). However, it should be noted that chirality is certainly not a requirement for biological activity. However, in situations where the bioactive agent contains one or more chiral centres, the desired biological property is often determined by a specific

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

absolute configuration (Tombo and Bellus, 1991; Brocks, 2006; Garrison, 2006).

The cornerstone in the understanding of chiral discrimination in biological systems is the multipoint attachment theory, postulated by Easson and Stedman in 1933, which states that the difference in activity results from the differential binding of a pair of enantiomers at a common site on an enzyme or receptor surface (Waldeck, 1993; Booth *et al*., 1997). According to this theory, at a minimum three of the four possible interactions occur for the 'more' active enantiomer as opposed to only two interactions with the 'less' active enantiomer (Lamzin *et al*., 1995; Greer and Wainer, 2002). In the experimental comparison of activities of (+)- and (−)-adrenaline, three functional groups, NH_2^+, phenylcatechol and alcoholic OH, attached to the asymmetric carbon of (−)-adrenaline were involved in the interaction with the receptor. In the mirror image (+)-adrenaline, the alcoholic OH group is oriented away from the site of the receptor, resulting in only two functional groups interacting between the molecule with the receptor, which according to Easson and Stedman explained the lower potency of the (+)-form (Patil and Miller, 2002).

Since the mid 1950s the three-point model has essentially become a key element in structure–activity relationship studies in medicinal chemistry and served as the basis for the design of a number of chiral stationary phases developed for chromatography (Booth, 1997; Mesecar and Koshland, 2000; Patel and Hutt, 2004). However, later studies showed that the simplified model does not universally hold.

For instance, Ogston's 1948 findings on the enzymatic decarboxylation of L-serine to glycine were also initially explained by the three-point interaction model. However, a re-examination of the process suggested that stereoselectivity was largely influenced by the 'correct' conformation at the binding site, which does not necessarily lie at the catalytic site. The critical step in the process was the stereoselective decarboxylation of a prochiral (nonchiral molecules that can be converted to a chiral molecule in one step) intermediate metabolite, aminomalonic acid (Booth *et al*., 1997). In which case, there were actually two interaction sites that produced binding interactions between the substrate and the enzyme. But because of the chirality of the enzyme, the catalytic site was positioned in such a way that only one of the conformations could be decarboxylated (Crossley, 1992; Booth *et al*., 1997). The same 'conformationally driven' chiral recognition mechanism was also used in describing the enantioselective discrimination by α-alkyl arylacetic acids on amylose tris(3,5-dimethylphenylcarbamate) chiral stationary phase (Booth *et al*., 1997).

More recently, by using the enzyme isocitrate dehydrogenase (IDH), Mesecar and Koshland (2000) proposed that a fourth 'location', which is not necessarily an 'interaction site', is essential in distinguishing between enantiomers in a protein structure. In their study, when a racemic mixture of isocitrate was introduced to Mg^{2+}-free crystals of IDH, only the L-isomer (2*S*,3*R*) bound to the enzyme. But when a racemic mixture of isocitrate was introduced to the enzyme crystals in the presence of Mg^{2+}, only the D-isomer (2*R*,3*S*) bound the enzyme. Further investigation revealed that three of the four groups attached to the tetrahedral C2 atom of D- and L-isocitrate bind to the same three locations in the IDH active site, the only difference being the fourth group (the hydroxyl of the C2 carbon). The –OH group of the L-isocitrate associates with an arginine residue at position 119 in the metal-free enzyme, while the –OH group of D-isocitrate associates with the metal and with two aspartate residues at positions 283′ and 307 in the enzyme. The authors concluded that it is the position of the fourth group that makes it possible for IDH to distinguish between the two enantiomers, further noting that the three-point attachment theory only worked if it is assumed that the ligand can approach a flat protein surface in only one direction (Mesecar and Koshland, 2000). If the binding sites on the protein are in a cleft or on protruding residues, a three-point attachment will not be sufficient to discriminate between isomers (Booth *et al*., 1997; Mesecar and Koshland, 2000). The 'four-location' model appears to be the current consensus among chiral-recognition mechanism studies (Patel and Hutt, 2004).

4 IMPORTANCE OF CHIRALITY IN XENOBIOTIC TOXICITY

The past 25 years have seen significant improvements in the asymmetric synthesis and chiral separation technologies that have allowed for the isolation of an increasing number of enantiomers on a laboratory scale and consequently, the evaluation of pharmacological properties of individual enantiomers (Agranat *et al*., 2002; Gorog, 2007; Shimazawa *et al*., 2008). An off-shoot of this is the rapid growth in the proportion of enantiomerically pure drugs entering the new drugs market.

From the mid to late 1980s, racemates accounted for 25% of the drug market (Simonyi *et al*., 1986; Patel and Hutt, 2004). Recent reports indicate that approximately 50% of commercially available drugs are chiral (Rentsch, 2002; McConathy and Owens, 2003). The proportion of single-enantiomer drugs that are being introduced in the market has grown steadily, rising from approximately 20% of new drugs 10 years ago to almost 75% in 2002 (Agranat *et al*., 2002). The world market share of single-enantiomer drugs increased from 27% in 1996 to 39% in 2002 (Shimazawa *et al*., 2008). The development of single enantiomers from existing racemates, known as 'chiral switches', has also become an important component of drug development portfolios

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat031
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Agranat *et al*., 2002). Beginning in the early 1990s, a number of regulatory authorities worldwide have asked for pharmacological, pharmacokinetic and toxicological profiles for individual enantiomers prior to the registration of a new chiral drug (Rentsch, 2002).

4.1 Toxicodynamic Complexities

The most significant factor responsible for differential pharmacological activities between enantiomers is in drug–receptor interactions, which are essentially 3D events (Maher and Johnson, 1991; Patel and Hutt, 2004). If the drug molecule is chiral this interaction can be expected to be stereoselective (Crossley, 1992; Triggle, 1994; Waldeck, 2003; Brocks, 2006). Moreover, stereoselectivity usually occurs at specific sites in the receptor (Ariens, 1986; Kwon and Triggle, 1991; Triggle, 1994). This is because interaction is primarily based on structural 'complementarity' of the drug molecule and its receptor site (Ariens, 1986).

A chiral molecule may interact with a number of receptor systems, including metabolic enzyme systems, neurotransmitter receptors linked to a second messenger system, or ligand/voltage-gated ion channels. These systems usually occur in structurally related families so that it is possible for enantiomeric pairs to have different pharmacodynamic actions as a result of activation of entirely different receptor populations, thereby contributing to side effects sometimes found in the racemates (Crossley, 1992; Maher and Johnson, 1991). For instance, differentiation between muscarinic acetylcholine receptor subtypes has been demonstrated by stereoisomers of atropine-like compounds. In the case of atropine itself, all the presynaptic muscarinic autoreceptor activity is due to the *R*-(+) enantiomer, but the postsynaptic activity is mainly due to the *S*-(−) enantiomer (Crossley, 1992).

A study of the enantiomers of hexahydrodifenidol and its chiral acetylenic analogues showed that the antimuscarinic potencies and receptor subtype selectivity of the compound depend on various structural parameters, including absolute configuration. The Ml (neuroblastoma), M2 (cardiac), M3 (pancreatic) and M4 (striatum) muscarinic receptors make qualitatively and quantitatively different stereochemical demands for the (*R*)- and (*S*)-enantiomers, resulting in different receptor selectivity profiles (Feifel *et al*., 1990). In addition, *S*-hexahydrodifenidol was found to be nonselective between muscarinic receptor subtypes, whereas the *R*-enantiomer was selective for the Ml receptor (Waelbroeck *et al*., 1991).

A number of psychiatric drugs currently in the market are chiral compounds whose individual enantiomers show marked differences with regard to their interaction with receptors and metabolizing enzymes. These include antidepressants (tricyclics, selective serotonin reuptake inhibitors, monoamine oxidase inhibitors, viloxazine, buprion, trazodone, mianserine, venlafaxine), benzodiazepines, zopiclone and several antipsychotics (Rentsch, 2002). *In vitro* studies have indicated (*S*)-fluoxetine, (*R*)-fluoxetine and (*S*)-norfluoxetine have similar potencies as 5-hydroxytryptamine (5-HT) reuptake inhibitors, but (*R*)-norfluoxetine is approximately 20 times less potent (Rentsch, 2002; Patel and Hutt, 2004). Similarly, *in vitro* studies have also shown that the *S*-(+)-enantiomers of another antidepressant drug, citalopram and its metabolites are more potent serotonin reuptake inhibitors over the corresponding *R*-(−)-enantiomers (Rentsch, 2002).

It is not uncommon that therapeutic effects are predominantly associated with one enantiomer, but adverse effects may be derived from the other enantiomer. For example, the potencies of the individual enantiomers of the anaesthetic and analgesic, ketamine, indicate a much higher potency of *S*-(+)-ketamine as compared with the *R*-(−)-enantiomer. However, *R*-(−)-ketamine, but not *S*-(+)-ketamine, was found to be responsible for the side effects associated with the racemate (e.g. hallucinations, restlessness and agitation during operative recovery in surgical patients) (Lien, 1995; Rentsch, 2002; Patel and Hutt, 2004).

Ligand- and voltage-gated ion channels represent major classes of pharmacologic receptors that show stereoselectivity in drug interactions (Triggle, 1994; 1996). The general characteristic of ion channels is that each possesses multiple drug binding sites. For instance, the voltage-gated Na^+ and Ca^{2+} channels, as well as the γ-amino butyric acid $(GABA)_A$-gated Cl^- channel each has at least five separate classes of drug binding sites (Triggle, 1994). Stereoselectivity of drug action at these binding sites is quite common (Clarkson, 1989; Triggle, 1994; Patel and Hutt, 2004).

The interpretation of stereoselectivity at these channels is complicated by differences in affinity and access to different channel states (Kwon and Triggle, 1991). In addition, membrane potential can also influence the stereoselectivity of drug interactions. For example, RAC-109 and its quaternary *N*-methyl derivative RAC-421 are local anaesthetics that act at the Na^+ channels without stereoselectivity in the resting state. However, stereoselectivity is observed with increased depolarization, as determined in the increased activity of the (−)-enantiomer, possibly resulting from differences in the binding site conformation between the resting, open and inactivated states of the Na^+ channel (Triggle, 1994). Similarly, the (*S*)-enantiomers of 1,4-dihydropyridines are activators, while the (*R*)-enantiomers are antagonists at the L-type Ca^{2+} channel. The activator properties of the (*S*)-enantiomer are membrane-potential-dependent, and at a sufficiently depolarized state it becomes antagonistic (Triggle, 1994).

DOI: 10.1002/9780470744307.gat031
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Enantiomers may also have opposing activities at the same receptor (Patel and Hutt, 2004). For example, the (+)-enantiomer of picenadol, a phenyl piperidine opioid analgesic, was shown to be two to three times as potent as morphine, while its antipode has about 1/10 of the activity of the morphine antagonist, naloxone. The (3*R*,4*R*)-(+)-picenadol is a strong μ-opioid receptor agonist while the (−)-antipode (3*S*,4*S*) is a weak antagonist at the same receptor (Leander and Zimmerman, 1983; Froimowitz and Coy, 1995; Shah *et al*., 1998).

There are a number of excellent reviews that detail both pharmacokinetic and pharmacodynamic similarities and differences between enantiomeric pairs of current pharmacologically important chiral drugs (Shah *et al*., 1998; Rentsch, 2002; Brocks *et al*., 2004; Mehvar and Brocks, 2004).

4.2 Toxicokinetic Complexities

The interaction of compounds with molecular targets is one of the fundamental rules of pharmacodynamics (Mayer and Testa, 1994). This rule also applies to pharmacokinetic and toxicokinetic processes. In addition to the so-called principal activity of stereoisomers, individual enantiomers may behave as distinctly different chemicals with respect to their absorption, distribution, metabolic transformation, excretion and toxicological properties in the body (Walle and Walle, 1986; Tocco *et al*., 1990; Tombo and Bellus, 1991; Mayer and Testa, 1994; Karim, 1996; Patel and Hutt, 2004). Therefore, stereoselectivity not only in toxicodynamic (pharmacological or toxicological), but also toxicokinetic (dispositional) processes may be responsible for the differential bioactivity of enantiomers.

4.2.1 Uptake

Stereoselectivity in a biological process often starts with the stereospecific recognition of a substrate by a biochemical entity, most often a protein, such as receptor or enzyme, responsible in facilitating that process. With respect to absorption, there are only a limited number of examples in the literature. In general, these studies indicate no significant stereoselectivity for chiral drugs, except in cases involving active transport (Walle and Walle, 1986; Karim, 1996; Waldeck, 2003; Brocks *et al*., 2004; Brocks, 2006).

The absorption and transport of a xenobiotic compound occur through a number of mechanisms. Passive diffusion depends on physicochemical properties of the agent, such as lipophilicity, polarity and molecular size. Carrier-mediated mechanisms such as facilitated diffusion occur via transmembrane carriers along concentration gradients. Active transport is mediated through carrier proteins, like P-glycoprotein, independent of the concentration gradient (Tsuji and Tamai, 1996; Zschiesche *et al*., 2002). For most drugs, the primary absorption and transport process across a biological membrane is through passive diffusion, suggesting that enantioselectivity may not play a prominent role in the absorption of most drugs (Walle and Walle, 1986; Mayer and Testa, 1994; Tsuji and Tamai, 1996; Patel and Hutt, 2004; Brocks, 2006). Enantioselectivity is not expected for drugs transported via passive diffusion, because enantiomers have identical physicochemical properties, such as lipid–water partitioning coefficients (Maher and Johnson, 1991; Patel and Hutt, 2004). In contrast, enantiomers of chiral drugs can be stereoselectively absorbed through carrier-mediated (active) membrane transport mechanisms such as those involved in intestinal absorption (Tsuji and Tamai, 1996; Itoh *et al*., 2001; Brocks, 2006).

Chiral drugs such as methotrexate, leucovorin, L-3,4–dihydroxyphenylalanine (L-DOPA), cephalexin and terbutaline have been shown to be stereoselectively absorbed (Wade *et al*., 1973; Tamai *et al*., 1988; Karim, 1996; Itoh *et al*., 2001; Patel and Hutt, 2004). L-DOPA, used in brain neurotransmitter replacement therapy for the treatment of Parkinson's disease, has been shown to be selectively absorbed in the intestine over the D-enantiomer (Wade *et al*., 1973). In fact, researchers have used these findings as evidence for the existence of an active transport mechanism for the intestinal absorption of L-DOPA.

Stereoselectivity was also reported in the absorption of methotrexate (L-(+)-enantiomer), a folic acid analogue, clinically used as an antineoplastic and antirheumatic agent (Hendel and Brodthagen, 1984; Itoh *et al*., 2001). Both folic acid and methotrexate were shown to be actively taken up into the brush-border membrane vesicles through the folate transporter of rabbit small intestines. In contrast, the affinity of the antipode D-amethopterin (D-(−)-enantiomer) to the folate transporter was approximately 60-fold lower than that of methotrexate (Itoh *et al*., 2001).

For most transporters, however, the magnitude of stereoselectivity is much smaller or almost negligible (Itoh *et al*., 1998; 2001). Only a 3.5-fold difference in affinity to the canalicular multispecific organic anion transporter was observed between amethopterin enantiomers (Itoh *et al*., 2001). Also, while significant diastereoselective renal secretion of carbenicillin stereoisomers was observed *in vivo*, *in vitro* studies using basolateral membrane vesicles of rabbit kidneys showed that transport by the organic anion transporter was not stereoselective (Itoh *et al*., 1998).

No stereoselectivity was observed for the mammalian P-glycoprotein-mediated intestinal secretion of the chiral β-adrenoreceptor-blocking drug, talinolol (Gramatte and Oertel, 1999; Zschiesche *et al*., 2002). But because most P-glycoprotein substrates are chiral (e.g. chloroquine, primaquine, itraconazole, cisapride, fexofenadine and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

talinolol), there is currently great interest in the potential stereoselectivity in P-glycoprotein-mediated efflux mechanisms (Patel and Hutt, 2004; Brocks, 2006).

4.2.2 Distribution

The most studied components of the human serum that play major roles in drug binding are human serum albumin and AGP (Fernandez *et al*., 1999; Patel and Hutt, 2004). Human serum albumin, the most abundant protein in the blood, has long been regarded as a general binder and carrier component (Simonyi *et al*., 1986). However, the AGP molar concentration in blood is approximately 30 times lower than that of human serum albumin, and therefore the binding capacity is expected to be much smaller. Nevertheless, its contribution to overall plasma protein binding has been observed (Albani *et al*., 1984), and in some cases, dominates certain slightly basic drugs (e.g. β-adrenergic blockers and psychotropic agents) (Simonyi *et al*., 1986; Patel and Hutt, 2004).

For instance, stereoselective binding of propranolol has been observed in human plasma, where *S*-(−)-propranolol showed higher mean binding over the *R*-(+)-enantiomer (Albani *et al*., 1984; Simonyi *et al*., 1986). The observed stereoselectivity has been attributed to the predominance of the enantioselective binding of the (−)-enantiomer to the AGP, rather than the human serum albumin, to which the (+)-propranolol enantiomer showed a higher (although not statistically significant) mean binding (Albani *et al*., 1984). Stereoselectivity in drug binding to human serum albumin and AGP has also been described for disopyramide (Lima *et al*., 1984), hydroxychloroquine (McLachlan *et al*., 1993) and the nonsteroidal anti-inflammatory drug (NSAID) 2-arylphenylpropionic acid (Jones *et al*., 1986). From these observations, the highly enantioselective nature of AGP has been exploited in the development of chiral stationary phase columns for the chromatographic resolution of a wide range of chiral compounds (Simonyi *et al*., 1986; Hermansson, 1989; Li and Lloyd, 1993).

Plasma protein binding studies of zopiclone (a short-acting hypnotic agent, available commercially as a racemate), showed (+)-zoplicone to have higher affinity for human serum albumin and AGP, although overall, the (−)-enantiomer was preferentially bound to plasma proteins, possibly due to the higher affinity of (−)-zoplicone to other plasma proteins (e.g. globulins and lipoproteins) (Fernandez *et al*., 1999).

Some drugs display interspecies differences in the direction of stereoselectivity in pharmacokinetic processes, including plasma protein binding (Fernandez *et al*., 1999; Brocks, 2006). For example, in the differential binding of disopyramide enantiomers, (*S*)-(+)-disopyramide was bound in higher concentrations than its antipode to serum proteins in humans, gorillas and pigs, while the reverse was true in serum and albumin from cows and sheep (Lima, 1988). Similarly, stereoselectivity in plasma protein binding of MK-571 (a potent leukotriene D_4 receptor antagonist developed for asthma treatment), enantiomers was found to be species dependent. Lin *et al*. (1990) were able to classify 12 mammalian species into three groups: (i) those that bind the *S*-(+)-enantiomer to a greater extent than the *R*-(−)-enantiomer (human, baboon, monkey, cow, dog and cat); (ii) those that bind the *R*-(−)-enantiomer more extensively (rat, guinea pig and sheep) and (iii) those that show no stereoselectivity (rabbit, hamster and mouse). Serum albumin was also found to be the major binding component for MK-571 enantiomers, and that the species differences in stereoselective binding were largely influenced by structural differences in the albumin molecule (Lin *et al*., 1990; Tocco *et al*., 1990). (−)-Propranolol is also more strongly bound in human plasma than (+)-propranolol, but the opposite is true in rats (Fernandez *et al*., 1999).

Specific and/or nonspecific binding to tissue proteins is another factor that may impart enantioselectivity in drug distribution (Simonyi *et al*., 1986; Patel and Hutt, 2004; Brocks, 2006). However, the molecular events involved are more complex than in plasma protein binding, and therefore not as well studied. Overall, the stereoselectivity in plasma protein binding of chiral drugs is well documented (Brocks, 2006). Summaries of some of these studies are provided by Brocks (2006), Mehvar and Brocks (2004) and Patel and Hutt (2004).

4.2.3 Metabolic Transformation

The wanted (therapeutic) and unwanted (toxicity) effects of drugs can be due to the parent compound and/or its metabolites. Biotransformation of a drug can lead to the formation of inactive metabolites that are eventually eliminated, or to therapeutically and/or toxicologically active metabolites responsible for part or all of the therapeutic and/or toxic effects (Testa, 1986) (*see* **Biotransformation of Xenobiotics**). As discussed previously, the interaction of enantiomeric substrates with macromolecules such as enzymes results in specific orientations to the catalytic site and the formation of energetically different pairs of complexes (Mayer and Testa, 1994; Caldwell, 1995). Thus, enantiomeric pairs are frequently metabolized at different rates and/or via different routes to yield products that vary in nature and/or extent (Caldwell, 1995; Patel and Hutt, 2004).

The largest enantiomeric differences in the pharmacokinetic properties of a chiral chemical are primarily derived from hepatic metabolizing activity (Walle and Walle, 1986). However stereochemical differences in presystemic drug metabolism is worth mentioning as well (Echeilbaum, 1988; Brocks, 2006). A few of the examples include the stereoselective first-pass metabolism of the more active *S*-(−)-verapamil enantiomer following oral dosing (Vogelgesang *et al*., 1984; Brocks, 2006; Hanada *et al*., 2008), as well as

S-carvedilol, which undergoes more extensive first-pass metabolism than *R*-carvedilol (Ishida *et al*., 2007), and the observed higher first-pass metabolism of the (*R*)-enantiomer of the anti-inflammatory compound tazofelone in humans (Clay *et al*., 1999).

Stereoselectivity in metabolic transformation has been classified into two basic types, substrate stereoselectivity and product stereoselectivity (Caldwell, 1995). Substrate stereoselectivity is observed when, under similar conditions, the biotransformation of enantiomers of a chiral drug is quantitatively and/or qualitatively different (Mayer and Testa, 1994; Patel and Hutt, 2004). On the other hand, product stereoselectivity occurs when quantitatively or qualitatively different stereoisomeric metabolites are generated from a single chiral, prochiral or proachiral substrate (Mayer and Testa, 1994; Caldwell, 1995). Additionally, in asymmetric inductions involving enzymatic reactions where there is a preferential formation of a particular diastereomeric product from one enantiomer, the term 'substrate–product stereoselectivity' was proposed (Mayer and Testa, 1994; Patel and Hutt, 2004).

Alternatively, stereoselective metabolic events can be classified according to the outcome of the transformation events, which include: (i) prochiral to chiral; (ii) chiral to chiral; (iii) chiral to diastereomeric; (iv) chiral to nonchiral transformations and (v) chiral inversion (Caldwell, 1995; Patel and Hutt, 2004).

The S- and N-oxidation of xenobiotic compounds is primarily mediated by the microsomal flavin-containing mono-oxygenase (FMO), in addition to the cytochrome P450 systems (Beedham, 1997; Cashman, 1998; Cashman, 2000). Prochiral to chiral transformation occurs readily with each system (Cashman *et al*., 1993; Moroni *et al*., 1995; Rodrigues *et al*., 1995; Cashman, 1998; Cashman, 2000). For example, for the ulcer treatment drug, cimetidine, S-oxidation is the preferred metabolic route leading to inactivation *in vivo*. Cashman *et al*. (1993) have shown that this process is primarily catalysed by FMO3 in human liver, leading to the formation of a chiral sulfoxide. Moreover, FMO showed stereopreference for the formation of (−)-cimetidine-S-oxide *in vivo*, as indicated in the urinary ratio of (+)25.5 : (−)74.5% (Cashman *et al*., 1993). Similarly, the broad-spectrum antihelmintic human and veterinary drug, albendazole is another example of a prochiral drug that is stereoselectively oxidized to S-oxide metabolites (Moroni *et al*., 1995; Velik *et al*., 2003). A high level of stereoselectivity was also observed in the extrahepatic sulfoxidation of the organophosphate and carbamate insecticides fenthion and methiocarb by FMO1 (Furnes and Schlenk, 2005). In fact, stereochemistry can be used to differentiate the contributions of FMO isoforms, as FMO1 and FMO2 are more stereoselective with regard to tolyl-sulfide sulfoxidation, whereas FMO3 provides a 50 : 50 mixture of enantiomers (Rettie *et al*., 1995).

In the racemic mixture of warfarin however, where the (*S*)-enantiomer is three to five times more potent than *R*-warfarin, both enantiomers are extensively metabolized in the liver. The biotransformation of the more potent *S*-enantiomer is stereoselective to (*S*)-7-hydroxywarfarin by CYP2C9, whereas the *R*-enantiomer is metabolized to (*R*)-6, (*R*)-7, (*R*)-8 and (*R*)-10-hydroxywarfarin by several cytochrome P450 isozymes, including CYP1A2, CYP3A4 and CYP2C19 (Uno *et al*., 2008). The enantiomers of warfarin in this case are transformed by different routes and/or at different rates producing metabolites that are not stereochemically different from the parent compound (Caldwell, 1995).

Other studies on the stereochemistry of warfarin metabolism in man have shown that ketone reduction in the side chain following the aromatic hydroxylation of mainly the *R*-enantiomer, produces a new chiral centre and diastereoisomers, (*R*,*S*)-warfarin alcohol or (*S*,*S*)-warfarin alcohol (Lewis *et al*., 1975; Hermans and Thijssen, 1992). This is an example of a stereoselective metabolic transformation of a prochiral group in chiral drugs yielding a diastereoisomer (Caldwell, 1995). Another example is hexobarbital. In addition to the relatively more rapid rate of metabolism of (+)-hexobarbital by rat liver microsomes, (+)-hexobarbital forms β-3′-hydroxyhexobarbital, whereas the (−)- enantiomer is preferentially metabolized to α-3′-hydroxyhexobarbital (Caldwell, 1995). Conjugation reactions, in some cases, may also result in enantiomers of chiral xenobiotics being conjugated at different rates with an achiral or chiral endogenous conjugating substrate to give pairs of diastereoisomeric conjugates. Some well-known examples include the glucuronide conjugates of 2-phenylpropionic acid and oxazepam, and the glutamine and glutathione conjugates of 4-chlorophenoxypropionic acid and bromovaleric acid, respectively (Caldwell, 1995; Hayball, 1996; Patel and Hutt, 2004).

Although it does not commonly occur, when chiral compounds undergo biotransformations at the chiral centre, chirality may be lost (Caldwell, 1995). An example is the oxidative aromatization of the dihydropyridine calcium-channel-blocking drug, nilvadipine at the N-chiral centre to produce an achiral pyridine analogue (Niwa *et al*., 1989). The stereoselective oxidation of omeprazole at the chiral sulfoxide centre to sulfone is another example (Abelo *et al*., 2000; Patel and Hutt, 2004; Brocks, 2006). The metabolic deamination of amphetamines to nonchiral phenylacetone and ammonia in rabbit liver microsomes was also stereoselective to (−)-amphetamine (Patil and LaPidus, 1972).

It has also been observed that certain chiral drugs may undergo interconversion wherein an enantiomer converts to another configuration, via enzymatic or nonenzymatic processes (Testa *et al*., 1993; Wsol *et al*., 2004). Thalidomide is perhaps the most well-known example. Banned for use as a sedative in the 1960s due to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat031
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

its propensity to cause serious birth defects, thalidomide recently attracted interest for its anti-inflammatory properties first demonstrated in the treatment of leprosy (Caldwell, 1995; Reist *et al*., 1998; Waldeck, 2003; Brocks, 2006). Initial studies using oral administration to rabbits and mice showed that both thalidomide enantiomers were equally teratogenic and had the same sedative effect. However, (*S*)-(−)thalidomide, rather than (*R*)-(+)-thalidomide, was shown to cause dose-dependent teratogenicity in both rats and mice when given intraperetoneally, leading to the premature conclusion that the adverse effect of thalidomide might have been avoided if only the pure (*R*)-(+)-enantiomer had been used (Vermeulen, 2003).

Further studies later confirmed that the sedative effect by thalidomide in man is related to the (*R*)-thalidomide (Shah *et al*., 1998). However, the teratogenic effect of thalidomide may still not have been avoided by using enantiopure (*R*)-thalidomide because thalidomide enantiomers undergo rapid bidirectional (racemization) interconversion in biological media, as shown in *in vitro* as well as *in vivo* studies (Waldeck, 2003; Brocks, 2006). This makes the determination of enantioselectivity in therapeutic and toxic action complicated for chiral drugs like thalidomide. Albumin, hydroxyl ions, phosphates and amino acids (in particular, basic amino acids like arginine and lysine), were found to influence the base-catalysed thalidomide enantiomer inversion *in vivo* (Testa *et al*., 1993; Reist *et al*., 1998). The rapid interconversion of thalidomide following oral administration explains the apparent lack of selectivity in the orally administered drug.

A few other examples of enzymatic reactions that lead to chiral interconversion are those of chiral NSAIDs, classified as arylpropionic acid derivatives (also known as the 'profens'), which undergo substrate- and species-dependent metabolic stereoisomer conversion (Testa *et al*., 1993; Caldwell, 1995; Hayball, 1996; Wsol *et al*., 2004; Hao *et al*., 2005; Brocks, 2006).

Chiral profens possess a chiral centre α- to the carbonyl group and their therapeutic activity is mainly concentrated in the *S*-(+)-enantiomer, with the *R*-(−)-enantiomers being weakly active or inactive (Caldwell, 1995). Most arylpropionates undergo unidirectional inversion from the *R*-(−)- to *S*-(+)-configuration, so that the reaction is essentially a bioactivation of the *R*-enantiomers, which in this case may be regarded as prodrugs for the pharmacologically active *S*-enantiomer (Hao *et al*., 2005). The molecular mechanism of the inversion reaction of profens involves a stereospecific formation of a coenzyme-A thioester from the *R*-enantiomer, which undergoes a series of steps (Caldwell, 1995; Wsol *et al*., 2004). The first step is the stereoselective activation of the *R*-(−)-enantiomer via the formation of acyl-CoA thioester in the presence of coenzymeA (CoA), adenosine-5′-triphosphate (ATP) and Mg^{2+}. This is followed by the enzymatic epimerization of the *R*-thioester to the *S*-(+)-thioester. The final step is the release of the active *S*-(+)-enantiomer by hydrolysis of the thioester (Williams *et al*., 1986; Hayball, 1996; Wsol *et al*., 2004). The toxicological importance of such chiral inversion processes has been attributed to the acyl-CoA thioester intermediates, which can modulate lipid metabolism by inhibiting mitochondrial β-oxidation of fatty acids and forming lipid acylglycerols that can be incorporated into membranes and could potentially alter membrane structure, function or second messenger signalling (Caldwell, 1995; Wsol *et al*., 2004).

4.2.3.1 Toxicological Consequences of Stereoselective Metabolism

The occurrence of stereoselectivity in metabolism can have serious consequences on the beneficial activity of the enantiomers of a racemic compound. For example, toxicity was shown to result from differential metabolism of the pyrethroid insecticide fenvalerate to a variety of species. Fenvalerate exists as a mixture of four enantiomers due to the presence of two chiral centres in its structure. Studies have shown that administration of the mixture of fenvalerate enantiomers resulted in granulomatous changes in mouse liver, spleen and mesenteric lymph node (Kaneko *et al*., 1986; Miyamoto *et al*., 1986; Okuno *et al*., 1986; Kaneko *et al*., 1988). Later toxicity evaluations of individual enantiomers indicated that the stereoselective metabolism of the 2*R*,α*S* enantiomer to a lipophilic conjugate, cholesteryl 2*R*-2-(4-chlorophenyl) isovalerate causes the granulomatous changes observed in the various tissues (Takamatsu *et al*., 1987). *In vitro* and *in vivo* biotransformation studies in mice, rats, dogs and monkeys, showed that all fenvalerate enantiomers were hydrolysed to 2-(4-chlorophenyl) isovalerate. However, only the 2*R*,α*S*-fenvalerate formed the cholesterol conjugate (Miyamoto *et al*., 1986; Takamatsu *et al*., 1987). As a result, the enantiopure fenvalerate that contains only the active isomer (2*S*,α*S*-fanvelerate), esfenvalerate, which does not produce the toxicity associated with fenvalerate, was developed and marketed.

The toxicological consequence of stereoselectivity in biotransformation is also depicted in chemotherapeutic agents (Vermeulen and Koppele, 1993). These compounds are usually prodrugs, characterized as having both desired (cytostatic) and undesired (cytotoxic) effects, the induction of which is largely influenced by the configuration of the parent compound (Vermeulen and Koppele, 1993). For example, animal model studies and clinical data of the anticancer prodrug, ifosfamide, showed enantioselective differences in cytochrome P450 metabolism between its two enantiomers (Roy *et al*., 1999). (*R*)-Ifosfamide contains the unique antitumour activity of this agent, and the ifosfamide-related toxicity is primarily related to the (*S*)-enantiomer (Vermeulen, 2003). Urotoxicity has been observed as a result of the production of

acrolein during the N-dechlorethylation of the drug. The CYP2B6 and CYP3A4 mediated N-dechlorethylation (inactivation, urotoxic), is a competing pathway for the 4-hydroxylation reaction (activation to desired effect) of the drug by the same enzyme (Roy *et al*., 1999; Brocks, 2006). 4-Hydroxylation was shown to be more rapid for the *R*-enantiomer, which was N-dechloroethylated to a significantly lesser extent than the corresponding *S*-enantiomer (Roy *et al*., 1999).

4.2.3.2 Interspecies Differences in Stereoselective Metabolism

Significant interspecies variation also exists in the activity of biotransformation enzymes, which could have serious consequences, especially since biotransformation studies on drugs and other chemicals are mostly based on experimental work in a restricted number of species, and findings extrapolated from animal studies to humans. These differences could be due to differences in enzyme structures or expression levels of enzymes between species (Walle and Walle, 1986; Cashman *et al*., 1993; Beedham, 1997; Wsol *et al*., 2004; Brocks, 2006).

For example, in the S-oxidation of the ulcer treatment drug, cimetidine, pig liver FMO1 showed a stereopreference for the formation of (+)-cimetidine-S-oxide (Cashman *et al*., 1993). This is in contrast to the human liver FMO (FMO3), which has stereopreference for the formation of the (−)-S-oxide. In the previous example, for the pyrethroid fenvalerate, interspecies differences were also observed in 2*R*-2-(4-chlorophenyl) isovalerate cholesterol ester formation, which could be due to differences in carboxylesterase isoforms (Miyamoto *et al*., 1986).

Another example is propranalol, which is extensively metabolized by several oxidative routes, which is then followed by glucuronidation. The *S*-enantiomer, which contains most of the racemic propranolol's activity is selectively glucuronidated in dog and human liver microsomes. In rats and rabbits however, UDP-glucuronosyltransferase (UGT) is more selective to the *R*-enantiomer. Moreover, *S*-propranolol was found to be a noncompetitive inhibitor of *R*-propranolol glucuronidation in dog liver microsomes, while *R*-propranolol noncompetitively inhibits the glucuronidation of its enantiomer in rabbit liver microsomes (Testa, 1986; Walle and Walle, 1986). Examples of interspecies differences in chiral inversion have also been reported, including in microorganisms (Wsol *et al*., 2004).

Carboxylesterases are involved in detoxification or metabolic activation of important drugs and agrochemicals (Godin *et al*., 2006; Anand *et al*., 2006; Nishi *et al*., 2006; Ross *et al*., 2006; Satoh and Hosokawa, 2006). Species differences and substrate specificities for stereoselective hydrolysis have been reported for various esterase substrates (Glickman *et al*., 1979; Yoshigae *et al*., 1997; Stok *et al*., 2004; Nishi *et al*., 2006). Carboxylesterases are also important enzymes involved in prodrug activation (Satoh and Hosokawa, 2006). For example, propranolol shows poor oral bioavailability, due to extensive first-pass metabolism, therefore ester prodrugs of propranolol have been designed to avoid presystemic metabolism via masking of glucuronidation site of propranolol (Yoshigae *et al*., 1997; Satoh and Hosokawa, 2006). The *R*-enantiomer of propranolol prodrugs were preferentially hydrolysed, however, rat liver cytosol showed extremely low hydrolytic activities, broad substrate specificities and poor stereoselectivities compared to the microsomes. In contrast, dog liver cytosol showed similar enantioselectivity and substrate specificity to microsomes (Yoshigae *et al*., 1997).

In conclusion, it is important to consider species differences every time extrapolation is to be made between species. It should be noted that differential metabolism could alter the enantiomer ratio significantly and, sometimes, different metabolites are formed in different species. Interspecies differences in the stereoselective metabolism of chiral compounds are also the subject of recent reviews (Wsol *et al*., 2004; Brocks, 2006).

4.2.3.3 Genetic Polymorphism

Another factor to consider in stereoselective metabolism is that of genetic polymorphism (a characteristic of some of the most important enzymes that mediate xenobiotic transformation) (Shah *et al*., 1998). The biotransformation of a number of drugs is under genetic control (Caldwell, 1995; Cashman, 2004; Cashman, 2005). When genetic polymorphism is a factor in stereoselective metabolism, the likely existence of sensitive subpopulations further complicates risk assessment of the chiral chemicals. The single nucleotide polymorphisms in CYP2C9 and CYP2C19 are among the most common examples (Uno *et al*., 2008).

Because of their importance in the metabolism of a wide variety of xenobiotics, the cytochrome P450 superfamily of metabolic enzymes is a major determinant of interindividual differences in the rate of drug elimination and pharmacological or toxicological response (Vermeulen and Koppele, 1993). Both enantiomers of warfarin, which exhibit huge quantitative differences in their activity, are eliminated via hepatic metabolism (Rettie *et al*., 1992; Rentsch, 2002; Veenstra *et al*., 2005). The polymorphic CYP2C9 is responsible for the metabolism of the pharmacologically active *S*-enantiomer (Rettie *et al*., 1992). Seven alleles of CYP2C9 that could be responsible for reduced or null enzyme activity have been identified (Lee *et al*., 2002; Veenstra *et al*., 2005). The CYP2C9*3 allele has been implicated with the retarded elimination of (*S*)-warfarin in polymorphic individuals (Rentsch, 2002; Veenstra *et al*., 2005; Gage *et al*., 2008). The CYP2C9*3 and the CYP2C9*2 variants are present in approximately 35% of Caucasian individuals, but significantly less prevalent in African-American and Asian populations (Lee

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 2002). CYP2C9 is also the main enzyme in the 7-hydroxylation of the (*R*)-enantiomer of another anticoagulant acenocoumarol, but CYP1A2 and CYP2C19 are also involved (Suszuki *et al*., 2004). CYP1A2 and CYP2C19 are also polymorphic, so that individuals with low enzyme activity could be at higher risk for bleeding episodes after a normal dosage (Rentsch, 2002).

CYP2D6 is an important oxidative enzyme responsible for metabolism of more than 30% of frequently prescribed drugs (Masuda *et al*., 2006). The lack of functional CYP2D6 has been reported in approximately 7.7% of Caucasian and 1.9% of Asian populations (Shimizu *et al*., 2003). Bufuralol, a nonselective β-adrenoceptor antagonist, consisting of two enantiomers, 1′*R*-bufuralol and the more active 1′*S*-bufuralol, is a well-known substrate of CYP2D6 (Caldwell, 1995; Narimatsu *et al*., 2003). Studies have shown bufuralol undergoes enantioselective and regioselective oxidation by CYP2D6 in extensive metabolizers, but not in poor metabolizers (Testa, 1986; Caldwell, 1995; Narimatsu *et al*., 2003; Masuda *et al*., 2006). Studies on substitution of phenylalanine by alanine at position 120 resulted in the elimination of substrate enantioselectivity of CYP2D6 (Masuda *et al*., 2006).

Oxazepam, a benzodiazepine receptor agonist, is metabolized primarily by hepatic glucuronidation. Oxazepam is formulated as a racemic preparation of *S*- and *R*-stereoisomers, although the *S*-enantiomer is thought to be much more active than its antipode. *S*-oxazepam has been shown to be stereoselectively glucuronidated by UGT2B15, whereas *R*-oxazepam is glucuronidated by multiple UGT isoforms. Studies have shown that *S*-oxazepam (but not *R*-oxazepam) is polymorphically glucuronidated in humans. A common genetic variation is seen in aspartate (UGT2B15*1) or tyrosine (UGT2B15*2) at position 85 of the UGT2B15 protein. Microsomes from human embryonic kidney (HEK)-293 cells overexpressing UGT2B15*1 showed five times higher *S*-oxazepam glucuronidation activity than did UGT2B15*2 microsomes (Court *et al*., 2002).

Human paraoxonase-1 (PON1), which belongs to the family of serum paraoxonases consisting of PON1, PON2 and PON3, has been extensively studied for protection from organophosphorus compound toxicity (Amitai *et al*., 2006; Yeung *et al*., 2008). Nerve agents such as cyclosarin and soman are racemic mixtures of two and four enantiomers, respectively. The stereoisomers of cyclosarin and soman differ significantly in their acetylcholinesterase (AChE)-inhibiting potency. This is mainly due to the preferential hydrolysis of wild-type PON1 of the less toxic stereoisomers P(+)-cyclosarin, and C(+)P(+)- and C(−)P(+)-soman enantiomers (Amitai *et al*., 2008). In humans, several polymorphisms of human PON1 are known to exist, which can have a substantial impact on PON1 activities (Yeung *et al*., 2008). In addition, variants of PON1 have been developed in recent years to increase catalytic efficiency of hydrolysis of the toxic stereoisomers of soman and cyclosarin, and other chemical warfare agents (Amitai *et al*., 2006; Amitai *et al*., 2008; Yeung *et al*., 2008).

The various stereochemical aspects of xenobiotic transformation of chiral drugs are the subject of extensive reviews by Vermeulen and Koppele (1993), Mayer and Testa (1994), Caldwell (1995), Cashman (1998; 2000), Mehvar *et al*. (2002), Vermeulen (2003), Wsol *et al*. (2004), Patel and Hutt (2004) and Brocks (2006).

4.2.4 Excretion

It should be noted that stereoselective appearance of enantiomers in the excreta may be reflective of stereoselectivity in the other dispositional pathways and may not necessarily be reflective of stereoselectivity of the excretion process itself. For the unbound drug, glomerular filtration across the kidney seldom shows enantioselectivity. However, transport proteins, such as P-glycoprotein, have been reported to be responsible for transporting drug molecules across canalicular cells and renal tubular cells, which could lead to enantioselective excretion (Lemma *et al*., 2006; Crettol *et al*., 2007). If any, in the majority of instances the selectivity is relatively modest, with enantiomeric ratios between 1.0 and 3.0. Often, it is only when carrier proteins are involved that enantioselectivity in the rates of filtration is observed (Patel and Hutt, 2004; Brocks, 2006).

5 ECOTOXICOLOGICAL CONSEQUENCES OF CHIRAL CONTAMINANTS

5.1 Chiral Agrochemicals

Generally, chiral agrochemicals are synthesized and supplied as racemic mixtures (**Table 2**). However, as with chiral drugs, the desired biological activity may be limited to individual enantiomers (Kurihara *et al*., 1997; Liu *et al*., 2005; Garrison, 2006). The percentage of chiral pesticides has increased from 19% in the 1980s to approximately 30.6% currently (Williams, 1996; Ulrich, 2007). Among these, pyrethroids and organophosphorus compounds are two of the most widely used pesticides worldwide (Amweg *et al*., 2006; Garrison, 2006; McCarthy *et al*., 2006; Scholz and Hopkins, 2006; Singh and Walker, 2006) (*see* **Toxicology of Pesticides**).

Physical and chemical processes in the environment (e.g. leaching, air–water exchange, sorption and other nonselective chemical reactions) do not usually differentiate between the enantiomers of the same compound. However, in biologically mediated processes enantioselective environmental attenuation has been observed in chiral legacy insecticides, chiral phenoxy

Table 2 Some well-known examples of chiral pesticides

	Number of enantiomers	Category
Pyrethroids		
cis-Bifenthrin	2	Insecticide
Permethrin	4	Insecticide
Fenvalerate	4	Insecticide
Cypermethrin	8	Insecticide
Cyfluthrin	8	Insecticide
Cyhalothrin	8	Insecticide
Organophosphorus		
Fonofos	2	Insecticide
Trichloronate	2	Insecticide
Leptophos	2	Insecticide
Profenofos	2	Insecticide
Methamidophos	2	Insecticide
Fenamiphos	2	Insecticide
Malathion	2	Insecticide
Acetamides		
Acetochlor		Herbicide
Metolachlor	4	Herbicide
Dimethenamid	4	Herbicide
Metalaxyl	2	Fungicide
Phenoxyalakanoic acids		
Dichlorprop	2	Herbicide
Mecoprop	2	Herbicide
Phenylpyrazole		
Fipronil	2	Insecticide
Organochlorine		
cis-Chlordane	2	Insecticide
trans-Chlordane	2	Insecticide
2,4′-DDT	2	Insecticide
2,4′-DDD	2	Insecticide
Hexachlorocyclohexane	2	Insecticide

herbicides and fungicides (Moller *et al*., 1994; Tanabe *et al*., 1996; Muller and Buser, 1997; Buser and Muller, 1998; Bidleman and Falconer, 1999; Lewis *et al*., 1999; Jarman *et al*., 2005; Garrison, 2006). Of the modern use insecticides, enantioselective degradation has been reported for a number chiral organophosphorus and pyrethroid insecticides (Garrison, 2004; Liu *et al*., 2005; Qin *et al*., 2006). In addition, isomer conversion or isomerization may also occur during enantioselective biodegradation, potentially influencing the activity and contributing to side effects of chiral pesticides in the environment (Muller and Buser, 1997; Jarman *et al*., 2005). Enantiomers of the same compound may also differ in their toxicity to target and nontarget species (Garrison, 2006). In most chiral pesticides only one of the two (or more) enantiomers is usually responsible for most, if not all, of its pesticidal activity. The other enantiomer(s), although inert to the target pest, end up as an undesirable chemical load to the environment and could be toxic to nontarget organisms.

Until recently, enantiomer-specific ecotoxicology studies have been lacking for most of the current-use chiral pesticides (*see* **Aquatic Toxicology: Concepts, Practice, New Directions**). Early experiments with rats have demonstrated that the (−)-*o*,*p*′-dichlorodiphenyltrichloroethane (DDT) enantiomer is a more active oestrogen mimic of the human oestrogen receptor in a yeast-based assay than the (+)-enantiomer (McBlain, 1987; Hoekstra *et al*., 2001). In the fish, Japanese medaka (*Oryzias latipes*), significant differences in the induction of the egg yolk precursor protein, vitellogenin, which is under oestrogen-receptor control, in adult male fish was reported for *cis*-bifenthrin enantiomers (Wang *et al*., 2007) (*see* **Endocrine Disruption in Toxic Responses**).

Enantioselectivity in acute toxicity to the aquatic invertebrate *Ceriodaphnia dubia* was also observed in fipronil, a phenyl-pyrazole broad-spectrum insecticide (Garrison, 2006). The (+)-enantiomer was found to be the more toxic component. Additionally, *in vitro* binding and functional assays with human oestrogen, androgen

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

or progesterone nuclear receptors, (−)-fipronil showed significantly higher androgen and progesterone activities than the corresponding (+) form (Konwick *et al*., 2005; Garrison, 2006).

Pyrethroids are highly toxic to fish and aquatic invertebrates due to the high affinity of pyrethroids to the molecular target in these species and/or significant differences in the pathways and rates of metabolism, from that in mammals (Bradbury and Coats, 1989; Chamberlain *et al*., 1998). Among the currently used pesticides, pyrethroids can have up to four to eight enantiomers resulting from multiple chiral centres, but only one or two enantiomers are responsible for the acute insecticidal activity (Kurihara and Miyamoto, 1998). For example, of the eight enantiomers in cypermethrin or cyfluthrin, only two (1*R*-3*R*-αS and 1*R*-3*S*-αS) have insecticidal activity, and the rest are mostly inert to the target organism (Naumann, 1990; Leicht *et al*., 1996). In *cis*-bifenthrin, only the 1*R*-*cis* enantiomer is biologically active, while the 1*S*-*cis* enantiomer is inactive (Naumann, 1990). Liu *et al*. (2005) reported large differences of up to 40-fold for acute toxicities of pyrethroid enantiomers to aquatic invertebrates, *Daphnia magna* and *Ceriodpahnia dubia*, indicating that aquatic toxicity is due to a specific enantiomer.

Similarly, chiral organophosphorus insecticides have been shown to stereoselectively inhibit cholinesterase enzymes. For example, acetylcholinesterase inhibition by the enantiomers and racemates of profenofos, fonofos and crotoxyphos was determined *in vivo* in aquatic invertebrates and fish, and also *in vitro*, with electric eel (*Electrophorus electricus*) (EE-AChE) and human recombinant (HR-AChE) acetylcholinesterases (Nillos *et al*., 2007). Variable sensitivity between acetylcholinesterase enzymes from different species, as well as variable magnitude of enantioselectivity in enzyme inhibition was observed. Similarly, the enantiomers of malathion were also enantioselective in their toxicity to anthropods (Garrison, 2004).

The stereoselective sulfoxidation of the organophosphate insecticide fenthion to (*R*)-(+)-fenthion sulfoxide by FMO represents a detoxification pathway. However, studies have also shown that subsequent oxidative desulfuration *in vivo*, could result in the bioactivation of (*R*)-(+)-fenthion sulfoxide to the significantly more potent acetylcholinesterase inhibitor, (*R*)-(+)-fenoxon sulfoxide (Gadepalli *et al*., 2007).

Enantioselective bioaccumulation is possible in a range of organisms in the environment (Buser and Muller, 1998; Bidleman and Falconer, 1999). For example, in almost all studies on α-hexachlorocyclohexane (α-HCH), the (+)-enantiomer was found to be more abundant in tissues of most aquatic organisms and mammals (Moller *et al*., 1994; Tanabe *et al*., 1996; Wiberg *et al*., 2000). This enantioselective bioaccumulation may have been a result of either greater accumulation rate of the (+) enantiomer, or faster metabolism of (−)-α-HCH, or both. In current-use pesticides, enantioselective bioaccumulation of fipronil has been observed in tissues of rainbow trout (*Oncorhynchus mykiss*) exposed to fipronil (Konwick *et al*., 2006). Significant selectivity was observed in the uptake of *cis*-bifenthrin enantiomers in the liver of Japanese medaka (Wang *et al*., 2007).

5.2 Chiral Pharmaceuticals in the Environment

Driven by advances in analytical techniques, the presence of pharmaceuticals in the environment is an issue that has received increasing attention from environmental scientists in recent years (Dietrich *et al*., 2002; Fent *et al*., 2006; Ankley *et al*., 2007; Daughton, 2007; Khetan and Collins, 2007; Stanley *et al*., 2007; Cooper *et al*., 2008). The occurrence of various classes of drugs has been reported in terrestrial and aquatic environments, particularly in Europe and North America (Bound *et al*., 2006; Ankley *et al*., 2007). While wastewater treatment could substantially reduce sewage concentration over time, it is not designed to completely remove these chemicals from the waste streams (Wong, 2006). Because these compounds have been designed to be biologically active, scientists began to question the consequences of exposure, particularly in nontarget organisms (Ankley *et al*., 2007; Stanley *et al*., 2007) (*see* **Toxicological Considerations for Pharmaceutical Products**).

Currently, knowledge of the ecotoxicological significance of pharmaceuticals in the environment is insufficient, even more so, the importance of stereochemistry in the environmental fate and effects of chiral drugs. As noted in this chapter, many of these pharmaceuticals are used as racemates. Studies on the occurrence of the chiral NSAID, ibuprofen, in surface waters and wastewater from water-treatment plants have shown high enantiomeric excess of the *S*-enantiomer (the pharmacologically active enantiomer) in wastewater influents (Buser *et al*., 1999). The same study showed similar enantiomeric excess in surface waters, although laboratory incubation of racemic ibuprofen with lake water indicated a more rapid dissipation, thus resulting in *R*-enantiomer excess after several days of exposure. Similarly, enantiomeric fractions (ratio of a single enantiomer concentration over the total concentration) of propranolol showed a nonracemic mixture following secondary wastewater treatment, indicating a biotransformation process occurring during treatment (Fono and Sedlak, 2005). More recently, Stanley *et al*. (2007) investigated the enantiomer-specific sublethal effects of the antidepressant, fluoxetine, in aquatic invertebrates and fish. Their findings indicated *S*-fluoxetine was more toxic to juvenile teleost fish (*Pimephales promelas*) in a short-term (seven days) survival and growth study. In contrast, in the same study, no significant difference was

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat031
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

observed between fluoxetine enantiomers to *D. magna* following a 21-day chronic exposure.

These studies suggest that enantiomers may have vastly different toxicological characteristics and may degrade at significantly different rates in the environment. Consequently, enantioselectivity in these processes may result in enhanced or reduced ecotoxicological risks that are not yet fully understood. The significance of enantioselective attenuation of chiral contaminants both in laboratory and field samples is of limited consequence if enantiomers of the same compound have comparable toxicity to nontarget organisms. The combined toxicity of the enantiomers in such case is expected to remain unchanged, and therefore changes in entiomeric ratios alone will not result in differential effects. Accordingly, if enantioselectivity only occurs in toxicity, but not in degradation, enantiomeric ratios would not be expected to change over time, so that environmental effects can be predicted from the racemate. It is therefore essential that enantioselective degradation studies are complemented with toxicity investigations in order to reduce uncertainty in the risk assessments of chiral contaminants (*see* **Risk Assessment of Chemicals**).

6 CONCLUSION

From molecules to humans, 'chirality' is a prominent feature of the living world, and also occurs in man-made chemicals, especially pharmaceuticals and agrochemicals. Thus, stereoselectivity can be expected in the interactions of chiral chemicals with biological macromolecules. In most chiral bioactive agents only one of the two (or more) enantiomers that comprise the chiral molecule is responsible for most or all the desired activity. The other enantiomer(s) is often assumed to be inactive 'isomeric ballast' of little or no activity. However, a significant number of enantiomer-specific toxicokinetic and toxicodynamic studies have shown that the 'inactive' enantiomer could be the stereoisomer that carries the toxic (side) effect.

The stereochemistry of a chemical should not be ignored when biomolecules (enzymes, carrier molecules, specific receptors and ion channels) are involved. As illustrated in the studies reviewed in this chapter, there are a number of possibilities that can occur when a racemic mixture interacts with a biological system, including: (i) only one of the enantiomers possesses all the desired activity, with the other enantiomer(s) biologically inert; (ii) both enantiomers have similar activities or (iii) the enantiomers have significantly different activities or different potencies. In addition, interindividual and interspecies sensitivity to the activity, as a result of difference in biotransformation enzymes, should also be considered when dealing with chiral compounds.

The last 30 years has seen a significant increase in published literature highlighting the important relationship between molecular geometry and bioactivity, particularly for chiral pharmaceuticals and agrochemicals. Nevertheless, a recent rough estimate of studies on popular chiral pharmaceuticals revealed that less than 100 publications on racemic drugs contain information on the chiral state of the drug or discussions on the consequences thereof (Waldeck, 2003). On average, that number accounts for $<3.0\%$ of the total number of published studies for any given drug. Although a similar evaluation is yet to be done, it is probably safe to assume a far more inferior publication record exists for pesticides and other chiral pollutants. However, as chiral agrochemicals become more prevalent in the market, the interest in these areas has exponentially increased in the last five years. However, there continues to be a significant lack of judiciousness when it comes to the need for properly identified stereochemical properties of these bioactive agents. The persistent reluctance to acknowledge the risks associated with the chirality of a chemical is no longer justified. Chiral technology has significantly developed to a point where we are allowed ample opportunities in enantiomer resolution and preparation techniques, which in turn offer new avenues for the pharmacologists and environmental toxicologists to explore the stereochemical properties of these ubiquitous agents.

The Influence of Temperature on Toxicity

Christopher J. Gordon and Pamela J. Rowsey

CONTENTS

1 INTRODUCTION

Why should temperature be considered as a significant factor in most toxicological studies? First, while body temperature of most mammals, including rodents, is normally stable over a wide range of ambient temperatures, altered regulation is seen upon exposure to toxicants, with the effects usually being more pronounced in rodents and other small mammals. Second, large mammals, such as humans, are able to regulate a stable core temperature following toxicant exposure, but environmental heat and cold stress will nonetheless exacerbate the physiological and behavioural responses to a toxicant. Third, by virtue of the stable nature of body temperature, any environmental perturbation or insult that changes temperature should be considered as a biologically significant event. Thus, one should look at temperature regulation as a hallmark of homoeostasis and consider the significance of temperature regulation as affected by a toxicant. To this end, one can use body temperature as a benchmark of toxicological exposure because a temperature change suggests a significant change in physiological homoeostasis. This chapter endeavours to explain the general effects of environmental toxicants on the thermoregulatory response of rodents and humans.

1.1 Thermoregulatory Profile

The toxicity of drugs, environmental contaminants and other chemicals is commonly evaluated in rats and mice. Their thermoregulatory response to toxic insults is pronounced, compared to that of humans and other large mammals. As will be discussed later, the increased thermal sensitivity of rodents is primarily attributed to their small size. Understanding the reasons behind their increased sensitivity requires an explanation of the rodent thermoregulatory profile (**Figure 1**). A thermoregulatory profile is an assessment of the effects of environmental temperature on the core and skin temperature, and activity of autonomic thermoeffectors. Measuring the activity of thermoeffectors; that is, metabolic rate (MR), evaporative water loss and skin blood flow (SkBF), over a range of ambient temperatures reveals a pattern of thermoeffector activity that is typical for rodents and other mammals (**Figure 1**). There is a range of ambient temperatures termed the *thermoneutral zone*, where MR is at or near basal levels. In this zone of ambient temperatures, temperature regulation is achieved by control of sensible heat loss without regulatory changes in MR or evaporative water loss. The control of body temperature in the thermoneutral zone is achieved with modulations in SkBF which controls the rate of heat loss with no additional metabolic requirements. As ambient temperature decreases below the thermoneutral zone, the

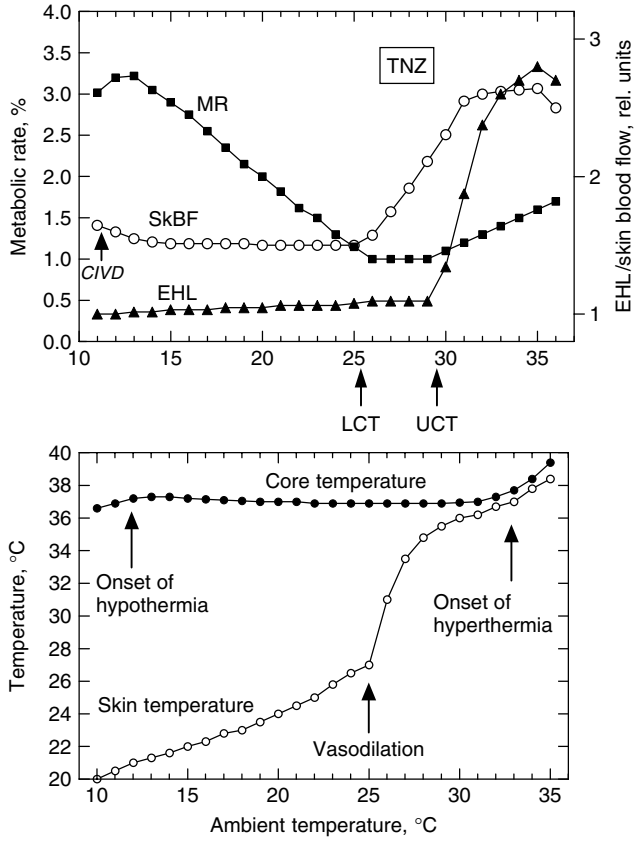

Figure 1 General pattern of core and skin temperature and activity of autonomic thermoeffectors as a function of ambient temperature in a homoeotherm. SkBF—skin blood flow, EHL—evaporative heat loss; MR—metabolic rate; LCT—lower critical temperature; UCT—upper critical temperature; TNZ—thermoneutral zone.

blood flow to the skin is minimized as a result of peripheral vasoconstriction. As ambient temperature decreases further, metabolism must increase above basal levels by shivering and nonshivering thermogenesis in order for heat production to match heat loss to the environment. The ambient temperature where MR increases is termed the *lower critical temperature* (LCT). As ambient temperature decreases below the LCT, skin temperature falls passively, but may increase with extreme cold exposure as a result of cold-induced vasodilation (CIVD) of the peripheral blood vessels. This is a protective response to keep exposed tissues from freezing. Eventually, a temperature is reached where MR cannot compensate for the heat loss and the core temperature decreases, leading eventually to hypothermic death.

As ambient temperature increases above the thermoneutral zone, SkBF increases and there is a disproportionate rise in skin temperature. However, if SkBF is maximal, skin temperature cannot increase above the internal core temperature. This means that as ambient temperature increases, the gradient between the skin and ambient temperature becomes smaller, thus limiting the rate of heat loss by convection, conduction and radiation. Hence, at temperatures above the thermoneutral zone, evaporative heat loss (EHL) mechanisms (i.e. panting, sweating, saliva grooming) must be activated to maintain thermal balance. This ambient temperature is termed the *upper critical temperature* (UCT). It is also identified with the point where core temperature and metabolism begin to rise (IUPS Thermal Commission, 2001). At around the point of the UCT, skin temperature has increased to a level that is just below core temperature, reflecting maximal redistribution of warm blood from the core to the periphery. With further increase in ambient temperature, skin and core temperature parallel each other until the point of thermoregulatory failure. At this point, evaporation is ineffective to maintain sufficient heat loss and core temperature spirals upward leading eventually to hyperthermic death.

1.2 Pharmacokinetic Modelling and Temperature

When studying the role of temperature on the efficacy of a drug or toxicant using *in vitro* or *in vivo* systems, thermal sensitivity is commonly expressed in terms of either the Q_{10} or the *temperature coefficient*. Q_{10} is defined as 'the ratio of the rate of a physiological process at a particular temperature to the rate at a temperature 10 °C lower, when the logarithm of the rate is an approximately linear function of temperature' and is calculated by the following equation (IUPS Thermal Commission, 2001):

$$Q_{10} = (R_2/R_1)^{10/(T_2-T_1)} \quad (1)$$

where R_1 = rate of activity at one temperature, T_1; and R_2 = rate of activity at another temperature, T_2.

Thus, a Q_{10} of two means that the activity doubles with each 10 °C elevation in temperature, a Q_{10} of three is tripling of activity, and so on. A Q_{10} of one means there is no change in activity with temperature and a Q_{10} of less than one means that activity increases with a reduction in temperature. The Q_{10} normally ranges between two and three for most biological processes. Comparative physiologists and toxicologists studying the effects of toxicants and drugs on the lower vertebrates and invertebrates often rely on Q_{10} to express the effects of temperature on physiological processes. Q_{10} varies with temperature, usually decreasing in magnitude with a progressive rise in temperature. Hence, it is essential to report the temperature range of its determination when reporting Q_{10} values (Cossins and Bowler, 1987).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat032
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The temperature coefficient is also a commonly used parameter to describe thermal sensitivity and interaction with drugs and toxicants and is defined as 'the ratio between the change in any temperature-dependant activity and the defined temperature range within which this change occurs' (IUPS Thermal Commission, 2001). In other words, the temperature coefficient is an expression of the change in activity of a process for a 1.0 °C change in temperature. Unlike the Q_{10} parameter, the temperature coefficient is either positive or negative, depending on how temperature affects the physiological process. Temperature coefficients are probably used more often than the Q_{10} value in studies on the effect of temperature on toxicological and pharmacological processes in birds and mammals. Like Q_{10}, temperature coefficient will also be dependent on the temperature range used in its calculation.

Temperature coefficients and/or Q_{10} values are critical in the development of physiologically based pharmacokinetic (PBPK) models. PBPK models are essential in toxicology and are used to predict the disposition and fate of a chemical and its physiological effects. PBPK modellers must factor temperature into their models because the temperature coefficient for all metabolic processes involved in the metabolic activation, deactivation and clearance of a toxicant will be a factor if the toxic agent affects body temperature. However, in addition to core temperature, there are other aspects of the thermoregulatory system that must be factored into PBPK models, including temperature acclimation and exercise. This was a popular area of research and is thoroughly reviewed in a paper by Ballard (1974).

We incorporate a basic PBPK model with a simple thermoregulatory model to show the potential interactions between core, skin and ambient temperature, and the efficacy of a toxicant (**Figure 2**). Homoeothermic organisms maintain a stable core temperature over a wide range of ambient thermal conditions. A stable core temperature is achieved with relatively large fluctuations in temperature of the peripheral tissues (skin and

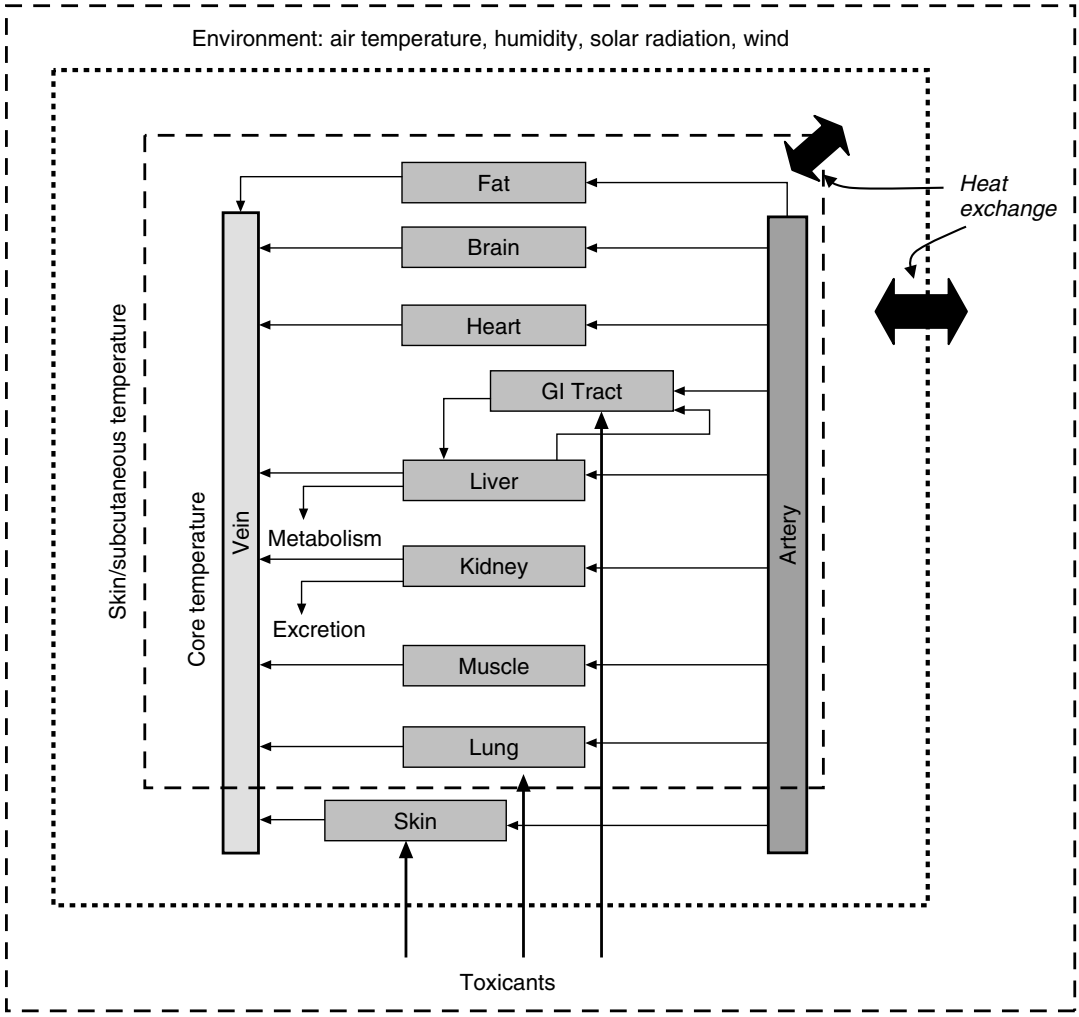

Figure 2 Combination of a simple pharmacodynamic/pharmacokinetic model and thermoregulatory model to demonstrate how core, peripheral and ambient thermal environments influence the kinetics and dynamics of toxicants (see Gordon, 2005).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat032

subcutaneous temperature) that are influenced by changes in ambient temperature, relative humidity, solar radiation and wind speed. Most components of a PBPK model are influenced by the core temperature, including brain, heart, gastrointestinal (GI) tract, liver, kidney, lung and skeletal muscle. If exposure to a toxicant changes core temperature, then the pharmacokinetics in these organ systems will be affected, depending on the temperature coefficients of each system. The temperature of the peripheral tissues is also critical because it may influence the uptake of certain toxicants. Warm temperatures raise skin temperature leading to an increase in SkBF and sweating, both of which encourage the transcutaneous absorption of organophosphate insecticides and nicotine from drug patches, and others (Gordon and Leon, 2005). For example, parathion absorption from the skin of humans increased by 180% when the ambient temperature of exposure was raised from 28 to 40.5 °C (Funckes *et al*., 1963). Although the lungs and GI tract are essentially surrounded by the *milieu* of the thermal core, their role in the intake of toxicant is also influenced by the ambient environment. The intake of an airborne toxicant will be dependent on minute ventilation which, in turn, is dependent on ambient temperature. Heat stress increases ventilation, resulting in greater intake of airborne toxicants, such as ozone (Mautz, 2003). Animals that pant to thermoregulate in the heat, such as dogs, sheep and other species, would be especially susceptible to this mode of action. Finally, the intake of toxicants in the GI tract can also be influenced by the thermoregulatory system. This can be pertinent in the study of wildlife species subjected to toxicant or natural toxins in their food supply. The increased energy demands in the winter mean greater intake of food that is tainted with toxic agents.

1.3 Forced and Regulated Changes in Temperature

It is important to understand whether a drug- or chemical-induced change in body temperature is forced or regulated (**Figure 3**). Normothermic body temperature can increase or decrease in a forced or regulated fashion. If the thermal response can be identified as being regulated, then one can be assured that the toxicant is affecting central nervous system (CNS) thermoregulatory mechanisms. A forced response could be mediated with or without activation of CNS pathways. An increase in the set-point temperature (T_{set}), as occurs with a fever, means there is a transient period where T_{set} is suddenly elevated above the core temperature (**Figure 3A**). That is, with an infection there is an inflammatory response and release of a variety of cytokines and other factors into the circulation. Cytokines such as IL-1 and IL-6 directly affect the CNS thermoregulatory centres in the hypothalamus resulting in an upward shift in the set-point. The animal responds as if it was cold and selects warmer ambient temperatures and activates thermoeffectors to increase heat production (shivering and nonshivering thermogenesis) and reduce heat loss (peripheral vasoconstriction).

Thermal physiologists view infectious fever as the cornerstone of a set-point elevation. Noninfectious agents can also increase the set-point and this phenomenon is also termed *regulated hyperthermia*. As the hyperthermic response progresses, there is eventually an equalling of T_{set} and core temperature and the animal reaches a steady state with an elevated body temperature. During *forced hyperthermia*, core temperature increases above T_{set}, as

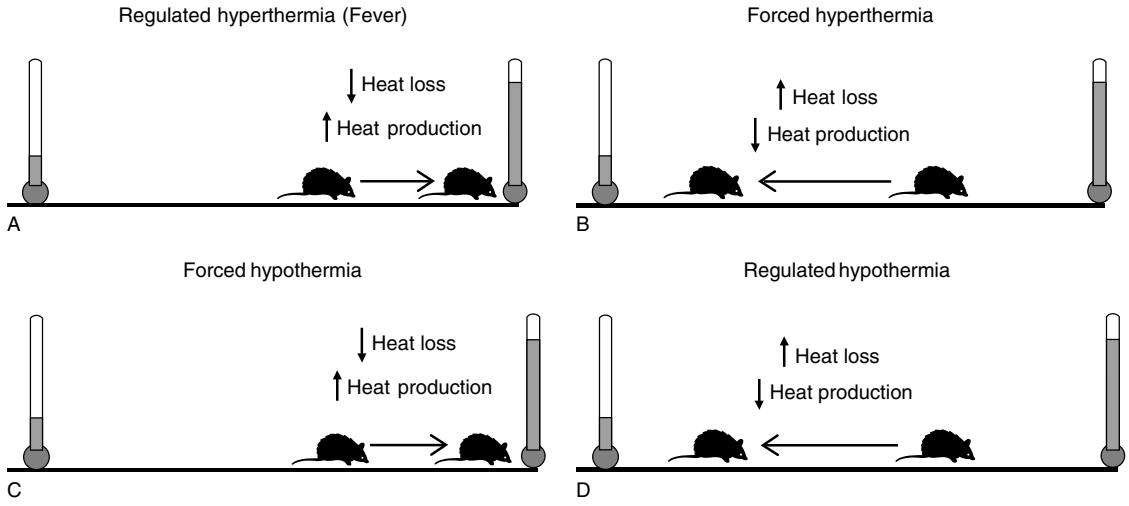

Figure 3 Summary of the possible thermoregulatory response to a toxicant or drug. A rodent under normothermic conditions prefers an ambient temperature in its thermoneutral zone (~30 °C). A chemical, pyrogen or other agent may affect the central control of thermoregulation or the ability for thermoeffectors to control body temperature leading to forced or regulated changes in core temperature. (Reproduced from Gordon, 1983. © Elsevier.)

would occur by exposure to high ambient temperatures or by administering toxicants or drugs that stimulate metabolic thermogenesis, but without affecting the CNS control mechanisms (**Figure 3B**). During forced hyperthermia, thermoeffectors are activated to reduce heat gain and increase heat loss to lower its core temperature. The animal seeks a colder environment to facilitate heat loss and lower body temperature to normal. *Forced hypothermia* refers to the state where core temperature is forced below T_{set}, as would occur during acute cold exposure or treatment with toxicants or drugs that impair metabolic thermogenesis, without affecting CNS control mechanisms (**Figure 3C**). The organism responds with an activation of thermoeffectors to minimize heat loss and increase heat production. A warmer environment is sought to reduce heat loss. *Regulated hypothermia* occurs when a chemical or drug causes a sudden lowering of T_{set} (**Figure 3D**). This is essentially opposite to that of a fever because the organism feels hot and responds by seeking cooler temperatures and activating thermoeffectors to increase heat loss and reduce heat production. These thermoeffector responses persist until T_c is equal to T_{set}, but at a lower body temperature. One also finds the term *anapyrexia* used to describe a pathological condition in which there is a regulated decrease in body temperature (IUPS Thermal Commission, 2001). Anapyrexia and regulated hypothermia are essentially the same, but we prefer the latter, especially in describing the responses to toxic agents.

1.4 Impact of Environmental Temperature on Toxic Response

Whether a toxicant will cause an increase, decrease or have no effect on body temperature will depend largely on the combined thermal environment of exposure (i.e. air temperature, relative humidity, wind speed and insulative quality of the cage and bedding material) and the animal's thermoregulatory response to the toxic agent (**Table 1**). The thermal environment of the test species should always be evaluated in any drug/toxicity study; however, this is often overlooked. Researchers not cognizant of thermoregulation often consider rats and mice to be poor thermoregulators. This is a misconception because untreated mice and rats are quite capable of defending a relatively constant body temperature over a wide range of ambient temperatures (for review, see Gordon, 1993b). This is done through the appropriate activation of thermoeffectors to increase heat production in the cold or activate heat loss mechanisms upon exposure to warm temperatures. When these effector responses are hampered by experimental manipulation (e.g. restraint) or by treatment with a drug or chemical that specifically targets one or more of the effector systems, then one will see marked changes in the rodent's body temperature.

The potential changes in temperature, indicated by the number of arrows in each block in **Table 1**, is dependent on whether the animal is housed in a cool, warm or thermoneutral environment. For example, a drug that blocks metabolic thermogenesis will manifest the most effective change in body temperature when exposure occurs at a relatively cool ambient temperature. A toxicant that induces peripheral vasoconstriction, thus restricting blood flow and heat loss from the skin will have relatively minor effects in a cold environment because the animal is in a state of peripheral vasoconstriction, but would lead to hyperthermia in a thermoneutral and warm environment. On the other hand, an agent that causes peripheral vasodilation would be mostly ineffective in a warm environment because SkBF is already elevated and an additional vasodilatory action should have little effect on total heat loss. Blocking salivation in rodents or sweating in humans would have little effect in the cold, but would lead to dramatic hyperthermia if the blocking agents are administered in a warm environment.

If the toxicant impairs one thermoeffector without affecting CNS thermoregulatory control, then one would expect the animal to utilize other thermoeffectors to maintain thermal homoeostasis. For example, if SkBF was elevated in a cold environment, then metabolic thermogenesis could increase to counter for the increased heat loss. Stimulation of metabolism in a warm environment, such as occurs by exposure to chemical agents that uncouple oxidative phosphorylation, is accompanied by a marked increase in evaporation (Wood *et al*., 1983). Overall, these are idealized situations and drugs and toxicants generally affect the function of more than one thermoeffector system.

Table 1 Relative hyperthermic (↑) and hypothermic effects (↓) of a toxicant or drug that stimulates or blocks thermoeffectors at cool, thermoneutral and warm ambient temperature. Number of arrows indicates relative magnitude of change in core temperature[a]

	Thermogenesis increased	Skin blood flow increased	Evaporation increased	Thermogenesis blocked	Skin blood flow blocked	Evaporation blocked
Cool temperature	↑	↓↓	↓	↓↓↓↓	—	—
Thermoneutral temperature	↑↑↑	↓	—	↓↓	↑↑↑	↑
Warm temperature	↑↑↑↑	—	—	↓	↑↑↑↑	↑↑↑↑

1.5 Acute Thermoregulatory Responses

There is an extensive database on the acute effects of drugs and chemicals on the body temperature of rodents and other species (Clark and Lipton, 1985a; 1985b). In test batteries that screen for toxicants, body temperature is frequently used as a benchmark of overt toxicity (Moser, 1995; Tamborini *et al*., 1990). A decrease in body temperature in a test species is considered a significant sign of acute toxicity, placed in the same class of sequelae as body weight loss, decreased appetite and reduced motor activity. There is often a problem with the manner in which body temperature is measured in rodents. Most studies rely on hand-held probes to measure the colonic or rectal temperature of animals that are extensively handled and manipulated. In many of these studies, one finds the so-called baseline core temperature of the control rats to be at least 38 °C, a value which is at least 1 °C above the rat's normal daytime temperature. This hyperthermic response obviates any subtle effects that a toxicant at low doses would have on body temperature and limits the usefulness of body temperature as a sensitive indicator of toxicity. Radiotelemetry provides the best means of monitoring the core temperature of undisturbed animals (Gordon *et al*., 2008). Recently, a set of recommendations was developed for researchers studying the effects of drugs and toxicants on the thermoregulatory system (**Table 2**). Overall, the best assessment of the effects of a toxicant on thermoregulation is made in undisturbed animals monitored remotely with telemetry. Restraint or repeated insertion of a temperature probe are the least desired methods because of the stress-induced changes in body temperature.

In the study of the acute effects of drugs and chemicals on thermoregulation, one needs to first understand

Table 2 Recommendations for rodent thermometry in toxicology studies, starting with the most ideal and ending with least ideal method[a]

1. Radiotelemetry. Monitoring of a temperature probe surgically implanted in a thermal core of the animal (abdomen, brain). Remote monitoring of animals housed in a vivarium isolated from disturbances from personnel. Maintenance of animals in a thermoneutral environment and/or with bedding that allows animals to adjust insulative qualities of microenvironment.
Disadvantages: Expensive start up costs; surgical implantation with anaesthesia required.
Advantages: provides best measure of true thermoregulatory patterns of mice and rats; continuous, automated monitoring of core temperature 24 hours/day. Allows for observations of acute, subchronic and chronic effects of drugs and toxicants.

2. Subcutaneous transponder ID chip. ID chips implanted under skin with trocar.
Advantages: less costly than telemetry; accurate measure of the subcutaneous temperature; no surgery or anaesthesia required.
Disadvantages: subcutaneous temperature is not a measure of the core temperature; personnel must be close proximity to animal to position receiver to collect temperature data. Data collection not automated; no 24 hour monitoring.

3. Infrared thermography
Advantages: provides noncontact measurement of skin temperature which can be valuable for interpreting effects of toxicants and drugs. Hand held devices relatively inexpensive.
Disadvantages: skin temperature does not provide any indication of core temperature; continuous, automated monitoring is costly. Personnel must be in close proximity to animal.

4. Colonic/rectal temperature probes (unrestrained rodents). Used on single housed animals undisturbed immediately prior to measurement.
Advantages: inexpensive and easy to perform; provides an accurate, single time-point measurement of the core temperature provided animal is undisturbed prior to probe insertion.
Disadvantages: Technique evokes stress resulting in change in body temperature; repeated use of device leads to inaccurate estimates of the core temperature due to stress. Difficult to use with multiple housed animals because disturbance causes stress and elevation in temperature as multiple animals are being measured.

5. Colonic/rectal temperature probes in semi-restrained animals (e.g. probe inserted and taped to tail)
Advantages: inexpensive, accurate measure of core temperature
Disadvantages: continuous stress of probe insertion leads to abnormally high body temperatures in rats. Animals must be restrained or carefully observed to assure probe remains in place.

6. Restraint with colonic probe
Advantages: Restrained animal easy to manipulate (i.e. nose only inhalation).
Disadvantages: Marked effects on thermoregulatory system. Rodents are much more sensitive to ambient temperature when restrained. Unable to use behaviour and thermoeffectors as effectively when restrained.

if the effect is forced or regulated, then consider how ambient temperature will impact the response (Gordon, 1983). The effects of changes in ambient temperature on the toxicity of a chemical could be diametrically opposed depending on whether the body temperature change is forced or regulated. That is, many toxicologists and pharmacologists are cognizant of the temperature-dependency and attempt to apply corrective measures to maintain a consistent thermal environment within the test subject. In many cases, the hypothermic effect of an agent is blocked by raising ambient temperature or by placing the animal on a heating pad. However, if the chemical is eliciting a regulated hypothermia, then raising ambient temperature and preventing the development of hypothermia is, in fact, more stressful. If the chemical simply impairs thermoeffectors that increase heat production, then raising ambient temperature will be beneficial.

Measuring core temperature alone is not sufficient to decide if the chemical is eliciting a forced or regulated change in temperature. Performing a thermoregulatory profile in a rodent exposed to a toxicant (e.g. **Figure 1**), can help elucidate if the change in body temperature is forced or regulated. For example, an increase in tail SkBF and a reduction in MR in a cold environment would suggest a CNS drive to lower core temperature. In fact, behavioural thermoregulation measured concomitant with core temperature is usually sufficient information to distinguish between forced and regulated changes in core temperature. Behavioural thermoregulation in rodents is measured using a temperature gradient or operant system. Temperature gradients mimic a natural type of option for the animal to seek out its optimum thermal environment with little energy expenditure. This can be important if the toxicant impairs motor activity. Moreover, thermoregulatory behaviour in a gradient can be learned quickly. Operant systems are also useful in toxicology studies because the animals can be instrumented easily to monitor physiological processes while quantifying its behaviour. However, considerable training is needed for animals to learn to use thermoregulatory behaviour in an operant system and the animal must continually work to maintain thermal reinforcements.

Our laboratory and others have used the temperature gradient to monitor telemetered rats and mice while dosed with toxic chemicals. The time-course of selected ambient temperature and core temperature in the rat monitored by telemetry exemplifies the regulated hypothermic response induced by administration of chlorpyrifos, an anti-choline esterase (ChE)-based insecticide (**Figure 4A**). When dosed with a control vehicle (corn oil), there was a transient decrease in selected temperature that reflects a heat dissipatory response from the stress of handling and injection. When dosed with chlorpyrifos, selected ambient temperature decreased from 30 to 25 °C and the behavioural response preceded a 2.5 °C decrease in core temperature (**Figure 4B**). At the nadir of the decrease in core temperature, selected temperature increased rapidly, a response that facilitated the recovery of core temperature. It is important to note that the rat has the option of selecting ambient temperatures as warm as 36 °C in the gradient. If the rat simply moved to a temperature range that was slightly above the thermoneutral zone, the hypothermic effects of chlorpyrifos would have been blocked. Administration of the organophosphate diisopropyl fluorophosphate (DFP) also induced an abrupt selection for cooler temperatures that occurred concomitantly with a decrease in core temperature (Gordon, 1994; 1997).

There are innumerable studies showing that acute exposure to toxic chemicals elicits hypothermia in mice and rats. A small number of studies have used techniques to measure autonomic and/or behavioural thermoeffectors to determine the nature of the hypothermic response and have shown that the hypothermia is regulated. Mice or rats placed in a temperature gradient and given toxic doses of heavy metals (nickel, cadmium, lead), solvents (ethanol, sulfolane) and antiChEs (chlorpyrifos, DFP) will consistently prefer cooler ambient temperatures as they become hypothermic (for review, see Gordon, 2005; Gordon *et al*., 1988b). So far, there is no report that an animal will select a warm temperature to block the acute hypothermic effects of the toxicant. It follows that the majority of toxic agents studied in mouse and rat that elicit hypothermia are likely evoking a regulated hypothermia. The hypothermic response is generally an adaptive response that improves survival with the toxicant (see section 1.8)

The best understood mechanism of action of regulated hypothermia has been documented with antiChE-based agents. The stimulation of CNS muscarinic pathways appears to be a primary cause of the acute hypothermic response elicited by antiChE insecticides. At high levels of stimulation of the muscarinic pathways in the thermoregulatory centres, the heat loss pathway is stimulated, meaning that the animal reacts as if it is hot and attempts to lower core temperature by increasing SkBF and selecting cooler ambient temperatures. Coadministration of muscarinic antagonists such as scopolamine or atropine blocks most of the hypothermic response elicited by antiChE agents (Gordon and Grantham, 1999; Maickel *et al*., 1991). The mechanism of action for other toxicants is not understood. How toxicants with a diversity of structures elicit a similar hypothermia response is not known. There may be common modes of action derived in peripheral tissues that drive the CNS thermoregulatory responses.

1.6 Thermoregulatory Effects of Alcohol

Special attention is given to the thermoregulatory effects of alcohol (ethanol). The toxicity of alcohol on the

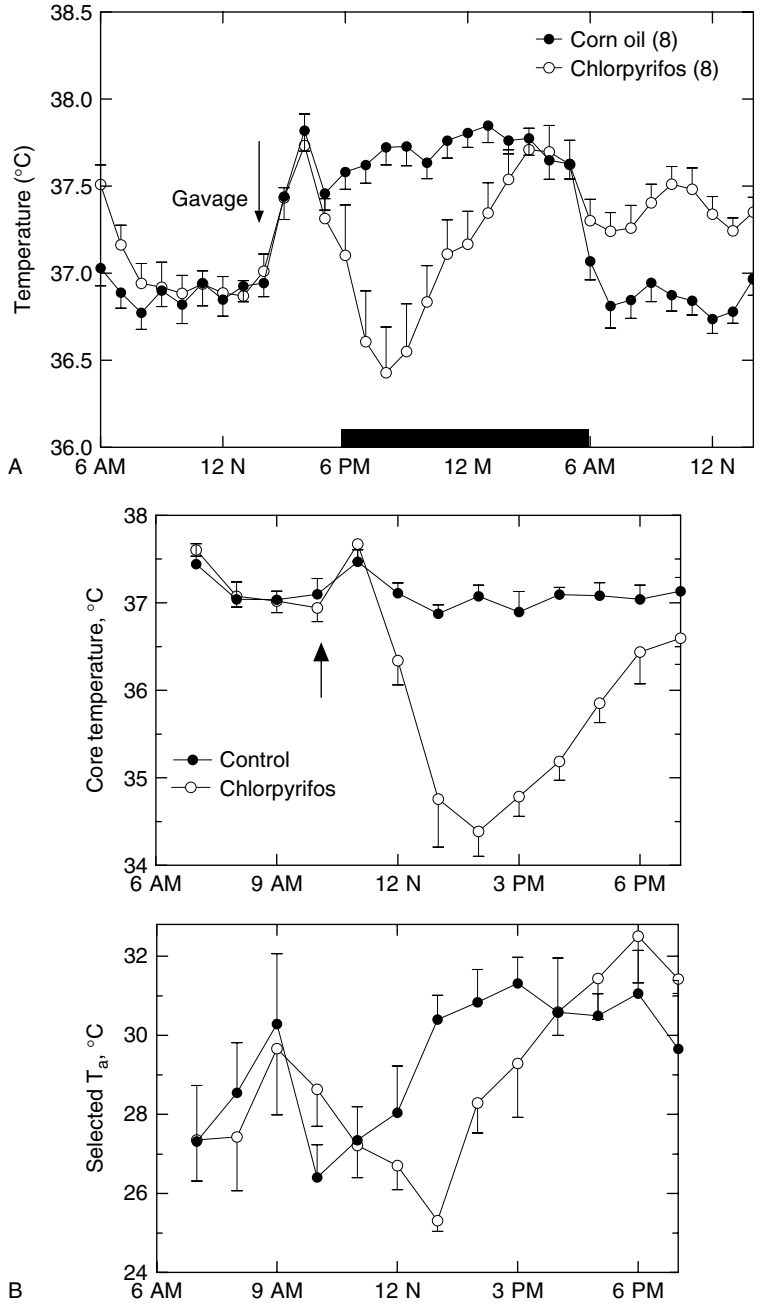

Figure 4 (A) Time-course of core temperature in female Sprague–Dawley rats given chlorpyrifos (from Rowsey *et al*., 2003). (B) Behavioural thermoregulatory response of female Long–Evans rats dosed with chlorpyrifos and housed in a temperature gradient to monitor selected ambient temperature and core temperature. (Reproduced from Gordon, 1997. © Elsevier.)

thermoregulatory system is well understood compared to any other toxicant. Hence, alcohol is an ideal agent to study in the extrapolation of thermoregulatory responses of toxicants from small to large species. It was well known that acute exposure to alcohol via an oral, inhalation or parenteral route elicits hypothermia in rats and mice housed at standard laboratory temperatures (~22 °C) (for a review, see Kalent and Le, 1984; Gordon, 2005). The hypothermic effects of alcohol are ambient-temperature-dependent and hyperthermia is elicited in rats and mice exposed to alcohol at ambient temperatures above their thermoneutral zone. In view of this response, Myers (1981) termed the thermoregulatory response of alcohol in the rat a 'poikilothermic' response, meaning that with acute intoxication, the rat's thermoregulatory system becomes dependent on the prevailing ambient temperature. In other words, alcohol intoxication reduces thermal homoeostasis to a condition normally

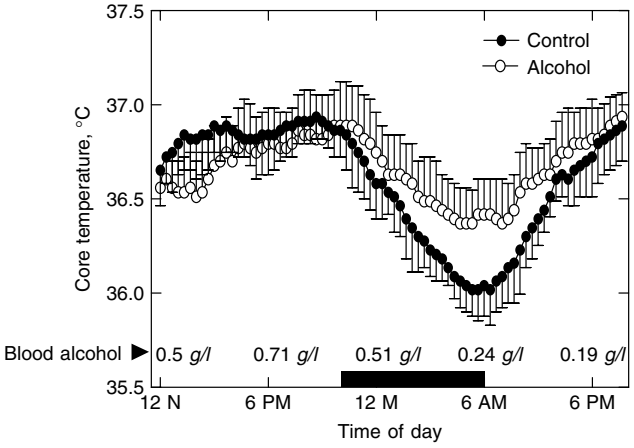

Figure 5 Circadian profile of core temperature of nine healthy men given a control fluid or 256 g of alcohol administered regularly over a 26 hour period. Note significant hyperthermic effect of ethanol only during the night. Also note transient hypothermia at start of alcohol exposure. Blood alcohol levels measured at selected hours is given in italics. (Data modified from Danel *et al*., 2001.)

observed in most of the so-called lower vertebrate (reptiles, amphibians, fish) that have little autonomic control of thermoregulation.

Poikilothermic species do have behavioural control of their body temperature and can regulate a relatively stable core temperature when housed in an environment that allows for behavioural thermoregulation. The same is true for rats and mice exposed to alcohol and given a choice of selecting from a range of ambient temperatures. Studies in our laboratory and others showed that when rats and mice were dosed with alcohol and allowed to behaviourally thermoregulate, they selected cooler ambient temperatures concomitant with a reduction in body temperature (Gordon and Stead, 1986; Gordon *et al*., 1988a; O'Connor *et al*., 1989; Briese and Hernandez, 1996). Thus, alcohol, like many other toxicants, evokes an apparent regulated hypothermia in rodents. Lomax (1980) postulated that alcohol elicited a reduction in T_{set} since they noted that rats dosed with alcohol became hypothermic and avoided a heat source.

Under standard laboratory conditions, a small hypothermic response can be elicited in humans who consume moderate doses of alcohol (**Figure 5**). As discussed later, a large body mass is a key factor in limiting the hypothermic response to toxicants and drugs. Thus, the marked hypothermic response seen in small laboratory rodents will be relatively meagre in healthy adult humans. On the other hand, there are emergency room reports showing marked hypothermia in some instances. These cases arise from acute intoxication of individuals in poor health combined with exposure to cold temperatures.

Measuring autonomic and behavioural thermoeffectors in humans dosed with alcohol under controlled conditions provides evidence of a regulated hypothermic response. Yoda *et al*. (2005) maintained human subjects at a warm ambient temperature of 33 °C (i.e. just above their thermoneutral temperature) while measuring SkBF, sweating and core temperature. Following a moderate amount of alcohol consumption (0.36 g kg^{-1}), the subjects had a feeling of warmth and this was accompanied by an increase in sweating and SkBF. With the onset of thermoeffectors to increase heat loss, core temperature fell by 0.3 °C. Following the principles outlined in **Table 1**, by maintaining the subjects at a warm ambient temperature, the effects of alcohol on sweating and SkBF should be easier to activate. That is, if alcohol activates a regulated hypothermic response then this response should be more profound if the subjects are housed in a warm environment. Overall, humans respond to alcohol with autonomic responses to increase heat loss. Moreover, the sensation of a feeling of warmth following moderate alcohol consumption should lead to a selection of a cooler ambient temperature. These responses are homologous to that of rodents with the exception that the hypothermia is miniscule in human subjects.

1.7 Toxic Chemicals Eliciting Hyperthermia

There are three classes of toxic chemicals that induce marked hyperthermia in laboratory rodents: dichlorodiphenyltrichloroethane (DDT), 2,4-dinitrophenol (DNP) and certain pyrethroids. DDT is an organochlorine that was well studied for its thermoregulatory and other effects prior to being banned. It is tremorigenic and a convulsant and is one of the few pesticides that can elicit an acute and apparently lethal increase in the core temperature (Hudson *et al*., 1985). The thermoregulatory effects of DDT are dependent on ambient temperature. When given a lethal dose (LD) of DDT (1000 mg kg^{-1}) and housed at 22 °C, tail skin temperature of the adult rat begins to increase prior to any change in core temperature by 3–5 hours after injection (Woolley, 1973). There is then a precipitous decrease in tail skin temperature that is concomitant with a marked increase in core temperature. At the point of death, around 6 hours after dosing, core temperature is 40–42 °C while tail skin temperature is nearly below pretreatment levels. It is interesting to note that if the DDT-treated rat is placed in a cold room maintained at 3–4 °C, core temperature will fall dramatically, reaching near hypothermic lethal levels within a few hours (Woolley, 1973). Hence, in spite of the intense tremorigenic activity of this agent, DDT-treated rats in the cold are unable to thermoregulate against a cold stress that is well tolerated by untreated rats. As with

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat032
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

other tremorigenic compounds, such as kepone, the heat from tremor in rats dosed with DDT appears to contribute little to the overall heat balance of the rat.

DNP is a classic uncoupling agent of oxidative phosphorylation and elicits a marked elevation in whole-body oxygen consumption. It is interesting to find that there is so little known about the thermoregulatory mechanisms of DNP in spite of the long history of its use as a herbicide (Takehiro *et al*., 1979). Intravenous infusion of DNP in the awake rat caused a near instantaneous elevation in MR, ventilatory frequency and minute ventilation concomitant with a steady rise in body temperature. The MR of the rat was increased from 34 to 51 ml kg^{-1} min^{-1} following repeated intravenous injections of DNP, with a total dose of 24 mg kg^{-1} in rats maintained at a cold ambient temperature of 15 °C. The increase in MR was associated with a 1.1 °C increase in core temperature. Pentachlorophenols (PCPs) have antifungal properties and have been used for many years as a wood preservative, and also uncouple oxidative phosphorylation. Human exposures in the timber industry are common with cutaneous and inhalation routes. Dangerous, prolonged elevations in core temperature, accompanied with profuse sweating have been reported in workers subjected to acute PCP exposure. For example, a 22-year-old male exposed to PCP on the work site was admitted to the emergency room with a core temperature of 41.8 °C; within 22 hours core temperature had increased to 42.2 °C and the subject died (Wood *et al*., 1983). One finds that the hyperthermia in these studies is termed 'fever' or 'hyperpyrexia'. However, assuming that the CNS control of body temperature is unaffected by PCP, then it can be assumed that the rise in core temperature is essentially a forced hyperthermia and not a true fever (see **Figure 3**).

The pyrethroid-based insecticides are widely used in domestic and agricultural applications, but there is surprisingly little information on their effects on thermoregulation. Pyrethoids are generally classified as Type I or Type II, depending on their neurophysiological and behaviour effects (see Ray and Fry, 2006 for summary). Type I pyrethroids keep sodium channels open momentarily (i.e. milliseconds), whereas Type II agents keep channels in an open state for minutes. In general, Type I pyrethroids elicit hyperthermic responses whereas Type II elicit hypothermia. However, the hypothermia elicited by Type II pyrethroids occurs at relatively high doses. For example, in rats monitored by radiotelemetry, the thermoregulatory response to deltamethrin, a commonly studied Type II agent, shows a biphasic response of hyperthermia at low doses and hypothermia at high doses (**Figure 6**). In spite of all that is known on

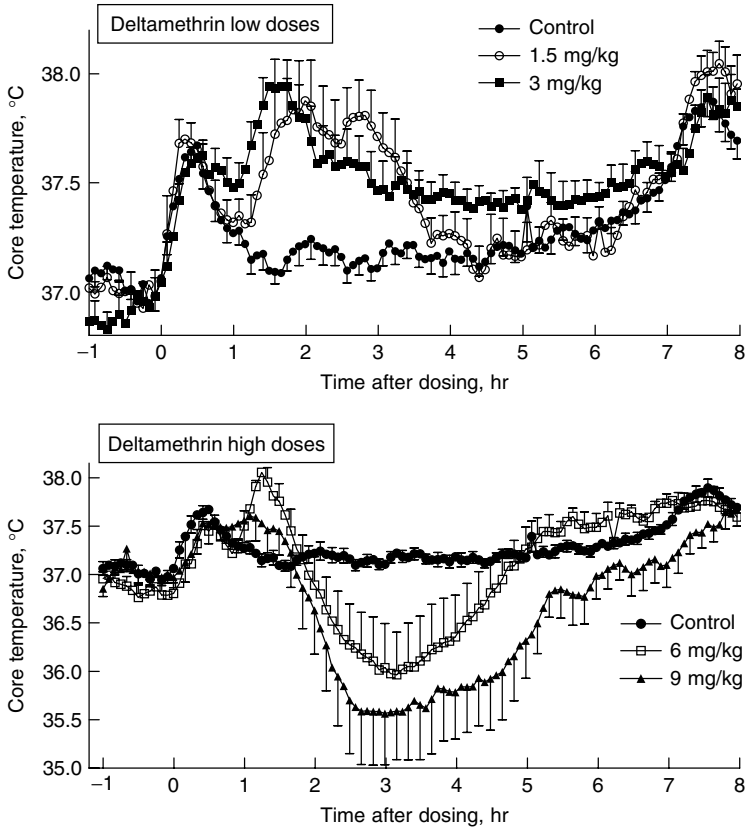

Figure 6 Time course of core temperature of rats monitored by radiotelemetry and administered deltamethrin by oral gavage. (Data from Wolansky *et al*., 2007.)

the neural mechanisms of pyrethroid toxicity, there is no understanding of how certain classes and doses of pyrethroids elicit hypothermic or hyperthermic responses in the rat.

1.8 Advantages of a Hypothermic Response

The direct effects of body temperature on the toxicity of drugs and toxic chemicals were recognized well over 100 years ago (for review, see Fuhrman, 1946). Prior to the development of modern analytical methods, frogs were often used as a species for bioassays of drugs and other chemicals. Because body temperature of frogs and other poikilotherms is directly dependent on ambient temperature, it was quickly determined in these early studies that body temperature had a marked effect on pharmacokinetics of drugs and toxicants. For example, studies in the 1890s on the toxicity of colchicines showed that the frog was 400–500 times as sensitive when dosed at an ambient temperature of 32 °C as compared to 20 °C. Toxicity studies in amphibians maintained at different temperatures led to a general conclusion for cholchicine that '. . . the temperature of the body is the chief factor influencing toxicity' (Fuhrman, 1946). The LD (e.g. LD_{50}) has conventionally been used in rodent studies as a benchmark of toxicity. While tests using death as an end point are rarely used in current research studies, these older studies are very useful for illustrating how overt toxicity is affected by body and ambient temperature. Keplinger *et al*. (1959) was one of the first to perform a systematic analysis of the LD of a variety of drugs and chemicals in the rat. The approximate LD of 58 compounds was determined in rats housed for 45 minutes before and 72 hours after dosing at environmental temperatures of 8, 26 and 36 °C. When compared to a temperature of 26 °C (i.e. slightly below the rat's thermoneutral zone) the LD was consistently lowered for all compounds administered to rats at an ambient temperature of 36 °C. In the selected examples in **Figure 7**, the percent lethality in mice administered given doses of toxicants and maintained at different ambient temperatures is plotted. In all cases, the incidence of lethality increases when the mice are maintained at warm temperatures that block their ability to become hypothermic. It is interesting to note the consistent effect of higher environmental temperatures on chemical lethality in spite of marked differences in the chemical's mechanism of action. For example, in rats, DDT causes tremor and hyperthermia and would be expected to be more toxic at higher temperatures by inducing hyperthermic death. On the other hand, many other agents that normally induce hypothermia such as ethanol, toluene and chlorpromazine at 26 °C are nonetheless more toxic in the heat (Keplinger *et al*., 1959).

1.9 Magnitude and Duration of a Toxicological Response

The physiological response or sensitivity to a drug would be expected to depend on both the tissue concentration (or magnitude) and length of time that the toxicant

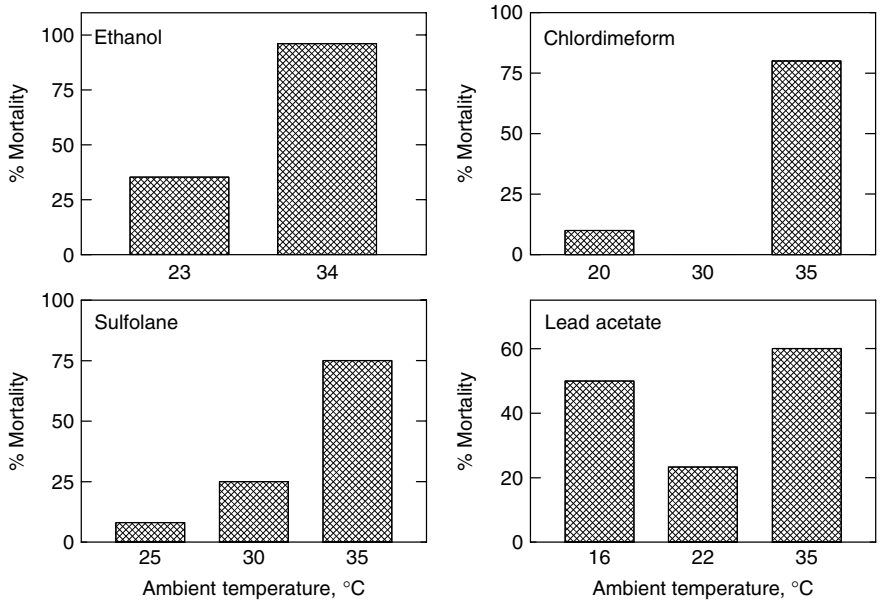

Figure 7 Effects of ambient temperature on lethality of various toxicants administered to mice. (Details from studies reviewed by Gordon, 2005.)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat032
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

persists in the body (Doull, 1972). In most cases, hypothermia is going to prolong the duration, but reduce the magnitude of toxicity. That is, when body temperature is lowered, the mechanism(s) responsible for metabolizing and excreting the toxicants are going to be depressed because the temperature coefficients for these processes are positively affected by temperature. Doull (1972) developed a general prediction of the response of biological systems to toxic levels of drugs that can also be applied to xenobiotic agents, 'Temperature is directly correlated with the magnitude and inversely correlated with duration of drug response in biological systems'. In other words, while the concentration of a toxicant will persist longer during hypothermia, the toxicity of the agent is reduced.

This tenet of Doull's was stated over 30 years ago and remains a critical issue in toxicology and pharmacology. The thermoregulatory system of mice and rats can respond rapidly with a hypothermic or hyperthermic response. These integrated thermoregulatory responses will have a marked impact on the pharmacokinetics and overall toxicity of the chemical or drug. Larger mammals, such as humans, do not sustain the changes in body temperature, as is seen with rodents. Thus, PBPK modellers who develop predictions based on data collected in laboratory rodents should consider how the potential thermoregulatory responses in the smaller species should be extrapolated to larger species.

The clearance of ethanol in mice maintained at different ambient temperatures illustrates the magnitude vs. duration principle of Doull (1972) (**Figure 8**). Ethanol elicits a marked hypothermic response in mice, but the magnitude of hypothermia can be modulated by altering ambient temperature. After an acute dose of ethanol and housing the mice at ambient temperatures of 4–35 °C, it was shown that the clearance of ethanol was directly affected by the core and ambient temperature. Mice housed at 22 °C became hypothermic with a core temperature of 35 °C and their ethanol elimination rate was 0.012 mg ml min^{-1}. When ambient temperature was raised to 35 °C, the hypothermic effect of ethanol was essentially blocked and the clearance of ethanol increased by 30%. Body temperature influences the rate of ethanol elimination, presumably through the thermal modulation of alcohol dehydrogenase activity in the liver (Romm and Collins, 1987; Bejanian *et al*., 1990). Hence, a warmer core temperature allows for a rapid clearance of the drug, but this is also associated with increased mortality (see **Figure 7**). Overall, hypothermia from alcohol exposure delays the clearance of the drug, but reduces its overall toxicity.

1.10 Delayed and Chronic Effects

Radiotelemetric monitoring of undisturbed rodents has provided valuable information on the delayed and chronic effects of toxicants on the thermoregulatory system. The stress of repeated handling and insertion of colonic probes in rats and mice tends to obviate any subtle effects of a toxicant on thermoregulation. Gallaher and Egner (1987) first used radiotelemetry to document a delayed hyperthermic response to acute ethanol exposure in rats. That is, following recovery of the hypothermic effects of ethanol at doses of 4–6 g kg^{-1}, there was a prolonged elevation in core temperature the day after dosing. In the time course of core temperature of humans dosed for several hours with alcohol (**Figure 5**), a delayed rise in core temperature is observed, similar to that observed in rodents exposed acutely to alcohol.

Our laboratory first showed a similar response to an organophosphate, DFP (Gordon, 1993a). The acute hypothermic effects of DFP in rats and mice were well characterized (Gordon, 1994). We found that the DFP-exposed rat maintained an elevated core temperature during the day for at least 48 hours after exposure. This delayed elevation in body temperature has been

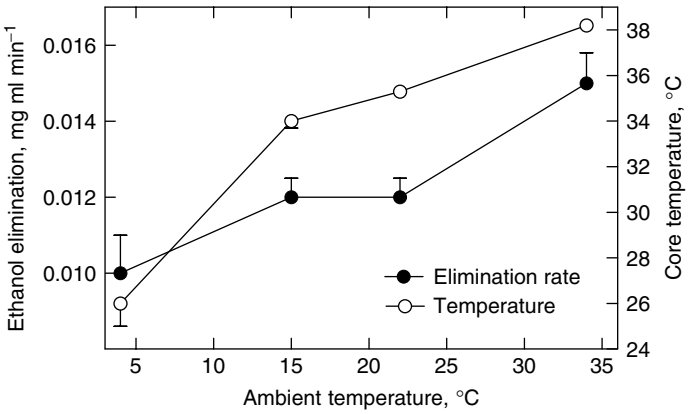

Figure 8 Effect of body temperature on the clearance of ethanol in mice. Ethanol-induced hypothermia was modulated by maintaining mice at different ambient temperatures. (Reproduced from Bejanian *et al*., 1990. © Elsevier.)

shown in rats dosed with organophosphate-based insecticides chlorpyrifos and diazinon, and carbaryl, a carbamate-based insecticide (Gordon and Mack, 2003). The elevation in core temperature is manifested during the daytime of the rat's circadian rhythm, corresponding with the time when core temperature is normally at its lowest point (see **Figure 4A**). This is a typical pattern in rodents subjected to infectious fevers (for discussion, see Gordon, 2005). In addition, the delayed rise in core temperature following exposure to an organophosphate is probably not a rebound from the acute period of hypothermia. Blocking the hypothermic response by maintaining the rats at thermoneutral ambient temperature has no effect on the development of the hyperthermic response to chlorpyrifos (Gordon, 1997). Moreover, the rise in temperature is blocked by administration of an antipyretic, suggesting that the temperature rise is akin to a fever and is mediated by activation of the cyclooxygenase pathway (Gordon *et al*., 1997; Gordon and Mack, 2003).

1.11 Human Responses

It is important to consider the differences in body size, surface area : mass ratio and MR when extrapolating toxicological effects from rodent to human. As discussed earlier for alcohol, the magnitude of the acute hypothermic response to toxicants and drugs that is observed in laboratory rodents is generally not seen in adult humans and other large mammals. In fact, a hyperthermic response is commonly seen in humans subjected to antiChE insecticides, metal fumes and a variety of other toxicants (Gordon, 2005; Saadeh *et al*., 1996; Namba *et al*., 1971). The hyperthermic response may be regulated, being similar to a fever, or it may be a forced elevation in core temperature. Humans exposed acutely to organophosphate insecticides can exhibit an elevated temperature that persists for days, suggesting that it is regulated.

As body size increases, the surface area : body mass ratio decreases, thus limiting the ability to dissipate heat. For example, a 30 g mouse has approximately 17 times the surface area : body mass ratio as compared to an adult 80 kg human. Hence, there are physical limitations to dissipate heat normalized per unit body weight with increasing body size. Rodents dissipate heat faster and have the ability to quickly lower core temperature in response to toxicant exposure. The thermal inertia of a large mammal, such as a human impedes the ability to lower core temperature in a rapid manner.

It appears that rodent models of thermoregulation are reasonable predictors of human responses provided that the aforementioned issues are taken into consideration. In view of the temperature dependency of biochemical and physiological systems (see Section 2), scaling the thermoregulatory responses from rodent to human can be important in the extrapolation of a variety of toxicological responses that are not associated with thermoregulation. Adult humans and other relatively large species are essentially trapped in their stable thermal milieu and cannot respond with a natural hypothermic response when faced with a toxic insult. The fact that hypothermia is protective and rodents are able to use this as an adaptive mechanism to a toxic insult, one may under estimate the risk of a toxicant when extrapolating from a small rodent to an adult human.

2 SUMMARY

Our understanding of the effects of temperature on toxic response has seen resurgence in the past several decades with the development of better methods to study the integration of autonomic and behavioural thermoregulatory responses in rodents and other species. Radiotelemetry provides researchers with the best tool to study the thermoregulatory responses in undisturbed rodents exposed chronically or acutely to toxic chemicals. The thermoregulatory response to acute exposure to many toxic chemicals involves a regulated hypothermic response, characterized by an increase in autonomic thermoeffectors to increase heat loss and a behavioural preference for cooler temperatures. This thermoeffector response is quickly manifested by a marked drop in the core temperature in rodents. However, in humans and other large mammals, the hypothermic response is meagre due to their large thermal inertia. A combination of exposure to cool temperatures and a moderate hypothermic response has been found to benefit survival to a variety of toxic agents. Thus, the integrated thermoregulatory response of rodents to lower their core temperature seems to be an adaptive response. On the other hand, fever or hyperthermia is often seen in humans and other large mammals exposed to various toxicants. A fever is also seen in rodents provided that core temperature is monitored without disturbing the animal (e.g. telemetry). The universal effects of temperature on chemical toxicity calls for researchers to have a better understanding of the thermoregulatory effects of environmental toxicants.

Development of Tolerance to the Toxicity of Xenobiotics

Frode Fonnum

CONTENTS

1 INTRODUCTION

Tolerance due to exposure to xenobiotics is a well-known phenomenon and is of great importance in our daily life. It is known to occur in animals, plants and microorganisms exposed to all types of chemicals that surround us. Tolerance, due to the chronic presence of a compound, is believed to result from a homeostatic process, in which a newly established effect is counteracted, thus transferring the situation back to normal. This can, in principle, be achieved either by reducing the response at the target or by preventing access of the active compound to the target.

Tolerance can be developed in several ways. It is often obtained by receptor changes, either the number of receptors or by decreased affinity for the receptor molecule. This is particularly noted in the superfamily of seven transmembrane G protein-coupled receptors (GPCRs). This represents the largest family of plasma membrane receptors. Examples of such receptors are the β-adrenergic receptor, the cholinergic muscarinic receptor and the opiate receptor. These GPCRs can be desensitized to activation by agonists and thereby develop tolerance. Desensitization requires phosphorylation of the receptor by G protein-coupled receptor kinases (GRKs). The phosphorylated GPCRs will then bind strongly to a group of proteins called arrestins which thereby uncouples them from G proteins. This prevents further stimulation and downstream signalling. Arrestins bind with much higher affinity (<1 nM) to GRK-phosphorylated GPCRs than to unphosphorylated receptors, and the presence of multiple phosphate groups on the receptor (i.e. more than three per receptor) is thought to be the primary trigger for high-affinity arrestin binding (Gurevich and Gurevich, 2004). The arrestin-bound receptor is then internalized to endocytes and removed.

Tolerance can also be developed by the presence of proteins that can bind or inactivate the agonist, thereby making it less readily available. An example of such a mechanism is the action of sublethal doses of cadmium on most organisms. Cadmium is toxic to several organs, but in particular the liver. Pretreatment with low concentrations of cadmium leads to tolerance to a large number of metals. Cadmium induces a protein with several SH groups called metallothionein, which has the ability to bind large amounts of cadmium and thereby prevent any toxic effects (Klaassen and Liu, 1998). Metallothionein plays an important part in the development of tolerance towards several metals, such

as cadmium, zinc, copper and mercury. Metallothionein, due to its high number of SH groups also shows tolerance to free-radical damage (Thornalley and Vasák, 1985). Animals with little or no metallothionein, such as sheep, are very sensitive to grazing on copper-containing soil (Søli, 1980). Cross-tolerance occurs when an organism is submitted to small doses of one compound leading to the induction of a protein that will also protect against other compounds simultaneously. Metallothionein, as shown above, can protect against several metals, although it is induced by only one of them. Another example of cross-tolerance is the induction of cytochrome P450 (CYP) enzymes, by administration of small doses of phenobarbital. This is accompanied by in increase in the enzyme CYP2E1 in the liver and some other organs. This enzyme has the ability to metabolize and detoxify several other substances, including ethanol. Therefore tolerance to alcohol is increased by exposure to phenobarbital.

Tolerance is a term used to describe the adaption of a single individual rather than the population. Tolerance usually occurs rapidly if it only requires an induction of a protein or takes more time when it requires more subtle changes in a signal system adhered to a receptor. When the stress is removed the tolerance is usually lost within a few weeks.

In general we separate the term tolerance into resistance and tolerance. The term 'resistance' suggests that the genetic constitution of a population allows it to resist a physiological effect. This means that the action is reduced or abolished by a few genes in the population, allowing some of the organisms to survive. An example is the discovery that dichlorodiphenyltrichloroethane (DDT) lost its toxic effects on several insects. The insects that survived the action of DDT contained an enzyme, DDT hydrochlorinase, that was able to metabolize DDT to the inactive dichlorodiphenyltrichloroethylene (DDE) (Sternburg *et al*., 1954). This enzyme was later identified as a glutathione transferase. Also, DDT attaches itself to one of the sodium channels of insects. A few individuals had two amino acid mutations which did not have any physiological effect on the channel, but prevented DDT acting on the channel. Again, these insects survived and were allowed to multiply and caused DDT to lose its insecticidal property. This simply means that organisms which do not have these genes do not survive, and thus allow those that do to survive and multiply. If these survival genes were present before the action we call this natural selection and this property will remain in the generations to follow.

2 TOLERANCE TO INHIBITORS OF ACETYLCHOLINESTERASE (AChE-I)

In the following we will discuss tolerance developed to acetylcholinesterase (AChE)-I because this involves changes to several different receptors and to different enzymes, which either bind or hydrolyse the inhibitors. AChE-I consists of two large groups of compounds known as organophosphates (OPs) and carbamates. They are important mainly as insecticides, but also as chemical warfare agents. The use of these compounds for peaceful purposes causes several accidental deaths every year. The compounds inhibit the enzyme AChE and thereby increase the level of acetylcholine (ACh) in the synaptic gap. The acute toxic effects of AChE-I are due to stimulation of the muscarinic and nicotinic receptors by ACh. Most emphasis will be given to OPs because they are partly irreversible inhibitors and their effects are more chronic.

The recovery of AChE in vertebrates is slow and the half-time for resynthesis of the enzyme is several days. There are several examples that prolonged exposure to toxic concentrations of OP give physiological effects that are smaller than expected from the degree of AChE inhibition (Bushnell *et al*., 1991). Barnes and Denz (1954) gave rats 50 ppm of the OP parathion for several months and observed that after three months several of the effects of AChE inhibition, such as fasciculation, lacrimation and salivation disappeared, although the animals still occasionally showed tremors. Normally animals die after having been exposed to 1 mg kg^{-1} day octamethylpyrophosphoramide (OMPA) for five days. But Rider *et al*. (1952) showed that after pretreatment of animals with 0.5 mg OMPA kg^{-1} day^{-1} for five days, the animals did not show any toxic effects after a dose of 1 mg kg^{-1} day for 41 days. Another example is that rats survived daily administration of 0.5 LD_{50} of the irreversible inhibitor soman for 11 days (Sterri, 1981). In fact, often the animals were symptom-free. There are several observations of physiological effects of sublethal doses of OP that cannot be explained by the recovery of AChE. Thus, when treating the pupil with the irreversible inhibitor soman, miosis, as a sign of AChE inhibition of the iris, was noted. After a single topical soman instillation into the conjunctival sac there was an almost linear relationship between the reduction in AChE activity and the reduction in pupillary diameter. Repeated topical administration of soman at 24 hour intervals, in doses capable of almost complete inhibition of AChE in the iris, was accompanied, however, by a reduced miotic effect. There were a reduced rate of soman-induced pupillary constriction, a less pronounced reduction in pupillary diameter and a more rapid return of the pupillary diameter to normal size on repeated administration. The decrease in response to repeated administration could not be explained by a reduced inhibitory effect of soman on AChE, nor by *de novo* synthesis of AChE, but could be a sign of developed tolerance (Soli *et al*., 1980). Also AChE inhibition led to hypothermia in animals and the rapid return from hypothermia seen after treatment could not be explained by recovery of AChE activity. It must have been due to some form of developed tolerance

(Gordon, 1997). More recently, animals with knockout (KO) AChE both in the peripheral and central nervous system have been produced and they survive up to one year (Xie *et al*., 2000). This can only occur because the animal develops tolerance to the absence of AChE.

Tolerance to AChE inhibitors has been noted after different forms of administration and in several species, such as mouse, rat, guinea pig and man. Tolerance can be developed in several ways. It can be due to changes in the number of or by decreased affinities of the cholinergic muscarinic or nicotinic receptor molecules. It can, however, also be obtained by proteins that can bind or inactivate the inhibitor. Examples are binding of the inhibitor to carboxylesterases (CarbEs), butyryl-cholinesterases (BuChEs) or albumin. In addition, tolerance can, in principle, be achieved through more rapid detoxification of OP compounds by OP-hydrolysing enzymes, such as paraoxonases (PONs) and somanases.

2.1 The Importance of Muscarinic Receptors

Muscarinic acetylcholine receptors (mAChRs) are heavily involved in the development of tolerance to AChE-I. The hypothesis that tolerance to chronic treatment with AChE-I could be due to inactivation of the cholinergic receptor was first stated by Brodeur and Dubois (1964). Changes in the muscarinic receptor have, in fact, been shown to be one of the most important ways for a cell or an individual to obtain tolerance towards AChE inhibitors. The presynaptic muscarinic autoreceptors respond rapidly to a high concentration of ACh in the synaptic gap by reducing release. The postsynaptic receptor responds, usually more slowly, by reduction in the number of mAChRs after AChE inhibition in the brain or peripheral nervous system (Ehlert *et al*., 1980; Schiller, 1979; Gazit *et al*., 1979) Some authors reported both a decrease in the number of mAChRs and in the affinity to the ligand in the ileum and striatum (Costa *et al*., 1981), but most authors have reported only a decrease in the number of mAChRs in the brain.

There are five subtypes of mAChRs, named m1, m2, m3, m4 and m5. Subtypes m1, m3 and m5 are coupled to the α-subunit of the Gq/11 class of G-proteins. The receptor–agonist interaction activates phosphatidylinositol-specific phospholipase C, resulting in the production of diacylglycerol and phosphoinositol. On the other hand, subtypes m2 and m4 inhibit adenyl cyclase through α-subunits of G-protein Gi/0 (Bonner, 1989). The liberated complex of β- and γ-subunits regulate the function of potassium and calcium channels (Herlitze *et al*., 1996). There is now good evidence that internalization of muscarinic receptors can take place via phosphorylation by GRKs and further binding to arrestin (Gainetdinov *et al*., 2004).

Assay of the muscarinic receptor is generally performed using binding of labelled 3-quinuclidinyl benzylate (QNB) which attaches all subtypes. QNB can be used to assay both mAChRs at the plasma membrane and in the cytoplasm, when they are internalized. In contrast *N*-methylscopolamine (NMS) is water soluble and does not penetrate cell membranes. NMS can only measure mAChRs localized at the plasma membrane and not when they are internalized. NMS binding has therefore been found to be more sensitive than binding with QNB. In two cell lines, NG108-15 and SK-N-Sh, carbachol caused a loss in NMS binding, but the binding of QNB was unchanged, thus indicating internalization of the receptor (Baumgold *et al*., 1989).

2.2 Postsynaptic Receptors

Prolonged treatment with a cholinergic agonist leads to a decrease in mAChRs. This is common for G-protein-linked receptors. Down-regulation follows receptor internalization and degradation, a process which takes several hours. For example, Chinese hamster ovary (CHO) cells stably transfected with the m1 subtype were exposed to the cholinergic agonist carbachol for 24 hours. This resulted in a decrease of 66% in muscarinic receptor binding and a 73% decrease in the m1 messenger RNA (mRNA) level (Wang *et al*., 1990). Likewise, in cultured granule cells, both subtypes m2 and m3 were reduced after carbachol treatment. This also resulted in a decrease in cyclic adenosine monophosphate (cAMP) production (50%) and a reduction in the corresponding mRNA by 30–50% (Fukamauchi *et al*., 1993). In contrast the m4 subtype receptors of neuroblastoma cells were reduced by 30% by 24 hour carbachol treatment, but in this case there was no effect on the corresponding m4 mRNA.

The decrease in mAChRs depends both on the duration of AChE inhibition and the degree of inhibition in experimental animals. Schwab *et al*. (1981) and Costa *et al*. (1981) showed that there was no immediate effect after acute inhibition of AChE in rats with OP. Jett *et al*. (1994) injected parathion over a 21 day period resulting in 84–90% AChE inhibition in the brain without overt signs of toxicity. To their surprise they found a reduction in m1 subtype receptors and m1 mRNA in the frontal cortex and m4 subtype receptors and m4 mRNA in the striatum, but no change in hippocampus mAChRs, although AChE inhibition was similar in all three regions. They concluded that hippocampus had different feed-back mechanism for regulation of the mAChR.

Yagle and Costa (1996) studied the effect of disulfoton (2 mg kg^{-1} for a fortnight) on proteins and mRNA levels of mAChR subtypes in brain tissue (m1 and m2) and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat034
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

peripheral mononuclear cells (m3). The AChE activity in the cerebral cortex was reduced to 19% of original level after 14 days and QNB binding was reduced to 72% during this period. The m1 subtype dominated in the cortex, hippocampus and striatum, whereas m2 dominated in the medulla and cerebellum. After the treatment m1 and m2 mRNA was reduced by about 25% in the hippocampus, whereas in the medulla m2 mRNA was reduced by 19%. Subtype m3 was reduced by 10% in the cortex, but not in lymphocytes. In contrast to Jett *et al*. (1994), there was no difference between the observed effects in the different regions.

In mice exposed to parathion in the diet there was a large variation in AChE inhibition due to intake of food (Jett *et al*., 1993). In these animals it was therefore possible to show a correlation between AChE inhibition and reduction in both QNB binding and 4-diphenylacetoxy-N-methylpiperidine methiodide (4-DAMP) binding. There was no effect on the affinities for these ligands. The maximal reduction in binding for these was 58%. In contrast, NMS binding was also reduced to 58%, but this occurred already at only 10% AChE inhibition.

A correlation between ChE inhibition and QNB and AF-DX 384 binding in the cortex and striatum of young and adult rats was also found by Li *et al*. (2005). They gave young rats (age seven days) and adult rats (age 90 days) chlorpyrifos and methyl parathion for seven days and found a correlation between ChE inhibition and muscarinic binding at one day and seven days postexposure.

The tolerance observed to hypothermia after treatment with OPs has also been suggested to be due to a decrease of mAChRs in the temperature-regulated region of the brain (Overstreet and Yammamura, 1979; Russel *et al*., 1975).

In conclusion, studies from AChE inhibition in the brain show that there is generally a correlation between AChE inhibition and reduction in mAChR binding. The degree of AChE inhibition is higher than the reduction in receptor binding. NMS binding, which can only measure the extracellular muscarinic receptor, is more sensitive than the other antagonists, which measure both extracellular and internalized receptor molecules. In general, the reductions in mAChRs are similar in different brain regions. In almost all cases examined there was a reduction in the number of muscarinic binding sites and not an effect on affinity to the binding site after exposure to AChE-I.

A complicating factor in the discussion of the effect of OP inhibition and mAChRs is the direct action between several OPs and mAChRs (Ward *et al*., 1993; Huff *et al*., 1994). Diisopropyl fluorophosphate (DFP), paraoxon, malaoxon and chlorpyrifos-oxon inhibit 1,3-dioxalan binding, which is a high-affinity ligand to a subset of the m2 subtype. QNB binding was only affected by echothiophate. The effect of OPs on dioxalan binding occurs in the same concentration range as for AChE inhibition. The m2 receptor is coupled to cAMP production and paraoxon, malaoxon and chlorpyrifosoxon all inhibit forskolin-stimulated c-AMP formation (Ward and Mundy, 1996).

2.3 Muscarinic Autoreceptor

Autoregulation of ACh release seems to play an important role in presynaptic mAChRs (Molenaar and Polak, 1980; Nordstrom and Bartfai, 1981; Dolezal and Wecker, 1991; Kirkpatrick and Richardson, 1993). This is a common feature of G-protein-linked receptors. The importance of the autoreceptor is demonstrated by the fact that the addition of atropin, the well-known cholinergic antagonist, to various brain slices or peripheral tissues increased the release of ACh. In contrast, the cholinergic agonist carbachol inhibited the release of ACh (Nordstrom and Bartfai, 1980; Aas and Fonnum, 1986; Dolezal and Wecker, 1990). Using antagonists specific for subtype m2 and m4 receptors, it was suggested that the regulation of ACh release from brain tissue was controlled by these two subtypes (Quirion *et al*., 1995). This was further investigated by the use of an antisense to m2 receptor and by using a very specific m4 antagonist during microdialysis of the hippocampus. In this way it was shown that the responsible subunit in the hippocampus was m2 (Kitaichi *et al*., 1999). The use of brain slices from an m2/m4 receptor single KO mice confirmed that autoinhibition is mediated primarily by the m2 receptor in the hippocampus and cerebral cortex, but predominantly by the m4 receptor in the striatum (Zhang *et al*., 2002).

The presynaptic autoreceptors in the brain reduce the release of ACh and thereby reduce the cholinergic effects on the postsynaptic receptors. The mechanism of inhibition of ACh release involves the stimulation of presynaptic GPCRs and is due to a restriction of the activity of the high-voltage-activated N or P/Q calcium channels (Krejcí *et al*., 2004). This restriction takes place by liberated β/γ subunits of the receptor, which interact with the activated calcium channels and inhibit calcium influx. The effect of autoreceptors on ACh release may have therapeutic consequences in, for example, Alzheimer's disease. AChE inhibitors used in therapy can inhibit the release of ACh. A consequence of this could be that the use of high-affinity M2 muscarinic antagonists may prevent inhibition of ACh release and facilitate learning and memory in experimental animals (Quirion *et al*., 1995).

In adult muscle, the m1-receptor-selective antagonist pirenzepine (10 μM) reduced evoked neurotransmission (approximately 47%), whereas the m2-receptor-selective antagonist methoctramine (1 μM) increased the evoked release (approximately 67%). Both the m1- and

m2-mediated mechanisms depend on calcium influx via P/Q-type synaptic channels (Santafé *et al*., 2006).

2.4 Nicotinic Autoreceptors

The nicotinic receptor dominates at the neuromuscular junction, but it is also widely distributed in the mammalian brain. The brain receptors are different from those in the ganglion and motor endplates. Nicotinic receptors are localized on both presynaptic axon terminals and postsynaptic somatodendritic sites (Sargent, 1993). The concept of ionotropic autoreceptors has been established primarily by indirect evidence measuring the overflow of radioisotope-labelled transmitters or whole-cell recording of excitatory postsynaptic current (EPSC) amplitude at postsynaptic cells (Bowman *et al*., 1990). In the brain the nicotinic receptor has been implicated in various physiological and pathological conditions, including cognition, Alzheimer's disease, Parkinson's disease, anxiety and addiction to tobacco products (Nordberg *et al*., 1989; Arneric *et al*., 1995).

The positive modulation of neurotransmitter release appears to be a widespread and potentially important role of presynaptic nicotinic ACh receptor channels (McGehee *et al*., 1995). Nicotinic autoreceptors have also been proposed to regulate ACh release at motor nerve terminals (Bowman *et al*., 1990) and in central cortical and hippocampal synaptosomes (Rowell and Winkler, 1984; Wilkie *et al*., 1996).

The increased release of ACh from brain synaptosomes caused by the nicotinic autoreceptor can only be detected in the presence of atropine, which inhibits the muscarinic autoreceptor (Wu *et al*., 2003). The nicotinic antagonist mecamylamine, but not nicotine, inhibits the release of ACh, indicating the specificity of the receptor. Sublethal DFP treatment ($2\,mg\,kg^{-1}$) over several days leads to a decrease in AChE activity, muscarinic receptor and nicotine binding in rat brain (van de Kamp and Collins, 1992). The mechanism behind the increased release may be due to an increased intracellular calcium level (Wilkie *et al*., 1996). Present studies indicate that the most important function of presynaptic neuronal nicotinic receptors (nAChR)s in either synaptic or nonsynaptic localization is to directly effect intracellular Na^+ and Ca^{2+} levels, followed by a depolarization sufficient to activate local voltage-sensitive Ca^{2+} channels, resulting in transmitter release (Szabo *et al*., 2008).

Several antiChEs have a direct effect on the nAChRs. The most potent OPs to inhibit the $\alpha4\beta2$ nAChRs are the oxidized metabolites of disulfoton, parathion-ethyl, parathion-methyl and fenthion (Smulders *et al*., 2004). The same oxidized OPs are effective AChE inhibitors and also the best for interaction with the muscarinic receptor. Both paraoxon and chlorpyrifos-oxon inhibit the nAChR and desensitize the receptor by binding to a different site from the ACh binding site (Katz *et al*., 1997). These OPs inhibit the release of ACh and will delay the symptoms of AChE poisoning. Even very toxic AChE-Is such as VX and sarin have effects on ion channels or receptors at levels close to their inhibitory potency of AChE. OPs like ecothiopate, DFP and VX block the open ion channel of the nicotinic receptor and desensitize the receptor of the electric organ of the torpedo and muscle endplate (Bakry *et al*., 1988; Eldefrawi *et al*., 1988).

A special case is that galantanine and physiostigmine, both AChE-Is, increase ACh release (Coyle *et al*., 2007). This is unexpected, but is due to their effect as allosteric ligands of the nicotinic receptors in the brain. It has been suggested that they act through the phosphatidyl-3-kinase and AKTpathway (Takada-Takatori *et al*., 2006). Nicotinic agonists have therefore been suggested to be used in the treatment of Alzheimer's disease, since they increase ACh release.

2.5 Adenosine Receptors

Adenosine has been shown to have powerful inhibitory action on neuronal activity and on the release of excitatory transmitters (Kirkpatrick and Richardson, 1993; Broad and Fredholm, 1996; Jin and Fredholm, 1997). In both the central nervous system (CNS) and the vertebrate neuromuscular junction, adenosine both inhibits and stimulates ACh release, depending on the type of adenosine receptor. In general, inhibition of release is mediated via A1 receptors and excitation through A2 receptors. The final outcome depends on the degree of the activation of the two receptors. Adenosine triphosphate (ATP) is known to be coreleased with ACh from the synaptic vesicles, and can be hydrolysed extracellularly by ecto-5-nuclidases to adenosine. Adenosine is also released from purinergic vesicles, motor endplates and postjunctional tissue. Adenosine is the active component, but ATP can substitute for adenosine if hydrolytic enzymes are not available.

Since adenosine and ATP are present in cholinergic structures and interfer with ACh release, the adenosine receptor can therefore be expected to be involved in tolerance to AChE-I poisoning. In agreement, in perfused rat cortical slices, the A1-selective agonist, N^6-cyclopentyladenosine (CPA), caused a dose-dependent inhibition of ACh release, which was attenuated in the added presence of the A1-selective antagonist 1,3-dipropyl-8-cyclopentylxanthine (DPCPX; $1\,\mu M$). In the neostriatum, the evoked release of [^{3}H]-ACh was significantly enhanced by the A2a agonist CGS 21680 but decreased by the A1 agonist, R-PIA. The effects of NECA (5′-*N*-ethylcarboxamidoadenosine), which is equipotent at both receptor subtypes, were dependent on the concentration used. With high concentrations NECA inhibited, and with low concentrations

enhanced, the evoked release of [^{3}H]-ACh. As an example of the importance of the adenosine receptors in modifying ACh release, the selective adenosine A1 receptor agonist CPA (N^6-cyclopentylxanthine) effectively attenuated the cholinergic symptoms and prevented mortality in lethally tabun- or sarin-intoxicated rats (van Helden *et al*., 1998). During AChE-I poisoning, the CPA-treated animals showed only a small elevation of extracellular ACh concentrations in the brain relative to the baseline value, whereas an 11-fold increase in transmitter levels was observed in animals not treated with CPA (Bueters *et al*., 2003).

In the motor endplate, the excitatory A2a receptors facilitate ACh release by interaction with the presynaptic nicotinic AChRs. This probably occurs through a cAMP-dependent mechanism (Correia-de-Sa and Ribeiro, 1994). Blockade of A2a receptors enhances desensitization, and blockade of A1 receptors enhances sensitization of the presynaptic nAChRs.

2.6 Tolerance in AChE Knockout Mice

The maximal tolerance to a high concentration of ACh must be found in the knockout animal for AChE (AChE (−/−)). Inhibitors of AChE like OPs are fast acting and lethal; it is therefore with some surprise that such a knockout animal can survive up to almost one year (Xie *et al*., 2000). Investigation of the peripheral nervous system using the phrenic nerve-hemidiaphragm showed that the knockout animal had developed markedly reduced and fragmented nicotinic receptors. To compensate for the absence of AChE activity, the size of the endplate was reduced. The junctional folds of the endplate and the number of nAChRs were heavily reduced. This allows smaller responses to ACh and also increases ACh diffusion out of the synaptic gap. The decay time of the miniature endplate potential was increased from 1 ms in the wild-type to 5 ms in the AChE-KO. BuChE activity was not increased, nor had it changed its general localization. Twitch tensions elicited in diaphragms of AChE (−/−) mice by single supramaximal stimuli had larger amplitudes and slower rise and decay times than did those in wild-type animals. In AChE (−/−) preparations, repetitive stimulation at frequencies of 20 and 50 Hz, and at 200 and 400 Hz produced decremental muscle tensions. Muscles from control mice maintained tension at all frequencies examined. Inhibition of BuChE activity led to larger responses of evoked released ACh, suggesting that the enzyme hydrolysed the extrasynaptic ACh (Adler *et al*., 2004; Girard *et al*., 2007).

In the central nervous system AChE was also eliminated, but there was no effect on the level and localization of choline acetyltransferase or on the ACh vesicle transporter. Extracellular ACh levels in the hippocampus were 60-fold elevated in AChE (−/−) mice compared with wild-type AChE (+/+) animals. In AChE (+/+) animals inhibition of BuChE did not affect extracellular ACh level, but in AChE (−/−) inhibition of BuChE increased extracellular ACh (Hartmann *et al*., 2007). There was a large increase in the choline plasma membrane transporter, probably to compensate for there being less choline available through reduced hydrolysis of ACh in the synaptic gap. There was a major reduction in mAChR numbers, including subtypes m1, m2 and m4, and there wase also a high degree of internalization of the mAChR subtypes. There were, however, no changes in the mRNA of the muscarinic receptor. Many of the symptoms usually seen in wild-type animals following the action of muscarinic agonists, such as induced hypothermia, tremor, salivation and analgaesia, and pilocarpine-induced seizures, could not be found in AChE (−/−) mice. It seems, therefore, that the most important way of obtaining tolerance in AChE (−/−) animals is a reduction in receptor numbers and not in regulation of ACh synthesis (Mesulam *et al*., 2002; Volpicelli-Daley *et al*., 2003).

A correct balance between muscarinic and adrenergic receptors was important to maintain the proper function of the lung in AChE (−/−). Muscarinic receptors were decreased to 50%, α1-adrenoceptors to 23% and β-adrenoceptors to about 50% of control. Changes were subtype specific, as α1A-, α1B- and β2-adrenoceptors were decreased while α1D-adrenoceptors remained unchanged. In contrast, receptor signalling into the cell, as measured by coupling to G-proteins, cAMP content and PI-phospholipase C activity was the same as control (Myslivecek *et al*., 2007).

3 ENZYMES

3.1 Carboxylesterase

Irreversible AChE-I, such as chemical warfare agents like sarin or soman (Sterri *et al*., 1980; Fonnum and Sterri, 1981) have a very slow or nonexistent recovery (Coult *et al*., 1966). Still, when 0.5 LD_{50} of these compounds are administrated daily for 11 days to rats, they will survive. This is caused by the presence of a protein which inactivates and binds OPs and thereby prevents them from reaching their target. In rodents this is due to an enzyme called carboxylesterase, which has a high affinity for OPs and is present in high concentrations in the plasma (Myers, 1952; Goutier, 1956). Unlike choline esterase (ChE), CarbE spontaneously recovers from inhibition with nerve agents and in that way may act as a scavenger.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat034
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are three criteria which define such a scavenger:

1. The binding between plasma CarbE and soman or sarin is rapid enough to pick up the compound before it leaves the blood.
2. The plasma CarbE is present in sufficient amounts to be able to inactivate each dose of soman or sarin.
3. The plasma CarbE–OP complex is spontaneously and sufficiently recovered before the next dose of soman or sarin is administered.

The quantitative contribution by plasma CarbE for repetitive exposure to the most toxic ChE inhibitors could be confirmed by pretreatment of the animals with specific inhibitors of CarbE. The estimated rate of detoxification of repetitively administered soman was reduced to 15% of the rate in the absence of triorthocresyl phosphate (TOCP), a CarbE inhibitor (Fonnum and Sterri, 1981; Sterri and Fonnum, 1984). This means that 80–90% of the repetitively administered soman must be inactivated through binding to the TOCP-sensitive active site of CarbE. In mice the LD_{50} of soman was reduced to about 6% by pretreatment with 35–50 mg kg^{-1} of the CarbE inhibitor CBDP (2-(*o*-cresyl)-4H-1,2,3-benzodioxa-phosphorin-2-oxide) (Casida *et al*., 1961; McKay *et al*., 1971; Boskovic, 1979). The acute LD_{50} of soman in rats and guinea pigs was reduced to one third by pretreatment with 100 mg kg^{-1} TOCP (Fonnum and Sterri, 1981; Sterri *et al*., 1981). The LD_{50} of sarin was reduced to about 20% by pretreatment with 40–50 mg kg^{-1} TOCP in rats (Myers, 1959; Polak and Cohen, 1969). The effects of CBDP on the LD_{50}s for several OP compounds confirm the importance of CarbE against the acute toxicity of highly toxic soman, sarin, tabun and paraoxon, but not against less toxic compounds such as dichlorvos and DFP (Maxwell, 1992). The less toxic ChE inhibitors have toxic concentrations in the plasma that are far beyond the plasma concentration of CarbE. Treatment with CarbE inhibitors showed that paraoxon toxicity depended on CarbE, but that DFP did not (Dettbarn *et al*., 1999).

As the name indicates, CarbE hydrolyses ester bonds and can inactivate insecticides with an active ester bond. The most prominent of such insecticides is malathion. Inhibition of CarbE with TOCP leads to a 100-fold increase in toxicity for malathion (Murphy *et al*., 1976).

Young rats have a low content of endogenous CarbE in the plasma (14 days old), and were protected from soman exposure by intravenous (iv) pretreatment with exogenous CarbE protein, partly purified from liver (Fonnum *et al*., 1985). This is the first example of use of a scavenger to reduce toxicity towards nerve agents. This has later inspired a large number of investigators to use other scavengers, like BuChE (Wolfe *et al*., 1987; Raveh *et al*., 1989; 1997; Broomfield *et al*., 1991; Maxwell *et al*., 1991; 1992; Doctor *et al*., 1993).

The recovery of CarbE after nerve-agent inhibition is due to the spontaneous reactivation of the inhibited enzyme (Polak and Cohen, 1969). Maxwell and Brecht (2001) suggested that the spontaneous reactivation may be due to a highly conserved histidine located in the active site of CarbE, but not present in AChE and BuChE. The position of histidine is similar to the histidine site introduced by Millard *et al*. (1995) to produce an OP-hydrolysing mutant of human BuChE.

The scavenger function of plasma CarbE is obviously of great importance for the understanding of soman detoxification in rodents. Rats, guinea pigs and primates, including man, are species with respectively high, medium and minor (zero) concentrations of plasma CarbE (Myers, 1952; Aldridge, 1953; Cohen *et al*., 1971; Li *et al*., 2005). It is therefore possible to explain the differences between species with respect to acute toxicity and to the effect of pyridostigmine prophylaxis on soman poisoning (Sterri and Fonnum, 1989). Thus, from insight into the mechanism of interference by CarbE, both the theoretical LD_{50} of soman and the theoretical protection factor of carbamate prophylaxis could be predicted for rat, guinea pig, marmoset and rhesus monkey (or man). The LD_{50} and protection factor found correspond well with the experimental value for subcutaneous (sc) LD_{50} of soman in rat (Sterri *et al*., 1980; 1985), guinea pig (Sterri *et al*., 1981) marmoset and rhesus monkey (Dirnhuber *et al*., 1979). The CarbE data also agreed with the experimental protection factor obtained for pyridostigmine prophylaxis against soman in rodents (Gordon *et al*., 1978) and primate species (Dirnhuber *et al*., 1979). From the experimental LD_{50}s of soman, it is suggested that rodent plasma CarbE may be a main scavenger for soman in both inhaled, iv and sc administration, whereas with percutaneous (pc) and interperitoneal (ip) administration there may be additional dermal and hepatic parameters for the threshold of soman (Sterri, 1989).

3.2 Acetylcholinesterase and Butyrylcholinesterase

The spontaneous reactivation of dimethoxy and diethoxy phosphorylated ChEs occurs within a few hours (Burgen and Hobbiger, 1951). Animals exposed to insecticides such as schradan (Rider *et al*., 1952), demeton (Barnes and Denz, 1954), disulfoton (Brodeur and Dubois, 1964), paraoxon (Wecker *et al*., 1977) and dichlorvos (Sterri, 1981) tolerate repeated exposure to sublethal doses for a long time. The symptoms and recovery from symptoms of dichlorvos poisoning correlated well with the timeframe of inhibition and spontaneous reactivation of AChE in different tissues (Sterri, 1981). The concentrations of plasma BuChE is 30-fold less that that of CarbE

(Li *et al*., 2005). Both the low concentration and insufficient recovery of plasma BuChE observed after each dose of soman or sarin in repetitive-exposure experiments exclude any tolerance by binding to BuChE (Fonnum and Sterri, 1981; Sterri *et al*., 1981). In accordance, Grubic *et al*. (1988) excluded any contribution of plasma BuChE to the tolerance developed to acute soman toxicity by using iso-OMPA to differentiate between inhibition of plasma BuChE and CarbE.

Recovery of plasma BuChE, AChE activity and muscle protein by *de novo* synthesis has been reported to be vital for development of tolerance to repetitive exposure to DFP in rats, especially restoration of AChE activity in skeletal muscle (Gupta and Dettbarn, 1986). Also, modifications in affinity of AChE for ACh in paraoxon-tolerant rats have been reported by Milatovic and Dettbarn (1996). They observed 20–25% increase in affinity (decrease in K_m) for ACh by both the brain and diaphragm AChE. This may be the result of structural changes in AChE or the result of altered levels of pre-existing isozymes of AChE.

3.3 Phosphoric Triester Hydrolases

Aryldialkylphosphatase/PON (EC 3.1.8.1) and DFPase/somanase (EC 3.1.8.2) are enzymes hydrolysing OP compounds with generally low affinity (K_m = 0.1–10 mM) (Aldridge and Reiner, 1972). The plasma enzymes therefore prefer to hydrolyse relatively high concentrations of OPs present in the blood. They are mainly important for detoxification of the less toxic OP compounds. As an example, PON1-knockout mice were extremely sensitive to the less toxic diazoxon, but did not show increased sensitivity to paraoxon (Li *et al*., 2000). In agreement, following injection of exogenous PON1 to the knock-out mice, the same authors observed protection against the less toxic diazoxon and chlorpyrifos-oxon, but not against paraoxon. PON1 is polymorphically distributed in human populations with an amino acid substitution (Gln/Arg) at position 192, which determines the catalytic efficiency of this 354 amino-acid protein. In addition to the variable catalytic efficiency determined by the position 192 amino acid, protein levels of PON1 vary by as much as 15-fold among individuals with the same genotype. Sensitivity to diazoxon exposure is primarily determined by the plasma level of PON1, whereas for chlorpyrifos-oxon exposure, both the plasma PON1 level and the position 192 amino acid are important. Mouse PON1 has good catalytic efficiency for the hydrolysis of diazoxon and chlorpyrifos-oxon, but a poor efficiency for paraoxon hydrolysis relative to rabbit PON1 (Li *et al*., 2000).

Somanase in blood has little effect on soman detoxification, but in liver may be important. Liver perfusion experiments with soman demonstrated 80–90% detoxification of soman during a single pass through the liver, and this was not due to inhibition of ChE or CarbE (Sterri *et al*., 1983). The high capacity of soman detoxification in liver might therefore mainly be due to somanase activity, and might explain the tolerance to acute toxicity of soman by ip administration, compared to sc administration (Fonnum and Sterri, 1981).

The organophosphorus nerve agent soman contains two chiral centres (a carbon and a phosphorus atom), resulting in four stereoisomers (C+P+, C−P+, C+P− and C−P−). The P-isomers exhibit a mammalian toxicity that is ~1000-fold greater than that of the P+ isomers. The different capacity for the binding or hydrolysis of the four stereoisomers is important to evaluate scavengers that have the potential to protect against soman intoxication. Using a gas chromatography-mass spectrometry-based approach, it was found that BuChE were found to bind soman with a relative preference for the more toxic stereoisomers (C−P− > C+P− > C−P+ > C+P+), while human serum albumin and PON1 interacted with the less toxic isomers (C−P+/C+P+ > C+P−/C−P−).

4 TOLERANCE TO MORPHINE

Tolerance to morphine is an important topic, both because of its use in medicine and because of its abuse. There are three opioid receptors, namely μ-, κ- and δ-opioid receptors, which are all of the GPCR type. There are large differences in development of tolerance among the opioid agonists. Many of them, particularly the peptides, follow the normal pattern of receptor internalization, whereas tolerance to morphine seems to follow another mechanism (Keith *et al*., 1996). It is therefore interesting to show this tolerance mechanism as an example. Mechanistic studies suggest that morphine does not promote significant internalization of μ-opioid receptors because it fails to stimulate adequate receptor phosphorylation by GRKs. This makes the subsequent attachment to arrestin difficult and receptor recruitment to the clathrin-dependent endocytosis pathway becomes limited (Zhang *et al*., 1998). There is significant circumstantial evidence in support of this supposition, because only overexpression of GRKs promotes morphine phosphorylation, and overexpression of arrestins also promotes morphine-induced μ-opioid receptor internalization (Whistler and von Zastrow, 1998). This suggests that morphine is not an optimal substrate for phosphorylation and receptor interactions with arrestins. Subsequent work has shown, however, that morphine may induce rapid internalization of opioid receptors in neuronal dendrites in the nucleus accumbence (Haberstock-Debic *et al*., 2005). This property may only be present in limited cell types.

The lack of receptor internalization stimulated scientists to look at processes beyond the receptor action and rather to study the pathway from the receptor. It was established many years ago that both acute and chronic exposure of morphine to cells *in vitro* produced effects on cAMP. Acute opiate exposure lead to inhibition of the cAMP pathway, whereas chronic stimulation led to the opposite effect, namely the return of cAMP to normal levels (Sharma *et al*., 1977). Opiates act on several parts of the brain, but two regions are particularly important, namely the locus coeruleus and the nucleus accumbence (MacDonald *et al*., 1992).

Aghajanian *et al*. (1983), using electrophysiological techniques were able to repeat the observations from *in vitro* experiment on cells in the locus coeruleus. They found that cells stopped firing after acute addition of morphine, and the cells returned to normal after chronic exposure to morphine. Nestler and Tallman (1988) showed that chronic stimulation of morphine activated c-AMP-dependent protein kinase activity in locus coreleus cells. Later they identified a series of phosphoproteins stimulated by morphine treatment (Guitart and Nestler, 1989).

Subsequent studies pointed to cAMP-response-element-binding protein transcription factor (CREB) as an important target. Phosphorylation of CREB is inhibited acutely by opiate and recovers during chronic treatment. These changes could in part be mediated by the induction of CREB expression by morphine in the locus coeruleus (Guitart *et al*., 1992).

Lane-Ladd *et al*. (1997) first demonstrated that the morphine-induced increases in adenylyl cyclase and protein kinase A (PKA) activity in the locus coeruleus are associated with selective increases in levels of immunoreactivity of types I and VIII adenylyl cyclase and of the catalytic and type II regulatory subunits of PKA. By using antisense oligonucleotides directed against CREB they found that this transcription factor mediated some of these effects.

5 CONCLUSION

Tolerance to a xenobiotic can be developed either by reduction if the response to a receptor or by proteins that are capable of binding or inactivating the compound. For many receptors the response is reduced by internalization and removal of the receptor. The large group of G-protein-binding receptors display a similar mechanism. An exception is morphine where the signal system attached to the receptor changes.

Examples of proteins binding xenobiotics are metalothionein, albumin and CarbE. A problem with albumin binding is that the binding is reversible and the xenobiotics may be released by other compounds.

1 INTRODUCTION

This chapter concerns statistical aspects of the design, conduct, analysis and interpretation of toxicological data. Intended mainly for the reader not qualified in statistics, it is more concerned with principles than with techniques. As such it avoids, where possible, the use of technical statistical terms, though Section 10 contains a glossary of terms which may be of interest. A major concern is with the typical long-term rodent carcinogenicity study, particular attention being given to the appropriate treatment of pathological data on the incidence of tumours and non-neoplastic findings. However, many of the principles and methods described apply much more widely in toxicology. The chapter ends with a section referring to additional reading which may be helpful when analysing, not only pathology, but also a range of other types of toxicological data.

2 ROLE OF THE STATISTICIAN

Having read this chapter and the references, the pathologist or toxicologist may then be in a good position to be able to carry out appropriate analyses in a number of standard situations. However, it is still important that an expert statistician be available for advice and assistance, even if only to confirm quickly that what has been done is sensible. All too frequently, where a statistician is not involved at any stage, reports and papers end up with conclusions that are invalid because the statistics have been carried out wrongly.

Although a statistician may carry out the statistical analysis, it is vital that the pathologist or toxicologist and the statistician have regular discussions. The pathologist or toxicologist should make it clear what questions are to be answered and, where relevant, describe how different variables inter-relate biologically. The statistician should ensure the pathologist or toxicologist fully understands why the selected methods of analysis have been chosen and what any output means. The pathologist or toxicologist should be reluctant to accept reports from the statistician consisting of hundreds of pages of computer-produced statistical tables where the vast majority of the output is irrelevant to the questions of interest.

3 SOME GENERAL PRINCIPLES

3.1 Bias and Chance

Any toxicological study aims to determine whether a treatment elicits a response. An observed difference in response between a treated and control group need not necessarily be a result of treatment. There are, in principle, two other possible explanations—*bias*, or systematic differences other than treatment between the groups, and *chance*, or random differences.

A major objective of both experimental design and analysis is to try to avoid bias. Wherever possible, treated and control groups to be compared should be alike in respect of all other factors. Where differences remain, these should be corrected for in the statistical analysis.

Chance cannot be wholly excluded, since identically treated animals will not respond identically. While even the most extreme difference might in theory be due to chance, a proper statistical analysis will allow the experimenter to assess this possibility. The smaller the probability of a 'false positive' the more confident the experimenter can be that the effect is real. Good experimental design improves the chance of picking up a true effect with confidence by maximizing the ratio between 'signal' and 'noise'.

3.2 Hypothesis Testing and Probability (p) Values

A relationship of treatment to some toxicological end point is often stated to be 'statistically significant ($p < 0.05$)'. What does this really mean? A number of points have to be made.

First, statistical significance need not necessarily imply biological importance, if the end point under study is not relevant to the animal's well-being.

Second, the statement will usually be based only on the data from the study in question and will not take into account prior knowledge. In some situations—for example, when one or two of a very rare tumour type are seen in treated animals—statistical significance may not be achieved, but the finding may be biologically extremely important, especially if a similar treatment was previously found to elicit a similar response.

Third, the p value does not describe the probability that a true effect of treatment exists. Rather it describes the probability of the observed response, or one more extreme, occurring, on the assumption that treatment actually had no effect whatsoever. A p value that is not significant is consistent with a treatment having no effect, but is also consistent with a treatment having a small effect, not detected with sufficient certainty in this study.

Fourth, there are two types of p value. A 'one-tailed (or one-sided) p value' is the probability of getting by chance a treatment effect in a specified direction as great as or greater than that observed. A 'two-tailed p value' is the probability of getting, by chance alone, a treatment difference in either direction which is as great as or greater than that observed. By convention p values are assumed two-tailed unless the contrary is stated. Where, unusually, one can rule out in advance the possibility of a treatment effect except in one direction, a one-tailed p value can be used. Often, however, two-tailed tests are to be preferred, and it is certainly not recommended to use one-tailed tests and *not* report big differences in the other direction. In any event it is important to make it absolutely clear whether one-tailed or two-tailed tests have been used.

It is a great mistake, when presenting results of statistical analyses, to mark, as do some laboratories, results simply as significant or not significant at one defined probability level (usually $p < 0.05$). This is a poor practice, as it does not allow the reader any real chance to judge whether or not the effect is a true one. Increasingly statisticians present the actual p value for every comparison made. While this gives precise information, it can make it difficult to assimilate results from many variables at the same time. One practice that can be used is to mark p values routinely using plus signs to indicate positive differences (and minus signs to indicate negative differences) as follows: +++ $p < 0.001$, ++ $0.001 \leq p < 0.01$, + $0.01 \leq p < 0.05$, (+) $0.05 \leq p < 0.1$. This highlights significant results more clearly and also allows the reader to judge the whole range from 'virtually certain treatment effect' to 'some suspicion'. Note that using two-tailed tests, bracketed plus signs indicate findings that would be significant at the conventional $p < 0.05$ level using one-tailed tests, but are not significant at this level using two-tailed tests. In interpreting p values it is important to realize they are only an aid to judgement to be used in conjunction with other available information. One might validly consider a $p < 0.01$ increase as chance when it was unexpected, occurred only at a low dose level, with no such effect seen at higher doses, and was evident in only one subset of the data. On the contrary, a $p < 0.05$ increase might be quite convincing if it occurred in the top dose and was for an end point one might have expected to be increased from known properties of the chemical or closely related chemicals.

3.3 Multiple Comparisons

When a p value is stated to be <0.05 this implies that, for that particular test, the difference could have occurred by chance less than one time in 20. Toxicological studies frequently involve making treatment–control comparisons for large numbers of variables and, in some situations, also for various subsets of animals. Some statisticians worry that the larger the number of tests, the greater the chance of picking up statistically significant findings that do not represent true treatment effects. For this reason, an alternative 'multiple comparisons' procedure has been proposed in which, if the treatment was totally without effect, then 19 times out of 20 *all* the tests should show nonsignificance when testing at the 95% confidence level. Automatic use of this approach cannot be recommended. Not only does it make it much more difficult to pick up any real effects, but also there is something inherently unsatisfactory about a situation where the relationship between a treatment and a particular response depends arbitrarily on which other responses happened to be investigated at the same time. It is accepted that in any study involving multiple end points there will inevitably be a grey area between those showing highly significant effects and those showing no significant effects, where there is a problem distinguishing chance and true effects. However, changing the methodology so that the grey areas all come up as nonsignificant can hardly be the answer.

3.4 Estimating the Size of the Effect

It should be clearly understood that a p value does not give direct information about the size of any effect that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

has occurred. A compound may elicit an increase in response by a given amount, but whether a study finds this increase to be statistically significant will depend on the size of the study and the variability of the data. In a small study, a large and important effect may be missed, especially if the end point is imprecisely measured. In a large study, on the other hand, a small and unimportant effect may emerge as statistically significant.

Hypothesis testing tells us whether an observed increase can or cannot be reasonably attributed to chance, but not how large it is. Though much statistical theory relates to hypothesis testing, medical statisticians increasingly prefer confidence interval (CI) estimation with differences between test and control groups expressed in the form of a best estimate, coupled with the 95% CI. Thus, if one states that treatment increases response by an estimated 10 units (95% CI 3–17 units), this would imply that there is a 95% chance that the indicated interval includes the true difference. If the lower 95% confidence limit exceeds zero, this implies the increase is statistically significant at $p < 0.05$ using a two-tailed test. One can also calculate, for example, 99% or 99.9% confidence limits, corresponding to testing for significance at $p < 0.01$ or $p < 0.001$.

In screening studies of standard design, the tendency has been to concentrate mainly on hypothesis testing. However, presentation of the results in the form of estimates with CIs can be a useful adjunct for some analyses, and is very important in studies aimed specifically at quantifying the size of an effect.

4 GOOD LABORATORY PRACTICE AND QUALITY ASSURANCE

Before going on to discuss specific considerations relating to the design, conduct and analysis of toxicological studies, it is important to refer to the concept of studies being performed to Good Laboratory Practice (GLP) with the inclusion of a formal quality assurance (QA) component. This aspect has been a response to examples of poor, and in some cases fraudulent, practice in studies in the past. GLP compliance requires written description of the experimental protocol and the development of standard operating procedures (SOPs) which govern how procedures are carried out. Specific attention is given to the collection and maintenance of the integrity of the raw data collected in a study. QA personnel responsible for monitoring studies for GLP compliance are likely to require evidence that the study was conducted according to the defined protocol, and that any statistical analyses and reporting of the data were carried out as described in the study protocol. Evidence will be needed that any statistical package used had previously been validated to ensure that it was providing appropriate results. GLP is now a central feature of standard toxicological tests carried out for regulatory purposes. Its influence and importance is likely to increase and the development of the related concept good scientific practice (GSP) for use in more basic experimental studies is now in progress.

5 EXPERIMENTAL DESIGN AND CONDUCT

5.1 Introduction

Issues relating to experimental design and conduct are considered in detail in Chapter 3 of Gart *et al*. (1986) and in Lee (1993), and will only be discussed briefly here. In many cases, the experimental design is governed in part by regulatory requirement and little further input of a statistical nature is either feasible or needed.

There are 10 facets of any study which may affect its ability to detect an effect of a treatment. The first six facets are concerned with minimizing the role of chance, while the last four relate to avoidance of bias. These are discussed in the following sections.

5.2 Choice of Species and Strain

Ideally, the responses of interest should be rare in untreated control animals, but should be reasonably readily evoked by appropriate treatments. Some species or specific strains, perhaps because of inappropriate diets (Roe, 1989) have high background tumour incidences, which make increases both difficult to detect and difficult to interpret when detected.

5.3 Dose Levels

This is a very important and controversial area. In screening studies aimed at hazard identification, it is normal, to avoid requiring huge numbers of animals, to test at dose levels higher than those to which man will be exposed, but not so high that marked toxicity occurs. A range of doses is usually tested to guard against the possibility of a misjudgement of an appropriate high dose and that the metabolic pathways at the high doses differ markedly from those at lower doses, and, perhaps, to ensure no large effects occur at dose levels in the range to be used by man. In studies aimed more at risk estimation, more and lower doses may be tested to obtain fuller information on the shape of the dose–response curve.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

5.4 Sample Size

This is obviously an important determinant of the precision of the findings. The calculation of the appropriate number depends on: (i) the critical difference, that is, the size of the effect it is desired to detect; (ii) the false positive rate—that is, the probability of an effect being detected when none exists (equivalent to the 'α level' or 'Type I error'); (iii) the false negative rate, that is, the probability of no effect being detected when one of exactly the critical size exists (equivalent to the 'β level' or 'Type II error') and (iv) some measure of the variability in the material.

Lee (1993) gives some tables showing the number of animals required to detect a critical difference for various combinations of α and β for normally and binomially distributed variables. These values can also be calculated more generally by software such as STUDYSIZE or nQUERY ADVISOR. As a rule of thumb, to reduce the critical difference by a factor n for a given α and β, the number of animals required will have to be increased by a factor n^2.

5.5 Duration of the Experiment

It is obviously important not to terminate the study too early for those fatal conditions which are normally strongly age-related. Less obviously, going on for too long in a study could be a mistake, partly because the last few weeks or months may produce relatively little extra data at a disproportionate cost, and partly because diseases of extreme old age may obscure the detection of tumours and other conditions of more interest. For nonfatal conditions, the ideal is to carry out a post-mortem examination of the animals when the average prevalence of the condition is around 50%.

5.6 Accuracy of Determinations

This is of obvious importance. Though GLP and improving technology have improved the situation here, there is an ever-present need for those taking part in the study to be diligent.

5.7 Stratification

To detect a treatment difference with accuracy, it is important that the groups being compared are as homogeneous as possible with respect to other known causes of the response. In particular, suppose that there is another known important cause of the response for which the animals vary, so that the animals are a mixture of hyper- and hyporesponders from this cause. If the treated group has a higher proportion of hyper-responders it will tend to have a higher response even if treatment has no effect. Even if the proportion of hyper-responders is the same as in the controls, it will be more difficult to detect an effect of treatment because of the increased between-animal variability.

Given that this other factor is known, it will be sensible to take it into account in both the design and analysis of the study. In the design, it can be used as a 'blocking factor' so that animals at each level are allocated equally (or in the correct proportion) to control and treated groups. In the analysis, the factor should be treated as a stratifying variable, with separate treatment–control comparisons made at each level, and the comparisons combined for an overall test of difference. This is discussed further in section 6.7 where we refer to factorial design as one example of the more complex designs that can be used to investigate the separate effect of multiple treatments.

5.8 Randomization

Random allocation of animals to treatment groups is a prerequisite of good experimental design. If not carried out, one can never be sure whether treatment–control differences are due to treatment or to 'confounding' by other relevant factors. The ability to randomize easily is a major advantage animal experiments have over epidemiology.

While simple randomization of all animals eliminates bias (at least in expectation), it may not be the optimal technique for producing a sensitive test. If there is another major source of variation (e.g. sex, or batch of animals), it will be better to carry out stratified randomization, (i.e. carry out separate randomizations within each level of the stratifying variable).

The need for randomization applies, not only to the allocation of the animals to the treatment, but also to anything that can materially affect the recorded response. The same random number that is used to apply animals to treatment groups can be used to determine cage position, order of weighing, order of bleeding for clinical chemistry, order of sacrifice at termination, and so on.

5.9 Adequacy of Control Group

While historical control data can, on occasion, be useful, a properly designed study demands that a relevant concurrent control group be included with which results for the test group can be compared. The principle that like should be compared with like, apart from treatment,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

demands that control animals should be randomized from the same source as treatment animals. Careful consideration should also be given to the appropriateness of the control group. Thus, in an experiment involving treatment of a compound in a solvent, it would often be inappropriate to include only an untreated control group, as any differences observed could only be attributed to the treatment/solvent combination. To determine the specific effects of the compound, a comparison group given the solvent only by the same route of administration would be required.

5.10 Animal Placement

It is not always generally realized that position of the animal in the room in which it is kept may affect the animal's response. An example is the strong relationship between incidence of retinal atrophy in albino rats and closeness to the lighting source. Systematic differences in cage position should be avoided, preferably via randomization.

5.11 Data Recording

Two distinct sources of systematic bias may occur in data recording. One is that awareness of treatment may, consciously or subconsciously, affect the values recorded by the measurer. This can be avoided by organizing data-recording so that observations are made blind of treatment. The second is that there is a systematic shift in the standard of measurement with time, coupled with a tendency for different groups to be measured at different time points. This is particularly important when a pathologist grades a lesion for severity and when the control and high-dose animals are read before the intermediate-dose animals. In some situations it may be necessary to reread all the slides blind and in random order to be sure that 'diagnostic drift' is avoided.

Valid analysis cannot be conducted unless one can distinguish animals which were examined and did not have the relevant response and animals which were not examined. It can also be important to identify why data are missing.

6 STATISTICAL ANALYSIS: GENERAL CONSIDERATIONS

6.1 Introduction

In the next section different techniques that might generally be applied to different types of toxicological data are summarized. Before doing so, a number of points are worthy of discussion. Some are quite general, while others relate more specifically to problems in dealing with data from pathological investigations.

6.2 Variables to be Analysed

Although some pathologists still regard their discipline as providing qualitative rather than quantitative data, it is abundantly clear that pathology, when applied to routine screening of animal toxicity and carcinogenicity studies, has to be quantitative to at least some degree so that statistical statements can be made about possible treatment effects. Inevitably, there will be some descriptive text which will not be appropriate for statistical analysis. However, the main objective of the pathologist should be to provide information on the presence or absence (with severity grade or size where appropriate) of a list of conditions, consistently recorded from animal to animal by well-defined criteria, which can be validly used in a statistical assessment.

Given statistical analysis is worth doing and data are available that could be analysed, should one then analyse all the end points recorded? Some arguments have been put forward against analysing all the end points studied, but none are convincing.

One argument is that some end points are not of interest. Perhaps the study is essentially a carcinogenicity study, so that non-neoplastic end points are considered to be 'background pathology' and almost *per se* unrelated to treatment. In our view, this is illogical. If the pathologist has gone to the trouble of recording the data, then surely, in general, they ought to be analysed; otherwise, why record them in the first place? After all, the costs of the statistical analysis are much less than those of doing the study and the pathology. While one might justify failure to analyse non-neoplastic data where tumour analysis has already shown the compound is clearly carcinogenic and no longer of market potential, the general rule ought to be to analyse everything that has been specifically investigated.

Another argument put forward against doing multiple analyses is that it may yield many chance significant p values that have to be 'explained away'. This seems to us a poor reason for not exploring the data fully. A detailed look at the data can only aid interpretation, provided one is not hide-bound by the false argument that statistical significance necessarily equates with biological importance and definitely indicates a true effect of treatment.

Another reason not to analyse might be that visual inspection of summary tables reveals no suspicion of an effect for some end point. This seems to be, in this age of rapid and efficient computer programs, totally the wrong way to organize things. Given the data are on

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

computer, it is much better and quicker to do the actual analysis than to do the inevitably subjective, unreliable and slow prescreening process. In any case, where there are substantial differences in survival between groups, it is very difficult to form a reliable view by inspection of non-age-adjusted frequencies on whether an effect might or might not have occurred.

A final, more valid, reason is that some end points occur only very rarely. One should, however, be clear what 'very rarely' is. For a typical study with a control and three dose groups of equal size, one would get a significant trend statistic if all three cases occurred at the top dose level or in the control group (two-tailed $p = 0.03$), so a total of three cases will normally be enough for statistical analysis. End points occurring once or twice only are not worth analysing formally, though, if only seen in the top-dose group, they may be worth noting in the report. This is especially true if they are lesions that are rarely reported.

6.3 Combination of Pathological Conditions

There are four main situations where one might consider combining pathological conditions in a statistical analysis.

The first is when essentially the same pathological condition has been recorded under two or more different names or even under the same name in different places. Here failure to combine these conditions in the analysis may severely limit the chances of detecting a true treatment effect. It should be noted, however, that grouping together conditions which are actually different may also result in the masking of a true treatment effect, particularly if the treatment has a very specific effect.

The second is when separately recorded pathological conditions form successive steps on the pathway of the same process. The most important example of this is for the incidence of related types of malignant tumour, benign tumour and focal hyperplasia. It will normally be appropriate to carry out analyses of: (i) incidence of malignant tumour, (ii) incidence of benign or malignant tumour, and, where appropriate, (iii) incidence of focal hyperplasia, benign or malignant tumour. It will not normally be appropriate to carry out analyses of benign tumour incidence only or of the incidence of hyperplasia only.

The third situation for combining is when the same pathological condition appears in different organs as a result of the same underlying process. Examples of this are the multicentric tumours (such as myeloid leukaemia, histiocytic sarcoma or malignant lymphoma) or certain non-neoplastic conditions (such as arteritis/periarteritis or amyloid deposition). Here analysis will normally be carried out only of incidence at any site, although in some situations site-specific analyses might be worth carrying out.

The final situation where an analysis of combined pathological conditions is normal is for analyses of overall incidence of malignant tumour at any site, of benign or malignant tumour at any site, or of multiple tumour incidence. While analyses of tumour incidence at specific sites are normally more meaningful, since treatments often affect only a few specific sites, these additional analyses are usually required to guard against the possibility that treatment had some weak, but general, tumour-enhancing effect not otherwise evident.

In some situations, one might also envisage analyses of other combinations of specific tumours, such as tumours at related sites (e.g. endocrine organs if the compound had a hormonal effect) or of similar histological type.

6.4 Taking Severity into Account

The same line of argument that suggests that if the pathologist records data it should be analysed, also suggests that if the pathologist chooses to grade a condition for severity, the grade should be taken into account in the analysis. There are two ways to carry out analysis when the grade has to be taken into account. In one, analyses are carried out, not only of whether or not the animal has a condition, but also of whether or not the condition is at least grade 2, at least grade 3, and so on. In the other approach, nonparametric (rank) methods are used. The latter approach is more powerful, as it uses all the information in one analysis, although the output may not be so easily understood by those without some statistical training.

Note that the analyses based on grade can be carried out only if grading has been consistently applied throughout. If a condition has been scored only as present/absent for some animals, but has been graded for others, it is not possible to carry out graded analyses unless the pathologist is willing to go back and grade the specific animals showing the condition.

6.5 Using Simple Methods Which Avoid Complex Assumptions

Methods for statistical analysis can vary considerably in their complexity and in the number of assumptions they make. Although use of statistical models has its place, more so for effect estimation that for hypothesis testing, and more so in studies of complex design than in those of simple design, there are advantages in using, wherever possible, statistical methods that are simple, robust and make as few assumptions as possible. There are three reasons for this. First, such methods are more

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

generally understandable to the toxicologist. Second, there are hardly ever extensive enough data in practice to validate any given formal model fully. Third, even if a particular model were known to be appropriate, the loss of efficiency in using appropriate simpler methods is often only very small.

The methods we advocate for routine use for the analysis of tumour incidence tend, therefore, not to be based on the use of formal parametric statistical models. For example, when studying the relationship of treatment to incidence of a pathological condition and wishing to adjust for other factors (in particular, age at death) that might otherwise bias the comparison, methods involving 'stratification' are recommended, rather than a multiple regression approach or time-to-tumour models. Analysis of variance (ANOVA) methods can be useful in the case of continuously distributed data for estimating treatment effects. However, they involve underlying assumptions (normally distributed variables, variability equal in each group). If the assumption of normality is violated, nonparametric methods based on the rank of observations, rather than their actual value, may be preferable for hypothesis testing.

6.6 Using All the Data

Often information is available about the relationship between treatment and a condition of interest for groups of animals differing systematically in respect of some other factor. Obvious examples are males and females, differing times of sacrifice, and differing secondary treatments. While it will be necessary, in general, to look at the relationship within levels of this other factor, it will also generally be advisable to try to come to some assessment of the relationship over all levels of the other factors combined. There are some situations where the effect of treatment varies markedly by level of the other factor, and where a combined inference is not sensible, but in far more situations this is not the case, and using all the data in one analysis allows a more powerful test of the relationship under study. Some scientists consider that conclusions for males and females should always be separately drawn, but there are strong statistical arguments for a joint analysis.

6.7 Combining, Pooling and Stratification

Suppose, in a hypothetical study of a toxic agent which induces tumours that do not shorten the lives of tumour-bearing animals, the data are as shown in **Table 1**.

Table 1 Tumour rates[a] by period and treatment in a hypothetical study

Period of study	Control	Exposed	Combined
Early deaths	1/20 (5%)	18/90 (20%)	19/110 (17%)
Late deaths	24/80 (30%)	7/10 (70%)	31/90 (34%)
Total	25/100 (25%)	25/100 (25%)	50/200 (25%)

[a]Data shown are number with tumour out of number examined (percentage with tumour).

It can be seen that if the time of death is ignored and the *pooled* data are studied, the incidence of tumours is the same in each group, resulting in the *false* conclusion that treatment had no effect. Looking within each time of death, however, an increased incidence in the exposed group can be seen. An appropriate statistical method would *combine* a measure of difference between the groups based on the early deaths and a measure of difference based on the late deaths, and conclude *correctly* that incidence, after adjustment for time of death, is greater in the exposed groups.

In this example, time of death is the 'stratifying variable', with two strata—early deaths and late deaths. The essence of the methodology is to make comparisons only within strata (so that one is always comparing like with like except in respect of treatment) and then to combine the differences over strata. Stratification can be used to adjust for any variable, or indeed combinations of variables.

Some studies are of factorial design, in which combinations of treatments are tested. The simplest such design is one in which four equal-sized groups of animals receive: (i) no treatment, (ii) treatment A only, (iii) treatment B only and (iv) treatments A and B. If one is prepared to assume that any effects of the two treatments are independent, one can use stratification to enable more powerful tests to be conducted of the possible individual treatment effects. Thus, to test for effects of treatment A for example, one conducts comparisons in two strata, the first consisting of groups 1 and 2 not given treatment B and the second consisting of groups 3 and 4 given treatment B. Combination of results from the two strata are based on twice as many animals, and are therefore markedly more likely to detect possible effects of treatment A than is a simple comparison of groups 1 and 2. There is also the possibility of identifying interactions, such as synergism and antagonism, between the two treatments.

6.8 Multiple Control Groups

In some routine long-term screening studies, the study design involves five groups of (usually) 50 animals of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

each sex, three of which are treated with successive doses of a compound and two of which are untreated controls. Assuming that there is no systematic difference between the control groups (e.g. the second control group in a different room or from a different batch of animals), it will be normal to carry out the main analyses with the control groups treated as a single group of 100 animals. It will usually be a sensible preliminary precaution to carry out additional analyses comparing incidences in the two control groups.

Table 2 Tumour rates[a] by period and treatment in a further hypothetical study

Period of study	Control	Exposed
Early deaths	0/20	0/20
Middle deaths	1/10	9/10
Late deaths	20/20	20/20
Total	21/50	29/50

[a]Data shown are number with tumour out of number examined.

6.9 Trend Analysis, Low-Dose Extrapolation and NOEL Estimation

While comparisons of individual treated groups with the control group are important, a more powerful test of a possible effect of treatment will be to carry out a test for a dose-related trend. This is because most true effects of treatment tend to result in a response which increases (or decreases) with increasing dose and because trend tests take into account all the data in a single analysis. In interpreting the results of trend tests, it should be noted that a significant trend does not necessarily imply an increased risk at lower doses. Nor, conversely, does a lack of increase at lower doses necessarily indicate evidence of a threshold (i.e. a dose below which no increase occurs).

Note that testing for trend is seen as a more sensitive way of picking up a possible treatment effect than simple pairwise comparisons of treated and control groups. Attempting to estimate the magnitude of effects at low doses, typically below the lowest positive dose tested in the study, is a much more complex procedure, and is heavily dependent on the assumed functional form of the dose–response relationship.

Such low-dose extrapolation is typically only conducted for tumours believed to be caused by a genotoxic effect which some, but by no means all, scientists believe have no threshold. For other types of tumours and for many non-neoplastic end points, a threshold is generally considered likely to exist. While the precise threshold cannot be estimated directly from data at a limited number of dose levels, a no observed effect level (NOEL) can be estimated by finding the highest dose level at which there is no significant increase in effects.

6.10 Need for Age Adjustment

Where there are marked differences in survival between treated groups, it is widely recognized that there is a need for an age adjustment (i.e. an adjustment for age at death or onset). This is illustrated in the example above, where, because of the greater number of deaths occurring early in the treated group, the true effect of treatment disappears if no adjustment is made. Thus, a major purpose of age adjustment is to avoid bias.

It is not so generally recognized, however, that, even where there are no survival differences, age adjustment can increase the power to detect between-group differences. This is illustrated in **Table 2**.

Here treatment results in a somewhat earlier onset of a condition which occurs eventually in all animals. Failure to age-adjust will result in a comparison of 29/50 with 21/50, which is not statistically significant. Age adjustment will essentially ignore the early and late deaths, which contribute no comparative statistical information, and be based on the comparison of 9/10 with 1/10, which is statistically significant. Here age adjustment sharpens the contrast, rather than avoiding bias, by avoiding diluting data capable of detecting treatment effects with data that are of little or no value for this purpose.

6.11 Need to Take Context of Observation into Account

It is by now widely recognized that age adjustment cannot properly be carried out unless the context of observation is taken into account. There are three relevant contexts, the first two relating to the situation where the condition is only observed at death (e.g. an internal tumour), the third where it can be observed in life (e.g. a skin tumour).

In the first context the condition is assumed to have caused the death of the animal—that is, to be *fatal*. Here the incidence rate for a time interval and a group is calculated by:

$$\frac{\text{(number of animals dying in the interval because of the lesion)}}{\text{(number of animals alive at the start of the interval)}} \quad (1)$$

In the second context, the animal is assumed to have died of another cause—that is, the condition is

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

incidental. Here the rate is calculated by:

$$\frac{\text{(number of animals dying in the interval with the lesion)}}{\text{(total number of animals dying in the interval)}} \quad (2)$$

In the third context, where the condition is *visible*, the rate is calculated by:

$$\frac{\text{(number of animals getting the condition in the interval)}}{\text{(number of animals without the condition at the start of the interval)}} \quad (3)$$

A problem with the method of Peto *et al*. (1980), which takes context of observation into account, is that some pathologists are unwilling or feel unable to decide whether, in any given case, a condition is fatal or incidental. A number of points should be made here.

First, where there are marked survival differences, it may not be possible to conclude reliably whether a treatment is beneficial or harmful unless such a decision is made. This is well illustrated by the example in Peto *et al*. (1980), where assuming all pituitary tumours were fatal resulted in the (false) conclusion that *N*-nitrosodimethylamine (NDMA) was carcinogenic, while assuming they were all incidental resulted in the (false) conclusion that NDMA was protective. Using, correctly, the pathologist's best opinion as to which were, and which were not, likely to be fatal, resulted in an analysis which (correctly) concluded NDMA had no effect. If the pathologist, in this case, had been unwilling to make a judgement as to fatality, believing it to be unreliable, no conclusion could have been reached. This state of affairs would, however, be a fact of life, and *not* a position reached because an inappropriate statistical method was being used. Alternative techniques, such as the PolyK test (Bailer and Portier, 1988), which do not take context of observation into account, cannot provide a valid analysis of data such as these (Lee and Fry, 2002a; 2002b).

Although it will normally be a good routine for the pathologist to ascribe 'factors contributory to death' for each animal that was not part of a scheduled sacrifice, it is in fact not strictly necessary to determine the context of observation for all conditions at the outset. An alternative strategy is to analyse under differing assumptions: (i) no cases fatal, (ii) all cases occurring in decedents fatal, (iii) all cases of same defined severity occurring in decedents fatal, with, under each assumption, other cases incidental.

If the conclusion turns out the same under each assumption, or if the pathologist can say, on general grounds, that one assumption is likely to be a close approximation to the truth, it may not be necessary to know the context of observation for the condition in question for each individual animal. Using the alternative strategy might result in a saving of the pathologist's time by only having to make a judgement for a limited number of conditions where the conclusion seems to hang on correct knowledge of the context of observation.

Finally, it should be noted that, although many non-neoplastic conditions observed at death are never causes of death, it is, in principle, as necessary to know the context of observation for non-neoplastic conditions as it is for tumours.

6.12 Experimental and Observational Units

In many situations, the animal is both the 'experimental unit' and the 'observational unit', but this is not always so. For determining treatment effects by the methods of the next section, it is important that each experimental unit provides only one item of data for analysis, as the methods all assume that individual data items are statistically independent. In many feeding studies, where the cage is assigned to a treatment, it is the cage, rather than the animal, that is the experimental unit. In histopathology, observations for a tissue are often based on multiple sections per animal, so that the section is the observational unit. Multiple observations per experimental unit should be combined in some suitable way into an overall average for that unit before analysis.

6.13 Missing Data

In many types of analysis, animals with missing data are simply removed from the analysis. There are, however, some situations where this can be an inappropriate thing to do. One situation is when carrying out an analysis of a condition that is assumed to have caused the death of the animal. Although an animal dying at week 83 for which the section was unavailable for microscopic examination cannot contribute to the group comparison at week 83, one knows that it did not die because of any condition in previous weeks, so it should contribute to the denominator of the calculations in all previous weeks.

Another situation is when histopathological examination of a tissue is not carried out unless an abnormality is seen at post mortem. In such an experiment one might have the data shown in **Table 3**.

Ignoring animals with no microscopic sections, one would compare $2/2 = 100\%$ with $14/15 = 93\%$ and conclude that treatment nonsignificantly decreased incidence. This is likely to be a false conclusion, and it would probably be better here to compare the percentages of the total animals in the group which had a post mortem abnormality which turned out to be a tumour, that is, $2/50 = 4\%$ with $15/50 = 30\%$. Unless some aspect of treatment made tumours much

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Hypothetical data for a tissue not examined routinely

Treatment group	Number of animals			
	Total	Abnormal at post mortem	Examined microscopically	With specific tumour
Control	50	2	2	2
Treated	50	15	15	14

easier to detect at post mortem, one could then conclude treatment did have an effect on tumour incidence.

Particular care has to be taken in studies where the procedures for histopathological examination vary by group. In a number of studies conducted in recent years, the protocol demands full microscopic examination of a given tissue list in decedents in all groups, in terminally killed controls and high-dose animals. In other animals, terminally killed low- and mid-dose animals, microscopic examination of a tissue is only conducted if the tissue is found to be abnormal at post mortem. Such a protocol is designed to save money, but leads to difficulty in comparing the treatment groups validly. Suppose, for example, responses in terminally killed animals are 8/20 in the controls, 3/3 (with 17 unexamined) in the low dose and 5/6 (with 14 unexamined) in the mid dose. Is one supposed to conclude treatment at the low and mid doses increased response, based on a comparison of the proportions examined microscopically (40, 100 and 83%), or decreased response, based on the proportion of animals in the group (40, 15 and 25%)? It could well be that treatment had no effect, but some small tumours were missed at post mortem. In this situation, a valid comparison can only be achieved by ignoring the low- and mid-dose groups when carrying out the comparison for the age stratum 'terminal kill'. This, of course, seems wasteful of data, but these are data that cannot be usefully used due to the inappropriate protocol.

6.14 Use of Historical Control Data

In some situations, particularly where incidences are low, the results from a single study may suggest an effect of treatment on tumour incidence, but be unable to demonstrate it conclusively. The possibility of comparing results in the treated groups with those of control groups from other studies is then often raised. Thus, a nonsignificant incidence of two cases out of 50 in a treated group may seem much more significant, if no cases have been seen in, say, 1000 animals representing controls from 20 similar studies. Conversely, a significant incidence of five cases out of 50 in a treated group as compared with none out of 50 in the study controls may seem far less convincing if many other control groups had incidences around five out of 50.

While not understating the importance of looking at historical control data, it must be emphasized that there are a number of reasons why variation between studies may be greater than variation within studies. Differences in diet, in duration of the study, in intercurrent mortality and in who the study pathologist is, may all contribute. Statistical techniques that ignore this and carry out simple statistical tests of treatment incidence against a pooled control incidence may well give results that are seriously in error, and are likely to overstate statistical significance considerably. Appropriate tests allow for the possibility of these additional sources of variation (Gart *et al*., 1986; Tarone, 1982).

7 STATISTICAL ANALYSIS: SUMMARY OF APPROPRIATE METHODS

7.1 Types of Response Variable

Responses measured in toxicological studies can normally be classified into one of the following three types:

1. Presence/absence: a condition either occurs or it does not.
2. Ranked: a condition may be present at various discrete levels.
3. Continuous: a condition may take any value, at least within a given range.

Strictly, each type of response requires a different sort of statistical technique. Methods for presence/absence data can be used for ranked or continuous data by defining a cut-off point above which is deemed present, but this is rather wasteful of data. Methods for ranked data can also be used for analysing continuous data, and probably should be if one is not confident about the assumptions of normality and homogeneity of variance underlying the standard parametric methods used, such as ANOVA.

7.2 Types of Comparison

There are three principal different types of comparison between groups. The first is the pairwise comparison, in which the responses in two different groups, usually a treated group and the control group, are compared. The second, only applicable to studies with more than two treatment groups, is the test for heterogeneity, which tests whether, taken as a whole, there is significant evidence

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of departure from the (null) hypothesis that the groups do not differ in their effect. The third, only applicable to studies with more than two treatment groups in which the different groups represent different doses of the same compound, is the test for a dose-related trend.

7.3 Recommended Methods for Between-Animal Comparisons

7.3.1 Presence/Absence Data

For pairwise comparisons, Fisher's exact test is recommended for unstratified data, though a 2×2 corrected chi-squared test will yield a sufficient approximation unless incidences are low. For stratified data, a corrected chi-squared test is usually used, although exact versions of this are available in some programs, and may be preferable where data are sparse.

For dose-related trend, the Cochran–Armitage test is often appropriate for stratified or unstratified data. Like the chi-squared test, it is only approximate, and again exact tests may be preferable.

To test for overall heterogeneity over k groups, the $2 \times k$ chi-squared test should be used for unstratified and stratified data. Exact versions of this are now available in many software packages.

The tests described above are illustrated in Lee (1993) with fuller details given in many textbooks.

Where context of observation has to be taken into account, the Peto/IARC (International Agency for Research on Cancer) method (Peto *et al.*, 1980) is appropriate for pairwise comparisons and tests for dose-related trend and heterogeneity, though exact versions of this method are available in some programs (see Section 8).

7.3.2 Ranked Data

It is clearly possible to use a cut-point, defining values above it as 'present' and below it as 'absent', with the methods described in Section 7.3.1 then being used. However, this is wasteful of information.

For unstratified data, pairwise comparisons should be made using the Wilcoxon (Mann–Whitney U) test, with a heterogeneity test based on Kruskal–Wallis one-way ANOVA. Both tests are described in Conover (2003). For trend tests, the nonparametric analogue of the Cochran–Armitage test, derived by Marascuilo and McSweeney (1967) and described by Lee (1993), is recommended, although alternatives are available (Jonckheere, 1954; Shirley, 1977).

The method of Fry and Lee (1988) (see also Lee, 1993) can be used to provide stratified rank tests of pairwise comparison, heterogeneity and dose-related trend.

7.3.3 Continuous Data

Bartlett's test (see Lee, 1993) should be used to test for homogeneity of variance. If the data show appreciable heterogeneity, transformation of the individual data items by logarithms and/or square roots can be considered, but analysis of the data using the ranked methods described in Section 7.3.2 is a simple and sound alternative.

Assuming the data are reasonably homogeneous, they should be analysed using standard methods for normally distributed data, that is, the Student's t-test for pairwise comparisons, the one-way ANOVA F test for heterogeneity and linear regression for the trend test (Guenther, 1964; Johnson and Leone, 1977). The Williams test (Williams, 1971; 1972) is an alternative trend test which, like the Shirley test (Shirley, 1977), attempts to estimate the lowest dose level showing a significant relationship with treatment.

Analysis of continuous data to correct for sources of potential bias is not normally carried out by methods involving stratification, but by the methods of analysis of covariance, multiple regression and linear models. These, and the more complex ANOVA methods required for factorial designs, probably need discussion with a statistician.

7.3.4 Multiple Comparison Tests

Although multiple comparison tests should be used with caution (see Section 3.3), it is worth pointing out that there are various standard procedures available. For parametric (continuous) data, there are the Dunnett test (Dunnett, 1955; 1964) and the Stepwise Dunnett test (Dunnett and Tamhane, 1991), while for nonparametric data there are the Bonferroni and Stepwise Bonferroni tests (Hochberg and Benjamini, 1990), the Steel test (Steel, 1959) and the Dunn test (Dunn, 1964). A detailed discussion of these is beyond the scope of this chapter, though it should be noted that Bonferroni correction is often used with quantitative data, such as toxicogenomic data.

7.4 Other Statistical Methods

The methods described in the previous subsection have concentrated on the common experimental situation where interest is centred on evidence of variation between groups in respect of a single variable, with the possible confounding effect of other variables taken account of by stratification. There are a number of different situations, considered briefly below, where alternative statistical techniques are required.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

7.5 Relationships between Two Variables

For presence/absence data, relationships between two variables can be studied by Fisher's exact test or a corrected chi-squared test. For ranked and continuous data, the correlation coefficients of, respectively, Spearman and Pearson can be used. Techniques are also available for determining whether these relationships differ for different treatment groups.

7.6 Multivariate Methods

Situations involving the inter-relationship of a large number of variables normally require the advice of a professional statistician. Multivariate statistical methods are now widely used in the developing discipline of toxicogenomics and its related field of proteomics and metabolomics. They are aimed at producing lists of genes with significantly different expression between treated groups, and profiles of genes with different expression which distinguish between samples and have potential predictive ability. A wide range of multivariate statistical methods are involved, such as cluster analysis, principal component analysis, discriminant functions and partial least squares. Specialized software is available for these approaches in both proprietary packages and through the use of the Bioconductor suites of programs developed using the statistical programming language R (Gentleman *et al*., 2005). The results of these analyses are linked with the appreciable Bioinformatic resources on the genes, proteins and metabolic pathways maintained by organizations such as the NCBI (National Center for Biotechnology Information) and the EBI (European Bioinformatics Institute). The statistical methods used are beyond the scope of this chapter, but the large numbers of statistical tests carried out raise issues with respect to multiple comparisons and the interpretation of statistical significant results. Other multivariate methods commonly used in other applications are multiple regression analysis and factor analysis.

7.7 Multiple Observations on the Same Animal

In long-term studies, it is common to make similar measurements—for example, of body weight—on the same animal at different stages of the study. To look for evidence of a between-group difference in changes in responses over a given period, the preferred technique is analysis of covariance, where differences in mean values at the second time-point are studied after adjustment for values observed at the first time-point. Alternatively, parametric growth curves may be fitted and the groups compared in respect of these parameters, but such techniques tend to be complex. Diggle *et al*. (2002) provide a comprehensive review of methods for the longitudinal analysis of data. Methods for the analysis of repeated measures data can be found in Crowder and Hand (1990).

7.8 Paired Data

Sometimes studies consist of pairs of animals, each pair of animals being similar in respect of important potential confounding variables, for example, litter, and differing only in respect of treatment. It is important to take the pairing into account for analysis. Appropriate techniques to use are the sign test or McNemar's test for presence/absence data, the Wilcoxon matched-pair signed-ranks test for ranked data and the matched-pair *t*-test for continuous data. Considerable care is needed to ensure that the appropriate paired or unpaired test is used. A common error in analysis is to use a paired test on unpaired data or vice versa.

7.9 LD_{50}

Some toxicological studies calculate the dose of a substance at which 50% of the animals respond. This is known as the LD_{50} when the response is death [lethal dose (LD)] and more generally as the median-effective dose. The classical technique to calculate the LD_{50} from data consisting of the percentage responding at each of a range of dose levels is known as probit analysis. Sequential methods which require fewer animals are increasingly being applied to reduce the number of animals used in this controversial and unpopular toxicological test.

8 SOFTWARE

The recommended methods for between-animal comparisons are all available in the comprehensive computer program for data entry, reporting and statistical analysis of pathological data, ROELEE. Various standard statistical packages, such as GENSTAT, MINITAB, SAS, S-PLUS, SPSS and SYSTAT, include many of the techniques described here. With the advent of much more powerful computers, there has been a tendency in many situations to move from the formerly used approximate asymptotic statistical tests to exact randomization tests. Most packages, including SAS, SPSS and STATXACT have facilities for exact tests, while ROELEE includes an exact version of the Peto *et al*. (1980) test, including an exact trend test. are helpful for determining appropriate group sizes when designing a study. See Section 11 for software addresses.

9 RECOMMENDED READING

Lee (1993) provides a simple text, aimed at toxicologists and including worked examples, for many of the methods we recommend. Peto *et al*. (1980) describes and justifies the most commonly used test for comparison of age-adjusted tumour incidences taking context of observation into account. Gart *et al*. (1986) is a more detailed text, aimed more at statisticians, describing methods of analysis of carcinogenicity data, while Krewski and Franklin (1991) is an extensive textbook covering a wide range of issues relating to statistics in toxicology. Two good general biostatistical textbooks are Altman (1991) and Armitage *et al*. (2001). For those concerned with estimation of effect rather than with determining statistical significance, Altman *et al*. (2000) gives details of how to calculate confidence limits for many tests. Gad (2005) also contains useful material on other types of data, such as body and organ weights, clinical chemistry, haematology, reproduction, teratology, dominant lethal assay and mutagenesis. Kirkland (1989) provides an overview of the statistical issues and methods used in genetic toxicology and mutagenicity studies.

10 GLOSSARY OF STATISTICAL TERMS

10.1 Types of Data

Dichotomous data: Data that can take one of two possible values, such as dead/alive, smoker/nonsmoker, present/absent. Also called binary data.
Ordinal data: Data that are classified into more than two categories which have a natural order, for example, nonsmokers, ex-smokers, light smokers and heavy smokers. Also called ranked data. Ordinal data are often reduced to two categories to simplify analysis and presentation, which may result in a considerable loss of information.
Categorical data: Data that are classified into two or more nonoverlapping categories. Race and type of drug (aspirin, paracetamol, etc.) are examples of categorical variables.
Continuous data: Data with a potentially infinite number of possible values within a given range. Height, weight and blood pressure are examples of continuous variables.

10.2 Measures of Central Tendency

Mean: An average value, calculated by adding all the observations and dividing by the number of observations. Also called the arithmetic mean.
Median: The value for which one-half of the observations (when ranked) will lie above that value and one-half will lie below that value. When the number of values in the sample is even, the median is computed as the average of the two middle values.
Mode: The value which occurs most frequently in the sample.

10.3 Measures of Variability

Variance: The average of the squared differences between data values and the mean.
Standard variation: A measure of the spread of values, calculated as the square root of the variance.
Standard error of the mean: The theoretical standard deviation of all sample means of size n drawn from a population. It depends on both the variance and the sample size (n), decreasing as n increases.

10.4 Distributions and Related Terms

Normal distribution: A bell-shaped statistical distribution with known properties commonly used as the basis of models to analyse continuous data. Key assumptions in such analyses are that the data are symmetrically distributed about a mean value, and the shape of the distribution can be described using the mean and standard deviation.
Skewness: This measures the deviation of the distribution from symmetry. If the skewness is clearly different from zero, then that distribution is asymmetrical, while Normal distributions are perfectly symmetrical. Often in toxicology, the data values themselves have a skew distribution, with many low values and a few high values, but the logarithms of the data values are symmetrically distributed and approximately satisfy a Normal distribution.
Other distributions: Other distributions commonly used in statistics are the t-distribution (or Student t-distribution), used to compare means of samples where the variance is estimated from the data, the F-distribution, used to compare two variances, the chi-squared distribution, used to compare frequencies in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat037
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

categorical data, and the Poisson distribution, used to describe the distribution of rare events.

Degrees of freedom: This is the number of categories or classes being tested minus 1. Thus, for example, the ratio of two variances, both calculated from a normally distributed sample, one of size n_1 and the other of size n_2, has an F distribution with degrees of freedom $n_1 - 1$ and $n_2 - 1$.

Quartile: Technically, this is any of the three values which divide ranked data into four equal parts, so that each part represents a quarter of the sampled population. In practice, the term quartile is often used to describe the parts themselves, for example, 'the data were divided into four quartiles', rather than 'the data were divided by three quartiles'.

***n*-tiles:** This is any of the $n - 1$ values which divide ranked data into n equal parts, so that each part represents an nth of the sampled population. The term is often used to describe the parts themselves. The median ($n = 2$), tertiles ($n = 3$), quartiles ($n = 4$), quintiles ($n = 5$), deciles ($n = 10$) and centiles ($n = 100$) are examples of n-tiles which are often used.

10.5 Some Other Terms

CI: For a specified statistic, such as the mean, the CI gives us a range of values around the statistic where the 'true' (population) statistic can be expected to be located with a given level of certainty. 95% CIs are very commonly used.

Correlation: The linear association between two variables, measured by a correlation coefficient, with values ranging from -1 to $+1$. A value of $+1$ implies perfect positive correlation, so that the values when plotted on a graph would fall perfectly on an increasing straight line.

Regression analysis: A statistical modelling technique used to estimate or predict the influence of one or more independent variables on a dependent variable, for example, the effect of age, sex and educational level on the prevalence of a disease. Logistic regression and meta-regression are types of regression analysis.

***p* value:** the probability (ranging from zero to one) that the results observed in a study (or results more extreme) could have occurred by chance if in reality the null hypothesis was true.

Power: The probability of rejecting the null hypothesis when a specific alternative hypothesis is true.

Nonparametric tests: Nonparametric tests are often used in place of their parametric counterparts when certain assumptions about the underlying population are questionable. Nonparametric tests may be, and often are, more powerful in detecting population differences when certain assumptions are not satisfied. All tests involving ranked data, that is, data that can be put in order, are nonparametric.

Pathological Techniques in Toxicology

Peter Greaves

CONTENTS

1 INTRODUCTION

For over 100 years microscopic evaluation of pathological alterations in human tissues has made major contributions to our understanding of diseases and it remains a significant diagnostic tool in human medicine. Rather than diminish in importance in the face of novel imaging techniques, recent advances in biotechnology have served to reaffirm the central role of histopathology in the diagnoses of human diseases, as well as in the study of adverse effects of xenobiotics on people. This has occurred partly because the transfer of new technologies into the pathology laboratory and the development of new histological visualization procedures. These new methods represent a logical extension to the use of special stains on tissue sections and have provided the pathologist with additional objective techniques to allow more precise morphological and functional correlation of changes in tissues.

Histopathological evaluation of tissue sections also represents a major technique in experimental studies of human disease. It has a central role in conventional toxicology studies which are performed to assess the toxicity of xenobiotics. The particular contribution of histopathology is its ability to assess the interaction of xenobiotics on complete body and organ systems rather than single cells or organs. The important place of histological assessment of tissues in regulatory toxicology has given rise to the development of the discipline of toxicological pathology. It needs to be underlined that this discipline is not simply the diagnosis of pathological lesions, but also the translation and integration of pathological diagnoses into meaningful summaries that can be understood by a diverse audience. A thorough knowledge of pathological techniques applicable to experimental pathology and problem solving in toxicology is an important and integral part of the skills needed by the toxicological pathologist.

1.1 Basic Techniques in Autopsy and Histology Practice

Fundamental to good histopathological evaluation of tissue sections is a detailed autopsy or necropsy. This requires careful observation of the organs for any abnormalities and appropriate selection of tissues. Whereas in human autopsy practice and in experimental pathology studies, tissue sampling is usually directed towards particular lesions or organs of direct relevance to the problem under study, a more systematic approach is usually adopted in conventional animal toxicity studies. Most international regulatory guidelines require 30 or 40 tissues to be taken from all animals in most conventional toxicity studies. These are defined by the standard protocols of laboratories performing work for government regulatory authorities, and recommended lists are available (Jacobs *et al*., 2003). However, it is important to remain acutely aware that even the most complete tissue list remains a selective process and a careful inspection of the tissues for abnormalities at autopsy remains mandatory.

The precise selection of blocks, orientation of tissues and number of slides examined varies between laboratories. However, these procedures have become more standardized over recent years and recommended tissue blocking and orientation procedures have been published (Ruehl-Fehlert *et al*., 2003; Kittel *et al*., 2004; Morawietz *et al*., 2004).

For routine purposes, most tissues are fixed in a formalin solution by most laboratories, followed by embedding in paraffin wax and cutting of histological sections. Exceptions are eyes and testes, for which formalin is a poor fixative. Here, Bouin's, Zenker's or Davidson's fixatives are used. Bouin's fluid is generally considered the best fixative for the testis although there has been a move away from this because of the safety concerns of its picric acid content (Latendresse *et al*., 2002). Formalin, when used under stringent conditions, is usually good as a fixative for many immunocytochemical and molecular biological techniques on tissue sections. Frozen sections are, however, usually needed for studies of enzyme activity or requiring intact RNA.

Haematoxylin and eosin remains the most widely used stain, supplemented where appropriate by a Romanovsky stain for haemopoietic cells, periodic acid Schiff (PAS) stain for hepatic glycogen, glomerular basement membrane and the acrosome on testicular germ cells, trichrome and elastic stains for the myocardium and blood vessels and oil red O for neutral lipids. Immunocytochemical techniques are now extensively used (see below).

The use of larger, semithin (1–3 μm thick) plastic- or resin-embedded sections is a cost-effective compromise between electron microscopy and conventional light microscopy. Sometimes termed 'high-resolution light microscopy', light microscopic evaluation of semithin sections provides a means of avoiding extensive use of the electron microscope because it can locate cytoplasmic organelles in a way sometimes not possible in paraffin wax-embedded material.

1.2 Organ Weights

The extent to which organs are weighed varies between laboratories, and government guidelines are not always consistent (Michael *et al*., 2007). Heart weight is a guide to potential cardiac alterations and especially important in the assessment of cardiovascular drugs. Likewise, the lungs are weighed in inhalation studies for this can provide a useful indication of the extent of oedema or accumulation of exudate. Brain weight is employed as stable reference point in adult animals for it is fairly independent of body weight changes and can be useful in the evaluation of weight change in some organs (Bailey *et al*., 2004). The weights of endocrine organs are useful guides to alterations in the endocrine status of laboratory animals.

Testicular weights correlate with testicular toxicity and weights can be compared with in-life measurement of testicular size (Heywood and James, 1978). Weighing the testis is a useful precaution at the early phase of development of a novel drug prior to any assessment of male fertility and is generally recommended (Sellers *et al*., 2007). By contrast, ovarian weight is highly variable, as a consequence of cyclical ovarian development and is therefore a less sensitive indicator of treatment-induced changes in the female reproductive system, so that choosing to weigh ovaries needs to be considered on a case-by-case basis.

1.3 Histopathological Evaluation of Toxicological Studies

Histopathological assessment requires, above all, a systematic and meticulous approach, correlating in-life observations, autopsy findings, organ weight and clinical pathology changes with histopathological alterations. Careful selection of diagnostic terminology is essential because many of the terms utilized in experimental pathology have been borrowed from human pathology, where they may by applied to quite specific clinical conditions not always relevant to laboratory animal species. Lucid summary reports are essential. Good practices for pathology reports in toxicology studies have been recently summarized (Morton *et al*., 2006).

In conventional subacute and chronic toxicity studies, as well as in carcinogenicity bioassays, a complete set of tissues from the top-dose and control animals is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

routinely examined. In addition, any target organs or tissues showing tumours or other macroscopic alterations at autopsy in animals from intermediate-dose groups are also assessed. This baseline approach is outlined in some of the regulatory guidelines. However, some pathologists avoid this selective approach and examine all tissues sampled from all animals. This approach is perhaps more costly from a histological processing point of view, but permits rapid reporting of all the salient histopathological findings in every dose group. Cause-of-death assignment is another component of the assessment of carcinogenicity studies in rodents which is widely practised to aid statistical evaluation (Kodell *et al*., 1995).

The error which develops from the increased awareness of a lesion by the pathologist only after examining a considerable number of animals has been aptly termed 'diagnostic drift' (Roe, 1977). Another point of debate is the appropriateness of blind slide reading as a means to avoid bias, and opinion is much divided (Holland, 2001). Blind slide reading as a routine process conflicts with the need to have relevant clinical, clinical pathology and macroscopic data to make an appropriate tissue diagnosis. For this reason, only doubtful lesions which persist after a careful and integrated nonblind review of tissue sections are those which should be evaluated in a properly designed blind review (Newberne and de la Iglesia, 1985).

Peer review of pathological findings and quality assurance audit of the processes in histopathological assessment have also become more important components of regulatory toxicology studies in recent years. Peer review is believed to ensure integrity of the pathological diagnoses, encourage consistency and facilitate learning (Ward *et al*., 1995). Moreover, it is generally accepted that a peer review or check of a percentage of the diagnoses in a study by a second pathologist provides a level of security for regulatory authorities. Reviews by groups of pathologists (pathology working groups) have also been proposed as a means of resolving difficult diagnostic issues in toxicological pathology (Ward *et al*., 1995).

For over 30 years the pathologist has been assisted in the evaluation of toxicity and carcinogenicity studies by computer recording, storage and collation of macroscopic findings and their corresponding histopathological diagnoses. This has been an important contribution to the timely and accurate reporting of carcinogenicity studies, where the number of observations in older animals renders hand recording and tabulation a time-consuming process, prone to transcription error.

Finally, it is worth noting that in the use of new genetically engineered animal models in carcinogenicity testing, the same basic principles of evaluation of tumours are still valid. Indeed, the range of pathological lesions in these genetically engineered animals demands a particularly good knowledge of both human and animal pathology.

1.4 Histochemistry and Cytochemistry

Histochemistry is a tool that is a system of chemical morphology which adds another dimension to the characterization of alterations in tissues. Changes to structures, cells or organelles can be assessed by the changes in their chemical structure or enzymatic activity. For instance, the well-studied methods for alkaline phosphatase demonstrate activity at the cell membrane where active transport occurs. This can be used to localize and detect changes in structures, such as the surface of the intestinal epithelium and the brush border of proximal renal tubules. The histochemical method for 5′-nucleotidase is also an excellent marker for plasma membrane. Measures of peroxidase activity can be used to localize peroxisomes. Succinate dehydrogenase is used as an indicator for the Krebs' cycle and mitochondrial enzyme activity (Chayen *et al*., 1973). The enzyme, γ-glutamyl transpeptidase has long been regarded as the classical marker for neoplastic foci in the rodent liver. Characterization of pH-sensitive adenosine triphosphatase (ATPase) activity is also the conventional method for identification of different skeletal muscle-fibre types, which is still employed (Westwood *et al*., 2005). It is important to underline that the use of histochemical methods for the simple localization of tissue constituents or pathological alterations is conceptually different to using histochemistry to measure enzyme activity at the tissue level. This approach has been referred to as quantitative cytochemistry. This form of cytochemistry combines procedures for the production of insoluble chromophores by rigorous, controlled biochemical reactions with optical methods for their measurement (Chayen, 1984).

1.5 Immunocytochemistry

The use of classical histochemical methods for the identification of tissue constituents has largely been superseded by immunocytochemistry, which can usually be performed on conventional sections rather than the fresh frozen sections required by many histochemical methods.

Immunocytochemistry of routinely fixed and processed tissues has been one of the major technological advances in the histopathological evaluation and diagnosis of human diseases, because it represents an independent, objective method of cell identification against which traditional subjective morphological criteria can be compared. Immunocytochemistry has been particularly useful in the characterization of human neoplasms. However, unlike enzyme cytochemistry, it can usually only demonstrate the presence of antigenic determinants and is less able to demonstrate activity of cellular systems. Nevertheless, it represents a powerful

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tool for solving of certain problems in toxicology. Although many available antibodies do not work well on tissue sections from laboratory animals, a number of monoclonal and polyclonal antisera crossreact well with the tissues of laboratory animals and can be used in the histopathological evaluation of toxicity studies, provided appropriate controls are applied. Examples include polypeptide and protein hormones, metabolizing enzymes, structural proteins and cell markers, cell cycle proteins and activated caspases for apoptosis (Jones *et al*., 1996; Eckle *et al*., 2004; Mikaelian *et al*., 2004; Kunder *et al*., 2007). Although haemopoietic cells retain species-specific surface markers, monoclonal antibodies to lymphocytic and monocytic surface-membrane markers are available for rodents and dogs, and can be used in the characterization of xenobiotic-induced alterations in the haemopoietic and lymphoid systems (Ward *et al*., 2006).

A number of web sites are available to help in the selection and use of antibodies for use in immunocytochemistry in animal toxicity studies (Erexson and Faucette, 2006).

1.6 Lectin Histochemistry

A technique closely allied to immunocytochemistry is that of lectin histochemistry. The term 'lectin' is applied to proteins and glycoproteins extracted from invertebrates and lower vertebrates that have the capacity to bind sugar groups and glycoproteins in specific ways. Cell surface glycoconjugates play a key role in cellular recognition, cell-to-cell adhesion and act as receptor molecules, so they can be important in the reaction of cells to xenobiotics and pathogens. For many years studies on red blood cells have been performed with the lectin, Concanavalin A, which possesses haemagglutination properties. Lectins labelled with peroxidase or fluorescein have been used to demonstrate specific sugar groups and glycoproteins histochemically in tissue sections (Nicholson, 1974; Spicer and Schulte, 1982). Lectin histochemistry has been used for the characterization of mucins, the demonstration of cell structures in normal tissues and changes in cell surface expression in malignant cells. In toxicology, their primary use is in the characterization of changes induced by xenobiotics in structures which are well delineated by labelled lectins such as the biliary canaliculus, testicular germ cell acrosome, renal tubule, bronchial and gastrointestinal epithelium, haemopoietic cells and microglia (Geleff *et al*., 1986; Masson *et al*., 1986; Fix *et al*., 1996; Dullmann *et al*., 2002; Gheri *et al*., 2002). Conventional formalin fixation and paraffin-wax embedding is frequently adequate for the application of labelled lectin histochemistry, although alcoholic fixation or unfixed frozen sections may provide superior results in some cases.

1.7 Electron Microscopy

Although electron microscopy is widely used as a basic research tool, transmission electron microscopy also has a well established role in the characterization of structural alterations in cells and tissues which have been modified by the effects of xenobiotics. Despite it providing only a static morphological assessment of cells, its ability to characterize changes in subcellular organelles provides valuable information about functional deficits. A conventional application of electron microscopy in regulatory toxicology studies is the characterization of cytoplasmic alterations associated with liver weight changes and hepatocellular hypertrophy. Electron microscopy allows the definition of changes such as proliferation of the smooth endoplasmic reticulum, peroxisomal or mitochondrial proliferation, apoptosis and phospholipidosis. It is also important in the exclusion of subcellular degeneration in vital organs such as the heart when unexplained macroscopic or weight changes are seen without light microscopic alterations.

A variety of methods for the selection, perfusion and immersion fixation of tissues have been proposed for the application of electron microscopy in toxicity studies. Optimum fixation is obtained by whole-body perfusion with an aldehyde fixative, but this may conflict with procedures necessary for other components of a toxicity study such as routine histopathological examination, biochemical, metabolism and kinetic studies. One good compromise is perfusion fixation of freshly isolated samples of organs such as lung or liver. This provides superior tissue preparation to that obtained by immersion fixation (Roberts *et al*., 1990).

Despite the technological advances in transmission electron microscopy, especially semi-automated tissue processing and staining, it remains a demanding and labour-intensive process. Furthermore, it is highly selective and only small samples of tissues can be examined. Therefore, any electron microscopic work performed within the context of a toxicity study should have precisely defined objectives so that appropriate samples are selected and examined. Electron microscopy is not a method for speculative study of tissues in toxicity studies and defining no-effect dose levels. Standard operating procedures for application to toxicity studies designed for government regulatory authorities have been proposed (Dykstra *et al*., 2002).

Scanning electron microscopy has some applications in the study of early chemical-induced changes on epithelial surfaces such as the gastrointestinal mucosa and the bladder epithelium. It also forms the basis for a robust technique for the examination of the middle ear in laboratory animals treated with ototoxic agents (Astbury and Read, 1982).

Immunocytochemistry can also be applied to electron microscopic study in order to define the subcellular distribution of antigenic sites (Dinsdale *et al*., 2004).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Ultrastructural autoradiography using tritium-labelled xenobiotics, especially when performed using quantitative methods such as the so-called hypothetical grain analysis, is valuable for the identification of sites of accumulation of drugs and chemicals within cells and may provide information on mode of cellular action (Read *et al*., 1985).

1.8 Microscopic and Imaging Technologies

Increasingly sophisticated imaging technologies are available for the analysis of pathological changes in tissues (Ying and Monticello, 2006). The use of the mainstay conventional microscope is now usually aided by the use of modern digital camera technology. Automated or semi-automated morphometric systems are also widely available. These represent potentially powerful tools applicable to the light and electron microscopic evaluation of xenobiotic-induced cellular and tissue changes. Whatever system used, morphometric analysis requires good statistical methods in the choice of numbers of animals, number of samples per animal, the quantity of data points per sample and in the mode of data analysis. In the measurement of basic parameters such as volume density, surface density and numerical density, account should be taken of potential artefacts due to shrinkage of tissues following fixation and processing, as well as the problems posed by magnification factors.

Another computer-based technological advance also being evaluated for use in toxicological pathology is so-called 'virtual microscopy'. This represents creating a digital replica of the content of a whole glass microscope slide and manipulating it on the computer to closely simulate looking at a slide with a traditional microscope (Dee, 2006). Virtual slides can be moved in two dimensions and through multiple magnifications, be annotated, compared side by side with slides stained by immunohistochemistry and used for image analysis.

Confocal imaging systems are based on the principle that both the illumination and detection systems are focussed on the same single volume element of the specimen. This enables examination of optical sections through intact tissue without the need for fixation, embedding, sectioning and staining. This has been applied to the study of a number of tissues, but notably to the translucent tissues of the eye in ocular toxicity studies (Jester *et al*., 1996).

Laser capture microscopy represents another innovation by which cells and tissues can be dissected from a histological section using a microscope combined with a laser system to remove and harvest for molecular biological analysis. In this way DNA can be extracted from specific tissues or cells in formalin-fixed slides or RNA from frozen sections (Green *et al*., 2003).

1.9 Molecular Biology Technology

Recombinant DNA technology represents the most recent transfer of basic research technology into the pathology laboratory. Molecular probes are being used to examine the structure and expression of specific genes in both normal and neoplastic human tissues. Over the last two decades these techniques have been widely applied in experimental pathology, where they have provided pathologists with new opportunities for the study of mechanisms in pathological processes. They have been used in the study of experimental tumourigenesis, examination of cell proliferation and gene rearrangements in various rodent organs (Malarkey and Maronpot, 1996). Although technically demanding, *in situ* hybridization enables demonstration of xenobiotic-induced alterations to the expression of specific messenger RNA (mRNA) in cells in histological sections (Doughty *et al*., 1995). Methods for the assessment of apoptosis in tissue sections are based on DNA polymerase-mediated or terminal deoxynucleotidyl transferase-mediated incorporation of biotinylated nucleotides to DNA strand breaks, so-called *in situ* end-labelling methods (Wheeldon *et al*., 1995).

Particular leading edge technology is so-called 'toxicogenomics' based on transcriptional profiling of tissues using one of a number of microarray platforms to assess induced alterations to gene expression (see **Toxicogenomics and the Evolution of Systems Toxicology**). In some laboratories this is being applied in an almost semiroutine basis in toxicological assessment (Foster *et al*., 2007). A well-designed genomic experiment undoubtedly provides a molecular signature of transcriptional events in response to xenobiotic exposure. It can aid in the characterization of toxic effects and provide the basis for mechanistic analysis. However, it should be underlined that gene changes do not necessarily indicate functional alteration and for this reason these technologies are best when they can be correlated with phenotypical alterations that can be seen using conventional evaluation, notably histopathology (Gant *et al*., 2005).

2 METHODS APPLICABLE TO SPECIFIC ORGAN SYSTEMS

2.1 Skin and Subcutaneous Tissue

Careful visual inspection remains the principle component of the assessment of skin alterations or changes in the pelage of laboratory animals in conventional toxicity

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

studies. Drugs and chemicals given systematically may affect the skin in a number of ways. Pigmented skin or hair may lose its normal colour and albino skin may become coloured by administration of pigmented compounds or chemicals with pigmented metabolites. Agents with effects on sebaceous glands may alter the normal glossy fur of laboratory animals. Ulceration and inflammation may be the result of diverse factors, both spontaneous and as a result of toxicity. Therefore, skin abnormalities detected during life or at autopsy in conventional toxicity studies should be examined histologically. In addition, sections taken from carefully selected standard sites should also be sampled for routine histopathological examination. Standard sites are important because skin thickness and structure varies between different anatomical regions. Haematoxylin and eosin staining is sufficient for most purposes.

Studies conducted to study topical irritancy, contact sensitization or phototoxic activity usually employ rabbits or guinea pigs (*see* **Cutaneous Toxicology**). Here, reliance is commonly placed on visual inspection and a semiquantitative assessment of the degree of erythema, swelling, erosion and ulceration of the treated skin. However, histopathological examination can be useful in assessing the nature of any changes and immunohistochemical study of inflammatory and immune cells, blood vessels, collagen and other structural elements can be helpful in the characterization of skin toxicity.

Histological examination of injection site injury and the local damage around subcutaneously implanted biomaterials and implanted controlled-release treatment systems is an essential part of the assessment of their irritancy potential. It is important to not only characterize the nature and severity of the surrounding cellular reaction to these materials, but also the time course of the inflammatory and healing process, in comparison with known negative and positive control substances (Autian, 1972; Andersen, 2001).

In carcinogenicity studies performed in rodents, tumours of the skin and subcutaneous tissues are usually diagnosed by conventional microscopic techniques and this is usually adequate. In certain instances, particularly when tumours are induced by treatment, immunocytochemistry for antigens such as myoglobin, lysozyme, α-1 antichymotrypsin, smooth muscle actin, intermediate filaments, the mitochondrial uncoupling protein and S100 is performed, although it often adds little to overall interpretation of the relevance of the findings (Hardisty *et al*., 2007).

2.2 Mammary Gland

In laboratory animals, the mammary gland represents a sensitive indicator of the pituitary–gonadal axis. In rodents it is liable to develop neoplasms either spontaneously with advancing age or following prolonged hormonal derangement induced by administration of xenobiotics. For these reasons mammary glands are examined carefully in conventional toxicity studies both during life and at autopsy. This is followed by histological examination. Very occasionally the mammary glands of experimental animals have been used to test the tissue compatibility of mammary implants using histological assessment (Devor *et al*., 1993).

As laboratory rodents and beagle dogs possess several pairs of mammary glands, routine histological examination is usually conducted on a selected number of sites, frequently on one gland from each side plus any other showing macroscopic abnormality. Conventional haematoxylin and eosin stained sections are usually sufficient for mammary gland assessment. Special staining techniques include immunocytochemical staining for cytokeratins and myosin for myoepithelial cells, collagen Type IV and laminin for basement membrane and Type I collagen and fibronectin as connective tissue markers as well as sex hormone receptors (Greaves, 2007).

2.3 Haemopoietic and Lymphatic Systems

In conventional toxicity studies, blood smears, haemopoietic organs and lymphoid tissues are routinely examined by light microscopy in conjunction with automated analysis of peripheral red and white blood cells (*see* **Haematology and Toxicology**). Weighing and careful histological examination of thymus, spleen and lymph nodes are widely considered to be important components in the examination of effects of xenobiotics on the immune system. They form part of the first tier of procedures adopted in immunotoxicity testing batteries in the National Toxicology Program and at the Chemical Industry Institute of Toxicology, as well as in government testing guidelines (Luster *et al*., 1988; Ruehl-Fehlert *et al*., 2005).

Blood smears are usually examined using classical Romanowsky stains and conventional histological sections are taken from spleen, selected lymph nodes, thymus and decalcified bone marrow sections. The cellularity of bone marrow varies between different sites in laboratory animals. In rodents, bone marrow from the femur, sternum and vertebral bodies are considered to be the most representative (Cline and Maronpot, 1985; Wright, 1989). The cytology of bone marrow cells in decalcified, paraffin-embedded sections is not ideal and Romanowsky-stained bone marrow smears provide better cytological detail. The technical problems posed by the need to decalcify bone have been surmounted in some toxicology laboratories by the use of 3 µm thick methyl methacrylate-embedded sections stained with modified Giemsa supplemented by Gomori's stain for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reticulin, a technique originally developed for human bone marrow biopsies (Burkhardt *et al*., 1982).

Critical histological examination of lymph nodes requires good orientation of the tissue to provide the basis for a clear assessment of the relative sizes of cortex, paracortex and medulla and their three-dimensional orientation. A semiquantitative assessment based on a standard approach defined by the World Health Organization, represents one good method for characterization of functional alterations in the B and T cell zones of the lymphoid system (Cottier *et al*., 1972). A descriptive approach to each lymph node compartment has been designed for toxicity studies (Haley *et al*., 2005; Ruehl-Fehlert *et al*., 2005). A similar approach has been recommended for the examination of the mucosal-associated lymphoid tissue (MALT) (Elmore, 2006). A detailed illustrated monograph on histopathological evaluation of lymphoid organs in toxicity studies has been published (Maronpot, 2006).

Whereas the spleen functions as a blood storage organ and a site of extramedullary haematopoiesis, its discrete nature in rodents makes is a useful organ with which to undertake morphometric analysis of the periarteriolar lymphoid sheaths (T cell zones) and germinal follicles (B cell areas). Spleen weight does not appear to be a reliable indicator of haemopoietic cellularity in the dog.

Conventional histological stains are readily supplemented by a variety of monoclonal antibodies for the immunohistochemical localization of surface markers of monocytic and lymphoid subsets. A large number of antibodies to rodent haemopoietic cell antigens are available and some have been reported to work on conventional paraffin-wax-embedded sections and occasionally antibodies to human T cell antigens react across different species (Ward *et al*., 2006; Kunder *et al*., 2007). However, more generally, antibodies to human antigens can be used on histological sections from monkey tissues (Li *et al*., 1993; Neubert *et al*., 1996). Antibodies to immunoglobulins or immunoglobulin light chains are usually sufficiently robust to be used in the characterization of B-lymphocytes in paraffin-wax-embedded sections. Lectin histochemistry may also help visualization of endothelial cells lining blood vessels and sinuses, dendritic cells and macrophages in lymphoid tissue in rodents (Dullmann *et al*., 2002).

2.4 Musculoskeletal System

An assessment of long bone growth is conveniently made by measurement of long bone length. The femur is frequently used for this purpose in laboratory animals. Appropriate laboratory processing of bone is a prerequisite of its good histological assessment. Formalin is adequate for most purposes, followed by decalcification using acidic fluids and embedding in paraffin wax. Use of polarized light microscopy is helpful in the identification of bone types in decalcified sections, for it can demonstrate the patterns of collagen orientation. Undecalcified sections using methacrylate or similar hard embedding media, supplemented by stains such as von Kossa, Goldner trichrome or solochrome cyanine are essential for the assessment of bone mineralization.

Choice of sampling site is particularly important for assessment of bone in toxicity studies in laboratory animals (*see* **Cartilage and Bone as Target Tissues for Toxic Materials**). It should be an identical site in all animals within a particular study, for it has been shown that even modest differences in sampling site can influence histomorphological variables of bone (Anderson and Danylchuck, 1978). In long bones, histological examination is usually directed to the metaphysis. Chondrocytes dividing in the metaphysis as columns of proliferating cells and maturing into hypertrophic cells are responsible for bone growth. Therefore, examination of this zone, particularly if morphometric analysis is also carried out, is an ideal place to evaluate bone formation and resorption in studies designed to evaluate xenobiotics which affect this process (Schenk *et al*., 1986). Vital fluorescent labels such as tetracycline, alizarin red S, calcein, procion or haematoporphyrin can be used to visualize sites of bone mineralization in tissue sections of bone from laboratory animals (Solheim, 1974).

Articular cartilage reacts to chemical insult only in a limited way. Like bone, it represents a stratified structure growing from the chondrosseous junction of the epiphysis which can be assessed histologically using conventional processing and staining procedures. Special stains such as toluidine blue, safranine O, lectin histochemistry and immunocytochemistry for collagens, fibronectin, cell cycle proteins and activated caspases, as well as electron microscopy represent further tools for the study of cartilage (Farnum and Wilsman, 1988; Burkhardt *et al*., 1997; Wancket *et al*., 2005).

Whether skeletal muscle is examined as part of a systemic toxicity study or for the study of the local irritancy of implanted or injected substances, sections are usually processed and stained conventionally. In the examination of implantation or injection sites, it is important to assess the extent and nature of local damage and the time course of the repair process.

The use of cryostat and histochemical reactions for ATPase activity has been accepted as the basis for identification of the slow twitch or Type I fibres and the fast twitch or Type II fibres for many years (Brooke and Kaiser, 1970). However, immunocytochemical staining for fast and slow isoforms of myosin correlate reasonably well with fibre analysis using the traditional method, but are applicable to formalin-fixed material in the study of the adverse effects of xenobiotics on muscle fibres (Behan *et al*., 2002; Westwood *et al*., 2005). Immunohistochemical stains for structural components such as collagen, fibronectin, myoglobin, laminin and desmin

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

have also be used as adjuncts to assess alterations induced by xenobiotics in skeletal muscle (Helliwell, 1988).

2.5 Pulmonary System

Nasal chambers are the structures which are first subjected to the effects of inhaled substances. Xenobiotic-induced damage to the lining of the nasal passages of both humans and laboratory animals is often site specific and dependent on the sensitivity of the nasal epithelial tissue to the specific chemical. Knowledge of the comparative anatomy of the nasal chambers is required (Harkema *et al*., 2006). Although nasal passages are not studied in great detail in conventional toxicity studies, they are examined histologically when drugs and other chemicals are administered by inhalation. In rodents, the small size of the bones of the nose and nasal sinuses make a simple transverse-blocking procedure following decalcification a cost-effective way to provide standardized histological sections. A series of standard diagrams for the examination and recording of lesions in the nasal passages of rats and mice have been devised (Mery *et al*., 1994). For large animals, a complex dissection is required for histological assessment of the nasal mucosa.

Careful inspection of the lungs in a good light after opening the thoracic cavity at autopsy provides important information about pathological alterations. Changes may be manifest by uneven collapse, enlargement or over-inflation, patchy discolouration or stiffness of the lung parenchyma, as well as the presence of oedema or pleural effusions. Total weight or dry/wet weight ratios can be sensitive indicators of lung damage and oedema (Parker and Townsley, 2004).

Various methods of lung fixation are available. Immersion fixation in neutral buffered formalin is widely employed for most routine purposes and has the advantage of retaining exudates and fluids within the air spaces and airways. Instillation of fixative via the trachea under constant pressure (25–30 cm water) shows structural alterations well, although it has a tendency to dislodge exudates. Use of formalin vapour, perfusion fixation via the vasculature and freezing in liquid nitrogen are other methods which are employed. Fixation via the trachea is generally the preferred method because its advantages seem to outweigh its disadvantages.

A standardized approach to selection of pulmonary tissue for histological examination in rodent toxicity studies has been proposed (Kittel *et al*., 2004). Specialist stereological methods have a place in the detailed investigation of pulmonary toxicity, although a particularly rigorous approach is needed to avoid sampling bias (Hyde *et al*., 2007). Ultrastructural study is used in the elucidation of selective structural damage to the pulmonary parenchyma, but the size of the lungs and diversity of its cellular components creates problems of fixation and sampling (Tyler *et al*., 1985).

Haematoxylin and eosin remains the most important stain supplemented by stains for reticulin, collagen and elastic fibres as well as mucins. As in other tissues, a variety of immunocytochemical, cytochemical and autoradiological techniques are used in the study of the effects of xenobiotics on lung tissue. These include immunocytochemical demonstration of lymphoid cells, xenobiotic metabolizing enzymes and endocrine cells, as well asstructural components such as the collagen and laminin (Greaves, 2007).

2.6 Cardiovascular System

Key to the pathological evaluation of the heart in toxicity studies is the careful visual inspection of the pericardium, myocardium, endocardium and valve cusps of each cardiac chamber. Cardiac weight in laboratory animals varies with body weight, body length, age and sex, and circulatory demand. For this reason, weighing the heart is not only a useful guide to the toxic effects of xenobiotics on the myocardium, but also a measure of functional adaptation to cardiac work load.

Careful sampling of representative sections of each cardiac chamber and large blood vessels is also important for adequate histological assessment. These should include segments of the coronary arteries, free walls of the atria and ventricles, valves and zones sensitive to ischaemia, such as the endocardium and papillary muscles of the left ventricle. This is relatively easily achieved in rodents, where a single, well-orientated section of the heart can reveal most of these areas (Morawietz *et al*., 2004). However, for study of the heart in larger animals and humans a careful sampling procedure is needed, which requires several sections for each heart (Keenan and Vidal, 2006). Histological examination of the cardiac conducting tissue is not conducted routinely in regulatory toxicity studies. for it requires a large number of tissue sections for thorough study. However, a simplified method for examination of the sinuatrial and atrioventricular nodes in the dog has been proposed which can be more routinely applied (Palate *et al*., 1995).

Conventional fixation, paraffin-wax embedding, haematoxylin and eosin with connective tissue, fibrin and elastic stains are the cornerstones for detection of myocardial and vascular alterations.

Other histological techniques include the detection of early myocardial damage in formalin-fixed tissue using demonstration of the loss of myosin, tropomyosin ATPase, creatine kinase or lactate dehydrogenase from muscle fibres (Doran *et al*., 1996; Zhang *et al*., 2006). Immunohistochemical markers for neurofilaments and glutamate receptors have also been used to study neural

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

structures and the conducting system (Mueller *et al*., 2003). Electron microscopy remains important for the characterization of damage to cytoplasmic organelles, particularly mitochondria (Hirano *et al*., 2001).

2.7 Digestive System

The mouth is subjected to visual inspection in conventional toxicity studies and the tongue is usually sectioned for histopathological examination of the oral mucosa. Major salivary glands are examined using conventional processing and staining techniques, although mucin histochemical stains are useful in the study of alterations in mucin secretion in these glands.

Whilst teeth are usually only inspected by the naked eye, it may be necessary to examine the dentition histologically in animals treated with xenobiotics. This is performed using the techniques employed for bone. Standardized sections for examination of rodent incisors have been proposed (Kuijpers *et al*., 1996).

Histological examination of the gastrointestinal tract is complicated by its great length and the fragility of the mucosa before fixation. Careful inspection without vigorous washing is essential to both locate lesions and to avoid artefacts which can mimic inflammation and ulceration in histological sections. Although selective blocking is usually appropriate if preceded by careful macroscopic inspection, the so-called 'Swiss roll' techniques are valuable for a detailed histological survey of the gastrointestinal epithelium. These methods can be adjusted for use in laboratory rodents, larger animal species and humans. They may be performed on fresh tissue or after fixation.

Mucin stains are particularly useful tools in the study of induced changes in the stomach and intestinal mucosa. This can be approached by either conventional mucin histochemistry or lectin histochemistry on formalin-fixed and paraffin-wax-embedded material. The techniques are applicable to study of the gastrointestinal mucosa from laboratory animals and humans, although there are considerable interspecies differences in the distribution of glycoconjugates demonstrated by these methods (Sheahan and Jarvis, 1976; Ishihara *et al*., 1984). The use of argyrophil staining is the traditional approach the characterization of enterochromaffin cells of the stomach and intestine because of their endogenous reducing activity. Immunohistochemistry is now more widely used for the characterization of enterochromaffin cells in the mucosa, notably using antisera to histamine, histidine decarboxylase, neurone-specific enolase and chromogranin A (Betton *et al*., 1988; Norlen *et al*., 2001). The study of cell proliferation using immunocytochemistry and antibodies to proliferating cell nuclear antigen (PCNA), Ki67 or bromodeoxyuridine is also useful in the assessment of the effects of xenobiotics on the gastrointestinal mucosa. The various techniques used for the characterization of apoptosis complete the repertoire in the study of the effects of drugs on cell turnover in the gastrointestinal tract (Pritchard and Watson, 1996).

Monoclonal antibodies against lymphoid surface markers are used for the study of the mucosa-associated lymphoid tissue or MALT in laboratory animals (Bland and Warren, 1985; Martin *et al*., 1986). Mucosal mast cells in rats have been shown to be demonstrable in conventionally processed tissues by prolonged toluidine blue staining (Wingren and Enerbäck, 1983).

As the principle site of metabolism and detoxification of drugs and other xenobiotics, the liver is a frequent site of alterations in toxicity studies, and is therefore the focus of careful histopathological assessment. In conventional studies, the liver is weighed prior to fixation and selection of blocks for processing for light and electron microscopy, as well as other techniques. The relatively large size of the liver presents problems in selection of tissue blocks and considerable variation exists between laboratories in the hepatic blocking schedule. In the National Toxicology Program rat carcinogenicity studies, the procedure involves the selection of two blocks taken from the widest parts of the left lobe and the right median lobe (Maronpot *et al*., 1989). Selection of two blocks appears to be the generally accepted practice for routine rodent liver histopathological examination in many laboratories.

As the liver is one of the most important sites for the adverse effects of xenobiotics, numerous special techniques have been employed in the microscopic evaluation of liver sections (*see* **Hepatotoxicity**). Not to be neglected are the conventional special stains such as oil red O for lipid, stains for collagen, reticulin and pigments. Electron microscopy, enzyme cytochemistry, immunocytochemistry and molecular biological methods all have well-accepted roles in the characterization of changes induced by xenobiotics in the liver of laboratory animals. It is frequently necessary to characterize proliferation of smooth endoplasmic reticulum, peroxisomes or mitochondria and lysosomal alterations such as phospholipidosis when treatment-induced changes in liver weight are recorded, or there is light microscopic evidence of hepatocyte hypertrophy. Quantification of both hepatic cell proliferation using PCNA, Ki67 or bromodeoxyuridine, and apoptosis with immunocytochemical detection of activated caspase and other methods such as *in situ* end labelling, are also useful (Wheeldon *et al*., 1995; Eckle *et al*., 2004).

As the liver possesses considerable functional heterogeneity within the lobule, cytochemical methods for reactions such as catalase, uricase, various dehydrogenases, alkaline phosphatase, 5′-nucleotidase and $NADH_2$ diaphorases, as well as glutathione, form a bridge between morphology and activity measured by classical biochemical techniques (Chayen, 1984).

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

A number of histochemical methods have been applied to the study of foci of cellular alteration in the rodent liver. These include the classical marker γ-glutamyl transpeptidase, glucose-6-phosphate dehydrogenase and immunohistochemical demonstration of placental glutathione S-transferase (Tatematsu *et al*., 1987; Tsuda *et al*., 2003).

Gene expression analysis of liver tissue is also believed to provide additional insights to the mechanisms involved in xenobiotic-induced hepatic pathological alterations (Heinloth *et al*., 2007). It has also been recently argued that conducting multiple hepatic microarray analyses can provide a general view of potential metabolic changes that occur (Mori *et al*., 2007).

The pancreas is usually examined using conventional stains, although the different populations of endocrine cells of the islets of Langerhans can be readily stained using immunocytochemical staining of insulin, glucagon, somatostatin and pancreatic polypeptide, as well as other peptides (Wieczorek *et al*., 1998).

2.8 Urinary Tract

The kidney is particularly important in toxicology because many xenobiotics or their metabolites are eliminated primarily through the urinary tract (*see* **Responses of the Kidney to Toxic Compounds**). In addition, the kidney is liable to be exposed quickly to peak concentrations of circulating xenobiotics by virtue of its high blood flow. Its ability to concentrate toxic solutes in tubular cells or in the tubular lumen is an additional risk factor.

Renal weight changes are a useful guide to renal toxicity, although renal weight may also alter as a physiological response to changes in renal demand. Hence, it is essential that assessment of renal toxicity includes careful visual inspection of the renal parenchyma at autopsy for appearances of toxicity such as swelling, pallor, congestion and haemorrhage followed by histopathological examination. Inspection of the contents of the renal pelvis for crystals, mineral and cellular debris is also important, for these substances may be lost in subsequent tissue handling and processing.

Conventional fixation and processing, followed by haematoxylin and eosin staining supplemented by PAS, notably to stain basement membrane is usually appropriate for most conventional toxicity studies. It is important that all parts of the nephron are examined microscopically, so histological sections should comprise both cortex and medulla and include the tip of the papilla.

A number of techniques are available for more detailed study of induced alterations in the nephron. Electron microscopy has a time-honoured place in the study of pathological alterations in both the glomerulus and renal tubule, although perfusion fixation may be needed for the appropriate degree of preservation of tubular cells. Light microscopy of plastic embedded sections 1–3 μm thick is a useful compromise which provides excellent resolution of renal structures.

Various parts of the renal tubule show different enzyme activities which relate to the function of different segments. Histochemical demonstration of enzyme activities can therefore be used as markers for components of the nephron and for structural–functional studies. For instance, lysosomal enzyme activity is highest in the proximal tubule, reflecting the role of this segment in degradation of reabsorbed macromolecules. Therefore, enzyme cytochemical demonstration of acid phosphatase or other lysosomal enzymes outlines the proximal tubule. Of interest to the pathologist as cytochemical markers are brush border enzymes, alkaline phosphatase, 5′-nucleotidase and γ-glutamyl transpeptidase which are useful in the study of tubular damage. Measurement of enzyme activity in the urine is also a useful complementary, noninvasive technique for the assessment of tubular toxicity in humans and laboratory animals, because cellular enzymes from damaged tubular cells spill into the urine in increased amounts. However, immunocytochemistry is now more often used to demonstrate the presence of brush border enzymes such as γ-glutamyl transpeptidase (Yasuda *et al*., 1986). Immunocytochemical demonstration of Tamm–Horsfall proteins, localized at the surface membrane of the thick ascending loop of Henle, has also been used for the study of renal tubular changes induced by xenobiotics. In the study of drug-induced alterations to the juxtaglomerular apparatus, immunocytochemical staining using antisera to renin or labelling of renin mRNA expression by *in situ* hybridization are superior to the classical, nonspecific techniques for renin-containing granules, such as the Bowie and Hartroft stains. Immunocytochemical staining for α-smooth muscle actin not only reveals smooth muscle in vascular smooth muscle, but also activated mesangial cells (Kaneko *et al*., 2001).

Labelled lectins can be used to localize different segments of the nephron histochemically and this can often be performed on formalin-fixed, paraffin-wax-embedded material. For instance, peanut lectin (*Phaseolus vulgaris*) and *Ricinus communis* stain the S1 and S2 segments of the rat proximal tubule whereas the S2 remains poorly stained. The mouse proximal tubule brush border stains with *Lotus tetragonolobus* (Schulte and Spicer, 1983).

Histological study of the bladder mucosa requires special care particularly in the study of proliferative lesions of the urothelium (Cohen *et al*., 2007). The best orientation of the epithelium is obtained following inflation of the bladder with fixative at autopsy, for this removes folds which can give a misleading impression of the thickness of the epithelium. However, this procedure may dislodge exudates and other material from the bladder lumen, so care should be exercised in its application. Assessment of cell proliferation can be important

in the assessment of hyperplasia and neoplasia of the bladder epithelium. Scanning electron microscopy is a useful special technique for the examination of chemically induced alterations to the superficial transitional epithelium (Cohen *et al*., 2007).

2.9 Reproductive System

The effects of xenobiotics on reproduction are usually examined in special reproductive studies, in which histopathological examination plays relatively little part (*see* **Reproductive Toxicology**). However, histopathological examination of the male and female reproductive tract is an important component of conventional toxicity studies. At an early stage of the development of a new medicine this histopathological examination may represent the only assessment of treatment-related effects on the reproductive organs and germ cells and needs to be performed with care.

In males the testes and accessory sex organs are examined routinely. Special fixatives are employed for light microscopic examination of the testes because formalin is a poor method of preservation of the germinal epithelium prior to embedding in paraffin wax. Immersion in Bouin's, Zenker's or Helly's fluids is commonly used, followed by paraffin wax embedding, sectioning and staining with haematoxylin and eosin (Latendresse *et al*., 2002). PAS is often used for the demonstration of the germ cell acrosome, for this enables the most precise staging of the germ cell cycle in laboratory animals and in humans. The approach to microscopic assessment of the testis in toxicity studies has been the subject of discussion for many years and international guidelines now exist. The recommended approach is a qualitative assessment of testicular histology followed by quantitative assessment or evaluation of seminiferous stages in special time-course studies, only when lesions are detected in conventional studies (Lanning *et al*., 2002; Creasy, 2003).

The female reproductive system is examined histologically using conventional histological techniques, paying close attention to the cyclical alteration in the endometrium, vaginal mucosa and ovarian tissue. The ovary requires careful orientation if sections are to include cortex, medulla and hilar tissue. As ovarian function is closely linked to the endocrine system, it is important that in any assessment of the reproductive tract, account is taken of endocrine organs.

2.10 Endocrine System

Histological examination of endocrine tissues is important in toxicity studies. When it is technically possible, histological examination is preceded by weighing of the organs. However, this may not be advisable for firmly bound organs such as the thyroid gland, for danger of disruption of histological sections.

Although haematoxylin and eosin staining is appropriate in most circumstances, immunocytochemistry is of importance. Antisera for many peptide hormones are widely available and, provided appropriate dilution and absorption controls are employed, they can be used in the examination of the endocrine tissues of most conventional laboratory animal species. C-cells in the thyroid gland can be particularly difficult to delineate in haematoxylin and eosin stained sections, but they can be clearly seen by immunocytochemistry for calcitonin. Immunohistochemical demonstration of the acidic protein, chromogranin A, is also a good marker in different species for many endocrine cells containing secretory granules.

The chromaffin reaction, which represents darkening on exposure to aqueous solutions of potassium dichromate as a result of oxidation and polymerization of catecholamines, remains a useful stain in the study of catecholamine activity in the medulla (Tischler *et al*., 1997). Neurone-specific enolase is consistently present in the rat and mouse adrenal medulla and can be used as a histochemical marker for proliferative and neoplastic alteration in this tissue (Wright *et al*., 1990). Others have used immunohistochemical staining for phenylethanolamine-*N*-methyltransferase and chromogranin A (Tischler *et al*., 1996). The examination of electron dense granules in the medulla is also useful for the detailed characterization of medullary cells.

2.11 Nervous System and Special Sense Organs

Histopathological assessment of the nervous system requires careful selection of nervous tissues, appropriate fixation, processing and staining in ways that are often different from the techniques employed for other tissues.

Perfusion fixation of the brain is the method of choice for the avoidance of artefacts, although immersion fixation followed by conventional processing is adequate for most routine purposes, but this must also be done with care (Fix and Garman, 2000). It is essential to be aware of the artefacts which can develop in the immersion fixation of brain so that they are not confounded with treatment-induced alterations. These artefacts have been described in detail (Garman, 1990).

Blocks for histological examination should be selected to include appropriate cerebral nuclei and fibre tracts. Sectioning should be sufficient to include grey and white matter from the cerebrum, cerebellum, brain stem, spinal cord as well as spinal ganglia and peripheral nerves. Key areas include basal ganglia, substantia nigra, dentate nuclei, Purkinji cells and optic tracts (Garman,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat039
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2003; Morawietz *et al*., 2004). Standard sections can be obtained by the use of a metal mould with cross channels for accurate slicing of the fixed brain and appropriate zones assessed by use of one of the stereotaxic atlas of neuroanatomy (Sidman *et al*., 1971; Paxinos and Watson, 1997; Bolon, 2000).

In addition to haematoxylin and eosin, special stains for myelin, neuronal bodies, axons and glial cells are helpful. Traditional silver methods still have a place in the evaluation of neuronal degeneration (Grant *et al*., 2004). Two novel anionic fluorescent compounds, Fluoro-Jade and Fluoro-Jade B have also been proposed as tracers for neuronal degeneration in toxicity studies (Schmued and Hopkins, 2000). Changes in peripheral nerve fibres are particularly well characterized in semithin plastic or epoxy resin embedded, toluidine-blue-stained sections.

Immunocytochemistry using a wide range of antisera also has a place in the assessment of toxicity of the nervous system. Immunocytochemistry using antisera to glial fibrillary acidic protein (GFAP). S100 protein, neurone-specific enolase and cytoskeletal components may provide valuable information for the identification of cell types and characterization of changes within them. Immunocytochemical localization of GFA protein is now considered a useful addition to the assessment of the effects of toxins on the central nervous system, particularly when used together with more conventional stains (Fix *et al*., 1996). The lectin *Griffonia simplicifolia* isolectin B_4 has also been used to stain in the study of the toxic effects of xenobiotics on the rat cerebral cortex (Fix *et al*., 1996). Electron microscopy also remains a valuable tool for problem solving in neuropathology although it is technically demanding and labour-intensive (Jones, 1988).

Eyes are examined by use of conventional histological techniques after use of special fixatives such as Davidson's fluid to avoid as much artefact as possible to the cornea, lens and retina. The lens poses particular problems in histological processing, but excellent results can be achieved using plastic-embedding procedures. Confocal microscopy has been shown to be a potentially powerful technique in the histological study of corneal irritation because it can be applied in a noninvasive manner (Jester *et al*., 1996).

The cochlea is not usually examined histologically in routine toxicity studies and reliance is placed on clinical assessment or specialist tests (*see* **Ototoxicity**). However, the middle and inner ear can be examined histologically after decalcification of the petrous bone and preparation of conventional sections. However, sectioning the cochlea to achieve the correct orientation requires considerable skill and this method can only demonstrate small numbers of sensory cells in the organ. One technique is a surface preparation technique which involves dissection of the cochlea and subdivision of the organ of Corti into short segments for examination by phase contrast microscopy (Engström *et al*., 1964). A modification of this technique using scanning electron microscopy is relatively simple to perform and can be used in the rat and other experimental animals (Astbury and Read, 1982; Liberman, 1990).

1 INTRODUCTION

Clinical pathology, consisting of routine haematology, coagulation, clinical chemistry and urinalysis, is an important part of safety assessment for food ingredients, drugs and chemicals, and is useful in predicting potentially important toxicity endpoints, detecting potential human responses to hazardous substances (chemicals) and selecting parameters for clinical monitoring (drugs) (OECD, 2001; Weingand *et al*., 1996; Redbook, 2003). Serial sampling with time allows the evaluation of the development, progression and recovery of changes to the test system. Some government and regional regulatory agencies and international organizations provide guidelines for clinical pathology testing in animal toxicity and safety studies. These testing guidelines vary between agencies and the scientists should be aware of these differences (see Regulatory Agency Web Sites).

1.1 Core Clinical Chemistry Testing

The core clinical chemistry tests appropriate for all test materials include evaluation of protein, lipid and carbohydrate metabolisms, liver and kidney functions and electrolyte balance (see **Table 1** for industry consensus). Additional clinical chemistry tests may be necessary to extend the search for toxic effects or elucidate toxic effects attributable to a test material (Redbook, 2003; OECD, 2001).

1.2 Blood Sampling and Intervals

The number of occasions of blood sampling for clinical pathology testing is dependent on study objectives, study duration, test material, animal species and regulatory requirements. Blood volume and techniques for each animal species should comply with all appropriate laws and regulations concerning animal welfare and husbandry (Weingand *et al*., 1996). Blood sample volume and frequency should not compromise the physiological status of the animal and the route and method should be chosen to maximize the possibility of an efficient and low-stress bleed (for both the technician and the animal). Guidance is provided by a joint European Centre for the Validation of Alternative Methods (ECVAM)/European Federation of Pharmaceutical Industries and Associations (EFPIA) publication (Diehl *et al*., 2001) and the principles of this guidance have general industry-wide agreement. Technical expertise in handling and sampling the chosen species is paramount to obtaining good samples, minimizing the variability between samples and reducing the likelihood of a failed sample.

There are no clinical pathology requirements in single-dose toxicity studies for test material from the nonpharmaceutical industry. In the pharmaceutical industry, clinical pathology evaluation is usually not required, except for acute animal studies conducted to provide the primary safety data supporting single-dose safety/kinetic studies in human trials. Clinical pathology should be performed ideally for maximum effect (24–48 hours post-dose) and recovery (14 days post-dose) (FDA, 1996). Where nonrodents are appropriate for investigation, the studies should be designed so that a maximum amount of information is obtained from the smallest number of animals (escalating dose or dose-range-finding studies are acceptable); in these studies, clinical pathology testing may or may not be extensive depending on the class of compounds to be tested, the objectives of the study and the company strategy (FDA, 1996; Smith *et al*., 2005).

The minimum requirements for blood sampling in repeated-dose studies in rodents and nonrodents are based on a document published in 1996 representing the consensus of a joint international scientific committee (Weingand *et al*., 1996). With respect to the rodents, the blood sampling should at least be done at termination. Interim testing may not be necessary for long-duration studies if testing was done in short-duration studies that used dose levels not substantially lower than those of the long-duration studies. For repeated-dose studies in nonrodents, testing should be done at least once before initiation (to allow some measure of intra- and interanimal variability), at least once during the study and at termination. The small number of animals generally used in nonrodent toxicity studies is balanced by the fact that pretreatment and serial samples can be taken, making interpretation of individual changes with time quite practical.

While clinical pathology testing is not recommended (Weingand *et al*., 1996) for rodents in studies longer than 52 weeks, because naturally occurring geriatric conditions obscure meaningful interpretation of laboratory data, some regulatory agencies suggest or require the testing to be done to maximize the information obtained from those animals (Redbook, 2006; EMEA, 2002).

Routine clinical chemistry analysis is carried out either in serum or plasma. For serum collection, no anticoagulant is required, whereas for plasma collection tubes coated with either heparin or lithium heparinate are required. Ethylenediaminetetraacetic acid (EDTA) is not suitable, since it will affect some electrolyte and enzyme measurements as it acts as an ion chelator. For most routine parameters both serum and plasma are suitable, but it is important to be consistent and build experience and background data in at least one matrix. In the USA serum is usually collected. In the UK and mainland Europe, plasma is usually collected. There may be differences in the clinical chemistry values between these matrices (Young *et al*., 2006).

Table 1 Core clinical chemistry tests in standard regulatory toxicity studies[a]

Total protein	Alanine aminotransferase	Sodium	Urea nitrogen
Albumin	Aspartate aminotransferase	Chloride	Creatinine
Cholesterol	Alkaline phosphatase	Potassium	—
Triglyceride	Gamma-glutamyltransferase	Calcium	—
Glucose	Total bilirubin	Phosphorus	—

[a]The laboratories, surveyed in 2007 and 2008, consisted of 54 clinical pathology laboratories in the pharmaceutical industry and contract research organizations (Parzych and Kimball, 2008).

Rat urine sampling in rodents is usually carried out by collection from specially designed collection cages, where animals can be deprived of food and water for several hours. Analysable samples from mice are difficult to obtain and not recommended because of the low volumes. In some nonrodent species, such as dogs and macaques, it may be practically possible to obtain bladder samples by catheterization or cystocentesis, but it can be stressful to animals (and it does not allow a timed sample to be collected to estimate volume). Of course, this has to be balanced against the stress associated with overnight collection and the scientific objectives of the study. In addition, overnight urine collection systems need to be scrupulously cleaned to avoid contamination. Several nonpharmaceutical regulatory guidelines require the collection of a timed urine sample, which mitigates towards the former method (Redbook, 2003; OECD, 1995b).

2 DATA INTERPRETATION AND REPORTING

Assuming that the current choice of animal models and the design of the studies are predictive of human hazard (Olson *et al*., 2000; Greaves *et al*., 2004), toxicity study interpretation and reporting assure that drugs in development or on the market will not cause harm to the patient, or that the use of chemicals will not be detrimental to human welfare/health. Therefore, the quality, integrity and completeness of the reporting of experimental data, including clinical pathology, from toxicity studies are essential. To avoid losing important aspects in an unnecessarily long document, reports should be as concise and precise as possible (Wells and Gosselin, 1996; OECD, 2001; Black, 2002).

In regulatory toxicity studies, clinical pathology data from animals treated with increasing doses of a test material are compared with data from concurrent control animals for rodent and nonrodent studies and pretest data for nonrodent studies (OECD, 2001). Clinical pathology data can be among the most difficult data within a given study to evaluate, because interpretations of many clinical pathology findings are interdependent and can be influenced by several factors, such as limitations of the assays, preanalytical variations, route of administration, environment, social housing and naturally occurring diseases. Clinical pathology results should also be correlated with in-life observations, necropsy findings, organ weights and histopathological changes, in order to make plausible and informative interpretations (Wells and Gosselin, 1996; Boone *et al*., 2005; Hall and Everds, 2008).

2.1 Preanalytical Variability

Reviews of factors (physiological, procedural or artefactual) which can complicate the interpretation of clinical chemistry findings may be found in the following references (Robinson and Evans, 1996; Loeb and Quimby, 1999; Young and Bermes, 2006; Hall and Everds, 2008). In a regulated environment, the protocol should be able to control several of the variables by specifying the species, strain, geographic region (monkeys), supplier, age of animals at the start of study, the use of certified diet and by fasting the animals prior to bleeding. The in-depth knowledge of standard operating procedures (SOPs) and appropriate technical training should control variables associated with blood collection site, order of sample collection, anaesthesia and poor blood samples (clotting, haemolysis, dilution due to excess of anticoagulant, evaporation, delay in serum/plasma separation). Fine-tuned scheduling of blood sample collection will take into consideration variations related to circadian rhythm (e.g. hormones), the most appropriate time after dosing for specific assays (e.g. troponins) and may help reduce fear/excitement/stress in the pretest period, by giving a chance for the animals to acclimatize to their new environment and activities.

2.2 Analytical Variability

Interpreting clinical chemistry results in regulatory toxicity studies requires the ability to discern toxicity from physiologic variability and laboratory error. Often, subtle trends in data that have a wide physiologic range may be masked by analytical variability. Minimizing variability is central to generating quality results from which

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

meaningful conclusions can be drawn, having a direct impact on the outcome of the test material under investigation. The quality of laboratory results is determined by the quality of the sample (preanalytical variation), the quality of the analysis (analytical variation) and the quality of laboratory records (postanalytical variation) (Stockham and Scott, 2002). Some degree of random analytical variation is unavoidable due to the physicochemical nature of analytical methodologies. In a regulatory environment, the acceptable degree of variability must be defined, monitored and controlled. A quality assurance (QA) programme must be implemented which specifies the procedures used to produce data of known variability (precision) and bias (accuracy). This set of operating principles serves as a means of monitoring analytical variability to ensure validity of results.

In a laboratory's QA programme, analytical variability must first be defined by means of equipment qualification and method validation. A review of policies and procedures that can be implemented in order to develop a validation process may be found in the following references (Bansal *et al*., 2004; CLSI, 2007; Garber and Carey, 2003). Thereafter, variability and bias are monitored and managed by way of specified equipment maintenance and analytical quality control (QC) SOPs. QC consists of a systematic process within a sample analysis methodology to assure that the process is in control. In QC, assay variability and bias are measured over time and compared against set criteria (Blick and Passey, 2003; CLSI, 2006). This is typically accomplished using commercially available QC (control) material that is analysed at the same time as the test sample. The recovered concentration of the control material is evaluated against specified acceptance criteria. In addition, external QC or proficiency programmes determine the quality of data produced by the laboratory by comparing laboratory results for an unknown (laboratory intercomparison samples and performance evaluation samples) with those of other laboratories using the same methods and equipment (Veterinary Laboratory Association, College of American Pathologists). Proper implementation of these robust internal and external QA programmes provides reasonable confidence regarding suitable instrument performance and accurate, precise and reproducible data generation, as prescribed within regulatory environments.

2.3 Are the Changes Related to the Test Material?

Safety evaluation of new chemical entities, whether they are industrial chemicals or potential new drugs, is not simple. It requires objectivity, careful attention to detail, knowledge of experimental models, historical perspective, knowledge of government regulatory requirements and experience in data interpretation. Safety evaluation of potential new drugs differs in approach to that used with industrial chemicals. The risk/benefit analysis in drug safety assessment must take into account the disease for which the drug is intended, the natural history of the disease without therapy and the availability of other treatments. With potential new drugs, not every effect seen in a preclinical study can be considered as unwanted or harmful. For example, drugs designed to treat diabetes would be expected to show significant to life-threatening hypoglycaemia in preclinical studies using euglycaemic animals (Dorato and Engelhardt, 2005).

The main goals for conducting most regulatory toxicity studies are (Wells and Gosselin, 1996; ECETOC, 2002; Lewis *et al*., 2002; Boone *et al*., 2005):

1. To define if the effects are due to the test material
2. If they are judged to be due to test material, it is to discriminate between those that are adverse and nonadverse
3. To identify the no observed adverse effect level (NOAEL)/no observed effect level (NOEL).

The difference between controls and animals treated with the test material is likely an effect of the test material if:

1. There is a dose response
2. It is observed in several animals (not an outlier) and in both sexes
3. The changes are consistent between individual animals (same direction either increase or decrease)
4. It is noted over more than one interval or the effect progressed over time
5. It was reported in previous studies with this test material (same animal species or other species)
6. It is a precursor to a known effect of the test material
7. The effect is expected with this class of test material.

Toxicokinetic results should be evaluated for isolated test material effect that may be due to erratic bioavailability of the test material. If the clinical pathology measurements are physiologically not credible, the measurements should obviously be excluded from consideration. The effect should also be differentiated from changes due to the vehicle, procedure (repeat bleedings), background findings associated with route of administration (continuous intravenous infusion, intramuscular or subcutaneous injection) and from naturally occurring diseases/disorders.

2.3.1 Statistics

Appropriate statistical methods should be used to analyse clinical pathology data. Regardless of the outcome of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

statistical analysis, scientific interpretation is necessary for the ultimate determination of test material effects. Statistical significance alone should not be used to infer toxicological or biological relevance of clinical pathology findings. Additionally, the absence of statistical significance should not preclude the possibility that test material effects exist (Weingand *et al*., 1996; OECD, 2001). Some statistical tools used in toxicology studies differ between laboratories and comparison of strategies for application have been evaluated recently (Kobayashi *et al*., 2008); however, each laboratory has a preferred approach.

In nonrodents, statistical analysis of changes in clinical pathology data is further complicated by interindividual and intraindividual variability and by the low number of animals per dose group. For these reasons, the use of statistical analysis in the evaluation of clinical pathology data augments, but does not replace, comparisons of individual data with concurrent controls in all species, nor does it replace comparisons of individual data with pretest values in nonrodents (Boone *et al*., 2005). For example, hepatotoxic signals such as elevations in alanine aminotransferase (ALT) in nonrodent preclinical studies may be found in one or two animals and not achieve statistical significance. The biological significance of relevant hepatotoxic signals should be clarified (EMEA, 2008).

2.3.2 Historical Control Data

The concurrent control data are more appropriate than historical reference ranges for comparison with test material treated groups. Ideally, historical control data (HCD) must come from the same laboratory, utilizing the same strain, age and sex of animals obtained from the same supplier, with identification of study procedures (route of administration, vehicle, clinical pathology methods/instrumentations, serum/plasma, site of collection, etc.) which could affect the values (OECD, 2001). HCD used to clarify a potential effect in a study should be reasonably contemporary to the study under evaluation (ECETOC, 2002; Lewis *et al*., 2002). In some studies, particularly when the rabbit is used as the animal model, the reproductive status (pregnant vs. nonpregnant) of the animals should be identified (Wells *et al*., 1999; de Rijk *et al*., 2002).

HCD are useful in evaluating the acceptability of the 'normal' data obtained from nonrodents in the pretest period or from controls during the treatment period, and may have some utility in placing test material changes into the context of severity (changes that remain within the limit of HCD have a lower risk than those that do not) and should not be seen as a convenient device for discounting test material findings (ECETOC, 2002; Clemo, 1997).

2.4 Are the Test Material Changes Adverse or Nonadverse?

An adverse effect may be considered to be a change (biochemical, functional or morphological) that may impair performance and generally have a detrimental effect on the general well-being, growth, development or life span of animals in toxicity studies. More specifically, an adverse effect in toxicity studies conducted for drug approval should be an effect that would be unacceptable if it occurred in a human clinical trial (Wells and Gosselin, 1996; OECD, 2001; Lewis *et al*., 2002; ECETOC, 2002; FDA, 2005; Boone *et al*., 2005; Dorato and Engelhardt, 2005).

In order to identify if a clinical pathology effect is adverse, it should be quantified (fold or % change vs. controls or in some cases pretest values), qualified (minimal to severe) and corroborated with clinical observations, morphologic pathology findings and/or any other clinical pathology changes. The change is unlikely adverse if it is transient and if it is considered an adaptive response or secondary to severe reduction in food consumption/anorexia, the moribund condition of the animal (liver/kidney failure, electrolyte imbalance) or excitement/stress (increased ALT/AST in monkeys). A change that is readily and completely reversible on cessation of treatment would suggest a lower level of concern. The change is more likely considered to be adverse if the effect is inconsistent with class effects, mode of action or what is otherwise known or expected of the test material. Before concluding that an effect is adverse, the intended clinical indication should be taken into consideration (hypoglycaemia with antidiabetic drugs; hypocholesterolaemia with lipid-lowering drugs), as well as if the finding has any human relevance. Microsomal enzyme inducers in rodents resulting in increased thyroid hormone turnover, thyroid stimulating hormone (TSH) stimulation, follicular hypertrophy/hyperplasia and the eventual progression to thyroid tumour is a well-known example which is irrelevant to humans. Other points to consider would be if the animal model is relevant (e.g. biologically responsive animal species are recommended for biopharmaceuticals), if there is tolerance over time (particularly with central nervous system drugs), and if the toxicity is due to a toxic metabolite not identified in humans.

The identification of the NOAEL can be a challenging process and should be determined for each toxicity study as a whole, rather than for individual findings (Lewis *et al*., 2002; Dorato and Engelhardt, 2005). In some cases, however, there may be more than one NOAEL (e.g. neoplastic vs. non-neoplastic findings, local vs. systemic toxicities) in a toxicity study. The initial opinions on where harmful and nonharmful effects occur may change as additional information related to the molecule is generated over the course of developing a

test material. Data from longer-term studies may give the toxicologist new, or additional, perspective on whether or not an observation thought to be subtle or minor in a short-term study is an early indicator of a harmful effect. For example, a liver enzyme elevation in a short-term preclinical study, without a histopathology correlate, will be noted, but may not be considered to be harmful. The outcome of longer-term studies, indicating a progression of effect and the occurrence of histological alteration in the liver, provides a new interpretation of the importance and/or relevance of the response and the duration of exposure associated with the first indications of an unwanted response (Dorato and Engelhardt, 2005).

3 PROTEINS

Plasma proteins perform a nutritive function, exert colloidal osmotic pressure and aid in the maintenance of acid–base balance. Individual proteins serve as enzymes, antibodies, coagulation factors, hormones and transport substances. The major site of plasma protein synthesis is the liver (albumin (ALB), most α and β globulins (GLOBs)) and the second major contributor is the immune system (γ GLOBs). Serum contains all of the plasma proteins except fibrinogen, factor V and factor VIII. Age is an important consideration in the interpretation of protein variations and it must be kept in mind that few protein changes are pathognomonic (Evans and Duncan, 2003; Kaneko, 1997b; Stonard and Evans, 1999).

ALB represents ~50–70% of the serum/plasma total protein (TPROT) concentration in laboratory animals (rats, dogs and monkeys); in humans, it ranges from ~64–69%. Because of its abundance and small size, ALB accounts for 75% of the colloidal osmotic activity of plasma. TPROT and ALB concentrations are directly measured while GLOB concentrations usually are calculated (total protein—albumin = globulin). GLOB and ALB can be separated and directly quantified by electrophoresis, however it is not recommended by the Committee for International Harmonization of Clinical Pathology Testing and is now rarely performed on routine toxicity studies (Evans and Duncan, 2003; Kaneko, 1997; Weingand *et al*., 1996).

In toxicity studies, the most frequent reason for increased TPROT concentration is dehydration. Possible correlative clinical observations include gastrointestinal (GI) fluid losses (e.g. vomiting, diarrhoea, excessive salivation), polyuria and reduced water consumption. Since water consumption in rodents is closely associated with food consumption, any cause of decreased food consumption in rodents has the potential to cause relative dehydration (Hall and Everds, 2008). Increased TPROT also has been associated with inflammatory conditions that stimulate the production of acute phase proteins (APPs) and immunoglobulins. Neither of these two parameters is routinely evaluated in regulatory toxicity studies. Immunoglobulins are discussed in Chapter **Immunotoxicology** of this book.

Decreased TPROT concentrations result from either decreased protein synthesis or increased protein loss. Concomitant decreases in ALB and GLOB occur with malnutrition, haemorrhage, intestinal malabsorption, protein-losing enteropathy, severe exudative skin lesions/burns and overzealous administration of fluids. Hypoalbuminaemia can be the result of hepatic insufficiency, anorexia/cachexia, glomerulopathy with proteinuria and high protein effusion (Evans and Duncan, 2003; Kaneko, 1997). In toxicity studies, small decreases in ALB are frequently observed in animals administered high doses of a test material. This may correlate with effects on other parameters (e.g. haematocrit, glucose, cholesterol (CHOL) and body weight) and is usually considered an indication of the overall poor condition of the animals rather that evidence of a specific toxic mechanism (Hall and Everds, 2008).

3.1 Acute Phase Proteins (APPs)

Most APPs migrate to the α- and β-globulin areas on routine electrophoresis. This method is much less sensitive than the individual APP assays. The current interest in APPs is generated by their potential use in providing an early and reliable signal for the presence of inflammatory processes and to monitor animals in toxicity studies and human patients (Epstein, 1999; Shao, 2006; Ceron *et al*., 2005; Eckersall, 2006). The usefulness of APPs has been shown with inflammatory lesions caused by phosphodiesterase inhibitors (Dietsch *et al*., 2006; Zhang *et al*., 2006). The APPs can be broadly classified into two categories depending on their blood circulating levels: ALB and transferrin are identified as negative APPs, while C-reactive protein, serum amyloid A, haptoglobin, α-1-acid glycoprotein (AGP) and ceruloplasmin are positive APPs. The magnitude of the increases varies from about 50% to as much as 1000-fold depending on the APPs and animal species (Epstein, 1999; Gentry, 1999; Ceron *et al*., 2005). The major APPs for humans, dogs and monkeys are C-reactive protein and serum amyloid A and for rats, α-2 macroglobulin and α-1 AGP (Kaneko, 1997; Gentry, 1999; Ceron *et al*., 2005; Car *et al*., 2006; Shao, 2006). Fibrinogen, previously the most widely used APP, is not a major responder in any species, including humans. Some proteins, such as AGP and ALB, function to bind drugs and they can have important pharmacokinetic implications because variations in the plasma levels of APPs during inflammation can alter the free plasma concentrations of drugs (Stonard and Evans, 1999; Ceron *et al*., 2005).

4 LIPIDS

CHOL is an essential lipid found in all mammalian cells, and is a major component of the membrane. In addition to its structural role in cellular membranes, CHOL is a precursor molecule for sterol-based compounds, including bile acids, oxysterols, neurosteroids, glucocorticoids, mineralocorticoids and sex hormones. In toxicity studies, CHOL and triglyceride (TRIG) concentrations are the most frequently measured lipid compounds in the blood. Insoluble TRIG and CHOL are transported through the blood by lipoproteins. Lipoproteins consisting of variable quantities of TRIG, CHOL, CHOL esters and phospholipids are synthesized by the liver and small intestine and secreted into plasma. Lipoprotein lipase produced by several tissues, mainly gastric mucosal cells, pancreatic acinar cells, adipocytes, myocytes and hepatocytes, and the presence of appropriate cell receptors are required for clearance of lipids from blood. Chylomicron, very low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs) and high-density lipoproteins (HDLs) are the main lipoprotein fractions. The HDL and LDL fractions are also classified as the good and bad CHOL carriers, respectively (Rifai and Warnick, 2006; Stockham and Scott, 2002; Evans and Duncan, 2003).

There are large species differences in lipoprotein profiles and the percentage of total CHOL carried by each lipoprotein class. Dog, rat and mouse are HDL-predominant species and are considered relatively resistant to atherosclerosis compared to LDL-predominant species, such as humans and nonhuman primates. Atherogenesis occurs in dogs only if CHOL is above 750 mg dl^{-1}. It is believed that HDLs exert a protective effect for the development of coronary artery disease because of their role in reverse cholesterol transport (RTC). RTC refers to the efflux of CHOL from peripheral tissues (including arteries) to HDLs for esterification and subsequent hepatic clearance. CHOL esters are retained by HDLs or transferred to VLDLs or LDLs for transport to the liver for disposal. This process is believed to be an efficient way of redistributing CHOL among lipoproteins for reuse by peripheral tissues or removal from the circulation through delivery to the liver and excretion in bile. In humans, two enzymes participate in the process (lecithin cholesterol acyltransferase (LCAT) and cholesteryl ester transfer protein (CETP)). It is of interest that CETP activity has been documented in nonhuman primates, but not in dogs or rats (Wagner *et al.*, 1999; Bauer, 2004; Movva and Rader, 2008).

In toxicity studies, increases or decreases in CHOL and TRIG concentrations are relatively frequent findings. The changes are usually small and are generally believed to represent minor alterations in lipid metabolism that do not adversely affect the health of the animals. Factors to consider include food consumption and assimilation, body weight and composition, liver function and hormone balance. TRIG concentration is elevated postprandially, while CHOL concentration is relatively stable. When fat is mobilized to meet energy requirements because of significant anorexia, starvation, malabsorption or maldigestion, TRIGs are usually increased, sometimes markedly; CHOL levels, however, are variable (Hall and Everds, 2008). Lipaemia, a term used for the milky appearance of serum/plasma caused by increased concentrations of TRIG-carrying lipoproteins, may interfere with laboratory assays (glucose, several electrolytes, haemoglobin, total bilirubin (TBILI)).

Conditions in veterinary medicine causing secondary hyperlipidaemia are relatively common. Increased CHOL concentrations reflect increased concentrations of the cholesterol-rich lipoproteins (e.g. LDL, HDL) and TRIG increases usually indicate chylomicronaemia and/or increased VLDL. In hypothyroidism, CHOL use decreases and CHOL synthesis increases. Hyperlipidaemia is variable, ranging from mildly increased CHOL and HDL concentrations to marked lipaemia with CHOL greater that 1000 mg dl^{-1}, hypertriglyceridaemia, and panhyperlipoproteinaemia. In diabetes mellitus, lack of insulin results in reduced lipoprotein lipase activity (insulin enhances lipoprotein lipase activity). Lipolysis is increased as lipids are used as an alternative source of energy. Marked hypertriglyceridaemia is associated with increased VLDL concentration; CHOL concentrations are mildly increased. Hyperchylomicronaemia may also be present. Liver disorders, including cholestasis, are frequently accompanied by alterations of serum and tissue lipids. In nephrotic syndrome, hypercholesterolaemia is secondary to enhanced synthesis of CHOL-containing lipoproteins. Lipoprotein synthesis presumably is stimulated by hypoalbuminaemia, and decreased plasma oncotic pressure. Sometimes TRIG concentration also is increased. Excess corticosteroid administration may result in hypertriglyceridaemia from increased lipolysis, insulin resistance and decreased lipoprotein lipase activity. Moderate hypercholesterolaemia, predominantly due to increased LDLs, may occur (Evans and Duncan, 2003). In the dog, TRIG concentration greater than 500 mg dl^{-1} usually mandates treatment, while TRIG concentration greater than 1000 mg dl^{-1} has been associated with pancreatitis, lipaemia retinalis, seizures, cutaneous xanthomas, peripheral nerve paralysis and behavioural changes (Elliott, 2005). In toxicity studies, intravenous infusion of lipid emulsion has been associated with significant neurologic toxicities in dogs; emesis/retching, somnolence and loss of consciousness (Miles *et al.*, 1991). In our experience, the severity of the clinical observations is dependent on the rate of the infusion and the composition of the lipid formulation.

CHOL, HDL, LDL and TRIG may be the pharmacologic targets of hypolipidaemic agents, leading to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

low blood concentrations at dose levels used in toxicity studies (Walsh, 1996; Von Keutz and Schluter, 1998). Some other compounds have been unexpectedly associated with markedly low CHOL in rats, with individual values less than 10 mg dl^{-1} to below the level of quantification (Everds, 2005; Wason *et al*., 2003; Abell and Mosbach, 1962; personal communication). The consequence of these low to very low CHOL concentrations is unclear in those instances, but teratogenicity, characteristically holoprosencephaly, was reported with compounds interfering with the final step of CHOL synthesis with secondary accumulation of 7-dehydrocholesterol (Roux *et al*., 1979; Kolf-Clauw *et al*., 1997; Dietschy and Turley, 2004). Drugs inhibiting 3-hydroxy-3-methylglutarate-coenzyme A (HMG-CoA) reductase (statins) in the early steps of the CHOL metabolic pathway have produced teratogenic effects, predominantly skeletal defects, while others with the same mechanism of action and at high maternal toxic exposures, did not produce teratogenicity (Dostal *et al*., 1994; Physicians' Desk Reference, 2008). Because animal studies have generated conflicting results and human data in pregnant women are limited, HMG-CoA reductase inhibitors currently on the market are contraindicated for pregnant women (Kazmin *et al*., 2007; Physicians' Desk Reference, 2008).

5 CARBOHYDRATES

The balance of glucose production and its uptake and utilization in peripheral tissues are regulated by a network of hormones, neural pathways and metabolic signals. Insulin plays a dominant and pivotal role in glucose production and utilization. In the fasting state, insulin is suppressed, allowing increased glyconeogenesis in the liver and the kidneys and enhancing glucose generation by the breakdown of liver glycogen. Low insulin levels also reduce glucose uptake and utilization in peripheral tissues and allow lipolysis and proteolysis to occur, which leads to the release of precursors for gluconeogenesis and provides alternative energy sources. Other hormones, such as glucagons, adrenaline (epinephrine), growth hormone and cortisol play less important roles in the control of glucose flux during normal physiologic circumstances. However, these hormones are critically important in response to hypoglycaemia where glucagon increases glucose concentration by glycogenolysis and gluconeogenesis while corticosteroids and catecholamines increase glucose concentrations via gluconeogenesis and glycogenolysis, respectively (Kaneko, 1997; Sacks, 2006).

In toxicity studies, the most frequent causes of increased glucose concentrations in the blood are failure to fast an animal and catecholamine release secondary to excitement, pain or fear. The fasting glucose of wild-caught or purpose-bred monkeys can be confused with diabetes mellitus (e.g. >150 mg dl^{-1}) when the animals have not yet been accustomed to their new environment. Moribund animals occasionally exhibit marked hyperglycaemia, probably as a result of both corticosteroid and catecholamine release (Hall and Everds, 2008). Animals infused intravenously with a glucose-containing formulation will have higher glucose concentration than pretest animals infused with saline; in this instance, the effect would be considered an artefact (Evans and Duncan, 2003). A large number of drugs may cause hyperglycaemia in normal individuals or impair metabolic control in diabetic patients. Potential hyperglycaemic drugs may have a direct effect on peripheral tissues that counter the actions of insulin or may inhibit insulin secretion directly or indirectly via depletion of K^+ (diuretics) (Davis, 2006). Corticoids, thiazide diuretics, megestrol acetate, ketamine and morphine are some of the drugs used in veterinary medicine that can be associated with increased glucose levels (Evans and Duncan, 2003).

In toxicity studies, decreases in glucose concentration are most commonly observed in animals that fail to thrive and gain body weight, with or without a concurrent decrease in food consumption. The differences between controls and test material-treated animals are considered secondary effects and likely not to affect the animals adversely (Hall and Everds, 2008). Hypoglycaemia has been associated with an excess of insulin or insulin-like factors, with decreased glucose production (hypoadrenocorticism, hypopituitarism, growth hormone deficiency, severe liver diseases, fasting, malnutrition, pregnancy) or with excess glucose consumption by tissues (sepsis, extreme exercise) (Hess, 2005).

Because severe hypoglycaemia can ultimately result in coma and death, animals must be carefully monitored when they are tested with rapid-acting insulin secretagogues and other hypoglycaemic drugs. Most clinical signs arise from the effect of hypoglycaemia on the CNS or from hypoglycaemia-induced release of catecholamines. The severity of the clinical signs (weakness, ataxia, disorientation, tremors, seizures, collapse) is proportional to the severity of the hypoglycaemia, its duration and the rate at which it develops (Hess, 2005). Clinical suspicion of hypoglycaemia should be associated with glucose levels of less than 60 mg dl^{-1} in the dog. Clinical signs of neuroglycopenia have been reported in monkeys at blood glucose concentrations of $\sim$40 mg dl^{-1} (2.2 mmol l^{-1}) or less (Chen *et al*., 1998).

6 ELECTROLYTES, FLUID BALANCE AND ACID–BASE

Electrolytes play integral roles in pH and fluid balance, electrical membrane potentials, muscular function, nerve

conduction and enzymatic reactions. The efficacy of many drugs relies on their desired target effects on electrolytes, acid–base and fluid balance. However, the same electrolyte changes can be manifested as serious adverse effects in the case of toxicity. Endocrine and transmembrane regulatory mechanisms work to maintain serum electrolyte concentrations tightly controlled within a narrow range. The resultant narrow standard deviations may yield changes with statistical significance that are not dose-related and do not correlate with histopathologic findings (Evans, 1996). However, even minor changes in electrolyte concentration can have a devastating impact on cellular function, with nervous, muscular and renal tissue being most sensitive. Sodium, potassium and calcium abnormalities are commonly associated with cardiotoxicity and nephrotoxicity (DiBartola, 2006b). Detection and monitoring of electrolyte abnormalities is essential in preclinical safety assessment programmes.

The interpretation of electrolyte abnormalities requires an understanding of the distribution of body water and of homoeostatic mechanisms for osmotic and electro-neutrality. Osmotically active solutes (sodium (Na^+), chloride (Cl^-), potassium (K^+), glucose, bicarbonate (HCO_3^-) and urea) determine water distribution in body compartments. Of lean body mass, 60% is composed of water located in the intracellular fluid (ICF) or extracellular fluid (ECF). Regulated ECF–ICF shifts maintain electroneutrality and tonicity. Potassium, magnesium (Mg^{2+}), phosphate and proteins predominate in the ICF, while Na^+, calcium (Ca^{2+}), Cl^- and HCO_3^- are the major ECF solutes. These molecules carry a positive (cation) or negative (anion) charge, and though ECF and ICF solute composition is different, electroneutrality and osmotic equilibrium are maintained. Changes in electrolyte concentrations result from altered hydration and electrolyte intake, transmembrane shifts, altered renal handling or loss via alimentary tract, skin or airways. Massive cellular lysis, loss of plasma membrane integrity, severe acid–base disturbances and multiorgan malfunction, as seen in moribund animals or in shock, are the most common nonspecific causes of mixed electrolyte abnormalities (DiBartola, 2006b).

Sodium must be interpreted with consideration to hydration status, ECF volume and measured osmolality. The most common causes of abnormalities in Na^+ are dehydration (hypernatraemia) and dietary insufficiency (hyponatraemia). The adverse clinical consequences of hyper- and hyponatraemia depend largely on the rapidity of onset and associated osmolality. In dogs, neurologic signs (disorientation, ataxia, seizures and coma) manifest themselves when Na^+ values are <120 mEq l^{-1} or >170 mEq l^{-1}. Other clinical signs are associated with hypovolaemia (tachycardia, decreased capillary refill time) or hypervolaemia (pulmonary oedema) (DiBartola, 2006a). Though many drugs target renal handling of Na^+, alterations in serum Na^+ concentrations and adverse effects may not be observed until high doses are attained due to compensatory homoeostatic mechanisms. While Na^+ is the major extracellular cation, Cl^- is the major extracellular anion, and the two ions tend to follow one another. As such, any alteration in Cl^- must be interpreted in the context of sodium. Dehydration and water overload both result in proportional changes in Cl^- and Na^+. Nonproportional changes between Na^+ and Cl^- occur secondary to losses or gains of one ion but not the other, or reflect the role of Cl^-, but not Na^+, in renal acid–base homoeostasis (de Morais and Biondo, 2006). Clinical signs of hyperchloraemia are associated with hypernatraemia and hyperosmolality, while signs of hypochloraemia are associated with metabolic alkalosis (Willard *et al*., 1999; Galla *et al*., 1984).

Plasma K^+ concentration is primarily determined by dietary Na and K intake, renal excretion and acid–base status (Church, 2005). Any cause of cellular lysis may result in release of potassium from the ICF and result in hyperkalaemia. In dogs, hyperkalaemia becomes adverse at values ≥ 7.5 mEq l^{-1} due to altered cardiac muscle conductance. Hypokalaemia may occur secondary to decreased intake, gastrointestinal loss or renal loss due to tubular injury and tubular acidosis (DiBartola and de Morais, 2006). Pharmaceutical compounds such as aldosterone, aminoglycosides, diuretics, antineoplastic agents and β-adrenergic agonists cause hypokalaemia (Evans, 1996). Hypokalaemia becomes clinically adverse when concentrations fall below 3.0 mEq l^{-1}, due to severe muscle weakness and cardiac contraction abnormalities (Willard *et al*., 1999).

Calcium (Ca^{2+}), magnesium (Mg^{2+}) and inorganic phosphate (Pi) are ions with many important structural and functional roles whose plasma concentrations are regulated in concert by way of dietary intake, GI absorption, renal function, parathyroid hormone (PTH), parathyroid hormone-related protein (PTHrP), calcitriol (1,25-dihydroxyvitamin D_3) and calcitonin.

Ca^{2+} exists in three fractions: ionized (iCa^{2+}), complexed and protein bound. Ionized calcium is the physiologically active fraction and its concentration is tightly regulated within a narrow range by PTH and calcitriol. Total calcium (tCa) as measured by most automated methods does not always reflect iCa^{2+} due to variability of protein binding that changes with pH and protein concentration. Increases in TPROT cause increases in tCa (pseudohypercalcaemia) while decreases result in pseudohypocalcaemia. Even after correction for TPROT, tCa may not reflect abnormalities in iCa^{2+}. Therefore, tCa is used only as a screening tool. A test panel including calcitriol, PTH and iCa^{2+} is recommended for compounds that are suspected to interfere with calcium homoeostasis. True hypercalcaemia is an uncommon but important finding. Though hypercalcaemia is normal in growing animals, in adults excessive iCa^{2+} is toxic to cells and results in nervous, gastrointestinal, cardiac and renal dysfunction. Most

often, adverse effects of hypercalcaemia (polydipsia/polyuria, anorexia, dehydration, lethargy, weakness and vomiting) are noted when tCa $\geq$15 mg dl^{-1}. However, tCa values of 12–14 mg dl^{-1} may also be adverse, depending on rapidity of onset and presence of acidosis or Na^+ and K^+ abnormalities. Dogs with tCa >19 mg dl^{-1} are severely ill and likely to develop soft tissue mineralization and concentrations >20 mg dl^{-1} are considered life threatening. Histopathologic changes correlating with clinical signs are more likely to be identified with persistent hypercalcaemia (Schenk *et al*., 2006). Causes of hypercalcaemia include hyperparathyroidism, hyperthyroidism, hypoadrenalism, poor venipuncture technique and exposure to drugs or toxins such as thiazides, lithium and calciferol (Evans, 1996).

Hypocalcaemia may occur with renal failure, fasting or inadequate intake of calcium or vitamin D, hypoparathyroidism, acute pancreatitis, hypercalcitoninism or drug/toxin exposure (diuretics, anticonvulsivants, fluoride, ethylene glycol) (Evans, 1996). The duration, magnitude and rate of decline determine severity of clinical signs. Hypokalaemia and alkalosis precipitate the onset of and magnify clinical signs. In dogs, concentrations <6.5 mg dl^{-1} cause hyperexcitability, disorientation, muscle tremors, pyrexia, cramping, stiff gait and seizures. Other signs include polyuria, polydipsia, hypercalciuria, anterior and posterior cataracts, tachycardia and increased QT intervals. Severe hypocalcaemia (<5.0 mg dl^{-1}) may cause death from cardiovascular failure or respiratory failure. A rapid decline to <4.0 mg/dl can cause left-sided myocardial failure and death (Schenk *et al*., 2006).

Phosphate is the major intracellular anion. Serum phosphate is primarily inorganic orthophosphate (Pi) and is protein bound, free anion, or complexed to Na^+, Mg^{2+} or Ca^{2+}. Concentrations are affected by diurnal cycle and pH. Hyperphosphataemia is normal in growing animals and may occur after a protein meal. Hyperphosphataemia results from increased GI uptake, cell lysis, tissue necrosis, acidosis, altered bone metabolism, decreased glomerular filtration rate (GFR) and hypoparathyroidism. In dogs, clinical signs of hyperphosphataemia (soft tissue mineralization) occur when the calcium phosphate solubility product ([Ca] × [Pi]) is greater than 60 (DiBartola and Willard, 2006). In rats, hyperphosphataemia ($\geq$13 mg dl^{-1}) causes myocardial hypertrophy, kidney dysfunction and osteoporosis-like lesions without soft tissue calcification (Neves *et al*., 2004). Hypophosphataemia results from diminished intestinal absorption, vomiting, transmembrane shifts due to dietary carbohydrates, insulin and iv dextrose, hyperventilation, hypothermia, tubular injury and hyperparathyroidism. Hypophosphataemia <1.5 mg dl^{-1} causes haemolysis, impaired leucocyte and platelet function, metabolic encephalopathy, decreased cardiac contractility and bone demineralization.

Magnesium is an important structural component of bone and muscle that predominates in the ICF and is found free, complexed or protein bound in blood. However, it is not well characterized or routinely assessed in preclinical studies. Hypomagnesaemia (<1 mg dl^{-1}) is more clinically significant than hypermagnesaemia, with important effects on cardiac and smooth muscle function. Studies in rats and dogs given magnesium-deficient diets showed poor growth rates, poor skin and hair, peripheral vasodilation, seizures and myocardial necrosis. Magnesium's function as a cofactor for adenosine triphosphatase (ATPase) pumps also results in potassium depletion accompanying magnesium deficiency (Bateman, 2006). In dogs, clinical signs associated with hypermagnesaemia (>10 mg dl^{-1}) include respiratory depression, apnoea, coma and cardiac arrest (Willard *et al*., 1999).

Blood gas analysis is required to evaluate acid–base balance, gas exchange and respiratory function. An evaluation of blood gas may be useful in some cases because many drugs, such as acetazolamide, ammonium chloride (NH_4Cl), calcium chloride ($CaCl_2$), antacids, gluconate and loop diuretics, affect acid–base balance and gas exchange. However, blood gases are not routinely measured in preclinical safety assessment because of extensive blood sampling and handling requirements. Instead, total carbon dioxide (tCO_2) is measured on automated chemistry analysers as an approximation for bicarbonate (HCO_3^-). Underfilled or uncapped tubes may have decreased tCO_2. Values <12 mEq l^{-1} indicate severe metabolic acidosis while values >30 mEq l indicate metabolic alkalosis. Adverse effects due to metabolic alkalosis are uncommon, and are generally a consequence of hypocalcaemia (decreased iCa^{2+}) (Fraser *et al*., 1991).

7 ENZYMOLOGY

Enzymes are powerful early indicators of drug-induced tissue damage and metabolic effects, including damage to the liver and bile duct (AST; ALT; ALP, alkaline phosphatase; LDH, lactate dehydrogenase; ID, iditol dehydrogenase; SDH, sorbitol dehydrogenase; GGT, γ-glutamyl transferase), cardiac and skeletal muscle (CK, creatine kinase; LDH; AST; ALT), bone (B-ALP, bone alkaline phosphatase), pancreas (amylase and lipase), intestine (amylase) and kidney (amylase; lipase; GGT; NAG, *N*-acetyl glucosaminidase; GST, glutathione-(S)-transferase), to name a few. As such, enzymology is indispensable to any safety assessment programme. Enzymes that are useful biomarkers of toxic injury originate from specific tissues and cells and their expression is usually confined to a specific cellular compartment (cytosolic, organelle, plasma membrane). Their activity in blood reflects changes in membrane integrity (leakage), metabolism or synthesis (induction), excretion/half-life, and/or inactivation (Stockham and Scott, 2002). The type and spectrum of change may

reflect the mechanism of toxicity while its magnitude often correlates with severity (Thrall, 2006).

Enzymes are proteins that catalyse chemical reactions. Those that catalyse the same reaction but arise from different genes are termed isoenzymes, whereas those that differ due to post-translational modification of the same gene product are termed isoforms (Stockham and Scott, 2002). Isoenzymes and isoforms tend to be highly tissue-specific and have unique half-lives. Most automated clinical chemistry analysers quantify the enzymatic catalysis of a specific chemical reaction, but cannot distinguish isoenzymes and isoforms. Therefore, increases in blood enzyme activity as determined by automated methods is variably tissue-specific depending on the enzyme activity in question, species and isoenzyme/isoform half-life. Though not routinely assessed in preclinical safety assessments, isoenzyme/isoform activity should be pursued when thorough evaluation of effects on a specific target organ is required.

8 LIVER

Hepatotoxicity has been the most frequent single cause of safety-related drug marketing withdrawals for the past 50 years and is not uncommonly observed in experimental studies with other test materials, such as pesticides. Hepatotoxicity discovered after approval for marketing has also limited the use of many drugs (FDA, 2007). Liver toxicities appear to be the consequence of the unique blood vessel, secretory, synthetic and metabolic features of this organ. About 75% of hepatic blood comes directly from the GI tract and spleen via the portal vein bringing drugs and xenobiotics absorbed by the gut directly to the liver in concentrated form (Jaeschke *et al*., 2002). There are six basic mechanisms or sites of action for chemically induced liver injury (Lee, 2003). These include:

1. Disruption of calcium homoeostasis leading to cell surface blebbing and lysis
2. Cholestasis and biliary canalicular injury
3. Stimulation of autoimmunity
4. Stimulation of apoptosis
5. Mitochondrial injury
6. Metabolic bioactivation of chemicals via cytochrome P450 to reactive species.

It is important to keep in mind that many of these mechanisms can be in play at the same time in an affected liver. Furthermore, the active proliferative responses of hepatocytes to cellular damage and injury makes the liver an important target for carcinogens (Jaeschke *et al*., 2002).

Hepatotoxicity in standard preclinical studies may be identified from clinical chemistry, histopathology and ultrastructural pathology, bioaccumulation, expression of xenobiotic metabolizing enzymes, generation of reactive metabolites and immune-related hepatotoxicity (EMEA, 2008). ALT, AST and ALP activities and TBILI, direct (conjugated) bilirubin, TPROT and ALB concentrations are considered suitable and applicable parameters for the evaluation of potential hepatic injury in preclinical studies because they can be correlated with parameters recommended for identification of hepatic injury in humans (Boone *et al*., 2005). This list can be modified to include other parameters that are optimized to the species of interest or to specific patterns of hepatic injury (EMEA, 2008).

8.1 Hepatocellular Toxicity

ALT and AST are recommended parameters for the assessment of hepatocellular injury in rats, dogs and nonhuman primates. Of these, ALT activities is considered the more specific and sensitive test. When activity of both enzymes are increased by hepatic injury, the magnitude of the ALT increase is usually greater than AST, in part due to the longer half-life of ALT, but also because a substantial amount of AST is present in mitochondria, ranging approximately 30–40% in dogs and 81–85% in rats (Boone *et al*., 2005; Solter, 2005). Assessment of AST release from rat liver following ischaemia has shown that hepatocytes do not lose mitochondrial AST until almost all cytosolic AST has leaked and not until there is appreciable loss of cell integrity, such as necrosis. This implies that more severe forms of hepatic injury are necessary for the release of mitochondrial enzymes than cytosolic enzymes (Solter, 2005).

Hepatic causes of increased serum ALT, with or without increased AST, include hepatocellular necrosis, injury or regenerative/reparative activity (Boone *et al*., 2005). The mechanism proposed to explain the appearance of cytosolic enzymes in blood with reversible damage involves the formation of membrane blebs that detach and allow the cell membrane to reseal without cell death. Greater increases of serum enzyme activity likely reflect principally irreversible cell damage and necrosis, while mild increases may indicate mostly membrane blebbing and therefore, reversible cell damage (Solter, 2005; Stockham and Scott, 2002).

Increases (rat and dog) in ALT may occur in conjunction with hepatic microsomal enzyme induction. In general, they are not associated with evidence of histopathological hepatic injury and therefore are considered adaptive in nature (Amacher *et al*., 1998; 2001). Occasional decreases in ALT have been associated with hepatic microsomal enzyme induction and assay interference by the test material (ECETOC, 2002; Boone *et al*., 1998; Young, 2000). Interestingly, hepatocytes and biliary epithelium

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

proliferation following the administration of epithelial growth factors have resulted in dose-related decreases in liver enzymes (ALT, AST and ALP) in the rat, but not in the monkey (Maraschin *et al*., 1995; Reindel *et al*., 2001). Reduced ALT/AST activities have a tendency to be dismissed even if they are identified as test material-related effects. The determination of whether a reduction in ALT/AST activities is adverse may become of greater importance when it is seen in the absence (at the same dose level) of any clear adverse findings when an overall NOAEL is being set for a study (PSD, 2007). Test material interference with the liver enzyme assays may reduce the sensitivity of ALT/AST activity to detect hepatocellular damage. Other potential causes of decreased ALT/AST activity may include decreased hepatocellular synthesis or release of the enzymes and inhibition or reduction of the enzyme activity (PSD, 2007; Hall and Everds, 2008).

ALT can also be affected by extrahepatic factors. Muscle injury can cause increases in the transaminases, but AST is generally higher than ALT when both are concurrently increased. In such cases, measurement of creatinine kinase activity, a specific indicator of muscle injury, may distinguish muscle injury from hepatic disease as the cause of increased enzyme activity (Bain, 2003). Procedure-related handling and type of restraint can cause increases in AST with or without increases in ALT in mice and nonhuman primates (Boone *et al*., 2005). Compounds resulting in hypotension or hypoxia (severe anaemia, congestive heart failure) with secondary hepatocellular damage may also be accompanied by liver enzyme increases (Webster, 2005). All data generated during toxicity studies (clinical signs, cardiovascular assessment, clinical pathology, histopathology) should be evaluated thoroughly to identify if the effect on liver enzymes is of hepatic or nonhepatic origin (skeletal muscle, heart, red blood cells (RBCs)).

Supplementary parameters of hepatocellular injury, such as activity of SDH, a cytosolic enzyme, and glutamate dehydrogenase (GLDH), mainly a mitochondrial enzyme, are useful when additional indicators of hepatic pathology are desired. Both parameters have been shown to be specific for liver injury (Boone *et al*., 2005). SDH has been considered the most sensitive and specific indicator of hepatocellular toxicity in rats and its interpretation is not confounded by compound interference with the assays as occurs with ALT/AST (Car *et al*., 2006). SDH is cleared fairly rapidly, yet remains in blood long enough to be of diagnostic value in acute hepatocellular injury (Hoffman *et al*., 1999). One disadvantage about the determination of SDH activity is that it requires rapid processing of samples from blood collection to chemistry analyser, unlike the more stable analytes, AST and ALT (Car *et al*., 2006). GLDH may become a more effective biomarker of acute hepatic injury than ALT, AST, SDH or ALP in the rat, based primarily on the large increase following hepatocellular injury, prolonged persistence in the blood following injury, high sensitivity for detection of injury, high tissue specificity and lower susceptibility to inhibition or induction. GLDH activity is higher in the centrilobular region of the liver than in the periportal zone. In contrast, AST is approximately homogeneously distributed in the liver lobules and ALT is mainly periportal (O'Brien *et al*., 2002). Recently, GLDH has been studied as a potential biomarker of liver injury in the dog (Jordan, 2007). Of note, neither GLDH or SDH are routinely utilized by physicians to evaluate human hepatic damage (Boone *et al*., 2005).

The magnitude of the increase in enzyme activities (ALT, AST, SDH, GLDH) depends on the number of hepatocytes affected, the severity of the injury, intracellular enzyme concentration, intracellular enzyme location and half-life of the enzyme (Bain, 2003; Stockham and Scott, 2002). If increases in ALT correlate with detrimental histologic changes it should be considered adverse. Additionally, concurrent increases in the activity of two or more enzymatic indicators of hepatic injury may potentially be considered adverse (Davies, 1992). Increase of ALT activity in the range of two- to fourfold and higher, compared to concurrent control mean or individual pretest values, without any other hepatic clinical chemistry abnormalities or in the absence of hepatic histological correlates, should raise concern as an indication of potential hepatic injury, unless a clear alternative explanation is present (Boone *et al*., 2005).

8.2 Hepatobiliary Toxicity

ALP and TBILI are recommended for identification of hepatobiliary injury, with GGT as a supplementary indicator (Boone *et al*., 2005). ALP and GGT are inducible enzymes, typically membrane-bound, and are not released into the blood with increased membrane permeability, while TBILI concentration is a measure of liver function (Bain, 2003). The mechanisms of drug-induced cholestasis are not clearly understood. A key component of bile secretion involves a series of ATP-dependent export pumps, such as the canalicular bile salt transport that moves bile salts and other bile constituents from the hepatocyte cytoplasm to the lumen of the canaliculus. Some drugs may bind to these canalicular transporter molecules and lead to the arrest of bile formation or movement within the lumen of the canalicular system. Secondary injury can result as bile salts have a detergent action that can damage cell membranes and injure biliary epithelium or hepatocytes in areas of cholestasis. Another possible mechanism leading to cholestasis involves disruption of actin filaments situated around the bile canaliculi preventing the normal pulsatile contractions that move bile through the canalicular system to the bile duct (Cullen, 2005).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In laboratory animals, hepatobiliary pathology and bone growth/disease are the two most common causes of increased ALP activity. Increases in ALP due to hepatobiliary pathology generally precede increases in bilirubin. Increased (rat and dog) or decreased (rat) ALP activity from the liver in the absence of cholestasis has been reported with concurrent microsomal enzyme inductions (Boone *et al*., 2005). In rats, a transient postprandial increase in circulating ALP may occur due to presence of the intestinal ALP isoenzyme, while fasting results in a decrease in circulating ALP (Loeb, 1999b).

Although ALP elevation is a sensitive indicator of hepatobiliary disease, its low specificity for liver disease confuses interpretation. The low specificity of ALP activity stems from the fact that increased ALP activity may reflect physiologic or pathologic changes other than those from hepatic origin (Fernandez and Kidney, 2007). For example, nonhepatic increases in ALP activity are found in young animals, in pregnant and lactating females and in association with high fat diets. Bone disease, endocrine disease, neoplasia, illness or stress, drugs (glucocorticoids and anticonvulsants) and other disorders can result in increased ALP activity. In a group of dogs with histologically confirmed hepatic disease (Center *et al*., 1992), the highest ALP activity (~10-fold increase) was reported in animals with cholestasis, followed by chronic hepatitis, corticosteroid-induced hepatopathy and hepatic necrosis (approximately sixfold increase).

Bilirubin is produced as a breakdown product of haemoglobin. The unconjugated bilirubin is transported in the blood (ionically bound to ALB) to the liver. Unconjugated bilirubin is taken up by hepatocytes, conjugated and excreted into bile (Bain, 2003). Secretion of conjugated bilirubin into bile canaliculi is an energy-dependent process and is the rate-limiting step in bilirubin excretion in most species (Cullen, 2007). Increases in circulating bilirubin level are generally due to retention subsequent to an impairment of intra- or extrahepatic bile flow (cholestasis), overproduction associated with accelerated RBC destruction/haemolysis or altered bilirubin metabolism. The unconjugated fraction (indirect-reacting) generated from the degradation of RBC and conjugated fraction (direct-reacting) comprise the TBILI. In toxicity studies, bilirubin fractionation is generally only of value for exploring drug-related inhibition of the bilirubin conjugation enzyme, uridine diphosphate glucuronosyltransferase (UGT1A1). Concomitant bilirubinuria is supportive of an increase in the circulating conjugated bilirubin level, which is often due to cholestasis (Boone *et al*., 2005).

In the absence of haemolysis or changes in other hepatic parameters, increases in TBILI alone are unlikely to be adverse to the animal or to indicate potential hepatic injury in humans (Boone *et al*., 2005). Dogs with TBILI concentrations $\geq 0.5\,\text{mg dl}^{-1}$ would be considered hyperbilirubinemic; icterus may not be detected clinically until TBILI exceeds $2\,\text{mg dl}^{-1}$ (Cullen, 2007). Additionally, concurrent increases in ALT and TBILI should be critically evaluated given the potential for serious outcomes with this pattern of changes in humans (Boone *et al*., 2005; FDA, 2007).

GGT in all species is found in highest concentration in the kidney, pancreas and liver. GGT increases in serum/plasma as a result of hepatobiliary disease and in urine during early renal tubular toxicity (Hoffman *et al*., 1999). GGT, a canalicular enzyme, is increased in cholestatic liver disease secondary to impaired bile flow and/or biliary epithelial necrosis. An increase in circulating GGT without evidence of biliary pathology is associated with the use of some anticonvulsants in humans and dogs and an increase in circulating glucocorticoids in dogs and rats. In both dogs and rats, GGT is less sensitive, but more specific for cholestasis, compared to ALP (Boone *et al*., 2005). In healthy rats, GGT is often undetectable; however, cholestasis results in marked GGT elevation (Loeb, 1999). Concurrent increases in GGT and ALP are considered more indicative of a hepatic enzyme source, but do not exclude concurrent bone disease (Boone *et al*., 2005).

8.3 Supplementary Tests for Hepatic Synthetic Function

The liver is responsible for the synthesis and homoeostasis of a wide variety of blood constituents. Approximately 70% or more of the functional hepatocytes must be lost before alterations of hepatic function are detectable by biochemical testing. Therefore it should not be unexpected to detect changes in enzyme activity before hepatic failure is identified (Bain, 2003). Total protein, ALB, TRIG, CHOL, glucose, blood urea nitrogen (BUN), activated partial thromboplastin time and prothrombin time may be instrumental in the identification of deleterious effects on glucose metabolism and hepatic synthesis of proteins, lipids and coagulation factors (Boone *et al*., 2005).

Additional parameters such as ALP isoenzymes, 5′-nucleotidase, α-glutathione-(S)-transferase (α-GST), lactate dehydrogenase (LDH), total bile acids and several others are not routinely assessed in preclinical studies for a number of reasons, such as no added value, not widely used by physicians, less sensitivity and/or lacks hepatic specificity (Boone *et al*., 2005).

Overt hepatotoxicity due to drug administration is a real and current issue in drug development and regulatory circles (Senior, 2007; Hunt *et al*., 2007; FDA, 2007; EMEA, 2008). The standard preclinical experimental designs conducted in at least two species, one rodent and one nonrodent for at least two weeks of repeated

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

dosing and using various multiples of the intended human therapeutic dose can predict subsequent adverse hepatic effects in the clinic over 50% of the time (Olson *et al*., 2000; Greaves *et al*., 2004). However, preclinical models are not infallible and are not always predictive. Whether the lack of predictivity is due to individual human genetic sensitivities, immunologically mediated phenomena, disease mediation or idiosyncratic reactions, the animal models are limited in detecting these characteristics and other low-incidence phenomena (Peters, 2005; Boelsterli and Lim, 2007; Kaplowitz, 2005). The draft EMEA (2008) guideline introduces a stepwise approach in an effort to identify hepatotoxicity signals. The first step is to optimize the interpretation of data generated during standard preclinical studies, followed by mechanistic studies to assess the clinical relevance of preclinical hepatotoxicity signals in terms of clinical settings.

9 KIDNEY

The kidney is a vital organ responsible for plasma filtration and maintenance of the body's internal biochemical environment. The kidney performs a wide variety of homoeostatic functions, including regulation of acid–base, electrolytes and water, metabolism and excretion of waste products and toxins, and endocrine regulation of minerals, blood pressure and tissue oxygenation capacity (Sands and Werander, 2005). The kidney's triple roles in plasma filtration, ultrafiltrate concentration and metabolism render it exceptionally sensitive to the toxic effects of xenobiotics. The kidney filters more than one quarter of cardiac output every day, exposing the glomerulus to high levels of drugs with even very short half-lives. Tubular epithelial cells metabolize drugs to generate products often with greater toxicity. In addition, tubular reabsorption concentrates toxins and metabolites in the ultrafiltrate. The 100- to 1000-fold increase in local drug exposure renders even low toxicity compounds quite damaging to the tubular epithelium (Evans, 1996; Sands and Werander, 2005).

Drug-induced nephrotoxicity accounts for approximately 35% of cases of renal failure in humans, and results in a high mortality rate (Zhang *et al*., 2005; Trof *et al*., 2006). In clinical drug development, the rate of project termination is highest for renal toxicity. Approximately 70% of urinary system toxicities result in compound termination, in contrast to 55% for hepatobiliary injury and function test abnormalities and 47% for cardiovascular (Olson *et al*., 2000). The pathogenesis of kidney injury involves a variety of mechanisms including vasoconstriction, altered glomerular haemodynamics, blood vessel injury, thrombotic microangiopathy, glomerular membrane damage, direct tubular toxicity, ischaemic tubular nephrosis, immune-mediated inflammation, drug crystallization/precipitation, osmotic nephrosis, retroperitoneal fibrosis and mineral deposition (Lash, 2005; Markowitz and Perazella, 2005; Evenepoel, 2004; Choudhury and Ahmed, 2006). The effects can be acute, beginning two weeks after drug exposure or sooner, or they may be chronic (Markowitz and Perazella, 2005). Though acute effects tend to be reversible, with function returning to baseline after the compound is withdrawn, chronic exposures can lead to irreversible damage (Zimmerman *et al*., 2007). Severe or prolonged damage leads to impaired renal function and eventual uraemia.

9.1 Serum Biochemistry/Renal Function

In preclinical toxicity studies, nephrotoxicity is routinely assessed by serum biochemistry, urinalysis and histopathology (Weingand, 1996; Greaves *et al*., 2004). Histopathology correlates best with human toxicity and is currently the gold standard for detection and monitoring of nephrotoxicity in animals (Olson *et al*., 2000). However, serum biochemistry and urinalysis provide *in vivo* assessments of kidney function and injury that can be correlated with clinical endpoints (Olson *et al*., 2000; Emeigh Hart, 2005). Traditional *in vivo* indicators of nephrotoxicity are of limited utility because they have low specificity and sensitivity for kidney injury and function. In contrast, the newer, nontraditional serum and urinary biomarkers offer promising alternatives for early detection of nephrotoxicity that correlates well with human toxicity and does not require invasive biopsies.

Changes in functional nephron (glomerulotubular unit) mass are most readily identified by estimating changes in GFR. BUN and creatinine are traditional indices of GFR in both humans and animals because they are freely filtered across the glomerulus and excreted in the urine with minimal secretion or reabsorption. Increases in BUN and creatinine above reference ranges (azotaemia) indicate that GFR is decreased, and form the basis for an investigation into renal drug effects.

Azotaemia can be classified as prerenal, renal or postrenal. Renal azotaemia occurs when loss of urine concentrating ability renders the urine isosthenuric (same concentration as glomerular filtrate: specific gravity (sp gr) = 1.008–1.012) (DiBartola, 2005). However, there can be significant renal disease without azotaemia. Because of compensatory hypertrophy and hyperfiltration mechanisms, damage to 90% of the original parenchyma has probably occurred before azotaemia is detected (Thrall, 2006). In rats, renal azotaemia correlates with microscopic lesions (vacuolar degeneration, acute tubular necrosis and inflammation) when BUN is $>20\,\text{mg dl}^{-1}$ and creatinine is $>1\,\text{mg dl}^{-1}$ (Sajedianfard *et al*., 2007). Increased inorganic phosphorus and potassium, decreased

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

TPROT, ALB, sodium and chloride, and acidosis or alkalosis provide support for a diagnosis of renal azotaemia (DiBartola, 2005). In chronic studies, nonregenerative anaemia may occur, due to diminished renal production of erythropoietin or anaemia of chronic disease (DiBartola, 2005). Clinical signs of renal azotaemia (uraemia) are nonspecific (lethargy, dehydration, depression, reduced food consumption, vomiting, ulcerative stomatitis and weight loss) (DiBartola, 2005).

Postrenal azotaemia results from urinary tract obstruction. Although drugs that cause retriperitoneal fibrosis (e.g. methysergide, ergotamine, atenolol, hydralazine) or crystalluria/lithiasis (acylclovir, methotrexate, sulfanilamide) may result in obstructive nephropathy, postrenal azotaemia is relatively uncommon in toxicologic studies (Choudhury and Ahmed, 2006). Postrenal azotaemia is associated with oliguria or anuria, severe hyperkalaemia (increased potassium) and metabolic acidosis. Prolonged postrenal urinary tract obstructions (>48–72 hours) can result in acute intrinsic renal failure, cardiac conduction abnormalities and coma.

Prerenal azotaemia occurs secondary to increased production of BUN/creatinine or from decreased renal blood flow. Since renal function is intact, urine is concentrated (sp gr >1.030). Causes of prerenal azotaemia that are not drug-related include age-related decreases in renal blood flow, blood loss and dehydration. Sex, age, strain, body weight and group housing are additional prerenal variables that impact upon GFR (Vadiei *et al*., 1990; Hackbarth and Hackbarth, 1981; Hackbarth *et al*., 1981; Henegar *et al*., 2001). BUN increases with hepatic ureagenesis secondary to high-protein diets, GI bleeding, starvation, infection and fever. Conversely, decreased ureagenesis due to diminished hepatocellular function or anorexia may decrease BUN. In contrast to BUN, creatinine synthesis is relatively constant (proportional to muscle mass) and concentrations are not as dependent on extrarenal factors. Age, gender, diet and endogenous muscle catabolism during sepsis or cachexia may affect serum creatinine concentrations. Because meals cause a transient increase in GFR (Thrall, 2006), fasting status must be consistent across groups and collection intervals. Drug-related prerenal azotaemia is common and must be distinguished from drug-induced renal azotaemia (nephrotoxicity). Volume depletion secondary to diuresis is frequently observed with antihypertensives due to their diuretic or vasodilator effects. Vasoconstrictors (ciclosporin, osmotic contrast dye) also reduce GFR in a prerenal manner. Though these effects are reversible and not indicative of renal toxicity per se, prolonged exposure can lead to loss of renal concentrating ability and tubular necrosis, resulting in renal azotaemia (Choudhury and Ahmed, 2006). In chronic studies, normal age-related deterioration of kidney function magnifies drug-induced nephrotoxicity (Espandiari *et al*., 2007).

BUN and creatinine are reabsorbed and secreted, respectively, by renal tubules resulting in under- and overestimation of GFR (Thrall, 2006; Darling and Morris, 1991; Emeigh Hart, 2005; Dieterle *et al*., 2008). Alternative blood markers that do not undergo tubular handling are currently actively sought and developed. Endogenous small molecules and low molecular weight (MW) proteins such as cystatin C and 2-(α-mannopyranosyl)-L-tryptophan (2-MPT) are emerging as sensitive indices of GFR (Emeigh Hart, 2005). Cystatin C is not affected by diet, age, muscle mass or hydration status. In rats, it is freely filtered in the glomerulus and is 99.5% reabsorbed and degraded by the tubules (Tenstad *et al*., 1996).

9.2 Urinalysis

Urine is an easily obtainable and valuable analytical substrate for the evaluation of nephrotoxicity. Urinalysis must take into consideration the urine collection method, hydration status, water intake, diet and presence of nonrenal disorders that alter renal fluid or electrolyte handling (Emeigh Hart, 2005; DiBartola, 2005). In large studies, overnight (16 hours) collections of freely voided urine are routine. Pans or trays placed beneath cages may be contaminated with drinking water, food and faeces. Though metabolic cages can be carefully designed to prevent contamination, in many cases, contamination is inevitable. This may significantly complicate interpretation of parameters, including water intake, urinary volume, concentration, pH, urobilinogen, bilirubin, protein and sediment examination. Timed urine sampling (24 hour) provides a more quantitative assessment of glomerulotubular function that is not as influenced by diurnal fluctuations in urine volume (common in rodents) and is more likely to detect early release markers. Bladders must be completely emptied at the beginning of a specified period after dosing and prior to urine collection. Water evaporation, solute decomposition and bacterial growth can be minimized by collecting samples into cooled containers (Emeigh Hart, 2005). Cystocentesis is a time-consuming urine collection method that is useful when contamination must be avoided, but is only amenable to small studies and does not provide timed urine volume measures.

Routine urinalysis for toxicologic studies in laboratory animals includes visual assessment, volume, concentration, semiquantitative biochemical analysis with reagent strips and microscopic sediment examination. Interpreted together, azotaemia, urine volume and urine concentration are important indicators of kidney function. Loss of urine concentration capacity is an earlier indicator of renal injury than azotaemia, occurring after loss of 66% of the functional renal parenchyma, in contrast to 75–90% for azotaemia (Thrall, 2006). Azotaemia

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

with dilute urine (sp gr <1.012), and decreased urine volume (oliguria or anuria) indicates decreased functional nephron mass. Dehydration with dilute urine strongly suggests tubular dysfunction (DiBartola, 2005). Azotaemia with large volumes of dilute urine indicates loss of urine concentrating capacity. Interpretation of urine volume and concentration must take into account other factors that impact free water balance. Drugs that undergo renal excretion may cause osmotic diuresis. Psychogenic polydipsia (central diabetes insipidus) is to be suspected in nonhuman primates with abundant, dilute urine (Rosenberg and Loomis, 1980; Fanton *et al*., 1987). In rodents, water consumption varies with strain, body weight and kidney weight (Hackbarth and Hackbarth, 1982) and diminishes with decreased food consumption. Decreases in water consumption may cause dehydration, prerenal azotaemia and decreased urine volume, but urine will still be concentrated (sp gr >1.035) (Griffiths *et al*., 2007).

Reagent test strips designed for human use are commonly used to semiquantitatively screen for pH, protein, glucose, ketones, bilirubin and occult blood in animals. Biochemical quantification of protein and glucose confirms reagent strip findings and detects more subtle changes (Espandiari *et al*., 2007). Other tests available on reagent strips, including specific gravity, leucocyte esterase and nitrites, are not useful in animals (Paquignon *et al*., 1993). Urinary pH is highly variable and dependent on dietary factors (Bertani *et al*., 1989), bacterial metabolism and evaporative loss of CO_2. Urinary pH does not substitute for blood pH determination because of renal handling of bicarbonate and hydrogen ions. Proteinuria is observed with haemorrhage, inflammation, renal tubular degeneration or glomerulopathy. If renal tubular degeneration is suspected as the cause of proteinuria, quantitative biochemical assessments of urinary proteins is indicated (see below). Alkaline urine may cause false positives for protein (Reagan *et al*., 2007). Proteinuria is normal in male rats due to androgen-dependent rat urinary protein α-2 μ-globulin. Furthermore, ageing male rats with chronic renal disease often have marked proteinuria (Bertani *et al*., 1989; Quimby, 1999). Proteinuria is also a normal finding in mice due to the presence of uromucoid, GLOBs, and major urinary protein (MUP) (Quimby, 1999). Spontaneous glomerular amyloidosis should be suspected in proteinuric rabbits (Hinton, 1981). Detection of urinary glucose by the reagent strip method is an abnormal finding that should prompt further investigation into hyperglycaemia or loss of tubular function. In most species, the proximal tubules reabsorb over 99% of filtered glucose (except in the gerbil in which glucosuria is normal) (McClure, 1999). Unless glucose reabsorption mechanisms are saturated (hyperglycaemia), glucosuria indicates proximal tubular dysfunction and occurs even prior to histological evidence of injury (Finco, 1997). Bilirubinuria occurs with disorders that cause hyperbilirubinaemia, while urobilinogenuria is not informative in animals. Many drugs cause false ketonuria (Willard *et al*., 1999). Other causes of ketonuria include excessive lipid catabolism due to anorexia and diabetes mellitus. Occult blood in urine may result from haematuria or haemoglobinuria, or may represent blood contamination due to external trauma.

Identification of particulate urine components such as drug crystals, erythrocytes, leucocytes, renal epithelial cells, casts or lipid droplets requires microscopic sediment examination. Normal urinary crystals must be morphologically differentiated from those associated with liver disease or with drug toxicity. The presence of intact RBCs distinguishes haematuria from haemoglobinuria. Large numbers of hyaline casts suggest proteinuria and glomerular damage. Renal tubular epithelial cells and granular or waxy casts composed of these cells are strong indicators of tubular degeneration (da Silva Melo *et al*., 2006). High numbers of leucocytes are indicators of inflammation in the urinary tract, while casts containing leucocytes confirm their renal origin. Finally, large quantities of lipid droplets can be seen in urine sediments after chronic glomerular damage in humans and rodents (Emeigh Hart, 2005).

9.3 Nonroutine Tests of Renal Injury and Function

Serum (BUN/creatinine) and urine analysis are the current standards for the identification and monitoring of nephrotoxicity. Though they are useful screening tools in both humans and animals, the many challenges associated with their interpretation limit their utility for early, sensitive and predictive assessments of drug-related kidney toxicity. Attention has focussed on quantitative biochemistry and molecular approaches that may better detect early kidney toxicity. Though not routinely performed, quantitative biochemical urinalyses can be useful for focussed evaluations to detect subtle renal injuries or functional deficits. This approach is particularly amenable to well-controlled safety pharmacology or investigative toxicity studies for which compounds are suspected to influence renal function. Quantitative urine biochemistry measurements can be used to specifically evaluate the functional nephron mass (clearance tests), glomerular injury/function (high MW proteins), tubular function (glucose, low MW proteins, pH, concentration, fractional excretion (FE) of electrolytes) and tubular injury (tubular enzymes and proteins) (Emeigh Hart, 2005).

Timed renal clearance studies are used to quantify GFR. Freely filtered endogenous molecules such as creatinine or cystatin C are most commonly measured to evaluate functional nephron mass by clearance tests. Exogenous molecules, including radiolabelled compounds,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

inulin and sulfanilate are less practical, but more accurate alternatives. However, even clearance tests lack the sensitivity to adequately monitor renal function because of abundant functional reserve. In dogs, a GFR <3.5 ml min kg^{-1} is associated with nephrotoxicity (Narita *et al*., 2007). In humans, significant renal haemodynamic toxicity has been defined as a $>20\%$ fall in GFR (Edwards *et al*., 1994).

The renal tubules are responsible for electrolyte homoeostasis as well as maintaining the renal medullary concentration gradient that determines urine concentration capacity. Alterations in urinary electrolytes relative to plasma reflect changes in tubular reabsorption and excretion. FE should be calculated when there are unexplained blood electrolyte abnormalities (Emeigh Hart, 2005). Accurate calculation of FE requires timed urine collection, though it can also be estimated by normalizing for creatinine (Stockham and Scott, 2002). Values depend on requirements for homoeostasis, and vary according to species, strain, nutrition, circadian and seasonal rhythm and body weight (Finco, 1997; Lefebvre *et al*., 2008; Hackbarth and Hackbarth, 1982). When dietary factors are controlled and there is no nonrenal electrolyte loss, increased electrolyte FEs are early indicators of tubular dysfunction and reduction in GFR (Emeigh Hart, 2005). In dogs, FE of sodium increases rapidly (hours) after an acute renal toxic insult, long before the onset of azotaemia (days) (Thrall, 2006). In rats, metabolic acidosis complicates interpretation of FE because it has multiple opposing effects on renal handling of sodium (Faroqui *et al*., 2006). Extrarenal causes of NaCl depletion result in loss of renal medullary concentration gradient, while potassium depletion causes collecting tubules to be refractory to antidiuretic hormone (ADH), both diminishing renal concentrating ability.

The glomerulus is a filtration barrier that limits the size and charge of ultrafiltrate solutes, with ALB and larger molecules being mostly restricted from passage (Lash, 2005). The little ALB that passes is reabsorbed by the tubules such that urinary ALB is negligible. Mild glomerular or tubular damage results in low-level albuminuria (microalbuminuria). Glomerular damage can be distinguished from tubular damage by the presence of protein markers of low (tubular injury) or high (glomerular injury) MW (Emeigh Hart, 2005). Low MW rat protein markers that are translatable to humans include cystatin C and retinol binding protein (RBP) (Emeigh Hart, 2005). Substantial glomerular damage is associated with high-level proteinuria of large proteins such as ALB. Timed urinary protein excretion measures are best and should be normalized to body weight. Normal values in dogs range from 5.1 to 22.4 mg kg^{-1}. When timed sampling is not possible, protein can be normalized for creatinine excretion by calculating the urine protein to creatinine ratio (U(P:C)). In dogs, U(P:C) values less than 1.0 are normal, while values greater than 2.0 are abnormal (Thrall, 2006). Additional potentially useful urinary protein biomarkers of tubular injury include fibronectin, collagen IV, α-GST, pap 5C10 antigen (Pap A1), clusterin, kidney injury molecule-1 (KIM-1), liver fatty acid binding protein (L-FABP) and cysteine-rich protein 61 (CYR 61) (Emeigh Hart, 2005). At present, α-GST, clusterin and KIM-1 demonstrate the most promise as early markers of tubular injury for preclinical drug-safety studies (Zhou *et al*., 2008; Yang *et al*., 2007; Espandiari *et al*., 2007; Vaidya *et al*., 2006). Clusterin is a proximal tubular glycoprotein whose secretion is induced rapidly after tubular injury and sustained during chronic injury. Rat urinary clusterin levels correlate with severity of damage (Hidaka *et al*., 2002). Antibodies for α-GST and clusterin are commercially available and these cross-react with both human and rat clusterin (Emeigh Hart, 2005).

Enzymes or protein biomarkers that are selective for tubule segment and subcellular location can be used to localize and estimate the severity of the tubular injury. These biomarkers are not present in blood or filtered by the glomerulus. As such, their presence in urine is highly specific and sensitive for renal tubular injury. The proximal convoluted tubule (PCT) is highly susceptible to toxic injury because it is the first site of ultrafiltrate concentration. It also metabolizes relatively harmless compounds into more reactive metabolites. Enzymes produced by the PCT include GGT, NAG, lysozyme, β-galactosidase, β-glucuronidase, β-glucosidase, alanine aminopeptidase (AAP) and intestinal alkaline phosphatase (IALP). The enzyme μ-GST is considered to be specific for distal tubules while renal papillary antigen (RPA) has been shown to be specific for papillary collecting ducts.

The most common enzyme measurements used in animals are GGT and NAG (Yang *et al*., 2007; Narita *et al*., 2007). Urinary GGT and NAG levels increase prior to azotaemia (Thrall, 2006). They are markedly increased in dogs with acute renal disease, whereas only slight increases are detected with chronic disease (Loeb, 1999a). Urinary NAG activity in male dogs is double that of female dogs (Nakamura *et al*., 1983). In the rat, urinary enzyme excretion followed a weekly biorhythm, emphasizing the importance of contemporaneous controls (Loeb, 1999b). After an acute toxic insult, rat urinary markers peak at 6 hours and return to normal levels within 48 hours (da Silva Melo *et al*., 2006; Yang *et al*., 2007). In one rat study, GGT, α-GST and μ-GST were more sensitive for low-level toxic insults than NAG (Yang *et al*., 2007). Enzymes used in humans, but with variable utility in animals, include lysozyme, β-galactosidase, β-glucuronidase, β-glucosidase, AAP and IALP (da Silva Melo *et al*., 2006; Emeigh Hart, 2005).

Traditional indices of renal injury and function such as BUN and creatinine are influenced by numerous nonrenal confounding factors and are late indicators of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

nephrotoxicity. Quantitative urinalyses and functional tests are not amenable to large screens and are fraught with sources of variability. These factors make interpretation of drug-related changes difficult and complicate decision-making in drug development. In preclinical safety assessment, there is a dire need for early, sensitive and predictive *in vivo* biomarkers of nephrotoxicity that are translatable to humans (Greaves *et al*., 2004). Molecules such as cystatin C, clusterin and KIM-1 are highly promising and are currently being developed and validated for use in animals. The utility of urinary markers as indicators of nephrotoxicity is greatly dependent on the agent, dose, species, sex and study design. Improvements in diagnostic sensitivity and specificity are likely to be based on panels comprised of multiple markers rather that single tests (Nahas *et al*., 1997). The growing genomics and proteomics arenas are becoming powerful tools for identification of new markers and promising platforms for drug-induced nephrotoxicity screening panels (Dieterle *et al*., 2008; Bandara *et al*., 2003; Schnackenberg *et al*., 2007).

10 CARDIAC MUSCLE

Cardiotoxicity is a significant cause of failure of compounds in clinical and preclinical development. Of the market withdrawals, 90% were caused by toxicity and of those, two out of three were either associated with hepatotoxicity or cardiotoxicity (Schuster *et al*., 2005). From 1960 to 1999, cardiovascular toxicity accounted for 9% of withdrawals of prescription drugs from worldwide markets (Fung *et al*., 2001) The predictivity of animal models for cardiotoxicity in humans is quite high (approximately 80%) particularly in nonrodents (Olson *et al*., 2000). Other xenobiotics, such as solvents, halogenated hydrocarbons and heavy metals are known to be cardiotoxic. There are several basic mechanisms of toxicity: (i) disturbance of ion homoeostasis (ii) inhibition of Na/K ATPase (iii) altered coronary blood flow (iv) oxidative stress (v) organellar dysfunction and (iv) apoptosis or oncosis. It is likely that no one mechanism of toxicity operates alone and more than one mechanism combines to elicit toxicity. Functional effects on the heart, for example arrhythmia, are often completely dissociated from degenerative structural effects, for example, myocardial necrosis. Purely functional effects do not result in the release of cellular constituents into plasma and are therefore not detected by clinical chemistry. The mainstay of detecting and evaluating cardiotoxicity remain the electrocardiogram and histopathology. However, clinical chemistry parameters have been of value in detecting and evaluating degenerative structural cardiotoxicity. Very few parameters are specific for cardiotoxicity and care is required in interpreting data. In addition, toxicity to the heart may be secondary to toxicity in other organs, for example kidney, erythrocytes.

CK and LDH were the standard traditional parameters used to identify cardiotoxicity. Increases in these enzymes, however, do not specify cardiac damage since their distribution is widespread in other tissues. CK has three isoenzymes which differ in their distribution CK-MM (muscle), CK-BB (brain) and CK-MB (cardiac muscle). Generally total CK is measured in toxicology studies and so interpretation of changes in this enzyme alone should be made with caution. In addition, the half-life of the CK enzyme is quite short and certainly less than one day (Lindena *et al*., 1986); therefore acute damage is not likely to be detected by CK at the end of a 28 day toxicity study, but may be of value where active damage is occurring. CK values are notably variable between individuals and are sometimes elevated as a result of the dose route (e.g. intramuscular), particularly since most CK is muscular in origin. Therefore the value of CK as an indicator of cardiotoxicity is limited. Similarly LDH distribution is widespread and there are multiple isoforms of LDH which differ with species. Handling of animals may also result in mild muscle trauma, which can result in release into plasma (O'Brien, 2008).

Troponins (Tns) are the three protein filament components of cardiac and skeletal muscles. TnI in the absence of Ca^{2+} binds to actin and inhibits actinomysin ATPase-induced contraction. TnT links the troponin complex to tropomyosin. TnI and TnT each have two different isoforms, each specific for cardiac and skeletal muscle. Thus the tissue origin of each can be identified. The two isoforms of TnC, which bind calcium do not discriminate between cardiac and skeletal muscle. Therefore only TnI or TnT are specific to the heart. Cardiac troponins have been the preferred biomarker for clinical myocardial infarction because of their high specificity and sensitivity (Babuin and Jaffe, 2005) and practical detection period postdamage (O'Brien *et al*., 2006). Its use as a biomarker of cardiotoxicity in laboratory animal models particularly for pharmaceuticals is growing and now becoming routine in pharmaceutical development for the major nonclinical species, although interlaboratory validation of the assays in order to ensure sensitivity, precision and accuracy is still active since there are a variety of commercially available assays and variable results have been obtained (ILSI HESI Technical Committee, 2008). O'Brien *et al*., (2006) note that there are several caveats to the effective use of cardiac troponins as markers of damage, including a background of high TnI as a result of stress, restraint, exertion, spontaneous cardiomyopathy in Sprague–Dawley rats, blood collection by cardiac puncture, and so on. However, relative to other biomarkers currently available it is considered as the 'gold standard' for myocardial injury associated with cardiotoxicity (O'Brien, 2008). For reviews of preclinical applications see Wallace *et al*. (2004),

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Adamcova *et al*. (2005) and Walker *et al*. (2006). The question whether to use TnT or TnI is best answered by the fact that there are currently multiple commercial suppliers of assay kits for TnI and only one for TnT.

Another potential marker of degenerative structural myocardial damage is fatty acid binding protein 3 (FABP3). This cytosolic protein involved in intracellular transport of long chain fatty acids is readily released from damaged cells and is thought to be highly sensitive as a marker of myocardial injury, perhaps more sensitive than troponins; however, its ready release means that FABP3 may be elevated in serum when physiological stress, for example, exercise or handling restraint trauma occurs. Somewhat like LDH and CK, FABP3 is also distributed in other tissues (e.g. muscle, brain and kidney). Therefore the cardiac origin of elevated serum FABP3 cannot be absolutely identified where FABP3 alone is the biomarker (Zhen *et al*., 2007). The analytical techniques used to detect FABP3 are not yet open to routine analysis in a clinical pathology laboratory.

11 SKELETAL MUSCLE

Increases in serum LDH and CK occur with degenerative or necrotic muscle injury. Most serum CK is muscular in origin. It is thought that CK is the more sensitive indicator of muscle injury, with peak activity reached in approximately 16–24 hours. The main isoenzyme found in skeletal muscle is MM. AST is often used alongside LDH and CK to investigate muscular injury. However, AST is fairly ubiquitous and without differential isoenzyme investigation of LDH and CK the origin of the increased serum enzymes is often uncertain. Variability associated with physiological and mechanical stress due to handling or exercise adds another layer of difficulty in interpretation. In addition, animals which are given intramuscular or other parenteral injections may have skeletal muscle damage resulting in elevated serum CK and LDH. Therefore good dosing and sampling techniques are vital to obtaining interpretable data. Monitoring of serum electrolytes would be useful in helping to identify myotoxicity since intracellular calcium, potassium and sodium concentrations are all vital in the functioning muscle fibre.

12 BONE

Many of today's pharmaceuticals directly target bone diseases (e.g. hormone replacement drugs, oestrogen receptor modulators, bisphosphonates and etidronate to treat osteoporosis, hyperparathyroidism, rickets/osteomalacia, Paget's disease of bone) or diseases characterized by secondary bone resorption (rheumatoid arthritis, diabetes mellitus, nephrotic syndrome, ethanol toxicity, oestrogen deficiency, acromegaly, hyperthyroidism). Conversely, many drugs induce toxicities that directly or indirectly affect bone metabolism (e.g. corticosteroids, anticonvulsivants, thiazide diuretics). Most common are indirect effects resulting from a wide variety of disorders including renal disease, disruption of hormonal or metabolic states, altered calcium/phosphorus/zinc homoeostasis, oxidative stress, inflammation, immobility and microvascular disease. Drug toxicity to bone is not routinely assessed in preclinical studies, though nonspecific indicators such as ALP, calcium and phosphorus, may raise suspicion for drug effects on bone (Woodard *et al*., 2002). In these cases, or when the drug has expected direct or indirect effects on bone, monitoring of bone toxicity is indicated.

Bone toxicity is most often assessed by quantifying changes in bone turnover rates (formation and resorption). Histopathology and histomorphometry are the gold standard to assess bone toxicity in terminal studies, while bone mineral density (BMD) is the gold standard *in vivo*. The drawback of BMD is that it can only detect significant changes after chronic exposures (more than six months) (Kleerekoper, 2001). Newer biochemical markers of bone turnover have the potential to detect *in vivo* changes earlier (within a few weeks, to three to six months) and with greater sensitivity. A detailed explanation of each marker is beyond the scope of this chapter (See reviews: Kleerekoper, 2001; Pagani *et al*., 2005; Delmas *et al*., 2000; Delmas, 2001). In general, markers should be selected such that results reflect both formation and resorption. Animal bone biomarkers are usually quantified by immunoassay using commercially available kits (RatLaps ELISA (Nordic Bioscience Diagnostics A/S, Denmark), Rat-MID osteocalcin ELISA (Nordic Bioscience Diagnostics A/S, Denmark), BTI Rat Osteocalcin EIA kit (Biomedical Technologies, MA), antirat TRACP-5b ELISA (IDS, AZ) and antimouse RANKL (R&D Systems) (Rachon *et al*., 2007; Brzoska *et al*., 2007; Stolina *et al*., 2005).

12.1 Sources of Variation

Because many markers are present in tissues other than bone, and most are influenced by nonskeletal processes, it should be borne in mind that changes are not tissue specific. In addition, changes are not disease specific, but reflect alterations in skeletal metabolism independent of cause. Renal clearance of biomarkers increases with decreasing renal function. Bone formation decreases with age, and is higher in males. Factors such as fracture repair, pregnancy/lactation and immobility all significantly impact results. Finally, blood levels vary on a circadian rhythm that can be modified by drugs (Shao *et al*., 2003; To *et al*., 2003).

12.2 Measures of Bone Formation

In new bone formation, osteoblasts develop new bone matrix, including osteocalcin (OCN) and osteonectin (OST), and secrete bone-specific alkaline phosphatase (BALP) to stimulate bone mineralization (Lee *et al*., 2008). Commonly used biomarkers of osteoblastic synthetic activity include OCN (bone gla-protein (BGP), OST), type I collagen propeptides and bone ALP (Pagani *et al*., 2005). OCN is the most abundant noncollagenous protein of bone (Lee *et al*., 2008). It is a small calcium-binding protein that leaks into blood during bone formation by osteoblasts, odontoblasts and hypertrophic chondrocytes. It is specific for bone formation because it does not enter the blood when released from bone matrix during resorption (Woodard *et al*., 2002; Delmas *et al*., 2000). OCN is rapidly degraded in serum to release intact peptide and various fragments that can all be quantified: undercarboxylated osteocalcin (ucOC), total OC (intact + N-mid fragment), intact OC (OC [1–49]) and N-mid fragment of OC (OC[1–43]). Measuring both intact and OCN fragments increases sensitivity. Urinary OCN quantification has also been described in humans (Ivaska *et al*., 2005). Increases in OCN may be seen in growing animals (Lee *et al*., 2008) or with conditions that cause increased bone turnover.

New bone formation leads to the production of collagen cleavage products and other bone matrix proteins that are elaborated during osteoblast differentiation, such as type I procollagen propeptides (C- and N-terminal procollagen I carboxyterminal propeptide (PICP) and procollagen type I N propeptide (PINP)) (Woodard *et al*., 2002; Delmas, 2001). Intact trimer of PINP is the most sensitive marker of bone formation in humans (Delmas *et al*., 2000).

In domestic animals, ALP is comprised of two isoenzymes: (i) I-ALP (intestinal) and (ii) tissue nonspecific ALP. Isoforms of tissue nonspecific ALP include L-ALP (hepatocytes and biliary epithelium) and B-ALP (osteoblasts). In addition, canine hepatocytes exposed to glucocorticoids express C-ALP (Stockham and Scott, 2002). Increased ALP activity identified in routine biochemistry panels represents total ALP activity, with variable relative contributions from the different isoforms. B-ALP may be responsible for increases in total ALP during new bone formation. Specialized assays such as heat denaturation, electrophoresis, precipitation, selective inhibition and immunoassays are required to distinguish B-ALP from other ALP isoforms, but are not well suited to regulatory environments.

12.3 Measures of Bone Resorption

During bone resorption, activated osteoclasts mediate the hydrolytic degradation of bone, releasing its structural constituents (calcium, phosphorus and collagen and noncollagen proteins) into blood and urine. (Brzoska *et al*., 2007; Lee *et al*., 2008). Simultaneous increases in both calcium and phosphorus are strongly suggestive of bone resorption, though other causes, such as renal failure and hypervitaminosis D must be ruled out. Over 90% of organic bone is type I collagen, which is released as a series of peptides that can be measured in serum and urine (Rachon *et al*., 2007). Collagen proteins that can be used as markers of bone resorption include hydroxyproline (HYP), hydroxypyridium crosslinks of collagen (pyridinolone (PYD) and deoxypyridinolone (DPD)) and type I collagen telopeptide crosslaps (N-terminal crosslinking telopeptides of type I (NTX-I) collagen and C-terminal crosslinking telopeptides of type I (CTX-I) collagen, C-terminal telopeptide of Type I Collagen (ICTP) (Delmas *et al*., 2000; Do *et al*., 2006). The majority of these are measured in urine. HYP is not recommended because it is nonspecific and affected by diet (Woodard *et al*., 2002; Delmas *et al*., 2000). DPD is formed during extracellular maturation of fibrillar collagens and released upon the degradation of mature collagens. It is more specific for bone collagen that PYD (Woodard *et al*., 2002).

Noncollagen proteins released from bone during resorption include bone sialoprotein (BSP) and tartrate-resistant acid phosphatase (TRAP isoform 5b). BSP accounts for 5–10% of noncollagenous matrix of bone and is the major synthetic protein product of osteoblasts and odontoblasts. TRAP-5b reflects osteoclastic activity as well as activity from prostate, blood cells and pancreas (Woodard *et al*., 2002). A newer biomarker of bone resorption is RANKL (receptor activator for nuclear factor κ B ligand). RANKL mediates osteoclast activation and is a useful indicator of osteoclastic activity. It is one of the earliest indicators of bone erosion and systemic bone loss (Stolina *et al*., 2005).

13 BLOOD VESSEL

Blood Vessel injury induced by drugs in preclinical studies is of concern. Dogs appear to be particularly sensitive to arterial injury and have a pattern of spontaneous arteriopathy (Stephan-Gueldner and Inomata, 2000), and as such are thought to be problematic models of human susceptibility. There are no established specific clinical pathology markers for blood vessel disease. Blood Vessel changes were traditionally predicted by blood pressure collapse associated with reflex tachycardia. Candidate molecules which have a mechanistic relevance to blood vessel damage originating from endothelial cells and/or smooth muscle cells are being evaluated and include von Willebrand factor, von Willebrand factor propeptide and caveolin-1 (Brott *et al*., 2007).

14 ENDOCRINE SYSTEM

The endocrine system is instrumental in regulating metabolism, growth, development and puberty, and tissue function. This is achieved by releasing hormones into blood and ECF which act as chemical messengers and modulate the function of organs and tissues. The endocrine glands include the hypothalamus, pituitary (anterior and posterior), thyroid, parathyroid, pancreas, adrenals, ovaries, testes and pineal gland. Other organs, such as the kidney, GI tract, liver and heart, also have endocrine functions. Toxicity associated with the endocrine glands is usually confined to the adrenals, testes, ovaries and thyroid (Ribelin, 1984). These tissues are the focus of this section; however, the measurement of hormones is generally not undertaken in toxicity screening studies unless there is cause for concern related to a known or suspected pharmacological or toxicological action. Measurement of the circulating levels of hormones can be a powerful technique to identify functional impairment of the endocrine system. The serum concentrations of many hormones are dependent on several factors, including time of day, age, sexual maturity, gender, nutritional status and stress, to name but a few. The effects of these variables can often diminish the diagnostic value of hormone assays. Therefore the standardization of the procedures and timing for blood collection is crucial to obtaining interpretable data. Hormones are generally one of four chemical types. Some examples of hormones from each of the chemical types secreted into the blood and their glandular origin are provided below (**Table 2**).

In order to have a robust biomarker for the detection of functional change, the hormone must be released in sufficient quantities to be detected in biological fluids (serum, plasma or urine), the origin of the hormone must be identifiable and it must be sufficiently stable to allow for practical application of the assay after the toxicological event.

14.1 Adrenals

The adrenal is the most common toxicological target in the endocrine system (Ribelin, 1984; Colby, 1996). The need for assessment of adrenal function is clear, yet in regulatory screening toxicity tests it is uncommon for adrenal function to be specifically assessed. There are no specific biomarkers of adrenal toxicity in the battery of clinical chemistry parameters routinely used.

Table 2 Chemical classes of major hormones and their glandular origins

Chemical type	Hormone	Tissue origin
Peptides and proteins	Follicle stimulating hormone (FSH)	Anterior pituitary
	Luteinizing hormone (LH)	Anterior pituitary
	Prolactin (PRL)	Anterior pituitary
	Thyroid stimulating hormone (TSH)	Anterior pituitary
	Adrenocorticotrophic hormone (ACTH)	Anterior pituitary
	Thyrotropin releasing hormone (TRH)	Hypothalamus
	Antidiuretic hormone (ADH)	Posterior pituitary
Steroids	Aldosterone	Adrenal cortex
	Cortisol/corticosterone	Adrenal cortex
	Oestradiol	Ovary/placenta
	Progesterone	Ovary/placenta
	Testosterone	Testis/ovaries/adrenal cortex
	Calcitriol	Kidney
Amino acid derivatives	Adrenaline (epinephrine)	Adrenal medulla
	Noradrenaline (norepinephrine)	Adrenal medulla
	Dopamine	Adrenal medulla
	Tri-iodothyronine (T_3)	Thyroid
	Thyroxine (T_4)	Thyroid
Fatty acid derivatives	Prostaglandin E_2	Most cells
	Thromboxane A2	Platelets
	Prostacyclin (PGI_2)	Endothelial cells

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The adrenal is divided into two distinct regions, the adrenal medulla (inner) and the adrenal cortex (outer). The cortex is further differentiated into the zona reticularis adjoining the adrenal medulla, and moving outwards the zona fasciculata followed by the outermost zona glomerulosa. The hormones of the cortex are steroid hormones formed by the further metabolism of CHOL, whereas the hormones of the medulla are amino acid derivatives. The high cytochrome P450 enzyme activities of the cortex attest to its biosynthetic function and are targets for drugs which inhibit steroidogenesis. The pituitary hormone adrenocorticotrophic hormone (ACTH) regulates the biosythesis of the mineralocorticoids (e.g. aldosterone), synthesized in the zona glomerulosa, and the glucocorticoids of the zona (e.g. corticosterone/cortisol). Evaluation of toxicity to the adrenals relies on histopathology, at least in screening studies. Further evaluation of suspected adrenal toxicity and functional change can be carried out by measurement of the three main hormones, corticosterone/cortisol, aldosterone and adrenaline. Adrenal toxicity may also result in perturbations to sodium, potassium, chloride and hydrogen in both serum and urine (which can be measured without resorting to hormone assays), since the mineralocorticoids regulate renal reabsorption of these ions. Similarly, since glucocoticoids stimulate gluconeogenesis, and fat and protein catabolism, secondary to disturbance in cortisol or corticosterone can be a reduction in serum glucose, CHOL and/or protein. Aminoglutethimide, etomidate, metyrapone, ketoconazole and suramin are associated with impaired steroidogenesis and in humans cortisol synthesis is inhibited by these drugs. Fungicides of the conazole group, used as pesticides on plants, inhibit sterol synthesis in fungi and have some activity on steroid metabolism in animals (see **Toxicology of Pesticides**).

A clinical chemistry approach to evaluating adrenal impairment can be direct measurement of adrenal hormones or evaluation of the response of the hormones to adrenal challenge by ACTH (Harvey *et al*., 2007; Harvey and Everett, 2003). The circulating background serum concentrations of adrenal hormones vary markedly, particularly associated with stress, and so blood-sampling techniques which minimize stress are crucial. Indwelling catheters may be recommended for investigative studies, but this approach is uncommon. Other factors affecting serum steroid concentrations include age, season, strain, sex, and light, handling and environment, circadian rhythm and episodic secretion (Evans, 1996). There are also species differences in the synthesis of corticosteroid (see **Table 3**). Rats and mice synthesize corticosterone as the predominant form of the hormone, whereas all other species, including humans, sythesize cortisol. Therefore one of the most valuable models of adrenal function and toxicity is the guinea pig, because of its small size and relatively large adrenals.

Table 3 Species differences in corticosteroid form

Species	Predominant form of corticosteroid	
	Cortisol	Corticosterone
Human, dog, primate, minipig, rabbit, hamster, guinea pig, sheep, cattle	Yes	No
Rat and mouse	No	Yes

In cases of adrenal insufficiency caused by inhibition of steroidogenesis, often the testis is affected too.

14.2 Gonads

The gonads comprise the testes in males and the ovaries in females. Both have dual functions in gametogenesis and as endocrine glands secreting the sex steroids. In males, testosterone, dihydrotestosterone and even small quantities of oestrogens are secreted. In females the sex steroids are oestrogens (principally oestradiol) and progesterone. Overall hormonal control of gonads is maintained by the hypothalamic–pituitary–gonadal axis. The gonadotropins of the anterior pituitary regulate the gametogenic and secretory functions of both male and female gonads. They are luteinizing hormone (LH) and follicle stimulating hormone (FSH). The major stimulatory effects of these two hormones are described in **Table 4** below.

The functional control of the gonads is complex and requires complex feedback mechanisms to work in concert. For a further review of the function of the reproductive system see **Hepatotoxicity**.

14.2.1 Testis

Histopathology is the traditional method to assess toxic insult to the testis, but is sometimes accompanied by seminology or flow cytometry. Several efforts have been made to identify noninvasive clinical chemistry markers of testicular toxicity in the battery of routine laboratory animal clinical chemistry tests, however, none

Table 4 Major stimulatory roles of FSH and LH

Hormone	Testis (male)	Ovary (female)
FSH	↑Spermatogenesis	↑Follicular development and maturation in the ovary
LH	↑Testosterone secretion from Leydig cells	↑Ovulation

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are commonly used in screening tests. The isoenzyme LDH-C4 (LDH-X) is testis-specific and is found in several stages of germ cells. It has been reported as being of value in evaluating testicular toxicity (Reader *et al*., 1991; Shen and Lee, 1984) and was seen to be elevated for up to 14 days in plasma after an acute toxic insult by ethylene glycol monomethyl ether. Androgen binding protein (ABP) is a marker of Sertoli cell function since it is secreted by the cell and has affinity for testosterone and dihydrotestosterone. ABP was reported to be a valuable marker of 1,3-dinitrobenzene toxicity when measured in plasma and was elevated both in testicular tissue and in plasma (Suter *et al*., 1998). However, this is not commonly used as a marker and the variability of ABP testicular values was very high, reducing the sensitivity of the marker. Urinary creatine has also been reported to be of value as a noninvasive marker in identifying testis-specific toxicity. Draper *et al*. (1996) showed that 2-methoxyethanol caused dose-dependent pathological damage to the testes which was detectable at the lowest dose in rats. Urinary creatine excretion was significantly raised at all doses, but testis weight was only significantly decreased at the highest two doses; serum testosterone was relatively insensitive and LDH-C4 was not significantly increased at any dose. In cadmium chloride-induced testicular toxicity, similarly creatine was a sensitive marker of testicular damage even in vasectomized rats demonstrating that the creatine reaches the urine via the blood stream (Draper and Timbrell, 1996). Creatine was also found to be of value as a murine marker of testicular toxicity caused by 2-methoxy acetic acid (Traina *et al*., 1997).

Measurement of the hormones and controlling gonadotropins associated with testicular cell function is the primary method for determining alterations in androgen status. Methods for steroid hormones, such as testosterone by radioimmunoassay are relatively easily transferable between species since the structure is the same, but for peptide or protein hormones, for example LH, FSH, the crossreactivity between species may be weak, leading to the need for robust validation of methods in the laboratory. The pulsatile and/or circadian rhythms of the sex hormones in different species add a layer of variability which make the control of timing and sampling procedure absolutely vital. Where possible, multiple samples should be taken from baseline and maximally stimulated animals during the days of evaluation (Creasy and Foster, 2002). Stimulation of LH/FSH release can be achieved by administering luteinizing hormone releasing hormone (LHRH) (gonadotropin releasing hormone (GnRH)), and testosterone release may be stimulated by administration of human chorionic gonadotropin (hCG). These functional tests may not be desirable or practical on screening studies, but are an effective method to further evaluate suspected testicular toxicant modes of action.

Age has an influence circulating levels of sex hormones. In ageing male rats, decreases in serum testosterone (Karpas *et al*., 1983; Wang *et al*., 1993; Zirkin *et al*., 1993; Chen *et al*., 1994) and gonadotropins (Zirkin *et al*., 1993) have been reported. In male dogs, conflicting reports show no decrease (Taha and Noakes, 1982; Lowseth *et al*., 1990) or a decrease (Bondarenko *et al*., 1979; Gunzel Apel *et al*., 1990). Similarly dog serum gonadotropin concentrations have been reported to decrease with age by Gunzel Apel *et al*. (1990).

14.2.2 Ovary

The ovary, like the testis, has the dual functions of gametogenesis and endocrine production of hormones. The female reproductive system has a regular cycle of oestrus, metestrus, diestrus and proestrus, which is of different lengths for different mammalian species. This cycle is regulated by hormones of the hypothalamic–pituitary–gonadal axis, largely LH and FSH. The structure and secretory activity of the ovary at any one time will reflect the stage of oestrus. Regulation of the female reproductive system is complex and the reader is referred to standard reference texts for further discussion. Therefore there is an inherent need to understand the stage of oestrus that each animal (both control and treated animals) is undergoing in order to interpret hormonal or structural differences. Ideally, baseline sampling should be carried out at multiple timepoints in order to provide an intra-individual control. For rodents this is generally not practical, but is possible for large animals, such as macaques, dogs and minipigs, providing sample volumes are minimized. The investigation of female gonadal function is rarely carried out on screening studies, since the assays often require serial sampling and circulating hormone concentrations are influenced by many variables including age, stress, nutritional status and so on.

Methods for measurement of female reproductive hormones in laboratory animals do exist, but they are often developed from the human clinical counterparts and therefore the volumes of plasma or serum required can be too high to be practical in rodent and primate assays. Hawkins *et al*. (1975) investigated the use of radioimmunoassay for measuring 17β-oestradiol and prolactin (PRL) levels in rats, and demonstrated significant fluctuations related to the oestrus cycle. In addition to the stage of the oestrous cycle, the PRL concentration was influenced by mode of blood collection, degree of haemolysis and choice of serum or plasma.

Measurement of PRL, FSH and LH, as well as circulating oestrogens, are the primary methods for clinical evaluation of female reproductive status. Assays for these are commercially available as immunoassays for the rat, dog and primate, but kits for other species may be available too. Validation of the assays with regard to sensitivity and range, accuracy and precision prior to use

in other species is important to ensure the quality of the data.

Further variability in gonadotropins and steroid hormones is related to age and reaching towards the end of the reproductive life span in female humans and in animals (Nass *et al*., 1984; LaPolt and Lu, 2001).

14.3 Thyroid

The thyroid and its secretions have been the focus of many a risk assessment. In laboratory animal toxicity and carcinogenicity studies the thyroid is a relatively common target organ, but in humans it is not often associated with drug treatment. In 1394 rodent carcinogenicity studies conducted by the National Toxicology Program the thyroid was the sixth most common site for tumours (Huff *et al*., 1991). The rodent is particularly susceptible and highly sensitive to chemically induced thyroid toxicity and carcinogenesis because of the species differences between humans and rodents.

The mammalian thyroid gland produces the major thyroid hormones thyroxine (T4), tri-iodothyronine (T3) and calcitonin. Calcitonin is produced by the C-cells or parafollicular cells, which are either located within the thyroid follicles, between the basal region of the follicular cells and the basement membrane, or in an interfollicular location (Capen *et al*., 2002). Calcitonin and PTH act in concert to control calcium in ECFs. PTH is thought to be responsible for the prevention of hypocalcaemia, particularly in calcium deprivation, and acts synergistically with vitamin D3 (calcitriol), whereas calcitonin is thought to prevent the development of hypercalcaemia due to postprandial absorption and protects against excessive calcium and phosphorus loss from maternal bone during pregnancy (Capen *et al*., 2002). Disturbances in calcium homoeostasis can be picked up routinely in screening studies by measuring serum calcium. However, the interpretation of fluctuations of serum calcium alone should be undertaken with care, since calcium homoeostasis is achieved by the interplay of many factors, including diet, intracellular storage, bone storage and tubular resorption/excretion.

The follicular thyroid consists of follicles of varying size (20–250 μm) that contain colloid in the lumen produced by cuboidal or columnar follicular epithelial cells. Thyroid hormone synthesis begins with the very efficient energy-dependent active transport of iodide into the follicular lumen where it is oxidized by thyroid peroxidase to iodine. Tyrosine is subsequently iodinated and the building blocks 3-monoiodotyrosine and 3,5-diiodotyrosine are formed. Thyroid hormones stored in the colloid are released as T3 and T4 bound to carrier proteins. Synthesis and release of thyroid hormones is under the control of the hypothalamic–pituitary–thyroid axis. Hypothalamic thyrotrophin releasing hormone (TRH) is released in response to low circulating T3/T4. This then, in concert with the low T3/T4 levels, stimulates the thyrotrophic cells of the anterior pituitary to secrete TSH (thyrotrophin). TSH acts directly on the thyroid to stimulate T3/T4 release. Therefore there are several points at which thyroid function can be disrupted. Serum T3, T4 and TSH are not commonly measured on routine screening studies for toxicity, but if there is histopathological evidence of functional change in the thyroid or a previous concern about thyroid function, then investigative studies can be useful to identify a mode of action. The measurement of thyroid parameters and functional challenge is a key part of the tool set available. Measurement of T3 and T4, which are amino acid derivatives, is straightforward and is quite transferable between species. TSH is, however, a glycoprotein and therefore the immunoassay method transferred from one species to another requires careful evaluation for sensitivity, accuracy and precision. There are marked species differences in the transport of thyroid hormones as shown in **Tables 5** and **6** below. Generally, the low-affinity, high-capacity binding to ALB, prealbumin and postalbumin of rodents is quite different from the high-affinity binding to thyroglobulin in other species. Consequently, the kinetics of T3/T4 clearance in serum differs between species, for example, serum T4 half-life in rats is approximately 12–24 hours, whereas in humans it is five to nine days. Dogs, monkeys and minpigs are more similar to humans in the way that they handle thyroid hormones. The differences in binding and kinetics of thyroid hormones probably accounts for much of the unique sensitivity to thyroid carcinogenesis induced by TSH stimulation in rodents.

Investigation of mode of action of thyroid functional disturbance starts with the measurement of circulating TSH, T3 and T4. There are a number of environmental and physiological factors which can have an impact on thyroid hormones, including food deprivation, handling, temperature and diurnal variation (Dohler *et al*., 1979), mandating extreme care in constructing the protocol, sampling and handling methods. Generally the volumes required for T3/T4 only allow for terminal sampling in the mouse. Further investigation of a potential disturbance in thyroid function may require investigation of iodide accumulation and organification by the perchlorate discharge test, usually carried out in rats, in which sodium perchlorate is administered and the ratio of thyroid to blood ^{125}I is measured. Propylthiouracil, an inhibitor of iodide organification reduced the thyroid:blood ratio, whereas SK&F 93479 which increases thyroid hormone clearance and thereby increases TSH drive, did not. This test helps to distinguish between direct and indirect effects (e.g. effects on metabolism and clearance of thyroid hormones) (Atterwill *et al*., 1987; Coelho-Palermo Cunha and van Ravenzwaay, 2007). Methods to investigate mode of action on the thyroid include investigation of the metabolism of T3

and T4, TSH response to TRH stimulation and investigation of the T3/T4 response to TSH stimulation.

An important group of thyroid toxicants is the alkylenebisdithiocarbamate fungicides. At least part of this toxicity is mediated by plant metabolites, ethylene thiourea in the case of the ethylenebisdithiocarbamates and propylene thiourea in the case of propineb. The Joint Expert Meeting on Pesticides Residues (FAO/WHO, 2000) cited a study by Freyberger, 1996, who concluded that depression of thyroid hormone synthesis and consequent stimulation of the hypothalamic–pituitary–thyroid axis caused the thyroid lesions induced by these compounds.

14.4 GI Tract and Pancreas

14.4.1 GI Tract

In humans, chemicals and drugs which are either intentionally or accidentally ingested through contaminated food or drink have the greatest potential for exposure in the highest concentration to the GI tract because this is the portal of entry. Once absorbed systemically, chemicals or metabolites that are secreted in the bile as a route of excretion are again potentially in contact with the gut at high concentrations. Finally enterohepatic circulation tends to prolong residence in the gut, again resulting in significant exposure. For these reasons and others related to specific tissue susceptibility metabolism or physicochemistry, the GI tract may have a unique susceptibility to toxicants. Therefore it is not surprising that the GI tract is a particular target and in toxicology studies, compounds which are given either in the diet or drinking water or by oral gavage, especially at high doses, are those where the potential for GI toxicity is highest.

Treatment-related effects on GI function of laboratory animals are often accompanied by disturbances in electrolyte and fluid balance, diarrhoea or constipation, vomiting (except in rodents, which cannot vomit) and, if prolonged, poor bodyweight gain and other conditions related to poor nutrition.

ALP is a marker enzyme of microvillius membranes and exists as soluble and membrane-bound forms. The tissue distribution of ALP is wide, but there are several tissue-specific isoenzymes found in serum, which include hepatic, bone, placental and intestinal forms. Generally found in the brush border of secretory/absorptive cells, in the rat, the bone and intestinal forms dominate, but in other species, the hepatic form generally dominates. In order to investigate the origin of increases in serum ALP, electrophoresis is used to separate the isoforms. Changes in intestinal ALP in response to intestinal toxicants have been documented (e.g. cysteamine, Japundzic *et al*., 1991; 1990; mepirizole and propionitrile), but there are few reports of the value of this enzyme in chemical-induced GI tract toxicity. Diamine oxidase, which metabolizes polyamines has been shown to be a useful serum biomarker of toxicity to the upper villus cells of the rat intestinal mucosa, for example, anticancer drugs (Moriyama *et al*., 2005), but use is not widespread. The GI damage induced by xenobiotics can also result in increased permeability to markers such as sucrose (gastroduodenal) and ^{51}Cr-EDTA (intestinal). When the urinary excretion of these orally administered substances was measured, the degree of excretion correlated with gross toxicological and pathological changes to the GI tract, including ulceration and bleeding due

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat040
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to nonsteroidal anti-inflammatory drugs (NSAIDs) or cisplatin (Yanez *et al*., 2003).

Haemorrhage into the GI tract is a consequence of loss of integrity of the mucosal lining. This is typical of NSAID toxicity and cytotoxic anticancer agents. Measurement of occult (hidden) blood in faecal samples can be carried out in laboratory animals to determine if loss of integrity resulting in haemorrhage has occurred. This procedure is generally carried out if an effect is suspected and is not used as a screening test. The methods used are based on the pseudoperoxidase activity of haemoglobin, however they are not specific to haemoglobin and there are high levels of false positives reported, at least in the clinical setting. This is also a concern in toxicology, particularly if the test compound has peroxidase activity, or if foods high in peroxidase activity are ingested (red meat, broccoli, parsnips and cantaloupe melon (by primates, dogs or minipigs). In contrast, foods high in vitamin C can produce false negative results (since vitamin C is an effective reducing agent).

14.4.2 Pancreas

The pancreas is a dual-functioning gland having both endocrine and exocrine secretions. The endocrine pancreas is comprised of clusters of cells called islets of Langerhans which are α cells secreting glucagon, β cells secreting insulin, δ cells secreting somatostatin or PP cells secreting pancreatic polypeptide. The exocrine pancreas secretes digestive enzymes into the small intestine (see **Toxicology of the Exocrine Pancreas**). Digestive secretions include trypsin, chymotrypsin, pancreatic lipase and pancreatic amylase produced by the acinar cells. In addition, centroacinar cells which line the pancreatic ducts secrete biocarbonate and salt into the small intestine.

Serum and/or urinary amylase activity has been used as a marker for toxicity to the exocrine pancreas. Isoenzymes are used to identify the tissue origin, since amylase may also arise from the salivary gland and intestine. Lipase is more specific for pancreatic injury. Recent work has shown that two peptide products of proteolytic cleavage (RA1609 and RT2864) are sensitive markers of exocrine pancreatic toxicity (Walgren *et al*., 2007a; Walgren *et al*., 2007b) in animals treated with caerulein but the surface-enhanced laser desorption/ionization (SELDI)-mass spectrometry analytical technique required to measure the peptides is outside the current scope of the average clinical chemistry laboratory. Whilst not ready now for use as a preferred marker in investigating pancreatic toxicity, these markers may be potentially useful in the future, once further evaluation and validation has taken place.

Testing β-cell function can be carried out by determining serum glucose or insulin after a single administration of glucose by oral gavage or by a parenteral route to bypass the insulin-stimulating gut hormones.

15 NERVOUS SYSTEM

There are very few biomarkers of damage to the central or peripheral nervous systems. Routine serum and urine samples have been of limited value in routine screens to identify neurotoxicity. Sampling of CNS is not a routine procedure and in laboratory animals (rats, mice, marmosets) it is a technical challenge requiring anaesthesia or an indwelling canula. The volume of CSF that can be obtained is very small and there is potential for contamination from surrounding tissues. There are essentially only two established specific markers of neurotoxicity, as described below.

15.1 Neural Esterases

Inhibition of acetylcholinesterase activity is a known effect of organophosphate and carbamate pesticides (Costa, 1988; Padilla, 1995; *see also* **Toxicology of Pesticides**). Acetylcholinesterase hydrolyses and therefore degrades and controls the concentration of the neurotransmitter acetylcholine. Inhibition of the enzyme in either the central or peripheral nervous system prolongs the action of the neurotransmitter and is thought to be responsible for the effects that these chemicals produce. However, reduction in cholinesterase activity does not necessarily indicate clinical symptoms of neurotoxicity, but it may impair the organism's ability to respond to additional exposures to anticholinesterases (US EPA, 1998a). In mammals and birds, signs of anticholinesterase poisoning include miosis, excessive salivation, tremors, respiratory difficulty and tetany. The cholinesterases that have to be considered are RBC or 'true' acetylcholinesterase, butyrylcholinesterase (plasma or pseudocholinesterase) and brain cholinesterase. Brain cholinesterase is predominantly acetylcholinesterase as is found in the RBC, indeed they are the same gene product, although butyrylcholinesterase activity is also present in the brain. Butyrylcholinesterase has a different substrate specificity from acetylcholinesterase and is a different gene product: plasma butyrylcholinesterase is synthesized in the liver. Inhibition of nonspecific butyrylcholinesterase has no known toxicological consequence but it is a potential indicator of exposure and acetylcholinesterase inhibition and can be measured in life, whereas brain acetylcholinesterase can only be measured by taking samples at necropsy. RBC and brain data are preferred for risk assessment. When assessing the

safety of new organophosphates or carbamates, measurements of brain, RBC and plasma cholinesterase are required in rat and dog. Studies in the dog use fewer animals per group, but they have the advantage that pretreatment values can be obtained, thus each animal will have its own control data. The method normally used to measure cholinesterase activity is based on a colorimetric reaction Ellman (1961), however it has the potential to underestimate reversible cholinesterase inhibition (Padilla *et al*., 2007). The method is liable to underestimation if pH changes or if the incubation time variable is not controlled, particularly for reversible inhibition (carbamates) in which reactivation can occur soon after sampling, or if diluted. An alternative method is a radiometric method. For further information on the measurement of cholinesterases and their use in risk assessment see US EPA (2000). A small number of organophosphates, for example phosporamidates and phosphonates have the potential to produce human delayed or late-onset manifestation of neurotoxicity or organophosphate-induced delayed polyneuropathy (OPIDP) also known as 'dying back polyneuropathy'. The clinical signs of neurotoxicity do not develop until at least six days after exposure in humans, but the rat and dog are not good models for this clinical syndrome. The adult chicken is a sensitive model for OPIDP and is the preferred species for the measurement of neuropathy target esterase (NTE) by hydrolysis of phenyl valerate (US EPA, 1998a; OECD, 1995b).

15.2 Glial Fibrillary Acid Protein

Astrocytes are the major glial cells in the brain with important physiological and supportive activities. In response to neurotoxic injury, they may undergo hypertrophy and produce more glial fibrillary acid protein (GFAP) (O'Callaghan, 1988; Garman *et al*., 2001). When increases in GFAP are corroborated by neuropathological change then GFAP can be used as a biochemical marker of neurotoxicity in tissue sections. In contrast, lack of response does not always mean that a neurotoxic effect has not occurred, since other neural targets will not involve an astrocyte response. Trimethyl tin, methylmercury, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and cadmium have all been shown to increase brain GFAP (Dorman *et al*., 2002).

16 SUMMARY

This chapter describes the routine measurement of the noncellular blood compartment (plasma or serum) and urine for biochemical composition in toxicology studies conducted in commonly used laboratory species. The measurement of a range of clinical chemistry parameters provides an indication of the overall health of the animal and is used in conjunction with other parameters to investigate the toxicity of drugs and chemicals. The range of parameters commonly used in toxicology studies has been carefully selected to include those considered by experts to be the most useful in determining health status and identifying change as a result of toxicity. The methods used are well defined and must be conducted according to SOPs, and the data generated are subject to strict QC procedures in order to minimize variability unrelated to the effect of the test article. The advantage of clinical chemistry is that provided the volume of blood taken or the method of urine collection is strictly controlled, generally the procedures are only minimally invasive and have a negligible or transient impact on the physiological status of the animal. Therefore serial samples can be taken, which is useful for investigating progression and recovery of changes in live animals within several organs often associated with toxicity. There are few routine clinical chemical parameters which are specific indicators of a single target organ toxicity; the interpretation of changes in the blood and urine composition requires integration of information from a variety of measurements, such as clinical signs, food consumption and bodyweight, haematology, electrocardiography, blood pressure and histopathology, to understand the pattern of change and put it into the context of identifying toxicity. Changes in clinical chemistry can help to identify toxicological end points such as the NOAEL and the maximum tolerated dose.

Haematology and Toxicology

Timothy C. Marrs and Simon Warren

CONTENTS

1 INTRODUCTION

Haematological investigations are of importance in toxicology in two different sets of circumstances. Firstly, toxicological effects on the blood and blood-forming organs may occur in humans; these effects may cause similar changes in animal studies. Secondly, toxicological parameters are routinely measured during toxicological studies, regardless of whether the test compound is thought to be specifically haematotoxic, and guidelines are available about how these investigations should be carried out (Weingand *et al*., 1996). Both in humans and in experimental animals, abnormalities observed may be due to toxicity to the haemopoietic organs such as the bone marrow, or be produced indirectly through effects on animal nutrition, or on organs such as the kidney, which affect haemopoiesis. Moreover, some xenobiotics can affect the peripheral blood directly, an example being the production of haemolysis by certain drugs. One of the most interesting aspects of haematology in humans is the frequent interaction of inherited traits, for example, porphyria and glucose-6-phosphate dehydrogenase deficiency, with xenobiotics, including pharmaceuticals.

2 STRUCTURE AND FUNCTIONS OF THE BLOOD AND ASSOCIATED ORGANS

Blood is a fluid containing a number of cellular elements, including the red cells, which contain the oxygen-transporting pigment, the white cells and the platelets. The white cells are frequently categorized into neutrophils, eosinophils, basophils, monocytes and lymphocytes.

2.1 Haematopoiesis

Haematopoiesis occurs from stem cells. In studies with irradiated mice it was noted that certain bone marrow cells had the ability to form haematopoietic colonies in irradiated mice (Till and McCulloch, 1961). It appears that the stem cells in the marrow can give rise to all types of blood cells and these stem cells are thus known as pluripotent stem cells (Barton *et al*., 1980). The pluripotent stem cells are also known as colony-forming

units spleen (CFU-S) from their properties in studies *in vitro* and they have a marked ability for self-renewal. The CFU-S assay can be used to quantitate pluripotent stem cells. Factors that control haematopoiesis have been studied (Opferman, 2007; Metcalf, 2008).

The pluripotent stem cell can differentiate into stem cells that are capable of giving rise to myeloid cell types, the colony-forming unit granulocyte/erythroid/monocyte/megakaryocyte (CFU-GEMM), which in turn give rise to progenitor cells, whose potential is more restricted, such as the colony-forming unit granulocyte/macrophage (CFU-GM), the colony-forming unit erythroid (CFU-E), and so on (Chanarin, 1985; Irons, 1991; Young and Weiss, 1997; Means, 1997; Dzierzak and Speck, 2008). There is some evidence that there may be more than one pathway to the various lineage fates (see review by Buza-Vidas *et al*., 2007).

In most mammals, including humans, haemopoiesis is first seen in the yolk sac and later in foetal life, in the liver and spleen. After birth, the bone marrow is, in humans, the major site of haemopoiesis. In rats and mice virtually all the bone medullary space is occupied by haematopoietic tissue, whereas in adult humans, dogs and rabbits such tissue becomes limited to the proximal epiphyses of the long bones and skull, the remainder of the marrow being occupied by fat. Increased haematopoietic activity is, in man, usually confined to the medullary space, except under conditions of extreme demand. In the mouse and the rat, this is not the case and splenic (and hepatic) haematopoiesis is much more common in conditions of very high demand. The bone marrow contains a network of thin-walled branching vessels called the venous sinuses. The wall of the sinuses consists of the endothelium, basement membrane and the adventitia, the last of which is associated with adventitial reticular cells. The endothelium is complete, that is, not fenestrated, but the basement membrane is discontinuous. Mature blood cells cross the wall of the sinuses to enter the circulation (Chanarin, 1985). In normal circumstances, the cellular component of the marrow remains fairly constant, unless disturbed by factors such as loss of blood; in such conditions the marrow can respond rapidly to bring the number of cells in the peripheral circulation back to normal; this is controlled by a number of factors that stimulate haemopoiesis, such as erythropoietin (see below).

2.1.1 The Red Cell and Haemoglobin: Erythropoiesis

The main role of the red blood cell is the reversible combination of the haemoglobin therein and oxygen. The erythroid series of cells is derived from the stem cell and thence the CFU-GEMM. The earliest progenitor restricted to the red cell lineage is the burst-forming unit-erythroid (BFU-E), from which is derived the CFU-E. This gives rise to the precursor cells, the various normoblasts (Irons, 1991; Means, 1997). The last stage in maturation to the non-nucleated biconcave erythrocyte is the reticulocyte, so-called because of its fine basophilic reticular network (see Sieff and Nathan, 1996). In situations in which erythrocyte production has been stimulated, reticulocytes may be seen in the peripheral blood. The regulation of production of red cells is dependent upon the oxygen requirement of the tissues, being controlled by humoral factors, including erythropoietin, whose main source is the kidney (Spivak and Graber, 1980; Koury *et al*., 1988), where the rate of production is dependent on tissue oxygenation, with a contribution from the liver (see reviews by Chanarin, 1985; Koury, 2005).

Haemoglobin is one of a number of oxygen-binding proteins that have evolved in the animal and plant kingdoms, and contains a tetrapyrole ring system, with ferrous iron at the centre. Chlorophyll, in the plant kingdom, resembles haemoglobin in so far as it has a similar ring, though magnesium takes the place of the iron of haemoglobin. Copper, found in haemocyanin, replaces the iron atom in many invertebrates and, in some sea squirts, vanadium is present. The structure of haemoglobin can be summarized: each molecule of haemoglobin consists of four amino acid chains: a pair of alpha chains and a pair of beta chains (Perutz, 1967–1968). The chains are folded and each carries a haem group, attached to a histidine residue at position 87 in the alpha chains and 92 in the beta chains. The haem group comprises a tetrapyrole ring with a central ferrous iron atom. The iron remains in the ferrous state during binding to both oxygen and carbon monoxide. If oxidized to the ferric state methaemoglobin (MetHb) is produced: this is discussed below.

The iron atoms of haemoglobin can each accept electrons from a maximum of six oppositely charged ions or neutral substances (Strang, 1977). Each iron atom forms six bonds: four with the nitrogen atoms of the tetrapyrole ring; one with the histidine residue of the amino acid chain and one with oxygen or, in cases of poisoning, with carbon monoxide. As the haemoglobin molecule takes up oxygen, its quaternary structure changes due to changes in the extent of loose bonding, or attraction, of the iron atom to other amino acid residues in the amino acid chains. These conformational changes lead to the haemoglobin molecule passing from a ‘tense’ configuration when in the deoxygenated state into a ‘relaxed state’ as oxygen atoms are taken up. In the relaxed state the affinity for oxygen is high: saturation occurs when the haemoglobin molecule has bound four molecules of oxygen. This sequential change in affinity for oxygen defines the sigmoid shape of the oxyhaemoglobin dissociation curve. It is interesting to note that if haemoglobin bound only one oxygen atom, that is, consisted of only one amino acid chain with a single haem group, the dissociation curve could be represented by a hyperbola: this is the case with myoglobin, a one-chain molecule. The

structure of haemoglobin differs in different species and that in the human foetus is different from that in the adult human: foetal haemoglobin (haemoglobin F) gives up its oxygen less readily than normal adult haemoglobin (Hoffbrand and Pettit, 1984). Abnormal haemoglobins in humans can produce diseases such as sickle cell anaemia and some types of hereditary methaemoglobinaemia.

In addition to haemoglobin, the red cell contains enzymes, such as glucose-6-phosphate dehydrogenase (G6PD). G6PD is of great importance in maintaining NADPH levels. NADPH is essential for reducing oxidized glutathione, reduced glutathione being required for the protection of intraerythrocytic sulfhydryl groups and the structural integrity of the cell. Maintenance of the reducing potential of the red cells is also necessary to prevent methaemoglobinaemia. Oxidant stress of the red cells will produce haemolytic anaemia, methaemoglobinaemia and/or Heinz bodies (see below).

2.1.2 White Cells

2.1.2.1 Granulocytes

The granulocytic series are derived from the CFU-GEMM, which gives rise to the CFU-GM. Three lineages give rise to mature granulocytes, which are known as polymorphonuclear leucocytes or polymorphs. They have segmented nuclei and cytoplasmic granules and in humans are divided into neutrophils, eosinophils and basophils according to the staining characteristics of their cytoplasmic granules (Irons, 1991; Liesveld and Lichtman, 1997). The granules contain a variety of enzymes and other substances characteristic of the inflammatory response and phagocytosis and the cells have a turnover rate of a few hours (Marsh, 1985). The primary role of polymorphs is phagocytosis and they perform the major part of this role in the tissues, into which they pass between the capillary endothelial cells. The granules of neutrophils are notable for their high alkaline phosphatase activity and polymorph leucocytosis is characteristic of bacterial infection, but also may occur in other conditions, for example, myeloid leukaemias. Eosinophils have a distinct progenitor cell, the colony-forming unit eosinophil (CFU-EO) (Young and Weiss, 1997) and are frequently present during allergic phenomena and in parasitic infestations. The granules of eosinophils have high peroxidase activity and contain a variety of hydrolytic enzymes. Basophils are the circulating equivalent of mast cells and the granules contain heparin and histamine: the function of basophils has long been obscure, but evidence is accumulating for a role in allergic disease. In humans, basophils are the prime early producers of cytokines crucial for initiating and maintaining allergic responses. Basophils are the main cellular source for early production of interleukins IL-4 and IL-13 (see reviews by Gibbs, 2005; Falcone *et al*., 2006). Granulocytopoiesis is under the control of factors such as granulocyte colony-stimulating factor (Shochat *et al*., 2007).

2.1.2.2 Monocytes

Monocytes are derived from the CFU-GM, in common with neutrophils. Once they reach the tissues they transform to tissue macrophages or more specialized forms such as the Kupffer cells of the liver. There is some evidence in mouse and human embryos that embryonic macrophages do not follow the monocyte pathway, that is, that the ontogeny of macrophages in early development is different from that occurring during adult development (Shepard and Zon, 2000). Monocytes are large cells, whose function is phagocytosis (see Takahashi *et al*., 1996).

2.1.2.3 Lymphocytes

Lymphocytes can be divided into T-lymphocytes and B-lymphocytes. These are so-called because of the involvement of the thymus in T-lymphocyte production, whereas, in birds, the site of B-lymphocyte development is the Bursa of Fabricius. In mammals the primary lymphoid organs are the thymus and bone marrow.

2.1.3 Platelets and Coagulation

Platelets are formed in the bone marrow by fragmentation of megakaryocytes, large cells (diameter 50–200 μm), which are derived from megakaryoblasts (Tarallo, 1985; Irons, 1991). Factors involved in the commitment and differentiation of these cells have been reviewed (Long, 1998). The function of platelets is to stop bleeding: thus platelet aggregation can produce primary haemostasis, while platelets are also concerned in the initiation of coagulation, by liberating various molecules. In addition, thrombocytopenia results in increased capillary fragility. If the platelet count falls below about $50\,000\,\mu l^{-3}$, spontaneous haemorrhage and haemorrhage after minor trauma are likely to occur (Chanarin, 1985). The process of coagulation involves both plasma factors and platelets to produce the so-called coagulation cascade. There is an opposing system, fibrinolysis, which removes unwanted fibrin.

2.1.4 Interspecies Differences

There are notable differences in the ratios of the various cell types of the blood in different laboratory animals. Thus in the rat, guinea pig and certain types of primate (e.g. lemurs), lymphocytes predominate over polymorphs in the blood, whereas in other animals, including humans, polymorphs predominate. Thus haematological data should be compared with control data from the same species. Historical control data, where used, should be from the same species, and, as strain differences can occur, also from the same strain. As well as quantitative differences between blood cell numbers, there are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat041
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

some notable morphological differences between species. There are major differences in red cell morphology between some species not commonly used in the laboratory, but the red cell of nearly all laboratory species resembles that in humans in being a biconcave disc; however central pallor is not seen in cats' red cells. Reticulocytosis is frequently observed in rats and a severalfold change may be taken as adverse, whereas in other species a more modest change is an indicator of increased red cell production. The size of erythrocytes varies considerably between species, being about 8 μm in humans and as small as 3 μm in the goat (Irons, 1991). The life span of the human red cell is approximately 120 days (Ashby, 1919), whereas in many other species, it is considerably shorter, for example, 30 days in the mouse (Irons, 1991). Amongst the white cells, amphophils, pseudoeosinophils or heterophils are the rabbit equivalent of the neutrophils of other species, as are the pseudoeosinophils of guinea pigs (Loeb *et al*., 1978); although these cells carry out approximately the same functions as do neutrophils in other species, the specific granules stain orange-red with Romanowsky stains. The size of the granules in basophils varies considerably depending upon the species. The bone marrow of mice and rats is notable for the paucity of fat by comparison with human marrow, while rat haematopoietic tissue is remarkable for its large number of mast cells.

3 PRACTICAL CONSIDERATIONS IN TOXICOLOGY STUDY TECHNIQUES

Given the high degree of automation available in a modern haematology laboratory, practical techniques used to get blood samples from the animal to the laboratory constitute one of the greatest sources of avoidable variability in a toxicology study. There are important considerations in training and adequacy of staff, sample volume, sampling technique, selection of anticoagulant and anaesthesia and sequencing of the procedure, each of which has the potential to influence the outcome of a study.

The benefit to the study and to the animals themselves of properly trained and proficient sampling personnel cannot be over-emphasized. Quite correctly, adequate training and maintenance of training is a Good Laboratory Practice (GLP) requirement; but even under non-GLP conditions animal use ethics require the attention to animal well-being and integrity of the sampling process that only full competence satisfies. Staff who are well-trained and adept are less likely to cause excessive stress to the animals and to sampling personnel themselves, and will tend to reduce the chance of injury to the animals, perform with appropriate rapidity (reducing time-to-sample), perform with greater consistency and have an established routine for organization of samples and equipment. Lower levels of stress should result in fewer mistakes; a shortened procedure time results in less duration of stressful stimuli in the animal room; appropriate attention may be given to documentation of the procedure, mixing of samples with anticoagulant and prompt despatch of samples for analysis. In some species, stress may cause the spleen to contract (Morton *et al*., 1993) releasing erythrocytes to the circulation, with the consequence that red blood cell count (RBC), packed cell volume (PCV) and haemoglobin concentration become temporarily increased. Avoidable errors might include use of too small a syringe needle (forcing blood through the needle resulting in a degree of haemolysis), or inadequate mixing in the sample tube (with potential for clotting). A toxicologist should be aware of these factors; they can vary with practice during the sampling procedure, and an appropriate sequence of test and control animals helps mitigate the consequences of procedural variability.

The volume of blood available for sampling is rarely a limitation in haematology studies with large species. However, in smaller animals (e.g. rodents) study design requires a balance between the volume of sample required for analysis (each parameter on the wish list adding to the volume required) and the volume of blood which might reasonably be drawn. Hence, useful considerations include choice of analytical instrument (which volume is required for each parameter) and potential selection of methodology for which a smaller sample is required. The sample size needed for a complete haematology blood count, complete blood count (CBC) is generally relatively small and manageable; but haematology samples are frequently drawn along with clinical chemistry samples, hence volume for haematology may not be the only limitation. Under such circumstances, selection of the size of the sample tube may be a relevant factor. Haematological CBC can currently (2008) be performed on samples of 100–200 μl; these volumes are readily obtainable from rats and mice, and sample tubes of appropriate volume are commercially available. However, most test guidelines in which haematology is required also include coagulation, and a substantial international consensus (Weingand *et al*., 1996) suggests prothrombin time and activated partial thromboplastin time (APTT) as a minimum. Sample volumes for coagulation (requiring citrate as anticoagulant) are larger than those for CBC, and therefore generally available from rodents mainly as a terminal procedure, although venepuncture sampling of appropriate volume is feasible from rats at 13 weeks or beyond in a toxicity study.

The site from which blood is sampled will to some extent be dictated by the sample size required; and may in turn dictate necessity for anaesthesia. Blood sampling methodology and conditions are extensively addressed by various rules, guidelines and national legislation, and are requently guided by expertise within each facility. For insightful guidance on blood sampling, including detailed

Table 1 Recommended sampling sites for blood

Species	Site
Mouse:	amputation of the tail tip, or venepuncture of the tail vein.
Rat:	venepuncture of the tail vein, or of the jugular vein
Rabbit:	venepuncture of the ear vein
Dogs:	venepuncture of the cephalic vein (forelimb) or jugular vein.

instructions for the various procedures, influence on the wellbeing of the animals, and limitations on volumes which might be drawn, the reader is referred to the excellent web site of the National Centre for the three Rs, *http://www.nc3rs.org.uk/bloodsamplingmicrosite/page.asp?id=313* which, although largely specific for the UK, has a European perspective and is a useful resource for toxicologists world-wide (see also **table 1**). The following paragraphs should be taken as guidance for consideration.

Small samples (e.g. the single drop required for a blood smear) may be taken by simple piercing of the tail vein in rodents. The tail vein of rats may also be used for slightly larger samples, of perhaps up to 500 µl. For such sampling it is helpful to warm the animal in a thermostatically controlled warming chamber so that the tail veins become dilated; warming of the tail vein alone does not reliably increase flow of blood sufficient for a sample as great as 500 µl. The tail tip of mice can be carefully amputated, but with care not to damage bone, thus limiting this procedure to no more than one or two occasions.

If a greater volume of blood is required (up to 0.3 ml in mice, or 1–2 ml in rats), blood can be drawn from the jugular (rats and mice) or from the sublingual vein (rats). These volumes can repeatedly be taken so long as intervals are no less than approximately 28 days. Advice on sample volumes are based on the basis that circulating blood volume is approximately 50–70 ml kg^{-1} bodyweight, and that up to 10% of the circulating blood volume may be drawn at this interval without undue consequence. Clearly, as animals grow larger greater volumes (perhaps up to 3.5 ml from a 500 g rat) might be drawn. Review of modern toxicology reports shows that sampling from the orbital sinus remains a very common technique, and provides excellent blood samples in well-practiced hands; however, it carries the possibility of severe consequences to the animal—including infection behind, and loss of function of, the eye—and for this reason use is discouraged by many experts. It must be recognized that apparatus such as the butterfly needle has been available for many years, making sampling from veins of small animals a more manageable technique than it once was. With all techniques, precautions to restrict 'dead volume' in the sampling apparatus are prudent; blood discarded in the sampling apparatus is wasted, and lengthy cannulae are unhelpful in this respect.

Far greater quantities of blood (5–15 ml in rats) can be drawn at sacrifice. This is generally well in excess of requirement for routine CBC haematology, but may be helpful if coagulation or extensive clinical chemistry investigation is required at the same time. Blood should be drawn as soon as possible after death, with the abdominal vena cava being an easily accessible site at necropsy. Temptation for a preterminal sample can be resisted. However, modern automation permits that the majority of results from a preterminal investigation can be available within hours of the samples being taken, giving opportunity to plan confirmatory or alternative assays in samples taken at termination. The toxicologist should be aware that sampling a few days before termination may result in changes to certain clinical chemistry and haematology values in terminal samples; hence this option is unlikely to be feasible following preterminal sampling restricted to control and top-dose animals. Further, samples drawn from different locations may differ slightly in cell content or biochemical properties; hence, samples taken at necropsy from the abdominal vena cava may not be directly comparable with samples drawn at an earlier timepoint from the tail vein or jugular vein. While this in no way invalidates the comparison of control and treated groups, longitudinal comparisons (changes over the duration of the study) should be done only with care, as should use of historical data, to account for possible differences in sampling methods.

Haematology sampling requires anticoagulant, typically ethylenediaminetetraacetic acid (EDTA) (for cell counts) or citrate (for coagulation tests). A specific quantity of anticoagulant is present in the sample tube, appropriate to the required volume of blood, so it is prudent for the volume of blood in the tube to be as close as reasonable to the specification. In toxicity studies, animals of the top dose are generally expected to show modest toxicity, which occasionally results in technical difficulty obtaining the same volume of blood as from controls. Should these cause the volume of blood sampled from any group of treated animals to be systematically smaller than that of the corresponding controls, there is the potential to create as a sampling artefact, an apparently treatment-related variation in anticoagulant concentration. This might be reflected as a degree of cell shrinkage. To minimize such artefacts, good practice suggests anticoagulant samples are drawn before the clotted sample used for clinical chemistry.

In considering use of any anaesthetic, the toxicologist must bear in mind the potential for unwanted toxicological consequences (e.g. hepatic enzyme induction). Dogs are normally sufficiently docile and compliant that blood samples may be drawn without anaesthesia, particularly if animals have even slight training. Use of general anaesthesia will aid restraint of small animals during blood sampling, thus reducing risk of injury, as well as

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat041
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

reducing the level of discomfort suffered by the animal, and for particularly invasive sampling methods such as cardiac puncture or orbital sinus sampling, general anaesthesia should be regarded as mandatory. There are several inhalation anaesthetic agents that are suitable for small animal use. All volatile anaesthetic agents may impair well-being of the operator unless used in a closed system with good ambient ventilation. With appropriate apparatus (e.g. a metered inhalation chamber) these agents have the advantage of being convenient, with rapid recovery. Use of ether as an anaesthetic is undesirable; not only is the vapour potentially flammable and explosive, but is irritant to nasal mucosae hence causing discomfort. More modern volatile agents such as methoxyfluorane are a preferred alternative. Use of carbon dioxide (e.g. a 70% CO_2/30% oxygen mix) may be permitted, although it must be questioned if this method is anaesthetic (prevents pain); further, risk of mortality is somewhat greater than with a well-metred volatile anaesthetic. The risk is yet greater if 100% CO_2 is used and, given the investment in time and expense required (i.e. to bring an experimental animal in a toxicology study to the point of blood sampling with recovery being required) use of CO_2 may easily be false economy. Use of CO_2 is a common method of rodent sacrifice and terminal blood samples will frequently be obtained via use of this agent; but it causes alkalosis of the blood, so is unsuitable if simultaneous blood gas measurements are attempted. Injectable anaesthetics may be used, particularly for large species, but do not have the popularity of inhalation agents.

3.1 Useful Parameters

Parameters recommended in the great majority of regulatory guidelines (e.g. those of the Organisation for Economic Cooperation and Development (OECD)) provide a screening procedure to identify if the blood is a target organ system. These parameters are discussed by Weingand *et al*. (1996). Further parameters may be helpful to help elucidate a process by which changes occurs.

3.1.1 Complete Blood Count (CBC)

The key parameters are red blood cell count, haematocrit, haemoglobin concentration, white blood cell count and platelet (thromobocyte) count. These values are easily determined using modern automated haematology analysers from a small blood sample, easily obtained from the mammalian species used in toxicity testing. It is important to be aware that haematology instrumentation is usually designed for analysis of human blood samples. While it is usual for a toxicology laboratory to have access to some of the many instruments with software that permits appropriate analysis of samples from most animal species, different instruments may, however, vary slightly in how 'abnormalities' in cell size or morphology are determined or detected.

Examination of blood smears (for reticulocytes, erythrocyte appearance or white cell differential counts) is frequently performed manually, so is labour intensive. For this reason, most guidelines permit examination of control and high-dose groups in the first instance. This limited procedure is not necessary if automated examination is available.

A key principle in haematology autoanalysers is that the blood sample is aspirated through a small aperture allowing few cells at a time, permitting cell number and size to be measured by light scattering or changes in electrical resistivity. The primary data obtained is thus cell count and cell volume, with haematocrit calculated from this information; cell indices of mean cell haemoglobin (MCH) and mean cell haemoglobin concentration (MCHC) are generally provided. Mean cell volume (MCV) is a key parameter in determination of whether an observed anaemia is macrocytic, microcytic or normocytic, an essential first step in understanding an anaemic process. White blood cells are frequently distinguished by presence of a nucleus, and differentiated either by biochemical and size characteristics, or by nuclear size and shape. Platelets are distinguishable by size.

Should results indicate a change in blood parameters—particularly anaemia—examination of a blood film may be helpful; this process is frequently manual, although some features may be determined by instrumentation. A blood smear requires particularly little blood, and it may be good practice to ensure a film is fixed and preserved (even if not necessarily examined) from each blood sample. From a blood film variation in cell shape, degree of staining, cellular inclusions and other features can be determined, and can be highly informative as to the cause of toxicological change. Reticulocytes are often part of the automated count and should be reported if available; reliable estimation of reticulocytosis in a blood smear, however, requires use of a vital stain additional to other procedures.

3.1.1.1 White Blood Cell Parameters

Total white blood cell counts, part of the automated CBC, can occasionally be informative, but the differential count is usually more helpful. A typical differential count will give the proportion of lymphocytes, neutrophils (banded and segmented), monocytes, basophils and eosinophils. Automated instrumentation is variable in methodology and ability to perform these counts, and while automated counts are sometimes presented, the count is often performed manually. A typical differential count will present results for each cell count as a percentage of total white cells; correction for total white cell count to give each cell type per unit volume (e.g. thousands per μl^3) will give a more accurate picture of how the differential

count may be changing. A typical differential count will, however, not differentiate T and B lymphocytes, for which more specialist techniques are possible should immunotoxicity be suspected.

It is of interest to note that a guideline requirement for 'blood smears in all animals' to be examined for differential count at 52 weeks and termination of carcinogenicity studies, in the absence of CBC measurement in most of the individuals concerned, is for the purpose of detecting haematologic neoplasia. Presenting and interpreting these data as group mean values is seldom useful.

3.1.2 Clotting Function

Most testing guidelines require some measure of clotting function; Weingand *et al*. (1994) indeed recommend both prothrombin time and APTT. Although platelet count may give indication of changes in clotting ability, this is, in isolation, not a sufficient measure. Since tests of clotting function require a larger sample of blood than the CBC, these are perhaps conducted less often than guidelines recommend, particularly in rodent studies, although means to obtain sufficient sample are discussed in an earlier paragraph. Prothrombin time (the Quick test) indicates effectiveness of the intrinsic clotting system, while APTT measures effectiveness of the extrinsic system. An effect on either parameter can usefully be followed up by more detailed examination to determine which elements of the clotting cascade might be specifically affected, although the volumes of blood required are unlikely to be available with ease in rodents.

3.1.3 Bone Marrow Smears

Toxicological effects on red or white cell production can be inferred from CBC, but confirmation of a process affecting cell production requires a bone marrow smear. Histology of 'bone and bone marrow' does not permit the differential count required, since cells are too tightly packed for a differential count. Marrow smears require a separate procedure usually conducted at termination; marrow should be sampled as soon as possible after sacrifice. From large animals it may be possible to take a known volume of marrow and obtain absolute counts (thousands per μl^3). From smaller animals, it is usually necessary to either flush marrow from bones with a small volume of saline, or to smear marrow directly onto a slide using a paintbrush. Either method yields differential counts, of white and red cell (myeloid and erythroid) precursor cell types. Appropriate cell density in the marrow smear facilitates the counting procedure (cells must be spread thinly enough for cytoplasm to be easily visible, but closely enough to be easily counted within the microscope field of view). 'Painting' a long smear up and down the slide with a paintbrush can be a helpful technique. A key piece of information obtained from marrow smears is the 'myeloid/erythroid ratio', showing a balance of white cell to red cell production. Interpretation of this ratio indicates if either myeloid or erythroid cell production shows impairment.

3.1.4 Methaemoglobin

MetHb measurement is not commonly done, but may be a key mechanistic parameter in studies where indications of haemolytic anaemia are seen, for example, decreases in numbers of erythrocytes, presence of Heinz bodies or increases in spleen size. MetHb should also be investigated if the chemical structure gives rise to suspicion that the test compound or metabolites may give rise to MetHb, for example, aminophenols and aniline derivatives. Sampling and measurement requires careful preparation; the assay needs be conducted within a very short time of the sample being drawn and typically, the analysis occurs in or very close to the animal room. MetHb levels in normal samples are very low (0–4% varying with species and more so with analytical methodology), but since haemoglobin in a sample tube oxidizes slowly to MetHb, time from sampling to analysis is critical. Since the assay is not commonly performed, historical data in a relevant time frame is usually lacking. The author has personal experience of one case in which the tempo of sampling was disturbed when samples for one group of animals needed to be reanalysed; reanalysis complied with the standard operating procedure (SOP) specification (within 10 minutes of the sample being drawn), but the additional delay—no more than 3–5 minutes—resulted in increases in MetHb, to a measurable 0.2–0.4%. While the degree of increase was biologically insignificant (levels in excess of 25% being thought necessary for notable impairment of oxygen transport), the position of some regulatory authorities is that 'any increase in MetHb is adverse' (Luttik and van Raaij, 2001)—as indeed was confirmed in this case. Hence, care with methodology can be of great importance, study designs capable of confirming experimental repeatability are advisable (adequate sequencing would have avoided the example cited above), and expert interpretation of results may be critical. MetHb can be rapidly reversible *in vivo*, so timing of sample relative to administration of the test material must be considered; rats are good at recovering from MetHb formation due to high innate MetHb reductive ability, while dogs are considered more closely representative of man in this respect (see also Section 4.3.2). MetHb levels may be measured by spectrophotometric means either directly (e.g. the IL 682 Co-Oximeter System[a]®) or before and after the addition of cyanide (the latter is the principle of the method of Evelyn and Malloy, 1938). Spectrophotometric measurement of MetHb is subject to a number of interferences; these are rarely a problem in animal toxicological studies, but may be important in the treatment of human cyanide

poisoning by MetHb formation. This is further discussed below.

4 ABNORMALITIES IN HAEMATOLOGICAL TESTS

As has been discussed at the beginning of this chapter, xenobiotics can affect the blood in numerous different ways. Experimental animals are, of course, generally used as models for human toxicological disease, but it must be remembered experimental animals are not perfect models for humans. As a generalization, laboratory animals are better predictors of dose-related haematological phenomena than of idiosyncratic human responses.

In both experimental animals and humans, increases and decreases in the numbers of particular blood cell types may be observed: a decrease in the number of red cells is characteristic of anaemia, while a diminution in the number of white cells is called leucopenia. A low platelet count is called thrombocytopenia. Leucopenia can affect all white cell types, or be more specific (e.g. granulocytopenia or lymphopenia). Cytopenias can be due to decreased production of the affected cell type, or to increased destruction. Increases in circulating cell types can also be seen: an increase in circulating red cells is called polycythaemia, of white cells, leucocytosis and of platelets, thrombocytosis. Again, specific white cell types may be affected, giving rise for example, to lymphocytosis. An increase in circulating eosinophils is often called eosinophilia. A feature of haematotoxicity is that changes in cell types rarely occur alone. Thus aplastic anaemia brings about a reduction in all formed elements of the blood and polycythaemia rubra vera is often characterized by increased circulating granulocytes and platelets, as well as red cells.

4.1 Changes in Red Blood Cells

4.1.1 Anaemia

Anaemia is a decrease in the number of red cells in the circulation, in the MCV or the MCH or any combination of these three (Irons, 1991). There are a number of mechanisms whereby xenobiotics may cause anaemia (**Table 2**). In some instances this may be a result of an interaction between an inherited predisposition; this is clearly the case in the haemolytic anaemia associated with G6PD deficiency and certain xenobiotics, where anaemia will only occur in the minority of the population carrying the deficiency. Toxic anaemias can be normocytic (e.g. aplastic anaemia), megaloblastic or microcytic. Toxic microcytic anaemias are often sideroblastic (see below).

4.1.1.1 Aplastic Anaemia

Aplastic anaemia is but one example of a group of conditions, the cytopenias, which result from bone marrow failure. Bone marrow failure may have various effects, granulocytopenia, thrombocytopenia, and so on, depending on the species, individual, xenobiotic involved or precise experimental conditions. These differences may be related to factors such as the rate of production and turnover of the various cell populations; a good example is sulphur mustard, where in experimental animals studies, all types of bone marrow failure can be produced depending on the type of study and the period that has elapsed after dosing (see **Toxicology of Chemical Warfare Agents**). Conditions where leucopenia or thrombocytopenia predominate are discussed below; those including anaemia are discussed in this section.

Aplastic anaemia is a severe form of pancytopenia. A number of xenobiotics, both drugs and other chemicals, give rise to bone marrow depression and, ultimately, aplastic anaemia (**Table 2**). There is a marked decrease in the cellularity of the bone marrow associated with a decrease in the number of circulating red cells, white cells and platelets. Immunosuppression may occur. In some cases, for example, with cytotoxic drugs, the condition is inevitable if the dose is sufficient, and the effect is dose-related, whereas in other cases the reaction is an idiosyncratic one, and is not dose-related. A large number of drugs have been reported on occasion to give rise to idiosyncratic aplastic anaemia. There is often difficulty with demonstrating a cause and effect relationship and this has also been a difficulty with some nondrug xenobiotics, for example, lindane (IPCS (International Program on Chemical Safety), 1991; Irons, 1992).

In the case of benzene, excessive exposure results in pancytopenia, and in severe cases aplastic anaemia (USDHHS, 1997), while low-dose exposure may cause falls in specific cell counts (i.e. anaemia, leucopenia or thrombocytopenia may occur separately). Lymphocytopenia seems to be a particularly reliable indicator of repeated benzene exposure (Irons, 1991). In animal studies, abnormalities of cellular and humoral immunity have been noted (Rozen and Snyder, 1985), while benzene and its metabolites may interfere with uptake of iron into bone marrow precursors, and it seems likely that reactive metabolites may play a part in benzene toxicity (USDHHS, 1997; Khan, 2007). Exposure to benzene is associated with leukaemia (see below).

Chloramphenicol has been known for many years to be haematotoxic. This antibiotic produces a dose-related, reversible anaemia with reticulocytopenia, sometimes with leucopenia and thrombocytopenia; this form of toxicity develops during drug treatment. Chloramphenicol, albeit rarely, can also produce aplastic anaemia, evident in the blood as a severe pancytopenia. The precise mechanisms whereby the toxicity arises is still unknown, but has been ascribed to single-stranded DNA breaks

Table 2 Xenobiotic-induced anaemia

Type of anaemia		Examples[a]
Aplastic		Benzene Trichothecene toxins Drugs: Chloramphenicol Phenylbutazone Gold salts
Megaloblastic	Interference with vitamin B_{12} absorption or action	Nitrous oxide Drugs: PAS
	Dihydrofolate reductase inhibitors	Drugs: Methotrexate Trimethoprim
	Interference with other aspects of folate utilization	Drugs: Phenitoin Primidone Barbiturates
	Antimetabolites	Drugs: 6-Mercaptopurine
Microcytic, including sideroblastic		Alcohol Lead Drugs: Isoniazid
Haemolytic	Oxidant materials	Aminophenols Anilines Nitrites Drugs: Dapsone Salazopyrin Phenacetin Pesticides: Propanil Sodium chlorate
	Immune mechanisms	Various drugs including: α-Methyldopa PAS Sulfonamides Sulfonylureas Penicillin Cephalosporins
	Glucose-6-phosphate dehydrogenase deficiency[b]	Various xenobiotics including fava (broad) beans[c] Drugs: Primaquine Tafenoquine
	Others	Copper Arsine

[a]Ueno (1983), Hoffbrand (1996), Weatherall (1996), Amess (1993), Fisher (1992), Shanks *et al*. (2001), Beutler *et al*. (2007).

[b]This deficiency is relatively common in populations exposed to malaria against which the deficiency appears to provide some protection (Beutler *et al*., 2007).

[c]The toxic component of fava beans responsible is not entirely clear, but such a component may be divicine, an unstable aglycon metabolite of the fava bean pyrimidine β-glucoside, vicine (McMillan *et al*., 1993).

produced by the chloramphenicol metabolite nitrosochloramphenicol, to the production of reactive oxygen species and to actions on mitochondria (Holt *et al*., 1993; 1997). There is disagreement as to whether the topical use of chloramphenicol represents a hazard (Rayner and Buckley, 1996; Smith *et al*., 1997; Walker *et al*., 1998; Doona and Walsh, 1998). Chloramphenicol is commonly used for eye infections in the UK, but rarely in the USA.

A number of other compounds can cause anaemia as part of pancytopenia, but the leucopenia is usually more prominent than the anaemia, for example, trichothecene mycotoxins (see below).

Pure selective red cell aplasia is unusual as a toxic effect, but can occur as an immune reaction to phenytoin and sulfathiazides (Krantz, 1983).

4.1.1.2 Megaloblastic Anaemia

Megaloblastic anaemia is characterized by large erythrocytes (macrocytosis), so that the haemoglobin is reduced and the MCV increased; additionally there is usually anisocytosis and poikilocytosis. The morphology of red cell precursors in the bone marrow is abnormal: changes are seen in the erythroid, granulocytic and megakaryocytic precursor cells, including large nuclei and Howell–Jolly bodies. The underlying abnormality is often disturbance of DNA synthesis, most commonly in human medicine as a result of an effect on vitamin B_{12} or folate. Megaloblastic anaemia as a toxic end point may result from interference with the absorption or metabolism of vitamin B_{12} or folate, or by a direct action on DNA metabolism. In fact, interference with the absorption of vitamin B_{12} by xenobiotics rarely causes severe deficiency, although a number of substances, such as ethanol, *p*-aminosalicylic acid (PAS) and colchicine are known to cause malabsorption of vitamin B_{12} (Hoffbrand, 1996). A number of drugs can interfere with folate metabolism: dihydrofolate reductase inhibitors interfere with the conversion of dihydrofolates to tetrahydrofolates, and include methotrexate and trimethoprim. Anticonvulsants, such as phenytoin, primidone and barbiturates can cause a deficiency of folate, possible due to poor absorption, enzyme induction, excess utilization or a combination of these three.

4.1.1.3 Sideroblastic and Other Microcytic Anaemias

In microcytic anaemia the haemoglobin is reduced, as is the MCV. Sideroblastic anaemia is one type of microcytic anaemia, in which there is excess iron in the bone marrow (see review by Alcindor and Bridges, 2002). The erythroblasts in the haemopoeitic organs contain granules of iron arranged in a ring around the nucleus ('ring sideroblasts'), these granules staining very easily with Prussian Blue (Weatherall, 1996). Alcohol intoxication is said to be the most common cause of toxic sideroblastic anaemia (Hines, 1969). Sideroblastic anaemia is characteristic of toxicants which interfere with the biosynthesis of haem and occurs in lead poisoning (Ramsden and Pawade, 2007), and after exposure to antituberculous drugs (isoniazid) and chloramphenicol. The microcytic anaemia of lead poisoning is only sometimes characterized by sideroblastic change in the bone marrow, but this anaemia is characterized in the periphery by prominent basophil stippling of the erythrocyte (Fried, 1997). Increased δ-aminolaevulinic acid (ALA) appears in the urine. Lead interferes with haem biosynthesis (see below) and also increases the fragility of the erythrocyte by binding to its membrane (Irons, 1992).

4.1.1.4 Haemolytic Anaemia

Haemolytic anaemias are characterized by reduced red cell survival, often accompanied by a raised bilirubin, reticulocytosis and, if severe, the presence of nucleated red cells in the peripheral circulation. Hyperplasia of erythropoeitic tissue occurs and extramedullary haematopoiesis can cause splenomegaly, which may be particularly prominent in rodents (Irons, 1991). There are two main mechanisms for xenobiotic-induced haemolytic anaemia: (i) oxidative stress and (ii) immune mechanisms. A combination of inherited G6PD deficiency and certain foreign compounds can give rise to a severe type of oxidative haemolysis, sometimes accompanied by intravascular haemolysis. This can be a serious problem with malaria therapy as this deficiency is relatively common in populations exposed to malaria, against which the deficiency appears to provide some protection (Beutler *et al*., 2007), precisely where antimalarials such as primaquine and tafenoquine are needed. With some drugs, for example, primaquine, the dose required to produce haemolysis of normal human erythrocytes is very much greater than that required in cells that are enzyme-deficient (Dern *et al*., 1955), but this is not the case with all drugs.

At least three mechanisms have been identified for immune haemolytic anaemia. Methyldopa is associated with an autoimmune reaction, while immune complexes can be responsible for PAS, sulfonamide and sulfonylurea-induced haemolytic anaemia. Penicillin and cephalosporins can act as membrane associated haptenes. The Coombs test is usually positive in drug-induced immune haemolytic anaemia (Hoffbrand and Pettit, 1984; Jacobs *et al*., 1990). Haemolytic anaemia due to oxidative stress may be accompanied by methaemoglobinaemia, sulfaemoglobinaemia and/or the appearance of Heinz bodies (see below). There are some compounds that can cause haemolytic anaemia, where the cause remains unclear, for example, copper (Fisher, 1992).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat041
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.1.2 Polycythaemia

Polycythaemia is the opposite of anaemia and is characterized by an increase in the haemoglobin and red blood cell count. An apparent polycythaemia will be observed in dehydration. Polycythaemia is seen in both experimental animals and humans as a compensatory phenomenon, where potential for tissue hypoxia exists. In human populations, polycythaemia is seen in those who dwell at high altitudes and in smokers, because of the intake of carbon monoxide by the latter. Cobalt is another cause of polycythaemia, apparently due to stimulation of renal erythropoietin release (Templeton, 1992). Polycythaemia rubra vera is an uncommon myeloproliferative disease seen in humans in which the polycythaemia is often accompanied by an increase in granulocytes and/or platelets. In the vast majority of cases the aetiology is not known, but cases have been described in personnel who took part in a test of nuclear weapons (Caldwell *et al*., 1984).

4.1.3 Toxicants Affecting Haemoglobin

The physiology of haemoglobin is considered at the beginning of this chapter. Toxicants can affect haemoglobin by: (i) influencing the synthetic pathway for haem (e.g. lead), (ii) by altering the final haemoglobin (e.g. various oxidant materials to produce MetHb) or (iii) by reacting with haemoglobin (e.g. carbon monoxide). The first process may cause anaemia, whereas methaemoglobinaemia and carbon monoxide poisoning both effectively decrease the oxygen carrying power of the blood, without necessarily causing anaemia.

4.1.3.1 Porphyria

The synthesis of haem involves the synthesis of porphyrins. This process involves the condensation of glycine and succinyl coenzyme A to form ALA and this is followed by a number of steps to protoporphyrin into which iron is inserted to form haem. Porphyrias are mostly hereditary diseases, but their importance to the toxicologist is twofold: (i) certain toxicants, for example lead, can cause acquired porphyria in normal human subjects and in experimental animals (ii) the (hereditary) acute porphyrias are often precipitated by various drugs in those predisposed to these diseases. These conditions are characterized by increased excretion of porphyrin precursors. Acute intermittent porphyria[b] is the most severe and most common of these conditions and is inherited as an autosomal dominant. The disease is particularly common in northern Sweden and is characterized by gastrointestinal, neurological and psychiatric abnormalities; it is caused by deficient activity of porphobilinogen deaminase (Deybach and Puy, 1995) and a notable diagnostic feature is that the urine turns dark (red-brown) on standing. Attacks may be precipitated by drugs such as phenobarbital, sulfonamides, oestrogens and alcohol. A full list of drugs that may precipitate attacks is available at *http://www.uq.edu.au/porphyria/*. In variegate porphyria, which is also inherited as an autosomal dominant, there is notable photosensitivity, systemic signs occur less frequently than in acute intermittent porphyria, but, as in the latter, coloration of the urine occurs (see McColl *et al*., 1996; Hift *et al*., 1997; Bari, 2007). This condition is particularly common in white South Africans and is caused by deficient activity of the protoporphyrinogen oxidase gene (Frank *et al*., 1998). Porphyria cutanea tarda is a chronic condition, only a proportion of cases being genetic: these are due to a reduction in activity of the enzyme, uroporphyrinogen III decarboxylase and the condition is inherited as an autosomal dominant. The main symptoms and clinical signs are photosensitivity, which leads to skin damage and scarring (Sarkany, 2001), and discoloured urine may also be reported (Rich, 1999). Lead produces an acquired porphyria by inhibiting the haem biosynthetic enzyme ALA dehydratase, while the activity of ferrochelatase is also reduced. By contrast, the activity of ALA synthetase is increased. As a result, levels of ALA in the blood and urine are increased, as are coproporphyrin III and zinc protoporphyrin (see Feldman, 1999). A number of other chemicals are porphyrogenic, for example, dichlorobenzene (NTP, 1987), the organochlorine pesticides lindane and heptachlor in sufficient dose (Simon and Siklósi, 1974; Mylchreest and Charbonneau, 1997; Taira and San Martin de Viale, 1998), hexachlorobenzene (WHO, 1997) and certain herbicides (Jinno *et al*., 1999). Indeed, hexachlorobenzene has been used to produce a model of porphyria cutanea tarda in the rat (Llambías *et al*., 2003). Disorders of haem biosynthesis have been described in animals, including cattle, pigs, sheep and cats. Porphyria cutanea tarda has been reported in pigs (Nezamzadeh *et al*., 2005). Where porphyria has been seen in experimental animals, discoloured urine is the usual clinical sign. The porphyrins causing discolouration are not specifically detected by the usual urine test strips; more detailed studies of pigments in the urine, liver and blood are then indicated.

4.1.3.2 Oxidant and Other Changes in Haemoglobin

Methaemoglobinaemia and carboxyhaemoglobinaemia, the latter resulting from the binding of carbon monoxide to haemoglobin, cause changes in the colour of the blood; carboxyhaemoglobin is a cherry-red colour and MetHb brown. In addition, a number of other derivatives of haemoglobin have been described (**Table 3**).

4.1.3.2.1 Methaemoglobin (MetHb)

MetHb is the pigment that results when the iron of haemoglobin, normally in the ferrous (Fe^{2+}) state, is oxidized to the ferric state (Fe^{3+}). The toxicological importance of MetHb is twofold:

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat041
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 3 Oxidant and other derivatives of haemoglobin

Pigment	How formed
Methaemoglobin (MetHb)	Oxidation of Fe^{2+} to Fe^{3+} in haemoglobin
Sulfhaemoglobin	Ill-characterized pigment associated with oxidant changes in the erythrocyte
Cyanmethaemoglobin	Reaction of cyanide with MetHb
Sulfmethaemoglobin	Reaction of sulfide with MetHb
Carboxyhaemoglobin	Reaction of carbon monoxide with haemoglobin

1. MetHb is incapable of carrying oxygen reversibly in the way that haemoglobin does, with the result that methaemoglobinaemia represents a loss of oxygen carrying power of the blood and very high levels of MetHb (>50%) are thus potentially lethal.
2. MetHb can combine with cyanide, sulfide and azides and thereby ameliorate their toxic effects (see **Antidotal Studies**).

A large number of compounds that produce other oxidant changes in the erythrocytes (**Table 2**) can also produce methaemoglobinaemia. However, there are also other causes of methaemoglobinaemia, some of which are nontoxicological. Two MetHb reductase enzymes serve to keep MetHb levels in the red cells low; deficiency, which may be inherited, causes raised level of MetHb. In human populations, certain unusual haemoglobins are more susceptible to oxidation that normal haemoglobin. This can result in high levels of MetHb, as can inherited low MetHb reductase activity. MetHb levels after exposure to MetHb-generating xenobiotics are determined by levels of the xenobiotic or its active metabolite, the intrinsic sensitivity of the haemoglobin to oxidation and the activity of MetHb reductase (Marrs and Bright, 1986; Bright and Marrs, 1986). But the marked interspecies differences that have been observed appear mainly to result from differences in the ability of the erythrocyte to reduce red cell MetHb levels, laboratory rodents having a high capacity and dogs, cats and humans and (probably) nonhuman primates having a much lower capacity (Kiese and Weis, 1943; Malz, 1962; Robin and Harley, 1966; Stolk and Smith, 1966; Smith and Beutler, 1966; Smith *et al*., 1967; Bolyai *et al*., 1972; Agar and Harley, 1972; Hawkins *et al*., 1981; Marrs *et al*., 1987; Purnell and Singh, 2005). In toxicological studies, where only rodents are used, the low propensity of rodents for demonstrating methaemoglobinaemia may cause the potential of a xenobiotic to cause toxic methaemoglobinaemia to be missed, a factor which is often not adequately appreciated by regulatory bodies. Suspicion of toxic methaemoglobinaemia in rodent studies should be triggered by anaemia with enlargement and discolouration of the spleen, and/or presence of Heinz bodies in erythrocytes. In practice, of species used in toxicological studies, dogs are probably the best models for humans.

Table 4 Some compounds producing methaemoglobinaemia[a]

Chemical or drug group	Examples
Aminophenols and derivatives	2-Aminophenol 4-Aminophenol 4-Dimethylaminophenol
Anilines	Aniline 4-Aminopropiophenone Propanil
Antimalarial drugs	Chloroquine Primaquine
Antileprotic drugs	Dapsone
Chlorates	Sodium chlorate
Nitrites	Amyl nitrite Sodium nitrite
Hydroxylamines	Hydroxylamine Phenylhydroxylamine
Sulphonamides	Sulfamethoxazole

[a]Kiese *et al*. (1950), Beutler (1985), Hall *et al*. (1986), Watt *et al*. (2005).

Chemically induced methaemoglobinaemia can result from exposure to a very large number of toxicants, many of which are aniline derivatives, aminophenols or nitrites (**Table 4**).

Aminophenol and its derivatives, including 4-dimethylaminophenol, appear to form MetHb by establishing an intraerythrocytic cycle in which a quinoneimine is formed by oxidation of the aminophenol by the oxygen from oxyhaemoglobin. On the reduction of the quinoneimine to the aminophenol, the Fe^{2+} iron of haemoglobin is oxidized to its trivalent state. With the aniline derivatives, including 4-aminopropiophenone (*p*-aminopropiophenone, PAPP), a nitroso intermediate is involved in the formation of MetHb. The methaemglobin formation observed with the antileprotic drug, dapsone, appears to be mediated by hydroxylamine metabolites (Vage *et al*., 1994). MetHb formation is strongly influenced by pO_2 (Kiese, 1974; Mansouri, 1985; Marrs *et al*., 1987).

Spectrophotometric measurement of MetHb is subject to a number of interferences, such as hydroxocobalamin (Lee *et al*., 2007) and methylene blue (Dötsch *et al*., 1999). It should be noted that the spectrophotometric characteristics of cyanmethaemoglobin and MetHb are different, so that in cyanide poisoning, incorrect dosages of MetHb-forming antidotes may be calculated, and misinterpretation of MetHb measurements can result from methods that fail to discriminate between the various pigments (Shih and Korte, 1996).

Methaemoglobinaemia may be treated with methylene blue or toluidine blue (Kiese *et al*., 1972; IPCS/CEC (International Program on Chemical Safety/Commission of the European Communities), 1993).

4.1.3.2.2 Heinz Bodies

Heinz bodies are inclusions in red blood cells that consist of denatured globin (White *et al*., 1951). Heinz bodies can be seen in wet preparations of blood, using phase contrast microscopy and they can also be stained with methyl violet (Bushby, 1970). Their appearance may be an accompaniment to haemolytic anaemia, produced by oxidant xenobiotics ('Heinz body anaemia'), including those substances that produce MetHb. However, there does not appear to be close correlation between ability to produce MetHb and Heinz bodies, or of the latter with erythrocytic depletion of reduced glutathione (Miller and Smith, 1970). Moreover, in toxicological studies, there can be marked species differences in the production of Heinz bodies with the same substance (Marrs *et al*., 1984).

4.1.3.2.3 Sulfhaemoglobin

Sulfhaemoglobin is a rather ill-characterized pigment that differs from MetHb by resistance to reducing agents. It should be distinguished form sulfmethaemoglobin (**Table 3**).

4.1.3.2.4 Carboxyhaemoglobin

Carbon monoxide binds to haemoglobin in precisely the same way as does oxygen, though the affinity of carbon monoxide for haemoglobin is about 245 times that of oxygen. This means that if the carbon monoxide saturation of haemoglobin is plotted against the partial pressure of carbon monoxide, a curve of precisely the same shape as the standard oxyhaemoglobin dissociation curve would be obtained. Indeed, if one adjusted the scales on the partial pressure axes, the curves could be superimposed. It is also worth recalling that, at saturation, 1.34 ml of either oxygen or carbon monoxide is carried per gram of haemoglobin. If haemoglobin is exposed to a mixture of oxygen and carbon monoxide, the gases will compete for the binding sites. At equilibrium the, relative concentrations of oxyhaemoglobin and carboxyhaemoglobin are given by the Haldane Equation:

$$[\mathrm{COHb}]/[\mathrm{O_2Hb}] = \mathrm{M} \cdot [\mathrm{PCO}]/[\mathrm{PO_2}] \qquad (1)$$

M is referred to as the Haldane coefficient.

The effect of the great affinity of carbon monoxide on the uptake of the gas relative to that of oxygen is discussed in **Air Pollution**.

In addition to reducing the capacity of haemoglobin to carry oxygen, carbon monoxide inhibits the release of oxygen by haemoglobin. Under normal circumstances, as oxygen atoms dissociate from haemoglobin, the affinity of the molecule for oxygen drops rapidly. This produces the sudden change in gradient at the shoulder of the oxyhaemoglobin dissociation curve. To move from the relaxed, high-oxygen-affinity state to the tense, low-affinity state, oxyhaemoglobin must lose oxygen atoms. In carbon monoxide poisoning, haemoglobin molecules do not carry either oxygen alone or carbon monoxide alone; on the contrary, haemoglobin molecules will likely carry a mix of oxygen and carbon monoxide molecules. As the partial pressure of oxygen falls, at the tissues, for example, oxygen molecules would normally be released and haemoglobin would move from the relaxed to the tense state. However, if the haemoglobin molecule is carrying carbon monoxide molecules in addition to oxygen, the carbon monoxide molecules will not be released and the relaxed, high-oxygen-affinity state will be maintained. This effect can be summed up as: the binding of carbon monoxide molecules to haemoglobin inhibits the release of oxygen. This is seen in carbon monoxide poisoning as a shift of the oxyhaemoglobin dissociation curve to the left. This shift is sometimes referred to as the Haldane shift, though the term is confusing, as it is also used to describe the shift in affinity of haemoglobin for carbon dioxide that occurs when haemoglobin loses oxygen molecules. The above details were worked out by J. S. Haldane and his son J. B. S. Haldane in the early years of the century (Haldane, 1912; Douglas *et al*., 1912).

The shift in the dissociation curve causes a major problem for the release of oxygen at the tissues. An often quoted example is the difference between the effects of anaemia, with the haemoglobin concentration reduced to 50% of normal, and carbon monoxide poisoning, with a carboxyhaemoglobin concentration of 50%. In the case of the anaemia the venous pO_2 would be about 3.6 kPa (27 mmHg); in the case of carbon monoxide poisoning the venous pO_2 would be about 1.9 kPa (14 mmHg): very significantly lower (Nunn, 1993).

Exposure to carbon monoxide results in equilibration of the gas across the alveolar/capillary barrier. As has been already stated, the equilibrium conditions are given by the Haldane Equation. The rate of increase of carboxyhaemoglobin conforms to a 'wash in' exponential function. More detailed modelling of the kinetics of carbon monoxide uptake has been undertaken (Coburn *et al*., 1965; Coburn, 1979) and complex equations have been produced.

Carbon monoxide poisoning is relatively common because the gas, which is odourless, can be formed by partial combustion of natural gas, a fuel commonly used for heating in many countries. At high concentrations of carboxyhaemoglobin (>50%), carbon monoxide causes death, while concentrations as low as 3–4% may cause angina, presumably through impaired oxygen transport (DoE, 1994). Additionally, delayed effects can occur in the central nervous system after apparent recovery.

The affinity of foetal haemoglobin for oxygen is greater than that of adult haemoglobin (Longo, 1976; Garvey and Longo, 1978; Longo *et al*., 1967; Power and Longo, 1975). In addition, the foetal oxyhaemoglobin dissociation curve is displaced to the left of the equivalent adult curve. Foetal haemoglobin also has a greater affinity for carbon monoxide than adult haemoglobin, though the

foetal/adult difference in affinity is not as great as that for oxygen. Engel gave the CO/O_2 affinity ratio as 175 for foetal haemoglobin, as compared with 245 for adult haemoglobin (Engel *et al*., 1969).

As in the adult, carbon monoxide shifts the foetal oxyhaemoglobin dissociation curve to the left. This is particularly dangerous, as the foetus is always at a significantly lower partial pressure of oxygen than the adult. A 10% level of carboxyhaemoglobin will move the maternal venous pO_2 to 26 mmHg, but the foetal venous pO_2 to 11 mmHg. Uptake into and release of carbon monoxide from the foetus are delayed compared with the mother. This is a reason for considering treatment with hyperbaric oxygen whenever carbon monoxide poisoning occurs during pregnancy.

It should be noted that carboxyhaemoglobinaemia can occur due to metabolism of methylene chloride, commonly used as a paint remover (Hughes and Tracy, 1993).

4.2 Changes in White Cells

Reductions in the number of white cells (neutropenia) may affect all, a few, or just one type of white cell. It may be part of a pancytopenia or, even if all blood cell types are affected, the leucopenia may predominate; this is common with T-2 mycotoxin, poisoning with which is often characterized by some degree of anaemia, but marked leucopenia and thrombocytopenia are usually the most prominent features (Smalley, 1973; Hayes *et al*., 1980; Ueno, 1984). Trichothecene toxins produced by fungal species such as *Fusarium* are responsible for a number of syndromes, including alimentary toxic aleukia (ATA) in Russia and red mould disease in Japan. ATA occurs after the consumption of over-wintered mouldy grain and includes leucopenia, haemorrhages, sepsis and bone marrow failure (Lutsky *et al*., 1981; Lautraite *et al*., 1995; Ueno, 1983; 1984; Wang *et al*., 1998).

4.2.1 Neutropenia/Granulocytopenia/Agranulocytosis

Severe neutropenia or granulocytopenia is often called agranulocytosis. Neutropenia may result from inadequate production or increased destruction, while an apparent neutropenia can result from a shift into the blood marginal pool (Marsh, 1985). The former may occur as part of aplastic anaemia, but many compounds capable of producing aplastic anaemia, sometimes affect granulocytes and their precursors more severely than cells of the erythrocyte series, perhaps because of the erythrocyte's longer life span. Granulocytopenia can be a dose-related predictable effect as with radiation (Cronkite, 1949), various anticancer drugs, chloramphenicol and the mustards (including the chemical warfare agent, sulphur mustard (Marrs *et al*., 1996; see also **Toxicology of Chemical Warfare Agents**) or an idiosyncratic response. Idiosyncratic neutropenias fall into two groups: the slowly-developing dose-dependant type which has been reported with chloramphenicol, phenothiazines, sulfonamides and numerous other substances. The rapidly developing type of idiosyncratic neutropenia is rare, often accompanied by eosinophilia and is sometimes catastrophic. There is often a history of prior exposure (Marsh, 1985) and the effect is notoriously difficult to predict from animal studies. Amongst compounds producing this effect are chloramphenicol, gold salts and nonsteroidal anti-inflammatory drugs. It will have been noted above that chloramphenicol can produce several types of neutropenia.

Neutropenia, analogous to haemolytic anaemia, can occur because of increased cell destruction that may result from immunological mechanisms, for example, with pyrazolone analgesics, including aminopyrine (Brogden, 1986; see review by Uetrecht, 1996).

Increases in the polymorph count are found in acute infections, in leukaemias of the myeloid series and also with lithium carbonate. A notable toxicological cause of eosinophilia was the eosinophilia-myalgia syndrome seen in the early 1990s, after contamination of certain preparations of the food supplement, and essential amino acid, L-tryptophan, with a contaminant (Harati, 1994).

4.2.2 Leukaemias

Leukaemias are a heterogeneous group of malignant diseases involving the precursors of peripheral blood cells. Most arise in the bone marrow and exhibit high levels of circulating white cells. They are classified by the cell type involved and also into acute and chronic (see Tsongas, 1985). Leukaemias are seen in many species, including man and experimental animals such as mice and rats (for review of appearances and diagnostic criteria in experimental animals see Della Porta *et al*., 1979). There are notable strain differences in susceptibility of mice to leukaemia and also in rats (F-344 having a notably high incidence) (see Haseman *et al*., 1998).

Exposure to a number of drugs and other chemicals can be associated with leukaemias, as can radiation. A notable example is benzene (see also above), where exposure of human populations seems causally related to acute nonlymphocytic leukaemia and chronic myelogenous leukaemia (Paxton *et al*., 1994; Jex and Wyman, 1996; Mehlman, 2006). Benzene causes chromosomal abnormalities in a number of cell types, including blood. The precise mechanisms of benzene leukaemogenesis have not been elucidated: benzene is metabolized to benzene oxide and thence to phenol in the liver (Tunek *et al*., 1978; Sawahata *et al*., 1985) and chronic exposure to benzene results in the presence of metabolites in the bone marrow, including hydroquinone and, additionally benzene itself. These compounds produce a reduction

in circulating lymphocytes and are immunotoxic (Pyatt *et al*., 1998) and they also bring about an increase in cells of the granulocyte series. Further, benzene and its metabolites have been shown to induce DNA damage, which may contribute to leukaemogenesis, plausibly perhaps in combination with the increased replication of primitive progenitor cells, as has been observed in laboratory animals (Farris *et al*., 1997). Another possibility is that activation of protein kinase C may alter activation and expression of cellular proto-oncogenes (see review by Snyder and Kalb, 1994). There is some evidence that benzene may be associated with other malignant conditions, including Hodgkin's disease (see Jex and Wyman, 1996).

Drugs where there is an association with leukaemias in laboratory rodents include anticancer drugs (Schmahl and Habs, 1978). Hydrocarbons such as methylcholanthrene, benzpyrene and dimethylbenzanthacene can also produce leukaemias in rodents (Rappaport and Baroni, 1962). Exposure to a number of chemicals in humans is associated with increased prevalence of leukaemia; furthermore there is an association of increased risk of leukaemia and certain occupations, for example, the rubber industry (Alder *et al*., 2006), where, however, the precise causative agent is not known (Irons, 1992).

4.3 The Clotting System

4.3.1 Trombocytopenia

Thrombocytopenia is amongst the commonest blood dyscrasias reported as due to xenobiotics, especially drugs (Irons, 1991). The results are purpura and spontaneous haemorrhage, or bleeding in response to minor trauma. As with red cells and granulocytes, a reduction in circulating platelets can result from decreased production or increased destruction. Decreased production of platelets may be seen with thiazide diuretics, which are toxic to megakaryocyte precursors (Levin, 1974). Other drugs which may cause thrombocytopenia by toxicity to the bone marrow include chloramphenicol (Yunis, 1973), sulfonamides (Pena *et al*., 1985) and phenytoin (Brown and Chun, 1986), however, many drugs that cause thrombocytopenia by an effect on the bone marrow can also produce other signs of bone marrow failure, depending on the circumstances, and isolated thrombocytopenia with some drugs, for example chloramphenicol, may proceed to aplastic anaemia. Increased destruction of platelets is generally of immunological origin, although not in the case of ristocetin, an antibiotic which has a dose-related effect on platelets, by a nonimmunological mechanism. Drugs that produce thombocytopenia by immune mechanisms include quinine and quinidine (Christie *et al*., 1985), and gold salts (Stavem *et al*., 1988).

4.3.2 Drugs Affecting the Coagulation System

Anticoagulants of the coumarin group, some of which are used as rodenticides, interfere with vitamin-K dependent blood-clotting factors (see Proudfoot, 1996; **Toxicology of Pesticides**. Coumarol, in mouldy sweet clover, is an important cause of haemorrhagic disease in cattle (Blood *et al*., 1983).

5 CONCLUSIONS

The components of the blood can be affected by many xenobiotics, most particularly therapeutic drugs. Many of the techniques used in human and veterinary medicine have not been widely applied to laboratory animal toxicology studies. This limits the use to which information from routine laboratory animal toxicology studies may be put. Part of the reason for this is that haematology is often the Cinderella of disciplines in the toxicology laboratory by comparison with clinical chemistry and particularly histopathology; there is also the tendency for guidelines rapidly to become a recipe, which has to be followed, but whose scope should not be exceeded unless specifically required by regulators. This is a great pity, because the haematological data in toxicology studies represent a great deal of effort and investment and, insofar as satellite groups of animals are employed, a cause of usage of additional experimental animals. It is therefore only right that such data should be exploited to the hilt and used to their best possible advantage.

Imaging Techniques in Neurotoxicology Research and Development

Philippe Hantson and Thierry Duprez

CONTENTS

1 INTRODUCTION

The brain as a major target organ in toxicology can be injured by numerous substances ranging from pharmaceuticals to illicit drugs and environmental agents. Dramatic improvements have been obtained in the last two decades in the knowledge of toxic damage to the brain regarding both morphological changes and functional disturbances of the neural circuitry (Lingford-Hughes, 2005). This review focusses on recent advancements in neuroimaging techniques and their implementation in clinical practice and on fundamental aspects of research and development (Laureys *et al*., 2002). The most commonly involved toxic substances are reviewed, together with the morphological and functional changes they are responsible for. A key feature of neuroimaging after toxic exposure seems to be the selective susceptibility of some brain subareas to toxins (Hantson and Duprez, 2006; Dietemann *et al*., 2004). The grey matter seems more vulnerable to anoxic or ischaemic insults because of higher demands in oxygen. The corpus striatum (putamina and caudate nuclei) is the most vulnerable grey area (**Figure 1A–E**). It is also affected by toxic-related metabolic disorders (metabolic acidosis, hypoglycaemia) and contains many sensitive dopaminergic and serotoninergic pathways which have major functional roles. Lesions to the white matter seem less frequent, but have been up to now less

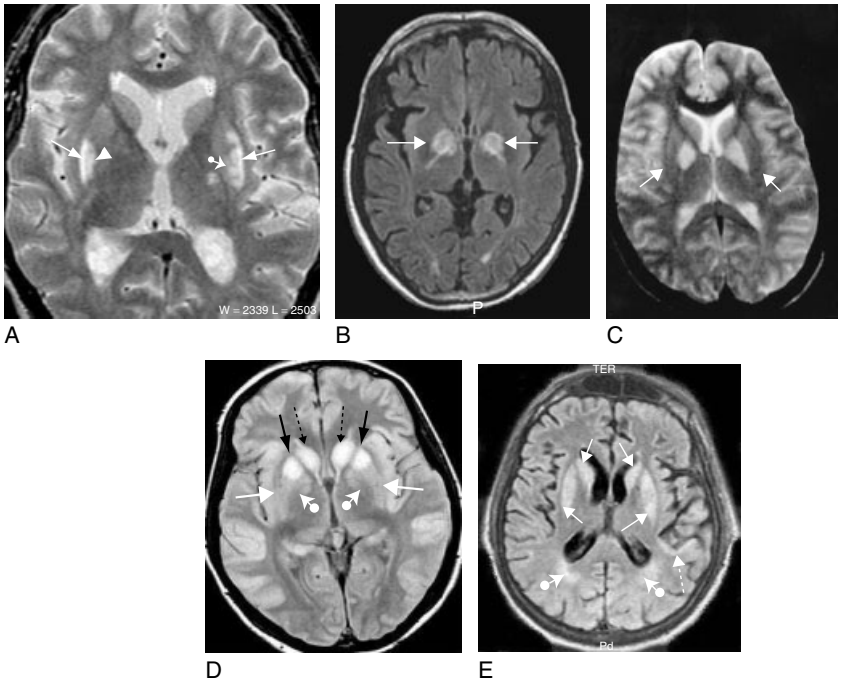

Figure 1 Illustration of the lenticulate involvement in different toxic or metabolic conditions. (A) Methanol-induced putaminal changes predominating in the posterior areas on T2-weighted sequences. (B) Relative preservation of the putamina, contrasting with the bilateral and symmetric involvement of the medial part of the globi pallidi in a patient exposed to cocaine and ecstasy. (C) Carbon monoxide poisoning with preferential injury of the whole globi pallidi also with sparing of the putamina. (D) Insulin overdose, with involvement of the anterior areas of the putamina. (E) Putamina and caudate nuclei appearing hyperintense after hypoxic injury due to cardiac arrest. (Reproduced with permission from Hantson, 1997. © Informa Healthcare.)

extensively investigated than grey matter damage. Besides morphological changes, recent neuroimaging techniques allow the additional investigation of ultrastructural parameters, metabolism, regional cerebral blood flow (CBF) and neuronal activation/reactivity. A deeper insight into the pathophysiology of drug abuse is expected from isotopic techniques using radiolabelled tracers acting as ligands to specific membrane receptors.

2 PRINCIPLES

2.1 Computed Tomography

The introduction of computed axial tomography in clinical practice in the early 1970s dramatically improved the diagnostic performance of neuroimaging. The technique, which used X-rays, was immediately considered to be best suited for the detection of cerebral abnormalities until the introduction of magnetic resonance imaging (MRI) one decade later, which demonstrated unsurpassed soft tissue contrast (see below). The technique, which is routinely called a CT scan uses an X-ray generating tube placed in opposition to X-ray detectors on a rotating frame. During rotation around the patient, the detectors collect continuous data about the attenuation of the X-rays when passing through the body at many different incidences. A backspace reconstruction algorithm of attenuation data allows the generation of a matrix image in which the attenuation coefficient of each voxel is visualized by a calculated value on a greyscale. Technological improvements, such as reduction in the size of the detectors, the helical acquisition technique, increases in the rotation speed of the tube-detector frame and the multirow detector configuration have led to higher temporal and spatial resolution, but without true impact on brain tissue contrast. Intravenous perfusion of an iodinated contrast agent allows enhancement of vascularized cerebral areas in which the breakdown of the blood–brain barrier (BBB) results in interstitial leakage of contrast molecules. Up-to-date systems enable reconstruction of 'isotropic' voxels of similar size in the three orthogonal dimensions, thereby resulting in a similar image quality for reformats in all planes.

2.2 Magnetic Resonance Imaging

MRI is derived from the NMR phenomenon described in 1948 by Bloch and Purcell. The initial technical application of the technique was the elucidation of the atomic structure of complex organic macromolecules such as the double helix of DNA. The MRI technique uses the magnetic properties of the hydrogen nuclei—the 'protons'—which are the main atomic component of water and fat. Protons behave like spinning charges and generate a very small dipolar magnetic field. In standard conditions, the proton dipoles have completely random orientation and statistically cancel each other so that there is no net magnetization of the tissues. When the patient's body is immerged into strong external 'basic' or 'static' magnetic field, the protons are compelled to align either in a 'parallel' low-energy state, or in an 'antiparallel' high-energy state. The excess in low-energy parallel spins constitutes the 'net magnetization' of the tissues. When an excitatory radiofrequency pulse is applied at a similar frequency to the spinning of the proton dipoles, the resonance phenomenon occurs and energy is transferred to the parallel spins, which are tipped in the antiparallel direction, thereby creating the disappearance of the longitudinal 'T1' magnetization. Moreover, the application of a resonant pulse generates a phase coherence of the processing spins, which creates the appearance of a transverse 'T2' magnetization. When the external pulse is stopped, the system comes back to equilibrium. The time needed to recover 66% of the value of the longitudinal magnetization is called the 'T1 relaxation time' and the time needed to destroy 66% of the transverse magnetization is called the 'T2 relaxation time'. T1 and T2 values, as well as the spin density, are intrinsic properties of the tissues. They differ for water and fat, and for free water when compared to bound water adsorbed to macromolecules. By appropriate manipulation of the pulse sequence parameters, one may create tissue contrast mostly depending on the T1 time (the so-called 'T1-weighting'), or on the T2 time ('T2-weighting'). Since grey and white matter have different proportions of water (e.g. cytoplasm) and fat (e.g. myelin), high-quality tissue contrast will be obtained for brain tissue. Anatomy is best depicted on T1-weighted images, but increases in free water content, such as inflammation, oedema or demyelination, is best detected on T2-weighted images. Intravenous paramagnetic contrast agents are magnetic polluters strongly decreasing the T1 relaxation time of adjacent protons, thereby leading to a dramatic increase in signal intensity on T1-weighted images. Additional contrast manipulations are available. In fluid-attenuated inversion recovery (FLAIR) images, the signal of free water is nulled, resulting in darkening of cerebrospinal fluid (CSF), but with preservation of the T2 contrast of the brain tissue. In diffusion-weighted (DW) images, the signal intensity is reduced according to the degree of restriction of free-water motion, that is, by microanatomical barriers, such as membranes, thereby giving ultrastructural information on tissues. A quantitative apparent diffusion coefficient (ADC) can be calculated to generate functional mapping of the restriction of water diffusion. In processes increasing the extracellular compartment, the ADC is increased. In turn, in processes in which diffusion is restricted, such as ischaemic cytotoxic oedema, or proliferative disorders involving dense cellularity, the ADC is lowered.

2.3 Functional Magnetic Resonance Imaging

Functional MRI of neuronal activation relies on the blood oxygen level dependant (BOLD) contrast principle (Ogawa *et al.*, 1990). Oxygenated haemoglobin (Hb) has a low magnetic susceptibility effect. In turn deoxyhaemoglobin has a higher susceptibility effect, resulting in a marked decrease in signal intensity. The overall drop in signal intensity is a function of the ratio between oxy- and deoxyHb within blood in capillaries. At baseline, a certain proportion of deoxyHb is present within a voxel. When neurons of the voxel are activated, a local increase in blood flow suddenly occurs, which exceeds the true increase in oxygen needs by neuronal and synaptic activity, resulting in a relative decrease in the ratio between deoxy- and oxyHb. The signal attenuation is diminished and the comparison of signal at rest and during the task allows the delineation of the brain voxels being activated by the task.

2.4 Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) was the original technique designed in the late 1940s and early 1950s to investigate the atomic structure of organic macromolecules. It relies on the principle of chemical shift, which is the small change in precession frequency of a defined atom according to its electronic, atomic and molecular environments. When combined with MRI, the technique allows the detection and quantification of defined metabolites. Proton magnetic resonance spectroscopy (^{1}H-MRS) is the most commonly used in the brain, allowing, for example, the study of choline (Ch), creatinine (Cr), *N*-acetyl aspartate (NAA), myoinositol (MI), alanine and lactate. Spectroscopic analysis of other nuclei (phosphorus, carbon, sodium, lithium) can be performed. Quantitative analysis of adenosine triphosphate (ATP) concentration is enabled by ^{33}P spectroscopy.

2.5 Positron Emission Tomography

The initial step leading to the development of positron emission tomography (PET) was tissue autoradiography which investigated *in vitro* the accumulation of organic molecules labelled with radioactive elements, thereby acting as tracers. Because glucose is the unique source of energy for neurons, a radioactively labelled form of glucose can be used to measure cerebral metabolism. Positron-emitting tracers are detected and located by multiple sensors positioned around the head. Functional PET imaging can be combined with high-anatomic-resolution CT or MRI (Otte and Halsband, 2006). The kind of information obtainable depends upon the nature of the radioisotopes. The most commonly used radioisotopes are oxygen-15, fluorine-18, carbon-11 and nitrogen-13. They can be combined with different molecules like water, glucose, benzodiazepine-receptor ligands etc. [^{18}F]-fluorodeoxyglucose (FDG) is captured by neurons. Since it is not an appropriate metabolite for the glucose kinase, it can not be further metabolized and remains trapped within the intracellular compartment. An FDG-PET scan thereby allows the mapping of regional variations in cerebral glucose uptake. PET using water labelled with oxygen-15 ($H_2{}^{15}O$) allows precise measurement of regional cerebral blood flow (rCBF). The very short half-life of the tracer (2 minutes) allows repeated experiments in the same session and prevents potentially harmful effects of longer exposure to radioactivity. Specially tailored PET tracers allow receptor imaging in clinical pharmacology and toxicology.

2.6 Single Photon Emission Computed Tomography

In contrast to PET, single photon emission computed tomography (SPECT) is based on the detection of individual photons (low-energy gamma rays) rather than positrons, which are paired. The radioisotopes used for SPECT have longer half-lives than those used for PET, thereby avoiding the need for the availability of an on-site cyclotron. However, the spatial resolution is lower with SPECT as is the range of the cerebral activities that can be investigated. Absolute quantification is not possible. The standard radioisotopes for SPECT are technetium-99m and iodine-123. Tc-99m-hexamethyl propylamine oxime (Tc-99m-HMPAO) is widely used for the determination of CBF. As the tracer remains within the brain for a longer period than PET isotopes, the capability for analysing long-lasting processes is an advantage of SPECT over PET (Marshall *et al*., 1997). Iodine-123-labelled ligands have been specifically developed to investigate interactions between brain receptors and neurotransmitters or drugs.

2.7 Electroencephalography

Electroencephalography (EEG) is the oldest technique for detecting electrical activity in the brain from the scalp. EEG is a routine validated procedure for the diagnosis of numerous brain disorders in neurology, neurosurgery and psychiatry. The EEG recording is the sum of activities of a large number of neurons, thereby resulting in low spatial resolution. In turn, excellent temporal resolution with a range of a few milliseconds can be obtained. Nonspecific EEG changes (diffuse slowing) are frequently observed in subjects with impaired consciousness due to toxic exposure. High sensitivity in detecting infraclinical seizure activity is the main advantage of the technique in day-to-day practice.

2.8 Evoked Potentials

Evoked potentials (EPs) are a recording of the electroencephalographic activities under different stimuli: visual, auditory or somatosensory. They can be used to test the integrity of the corresponding neural pathways. They are mainly used in patients presenting acute neurological disorders (brain anoxia, brain trauma).

Brainstem auditory evoked potentials (BAEPs) and median nerve somatosensory evoked potentials (SEPs) investigate the brainstem, while the cerebral cortical level is assessed by median nerve SEPs and flash visual evoked potentials (fVEPs). At the same time, the peripheral structures are also assessed.

BAEPs bring information about the functioning of cochlea (wave I), VIIIth nerve (waves I and II), cochlear nuclei (wave II), trapezoidal bodies (wave III) and lateral lemniscus (waves IV and V). Median nerve SEPs allow, thanks to a multilevel recording, checking of the somatosensory lemniscal pathways from peripheral nerve (N9 wave at the Erb's point) to associative cortex (parietal P45 and frontal P30 waves) going through the spinal structures (cervical N13 wave), the medial lemniscus (P14 wave) and the primary cortex (parietal N20 wave). fVEPs give information on retinal functioning (wave I), on primary occipital cortex functioning (waves III and IV) but also on associative cortex activation (wave VII and rhythmical after-discharge). A bilateral occipital recording allows the detection of a retrochiasmatic lateralization between left and right occipital areas.

The latency between peaks gives an idea of the conduction time between these different structures (interpeak latencies between the BAEPs wave, central

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

conduction time between cervical N13 and parietal N20 of the median nerve SEPs) and allows, among others, the assessment of subcortical conduction. In the case of some specific question, other modalities can be used. If a prechiasmatic visual assessment is necessary, a monocular stimulation can be used; if the patient is conscious, checkerboard reversal stimulation can be performed in order to evaluate more precisely the macular function and the optic nerve, since the flash assesses more specifically the peripheral retina and is less sensitive to an optic nerve lesion.

Like EEGs, EPs are potentially influenced by some drugs or toxic substances. They will affect one or several modalities, according to the properties of the substance, and will influence the latency, amplitude, duration or topography of the waves. Some EP components could be related to the mental attention of the subject when the stimulus occurs (the so-called 'cognitive' or 'endogenous' EPs).

3 APPLICATIONS TO CLINICAL PRACTICE AND RESEARCH IN TOXICOLOGY

3.1 Carbon Monoxide

The radiological features of carbon monoxide (CO) intoxication have been extensively documented. While brain CT examination is often unremarkable in the condition, the exquisite tissue contrast yielded by MRI allows the technique to depict diseased brain as early as 1 hour after exposure in experimental models. Distinction between early changes of the acute phase and delayed changes due to subacute encephalopathy has to be made (Lo *et al*., 2007). At the acute phase, the globus pallidus is the most commonly involved brain area in CO poisoning (O'Donnel *et al*., 2000; Chu *et al*., 2004) (**Figure 1C**). As expected, damage is usually symmetrical. Extension to other areas (putamina, caudate nuclei, thalami and substantia nigra) are frequently seen. Tissue characterization of CO-related brain damage can be further done using different kinds of MRI sequences: cystic necrosis appears very bright on T2-weighted images and very dark on T1-weighted ones. Cytotoxic oedema—which is often present within striatum—is detected by reduced ADC values due to cell swelling on DW parametric maps and high signal intensity on DW images (Kinoshita *et al*., 2005). Haemorrhagic transformation commonly observed in pallidi (Bianco and Floris, 1996) is best depicted by magnetic susceptibility artefacts due to the presence of haemoglobin degradation products on gradient-echo T2-weighted sequences. However, necrosis of the globi pallidi does not necessarily mean parkinsonism, and vice versa, probably because the damage to the nigrostriatal pathway is incomplete (Prockop, 2005). The prevalence of white matter hyperintensities on T2-weighted images appears highly variable (Parkinson *et al*., 2002). They seem preferentially located deep at the border of the lateral ventricles and centrum semiovale. White matter changes are usually permanent, even though some reversibility, which could be due to remyelination of the injured areas, has been demonstrated (Choi *et al*., 1993; Yoshii *et al*., 1998). The relationship between white matter hyperintensities and neuropsychological outcome is still debated, as MRI changes are not prominent in a majority of patients with cognitive impairment. Delayed encephalopathy following CO poisoning is characterized by the recurrence of neurological or psychiatric symptoms after complete clinical recovery of variable duration (usually between two and three weeks) from acute phase symptoms. White matter demyelination may be responsible for delayed neuropsychiatric syndrome (Chang *et al*., 1992; Murata *et al*., 2001; Kim *et al*., 2003) DW images highlight confluent areas of high signal intensity in the periventricular and centrum semiovale white matter corresponding to cytotoxic oedema, as demonstrated by ADC parametric maps. (Kim *et al*., 2002).

Regional CBF disturbances in the acute phase of CO poisoning have been described in the frontal cortex, basal ganglia and parietal cortex (Pach *et al*., 2004; 2005). A significant degree of asymmetry between the two hemispheres has been detected in basal ganglia and the prefrontal cortex. Delayed follow-up ^{99m}Tc-HmPAO SPECT studies have demonstrated the best reversibility of the anomalies within the parietal cortex. No unequivocal (precise) correlation between imaging features and neuropsychological testing at six months has been demonstrated.

3.2 Cyanide

Cyanide is toxic either by inhalation or by ingestion of cyanide salts. Cyanide has a similarly high affinity to CO for anatomical structures with very high oxygen demands. Again, lesions are prominent within the putamina and globi pallidi. They can be associated with the onset of extrapyramidal signs. Extension of tissue damage to the cortical grey matter may occur. Cortical laminar necrosis, previously described in neuropathological studies, may also be seen on MRI. (Kasamo *et al*., 1993; Riudavets *et al*., 2005). In a patient who survived a suicide attempt after ingestion of a high amount of potassium cyanide, biphasic changes were observed in CBF measurement by 99m-Tc-HMPAO SPECT (Zaknun *et al*., 2005). CBF values at the upper normal range were noted at the early stages, at a time the patient had choreoathetotic movements. Later on, after akinetic mutism had clinically developed, the CBF

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat042
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

dropped to abnormally low values. [^{18}F]-FDG-PET revealed a global decreased tracer uptake within the cortical grey matter. The reduction was marked in the frontal lobes and striatum bilaterally, and to a lesser extent in the anterior part of the temporal lobes. A SPECT investigation was also done using [123-I]-2β-carbomethoxy-3-β-(4-iodophenyl)-tropan (β-CIT) as tracer, reflecting the density of striatal presynaptic dopamine transporters (DATs). A progressive loss in nigrostriatal dopaminergic neurons was suspected on two serial examinations.

3.3 Insulin

Insulin overdose is responsible for cerebral hypoglycaemic insult which prominently involves the grey matter. Within basal ganglia, hyperintensities on T2-weighted images are bilaterally seen within caudate and lenticular nuclei, but thalami are usually spared for unknown reasons (Jung *et al*., 2005) (**Figure 1D**).

3.4 Methanol

Methanol poisoning results in severe metabolic acidosis due to formic acid accumulation that usually becomes critical after a delay of several hours. Ancient neuropathological descriptions suggested that methanol-related brain injury involved basal ganglia, mainly the putamina. The first CT investigations reported that putaminal necrosis and haemorrhages were frequent. There was, however, no clear relationship between CT findings and clinical outcome. The preferential involvement of the putamina was further highlighted by MRI (Sefidbakht *et al*., 2007) (**Figure 1A**). DW sequences demonstrate cytotoxic oedema within the putamina, appearing after several hours. This delay may correspond to the time needed for the biotransformation of methanol into formic acid. Involvement of the subcortical white matter within frontal and/or occipital lobes has also be reported (Hantson *et al*., 1997). Patients with extensive putaminal necrosis more frequently develop permanent visual impairment. But, the origin of this deficit is an optic nerve injury that cannot be demonstrated by neuroimaging techniques, but well by visual evoked potential (VEP) examination. Blindness or severely decreased visual acuity may be observed in patients who survive methanol poisoning. There is strong scientific evidence that formic acid is the metabolite responsible for this specific toxicity. Experiments in nonhuman primates have shown that the ocular toxicity is usually biphasic. Early retinal dysfunction can be diagnosed by electroretinography (ERG). Retinal dysfunction is potentially reversible and a relationship can be found between ERG changes and blood formate concentrations, with a threshold value for retinal dysfunction. With large excesses of formate, retinal dysfunction will be followed within a few hours or days by a toxic optic neuropathy. This injury could still progress weeks after exposure, but a partial recovery is possible. Investigations of visual impairment in human methanol poisoning cannot be easily achieved, particularly in comatose patients. Hantson *et al*. (1999) were able to investigate 17 methanol-poisoned patients at the acute stage. They confirmed the biphasic pattern of visual injury using fVEPs. The risk for developing permanent visual injury was well correlated with the severity of metabolic acidosis and with the peak value of blood formate concentration (Hantson *et al*., 1999).

3.5 Ethylene Glycol

In contrast to methanol poisoning, ethylene glycol intoxication is usually not followed by permanent neurological impairment. Brain death is, however, possible in hyperacute forms complicated by severe metabolic acidosis and brain oedema. On CT images, the early appearance of diffuse cerebral oedema may appear, but usual hypointense areas within the central white matter, basal ganglia, thalami, midbrain and upper pons are seen only after a delay of 24–48 hours. (Morgan *et al*., 2000). Nonspecific cerebellar white matter abnormalities have also be described on brain MRI (Freilich *et al*., 2007).

3.6 Ethanol

Neuroimaging techniques have demonstrated structural and functional abnormalities in uncomplicated alcoholics who are cognitively impaired (Pfefferbaum *et al*., 1997; Lyons *et al*., 2001). Alcoholics have a reduction in brain volume and weight that is largely accounted for by a reduction in white matter volume. The reduction of the prefrontal white matter is particularly important in patients with Wernicke–Korsakoff syndrome. The mechanism underlying the white matter changes can be investigated by ^{1}H-MRS, which shows a decrease in NAA signal in the frontal white matter, suggestive of demyelination and loss of axonal integrity (Videen *et al*., 2001).

At low doses, ethanol can act as a stimulant (increased cerebral activity, behavioural disinhibition, etc.), while at higher doses, ethanol can result in motor and sensory impairments. Imaging studies in humans have shown that with low doses of ethanol intake, there was an increase in CBF in a region-specific manner. The frontal cortex seems sensitive to the lowest doses, while higher doses are required to elicit effects in the temporal cortex

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat042
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Tiihonen *et al*., 1994). High doses of ethanol decrease CBF and local cerebral glucose utilization globally in humans. The cerebellum is the site where functional activity is frequently reduced at moderate doses. It has still to be determined whether the regions in which blood flow is elevated (prefrontal regions and temporal cortex) are those involved in the cerebral reward system, as it has been also suggested for cocaine craving.

Alcoholics usually exhibit poor task performance. This could be associated, not only with structural changes (brain atrophy), but also with functional disorders in some specific areas. Several studies have focussed on the prefrontal cortex. One of the limitations of scintigraphic studies is that an apparent decrease in functional activity in the frontal cortex could be only the result of a structural decrease in brain tissue with otherwise normal metabolic activity. Nevertheless, consistent results were obtained by SPECT studies. They showed repeatedly a reduction of rCBF in the prefrontal cortex that was greater than in any other region. The changes in rCBF appear to be independent of the magnitude of brain atrophy, which is usually more pronounced in the periventricular regions (Melgaard *et al*., 1990). Alcoholics with poor task performance have frontal hypoperfusion, irrespective of brain atrophy. Interestingly, the subjects without significant brain atrophy have a better recovery of frontal perfusion after abstinence. The delay for perfusion recovery may be as long as several years.

Ethanol abuse may be complicated by different types of acute or subacute encephalopathy: central pontine myelinolysis, Marchiafava–Bignami encephalopathy or Wernicke–Korsakoff encephalopathy). These entities are now easily identifiable by MRI. Marchiafava–Bignami encephalopathy is a rare disease and is seen in chronic ethanol abusers. The main pathological feature is acute demyelination or necrosis of the corpus callosum (mainly the splenium). Several MRI reports have shown an extension of the lesions to the hemispheric white matter. This is particularly well explored by the FLAIR or DW imaging sequences (Johkura *et al*., 2005). Central pontine myelinolysis was first described in alcoholic and malnourished patients. It can also be observed following metabolic disorders, and particularly after rapid correction of hyponatraemia. Pathologically, it is defined by a symmetric area of myelin disruption in the centre of the basis pons, but extrapontine myelinolysis can be documented in other brain areas (cerebellar and neocortical white/grey matter junctional areas, thalamus and striatum). Typically, central pontine myelinolysis is confirmed with T2-weighted MRI showing a typical trident-like hyperintensity on the centre of the pons. DW imaging findings in the acute phase are consistent with cytotoxic oedema, which is potentially reversible. MRS data are scarce, but suggest a decreased NAA/Cr ratio and an increased Ch/Cr ratio during the acute phase (Cramer *et al*., 2001; Guo *et al*., 2006).

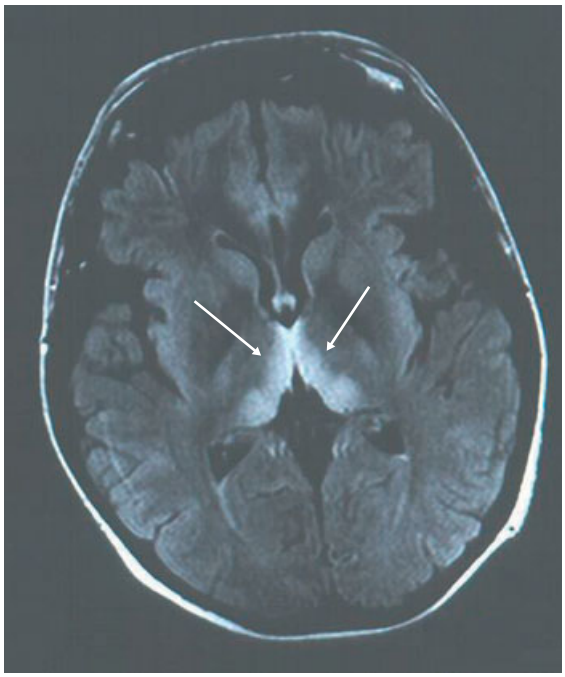

Figure 2 Brain MRI performed in a 33-year-old woman admitted with altered consciousness and ophthalmoplegia. Thiamine deficiency due to chronic ethanol abuse. Hyperintense lesions were seen on T2-weighted sequences in the thalamic area, around the third (see arrows) and fourth ventricle and the periaqueductal midbrain. Further development of Korsakoff syndrome.

Wernicke–Korsakoff encephalopathy is also not restricted to alcoholics, but is reported in other diseases, particularly after starvation. The causative mechanism is a thiamine deficiency. Typically, the T2-weighted and FLAIR sequences demonstrate hyperintense lesions in the medial thalami and the periventricular region of the third ventricle, in the periaqueductal area, in the mamillary bodies, in the tectal plate or in the dorsal medulla (Zuccoli *et al*., 2007) (**Figure 2**). The value of DW imaging as a prognostic tool should be further investigated (Lapergue *et al*., 2006).

Global decreases or no change in functional activity were found in patients presenting with Wernicke's encephalopathy. In the acute phase, decreased rCBF can be observed in the frontal cortex (Hunter *et al*., 1999). As the Papez circuit is involved in the generation of memories, it appears logical to observe a reduction of local cerebral glucose utilization in the cingulate gyrus, basal forebrain, hippocampus and thalamus (Fazio *et al*., 1992; Crews *et al*., 2005).

Spectroscopic alterations of NAA- and Ch-containing compounds have been found in the frontal cortex and in the cerebellum of alcoholic-dependent patients. In particular, the decreased Ch signal observed in frontal white matter and cerebellar regions could be at least partially reversible with abstinence. There is also a

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

correlation between the increase of Ch signals and recovery from grey and white matter atrophy (Ende *et al*., 2006).

Ethanol withdrawal syndrome is characterized by various clinical signs, the most severe being cardiovascular or neurological disturbances. The direct consequences of ethanol withdrawal on long-term brain function are not precisely known, but it can be at least suspected that withdrawal could play a role in the cognitive deficits known to occur in alcoholics. Increase or decrease in global CBF was reported during withdrawal. In the context, agitation and auditory or visual hallucinations are common experiences. This may be associated to an increased functional activity in the frontal lobes (Berglund and Risberg, 1981). Experimental animal models confirmed the possibility of localized changes in brain function. The reactivities of some brain structures are clearly different during acute ethanol intoxication or withdrawal. The sensorimotor areas, the sensory systems and the cingulate cortex exhibit increased glucose utilization during withdrawal, without significant changes during intoxication. In turn, the cerebellum and the limbic regions are highly sensitive to the acute effects of ethanol, but do not show increased functional activity during withdrawal.

3.7 Cannabis

Cannabis is the most commonly used illicit substance. There is minimal evidence that chronic cannabis use could induce structural brain abnormalities, and in particular a reduction of white or grey matter volumes (Tzilos *et al*., 2005).

The principal psychoactive compound of cannabis, delta-9-tetrahydrocannabinol (THC), acts centrally via the cannabinoid 1 (CB1) receptor. Thalamic nuclei and limbic regions have a higher receptor density, as do the globi pallidi and ventral pallidum within the basal ganglia.

Numerous studies have looked at the effects of cannabis on brain function (Quickfall and Crockford, 2006). However, their study designs differed in regard to several aspects: definition of 'chronic' or 'occasional' cannabis use, association or not with other substances, period of prestudy abstinence and so on. Nevertheless, the results of the reported studies are reasonably consistent (Pearlson, 2001). Quantification of exposure remains a great concern, as the THC content of smoked cannabis has substantially increased over the past 20 years. Concerning the methodology, SPECT also appears less sensitive than PET or functional magnetic resonance imaging (fMRI) to detect changes in some specific brain regions. During exposure, there is an overall increase in brain activity, and more specifically in frontal, limbic and cerebellar regions. In turn, there is a reduction of activity in the same areas during abstinence. There is an overlap of the regions involved with those usually implicated in other substance use disorders (e.g. ethanol). The current neuroimaging data are insufficient to clarify whether residual cognitive disorders either resolve or not with abstinence alone.

3.8 Ecstasy

3,4-Methylene dioxymetamphetamine (MDMA, 'ecstasy') is a synthetic amphetamine with stimulant and hallucinogenic effects. MDMA influences both serotoninergic and dopaminergic transmission. The primary effects of MDMA are believed to be indirect, but it also binds to a number of postsynaptic receptor sites, with a great affinity for the serotonin transporter (SERT) and for the serotonin (5-hydroxytryptamine (5-HT)) receptor, particularly the 5-HT_2A type. There is now considerable evidence that MDMA has highly selective neurotoxic effects on the 5-HT brain neurons, but in some species the neurotoxic effects could extend to the dopaminergic neurons. Experiments with MDMA in nonhuman primates seem to indicate that the loss of brain serotonin markers following repeated MDMA exposure may persist for several years. Some recovery is still possible, but probably with an aberrant neural organization. The early studies that attempted to determine the neurotoxic effects of MDMA in humans used indirect markers, like the measurement of 5-hydroxyindolacetic acid (5-HIAA) in the cerebrospinal fluid. These indirect measures probably underestimated the potential of MDMA-induced neurotoxicity.

The possibility of long-term neurotoxicity is still a matter of debate in humans. There is a limited comparability of MDMA doses in animal models or human studies. The lowest dose to induce neurotoxic changes in nonhuman primates was found to be 40 mg kg^{-1} body weight. The usual 'ecstasy' doses used by humans per weekend are in the range 75–250 mg.

Several studies have addressed either the morphological or functional changes induced by MDMA in humans (Cowan, 2007).

Structural changes to brain grey matter seem limited after MDMA exposure, in humans as well as in animal models. Cowan *et al*. (2003) used voxel-based morphometry with MRI to compare regional brain grey matter concentration in MDMA users and controls. These authors found that MDMA users had multiple areas of reduced grey matter concentration in the brainstem, cerebellum and mostly the left-sided neocortex. However, these results could not be replicated by the subsequent studies; there was no consistent overlap with brain regions showing altered serotoninergic function or altered neurochemistry or metabolism in other neuroimaging studies.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat042
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Heavy ecstasy use has been associated with neurocognitive deficits in various behavioural and brain imaging studies. The few available fMRI studies have primarily focussed on working memory and generated inconclusive results concerning the effects of ecstasy on brain activity patterns and the specific brain areas that are affected (Daumann *et al*., 2004). In a recent study, Jager *et al*. (2008) tried to clarify the specific effects of ecstasy on neurocognitive brain function by separating heavy ecstasy users from polydrug users. They concluded that ecstasy alone had no effect on working memory and attention, while polysubstance ecstasy users had reduced associative memory performance. Incidental use of ecstasy seems devoid of significant effects on cognitive brain function (Jager *et al*., 2007).

Contrasting results have been published concerning the patterns of rCBF measured by SPECT. Reneman *et al*. (2001) investigated the changes in rCBF in a group of MDMA users abstinent for a period of at least three weeks. Compared with controls, the MDMA users had a relative increase of rCBF values in the globi pallidi. This could be the result of a loss of serotoninergic vasoconstrictive effects to globus pallidus arterial vessels. The same authors found, with MRI, an increased ADC in this specific area in the MDMA users cohort. In an other rCBF study, Chang *et al*. (2000) explored the effects of prior MDMA exposure on rCBF in drug-abstinent MDMA users at baseline and again after administration of MDMA. At baseline, there was no difference in rCBF between MDMA users and controls. After the readministration of MDMA, a significant reduction of rCBF was noted in multiple brain regions (bilateral caudate, bilateral superior cortex, right dorsolateral prefrontal cortex).

The investigation of MDMA-induced neurotoxicity progressed after the development of radioligands capable of binding selectively to brain serotonin terminals (McCann *et al*., 2001). The technique was first developed for SPECT ligands and thereafter for PET. The first SPECT studies in MDMA users were performed using a cocaine analogue, [123I]β-CIT, that binds to both SERT and DAT. A reduction in cortical [123I]β-CIT binding was found primarily in the primary sensorimotor cortex. This reduction was more evident in cases of recent MDMA use (Semple *et al*., 1999). The density of SERT can be investigated in humans by PET studies using different specific ligands. The first documentation by PET of MDMA-induced 5-HT neurotoxicity was obtained in baboons. With the same radioligand, (+) [11C]McN5652, it was possible to demonstrate global and regional reductions of binding sites in MDMA users. A direct correlation was found with the extent of previous MDMA use (McCann *et al*., 2005). In abstinent MDMA users, compared to a nonMDMA control group, a global reduction in brain SERT density was demonstrated, with a variability within the different brain areas. Some degree of regeneration of serotonin axons and axon terminals was possible. It appears also that the reduction in the PET-binding parameters could underestimate the true extent of SERT loss. Analyses suggest a positive relationship between SERT binding and duration of abstinence, and a negative relationship between SERT binding parameters and MDMA use intensity. The interpretation of these PET findings remains challenging, as the potential relationship between brain measures of SERT and functional consequences of MDMA has still to be determined. The effect of lower exposure is also not precisely known. (McCann *et al*., 1998; Buchert *et al*., 2004). An other PET human study was conducted in MDMA users with 2–18[F]- FDG as tracer. The subjects were chronic MDMA users (cumulative dosages ranging from 12 to 840 tablets), who were observed after an abstinence period of at least two months. A reduced glucose metabolic uptake was noted in the amygdala, hippocampus and frontal cortex. This is more indirect evidence for persistent effects on neural activity resulting from brain 5-HT neurotoxicity (Obrocki *et al*., 1999).

Two brain metabolites, NAA and MI, have been extensively investigated by MRS in MDMA users. To date, no consistent results have been obtained. In particular, a reduction of NAA in cortical frontal areas was only observed in the population with the greatest MDMA exposure (Daumann *et al*., 2004).

3.9 Cocaine

With 3,4-MDMA ('ecstasy') and cocaine, there is a well-documented risk of cerebrovascular accidents. As expected, the globi pallidi seem highly vulnerable. (De Roock *et al*., 2007; Reneman *et al*., 2000) (**Figure 1B**).

The primary neurochemical action of cocaine in the brain is the blockade of the reuptake of dopamine, norepinephrine and serotonin. The reinforcing effects of cocaine are thought to be mediated by the dopaminergic pathway extending from the ventral tegmental area to the nucleus accumbens. PET studies in humans were helpful to demonstrate that the higher concentrations of synaptic dopamine corresponded to the peak physiological effects of cocaine (Schlaepfer *et al*., 1997). Additional data were procured by fMRI. The fMRI signal changes are influenced by alterations both in perfusion and function. Following acute cocaine administration, an increased signal intensity is usually observed in the ventral striatum/subcallosal cingulate, ventral tegmentum and several other cortical regions. It is still debated whether chronic cocaine use can produce long-term changes in brain structure and function. It seems likely, according to *in vivo* experiments in nonhuman primates and also in humans, that repeated exposure to cocaine

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat042
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

could increase the density of DAT in some brain subregions (Little *et al*., 1999). However, it is exceedingly difficult to examine the temporal development of changes in DAT in binding sites in human cocaine abusers. Data obtained from cocaine self-administering monkeys seem to indicate that the increases associated with prolonged cocaine exposure begin to occur on the order of months rather than years (Letchworth *et al*., 2000). Cocaine users have significantly lower levels of dopamine D2 receptors when compared to drug-naive subjects. This down-regulation could persist for a long period following cocaine abstinence (Volkow *et al*., 1993). In parallel, changes in both resting levels of cerebral metabolism and blood flow, as well as altered responses to pharmacological challenge, have been demonstrated in cocaine abusers. Biphasic changes in cerebral metabolism can be found according to the duration of abstinence. Within the first few weeks, increases in cerebral metabolism have been reported within the basal ganglia and orbitofrontal cortex, while, at a later stage, lower rates of cerebral metabolism is correlated to decreased D2 receptor availability.

As craving is a hallmark feature of cocaine addiction, special attention has to be given to the neuroimaging techniques in an effort to describe the neural substrates involved in craving (Porrino *et al*., 2001). PET scans are able to demonstrate increases either in CBF or glucose utilization in some specific brain areas (frontal cortex, amygdala, cerebellum).

3.10 Opioids

With regard to illicit substances, chronic exposure to heroin has been particularly well investigated by MRI. The typical pattern is called 'spongiform encephalopathy'. It corresponds to spongiform degeneration of the white matter associated with multivacuolar degeneration of the oligodendrocytes. The lesions usually appear after chronic inhalation of heated heroin ('chasing the dragon'). On T2-weighted MRI, hyperintense areas within the white matter of the cerebellar hemispheres and brainstem are described, while the subcortical white matter and the anterior limbs of the internal capsules are usually spared. (Gacouin *et al*., 2003; Keogh *et al*., 2003).

The opiod-receptor system is characterized by three basic forms of receptors, mu (μ), delta (δ) and kappa (κ). In particular, the μ receptor is thought to mediate the analgesic and euphoric effects of opioids, as well as the addictive properties. PET studies using ligands for the opioid system can be performed either in normal volunteers or in opioid-dependent subjects (Nutt and Daglish, 2001). In healthy volunteers, the main areas of concentration of opioid receptors are found in the thalamus, caudate nucleus, and the temporal, frontal and parietal cortices (Jones *et al*., 1988). More specifically, the μ-opioid receptor is mainly represented in the thalamus, while the δ-opioid receptor is chiefly present in the putamen and caudate nucleus. It is essential to know that the number and distribution of opioid-binding sites vary with age and gender. The usual finding in the opioid system is that the density of binding sites may increase with age, but with significant differences throughout the brain, and also according to gender (Zubieta *et al*., 1999). PET studies in monkeys have shown that the elimination half-life of the opioids from the brain will depend upon their lipophilic characteristics. For ethical reasons, studies on the acute effects of opioids in healthy volunteers are rather limited. Fentanyl can cause an increase of rCBF in the anterior cingulate cortex and the prefrontal and orbitofrontal cortices, but a decrease in other areas (frontal, temporal, cerebellar) (Firestone *et al*., 1996). The increase of rCBF is already observed at rest but is still augmented by pain. The study by neuroimaging of the effects of acute doses in addicts is complicated by many practical problems. For example, in animal models, there are differences in effect, dependent on whether the drug is self-administered or not. If the subjects are opioid-free as a result of a recent detoxification, the ethics of a new administration of opioid have to be considered carefully. Even in chronic opioid addicts, the washout period of opioids from the brain can be extremely variable. Finally, the circumstances of drugs use can also influence the subjective effects and the neuroimaging results. When rCBF is measured by HMPAO SPECT in subjects who are currently abstinent or actively dependent, according to the nature of the opioid-receptor that is stimulated, a correlation between changes in rCBF and subjective effects can be demonstrated. 'Bad effects' could be associated with an increase in rCBF in the anterior temporal lobes, whereas euphoria is accompanied by increased rCBF in the anterior cingulate, thalamus and amygdala regions (Schlaepfer *et al*., 1998). By contrast, the measurements of regional cerebral metabolic rate of glucose are consistent with a widespread decease of cerebral metabolic activity throughout the majority of brain regions. The correlation between the subjective responses and the reduced cerebral activity is usually poor (London *et al*., 1990).

The next issue to be discussed is the chronic effects of these substances. It has been shown that hypoperfusion defects can be found following chronic use of cocaine or heroin. Ideally, the studies should be performed using high doses of opioids because opioid-dependent subjects develop tolerance. Due to practical and ethical problems, most of the paradigms are analysing the effects of methadone or buprenorphine substitution in a group of heroin-dependent individuals. Contrasting with the acute studies, a reduction in rCBF is observed in a population receiving chronic methadone treatment. The subjects who had higher methadone maintenance doses had smaller

decreases in perfusion (Danos *et al*., 1998). Interestingly, a different pattern could be observed with buprenorphine. In comparison with the placebo group that had worsening perfusion deficits following detoxification, there was a dose-dependent improvement in hypoperfusion for the subjects treated by buprenorphine (Holman *et al*., 1993). Methadone treatment is also able to influence the opioid-receptor availability. PET studies have illustrated that methadone could produce a decrease in the index of free-receptor density; no correlation was obtained with plasma methadone levels (Melichar *et al*., 1999).

Opioid withdrawal is also investigated by different neuroimaging techniques. In heroin-dependent subjects undergoing detoxification, HMPAO SPECT at one week revealed focal perfusion deficits, with a delayed improvement at three weeks (Rose *et al*., 1996). The interpretation of such results remains difficult, as the scans are usually obtained after the resolution of the withdrawal signs. In an other experimental model using the administration of an opioid antagonist (e.g. naloxone or naltrexone) to subjects maintained on methadone or buprenorphine, conflicting results regarding CBF changes (increase or decrease) have been published (van Dyck *et al*., 1994; Krystal *et al*., 1995). Finally, the involvement of the mesocortical-limbic system in the opioid reward system can be confirmed by both animal and human studies. There is increasing evidence that the nucleus accumbens is the main site of dopamine release (Wise *et al*., 1995).

3.11 Nicotine

There are a limited number of morphological date available regarding the structural brain damage induced by nicotine. In comparison with never-smokers, it was possible to demonstrate, in a study performed on 22 smokers, that there was a significantly smaller grey matter volume and lower grey matter density in the frontal regions (anterior cingulate, prefrontal and orbitofrontal cortices), the occipital lobe and the temporal lobe, including the parahippocampal gyrus (Gallinat *et al*., 2006).

Nicotine affects cognitive strategies on working memory tasks and improves attention and performance on working memory tasks. There are conflicting data on whether administration of nicotine increases or decreases CBF. When fMRI is used to investigate possible alterations in task-related activation as a result as nicotine use, it is not clearly demonstrated that the changes in CBF could be coupled to changes in neuronal activity (Murphy *et al*., 2006).

Nicotine may share with other substances neural circuits implicated in the processes of reinforcement. Nicotine also illustrates the importance of the manner in which the drug is delivered. Nicotine given intravenously or from cigarette smoking may result in a somewhat different pattern of increased rCBF. The increased rCBF that is observed in the frontal cortex and in the nicotine-receptor-rich reticular system of the pons, midbrain and thalamus is greater after inhalation rather than after intravenous administration. It appears also that dopamine release within the ventral striatum is observed in nicotine-dependent individuals when smoking a cigarette. By contrast, intravenous nicotine administration to nonhuman nondependent primates should only produce minor changes (Brody *et al*., 2004; Rose *et al*., 2003).

3.12 Metals

3.12.1 Manganese

Manganese is a well-identified neurotoxicant. Exposure to excessive amounts of manganese is associated with a variety of psychiatric or motor disturbances (parkinsonian symptoms). An increased signal in T1-weighted images was observed in experimental manganese poisoning in nonhuman primates. A similar MRI pattern has also been reported in workers exposed to manganese. There is a bilateral symmetrical increase in signal intensities that is confined to the globus pallidus and midbrain. However, it is essential to understand that the increased signal intensities reflect a target site, but not necessarily manganism. A reversibility is possible after cessation of professional exposure (Kim, 2006).

3.12.2 Methylmercury

Methylmercury poisoning may cause visual impairment and deafness, especially if exposure occurs prenatally. Children could also be particularly vulnerable after exposure to contaminated seafood. Electrophysiological investigations have revealed delays in EP latencies, and particularly of the peak III in BAEPs and of the N145 in pattern-reversal VEPs (Murata *et al*., 1999; 2007). EPs could therefore be considered as an objective method for assessing methylmercury toxicity. However, the clinical relevance of minimal changes following low-level methylmercury exposure is still debated.

3.12.3 Lead

As lead exposure impairs hearing and nerve conduction in the auditory system, there is also evidence that BAEPs could be affected in both children and adults. Some publications suggest that lead exposure could interfere with BAEPs in a dose-dependent manner (Bleecker *et al*., 2003).

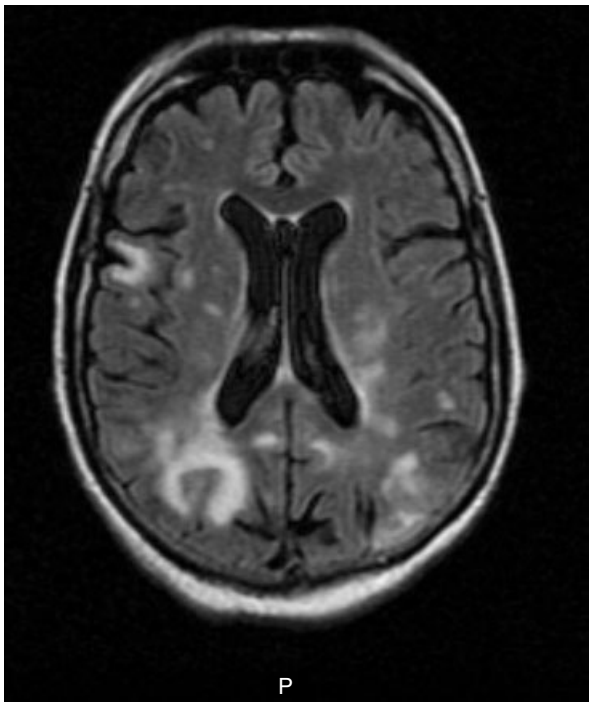

Figure 3 Brain MRI obtained in a 54-year-old patient admitted with coma. Recent medical history of heart transplantation. Immunosuppressive treatment with tacrolimus leading to excessive blood concentration after the progression of renal failure. FLAIR and T2-weighted sequences demonstrated hyperintense lesions bilaterally within the white matter in the frontal, parietal, temporal and occipital regions. The apparent diffusion coefficient (ADC) is increased in the corresponding areas. This is suggestive of vasogenic oedema.

3.13 Solvents

Organic solvents are responsible for chronic demyelinating lesions within the white matter. Hyperintensities on T1- and T2-weighted images are seen with trichloroethane in the lenticular nuclei, in the putamina and in the internal occipital region. Chronic exposure to toluene determines global corticosubcortical atrophy with changes also in the white matter and grey nuclei.

VEPs have also been used to investigate solvent-related encephalopathy (Verberk *et al*., 2004). A decrease of visual contrast sensitivity was confirmed by VEPs performed under specific experimental conditions ('low contrast').

3.14 Posterior Reversible Encephalopathy

Posterior reversible encephalopathy syndrome (PRES) was first identified in patients with eclampsia and in those who had undergone transplantation. The typical syndrome is combining headache, altered mentation, visual disturbance, severe hypertension and generalized seizures. The role of immunosuppressive drugs (cyclosporine, tacrolimus) or of some chemotherapy agents (methotrexate) has been discussed. The mechanisms behind this neurotoxic syndrome remain controversial. Disruption of the blood–brain barrier, with subsequent vasogenic oedema is one hypothesis (Lamy *et al*., 2004). The MRI pattern consists of hyperintensities in the T2-weighted and FLAIR sequences present in the subcortical white matter, and particularly in the parietal and occipital lobes (**Figure 3**). Involvement of the basal ganglia, brainstem or deep white matter is less common (Bartynski and Boardman, 2007).

Alternatives to *In vivo* Studies in Toxicology

Shayne C. Gad

CONTENTS

1 INTRODUCTION

The key assumptions underlying modern toxicology are: (i) that other organisms can serve as accurate predictive models of toxicity in man; (ii) that selection of an appropriate model to use is the key to accurate prediction of potential hazard in man and (iii) that understanding the strengths and weaknesses of any particular model is essential to translating potential hazards identified in these models to assess relevant hazard in man, and in the subsequent management of actual risks. The nature of models and their selection in toxicological research became the subject of critical scientific review starting in the 1980s. Usually in toxicology, when we refer to 'models', we really have meant test organisms or systems, although, in fact, the manners in which parameters are measured (and which parameters are measured to characterize an end point of interest) are also critical parts of the model (or, indeed, may actually constitute the 'model').

Although there have been accepted principles for test organism selection, these have not generally been the actual final basis for such selection. It is a fundamental hypothesis of both historical and modern toxicology that adverse effects caused by chemical entities in higher animals are generally the same as those induced by those entities in man. There are many who point to individual exceptions to this and conclude that the general principle is false. Yet, as our understanding of molecular biology advances and we learn more about the similarities of structure and function of higher organisms at the molecular level, the more it becomes clear that the mechanisms of chemical toxicity are largely identical in all higher life forms, including humans. The target sites are molecular, and differences in responses are all about similarities in receptor populations, receptor population distribution in organ systems, and in the manner and means of getting toxicophores to these sites or preventing them from reaching these sites. In this sense, it is now the age of translational toxicology. This increased understanding has caused some of the same people who question the general principle of predictive value to in turn suggest that our state of knowledge is such that mathematical models or simple cell culture systems could be used just as well as intact higher animals to predict toxicities in man. This last suggestion has unfortunately missed the point that the final expressions of toxicity in man or animals are frequently the summations of extensive and complex interactions on cellular and biochemical levels. Zbinden (1987) and Gad (1996) published extensively in this area, including a very advanced defence of the

value of animal models. Lijinsky (1988) has reviewed the specific issues about the predictive value and importance of animals in carcinogenicity testing and research. Although it was once widely believed, and may still be believed by many animal rights activists, that *in vitro* mutagenicity tests would entirely replace animal bioassays for carcinogenicity, this is clearly not the case on either scientific or regulatory grounds (despite the limitations of the current bioassay models). Although there are differences in the responses of various species (including man) to carcinogens, the overall predictive value of such results, when tempered by judgement, is clear. At the same time, a well-reasoned use of *in vitro* or other alternative test model systems is essential to the continued development of a product safety assessment programme that is effective, efficient and relevant to human safety (Gad, 1990a; 1996; 2002; 2007).

The subject of intact animal models and their proper selection and use has been addressed elsewhere (Gad, 2007) and will not be further addressed here. However, alternative models which use other than intact higher organisms are seeing increasing use in toxicology for a number of reasons.

The first and most significant factor behind the interest in so-called *in vitro* systems has clearly been philosophical and political—an unremitting campaign by a wide spectrum of individuals concerned with the welfare and humane treatment of laboratory animals (Singer, 1975), though some are also clearly simply antiscience and antitechnology. Russell and Burch (1959) first proposed what have come to be called the three Rs of humane animal use in research—replacement, reduction and refinement. These have served as the conceptual basis for reconsideration of animal use in research.

Replacement means utilizing methods that do not use intact animals in place of those that do. For example: veterinary students may use a canine cardiopulmonary-resuscitation simulator, Resusci-Dog, instead of living dogs; cell cultures may replace mice and rats that are fed new products to discover substances poisonous to humans. In addition, using the preceding definition of animal, an invertebrate (e.g. a horseshoe crab) could replace a vertebrate (e.g. a rabbit) in a testing protocol.

Reduction refers to the use of fewer animals. For instance, changing practices allow toxicologists to estimate the lethal dose of a chemical with as few as 1/10 the number of animals used in traditional tests. In biomedical research, long-lived animals, such as primates, may be used in multiple sequential protocols, assuming that they are not deemed inhumane or scientifically conflicting. Designing experimental protocols with appropriate attention to statistical inference can lead to decreases or to increases in the numbers of animals used. Through coordination of efforts among investigators, several tissues may be simultaneously taken from a single animal. Reduction can also refer to the minimization of any unintentionally duplicative experiments, perhaps through improvements in information resources.

Refinement entails the modification of existing procedures so that animals are subjected to less pain and distress. Refinements may include administration of anaesthetics to animals undergoing otherwise painful procedures; administration of tranquilizers for distress; humane destruction prior to recovery from surgical anaesthesia and careful scrutiny of behavioural indices of pain or distress, followed by cessation of the procedure or the use of appropriate analgesics. Refinements also include the enhanced use of noninvasive imaging technologies that allow earlier detection of tumours, organ deterioration or metabolic changes, and the subsequent early euthanasia of test animals.

Progress towards these first three Rs has been previously reviewed (Gad, 1990b; 1994; Salem, 1995; Salem, 1998; Gribaldo, 2007). However, there is a fourth R—responsibility, which was not in Russell and Burch's initial proposal. To toxicologists this is the cardinal R. They may be personally committed to minimizing animal use and suffering, and to doing the best possible science of which they are capable, but at the end of it all, toxicologists must stand by their responsibility to be conservative in ensuring the safety of the people using or exposed to the drugs and chemicals produced by our society.

Since 1980, issues of animal use and care in toxicological research and testing have become one of the fundamental concerns of both science and the public. Are our results predictive of what may or may not be seen in man? Are we using too many animals, and are we using them in a manner that gets the answer we need with as little discomfort to the animals as possible? How do we balance the needs of man against the welfare of animals?

During the same timeframe, interest and progress in the development of *in vitro* test systems for toxicity evaluations have also progressed. Early reviews by Hooisma (1982), Neubert (1982) and Williams *et al.* (1983) record the proceedings of conferences on the subject, but Rofe's (1971) review was the first found by this author. Although it is hoped that in the long term some of these (or other) *in vitro* methods will serve as definitive tests in place of those that use intact animals, at present it appears more likely that their use in most cases will be as screens. Frazier (1992), 1994 and Gad and Chengelis (1997) give recent overviews of the general concepts and status of *in vitro* alternatives.

The entire product-safety assessment process, in the broadest sense, is a multistage process in which none of the individual steps is overwhelmingly complex, but the integration of the whole process involves fitting together a large complex pattern of pieces. The single most important part of this product-safety evaluation

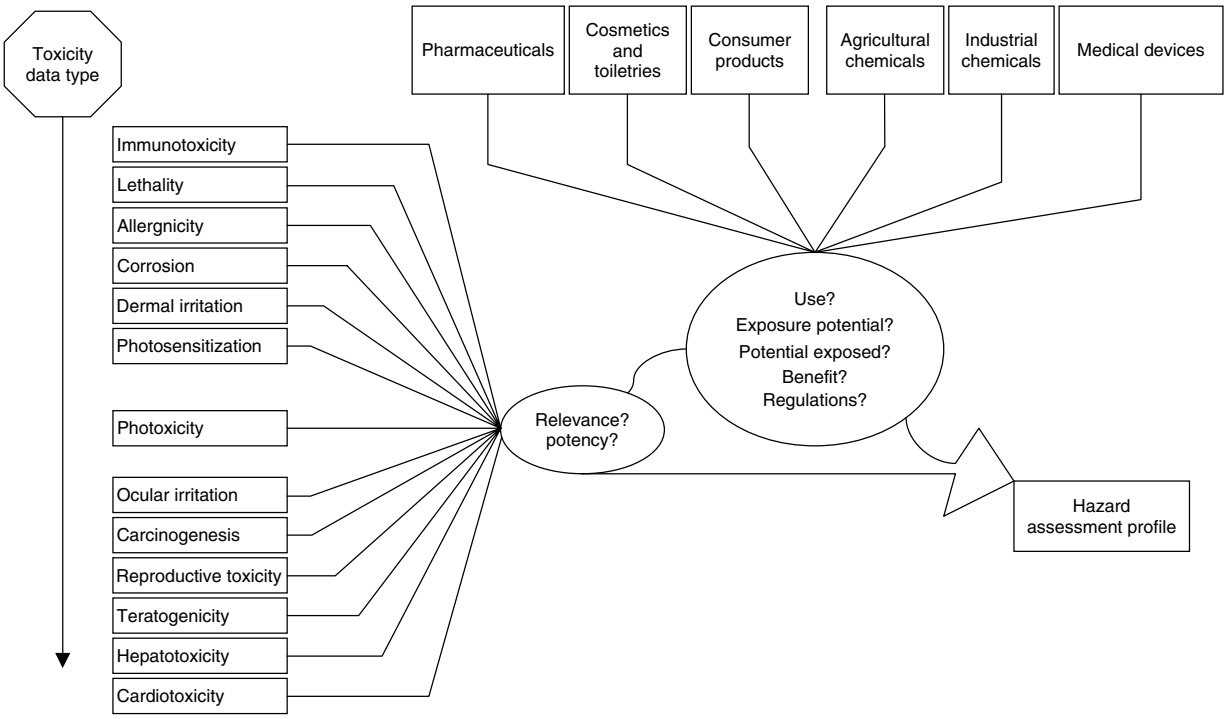

Figure 1 The hazards associated with a new product are a multidimensional problem depending on the product's intended use, its innate toxicity, its physiochemical properties, and the potential human and environmental exposure. This matrix diagrammatically illustrates the key questions involved in developing the final hazard assessment profile. There is also the special case of pharmaceutical and pesticide products, where there are regulatory mandated minimum test batteries.

programme is, in fact, the initial overall process of defining and developing an adequate data package on the potential hazards associated with the product life-cycle (the manufacture, sale, use and disposal of a product and associated process materials). To do this, one must ask a series of questions in a highly interactive process, with many of the questions designed to identify and/or modify their successors. The first is—what information is needed?

Required here is an understanding of the way in which a product is to be made and used, and the potential health and safety risks associated with exposure of humans who will be associated with these processes. Such an understanding is the basis of a hazard and toxicity profile. Once such a profile has been established (as illustrated in **Figure 1**), the available literature is searched to determine what is already known.

Taking into consideration this literature information and the previously defined exposure profile, a tier approach (**Table 1**) has traditionally been used to generate a list of tests or studies to be performed. What goes into a tier system is determined by regulatory requirements imposed by government agencies, as well as the philosophy of the parent organization, economics and available technology. How such tests are actually performed is determined on one of two bases. The first (and most common) is the menu approach: selecting a series of standard design tests as 'modules' of data. The second is an interactive/iterative approach, where strategies are developed and studies are designed, based on both needs and what has been learned to date about the product. This process has been previously examined in some detail. Our interest here, however, is in the specific portion of the process involved in generating data—the test systems.

2 TEST SYSTEMS: CHARACTERISTICS, DEVELOPMENT AND SELECTION

Any useful test system must be sufficiently sensitive to ensure that the incidence of false negatives is low. Clearly a high incidence of false negatives is intolerable. In such a situation, large numbers of dangerous chemical agents would be carried through extensive additional testing only for it to be found that they possess undesirable toxicological properties after the expenditure of significant time and money. One the other hand, a test system that is overly sensitive will give rise to a high incidence of false positives, which will have the deleterious consequence of rejecting potentially beneficial chemicals. The 'ideal' test will fall somewhere between

Table 1 The usual way of characterizing the toxicity of a compound or product is to develop information in a tier approach manner. More information is required (a higher tier level is attained) as the volume of production and potential for exposure increase. A common scheme is shown

Tier Testing			
Testing tier	Mammalian Toxicology	Genetic Toxicology	Remarks
0	Literature review	Literature review	Upon initial identification of a problem, database of existing information and particulars of use of materials are established.
1	Cytotoxicity screens GPMT or LLNA Acute systemic toxicity Receptor binding i.e., hERG	Ames test *In vitro* SCE *In vitro* cytogenetics Comet assay	R&D material and low-volume chemicals with severely limited exposure.
2	Subacute studies ADME Primary dermal irritation Safety pharmacology Eye irritation	*In vivo* SCE *In vivo* cytogenetics	Medium-volume materials and/or those with a significant chance of human exposure.
3	Subchronic studies Reproduction Developmental toxicity Chronic studies Mechanistic studies	K	Any materials with a high volume or a potential for widespread or long-term human exposure or one that gives indications of specific long-term effects.

these two extremes and thus provide adequate protection without unnecessarily stifling development.

The 'ideal' test should have an end-point measurement that provides data such that dose–response relationships can be obtained. Furthermore, any criterion of effect must be sufficiently accurate in the sense that it can be used reliably to resolve the relative toxicity of two test chemicals that produce distinct (in terms of hazard to humans), yet similar responses. In general, it may not be sufficient to classify test chemicals into generic toxicity categories. For instance, if a test chemical falls into an 'intermediate' toxicity category, yet is borderline to the next more severe toxicity category, it should be treated with more concern than a second test chemical that falls at the less toxic extreme of the same category. Therefore, it is essential for a test system to be able to both place test chemicals in an established toxicity category and rank materials relative to others in the category.

The end-point measurement of the 'ideal' test system must be objective. This is important, to ensure that a given test chemical will give similar results when tested using the standard test protocol in different laboratories. If it is not possible to obtain reproducible results in a given laboratory over time or between various laboratories, then the historical database against which new test chemicals are evaluated will be time/laboratory-dependent. If this condition is the case, then there will be significant limitations on the application of the test system since it could potentially produce conflicting results. From a regulatory point of view this possibility would be highly undesirable. Along these lines, it is important for the test protocol to incorporate internal standards to serve as quality controls (QCs). Thus, test data could be represented utilizing a reference scale based on the test system response to the internal controls. Such normalization, if properly documented, could reduce interest variability.

From a practical point of view, there are several additional features of the 'ideal' test which should be satisfied. Alternatives to current *in vivo* test systems basically should be designed to evaluate the observed toxic response in a manner as closely predictive of the outcome of interest in man as possible. In addition, the test should be fast enough to ensure that the turnaround time for a given test chemical is reasonable for the intended purpose, very rapid for a screen, timely for a definitive test. Obviously the speed of the test and the ability to conduct tests on several chemicals simultaneously will determine the overall productivity. The test should be inexpensive, so that it is economically competitive with current testing practices. And finally, the technology should be easily transferred from one laboratory to another without excessive capital investment (relative to the value of the test performed) for test implementation.

It should be kept in mind that although some of these practical considerations may appear to present formidable limitations for any given test system at the present time, the possibility of future developments in testing technology could overcome these obstacles. In reality, these practical considerations are grounds for consideration of multiple new candidate tests on the basis

Table 2 Rationale for using *in vivo* test systems

1. Provides evaluation of actions/effects on intact animal organ–tissue interactions.
2. Either neat chemicals or complete formulated products (complex mixtures) can be evaluated.
3. Either concentrated or diluted products can be tested.
4. Yields data on the recovery and healing processes.
5. Required statutory tests for agencies under such laws as the Federal Hazardous Substances Act (unless data are already available), Toxic Substances Control Act, Federal Insecticides, Fungicides and Rodenticides Act (FIFRA), Organization for Economic Cooperation (OECD) and Food and Drug Administration Laws.
6. Quantitative and qualitative tests with scoring systems generally capable of ranking materials as to relative hazards.
7. Amenable to modifications to meet the requirements of special situations (such as multiple dosing or exposure schedules).
8. Extensive available database and cross-reference capability for evaluation of relevance to human situation.
9. The ease of performance and relative low capital costs in many cases.
10. Test are generally both conservative and broad in scope, providing for maximum protection by erring on the side of over prediction of hazard to man.
11. Tests can be either single end point (such as lethality, corrosion, etc.) or shot-gun (also called multiple end point, including such test systems as a 13 week oral toxicity study).

of competitive performance. The most predictive test system in the universe of possibilities will never gain wide acceptance if it takes years to produce an answer or costs substantially more than other test systems that are only marginally less predictive.

The point is that these characteristics of the 'ideal' test system provide a general framework for evaluation of alternative test systems in general. No test system is likely to be 'ideal'. Therefore, it will be necessary to weigh the strengths and weaknesses of each proposed test system in order to reach a conclusion on how 'good' a particular test is.

In both theory and practice, *in vivo* and *in vitro* tests have potential advantages. **Tables 2** and **3** summarize these advantages. How, then, might the proper tests be selected, especially in the case of the choice of staying with an existing test system or adopting a new one? The next section will present the basis for selection of specific tests.

3 CONSIDERATIONS IN ADOPTING NEW TEST SYSTEMS

Any new test system starts out promising advantages in every way over previous systems. Over time, however, the scientific community comes to recognize the strengths and weaknesses of what may turn out to be a valuable tool in the overall field of risk 'identification, assessment and management'. Conducting toxicological investigations in two or more species of laboratory animals

Table 3 Limitations of *in vivo* testing systems which serve as a basis for seeking *in vivo* alternatives for toxicity tests

1. Complications and potential confounding or masking findings of *in vivo* systems.
2. *In vivo* systems may only assess short-term site of application or immediate structural alterations produced by agents. Specific *in vivo* tests may only be intended to evaluate acute local effects (i.e. this may be a purposeful test system limitation).
3. Technician training and monitoring are critical (particularly in view of the subjective nature of evaluation).
4. *In vivo* tests in animals do not perfectly predict results in humans if the objective is to exclude or identify severe-acting agents.
5. Structural and biochemical differences between test animals and humans make extrapolation from one to the other difficult.
6. Lack of standardization of *in vivo* systems.
7. Variable correlation with human results.
8. Large biological variability between experimental units (i.e. individual animals).
9. Large, diverse and fragmented databases which are not readily comparable.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat043

remains the generally accepted standard as the prudent and responsible practice in evaluating the systemic toxicity of a new chemical, entity, especially one that is expected to receive widespread use and to have exposure potential over human lifetimes.

But this paradigm—and that one of the species needs to be (or even should) be a mouse is now widely open to question. Adding a second or third species to the testing regimen offers an extra measure of confidence to the toxicologist and the other professionals who will be responsible for evaluating the associated risks, benefits and exposure limitations or protective measures. Although undoubtedly broadening and deepening a compound's profile of toxicity, the practice of enlarging on the number of test species is an indiscriminate scientific generalization, as has been demonstrated in multiple points in the literature (Gad and Chengelis, 1997). Moreover, such a tactic is certain to generate the problem of species-specific toxicosis. This is defined as a toxic response or an inordinately low biological threshold for toxicity that is evident in one species or strain, while all other species examined are either unresponsive or strikingly less sensitive. Species-specific toxicosis usually implies that either different metabolic pathways for converting or excreting xenobiotics or anatomical differences are involved. The investigator confronting such findings must be prepared to address the all-important question, 'Are humans likely to react positively or negatively to the test agent under similar circumstances?' Assuming that numerical odds prevail and that humans automatically fit into the predominant category would be scientifically irresponsible, whether on the side of being safe or at risk. Such a confounded situation can be an opportunity to advance more quickly into the heart of the search for predictive information. A species-specific toxicosis can frequently contribute towards a better understanding of the general case if the underlying biological mechanism either causing or enhancing toxicity is defined, and especially if it is discovered to uniquely reside in the sensitive species.

The design of our current tests appears to serve society reasonably well (i.e. significantly more times than not) in identifying hazards that would be unacceptable. However, the process can just as clearly be improved from the standpoint of both improving our protection of society and doing necessary testing in a manner that uses fewer animals in a more humane manner.

4 *IN VITRO* MODELS

In vitro models, at least as screening tests, have been in use in toxicology since the early 1980s. The last 20+ years have brought a great upsurge in interest in such models. This increased interest is due to economic and animal welfare pressures and technological improvements.

Criteria against which an *in vitro* model should be evaluated for its suitability in replacing (partially or entirely) an accepted *in vivo* model are incorporated in the process detailed in **Table 4**, which presents the proposed steps for taking a new *in vitro* testing technology from being a research construct to a validated and accepted test system.

There are substantial potential advantages in using an *in vitro* system in toxicological testing, which include isolation of test cells or organ fragments from homeostatic and hormonal control, accurate dosing and quantification of results. It should be noted that, in addition to the potential advantages, *in vitro* systems per se also have a number of limitations, which can contribute to there not being acceptable models. Findings from an *in vitro* system that either limit their use in predicting *in vivo* events or make them totally unsuitable for the task include wide differences in the doses needed to produce effects, or differences in the effects elicited. Some reasons for such findings are detailed in **Table 5**.

Tissue culture has the immediate potential to be used in two very different ways by industry. First, it has been used to examine a particular aspect of the toxicity of a compound in relation to its toxicity *in vivo* (i.e. mechanistic or explanatory studies). Second, it has been used as a form of rapid screening to compare the toxicity of a group of compounds for a particular form of response. Indeed, the pharmaceutical industry has used *in vitro* test systems in these two ways for years in the search for new potential drug entities.

The theory and use of screens in toxicology have previously been reviewed (Gad, 1988a; 1988b; 1989a; 1989b). Mechanistic and explanatory studies are generally called for when a traditional test system gives a result that is either unclear or is one for which the relevance to real-life human exposure is doubted. *In vitro* systems are particularly attractive for such cases because they can focus on very defined single aspects of a problem or pathogenic response, free of the confounding influence of the multiple responses of an intact higher-level organism. Note, however, that first one must know the nature (indeed the existence) of the questions to be addressed. It is then important to devise a suitable model system which is related to the mode of toxicity of the compound.

There is currently much controversy over the use of *in vitro* test systems—will they find acceptance as 'definitive tests systems' or only be used as preliminary screens for such final tests? Or, in the end, not be used at all? Almost certainly, all three of these cases will be true to some extent. Depending on how the data generated are to be used, the division between the first two is ill-defined at best.

Before trying to definitely answer these questions in a global sense, each of the end points for which *in vitro*

Table 4 Multistage scheme for the development, validation and transfer of *in vitro* test system technology in toxicology

STAGE I: STATEMENT OF TEST OBJECTIVE
(A) Identify existing test system and its strengths and weaknesses.
(B) Clearly state objectives for alternative test system.
(C) Identify potential alternative test system.

STAGE II: DEFINE DEVELOPMENTAL TEST DESIGN
(A) Identify relevant variables.
(B) Optimize test performance.
(C) Understand what the test does in a functional sense.
1. Is it a simulation of an *in vivo* event?
2. Is this simply a response to the presence of the agent?
3. Is the measured response a functional step or link in the *in vivo* event of interest?
4. Is the measured response a functional step or link in the *in vivo* event of interest or some intermediate stage?
5. Is this an effect on some structure or function analogous to the *in vivo* structure or function?

STAGE III: EVALUATE PERFORMANCE OF OPTIMUM TEST
(A) Develop library of known positive- and negative-response materials of diverse structure and a range of response potencies (i.e. if the end point is irritation, then materials should range from nonirritating to severely irritating).
(B) Use optimum test design to evaluate the library of 'knowns' under 'blind' conditions.
(C) Compare correlation of test results with those of other test systems and with real cases of interest—results in humans.

STAGE IV: TECHNOLOGY TRANSFER
(A) Present and publish results through professional media (at society meetings, in peer-reviewed journals).
(B) Provide hands-on training to personnel from other facilities and facilitate internal evaluations of test methods.

STAGE V: VALIDATION
(A) Arrange for test of coded samples in multiple laboratories (i.e. interlaboratory validation).
(B) Compare, present and publish results.
(C) Gain regulatory acceptance.

STAGE VI: CONTINUE TO REFINE AND EVALUATE TEST SYSTEM PERFORMANCE AND UTILIZATION
(A) Continually strive for an understanding of why the test 'works' and its relevance to effects in man.
(B) Remain skeptical. Why should any one of us be the one to make the big breakthrough? Clearly, there is some basic flaw in the design or conduct of the study which has given rise to these promising results. Doubt, check and question; let your most severe critic review the data; go to a national meeting and give a presentation; then go back home and doubt, check and question some more!

STAGE VII: REGULATORY ACCEPTANCE AND ADAPTATION
(A) Accepted use will first be side by side with existing system, which it will come to supplant.
(B) It will be modified in use as practical factors reveal means of optimization.

Table 5 Possible interpretations when *in vitro* data do not predict results of *in vivo* studies

1. Chemical is not absorbed at all or is poorly absorbed in *in vivo* studies.
2. Chemical is well absorbed, but is subject to 'first-pass effect' in the liver.
3. Chemical is distributed so that less (or more) reaches the receptors than would be predicted on the basis to its absorption.
4. Chemical is rapidly metabolized to an active or inactive metabolite that has a different profile of activity and/or different duration of action from that of the parent drug.
5. Chemical is rapidly eliminated (e.g. through secretory mechanisms).
6. Species of the two test systems used are different.
7. Experimental conditions of the *in vitro* and *in vivo* experiments differ and may have led to different effects from those expected. These conditions include factors such as temperature or age, sex and strain of animal.
8. Effects elicited *in vitro* and *in vivo* by the particular test substance in question differ in their characteristics.
9. Tests used to measure responses may differ greatly for *in vitro* and *in vivo* studies, and the types of data obtained may not be comparable.
10. The *in vitro* study did not use adequate controls (e.g. pH, vehicle used, volume of test agent given, samples taken from sham-operated animals), resulting in 'artefacts' of method rather than results.
11. *In vitro* data cannot predict the volume of distribution in central or in peripheral compartments.
12. *In vitro* data cannot predict the rate constants for chemical movement between compartments.
13. *In vitro* data cannot predict the rate constants of chemical elimination.
14. *In vitro* data cannot predict whether linear or nonlinear kinetics will occur with specific dose of a chemical *in vivo*.
15. Pharmacokinetic parameters (e.g. bioavailability, peak plasma concentration, half-life) cannot be predicted solely on the basis of *in vitro* studies.
16. *In vivo* effects of chemical are due to an alteration in the higher-order integration of an intact animal system, which cannot be reflected in a less complex system.

systems are being considered should be overviewed and considered against the factors outlined to this point.

5 LETHALITY

Many of the end points of interest in toxicology present a fundamental limitation to the development and use of an *in vitro* or nonmammalian system in place of established *in vivo* methods. While cytotoxicity is a component mechanism in many of these toxic responses, disruption or diminution of the integrated function of multiple cells and systems is just as important.

The evaluation of lethality (symbolized in the public mind by the LD_{50} test) would seem to offer a unique opportunity for the development and use of alternatives. Approaches to alternatives for lethality testing include no living materials at all (the structure–activity relationship (SAR) or computer model approaches), those that use no intact higher organisms (but rather cultured cells or bacteria) and those that use lower forms of animal life (invertebrates and fish, for example). Each of these approaches presents a different approach to the objective of predicting acute lethality in humans or, rarely, economic animals, and will be examined in turn.

There are systems that do not directly use any living organisms but, rather, seek to predict the lethality (in particular, the LD_{50}) of a chemical on the basis of what is known about structurally related chemicals. Such SAR systems have improved markedly over the last 10 years (Enslein *et al*., 1983a; Lander *et al*., 1984), but are still limited. Accurate predictions are usually possible only for those classes of structures where data have previously been generated on several members of the classes. For new structural classes, the value of such predictions in minimal. Accordingly, this approach is valuable when working with analogues in a series, but not for novel structures. It is also a strong argument for getting as many data as possible into the published literature.

A more extensive and once promising approach has been the use of various cultured cell systems. Kurack *et al*. (1986), for example, have developed and suggested a system based on cultured mammalian hepatocytes. The system does metabolize materials in a manner like mammalian target species, and has shown promise in a limited battery of chemicals. Such mammalian cell culture and bacterial screening systems have significant weaknesses for assessing the lethality of many classes of chemicals, since they lack any of the integrative functions of a larger organism. Thus, they would miss all agents that act by disrupting functions, such as the organophosphate pesticides, most other neurologically mediated lethal agents and agents that act by modifying hormonal or immune systems.

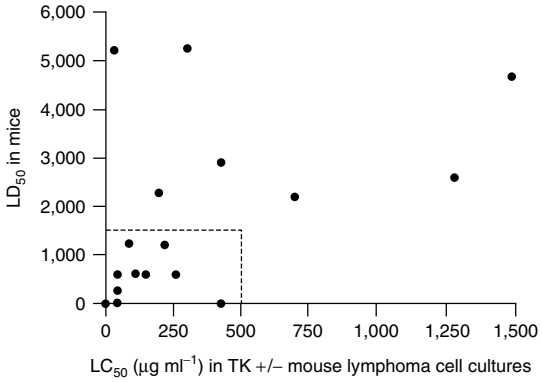

Figure 2 Graph showing a comparison of the lethalities of a group of 18 drugs of diverse structure in *in vivo* (mouse) and *in vitro* (cultured mouse lymphoma cells) test systems. Correlation of these LD_{50}/LC_{50} values is very poor, though extreme high- and low-scale values seem to be more closely associated in the two systems.

Clive *et al*. (1979) have reported on the correlation of the LC_{50}s of a variety of chemicals in mouse lymphoma cell cultures with their oral LD_{50}s in mice, as shown in **Figure 2**. No linear correlation is present, but highly cytotoxic substances (in this group) are significantly more toxic orally. Given the impression of some LD_{50} values, due to such factors as steepness of slope of the lethality curve, the lack of linear correlation should be no surprise. Most recently, Ekwall *et al*. (1989) have reported on the Multicenter Evaluation of *In Vitro* Cytotoxicity (MEIC) programme system, which utilizes a battery of five cellular systems. For a group of 10 chemicals, the system provided good correlation with, or predictive power of, rat LD_{50}s.

Recently Parce *et al*. (1989) reported on a biosensor technique in which cultured cells are confined to a flow chamber through which a sensor measures the rate of production of acidic metabolites. It is proposed to use this as a functional measure of cytotoxicity and as a screening technique for a number of uses, including *in vivo* lethality.

Three lower species of intact animals have been proposed for use in screening or testing of the lethal effects of chemicals. First, some researchers have shown a good correlation between the LD_{50} of the same chemicals in rats. This correlation is nonlinear, but still suggests that more toxic materials could be at least initially identified and classified in some form of screening system based on *Daphnia*. A broader range of chemical structures will need to be evaluated, however, and some additional laboratories will need to confirm the findings. It must also be kept in mind that the metabolic systems and many of the other factors involved in species differences (as presented in Gad and Chengelis, 1988; 1992; Gad, 2006) contribute to a nonlinear correlation and may also make the confidence in prediction of human effects in cases somewhat limited.

Earthworms have been one of the more common species used to test chemicals for potential hazardous impact on the environment. The 48 hour contrast test has proved to be a fast and resource-effective way of assessing acute toxicity of chemicals in earthworms and is outlined in **Table 6**. The standardized method, approved by the EEC, is discussed by Neuhauser *et al*. (1986). This test is for environmental impact assessment where crosslaboratory comparisons are important. If, however, one wishes to adopt this technology for the purpose of screening new chemicals or releasing batches of antibiotics, then variants of this method may be acceptable, as internal consistency is more important than interlaboratory comparisons. There are two important considerations. First, because of seasonal variations in the quality of earthworms obtained from suppliers, positive controls or comparator chemicals should be

Table 6 Earthworm 48 hour contact test—acute lethality

1. Place filter paper of known size (9 cm or 12 × 6.7 cm) in a Petri dish or standard scintillation vial.
2. Dilute test article in acetone or some other volatile solvent.
3. Slowly and evenly deposit known amounts of test article solution onto filter paper.
4. Dry thoroughly with air or nitrogen gentle stream.
5. Add 1.0 ml of distilled water to filter paper.
6. Add worm (*L. rubellus*). Use 400–500 mg body weight range.
7. Ten replicate vials per concentration.
8. Store/incubate in the absence of light at 15–20 °C for 48 h.
9. Examine for lethality (swollen, lack of movement upon warming up to room temperature, lack of response to tactile stimulation).
10. Express dose as μg cm^{-2} and mortality as usual. Calculate LD_{50} using standard techniques.
11. Always include negative and positive (benchmark) controls.

Table 7 Earthworm toxicity—toxicity rating

Rating	Designation	Rat LD_{50} (mg kg^{-1})	*Eisenia foetida* LC_{50} (μg cm^{-2})
1	Supertoxic	<5	<1.0
2	Extremely toxic	5–50	1.0–10
3	Very toxic	50–500	10–100
4	Moderately toxic	500–5000	100–1000
5	Relatively nontoxic	>5000	>1000

From Neuhauser *et al*. (1985a, 1985b).

included on every assay run. Second, distilled water must be used, as worms are quite sensitive to contaminants that may occur in chlorinated water. The filter paper should completely cover the sides of the vessel; otherwise the worms will simply crawl up the sides to escape the adverse stimulus the chemical contact may provide.

Using these techniques, Roberts and Dorough (1985) and Neuhauser *et al*. (1986) have compared acute toxicity in a variety of organic chemicals in several earthworm species. While there are some obvious differences between worm species, in general the rank order of toxicity is about the same. *Lumbricus rubellus* tends to be the most sensitive species. All earthworms are very sensitive to carbofuran under the conditions of this test. Neuhauser *et al*. (1985a, 1985b) have proposed a toxicity-rating scheme based on acute lethality in the earthworms which is similar to the more familiar scheme based on acute lethality in rodents (**Table 7**). Roberts and Dorough (1985) and Neuhauser *et al*. (1986) have published extensive compilations of acute lethality in worms and compared these with acute lethality in rats and mice. A selection of these is shown in **Table 8**. Applying the rating scheme of Neuhauser, most chemicals receive about the same toxicity rating based on results in *Eisenia foetida* and mice. This may suggest that replacing the LD_{50} with the LC_{50} for rating toxicity (for transportation permits, for example) deserves serious consideration.

The main advantages of the 48 hour contact test are the savings of time and money. The cost savings fall into three categories. First, earthworms are cheap. One hundred *L. rubellus* will cost about US$2.00. The 100 mice they could replace in screens and QC testing, for example, would cost $300–400 (€150–200 at an exchange rate of $2.00 = €1.00). Second, earthworms require no vivarium space, and their use could reduce the number of rodents used, resulting in a net decrease in vivarium use. Third, adapting the 48 hour contact test would require little capital investment, other than a dedicated under-the-counter refrigerator set as 15–20 °C. Otherwise, the assay can be easily performed in a standard biochemistry laboratory. With regard to time savings, the standard lethality test with rodents requires 7–14 days of postdosing observations. The 48 hour contact test is completed in 48 hours. Not only is the turnaround time faster, but also the amount of time that technical personnel will have to spend observing animals and recording observations will be reduced. An incidental advantage of earthworms is that they are cold-blooded invertebrates, and thus as exempt from current animal welfare laws.

Table 8 Earthworm acute lethality—comparative values

Chemical	*Eisenia foetida* (LC_{50})	Mouse (LD_{50})
2,4-Dinitrophenol	0.6 (1)	45 (2)
Carbaryl	14 (3)	438 (3)
Benzene	75 (3)	4 700 (4)
1,1,1-Trichloroethane	83 (3)	11 240 (5)
Dimethylphthalate	550 (4)	7 200 (5)

There are two main disadvantages to the use of earthworms in acute toxicity testing. First, there are a limited number of end points. Other than death and a few behavioural abnormalities (Stenersen, 1979; Drewes *et al*., 1984), the test does not yield much qualitative information. Second, there probably is some institutional bias. Because the test is basically low-technology (no tissue culture) and uses a nonmammalian model, it may be easy to dismiss the utility of the test.

Finally, the use of smaller species of fish as a surrogate for man has gained some supporters. Currently, the zebra fish has shown significant promise as a surrogate model for mammalian species toxicity (Hill *et al*., 2005; Chiu *et al*., 2008; Tanguay and Reimers, 2008) and as a screen for carcinogens (Stern and Zon, 2003; Berghmans *et al*., 2005). There is certainly no reason why they could not be used for screening water-soluble compounds for extreme acute toxicity.

Although the intact organisms would seem to be the most utilitarian on the face of it, they still will not totally replace mammalian systems, owing to the need to be concerned about those systems that are significantly different in higher organisms. Still, it would appear that for those compounds for which human exposure is not intentional, testing in an intact lower organism systems (or perhaps

Table 9 Rationales for seeking *in vitro* alternatives for eye irritancy tests

1.	Avoid whole animal and organ *in vivo* evaluation.
2.	Strict Draize scale testing in the rabbit assesses only three eye structures (conjuctiva, cornea, iris) and traditional rabbit eye irritancy tests do not assess cataracts, pain, discomfort or clouding of the lens.
3.	*In vivo* tests assess only inflammation and immediate structural alterations produced by irritants (not sensitizers, photoirritants or photoallergens). Note, however, that the test was (and generally is) intended to evaluate any pain or discomfort.
4.	Technician training and monitoring are critical (particularly in view of the subjective nature of evaluation).
5.	Rabbit eye tests do not perfectly predict results in humans, if the objective is either the total exclusion of irritants or the identification of truly severe irritants on an absolute basis (that is without false positives or negatives). Some (such as Reinhardt *et al*., 1985) have claimed that these tests are too sensitive for such uses.
6.	There are structural and biochemical differences between rabbit and human eyes which make extrapolation from one to the other difficult. For example, Bowman's membrane is present and well developed in man (8–12 μm thick) but not in the rabbit, possibly giving the cornea greater protection.
7.	Lack of standardization.
8.	Variable correlation with human results.
9.	Large biological variability between experimental units.
10.	Large, diverse and fragmented databases which are not readily comparable.

even in a cell culture system) should be sufficient to identify agents of significant concern. In these cases, lethality testing in intact mammals is probably unwarranted.

5.1 Ocular Irritation

Testing for potential to cause irritation or damage to the eyes remains the most active area for the development (and validation) of alternatives, and the most sensitive area of animal testing in biomedical research. This has been true since the beginning of the 1980s. **Table 9** presents an overview of the reasons for pursuing such alternatives. The major reason, of course, has been the pressure from public opinion.

Indeed, many of the *in vitro* tests now being evaluated for other end points (such as skin irritation and lethality) are adaptations of test systems first developed for eye irritation uses. A detailed review of the underlying theory of each test system is beyond the scope of this chapter. Frazier *et al*. (1987) and Gad (2007) performed such reviews, and **Table 10** presents an updated version of the list of test systems overviewed in those volumes.

There are six major categories of approach to *in vitro* eye irritation tests. Because of the complex nature of the eye, the different cell types involved and interactions between them, it is likely that a successful replacement for existing *in vivo* systems (such as the rabbit) would require some form of battery of such test systems. Many individual systems, however, might constitute effective screens in defined situations. The first five of these aim at assessing portions of the irritation response, including alterations in tissue morphology, toxicity to individual component cells or tissue physiology, inflammation or immune modulation, and alterations in repair and/or recovery processes. These methods have the limitation that they assume that one of the component parts can or will predict effects in the complete organ system. While each component may serve well to predict the effects of a set of chemical structures which determine part of the ocular irritation response, a valid assessment across a broad range of structures will require the use of a collection or battery of such tests.

The sixth category contains tests that have little or no empirical basis, such as computer-assisted SAR models. These approaches can only be assessed in terms of how well or poorly they perform. **Table 11** presents an overview of all six categories and some of the component tests within them, updated from the assessment by Frazier *et al*. (1987) along with references for each test.

Given that there are now some 80 or more potential *in vitro* alternatives, the key points along the route to the eventual objective of replacing the *in vivo* test systems are thus: (i) how do we select the best candidates from this pool?; (ii) how do we want to use the resulting system (as a screen or test)?; (iii) how do we gain regulatory and user acceptance of the appropriate test systems?

MORPHOLOGY
Enucleated superfused rabbit eye system (Burton *et al*., 1981).
Balb/c 3T3 cells/morphological assays (HTD) (Borenfreund and Puerner, 1984).
CELL TOXICITY
Adhesion/cell proliferation
BHK cells/growth inhibition (Reinhardt *et al*., 1985).
BHK cells/colony formation efficiency (Reinhardt *et al*., 1985).
BHK cells/cell detachment (Reinhardt *et al*., 1985).
SIRC cells/colony forming assay (North-Root *et al*., 1982).
Balb/c 3T3 cells/total protein (Shopsis and Eng, 1985).
BCL/D1 cells/total protein (Balls and Horner, 1985).
Primary rabbit corneal cells/colony forming assay (Watanabe *et al*., 1988).
Membrane integrity
LS cells/dual dye staining (Scaife, 1982).
Thymocytes/dual fluorescent dye staining (Aeschbacher *et al*., 1986).
LS cells/dual dye staining (Kemp *et al*., 1983).
RCE-SIRC-P815-YAC-1/Cr release (Shadduck *et al*., 1985).
L929 cells/cell viability (Simons, 1981).
Bovine red blood cell/haemolysis (Shadduck *et al*., 1987).
Mouse L929 fibroblasts-erythrocin C staining (Frazier, 1988).
Rabbit corneal epithelial and endothelial cells/membrane leakage (Meyer and McCulley, 1988).
Agarose diffusion (Barnard, 1989).
Corneal protein profiles (Eurell and Meachum, 1994).
Cell metabolism
Rabbit corneal cell cultures/plasminogen activator (Chan, 1985).
LS cells/ATP assay (Kemp *et al*., 1985).
Balb/c 3T3 cells/neutral red uptake (Borenfreund and Puerner, 1984).
Balb/c 3T3 cells/uridine uptake inhibition assay (Shopsis and Sathe, 1984).
HeLa cells/metabolic inhibition test (MIT-24) (Selling and Ekwall, 1985).
MDCK cells/dye diffusion (Tchao, 1988).
CELL AND TISSUE PHYSIOLOGY
Epidermal slice/electrical conductivity (Oliver and Pemberton, 1985).
Rabbit ileum/contraction inhibition (Muir *et al*., 1983).
Bovine cornea/corneal opacity (Muir, 1984).
Proposed mouse eye/permeability test (Maurice and Singh, 1986).
INFLAMMATION/IMMUNITY
Chlorioallantonic membrane (CAM)
CAM (Leighton *et al*., 1983).
HET-CAM (Luepke, 1985).
Bovine corneal cup model/leucocyte chemotactic factors (Elgebaly *et al*., 1985).
Rat peritoneal cells/histamine release (Jacaruso *et al*., 1985).
Rat peritoneal mast cells/serotonin release (Dubin *et al*., 1984).
Rat vaginal explant/prostaglandin release (Dubin *et al*., 1984).
Bovine eye cup/histamine (Hm) and leukotriene C4 (Lt/C4) release (Benassi *et al*., 1986).
RECOVERY/REPAIR
Rabbit corneal epithelial cells-wound healing (Jumblatt and Neufeld, 1985).
OTHER
EYTEX assay (Gordon and Bergman, 1986; Soto *et al*., 1988).
Computer-based structure-activity (SAR) (Enslein, 1984; Enslein *et al*., 1988).
Tetrahymena/motility (Silverman, 1983).

SAR model	NA	No	Firestone and Guy (1986)

[a]Evaluated by comparison of predictive accuracy for a range of compounds compared with animal test results. Not validated in the sense used in this chapter.
NA = not available.

There have been some large-scale validations of some of these tests (IRAG, 1993). Most of the individual investigators have performed smaller 'validations' as part of their development of the test system, and in a number of cases trade associations have sponsored comparative and/or multilaboratory validations. At least for screening, several systems should be appropriate for use and, in fact, are used now by several commercial organizations. But the Interagency Regulatory Alternatives Group (IRAG, 1993) and the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM, 1997) have coordinated and reported on large-scale evaluations. In terms of use within defined chemical structural classes, use of *in vitro* systems for testing of chemicals for nonhuman exposure should supplant traditional *in vivo* systems once validated on a broad scale by multiple laboratories. Broad use of single tests based on single end points

(such as cytotoxicity) is not likely to be successful, as demonstrated by such efforts as those of Kennah *et al*. (1989).

5.2 Dermal Irritation

Extensive progress has been made in devising alternative (*in vitro*) systems for evaluating the dermal irritation potential of chemicals since this author first reviewed the field (Gad and Chengelis, 1988). **Table 11** overviews 20 proposed systems which now constitute five very different approaches.

The first approach (I) uses patches of excised human or animal skin maintained in some modification of a glass diffusion cell, which maintains the moisture, temperature, oxygenation and electrolyte balance of the skin section. In this approach, after the skin section has been allowed to equilibrate for some time, the material of concern is placed on the exterior surface and wetted (if not a liquid). Irritation is evaluated either by swelling of the skin (a crude and relatively insensitive method for mild and moderate irritants), by evaluation of inhibition of uptake of radiolabelled nutrients or by measurement of leakage of enzymes through damaged membranes.

The second set of approaches (II) utilizes a form of surrogate skin culture comprising a mix of skin cells which closely mirror key aspects of the architecture and function of the intact organ. These systems seemingly offer a real potential advantage but, to date, the 'damage markers' employed (or proposed) as predictors of dermal irritation have been limited to cytotoxicity.

The third set of approaches (III) is to use some form of cultured cell (either primary or transformed), with primary human epidermal keratinocytes (HEKs) preferred. The cell cultures are exposed to the material of interest, then either cytotoxicity, release of inflammation markers or decrease of some indicator of functionality (lipid metabolism, membrane permeability or cell detachment) is measured.

The fourth group (IV) contains two miscellaneous approaches—the use of a membrane from the hen's egg with a morphological evaluation of damage being the predictor end point (Reinhardt *et al*., 1987), and the SKINTEX system, which utilizes the coagulation of a mixture of soluble proteins to predict dermal response.

Finally, in group V there are two SAR models which use mathematical extensions of past animal results correlated with structure to predict the effects of new structures.

Many of these test systems are in the process of evaluation of their performance against various small groups of compounds for which the dermal irritation potential is known. Evaluation by multiple laboratories of a wider range of structures will be essential before any of these systems can be generally utilized.

5.3 Irritation of Parenterally Administered Pharmaceuticals

Intramuscular (im) and intravenous (iv) injection of parenteral formulations of pharmaceuticals can produce a range of discomfort resulting in pain, irritation and/or damage to the muscular or vascular tissue. These are normally evaluated for prospective formulations before use in humans by evaluation in intact animal models—usually the rabbit (Gad and Chengelis, 1988).

Currently, a protocol utilizing a cultured rat skeletal muscle cell line (the L6) as a model is in an inter-laboratory validation programme among more than 10 pharmaceutical company laboratories. This methodology (Young *et al*., 1986) measures creatine kinase levels in media after exposure of the cells to the formulation of interest, and predicts *in vivo* im damage based on this end point. It is reported to give excellent rank-correlated results across a range of antibiotics (Williams *et al*., 1987), and in a recent multilaboratory evaluation a broader structural range of compounds (PMA/Drusafe In Vitro Task Force, 1994).

Another proposed *in vitro* assay for muscle irritancy for injectable formulations is the red blood cell haemolysis assay (Brown *et al*., 1989). Water-soluble formulations are gently mixed at a 1:2 ratio with freshly collected human blood for 5 s, then mixed with a 5% w/v dextrose solution and centrifuged for 5 min. The percentage red blood cell survival is then determined by measuring differential absorbance at 540 nm, and this is compared with values for known irritants and nonirritants. Against a very small group of compounds (four), this is reported to be an accurate predictor of muscle irritation.

There is no current candidate alternative for the venous irritation test, but the *in vitro* alternative for pyrogenicity testing—the *Limulus* test—is one of the success stories for the alternatives movement. It has totally replaced the classical intact rabbit test in both research and product release testing. The test is based on the jellying or colour development of a pyrogenic preparation in the presence of the lysate of the amoebocytes of the horseshoe crab (*Limulus polyphemus*). It is simpler, more rapid and of greater sensitivity than the rabbit test it replaced (Cooper, 1975).

5.4 Sensitization and Photosensitization

There are actually several approaches available for the *in vitro* evaluation of materials for sensitizing potential.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat043
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

These use cultured cells from various sources and, as end points, look at either biochemical factors (such as production of migration inhibition factor (MIF)) or cellular events (such as cell migration or cell 'transformation').

Milner (1970) reported that lymphocytes from guinea-pigs sensitized to dinitrofluorobenzene (DNFB) would transform in culture, as measured by the incorporation of tritiated thymidine, when exposed to epidermal proteins conjugated with DNFB. This work was later extended to guinea-pigs sensitized to phenylenediamine. He also reported (Milner, 1971) that his method was capable of detecting allergic contact hypersensitivity to DNFB in humans, using human lymphocytes from sensitized donors and human epidermal extracts conjugated with DNFB.

Miller and Levis (1973) reported the *in vitro* detection of allergic contact hypersensitivity to dinitrochlorobenzene (DNCB) conjugated to leucocyte and erythrocyte cellular membranes. This indicated that the reaction was not specifically directed towards epidermal cell conjugates. Thulin and Zacharian (1972) extended others' earlier work on MIF-induced migration of human peripheral blood lymphocytes to a test for delayed contact hypersensitivity. Burka *et al*. (1981) reported on an assay system based on isolated guinea-pig trachea. No further mention of this has been found in the literature. None of these approaches has yet been developed as an *in vitro* predictive test, but work is progressing. Milner (1983) published a review of the history and state of this field which still provides and accurate and timely overview.

Any alternative (*in vitro* or *in vivo*) test for sensitization will need to be evaluated against a battery of 'known' sensitizing compounds. The Consumer Product Safety Commission in 1977 proposed such a battery, which is shown in **Table 12**. This has not yet been done for any of the proposed systems. Owing to the complexity of the system involved, it is unlikely that a suitable *in vitro* replacement system will be available soon.

Gad *et al*. (1986) have published comparative data on multiple animal and human test system data for some 72 materials. Such a database should be considered for the development and evaluation of new test systems.

Table 12 Requested reference compounds for skin sensitization studies (US Consumer Product Safety Commission)

Hydroxylamine sulfate	Penicillin G
Ethyl amino benzoate	*p*-Phenylenediamine
Iodochlorohydroxy quinoline (Clioquinol, Chinoform)	Epoxy systems (ethylenediamine, diethylenetriamine, diglycidyl ethers)
Nickel sulfate	Toluene-2, 4-diisocyanate
Monomethyl methacrylate	Oil of Bergamot
Mercaptobenzothiazole	

5.5 Phototoxicity and Photosensitization

The Daniel test for phototoxicity (also called photoirritant contact dermatitis) utilizes the yeast *Candida albicans* as a test species and has been in use for more that 20 years (Daniel, 1965). The measured end point is simply cell death. The test is simple to perform and cheap, but does not reliably predict the phototoxicity of all classes of compounds (for example sulfanilamide). Test systems utilizing bacteria have been suggested as alternatives over the last 10 years (Harter *et al*., 1976; Ashwood-Smith *et al*., 1980) for use in predicting the same end point.

Most recently, ICI has conducted studies on an *in vitro* phototoxicity assay which involves using three cultured cell lines: the A431 human epidermal cell line (a derived epidermal carcinoma), normal HEKs (a primary cell line derived from cosmetic surgery) and the 3T3 Swiss mouse fibroblast cell line. The protocol for this assay involves subculturing the particular cell type into microtitre tissue-culture-grade plates and incubating them over a period of 24 hours. Following incubation, the cultures are exposed to the test compound at a concentration predetermined as nontoxic. After a 4 hour exposure to the compound, the cell cultures are exposed to either UV A (320–400 nm) or UV A/B (280–400 nm) radiation for varying lengths of time. The degree of enhanced toxicity effected by either UV A or UV A/B radiation in the presence of the test compound relative to the control is assessed, using the MTT assay. MTT, abbreviated from 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide, undergoes a reduction reaction which is specific to mitochondrial dehydrogenases in viable cells. Work on validation of this test using 30 compounds of know phototoxic potential has shown a high degree of correlation between *in vitro* and *in vivo* results. Jackson and Goldner (1989) have described several other *in vitro* assay systems for this end point.

The area of development of *in vitro* photosensitization assays has been a very active one, as the review of McAuliffe *et al*. (1986) illustrates. Such tests have focussed on being able to predict the photosensitizing potential of a compound and variously employed cultured mammalian cell lines, red blood cells, micro-organisms and biochemical reactions. McAuliffe's group has developed and proposed a test that measures the incorporation of tritiated thymidine into human peripheral blood mononuclear cells as a predictive test (Morison *et al*., 1982). They claim to have internally validated the test, using a battery of known photosensitizers.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat043
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Bockstahler *et al*. (1982) have developed and proposed another *in vitro* test system which uses the responses of two *in vitro* mammalian viruses—host cell systems to the photosensitizing chemicals proflavine sulfate and 8-methoxypsoralen (8-MOP) in the presence of light as a predictive system. They found that infectious simian virus 40 (SV40) could be induced from SV40-transformed hamster cells by treatment with proflavine plus visible light or 8-MOP plus near-UV radiation. The same photosensitizing treatments inactivated the capacity of monkey cells to support the growth of herpes simplex virus. SV40 induction and inactivation of host cell capacity for herpes virus growth might be useful as screening systems for testing the photosensitizing potential of chemicals. Advantages (ease and speed of conduct) and disadvantages (use of potentially infective agent and the limited range of compounds evaluated to date) were found to be associated with both of these test systems.

5.6 Development Toxicity

The area of developmental toxicology actually is one of the earliest to have alternative models suggested for it, and has one of the most extensive and oldest literatures. This is, of course, partly owing to such models originally being used to elucidate the essential mechanisms and process of embryogenesis.

Because of the complicated and multiphasic nature of the developmental process, it has not been proposed that any of these systems be definitive tests, but rather that they serve as one form or another of a screen. As such, these test systems would either preclude or facilitate more effective full-scale evaluation in one or more of the traditional whole-animal test protocols.

The literature and field are much too extensive to review comprehensively here. There are a number of extensive review articles and books on the subject (Wilson, 1978; Clayton, 1981; Kochhar, 1981; Saxen, 1984; Homburger and Goldberg, 1985; Faustman, 1988; Daston and D'Amato, 1989), which should be consulted by those with an in-depth interest.

The existing alternative test systems fall into six broad classes: (i) lower organisms; (ii) cell culture systems; (iii) organ culture systems; (iv) submammalian embryos; (v) mammalian embryos and (vi) others.

Table 13 provides an overview of the major representatives of these six groups, along with at least one basic reference to the actual techniques involved and the system components for each.

The comparative characteristics of these different classes of test systems are presented in **Table 14**. The key point is that these systems can be used for a wide range of purposes, only one of which is to screen compounds to determine the degree of concern for developmental toxicity.

The utility of these systems for screening is limited by the degree of dependability in predicting effects primarily in people and secondarily in the traditional whole-animal test systems. Determining the predictive performance of alternative test systems requires the evaluation of a number of compounds for which the 'true' (human) effect is known. In 1983 a consensus workshop generated a so-called 'gold standard' set of compounds of known activity (Smith *et al*., 1983). The composition of this list has been open to a fair degree of controversy over the years (Flint, 1989; Johnson, 1989; Johnson *et al*., 1989). However, an agreed-upon 'gold standard' set of compounds of known activity is an essential starting point for the validation of any single test system or battery of test systems because of the multitude of mechanisms for developmental toxicity. It is unlikely that any one system will be able to stand in place of segment II studies in two species, much less to accurately predict activity in humans. Their use as general screens or as test systems for compounds with little potential for extensive or intended human exposure will, however, probably be appropriate.

5.7 Target Organ Toxicity Models

This last model review section addresses perhaps the most exciting potential area for the use of *in vitro* models—as specific tools to evaluate and understand discrete target organ toxicities. Here the presumption is that there is reason to believe (or at least suspect) that some specific target organ (nervous system, lungs, kidney, liver, heart, etc.) is or may be the most sensitive site of adverse action of a systemically absorbed agent. From this starting point, a system that is representative of the target organ's *in vivo* response would be useful in at least two contexts.

First, as with all the other end points addressed in this chapter, a target organ predictive system could serve as a predictive system (in general, a screen) for effects in intact organisms, particularly man. As such, the ability to identify those agents with a high potential to cause damage in a specific target organ at physiological concentrations would be extremely valuable.

The second use is largely specific to this set of *in vitro* models. This is to serve as tools to investigate, identify and/or verify the mechanisms of action for selective target organ toxicities. Such mechanistic understandings then allow for one to know whether such toxicities are relevant to man (or to condition of exposure to man), to develop means either to predict such responses while they are still reversible or to develop the means to intervene in such toxicosis (i.e. first aid or therapy), and finally to potentially modify molecules of interest to avoid

VI: Other	Structure–activity relationships (SAR)	Mathematical correlations of activity with structural features	Enslein *et al*. (1983b) Gombar *et al*. (1990)

unwanted effects while maintaining desired properties (particularly important in drug design).

In the context of these two uses, the concept of a library of *in vitro* models (Gad, 1989c; 1996) becomes particularly attractive. If one could accumulate a collection of 'validated', operative methodologies that could be brought into use as needed (and put away, as it were, while not being used), this would represent an extremely valuable competitive tool. The question becomes one of selecting which systems/tools to put into the library, an how to develop them to the point of common utility.

Additionally, one must consider what forms of markers are to be used to evaluate the effect of interest. Initially, such markers have been exclusively either morphological (in that there is a change in microscopic structure), observational (is the cell/preparation dead or alive or has some gross characteristic changed?) or functional (does the model still operate as it did before?). Recently it has become clear that more sensitive models do not just generate a single-end-point type of data, but rather a multiple set of measures which in aggregate provide a much more powerful set of answers.

There are several approaches to *in vitro* target organ models.

The first and oldest is that of the isolated organ preparation. Perfused and superfused tissues and organs have been used in physiology and pharmacology since the late nineteenth century. There is a vast range of these available, and a number of them have been widely used in toxicology (Mehendale, 1989 presents an excellent overview). Almost any end point can be evaluated in most target organs (the central nervous system being a notable exception), and these are closest to the *in vivo* situation and therefore generally the easiest to extrapolate or conceptualize from. Those things that can be measured or evaluated in the intact organism can largely also

be evaluated in an isolated tissue or organ preparation. However the drawbacks or limitations of this approach are also compelling.

An intact animal generally produces one tissue preparation. Such a preparation is viable generally for a day or less before it degrades to the point of losing utility. As a result, such preparations are useful as screens only for agents that have rapidly reversible (generally pharmacological or biomechanical) mechanisms of action. They are superb for evaluating mechanisms of action at the organ level for agents that act rapidly, but not generally for cellular effects of for agents that act over a course of more than a day.

The second approach is to use tissue or organ culture. Such cultures are attractive, owing to maintaining the ability for multiple cell types to interact in at least a near-physiological manner. They are generally not as complex as perfused organs, but are stable over a longer period of time, increasing their utility as screens somewhat. They are truly a middle ground between perfused organs and cultured cells. Only for relatively simple organs (such as the skin and bone marrow) are

good models which perform in a manner representative of the *in vitro* organ available.

The third and most common approach is that of cultured cell models. These can be either primary or transformed (immortalized) cells, but the former have significant advantages in use as predictive target organ models. Such cell culture systems can be utilized to identify and evaluate interactions at the cellular, subcellular and molecular level on an organ- and species-specific basis (Acosta *et al*., 1985). The advantages of cell culture are that single organisms can generate multiple cultures for use, that these cultures are stable and useful for protracted periods of time and that effects can be studied very precisely at the cellular and molecular levels. The disadvantages are that isolated cells cannot mimic the interactive architecture of the intact organ, and will respond over time in a manner that becomes decreasingly representative of what happens *in vivo*. An additional concern is that, with the exception of hepatocyte cultures, the influence of systemic metabolism is not factored in unless extra steps are taken. Stammati *et al*. (1981) and Tyson and Stacey (1989) present some excellent reviews of the use of cell culture in toxicology. Any such cellular systems would

be more likely to be accurate and sensitive predictors of adverse effects if their function and integrity were evaluated while they were operational. For example, cultured nerve cells should be excited while being exposed and evaluated.

A wide range of target-organ-specific models have already been developed and used. Their incorporation into a library-type approach requires that they be evaluated for reproducibility of response, ease of use and predictive characteristics under the intended conditions of use. These evaluations are probably at least somewhat specific to any individual situation. **Tables 15–20** present overviews of representative systems for a range of target organs: respiratory, nervous system, renal,

cardiovascular, hepatic, pancreatic, gastrointestinal and reticuloendothelial. These tables do not mention any of the new coculture systems in which hepatocytes are 'joined up' in culture with a target cell type to produce a metabolically competent cellular system.

While in Europe there are numerous validated (by European Centre for the Validation of Alternative Methods (ECVAM) Standards) *in vitro* alternatives for personal care products, industrial and agricultural chemicals (though only two—theLAL assay for pyrogenicity and the 3T3 cell assay for phototoxicity—have acceptance for use with pharmaceutical regulators) with regulatory acceptance (as summarized in **Table 21**), this is not the case in the US. Indeed, only four alternatives have been approved by the ICCVAM process to date (Gaul, 2008). Though there is considerable research continuing on the development (and putatively, on the validation) of many more methods (Kuehn, 2008), progress in obtaining regulatory acceptance of such methods to take the place of animal test methods is very slow, and those methods that are accepted are limited in scope screens for eye and skin irritation pyrogenicity, phototoxicity and genotoxicity.

This regulatory acceptance is, indeed, as it has been for 20 years, the final frontier and true obstacle to any further significant reduction in animal use.

6 SUMMARY

The tools are currently at hand (or soon will be) to provide the practising toxicologist with unique opportunities both for identifying potentially toxic compounds in a much more rapid and efficient manner than before and for teasing apart the mechanisms underlying such toxicities on an integrated basis (from the level of the molecule to that of the intact organism). The *in vitro* systems overviewed here, once understood (by investigators and

Table 21 Status of nonanimal methods that have regulatory standing

Test method	Test system	End point	OECD/TG or other regulatory comments
In vitro test methods for which there are OECD health effects test guidelines (including draft guidelines under review for acceptance) can be found at http://www.oecd.org/home/			
Transcutaneous electrical resistance test (TER)	Monitors changes in the electrical resistance as a measure of loss of corneum integrity and barrier function; involves skin disks from euthanized rats	Skin corrosion (topical agents)	TG 430
Human skin models (EpiDerm™, EPISKIN™)	Reconstructed human epidermal equivalent (commercial system) used to assess cell viability, involving the MTT reduction test	Skin corrosion (topical agents)	TG 431
3T3 NRU phototoxicity test	BALB/c 3T3 (murine) cell line cytotoxicity based on Neutral Red uptake to measure cell viability; not direct replacement alternative, as there is no *in vivo* equivalent test	Phototoxicity	TG 432/FDA guidance
Corrositex™ membrane barrier test	An artificial barrier system coupled to a pH-based chemical detection system	Skin corrosion (topical agents)	Draft TG 435
Bacterial reverse mutation test (Ames)	Revertant bacteria detected by their ability to grow in the absence of the amino acid	Genotoxicity	TG471/ICH,ISO, FDA guidance
In vitro mammalian chromosome aberration test	Microscopic detection of chromosomal damage to cells in culture	Genotoxicity	TG473/ICH, ISO, FDA guidance
In vitro mammalian cell gene mutation test	Functional bioassays to monitor mutations in enzyme encoding genes	Genotoxicity	TG476
Sister chromatid exchange assay	Cells in culture are examined after two rounds of division by metaphase arrest and chromosomal preparation; chromatid exchange is monitored by microscopy	Genotoxicity	TG479/ICH, ISO, FDA guidance
Gene mutation assay in yeast	*Saccharomyces cerivisiae* exposed to the test substance are grown under different culture conditions used to monitor mutagenic potential (cf. Ames test)	Genotoxicity	TG 480
Mitotic recombination assay in yeast	Crossover or gene conversion following exposure of yeast to the test substance; relies on different growth requirements of mutated and wild-type yeast strains	Genotoxicity	TG 481
Unscheduled DNA synthesis in mammalian cells	Measures the DNA repair synthesis after deletions caused by the test substance based on the incorporation of radioactive nucleotides into the newly synthesized DNA	Genotoxicity	TG 482/ICH, ISO and FDA guidance
In vitro micronucleus test	Cell-based assay; supplement to TG 474 (*in vivo* micronuleus test); detection of chromosome damage and formation of micronuclei in interphase	Genotoxicity	Draft TG 487/ICH guidance
Sex-linked recessive lethal test	*Drosophila* are exposed to the test substance. Germline transmission of mutations is monitored through two successive generations	Reproductive toxicity	TG 477

Table 21 (*continued*)

Test method	Test system	End point	OECD/TG or other regulatory comments
Validated methods that are yet to be introduced into regulatory use			
EpiOcular™	Human keratinocyte derived model of the corneal epithelium barrier function	Eye irritation (topical application)	Retrospective (weight-of-evidence) validation (ECVAM)
In vitro micronucleus test	CHL/IU, CHO, SHE or V79 cell lines are commonly used, with or without metabolic activation, to monitor damage and formation of micronuclei in interphase	Mutagenicity	Retrospective (weight-of-evidence) validation (ECVAM)
Embryonic stem cell test	3T3 cell cytotoxicity and differentiation of embryonic stem murine cell lines used to examine teratogenic potential	Developmental toxicity	Endorsed as screening test (EU)
Postimplantation rat whole embryo test	Morphological assessment of rat embryos	Developmental toxicity	Endorsed as screening test (EU)
Micromass test	Micromass cultures of rat limb are bud monitored for inhibition of cell proliferation and differentiation	Developmental toxicity	Endorsed as screening test (EU)
Methods undergoing validation			
EPISKIN™	Reconstructed human skin system used with MTT assay to monitor barrier function	Skin irritation	Report stage in EU
EpiDerm™	Similar to EPISKIN™	Skin irritation	Report stage in EU
Prevalidated methods			
SkinEthic eye model	Epithelial corneal cell line used for cytotoxicity testing based on the MTT reduction assay	Eye irritation	Appraisal stage in EU
Methods undergoing development, prevalidation or evaluation			
Tissue culture models	Neutral Red release and silicon microphysiometry or fluorescein leakage bioassays with human keratinocytes and MDCK cells, respectively; red blood cell (RBC) haemolysis test	Eye irritation	Being reviewed by ICCVAM for possible retrospective (weight-of-evidence) validation
Organotypic models	Bovine corneal opacity and permeability (BCOP) assay, with postmortem corneas; hen's egg test on the chorioallantoic membrane (HET-CAM assay); isolated rabbit and chicken eye tests (IRE and ICE)	Eye irritation	Being reviewed by ICCVAM for possible retrospective (weight-of-evidence) validation
Modified Leydig cell line	Analysis of progesterone production as a measure of the test substance effects on steroid hormone production	One/two generation study	For use as part of test battery
Testis slices	Assessment of steroid production capacity of the Leydig cells upon exposure of *ex vivo* rat tissue to toxicants	One/two generation study	For use as part of test battery
Human carcinoma cell line	Assay to allow entire steroid pathway effects to be mapped	One/two generation study	For use as part of test battery
Placental microsomal aromatase assay	Monitors the ability of substances to affect steroid production; a subcellular microsomal assay is used industrially	One/two generation study	For use as part of test battery

This is a comprehensive list of methods that have been validated or that are at various stages of development for toxicity testing. More information about these methods and how they can be applied is available from: *http://www2.defra.gov.uk/research/project_data/more?!=CB01067&M=KWS&V=reach&scope=0* and OECD, 2005.

regulators) in how they function and fail (just as *in vivo* systems have come to be understood), will allow this to happen while reducing the need to have recourse to intact mammalian test systems. However, the intact animal models—and, indeed, human for pharmaceuticals—will still be an essential element in the safety assessment armamentarium for the foreseeable future.

Nanotoxicology—The Toxicology of Nanomaterials

Kristin Gellein and Tore Syversen

CONTENTS

1 INTRODUCTION

Since ancient times, humans have been exposed to nanosized materials originating from combustion processes, such as forest fires and volcanoes, as well as natural sources, such as sea spray. This exposure drastically increased with the industrial revolution, when anthropogenic sources of nanosized particles were introduced. Now, with the rapid development of nanotechnology, we have a new source of exposure to nanosized materials.

Nanotoxicology is a new field of study that emerged because nanometre-scale particles may behave different from their physically larger chemical counterparts (Donaldson *et al*., 2004). The term nanotoxicology refers to the study of interactions of nanostructures with biological systems, with an emphasis on the relationship between the physical and chemical properties of nanostructures and induction of toxic responses (Fischer and Chan, 2007).

Nanomaterials (NMs) are defined as engineered structures with at least one dimension of 100 nm or less. They include nanoparticles, nanofibres and nanotubes, composite materials and nanostructured surfaces. Engineered NMs have unusual physicochemical properties because of their small size, chemical composition, surface structure, solubility, shape and aggregation (Nel *et al*., 2006). NMs usually differ substantially from bulk materials of the same chemical composition.

NMs are expected to have a substantial impact on many industrial products and areas of society because of their unique and novel properties (Hardman, 2006). However, such widespread use will inevitably also raise concern about possible adverse biological effects (Nel *et al*., 2006). Our understanding of the interactions of nanostructures with biological systems is still very limited, and it is still unclear to what extent exposure to humans, animals, insects and plants may produce harmful biological responses (Fischer and Chan, 2007). In particular, our understanding of the ecotoxicology of NMs is very limited compared to other chemicals with a similar distribution in the environment.

The interaction of NMs with biological systems is affected by several factors such as: size, surface area, shape, chemical composition, lattice structure, surface chemistry, surface charge and aggregation state. These are all physicochemical properties that can affect the toxicity of NMs (Zuin *et al*., 2007). Because of their special physical and chemical features, the study of NMs as potential toxic agents requires an interdisciplinary approach, including disciplines ranging from physics and chemistry to biology and medicine (Fubini *et al*., 2007).

Nanotoxicology is a fast-growing discipline. The concept and background for this new discipline has been thoroughly reviewed by Oberdörster *et al*. (2005a), Donaldson *et al*. (2004) and Nel *et al*. (2006).

2 NANOMATERIALS

2.1 Properties and Use

Size is the major characteristic which differentiates these materials from other chemically similar materials. However, size has an important impact on a range of other important features that may influence toxicity. Such properties are summarized below (Borm and Kreyling, 2004; Nel *et al*., 2006):

- Nanosize
- Extremely large surface
- High surface-to-mass ratio
- High surface reactivity
- High strength, conductivity and reactivity
- Catalytic promotion of reactions
- Ability to absorb and carry other compounds
- Ability to escape defence systems *in vivo*
- Ability to cross cellular and subcellular membranes
- Specific reactivity arising at the nanolevel
- Strong interparticle forces.

Some of these properties make NMs very attractive for a broad range of applications. Engineered NMs may increase the performance of existing products as well as induce the development new products (Oberdörster *et al*., 2005a). NMs are increasingly being used for commercial purposes such as cosmetics, sunscreens (e.g. TiO_2, ZnO), car tyres, electronics, microelectronics and semiconductors. Other applications which are rapidly developing are, for example, fuel cells, coatings and catalysts. There is also a potential for the use of NMs in applications such as high-performance materials, energy storage and conversion, self-cleaning surface coatings and stain-resistant textiles (Oberdörster *et al*., 2005a). Perhaps one of the most exciting and promising areas of nanotechnology is within medical diagnosis and therapy. In this area NMs are increasingly being utilized in medicine for the purposes of diagnosis, imaging and drug delivery (Nel *et al*., 2006).

2.2 Different Types of Engineered NMs

There is a broad range of engineered NMs, for example nanoparticles, carbon-based NMs, metal particles and oxides, and quantum dots (QDs). Within these groups there are numerous subgroups.

2.2.1 Nanoparticles

Nanoparticles are defined as single spherical particles with a diameter less than 100 nm (Oberdörster *et al*., 2005a). Nanoparticles can be divided into combustion-derived nanoparticles, such as diesel soot, engineered nanoparticles, and naturally occurring nanoparticles from volcanic eruptions, atmospheric chemistry and so on. Examples of engineered nanoparticles include titanium dioxide, zinc oxide, alumina, carbon black and buckminster fullerenes (C_{60}) (Borm *et al*., 2006).

2.2.2 Carbon-Based NMs

Carbon-based NMs are composed of carbon, often with some residues from the production process (Hurt *et al*., 2006). This group of products include, but are not limited to, carbon dots, nanodiamonds and fullerenes such as buckyballs (e.g. C_{60}), nanotubes and nanofibres. CNTs are considered among the most promising materials in nanotechnology because of their extraordinary electronic and mechanical properties (Helland *et al*., 2007). They are tubelike structures of graphene sheets, with diameters as small as 1 nm and potential lengths of several hundred nanometres. CNTs include single-walled carbon nanotubes (SWCNTs) and multiwalled carbon nanotubes (MWCNTs).

2.2.3 Quantum Dots

QDs are semiconductor nanocrystals (2–100 nm) with unique optical and electrical properties currently applied in biomedical imaging and electronic industries (Hardman, 2006). QDs have a fluorescence spectrum that renders them optimal fluorophores for biomedical imaging (Hardman, 2006). They can also target specific biological events and cellular structures and are therefore attractive in site-specific gene and drug delivery. For biological applications QDs typically have a core/shell conjugate structure where the core typically is composed of metals from Groups 3–5 (e.g. Cd/Se, Cd/Te and Zn/Se). Many of these core metals are known to be toxic at low concentrations, and toxicity related to degradation of the core is therefore expected (Lewinski *et al*., 2008).

3 TOXICOLOGY OF NANOMATERIALS

3.1 Background

Our understanding of NMs toxicity is limited as they are novel materials and methods for toxicity testing are not readily available (Yang *et al*., 2008). NMs are currently available in a wide variety of compositions, from very simple structures, such as titanium oxide, to very complex structures with surface modifications or coatings. As a result, the traditional approaches of toxicity testing are not directly applicable (Donaldson *et al*., 2004). NMs

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat044
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are not toxic entities *per se* just because of their size. However, it is clear that these materials hold unusual properties due to their nanosize, which may affect their toxicity. A current paradigm to nanotoxicology is the adverse health effects of ultrafine particles (UFPs) found in air and working environments, which indicates that exposure to nanosized materials can cause significant health problems, such as pulmonary and cardiovascular diseases (Donaldson *et al*., 2004; Oberdörster *et al*., 2005a).

Particle size and surface area are important characteristics from a toxicological viewpoint. In a study of carbon black, it was found that biological effects such as inflammation, genotoxicity and histology were related to surface area and not particle mass (Yang *et al*., 2008). Additionally, the extremely small size of NMs means that they more readily gain entry into the human body compared to larger-sized particles. The behaviour of these nanoparticles inside the body is a major question that needs to be resolved. There is also concern because of their potential for interaction with biological processes inside the body. Because of their large surface area, nanoparticles will adsorb on to their surface some of the macromolecules present in their environment. This may, for instance, affect the regulatory mechanisms of enzymes and other proteins. There is also the question about what happens when nondegradable or slowly degradable NMs accumulate in body organs.

As CNTs are considered to be perhaps the most promising materials in nanotechnology, they are among the most studied NMs. *In vitro* studies in rats have shown that they have the potential to cause pulmonary toxicity (Lam *et al*., 2004; Warheit *et al*., 2004). Due to their needle-like fibre shape, these nanotubes have a structural resemblance to asbestos, which is known to induce asbestosis, lung cancer and malignant mesothelioma of the pleura (LaDou, 2004). In a recent study that introduced CNTs into the abdominal cavity of mice, CNTs showed the same effects as long thin asbestos fibres, raising concerns that exposure to CNTs may lead to mesothelioma (Poland *et al*., 2008).

3.2 Human Exposure to Nanomaterials

People become exposed to NMs in a variety of ways, such as at the workplace (e.g. engineers, researchers and clinicians), as patients during therapeutic or diagnostic administration or as consumers through the use of products containing nanostructures (e.g. cosmetics, sunscreens). At this point, not much is known about levels of exposure via the different routes for NMs and the relative importance of direct exposure or indirect exposure through environmental contamination (Oberdörster *et al*., 2005a).

Potential routes of NMs exposure include the gastrointestinal tract, skin, lung and systemic administration for diagnostic and therapeutic purposes. In all cases, there will be unique routes of exposure that will dictate the specific fate of the nanostructures. Inhalation is the most significant exposure route for airborne NMs, and inhaled nanoparticles are efficiently deposited by diffusion mechanisms in all regions of the lung (Oberdörster *et al*., 2005a). Consumer exposure to nanoparticles presents another exposure route for these materials. Engineered nanoparticles are used in personal-care products, for example, cosmetics and sunscreens. It is impossible to assess the quantities and types of NMs in these products as such information is often protected from public disclosure by trade secrets (Colvin, 2003). Even though dermal exposure to NMs occurs regularly through the use of cosmetics and sunscreens, the epidermis in healthy skin provides excellent protection against particles spread to the dermis (Nel *et al*., 2006).

Once the NMs has entered the body they will distributed through the bloodstream to various tissues by processes of partitioning and diffusion (Garnett, 2007). At the target site, NMs may trigger tissue injury. The nanostructures may also enter cells of target organs and remain in the cells for some time before moving to other organs or being excreted (Fischer and Chan, 2007). The interactions of NMs with cells, body fluids and proteins play a important role in both their biological effects and their ability to distribute throughout the body (Nel *et al*., 2006). NMs binding to proteins may generate complexes that are more mobile and can enter tissue sites that would normally be inaccessible. Depending on the chemical composition, the NMs may remain unchanged, become modified, or even metabolized. Known sites of localization of nanoparticles are bone marrow, spleen, brain and lymph nodes (Garnett, 2007). All of these organs contain macrophages, and thus it is probable that nanostructures are taken up by phagocytic cells. Opsonization is the interaction of nanostructures with proteins and this process contributes to the uptake of NMs by the liver and several other tissues (Garnett, 2007). Little is known about what happens to the nanostructures after they have been distributed and sequestered into cells. The breakdown of the nanostructures could elicit unique molecular responses that are difficult to predict.

It is important to recognize, evaluate and control the exposure of NMs to protect the health of researchers, production workers, users and members of the public. The exposure of workers and consumers to nanotechnology products is of immediate concern. Many of these products will eventually enter the environment and in the longer term, there will be a much wider exposure of the entire ecosystem to engineered NMs through water and soil (Nel *et al*., 2006).

3.2.1 Ultrafine Particles

Increases in urban air pollution have been found to be associated with a range of adverse health effects. Because few of the components in this type of pollution are intrinsically very toxic, the focus has been towards the ultrafine components. UFPs (<100 nm) in urban environmental air pollution are most often produced by combustion processes. Contrary to engineered NMs, these particles have a wide size range and represent a heterogeneous chemical composition (Colvin, 2003). Many methods exist to quantify and characterize UFPs. The number of particles can be measured by a condensation particle counter (CPC), a scanning mobility particle sizer (SMPS) or an electrical low-pressure impactor (ELPI) (Brouwer *et al*., 2004). Particle characterization is also done by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) (Brouwer *et al*., 2004).

UFPs may exist as singlet particles or they may exist as aggregates and the latter will change their deposition characteristics due to a greater diameter than single particles (Donaldson *et al*., 2001). Studies have shown that UFPs can contribute to adverse health effects in the respiratory tract as well as in extrapulmonary organs (Oberdörster *et al*., 2005a). Such health effects are primarily found in susceptible subgroups and not in healthy people unless they are exposed at very high concentrations (Donaldson *et al*., 2001). *In vivo* and *in vitro* studies have shown that these UFPs can cause both oxidative stress and proinflammatory effects (Donaldson and Stone, 2003). The mechanisms are still unclear, but it seems that the large surface area of UFPs play an important role (Donaldson and Stone, 2003).

3.2.2 Nanomaterials in the Workplace

As the production demand for NMs develops there will be an increase in occupational exposure, both during primary manufacture of the production and use of NMs in consumer products. Animal studies suggest that engineered NMs may pose a health hazard to employees, which underscores the need for preventive measures against both adverse affects and exposure (Schulte *et al*., 2008; Seaton and Donaldson, 2005). Even though NMs differ from their bulk counterparts, many of the workers using these substances have no formal safety training beyond those adapted for bulk solids (Colvin, 2003). At present, there is considerable uncertainty as to how we should assess the potential work-related health risks and how we should manage such risks.

In the absence of appropriate techniques we must consider occupational exposure to NMs as a logical subset of traditional exposure assessment for chemical hazards in the workplace. As we develop improved techniques for the relevant toxicology and health assays we will be able to more accurately characterize hazardous materials or procedures (Schulte *et al*., 2008). The large and diverse group of manufactured NMs arising from nanotechnology represents inhalation, skin and oral hazards of unknown potential. The actual body burden of NMs will be a mixture of these exposure possibilities. Workers can be exposed through the transfer of nanoparticles directly to skin, clothing or other objects. This can again generate airborne nanoparticles, some of which may be removed by ventilation systems, settle on surfaces or be inhaled. Contaminated surfaces can include equipment, tools, floors and stairs, clothing and areas of exposed skin. Settled particles may also be transferred to clothing or hands through direct contact with contaminated surfaces (Hoover *et al*., 2007). The proper way to handle such exposure situations is through preventive measures such as gloves, appropriate clothing and respirators, as well as procedures to keep the workplace clean and tidy.

Measuring airborne NMs in the workplace is an important element of the evaluation of possible health hazards to employees. Particle (dust) measurements are usually based on mass only, but for NMs such characterization should include surface area and number of particles as well (Brouwer *et al*., 2004; Han *et al*., 2008). Also, chemical composition, surface reactivity, aggregation or agglomeration and other physicochemical factors can influence the toxicity and should be considered, depending on the type of NMs being encountered (Schulte *et al*., 2008).

Epidemiological data specifically from nanoparticle-exposed humans are so far not available (NIOSH, 2007). The very few studies with experimental short-term human exposure to NMs have failed to demonstrate reproducible health outcomes (Beckett *et al*., 2005; Scharrer *et al*., 2007). In the absence of human data, extensive experience with welders and flame-based metal cutters may be a model (although imperfect) for estimating the potential health effects of occupational exposure to NMs (Nasterlack *et al*., 2008). Decrements in lung function have been observed in a small number of heavily exposed welders, infrequent cases of fibrosis have been attributed to improper workplace ventilation or mixed dust exposure, while central nervous system (CNS) and reproductive effects have been absent or inconsistent (Nasterlack *et al*., 2008). A relationship between lung cancer and welding has never been established, except for stainless-steel welding. This experience derived from welding cannot, of course, dismiss health concerns related to engineered NMs, but may help to set some of the concerns in perspective (Nasterlack *et al*., 2008).

From *in vivo* and *in vitro* studies we know that engineered NMs have the potential to cause mild inflammatory effects, generate reactive oxygen species (ROS) and oxidative stress, increase macrophage sensitivity to complementary components and inhibit phagocytosis (Oberdörster *et al*., 2004). The ability of NMs to redistribute from their original site of deposition is of special

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat044
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

concern. Also, NMs have the ability to pass the normal phagocytosis defence without being detected, and thereby get access to, for example, blood and the nervous system (Oberdörster *et al*., 2004). It has also been reported that NMs have the potential to translocate to the brain via the olfactory nerve endings in the nose (Oberdörster *et al*., 2004).

3.2.3 Pulmonary Effects

Pulmonary toxicology is a well-established area of medical research, and appropriate techniques and procedures have been established for toxicity testing, as well as characterization of occupational diseases. Although the danger of inhaling fumes or very small smoke particles has been recognized since ancient times, systematic research into the effects of nanometre-sized particles on health did not start until the 1980s (Donaldson *et al*., 2005). Most of the toxicity research on NMs *in vivo* has been carried out in mammalian systems, with a focus on respiratory exposure (Oberdörster *et al*., 2005a).

The main mechanism for deposition of inhaled nanoparticles in the respiratory tract is diffusion due to displacement when they collide with air molecules (Oberdörster *et al*., 2005a). Inhaled nanoparticles of different sizes can target all three regions of the respiratory tract, the nasopharyngeal, tracheobronchial and alveolar region. The larger surface area of the alveoli and the intimate air–blood contact in this region make the alveoli less well protected against inhaled substances, such as nanoparticles, compared to the trachea, bronchi and bronchioles (Yang *et al*., 2008). Concern that inhalation of engineered nanoparticles may have adverse effects arises from the fact that, compared to coarse or fine particles, nanoparticles exhibit a high degree of deposition in the conducting and respiratory zones of the lung (Shvedova *et al*., 2005).

Clearance of inhaled nanoparticles from the lung depends mainly on particle size and on particle surface characteristics. In addition, alveolar macrophages appear to be unable to recognize particles less than 70 nm as being foreign, thus allowing such particles to gain access to the pulmonary interstitium and thence the capillary blood flow. Particle size may also affect the clearance mechanism. Nanofibres measuring more than 20 μm in one axis are too long to be phagocytosed and will be cleared very slowly, staying in the lungs for months or possibly years. This can, again, induce a general nonspecific pulmonary inflammatory response.

Once the nanoparticles have escaped clearance by alveolar macrophages and entered the alveolar interstitium, they can migrate to the pulmonary capillary blood and translocate to systemic sites by different transfer routes and mechanisms. One of the mechanisms is trancytosis across epithelia and access to the blood circulation directly or via lymphatics, from where the particles are then distributed throughout the body. Another mechanism is uptake by sensory nerve endings embedded in airway epithelia, followed by axonal translocation to ganglionic and CNS structures (Oberdörster *et al*., 2004). This transport mechanism is specific for NPs. It should be noted, however, that no definite conclusion about the systemic translocation of inhaled nanoparticles can be drawn to date, based on the conflicting results of animal and human studies.

3.2.4 Cardiovascular Effects

The relationship between air pollution and adverse cardiovascular effects is well documented in epidemiological studies (Donaldson *et al*., 2005). In both epidemiological and experimental studies, a positive association between particulate matter in air pollution and adverse cardiovascular outcomes has been found (Peters *et al*., 2004; Pope *et al*., 2004). One of the key processes that could mediate adverse effects on the cardiovascular system is inflammation of the lung caused by deposited particles. So far, little is known about the potential of NMs to affect the cardiovascular system, however it is plausible that exposure to NMs might trigger similar effects as have been observed to result from particulate air pollution.

Inhaled NPs may influence the vasculature through indirect effects mediated by pulmonary inflammation or through the direct action of particles that have become blood-borne (Duffin *et al*., 2007). Inflammatory effects and blood translocation could explain adverse cardiovascular effects observed in epidemiology studies with particulate air pollution (Duffin *et al*., 2007). Support for this contention comes from studies using model NPs and combustion-derived NPs, where adverse effects such as clotting, plaque development and endothelial dysfunction were enhanced after NP exposures using several different models (Mills *et al*., 2005; Radomski *et al*., 2005; Sun *et al*., 2005). Atherosclerosis is an inflammatory process, initiated via endothelial injury. Exposure of NMs may exacerbate the vascular inflammation of atherosclerosis and promote plaque development or rupture (Duffin *et al*., 2007; Sun *et al*., 2005).

Several studies have demonstrated that SWCNTs induce pulmonary toxicity (Lam *et al*., 2004; Shvedova *et al*., 2005; Warheit *et al*., 2004). The unique physical characteristics of NTs, as well as the pulmonary toxicity, are predictors for potential cardiovascular injury (Simeonova *et al*., 2007). Initial studies have demonstrated that respiratory exposure to high concentrations of SWCNTs provokes, not only pulmonary toxicity, but vascular effects related to mitochondrial oxidative modifications and accelerated atheroma formation (Simeonova *et al*., 2007). SWCNTs may induce cardiovascular effects either directly or indirectly through mitochondrial oxidative perturbations, which can result in altered vessel homeostasis (Simeonova *et al*., 2007).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat044
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There is some evidence that carbon microscale particles can affect vascular haemostasis and precipitate thrombosis. Radomski and colleagues (Radomski *et al*., 2005) have studied the *in vitro* effects of engineered NMs on human platelet aggregation and rat vascular thrombosis. They found that nanotubes and carbon black particles, but not C_{60} bucky balls, stimulated platelet aggregation, and the same ranking was observed in their ability to induce vascular thrombosis in rat carotid arteries.

3.2.5 Neurotoxicology

The brain and other parts of the nervous system are protected by well-developed barriers. However, small and hydrophobic molecules can penetrate these barriers and nanoparticles in the size range 20–50 nm may enter the central nervous system. Acute toxicity would seem to be unlikely except in extreme circumstances, but chronic toxicity might occur (Gibson, 2007).

Nanoparticles may enter the brain where the blood–brain barrier (BBB) is absent or limited, such as the circumventricular structures, or after pathophysiological changes to the BBB induced by injury, disease or ageing (Gibson, 2007). Alternatively, following inhalation, nanoparticles may gain access to the brain via the olfactory nerve pathway (Oberdörster *et al*., 2004). The olfactory system represents a unique interface between the nervous system and the external environment, since there is an intimate association between the nasal epithelium and olfactory neurons (Gibson, 2007). This route has been investigated thoroughly for metals such as manganese (Aschner *et al*., 2005), and has also been demonstrated for CNTs and manganese oxide (Oberdörster *et al*., 2004).

Today, little is known about the consequences of manufactured nanoparticles reaching the CNS. It has been proposed that the large surface area and high surface reactivity of nanoparticles are likely to induce oxidative stress, ROS and inflammation (Nel *et al*., 2006). The nervous system is very sensitive to oxidative stress. There is evidence that ambient UFPs are linked to brain inflammation and neurological effects (Campbell *et al*., 2005), but a direct contribution from UFPs has been difficult to prove (Gibson, 2007). Recent studies do, however, suggest that pure nanoparticles can induce inflammation in the brain (Elder *et al*., 2006). Clearly, there is a need to study the neurotoxicology of nanoparticles further.

3.2.6 Dermal Effects of NMs

Skin is a complex and dynamic organ that has several functions, the primary one being to act as a barrier to the external environment. The skin is the largest organ of the body and serves as a primary route of environmental and/or occupational exposure. It consists of three layers, the epidermis, dermis and hypodermis. The epidermis consists of five layers and the outermost layer, the stratum corneum, serves as an effective barrier (Madison, 2003). However, the epidermis also provides an environment where particles could potentially lodge and not be susceptible to removal by phagocytosis (Monteiro-Riviere *et al*., 2007). Even though the skin is a primary route of potential exposure to toxicants, there is little information on whether NMs are absorbed across the stratum corneum barrier or whether systemically administered particles can accumulate in dermal tissue (Monteiro-Riviere *et al*., 2007). The ability of NMs to traverse the skin is a primary determinant of their dermatotoxic potential.

Dermal toxicology studies have shown that NMs can interact with human epidermal keratinocytes (HEK), and the effects depend on the composition, size and surface properties of the NMs (Monteiro-Riviere *et al*., 2005; Sayes *et al*., 2006). Titanium dioxide (TiO_2) is a naturally occurring mineral that is widely used in sunscreens and cosmetics due to its ability to filter ultraviolet (UV) radiation. The ability of TiO_2 in sunscreen preparations to penetrate the protective stratum corneum barrier is controversial. Larger particles of zinc and titanium oxide used in topical skincare products have been shown to penetrate the stratum corneum barrier of rabbit skin (Lansdown and Taylor, 1997). Nanoscale TiO_2 is now being proposed for use in sunscreens due to greater UV filtering ability and greater transparency. These potential benefits are countered with concerns of increased depth of skin penetration, increased reactivity and increased toxicity (Monteiro-Riviere *et al*., 2007). Studies thus far, however, indicate that nanosized TiO_2 does not penetrate the viable layers of skin in healthy adults (Kiss *et al*., 2008; Sayes *et al*., 2006). Even though, more studies on exposure to TiO_2 via the dermal route is needed.

Data is limited on the dermal effects of manufactured carbon-based NMs. HEK has showed significant decrease in viability after being exposed to SWCNTs ($0.00005–0.05\ mg\ ml^{-1}$) for 24 hours (Zhang *et al*., 2007). HEK exposed to MWCNTs has shown a concentration-dependent decrease in viability and also increased interleukin-8 (IL-8) (Monteiro-Riviere *et al*., 2005). These studies suggest a significant dermal hazard after topical exposure to SWCNTs and MWCNTs, provided that they penetrate the stratum corneum barrier. Topical administration of 200 µg of fullerenes to mouse skin over 72 hours, however, did not show any effect on either DNA synthesis or ornithine decarboxylase activity (Nelson *et al*., 1993).

QDs can be obtained commercially in liquid and powder forms, to which both producers and consumers may be exposed. It has been shown that QDs are able to penetrate porcine skin after exposure for 8–24 hours (Ryman-Rasmussen *et al*., 2006). Accumulating *in vitro* evidence indicates that exposure to QDs during manufacture and handling may be hazardous, depending upon the physicochemical composition of the QDs, the cell types

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

involved and environmental factors (Monteiro-Riviere *et al*., 2007).

3.3 Ecotoxicology

The environment does contain many natural sources of particles in the nanometre scale, such as volcanic dust, seaspray and particles from soil erosion. Since these materials have been in the environment since ancient times, organisms have adapted to the presence of many of these materials. The presence of manufactured NMs in the environment now seems inevitable, given the rapidly growing number of products containing these materials, and the possible environmental impacts of these materials remain largely unknown. Engineered NMs are designed to have particular surface properties and chemistries that are less likely to be found in natural particles. They might therefore present enhanced or novel physicochemical or toxicological properties in comparison to natural NMs (Handy *et al*., 2008c). As a result of their remarkably high surface-area-to-volume ratio and complexing capability, engineered NMs may adsorb pollutants, which may change the transport and bioavailability of both the NMs and the pollutants in natural systems (Navarro *et al*., 2008).

Although environmental concentrations of manufactured NMs have not yet been routinely measured, there are concerns that NMs will be released from products over their life cycle. These novel materials will be released from products that are in current use and we are only just starting to explore their ecotoxicology and environmental chemistry. Data on biological effects show that NMs can be toxic to bacterial algae, invertebrates and fish species, as well as mammals, often in concentrations as low as $1\,\mathrm{mg\,l^{-1}}$ (Handy *et al*., 2008b). However, much of the ecotoxicological data is limited to species used in regulatory testing and freshwater organisms. Data on bacterial, terrestrial species, marine species and higher plants is particularly lacking. There are recent reviews on NM effects on algae (Navarro *et al*., 2008), bacteria and other microbes (Neal, 2008), invertebrates (Baun *et al*., 2008), and fish and lower vertebrates (Handy *et al*., 2008a). It is clear that more studies are needed on marine and terrestrial invertebrate species, as well as other vertebrates, including amphibians, reptiles and birds. Data on terrestrial plants and other photosynthetic organisms are also lacking.

The detection of NMs in the environment is complicated because of low concentrations and relatively high background levels of natural nanoparticles. Methods must be developed for samples collected in the field in order to characterize physical and chemical properties. Such methods must be validated before they can be used in environmental monitoring programmes. Most likely these methods will involve size fractionation, and total element or isotope analysis, along with suitable labelling and ancillary measurements (Handy *et al*., 2008c). Handy *et al*. (2008c) has summarized methods that may be useful in characterizing and measuring NMs in the environment.

3.4 Nanomedicine

Nanomedicine uses nanotechnology to maintain and improve human health. Nanomedicine includes the treatment, monitoring, repair, construction and control of human biological systems at the molecular level, using engineered nanodevices and nanostructures. Current and potential applications of nanotechnology in medicine are in diagnostic devices, drug delivery, nutraceuticals and the production of improved biocompatible materials. The development of a wide spectrum of nanoscale technologies is beginning to change the foundations of disease diagnosis, treatment and prevention. These technological innovations have the potential to turn molecular discoveries arising from genomics and proteomics into widespread benefit for patients (Moghimi *et al*., 2005).

The advantage of nanomedicine over conventional medicine lies in the size. Nanotechnology contributes to the development of novel drugs, especially in the area of cancer therapy and treatment to neurological disorders. It produces nanosized drugs that are only slightly larger in size than proteins and are therefore small enough to move across barriers, escape the vasculature and enter cells directly (Chan, 2006). The potential to cross the BBB, especially, may open new ways for drug delivery to the brain. Drugs of nanosize also have an earlier onset of therapeutic action and can be used in lower concentrations, thus reducing the risk of adverse effects (Chan, 2006).

Nanoparticles are attractive for medical purposes because of their unique features, such as their high surface-to-mass ratio, their quantum properties and their ability to adsorb and carry other compounds. The surface is able to bind, adsorb and carry other compounds, such as drugs, probes and proteins. Thus, nanoparticles can act as carriers of therapeutic agents which can be encapsulated, covalently attached or adsorbed onto the surface. This opens the possibility of controlled drug delivery by directing these carriers to a specific location (Moghimi *et al*., 2005). The carrier can then be activated on demand in a limited region. This is a great advantage and provides new opportunities, especially in cancer therapy. Also, by nanosizing a formulation, the drug dissolution rate can be increased, leading to enhanced drug adsorption and bioavailability. Improved tissue selectivity can also be achieved due to the selective uptake of nanoparticles in certain tissues.

Nanoparticles for medical use are based on material of both biological and chemical origins. Source materials

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat044

of biological origin are, for example, phospholipids, lipids, lactic acid, dextran and chitosan, while chemical sources include various polymers, carbon, silica and metals (De Jong and Borm, 2008). Colloidal gold, iron oxide nanocrystals, nanoshells and QDs are examples of nanoparticles that have diagnostic applications in biology and medicine (Moghimi *et al*., 2005). Incorporation of cancer-killer genes into nanocapsules is also being investigated (Chan, 2006).

While nanomedicine provides great promise, it also implies substantial challenges to public health. Nanoparticles for imaging and drug delivery are often purposely coated with bioconjugates such as DNA, proteins and monoclonal antibodies to target specific cells. As these nanoparticles are intentionally engineered to interact with cells, it is important to ensure that these enhancements do not cause any adverse effects (Lewinski *et al*., 2008). Not all NMs are toxic, and it is important to identify those with undesirable properties in order to control risk towards patients (Chan, 2006). It is obvious that the potential interaction with tissues and cells, and thus toxicity, greatly depends on the actual composition of the nanoparticle formulation. For biomedical purposes, especially *in vivo* applications, toxicity is a critical factor to consider when evaluating potential use in patient care.

3.5 Toxicity Testing

3.5.1 Sample Preparation

The collection and preparation of relevant samples of nanostructures for toxicity testing is a critical step in obtaining results that are comparable between studies/laboratories and provides reliable information about the toxicity. It is important that all physicochemical characteristics that are potentially significant are measured in the samples (Warheit, 2008). The following physicochemical properties should be characterized in the context of toxicity screening tests: particle size distribution, agglomeration state, particle shape, crystalline structure, chemical composition, surface area, surface charge and porosity (Tsuji *et al*., 2006). The relevant inhalation dosimetry in risk assessment of NMs may be surface area rather than mass per air volume or mass per body weight. The characterization of the test material should therefore as a minimum also include surface area per mass and particle number per mass (Oberdörster *et al*., 2005b). As mass may not be the proper dose metric for comparing the toxicity of nanoparticles, the dose should be monitored as mass delivered or inhaled. The dose can then be converted to a surface area or particle-number dose as appropriate.

It is recommended that NMs preparation methods are fully documented, including the selection of dispersion media, methods of dispersion in the media and agglomeration state in the medium (Oberdörster *et al*., 2005b). The specific preparation techniques will depend on the material and test protocols being used. However, caution is advised when using ultrasonic agitation to disperse materials, as at high energies the method may be sufficiently aggressive to alter the characteristics of the material.

3.5.2 Testing in Animals

In vivo studies of inhalable particles are complicated, but provide important information about the toxicity of NMs. Nanostructures may interact with biological components, such as proteins and cells, possibly leading to unique biodistribution, clearance, immune response and metabolism. An understanding of the relationship between the physical and chemical properties of the nanostructures and their *in vivo* behaviour would provide a basis for assessing toxic response and more importantly could lead to predictive models for toxicity (Fischer and Chan, 2007).

Inhalation is the physiologically relevant and therefore preferred method of pulmonary exposure. Physicochemical characterization of the generated aerosol is essential in these studies. Inhalation studies can be performed as whole-body exposure or nose-only exposure (**Mixed Routes of Exposure**, Section 2.2.1). Nose-only exposure is more stressful on the animal. However, dermal and oral exposure is minimized in nose-only studies. With whole-body exposure, grooming will inevitably result in some oral exposure. A critical barrier to conducting inhalation studies with NMs is that the amount of material is often limited. Intracavity instillation, where the NMs are administered in a liquid medium, uses less material than inhalation exposure. Intracavity instillations can be performed as intratracheal, pharyngeal or laryngeal instillations.

In vitro experiments may be helpful in determining the dose range to be used for *in vivo* studies. *In vitro* cell cultures, flow-through diffusion cells and perfused skin models can be used (Holsapple *et al*., 2005). Although standard OECD protocols for dermal testing are well established, such protocols are not directly applicable to NMs. However, the procedures for occluded testing should be used, and exposure time and so on must be determined by the aim of the study (e.g. systemic absorption, irritation). The quantitative prediction of the rate and extent of percutaneous penetration (into skin) and absorption (through skin) of topically applied NMs is complicated because the processes driving nanoparticles into skin may be different from those governing other materials (Holsapple *et al*., 2005). It is important to have analytical methods that are able to discriminate between epidermis, dermis and hair follicle.

It is possible that NMs may appear in the water supply or be inadvertently ingested and the effects of oral exposure to NMs should also be investigated. Peroral

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat044
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

exposure could be done by a single gavage at a dose which would represent the worse-case human exposure, or by continuous administration (**Peroral Toxicity**). Rats or mice are the recommended model system (Oberdörster *et al*., 2005b). The administration of the test materials could be by capsules or tablets, where a stainless steel or flexible tube is used to deliver the substance to the stomach, or it can be incorporated into the diet or drinking water.

3.5.3 In Vitro

In vitro studies are an important tool towards understanding how an agent will react in the body. Compared to animal experimentation, cellular testing is less ethically ambiguous, easier to reproduce and control and less expensive. *In vitro* techniques are, in general, seen as important adjuncts to *in vivo* studies. Studies in animal models will identify the organs of interest, in turn leading to identification of the best cell types for *in vitro* studies and the focus of studies on how these cells respond to the nanostructures. *In vitro* studies allow specific biological pathways to be tested under controlled conditions that are not available in studies *in vivo*. There are of course, well-documented problems with *in vitro* approaches, such as lack of validation against *in vivo* adverse effects, dosimetry mismatch, oversimplicity and noninvolvement of the complete inflammatory response (Oberdörster *et al*., 2005b).

An increasing number of *in vitro* studies of NMs have been published. These studies include a wide range of nanoparticle concentrations and exposure times, which makes it difficult to compare studies and determine whether the observed cytotoxicity is physiologically relevant. A wide range of different cell types, culturing conditions and end points can and have be used for *in vitro* studies. This adds to the problem of comparison between different studies. *In vitro* tests can be divided into portal-of-entry toxicity and target-organ toxicity. Cell lines represent the most amenable source of human cells for analysis of the potential toxicity of NMs. These cells are largely, but not exclusively derived from tumours, and a number of cell lines are available, derived from a wide variety of organs. For studies on the nervous system, primary cells are widely used. These cells are derived from dissected embryonic or early postnatal tissue, which are dissociated either mechanically or enzymatically.

The majority of cytotoxicity assays measure cell death and viability by colorimetric methods. There is, however, a technical problem in using such cytotoxicity tests for carbon-based NMs. These materials are black and absorb light in the tests, which are based on colorimetric measurement. The carbon-based NMs interact with the light absorption of a number of the indicator dyes commonly used. MTT (2-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) (Pulskamp *et al*., 2007; Worle-Knirsch *et al*., 2006), Alamar Blue (Casey *et al*., 2007), WST-1 (2-(4-iodophenyl)-3-(4-nitrophenyl)-5 (2,4-disulfophenyl)-2H-tetrazolium) (Casey *et al*., 2007) and Neutral Red (Casey *et al*., 2007) all interact with these carbon-based materials, leading to false readings and misinterpretations. For carbon-based NMs, other end points need to be developed and validated. The clonogenic assay has been introduced by Herzog *et al*. (2007) as an alternative to colorimetric methods. This method was first developed by Puck and Marcus (1956) and measures a single cell's ability to form a colony. The method has been further developed and validated for carbon nanotubes (Gellein *et al*., 2009).

4 FUTURE CHALLENGES

The revolution in nanotechnology is bringing advantages to almost every area of our lives. Nanotechnology itself has the potential to exceed the impact of the industrial revolution and it has been projected to become a $1 trillion market by 2015. As the quantities and types of NMs used in society increase, so does the potential for unintended consequences on human health and the environment. A proactive research is critical to ensure a sustainable and safe nanotechnology industry.

The diversity of engineered NMs and potential effects represent major challenges and research needs in nanotoxicology. A multidisciplinary effort is needed, involving researchers in toxicology, materials science, medicine, molecular biology, bioinformatics, chemistry and their subspecialties. The establishment and standardization of test procedures to ensure safe manufacture and use of NMs in the marketplace is urgently required and achievable.

NMs cannot simply be considered as a single homogeneous class. The toxicity of NMs depends on specific physiochemical factors, and the toxic potential of each type of material needs to be evaluated individually. In the testing of NMs, there needs to be an emphasis on the characterization of the materials themselves. The appropriate route of exposure and the appropriate end points also need to be considered in the design of toxicity studies. Another very important issue is determining the appropriate dose. Exposure levels relevant to human and environmental exposure should be utilized.

Antidotal Studies

D. Nicholas Bateman and Timothy C. Marrs

CONTENTS

1 INTRODUCTION

An antidote is defined in Webster's New Collegiate Dictionary (Webster, 1986) as a remedy to counteract the effects of a poison. Antidotes in this sense are usually considered to be specific chemical entities, but sometimes the definition is broadened to include nonspecific measures, such as administration of oral activated charcoal, or treatments such as haemoperfusion, dialysis and so on (Bateman and Chaplin, 1989). This chapter deals solely with chemical antidotes.

Experimental studies on antidotes are carried out for the same reasons as on other drugs, to demonstrate efficacy and to assess safety in use. However, antidotes differ from many other drugs both in the way they are used and in the manner in which their effectiveness and toxicity need to be assessed. Antidotes are usually only used in life-threatening situations and are often administered as a single dose or, at most, as a short treatment course. They are sometimes used, principally under conditions of war, is a prospective manner, but more often after exposure to the toxin. This means that many of the toxicological data required for drugs used over longer periods in less serious diseases may well be considered unnecessary by many people. Indeed many antidotes, particularly older ones, have been introduced after only minimal animal toxicity studies and in some cases the impetus to the introduction of antidotes has been military. A further difference from many other drugs is that randomized clinical trials, including placebo groups, are rarely possible because of ethical considerations. Although trials on efficacy in humans can be designed, these often use a retrospective control group or a parallel group treated with an established antidote and may be less than totally satisfactory from a scientific point of view. This means that one is more than usually reliant on animal studies for the evaluation of efficacy. Assessment of safety may also be more difficult as the clinical action of the antidote in a nonpoisoned animal or patient may be different to that when the toxin is present. This is perhaps best exemplified by the cyanide antidote dicobalt edetate, which is more likely to result in acute adverse effects in the absence of cyanide.

2 THE POISON

A programme of antidote development requires some knowledge of the toxicology of the poison. There are two purposes in this: firstly, to identify an antidotal approach that is likely to be successful and secondly, to enable the design and interpretation of an antidote efficacy study.

The acute toxicity of a poison compound has traditionally been quantified by the LD_{50}. The use of the LD_{50} test has been criticized on both humane and scientific grounds (British Toxicology Society, Working Party on Toxicity, 1984; Society of Toxicology, 1989; DePass, 1989), but many antidotal efficacy studies use experimental designs that require the use of this test. When the LD_{50} is carried out, the slope of the log dose–probit mortality line should be recorded because the slope is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

often changed by antidotal treatment (Natoff and Reiff, 1970); furthermore, the slope will be useful in calculating the dosing schedules of the poison in studies in which any antidote is to be administered. Ideally acute toxicity studies should be carried out in several species of animal. Animals may show marked differences between one another and from humans in the quantitative or qualitative toxicity of the poison; such species differences will clearly influence the choice of a suitable animal model for experimental work. It is also relevant to consider the dosage of antidote and the dosage of poison in any model. Doses of a poison close to the LD_{50} are more likely to benefit from an antidote. Scaling the appropriate dosages to man also requires consideration. Species differences in paracetamol (acetaminophen) toxicity are a good practical example of these issues.

Where the objective of the treatment is the amelioration of a nonlethal, but crippling, effect, for example, blindness in methanol poisoning, measurement of the ED_{50} (lowest dose giving the effect of interest in 50% of the animals) for the effect will be needed. In such cases, species sensitivity to the appropriate toxic effect will be an important consideration in the choice of species in efficacy studies.

The subacute or chronic toxicity of a poison is not usually of interest specifically in the design of experiments to measure the effects of antidotes. However, delayed effects from acute toxicity may be important, for example, the delayed exposure toxicity of carbon monoxide (Garland and Pearce, 1967; Werner *et al*., 1985; Lee and Marsden, 1994; Lo *et al*., 2007) and the 'intermediate syndrome' associated with acute organophosphorus toxicity (Senanayake and Karalliedde, 1992; Karalliedde *et al*., 2006). The ED_{50} may be a suitable measure of toxicity where the delayed effects are nonlethal.

It is reassuring for the toxicologist to know that the target organ is the same in an animal species as in man. Sometimes an indication of this may be gleaned from acute lethality studies, but on most occasions the effect of sublethal doses of the poison will have to be studied. This is usually necessary since death of some of the animals during acute lethal toxicity studies makes interpretation of the histopathology, a useful indicator of organ specific effects, difficult; moreover, other investigations, for example, haematological and clinical chemistry parameters, helpful in demonstrating organ-specific toxicity, are typically not measured during such studies. Mechanistic studies on particular cell types within the target organ, while desirable and possibly helpful in the initial design of an antidotal approach, are in practice rarely necessary in the assessment of antidote efficacy. Newer imaging techniques, including magnetic resonance imaging (MRI) and positron emission tomography (PET) scanning are another way in which organ toxicity can be followed in real time.

Elucidation of the metabolic pathways of a poison is most useful where conversion to a toxic metabolite is a prerequisite for toxicity. In such instances it is essential that the species used in experimental studies handle the poison in a similar manner to man. Data on this aspect are often weak, but new metabomic and genomic techniques should offer better insights in future. In the situation where the antidote and poison directly react together, for example chelating agents and metals, differences in tissue distribution of the toxin or antidote are likely to be less important. Species differences in rates of metabolism may suggest a difference in the time relationship of antidote dosage and efficacy. Thus knowledge of the pharmacokinetics of the poison in animals and man, while less useful in identifying an antidotal mechanism, may be useful in designing animal efficacy studies, particularly with respect to the choice of an animal model and the choice of appropriate dosing regimes.

3 INTRODUCTION OF NEW ANTIDOTES

The introduction of new antidotal approaches have only rarely occurred by the chance finding of antidotal action, for example, as part of a screening programme. It has usually been based on an extensive substructure of the knowledge of the mechanism of action of the poison, or, in the case of pharmacological antagonists, study of structure–activity relationships. With application of pharmacological, biochemical or chemical expertise it has then been possible to find a way in which the poison could be detoxified or its toxic effects reversed. If one considers the introduction of antidotes at present available, it is clear that most antidotes evolved from the study of an antidote which was less than optimal, a 'lead compound' (Burger, 1982). Analogous compounds were then studied and usually the one with the best therapeutic index was that eventually adopted as the standard treatment. Examples of this approach include the introduction of sodium nitrite, a component of the classic therapy for cyanide which arose from the discovery by Pedigo (1988) of the usefulness of amyl nitrite in cyanide poisoning. Another example is the use of acetylcysteine for the treatment of paracetamol poisoning, which followed the earlier introduction of cysteamine (see Prescott *et al*., 1976). The discovery of the oxime organophosphorus antidotes, pralidoxime chloride (2-PAM), obidoxime and HI6, followed from the discovery of the antidotal effect of hydroxylamine (Bismuth *et al*., 1992). The introduction of dicobalt acetate as a cyanide antidote by Paulet (1960) was an attempt to improve upon the experimentally effective, but toxic, inorganic cobalt salts. More recent examples include 4-methyl pyrazole (fomepizole) as an antidote to toxic alcohols and hydroxocobalamin as a chelating agent in cyanide poisoning. Thus probably the single most challenging part of the process

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of bringing new antidotes into clinical practice is the discovery of 'lead antidotes' and this is usually dependent on a hypothesis for the mechanism of toxicity of a particular poison.

4 MECHANISM OF ANTIDOTAL ACTION

It is difficult to produce a classification of antidotes that is satisfactory in all respects, although a number of workers have attempted to do so (Marrs, 1987; 1992; Bismuth, 1987; Bateman and Chaplin, 1989). To some extent this is because the mode of action of certain well-known antidotes is controversial, while others appear to act in more than one way.

It is possible to envisage a number of ways in which the toxicity of poisons might be opposed (**Table 1**). Broadly they can be divided into three main classes: (i) antidotes that remove the active poison from its site of action, usually by bringing about chemical detoxification of the poison; (ii) antidotes that act specifically at pharmacological receptors or other macromolecules and (iii) antidotes that act in a functional manner.

4.1 Antidotes that Act Chemically

4.1.1 Antidotes that Act Directly on the Poison

The most simple and most easily understood mode of antidotal action is direct chemical reaction between an antidote and a poison to form a product which is less toxic, and may be more rapidly excreted. There are numerous examples of such antidotes, including the chelating agents used in poisoning with a variety of toxic metals, as well as the cobalt-containing cyanide antidotes and Fab fragments, used in digoxin poisoning. Studies *in vitro*, often unhelpful in antibody assessment, have been used in some of these examples to elucidate the chemistry of the reactions.

4.1.1.1 Chelating Agents

The term 'chelation' is often used with a lack of precision. The word comes from the Greek for a claw and it has been argued that monothiol compounds should not be described as chelating agents since they only have one reactive group. Nevertheless, the term is often used as a general term to describe those drugs whose action is to complex metals. The beneficial effect is the result of a number of processes: the complex may be less toxic than the free metal, mobilization from critical sites of toxic actions may occur or else elimination from the body. In many instances all three processes contribute to an antidotal efficacy.

One of the earliest chelating agents was dimercaprol (British anti-Lewisite (BAL)). Like many advances in toxicology the introduction of this substance was stimulated by military considerations. Dimercaprol was intended for use in treatment of poisoning by the chemical warfare agent lewisite, an extremely toxic organic arsenical compound. The use of dimercaprol had its origin in the suspicion, subsequently confirmed, that the toxicity of arsenic was due to the ability to combine with sulfydryl groups in biological molecules, in particular in lipoic acid, part of the pyruvate decarboxylase complex. Dimercaprol and some similar compounds were extensively studied by Stocken and Thompson (1946), and dimercaprol was the first dithiol chelating agents to be used clinically. More recently, two more related drugs have been introduced, dimercaptosuccinic acid (DMSA) and dimercaptopropane sulfonic acid (DMPS). These possess the same dithiol chelating grouping as dimercaprol, but the molecules as a whole are more hydrophilic. Unlike dimercaprol, which has to be injected, DMSA and DMPS can be used orally and both have better therapeutic indices than the older drug (Aposhian *et al.*, 1984).

The toxicity of many metals other than arsenic is due, at least in part, to reaction with sulfydryl groups. It is, therefore, not surprising that the active part of some other chelators also contain sulfydryl groups. Penicillamine, which is a monothiol chelator has been used for some years for the treatment of Wilson's disease, a condition in which copper overload is responsible for hepatic and central nervous system damage. Therapy with penicillamine will chelate a variety of other metals, including lead. Other chelating agents contain active groups other than sulfydryl groups. Disodium calcium ethylene diamine tetra-acetate and its analogues chelate lead and zinc and can be used in acute cadmium poisoning. Desferrioxamine is a compound of natural origin that binds iron and aluminium. A considerable amount of work has been carried out on reactions of the chelating agents (ligands) with metals, and it is possible to predict the efficacy of particular chelating agents, in individual metal poisonings on the basis of the affinity constant of the metal and chelator (Ringbom, 1963; Pearson, 1968; Ayers, 2007). However, despite their logical derivation, net affinity (conditional stability) constants of metal complexes can be misleading. As discussed above the beneficial action of chelating agents is probably the result of a combination of effects, including detoxication by complexation (i.e. the complexed metal is less toxic than the uncomplexed metal), mobilization and elimination. In order to detoxify effectively, chelating agents must gain access to the tissue were the metal is exerting its action. In the case of mobilization, the process must occur in a toxicologically desirable direction; that is away from the critical site of toxic action of the metal. Unfortunately, net affinity constants cannot predict the extent to which

Table 1 Mechanism of action of antidotes

Class	Subclass			Poison
Antidotes that act chemically	Direct chemical detoxicants	Chelating agents		Metals
		Cobalt compounds		Cyanide
		Antibodies and derivatives	Monoclonal antibodies	Soman
			Fab fragments	Digoxin
Enzymatic detoxicants	Co-substrates	Sodium thiosulfate		Cyanide
	Enzymes	Rhodanese		Cyanide
		Acetylcholinesterase		OPs
	Prevention of formation of toxic metabolite	Ethanol		Methanol, ethylene glycol
Antidote gives rise to a detoxifying substance	Methaemoglobin-formers			Cyanide and sulfide
Antidote reacts with enzyme-poison complex	Oximes			OPs
Antidote reacts with toxic metabolite	*N*-acetylcysteine and methionine			Paracetamol
Antidote that act pharmacologically	At characterized pharmacological receptors	Naloxone		Opiates
		Flumazanil		Benzodiazepines
		Prenalterol		β-Blockers
	At other macromolecules	Oxygen		Carbon monoxide
Functional antidotes	Diazepam			OPs

chelation occurs *in vivo*, or whether mobilization of the metal occurs in a beneficial direction. Thus, Catsch and Harmuth-Hoehne (1975) found that penicillamine was a more effective mobilizing agent in mercury poisoning than diethylene triamine pentacetate, whereas the corresponding affinity constants would suggest otherwise. In an attempt to refine studies *in vitro* Yokel and Kostenbauder (1987) hypothesized that hydrophobicity of the chelated complex was important in successful chelation therapy. They therefore studied chelating agents for use in aluminium poisoning *in vitro* in an octanol–aqueous system and *in vivo* in rabbits poisoned with this metal. They concluded that the ideal chelator should have sufficient affinity for the metal of interest, be sufficiently water soluble to take by mouth and be sufficiently lipid soluble to distribute to sites of accumulation of the metal. If this theoretical model were to be directly applicable to experimental investigations of antidotal efficacy *in vivo*, it would be a great advantage. Unfortunately the *in vivo* situation cannot be adequately approximated *in vitro*, even for chelating agents, a group of antidotes where *in vitro* studies would seem the most promising.

4.1.1.2 Cobalt-Containing Cyanide Activities

It has been known from many years that transition metals can form stable and often relatively nontoxic complexes with cyanide. Clinically, this property of the transition metals has only been exploited in the case of iron (see methaemoglobin below) and cobalt. Cobalt is a metal whose toxicity is well recognized and it has therefore generally been considered that toxicity of inorganic cobalt salts preclude their clinical use. Muschett *et al.* (1952) showed that hydroxocobalamin (Vitamin $B12_a$) was an effective antidote in experimental cyanide poisoning in mice. In clinical practice, hydroxocobalamin presents a number of problems. The molecular weight

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat045
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is high and the compound binds cyanide in a ratio of 1 mole of hydroxocobalamin:1 mole of cyanide. This means that very large quantities of hydroxocobalamin are necessary for meaningful cyanide antidotal action. Paulet (1960) studied a number of cobalt derivatives in order to find a compound of lower mass which had the antidotal effectiveness of hydroxocobalamin, but which lacked the toxicity of inorganic cobalt salts. The cobalt compounds studied were the chloride, acetate, gluconate and glutamate salts and cobalt histidine and dicobalt edetate. The last two were effective and less toxic than the other compounds. On the basis of efficacy studies in dogs and acute lethality studies in mice, dicobalt edetate, in the formulation known as Kelocyanor, was widely adopted in Europe. Kelocyanor has given rise to adverse reactions, especially when given in the absence of substantial cyanide poisoning. More recently, studies have been undertaken into other organic derivatives of cobalt, notably porphyrins (McGuinn *et al*., 1994). There has been a recrudescence of interest in hydroxocobalamin. A retrospective review of cases of acute cyanide poisoning (mostly ingested potassium cyanide) treated with hydroxocobalamin was undertaken by Borron *et al*. (2007); this suggested that hydroxocobalamin was an effective antidote. Erdman (2008) suggests that there is, as yet, insufficient evidence to demonstrate either the safety or clinical efficacy of hydroxocobalamin when administered after exposure to hydrogen cyanide, which is rapidly absorbed and distributed, and essentially acts immediately. Hydroxocobalamin also has logistical drawbacks for emergency use, in that it would have to be given intravenously over at least 15 minutes in a large volume of fluid to counteract the effects of a poison with rapid effects.

4.1.1.3 Fab Fragments and Monoclonal Antibodies

Antisera have long been used to treat poisoning with toxins of biological origin, such as botulinus toxin and toxins in snake venom: this approach can theoretically be adopted from other poisons. It is an attractive option for many poisons where no chemically detoxifying antidote of sufficient efficacy and an adequate lack of toxicity is available. Thus, monoclonal antibodies have reportedly been successful in experimental poisoning by the organophosphorus nerve agent soman (Lenz *et al*., 1984), while monoclonal antibodies against Paraquat have been produced (Johnston *et al*., 1988). In the best known example of immunotherapy for poisoning with a drug, poisoning with digoxin, whole antibodies are not used. Instead poisoning with this cardiac glycoside is treated with Fab antibody fragments (Stolshek *et al*., 1988). Fab fragments have the advantages that they can be eliminated by glomerular filtration through the kidney (Cole and Smith, 1986) and are less immunogenic than whole antibodies (see review by Bateman, 2004). Immunotherapy can, in theory, be used to treat any poisoning where detoxicating antibodies can be made against a toxicant. However, in practice the size of the dose of poison makes the approach of limited practical value for many clinical poisonings. Biotechnology, making, as it does, large-scale manufacture of monoclonal antibodies easier, adds to the attractiveness of immunotherapy, making wider use more likely in the future.

4.1.2 Antidotes that Act on the Poison via an Enzyme-Catalysed Reaction

The existence of enzymatic pathways of detoxication can be exploited in two main ways. Detoxifying cosubstrates can be used, but will usually only be effective if the rate of reaction of that particular metabolic pathway is cosubstrate limited. Alternatively, the amount of enzyme present can be increased by injecting enzyme derived from an exogenous source. A further way of influencing an enzymatic process is the exogenous supply of an alternative substrate, or the use of an enzyme inhibitor. This may be helpful where poisoning results from metabolism of an indirectly acting poison to a toxic metabolite.

4.1.2.1 Cosubstrates

Sodium thiosulfate is probably not the physiological sulphur donor of the enzyme rhodanese. Nevertheless, this cyanide antidote appears to act by increasing the supply of sulphur for the enzyme, which is normally rate-limited by sulfane sulphur availability. The rhodanese reaction accelerates the rate of cyanide transulfuration to thiocyanate, an ion which is considerably less toxic than cyanide. Sodium thiosulfate, when used alone, is not particularly effective because, although it can increase the rate of cyanide transulfuration very considerably (Cristel *et al*., 1977), the blood level of cyanide does not fall fast enough, in the context of acute cyanide poisoning, to counteract the poisoning effectively. The possible reason for this is that rhodanese is a mitochondrial enzyme, while sodium thiosulfate administered intravenously remains largely extracellular. Because of the slow nature of the fall in cyanide blood levels that are observed after the use of sodium thiosulfate, the main use of this cyanide antidote has been as a second-line antidote to one of the methaemoglobin formers (see below), such as sodium nitrate or 4-dimethylaminophenol.

Other sulphur compounds, including sodium ethane thiosulfonate and propane thiosulfonate have been studied in the expectation that they would enter the mitochondria. In some animal studies, these sulfonic acid derivatives were superior to sodium thiosulfate, but they have not been used clinically. Cyanide detoxication by transulfuration has also been carried out using another endogenous enzyme: β-mercaptopyruvate sulphur transferase. In this case sodium β-mercaptopyruvate was the experimental antidote (Way *et al*., 1985).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat045
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.1.2.2 Exogenous Enzymes

Exogenous enzymes suffer from the disadvantage of being potentially foreign proteins, but have nevertheless been used experimentally as antidotes. Thus, in an attempt to place the rhodanese in the extracellular space, the use of intravenous bovine heart rhodanese accompanied by sulphur-containing cyanide antidotes has been studied in animals (Frankenberg, 1980). Another antidote that has been studied is acetylcholinesterase in the treatment of anticholinesterase poisoning. Thus Wolfe *et al*. (1992) found that foetal bovine serum acetylcholinesterase and horse serum butyrylcholinesterase were effective pretreatments in experimental soman toxicity in rhesus monkeys.

4.1.2.3 Alterations of Toxic Metabolite Formation

An enzymatic method of detoxication which is only applicable to indirectly acting poisons is the inhibition of the formation of a toxic metabolite. Clinically, such an approach is adopted when ethanol is used to compete at the active site of the enzyme alcohol dehydrogenase and thus to inhibit the formation of formic acid and formaldehyde in methanol poisoning (Cooper and Kini, 1962). Ethylene glycol poisoning can be treated in the same way (see review by Kraut and Kurtz, 2008). Additionally, in experimental studies, pyrazole or 4-methylpyrazole have been used to inhibit alcohol dehydrogenase in these poisonings (Clay *et al*., 1975).

4.1.3 Antidotes Giving Rise to Detoxifying Substances

4.1.3.1 Methaemoglobin-Forming Antidotes

A group of antidotes that do not themselves act by chemically binding a poison, but produce a substance that does, are the cyanide antidotes that induce a therapeutic methaemoglobinaemia. Methaemoglobin is a form of haemoglobin in which the iron has been oxidized from Fe^{2+} to $Fe3^{+}$. Methaemoglobin is unable to carry oxygen reversibly in the way that haemoglobin does, but it has a high affinity for cyanide and sulfide. The first of this group of antidotes introduced for the use of cyanide poisoning was amyl nitrite. Although this is still sometimes used, the most widely available methaemoglobin producer is sodium nitrite and this is still used in the USA and elsewhere as a primary cyanide antidote. The more recently-introduced 4-dimethylaminophenol (DMAP) is used in Germany while 4-aminopropiophenone (PAPP) is primarily of military interest (Bright, 1987). Sodium nitrite and DMAP produce methaemoglobin, but in different ways, the former somewhat more slowly. The aim in both instances is to produce methaemoglobinaemia of sufficient degree to bind substantial quantities of cyanide, without producing such a high level of methaemoglobin as to produce an appreciable danger of tissue anoxia. In fact, there appears to be a number of instances where dangerously high levels of methaemoglobin have been produced, perhaps because of individual susceptibility, or overenthusiastic use of the antidotes. It is unfortunate that the therapeutic monitoring of methaemoglobin during the treatment of cyanide poisoning is usually not possible, since common methods for measuring methaemoglobin do not separately measure haemoglobin, cyanmethaemoglobin and methaemoglobin (see **Haematology and Toxicology**). Cyanmethaemoglobin is the pigment produced by the reaction of cyanide with methaemoglobin. Adverse outcomes seem to be more common with DMAP than sodium nitrite, a fact which is surprising in view of the much longer time during which the latter has been used (Van Heijst *et al*., 1987; Marrs, 1989). It is also worth noting that some authorities doubt whether the main action of sodium nitrite is for it to form methaemoglobin, and suggest a vasoactive action (Way *et al*., 1987).

4.1.3.2 Antidotes that React with an Enzyme–Poison Complex

4.1.3.2.1 Oximes

Hydroxylamine was studied as an antidote to poisoning with organophosphate anticholinesterase because it was, in certain respects, similar to the substrate of the enzyme, namely acetylcholine. It was superseded by the pyridinium oximes and organophosphate poisoning is now often treated by an oxime together with atropine, an anticholinergic drug. The oxime that is used in many countries is the monopyridinium oxime, 2-PAM. Additionally one or two countries use other salts of pralidoxime; the methanesulfonate is used in the United Kingdom and the methylsulfate in France and some other countries; the methiodide is also available in certain pharmacopeias. The bis-pyridinium oxime, obidoxime has certain advantages in the therapy of organophosphate chemical warfare agents, particularly in that there is evidence that it may be effective in tabun poisoning. Even here, Marrs *et al*. (2006) suggested that there are no clinically important differences between pralidoxime, obidoxime and HI-6 (another bis-pyridinium oxime) in the treatment of nerve-agent poisoning, if studies employing pretreatment with pyridostigmine are excluded, except possibly with cyclosarin. There appear to be no clear differences between 2-PAM and obidoxime in organophosphorus pesticide poisoning (see review by Marrs and Vale, 2005). The principle action of oximes is the dephosphorylation and consequent reactivation of acetylcholinesterase, and, in this respect, the main weakness in their activity is against acetylcholinesterase which has undergone ageing. The ageing process, which is monodealkylation of the dialkyl phosphorylated enzyme, renders the enzyme refractory to both oxime-induced and spontaneous reactivation (Bismuth *et al*., 1992). It is probable that ageing occurs to some extent with all

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat045
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

organophosphate anticholinesterases and it is possible that it may cause clinical problems in organophosphate pesticide poisoning, where treatment is initiated very late. It is, however, a very serious problem with the nerve agent soman, whose complex with acetylcholinesterases ages with a half life of a few minutes (see Wilson *et al*., 1992). Of the numerous oximes that have been studied, the only ones where much activity is exerted on aged enzyme complexes are the Hagedorn oximes such as HI-6. However, there is controversy whether the activity of this oxime in the situation where appreciable ageing has occurred is attributable to acetylcholinesterase reactivation or to other direct effects of the oxime (see Marrs *et al*., 1996a).

4.1.3.3 *Antidotes that Act on a Toxic Metabolite of the Poison*

In the case of poisons requiring metabolism before they become toxic, any of the above antidotal methods could, in principle, be applied. In practice, however, poisoning with such materials is treated by bringing about direct reaction with a toxic metabolite. An example is paracetamol poisoning. Paracetamol (acetaminophen) is toxic by virtue of its metabolic transformation to a reactive metabolic *N*-acetyl-*p*-benzoquinoneimine (NABQI). Under normal conditions of use, paracetamol is harmless, but in an overdosage causes cell damage and this leads to, among other things, hepatic necrosis. The lead antidote cysteamine, although effective in animal models, caused adverse reactions in man, especially nausea. Acetylcysteine probably acts by conjugating with NABQI; methionine, an alternative antidote may also do so, but only after conversion in the liver to homocysteine (Prescott, 1983; Seddon *et al*., 1987). Recent data suggests that the adverse effect profile of acetylcysteine in man is worse in the absence of paracetamol, raising interesting questions on the relationships between the antidote and the mechanisms of its adverse effects (Pakravan *et al*., 2008).

4.2 Antidotes that Act Pharmacologically

It is convenient to divide antidotes that act pharmacologically into those antidotes where antagonism occurs at characterized pharmacological receptors and those were antagonism occurs at other macromolecules: this division, though somewhat artificial, is nevertheless useful.

4.2.1 *Antidotes that Act as Characterized Pharmacological Receptors*

Such antidotes include naloxone, an antidote for opiates (Evans *et al*., 1973; IPCS, 1993) and flumazanil, which is effective in reversing the effects of benzodiazepines (Scollo-Lavgizzari, 1983), although not licensed for the management of poisoning in the UK. In severe poisoning with β-blockers, adrenergic agonists, such as isoprenaline or the more specific and cardioselective prenalterol, provide examples of receptor antagonism (Wallin and Hulting, 1983). In some cases the receptor can be bypassed and second messenger systems stimulated directly, as with the action of glucagon in β-blocker poisoning. Development of compounds within the class requires a knowledge of the pharmacological profile of a drug and the particular pharmacological property responsible for toxicity.

4.2.2 *Antidotes that Antagonize Other Macromolecules*

Carbon monoxide is poisonous by virtue of its tight binding to haemoglobin and other cellular components. Carbon monoxide can be displaced competitively from such sites by oxygen.

4.2.3 *Related Antidotal Mechanisms*

Antagonism of clinical poisoning does not necessarily take place at the same receptor as that at which the poison acts. Atropine is an anticholinergic drug and acts upon muscarinic cholinergic receptors. However, this drug is used as an antidote in poisoning with organophosphate and carbamate anticholinesterases, substances whose major action is not directly on the cholinergic receptor. The macromolecule to which the anticholinesterases binds is the enzyme acetylcholinesterase, and the poisoning is a consequence of accumulation of acetylcholine, the normal substrate of that enzyme. It is this effect which is antagonized by atropine (see review by McDonough and Shih, 2007). Analogous to this is the use of physostigmine in atropine poisoning: this anticholinesterase promotes acetylcholine accumulation, which overcomes the effect of atropine.

4.3 Functional Antagonism

There are a number of antidotes which are used symptomatically in poisoning and as such are difficult to classify. In some cases, further study may show these to have antagonistic actions that belong to one of the above groups. An example is the wide use of diazepam to combat the convulsions in a wide range of poisoning, and, in the case of organophosphate poisoning, an additional benefit is reduction in muscle fasciculations (Sellström, 1992; Marrs and Sellström, 2007). Diazepam acts allosterically on the γ-aminobutyric acid A ($GABA_A$) receptor. The GABA system is an inhibitory neurotransmission system and the agonistic effect of diazepam is to ameliorate or prevent the convulsions

which may occur in organophosphate poisoning (see review by Marrs, 2004).

5 ASSESSMENT OF ANTIDOTAL EFFICACY

Antidotal efficacy can be assessed *in vitro*, in experimental animals and, to some extent, in human poisonings. All these approaches have limitations: studies *in vitro* cannot adequately simulate the situation *in vivo*, even in the case of the most straightforward antidotes which react with and detoxify the poison. Studies *in vitro*, however, are useful preliminaries to animal studies, particularly in narrowing down the choice amongst a series of related antidotes (Marrs, 1992). Moreover, in mechanistic studies of the action of antidotes, an *in vitro* approach is often extremely useful. Studies in experimental animals, possibly the most useful of the three approaches, are limited by the problems of extrapolation for two different substances, the toxin and the antidote, from animals to man, and by the need for very careful attention to experimental design. The limitations inherent in data on human poisonings are quite different: for example, Poison Centre data normally relate to suicidal and accidental exposure and so the dose of poison is uncontrolled and often unknown. While large multicentre trials would be very useful, these are extremely difficult to conduct, as ethical committees often require consent in advance of intervention, which is difficult to obtain in distressed patients. Such studies are extremely rare, and may be negative (Eddleston *et al*., 2008). Thus these do not usually provide information which can properly replace animal studies.

5.1 Assessment of Antidotes in Experimental Animals

There are many ways in which studies of antidotal efficiency can be performed and some of the factors to be considered in experimental design are listed in **Table 2**.

Table 2 Variables

Animal model	a. Species, strain and sex b. Numbers and controls
Poison	a. Dose b. Route of administration c. Solvent and excipients
Antidote	a. Dose b. Route of administration c. Solvent and excipients d. Time between administration of poison and antidote
End point	a. Lethality b. Other i. Clinical ii. Biochemical iii. Haematological iv. Electrophysiological v. Histopathological vi. Behaviour

5.1.1 Animal Models

One of the main features requiring attention is the choice of species of experimental animal. However well constructed the study is in other respects, unless the behaviour of the poison and antidote are similar in the chosen species and in humans, the results will be valueless (see Calabrese, 1982; Marrs, 1987). Species' suitability will be determined by similarity between the chosen species and humans in absorption, distribution, metabolism, excretion and response to the poison. The relative importance of these considerations depends on the mode of action of the poison: if it is a directly active poison, for example, cyanide, similarity in rate of endogenous detoxification would appear to be the most important consideration, while, for those substances which are toxic in humans only after a metabolic activation step, the occurrence of this conversion at a similar rate in the chosen species to that in man is probably the most important factor.

Major quantitative differences in lethality of chemicals between a given species and humans indicate that the species is probably a poor choice. Such differences exist with respect to methanol (Clay *et al*., 1975), ethylene glycol (Gessner *et al*., 1961), certain organophosphates (Crawford *et al*., 1976) and paracetamol (Prescott, 1996). It must be further borne in mind that the choice of scarce, large or exotic animals will increase the cost of the experiment and may thereby tend to reduce the numbers that can be used. This will clearly decrease the power of the study. Moreover normative data on such animals is usually scanty or nonexistent. All the forgoing considerations apply, of course, to the evaluation of any xenobiotic in animals; however, with antidotal studies the same considerations also apply with respect to the antidote, so that the species chosen must be similar to the human in its handling of both the poison and the antidote. This fact may greatly complicate the choice of animal model and indeed there may be no perfect solution.

A particular difficulty arises with the organophosphate nerve agent, soman. This is because this substance forms a complex with acetylcholinesterase which ages (loses an alkyl group) rapidly, rendering the complex refractory to reactivation by most pyridinium oximes. Ageing rates

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat045
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

are species-dependant, so that realistic antidotal studies undertaken in species other than primates must be interpreted with great care (Eyer and Worek, 2007).

The species having been decided upon, the numbers of animals and controls must be determined. Two main types of experimental design have been adopted for the evaluation of antidotes. In the first, 'LD_{50} ratio', the LD_{50} of the poison is measured with and without the administration of the antidote. This procedure has the advantage that the result produced is a single figure, the protection ratio, but is has the disadvantage that it is necessary to use a relatively large number of animals. Moreover, the slope of the treated and untreated log dose–probit mortality curves may not be the same (Natoff and Reiff, 1970), and this will impair the value of the single figure. The protection ratio design is usually employed when small laboratory animals are used, although there are instances of the use of this type of design with larger animals, such as sheep by Burrows and Way (1979), studying cyanide antidotes, and monkeys by Dirnhuber *et al.* (1979), studying pyridostigmine prophylaxis in soman poisoning. Although performance of LD_{50} ratio-type studies sounds easy, multiple pilot experiments are often needed to bracket the median lethal dose. This difficulty is aggravated by the fact that LD_{50}s are often not measured nowadays for regulated chemicals such as pesticides, other measures of acute toxicity being used for classification purposes (see **Acute Toxicity**).

The other principle design is the comparison of survival in groups of animals given the same supralethal dose of poison, one group being treated with the antidote and the other being left untreated. The number of animals used is much less than with protection-ratio design, but the information supplied is also less. This approach has been criticized on the grounds that antidotes capable of increasing the LD_{50} of the poison by comparatively small amounts can produce dramatic increases in the proportion of animals surviving (Way *et al*., 1987); nevertheless, such experimental designs are frequently being used with large laboratory animals such as dogs. An example of the use of this design with laboratory rodents is a study by Jokanović and Maksimović (1995), who compared the four pyridinium oximes, trimedoxime, obidoxime, pralidoxime and HI-6 in the treatment of oral poisoning with a number of organophosphorus pesticides in the male Wistar rat.

If this approach is adopted, it is essential to have an untreated, but poisoned, control group within the study. The reliance on literature LD_{50}s, where the animals, normally of the same strain, may have been studied under different conditions and with different formulations of poisons, is reprehensible and renders the study valueless.

Whichever type of design is adopted, consideration should be given to the inclusion of a treatment-only group.

5.1.2 Poison

The dose of poison used depends on the overall design of the study. Where a design of protection-ratio type is used, dosing is, as with any LD_{50} estimate, designed to bracket the lethal dose. Adjustment of the dose range upwards may be required in the antidote-treated group. Often siting shots will be necessary preliminaries to a substantive experiment in both antidote-treated and untreated groups. Where survival is compared in two groups of animals, one poisoned and untreated and the other poisoned and treated with the antidote, the dose of poison chosen is usually a dose which will be supralethal in animals not treated with antidote. It must also be a dose against which there is a reasonable chance of survival with antidote. To obtain a reasonable idea of the maximum dose of toxicant against which an antidote will protect, it may be necessary to use several different doses of poison.

The poison should normally be given by the route by which it commonly gains access to man. In the case of a large number of poisons, this will be by mouth, so that gavage is appropriate in animal studies. Percutaneous and inhalation poisoning present problems, the former because the reproducibility of lethality figures tends to be poor and human skin is different in structure to animals, the latter because of the relative scarcity of inhalation facilities in laboratories. Intratracheal installation has been used as a substitute for inhalation studies, but it does not appear to be satisfactory, particularly with toxicants acting locally on the lungs (Richards *et al*., 1989).

Where poisoning by a pharmaceutical preparation is being studied, formulations are readily available for experimental purposes and are often used. The use of the formulation, rather than the active ingredient by itself, should be considered with other formulated materials, such as pesticides.

5.1.3 Antidote

In the case of an antidote already in use in man, it may be appropriate to adjust the dose to the size of the animal in experimental studies. In certain instances, however the choice of dose is more complicated. For example, it would be unwise to ignore species differences in methaemoglobin generation when studying methaemoglobin-producing cyanide antidotes.

The antidote is usually assessed after administration by the route by which it will be used. Furthermore, while in the early stages of development, the antidote will be frequently studied in its pure state, at some point it should be evaluated in the formulation in which it will be used clinically.

One of the most difficult points to resolve is the time relationship between administration of the poison and the antidote. This is a problem which is particularly important with rapidly acting poisons, and careful

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat045
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

attention must be applied to this aspect of the design of the study if data are to be produced which can be extrapolated to clinical human poisonings. The use of prophylactic administration of antidotes is not valid, except where mechanistic studies are being carried out or where the antidote is intended for prophylactic use (Way *et al*., 1987). Even when the antidote is given after poisoning, there is still the problem of the precise time interval between the challenge and the administration of the antidote. Marrs *et al*. (2006) cited unpublished data from Porton Down which showed a drastic decrease in the effect of atropine, pralidoxime and diazepam on protection ratios in guinea pigs given pyridostigmine 30 minutes before nerve agent, depending on the interval between poisoning and the administration of therapy. With the three nerve agents, sarin, soman and VX, delay from one to four minutes approximately halved the efficacy of the atropine/pralidoxime/diazepam therapy. Thus the interval between poisoning and treatment may be critical. Usually the antidote is given at a fixed time after poisoning or at the onset of a well-defined clinical sign. Unfortunately the time interval has often been chosen so as to be unrealistic compared with the time between clinical poisoning and when clinical therapy is likely to be available. On the other hand, the use of clinical signs as a cue for antidote administration invites the possibility of observer bias. A possible solution is to use a fixed time interval, but one somewhat longer than those customarily employed. In addition, it is of value to consider a study design in which the antidote is administered at intervals after the toxin, a situation that more closely resembles clinical poisoning. Temporal considerations (discussed above) tend to be much less important with poisons whose clinical effects have slow onset, or in the treatment of chronic or delayed poisoning, than in acute poisonings.

5.1.4 End Point

Although the vast majority of antidote efficacy studies employ death or survival as the end point, a possible alternative is change in time of survival. Clinical end points other than lethality may be used, but observer bias should be carefully avoided. The efficacy of the antidote against sublethal effects, often behavioural ones, has also been used; this approach is attractive in military contexts, where knowledge of a poisoned individual's ability to keep fighting is desired. Biochemical end points, such as liver function and clotting changes in paracetamol overdose, are well established. Others, such as reactivation of cholinesterase in organophosphate poisoning, or mobilization of a metal in heavy-metal poisoning may be used (e.g. Kreppel *et al*., 1995; Tandon *et al*., 1996), but can have a potential problem, in that biochemical improvement does not always correlate with clinical efficacy of the antidote.

5.1.5 More Complex Studies

5.1.5.1 Comparison of Antidotes

It is frequently necessary to evaluate a new antidote against an existing one, or to survey a series of structurally related antidotes. The aim should be study the antidotes under reasonably realistic conditions. In this case the animal model chosen must be suitable for the evaluation of the toxic effects of the poison and of more than one antidote, as well as be able clearly to show comparative efficacy. It may be appropriate to use control groups, these animals receiving each antidote alone, another group receiving the poison alone and further groups receiving the poison together with each treatment. Alternatively, a full dose–response evaluation, which will yield a protection ratio for each antidote, can be carried out and in fact has frequently been done (see, for example, Schwartz *et al*., 1979). Although most of the variables discussed earlier will also apply to an evaluation of two or more antidotes in the same study, it is usually more difficult to standardize experimental conditions in a study employing more than one antidote.

5.1.5.2 Use of More than One Antidote in the Same Animal

More than one antidote, used together, may be used to treat a poisoning. Thus, organophosphates are usually treated with atropine and an oxime, and cyanides frequently with sodium nitrite and sodium thiosulfate (see above). The combined effects of such treatments may be additive, synergistic or less than additive. There is no particular problem with assessing treatment regimes of this type, the usual procedure being to appraise each antidote separately in experimental animals and then together: an example is the study of the efficacy of dimercaptosuccinic acid and calcium disodium edetate in lead-intoxicated rats by Flora *et al*. (1995). It will frequently be necessary to use multiple dosing combinations and it should not be forgotten that antidotes may interact chemically if mixed together before administration.

5.1.6 Antidotal Studies for Regulatory Purposes

Antidotal studies are sometimes done for regulatory purposes, notably on anticholinesterase organophosphate and carbamate insecticides. Many studies are in the open scientific literature, while others are in regulatory submissions and can be obtained from national pesticide registration authorities. Many have been reviewed in the toxicological monographs prepared by the Joint Expert Meeting on Pesticide Residues and published by the Food and Agricultural Organization in Rome (*http://www.inchem.org/pages/jmpr.html*). These studies are not always well-designed, insufficient attention often being given to statistical power.

5.2 Studies of Antidotes *In Vitro*

In Section (4.1.1) it was stated that studies *in vitro* were often unhelpful in antibody assessment. Nevertheless they can be useful in investigating the mechanism of antidotal action. Another role of studies *in vitro* is where it is desired to compare similar antidotes, whose mechanism of action is known. Thus, Worek *et al*. (1997; 1998a; 1998b) compared the reactivating capability of various pyridinium oximes against nerve agent-inhibited acetylcholinesterase. The problem with using studies *in vitro* to assess the likely efficacy of antidotes in humans is that such studies cannot allow for the pharmacokinetics of the poisons and antidotes.

5.3 The Assessment of Antidotes in Human Beings

Provided that certain ethical guidelines are followed (Royal College of Physicians of London, 1986) and given appropriate ethical committee approval, studies of poisons or antidotes may be carried out on human volunteers. Such studies would be performed for a number of different purposes.

It may be necessary to establish the pharmacokinetics or pharmacodynamics of a poison or antidote in man; further, the observer may wish to study the distribution and metabolism of both in humans. Thus a number of pesticides have been studied in human volunteers (Wilks and Woolen, 1994), as have chemical warfare agents (Marrs *et al*., 1996b; Sidell, 2007). Human studies may be carried out during clinical use, either as part of a controlled clinical trial or by observation during routine clinical use; antidotes can also be studied in human healthy volunteers. Some compounds that are used as antidotes have already passed through such studies, since they are already used as therapeutic substances in other clinical situations. An example might be the use of β-adrenergic antagonists in the management of theophylline poisoning.

The second area where it may be necessary to study effects of antidotes in volunteers is in the evaluation of adverse effects. Sometimes, this may occur after the antidote has undergone clinical use, as was the case in studies that were carried out on acetylcysteine. In these experiments, intradermal acetylcysteine was given to volunteers, and to patients who had undergone treatment for paracetamol poisoning and had suffered adverse reactions (Bateman *et al*., 1984). More recent work has been carried out in patients to further explore the nature and mechanisms of adverse effects from this antidote (Pakravan *et al*., 2008).

For antidotes that act as agonists and antagonists at pharmacological receptor sites, studies of the pharmacodynamic reaction in volunteers may be carried out prior to the administration of the drugs to patients. Thus, the opiate antagonist naloxone and the benzodiazepine antagonist flumazanil were studied in volunteers prior to being given to patients.

Clinical studies in patients may involve the use of single doses in intoxicated patients, and comparison with control groups to assess response. This technique was used when naloxone was introduced, and had been shown to be efficacious in opiate poisoning, but without affecting benzodiazepine and barbiturate poisoning. In addition, clinical studies need to be done in patients to establish the appropriate dosing regime, and this is particularly the case for pharmacological antagonists such as naloxone, for which studies were carried out to clarify the most appropriate dosing format (Goldfrank *et al*., 1986).

6 CONCLUSION

Poisons and their antidotes may be studied in experimental animals, *in vitro* or in humans. The design of studies in all three situations presents major challenges. In the case of animal studies, great rigour is needed to ensure that studies are designed to simulate realistic treatment scenarios.

Toxicity Data Obtained From Human Studies

Martin F. Wilks and Hugo Kupferschmidt

CONTENTS

1 INTRODUCTION

Animal or *in vitro* models for toxicity testing are assumed to offer a reasonable prediction of what may happen in humans as the ultimate species of interest in most cases. The main tasks of experimental toxicology have been defined as relating to the spectrum of toxicity (detection of adverse effect and description of dose–response relationship), extrapolation to other species, particularly to humans, and prediction of safe levels of exposure (Zbinden, 1991). In contrast, most toxicity data from humans are observational and subject to much larger uncertainties and variations than animal toxicology studies (**Table 1**). Although regulators as well as the concerned public are looking for actual human data to confirm or refute perceived health risks from chemical exposure, they appear increasingly unwilling to accept experimental data from human studies, even though they may have been obtained in accordance with strict ethical and scientific guidance.

The purpose of this chapter is to explore the ethics, benefits and limitations of various types of human studies which are of use in toxicity evaluations. This will be made in the context of specific subsets of human exposure to xenobiotics, for example exposure to industrial chemicals, pharmaceuticals or agricultural chemicals, in which certain types of studies have a particular relevance.

2 ETHICAL ISSUES

All research involving human subjects should only be conducted once ethical issues have been formally considered and documented. The principle of an ethical 'Code of Conduct' for such research was first enshrined following the trial of Nazi physicians who had conducted atrocious experiments on prisoners and detainees during the Second World War (US Government Printing Office, 1949). This so-called 'Nuremberg Code' was designed to protect the integrity of the individual, setting out conditions for the ethical conduct of research involving human subjects, in particular the principle of 'voluntary consent' to research. In 1966, the General Assembly of the United Nations adopted the International Covenant on Civil and Political Rights, of which Article 7 states: 'No one shall be subjected to torture or to cruel, inhuman or degrading treatment or punishment. In particular, no one shall be subjected without his free consent to medical or scientific experimentation.'

The Declaration of Helsinki, adopted in 1964 by the World Medical Association, has become the fundamental document in the area of biomedical research, and has formed the basis for international and national legislation and codes of conduct. The Declaration has been revised and updated several times, most recently at the Seoul Meeting of the Association in 2008. The Declaration sets out ethical guidelines for physicians engaged in clinical (patient) and nonclinical

Table 1 Some characteristics of animal experiments and human studies in toxicology

	Animal experiment	Human study
Genetic variability	Homogenous	Heterogenous
Age distribution	Uniform	Variable
Pre-existing morbidity	None	Frequent
Diet	Controlled	Uncontrolled
Environment	Controlled	Uncontrolled
Exposure	Onset and duration known	Onset and duration usually not known, or variable
	Single-agent exposure	Multiple-agent exposure
	Exposure route defined	Multiple exposure routes
	Multiple dose levels	Dose unknown
Effect	Prospectively defined by observation, laboratory analysis and histopathology	Frequently established by retrospective analysis of morbidity and mortality data

(nonpatient volunteer) biomedical research (WMA, 2008).

In view of the special circumstances of developing countries, the Council for International Organizations of Medical Sciences (CIOMS) and the World Health Organization (WHO) issued in 1982 the 'Proposed International Guidelines for Biomedical Research Involving Human Subjects'. The purpose was to indicate how the ethical principles enshrined in the Declaration of Helsinki could be effectively applied, particularly in developing countries. The 'Proposed Guidelines' were adopted by the XXVIth CIOMS Conference in 1992, and, in revised form, in 2002 (CIOMS—Council for International Organizations of Medical Sciences, 2002).

In the revision of the 'Proposed Guidelines' it became clear that special attention needed to be paid to epidemiological studies because of their growing importance, particularly in the public health sector, and the relative paucity of guidance available. The result was the issuing of the 'International Guidelines for the Ethical Review of Epidemiological Studies' (CIOMS—Council for International Organizations of Medical Sciences, 1991). These focus particularly on the safeguarding of confidentiality in the absence of informed consent.

Numerous pieces of legislation and other guidelines are available at national and international level (for details see CIOMS—Council for International Organizations of Medical Sciences, 2002). The controversy that has surrounded human volunteer studies with pesticides in recent years is discussed in detail later in this chapter. In general, a central question in ethical considerations regarding human volunteer studies is concerned with the risk of harm. In the case of nonpatient human volunteer studies there is no direct benefit to the individual participating in the investigation. It follows that, where there is no direct benefit, the risk to the volunteer of coming to harm as a result of participation in the study should be no greater than minimal. In the third edition of their guidelines on the practice of ethics committees the Royal College of Physicians of London (1996) has elaborated on the term 'minimal risk': this could include everyday risks such as travelling on public transport or in a private car (the latter having considerably higher risk), but would not include travel by pedal or motorcycle—in other words, minimal risk is seen at a lower level than many people are prepared to take in many areas of life. This notion has been challenged as overly restrictive and it has been argued that research participants might be exposed to more than minimal risk of harm if, first, they give valid informed consent; second, the potential benefit of the research is large and, third, there is unlikely to be a public reaction against research as a result of harm to participants (Hope and McMillan, 2004).

However, such an approach is not without problems. Where there is no direct benefit to the individual, the knowledge gained is expected to somehow benefit the community. This carries the burden of demonstrating the societal value of the research, something which is very dependent on the position of the enquirer (Dayan, 1997). For example, improving the therapy of a rare but particularly aggressive form of cancer might be regarded as a worthier cause than demonstrating that a particular deodorant does or does not cause itching. Yet, we are all likely to use the latter, whereas the majority of us fortunately do not suffer the former.

The issue of risk of harm is also directly linked to the question of what happens when harm occurs. The CIOMS Guideline 19 deals with this in two distinct but closely related ways (CIOMS—Council for International Organizations of Medical Sciences, 2002). The first is the uncontroversial entitlement to free medical treatment and compensation for accidental injury which may have been caused by procedures performed exclusively to accomplish the purposes of research (nontherapeutic procedures). The second is the entitlement to material compensation for death or disability occurring as a direct result of study participation. In nontherapeutic research, it is generally unreasonable to assume that an investigational drug or other substance studied holds out the prospect of direct benefit for the individual subject; accordingly,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat046
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

compensation is usually owed to individuals who become disabled as a result of participating as subjects in such studies. Subjects must not be asked to waive their rights to compensation or required to show negligence or lack of a reasonable degree of skill on the part of the investigator in order to claim free medical treatment or compensation. The informed consent process or form should contain no words that would absolve an investigator from responsibility in the case of accidental injury, or that would imply that subjects would waive their right to seek compensation for impairment, disability or handicap. Prospective subjects should be informed that they will not need to take legal action to secure the free medical treatment or compensation for injury to which they may be entitled. They should also be told what medical service or organization or individual will provide the medical treatment and what organization will be responsible for providing compensation. Before the research begins, the sponsor should agree to provide compensation for any physical injury for which subjects are entitled to compensation, or come to an agreement with the investigator concerning the circumstances in which the investigator must rely on his or her own insurance coverage (for example for negligence or failure of the investigator to follow the protocol, or where government insurance coverage is limited to negligence). Sponsors should seek adequate insurance against risks to cover compensation, independent of proof of fault.

All research involving volunteers must be approved by an appropriately constituted, independent ethics committee (in the USA the term 'institutional review board' (IRB) is frequently used). This requires a balance of medical and nonmedical, scientific and lay men and women who act independently of the study sponsor. It is the ethics committee's duty to ensure that there is adequate justification for the proposal, that the previously mentioned acceptability criteria are being followed, and that every effort is being made to safeguard the health and welfare of the volunteers. The ethics committee must be prepared to co-opt experts to advise on specific scientific aspects of the study or the risks involved. The Committee will have to pay particular attention to adequate volunteer information and informed consent, and it approves payment of the volunteers. Ethics committees should be informed without delay of any significant untoward event occurring during the course of the study, and should be consulted about significant changes in a project. For some types of study a class approval may be given to avoid repetitive submissions of projects differing only in detail. This is particularly appropriate for projects that pose no risk of distress or injury to subjects (Royal College of Physicians of London, 1996).

Ethical considerations should also include the timely publication of study results, irrespective of whether they are positive or negative, and public access to such information. In recent years, the registration of clinical trials with independent agencies has become commonplace. Following the establishment of the first clinical trials registry by the National Library of Medicine in the USA (*www.clinicaltrials.gov*), many registries have been set up in other countries. The International Committee of Medical Journal Editors (ICMJE) announced in 2004 that it would in future only consider manuscripts dealing with clinical trials if they had been registered with a public trials registry meeting certain criteria (DeAngelis *et al.*, 2004). The definition of a clinical trial was subsequently expanded to include any research study that prospectively assigns human participants or groups of humans to one or more health-related interventions to evaluate the effects on health outcomes (Laine *et al.*, 2007). The World Health Organization maintains a clinical trials registry platform which allows a single point of access to different registries and the unambiguous identification of clinical trials (WHO, 2008). While the above-mentioned registries are primarily concerned with providing information about the existence of ongoing trials, the latest developments concern the provision of results from such studies. For example, pharmaceutical companies have set up a repository for providing results of all hypothesis-testing studies of marketed drugs (*www.clinicalstudyresults.org*).

Most of the available legislation and guidance have stemmed from the need to regulate the development of medicines, with particular attention being paid to human volunteer studies. The basic principles, however, are equally applicable to other areas of human studies. Thus, a framework has been established with criteria which any human study needs to fulfil (Wilks, 2001):

1. There must be a detailed experimental protocol including provisions for appropriate ethical review.
2. The objectives of the research must be scientifically sound and directed to an advancement of biomedical knowledge. The desired information must not be obtainable otherwise, for example through animal or *in vitro* studies. The study should use as few subjects as possible, but as many as necessary to ensure scientific validity.
3. The procedures must be justifiable in terms of the objectives. This requires respect for the individual and the avoidance of unnecessary, trivial or degrading procedures.
4. A formal risk—benefit analysis must have been carried out. As a general rule, the smaller the direct benefit to the individual involved, the lower the risk must be.
5. The responsible investigators must be appropriately qualified to carry out the research. The welfare of the individual participating in the study must be paramount and all data generated must be confidential.
6. Informed consent has to be obtained from all subjects participating in a study, except in clearly defined

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

circumstances. For example, a retrospective analysis of hospital records may not require informed consent, provided that anonymity is guaranteed. Informed consent requires a full explanation of the study and the risks involved in language which the subject can understand. Subjects must be free to withdraw from the study at any time without the need for explanation and without penalty. Special consideration needs to be given to informed consent when studying population groups which are not considered to be independent, self-controlling individuals, such as children, those with defects of cognition and people who do not enjoy a free life (e.g. prisoners, members of the armed forces).

7. Study subjects should be compensated for the inconvenience of participating in a study, but the level of compensation should not act as an inducement to participate against their better judgement and should never be for undergoing risk.

3 EVALUATION OF DATA FROM HUMAN STUDIES

All human studies should be designed and conducted according to accepted scientific principles. This is nowhere more important than in the evaluation of data derived from the study. It is therefore paramount to establish *a priori* what the purpose of the study is, and whether the data generated are likely to fulfil the objective. Human studies fall broadly into two categories: those which are used to generate a hypothesis, and those which test a hypothesis (Cohrssen and Covello, 1989).

Hypothesis-generating studies are usually of a descriptive nature. They include single or multiple case reports, reports of adverse reactions and studies which demonstrate a correlation between the occurrence of illness and the existence of occupational or environmental hazards.

In contrast, hypothesis-testing studies are observational, looking at individuals or small groups of people. These studies are analysed using established statistical methods to determine if an association exists between presence of an exposure hazard and the occurrence of illness. Often, the hypothesis examined has been previously generated by a descriptive study. Examples include two widely used types of epidemiological study: case—control and cohort studies (see **Essentials of Epidemiology for Toxicologists**), as well as most human volunteer studies.

3.1 Qualitative Evaluation of Human Data

The process of human-data evaluation has traditionally been one of inductive reasoning, beginning with fragments of data from which to derive a hypothesis which aims to explain the development of illness by attributing its origin to one or more causes or risk factors (Hoel and Landrigan, 1987). The observational nature of many of the studies has led to the establishment of principles to examine cause—effect relationships (Hill, 1962). While the focus has largely been on the traditional epidemiology studies, the criteria proposed by Hill (1965) can and should be applied to any human data generated in the process of establishing whether an observed association represents causality:

1. **The strength of the association:** In epidemiological studies this is usually expressed in terms of relative risk, that is, the stronger the relative risk, the greater the likelihood that the association is of a causal nature. However, confounding factors need to be carefully taken into account, for example smoking when studying the chemical origins of respiratory disease or lung cancer.
2. **The consistency of the association:** The reproducibility of a finding 'by different persons, in different places, circumstances and times' (Hill, 1965) is one of the strongest arguments for the existence of causality.
3. **The specificity of the association:** If exposure to a specific hazard is associated with one type of illness and vice versa, there is strong evidence for causality. While this is not all that common in xenobiotic-induced illness, there are examples such as asbestos and mesothelioma, aromatic amines and bladder cancer, or vinyl chloride and haemangiosarcoma of the liver. However, absence of specificity does not exclude causality.
4. **The temporal relationship between cause and effect:** For causality to exist exposure must have preceded illness. In the case of latency periods it is important to conduct the study at a time when the exposure is likely to have produced an effect.
5. **The biological gradient of the association:** The establishment of a dose—response relationship is a powerful argument for causation. Likewise, any alteration in exposure leading to a change in disease frequency supports a causal relationship.
6. **The plausibility of the association:** It is helpful if the suspected causation is biologically plausible. This means that it should not seriously conflict with known biological and pathophysiological disease mechanisms. However, this is by no means an absolute criterion since it very much depends on the biological knowledge of the day.
7. **The coherence of the association:** The cause and effect interpretation of the data should not seriously conflict with the known facts about the natural history and biology of the disease.
8. **Experimental evidence for the association:** It is sometimes possible to test the presumed association

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in intervention studies, for example reduction in occurrence of lung cancer in people who have stopped smoking.

9. **Analogy with other known associations:** If the situation under review is similar to situations where causality has already been accepted, for example by similarity of agents or exposure circumstances, this may increase confidence in causal association by analogy.

3.2 Quantitative Evaluation of Human Data

Analysis of human data is considered a critical component of quantitative risk assessment. This is a stepwise process in which the occurrence of disease in an exposed population is related quantitatively to the intensity and duration of exposure (for a definition of the terminology used see IPCS—International Programme on Chemical Safety, 2004). The individual steps in the process are:

1. **Hazard identification:** This answers the question of whether a particular agent can cause a specific biological effect or illness. Although hazard assessment is the domain of experimental studies, human data sometimes provide the initial information.
2. **Dose—response relationship:** Is there a linear, nonlinear or threshold pattern in the relationship between exposure and effect?
3. **Exposure assessment:** What is the intensity, frequency and duration of human exposure to the agent in question? This is often the most difficult part of the assessment, particularly when direct exposure measurements are not available, as is the case for most retrospective studies.

The latter two steps combine to form the *risk characterization* part of the process. This relies heavily on the use of models for the calculation of risk. However, any such calculations have to be treated with great caution because of the uncertainties, in particular when combining data from animal studies, usually carried out using high doses, and estimates of human exposure which themselves are rarely precise. It is customary to include uncertainty or assessment factors when trying to quantify risk to account for some of these variables. A default value of 100 is frequently used, which consists of two 10-fold factors: one to account for interspecies difference and one to reflect human intra-individual variability. Refinements to this general approach using human data have been suggested (Dorne and Renwick, 2005). Details of the methodologies involved and their applications can be found elsewhere (Richmond *et al*., 1981; Cohrssen and Covello, 1989; Hallenbeck, 1993).

Since there is little formal guidance on how human data can be interpreted and used for risk assessment it is not surprising that such data are not consistently used and evaluated in chemical risk assessments. The European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC), in collaboration with the International Programme on Chemical Safety (IPCS), the Organisation for Economic Co-operation and Development (OECD) and the EU Joint Research Centre, therefore held a workshop with the aim of discussing and bringing consensus to the topic (ECETOC, 2004). The workshop concluded that all forms of human data can be useful when making risk assessment decisions, but that good-quality human data are often not readily accessible and/or their usefulness is frequently constrained by a lack of information on exposure. However, this situation could be accounted for if a framework could be developed that enabled different sources of human data to be collected, evaluated and applied as part of the risk assessment process. Subsequent to the 2004 workshop, the IPCS held a follow-up activity that examined how the information held by poisons centres could be developed and assembled to be more useful for risk assessors (IPCS—International Programme on Chemical Safety, 2005). The IPCS activity served to bring clarity to how poisons centre data might be collected and archived in order to increase the likelihood of it being useful for subsequent risk assessments. As a further step, a framework for the integration of human and animal data in chemical risk assessment has now been proposed (ECETOC, 2009). This report is particularly concerned with quality aspects of human as well as animal data, since they play an important role in the choice of key data sources regarding the lead health effect(s) in the risk assessment process.

4 SOURCES OF HUMAN DATA

There are various ways of looking at sources of human data, depending on their ultimate use. One which has already been mentioned is the classification into hypothesis-generating and hypothesis-testing studies. Another way would be to focus on the study subjects or populations in terms of whether an intervention is carried out, such as withdrawing a subject from exposure, or whether observations are being made without interventions. If the study focuses on the individual, it is often referred to as a clinical study, whereas epidemiological studies look at population groups or subsets. Finally, the nature of the study can be either retrospective, that is, taking an individual's or population group's health status or disease incidence and trying to correlate it with past exposure (e.g. case—control studies), or prospective, where the development of the disease is followed in exposed and nonexposed subjects over time, possibly over many years (cohort studies).

Some principles of epidemiology have already been referred to above; further details can be found elsewhere in this book (see **Essentials of Epidemiology for Toxicologists**). For the purpose of this chapter, those sources of human data are selected which allow a direct, though not always easily quantifiable, assessment of individual chemical exposure and health effects. Thus, the principle sources of information are case reports and surveillance schemes, use of chemicals as therapeutic agents, exposure and health surveys, and human volunteer studies.

4.1 Case Reports and Surveillance Schemes

Case reports identify one or more cases of disease which have been detected, usually by clinicians, as a result of the treatment of a patient, whereas case series often stem from active surveillance (e.g. in occupational medicine) or passive reporting (e.g. adverse drug reaction reporting). In many instances, case reports have served to alert physicians to the existence of occupational or environmental illness. The earliest recorded examples of case series of occupational or environmental illness are reports of lung disease among potters and weavers (Ramazzini, 1713), and observations of scrotal cancer among chimney sweeps (Pott, 1775). Many of the known human carcinogens were identified through case reports (Miller, 1978). For example, the first three cases of haemangiosarcoma of the liver in vinyl chloride-exposed workers were reported by a company physician, John Creech, in a PVC (poly(vinyl chloride)) resin manufacturing plant in Louisville, Kentucky, USA (Creech and Johnson, 1974). Frequently, such case reports are then followed by further epidemiological studies and/or animal studies to confirm or refute the validity of the original observation. Thus, in most instances, case reports serve to generate a hypothesis.

A distinct advantage of case reports over most other types of studies is their low cost. Most of the work necessary to allow reporting of a case or case series is performed by healthcare workers in the course of their normal duties, thus the cost is largely absorbed by the medical care system. In addition, the time interval between identification of cases and publication is often short, indeed, many medical journals allow for the rapid publication of case reports by speeding up editorial review. Case reports are often highly specific: in many instances they contain extensive descriptions of symptoms and clinical signs. Frequently coupled with good exposure information (e.g. analytical verification in the case of drug overdose), they are uniquely able to define a dose—response relationship of chemical exposure.

Limitations of case reports are publication bias (i.e. preferential reporting of positive associations between an exposure and a health outcome) and the fact that they usually deal with single incidents or relatively small numbers. Extrapolation or generalization may therefore be difficult, especially since there is no information on the size or definition of the population at risk. They also rely on the individual effort of usually very busy healthcare workers who need to find the time for writing and literature searches. The role of case reports as 'early warning systems' is less useful when cases are sporadic, the relative risk is low, the outcome is a common disease, the aetiology is multifactorial, or there is a long latency period between exposure and effect (Cone *et al*., 1987).

Case reports which are generated through a formal reporting system are of enormous use in disease surveillance, either as part of drug monitoring or toxicovigilance.

4.1.1 Drug Surveillance Schemes

These are used extensively to evaluate toxicity resulting from the use of pharmaceuticals, and may include chemicals which form part of prescription pharmaceuticals. Serious, but rare toxicity, occurring with a frequency of 0.1% or less, may not be manifest until after widespread general usage, and general patterns of toxicity may not be recognized unless systematic drug surveillance schemes are employed. The statistical background to adverse drug reactions is well defined (Talbot and Waller, 2004) and gives an indication of the size of the exposed patient population required to manifest adverse drug reactions which occur infrequently.

Efforts have been undertaken to develop a new framework of risk management, particularly in the last 10 years, by the International conference on Harmonization (ICH) and the CIOMS (Tsintis *et al*., 2004), together with formal regulatory guidelines from the Committee for Medicinal Products for Human Use (CHMP) of the European Medicines Agency (EMEA) (Moseley, 2004) and the US Food and Drug Administration (FDA) (FDA, 2005a; 2005b; 2005c). The documents describe methods and provide clarification and harmonization of practices for overall safety surveillance, early risk detection and risk-management processes. The ICH E2E (ICH, 2004), CIOMS VI (CIOMS—Council for International Organizations of Medical Sciences, 2005), US FDA and EMEA guidelines on safety risk management are all complementary. The new framework makes safety risk management more continuous throughout the life cycle of a product. Thus pharmacovigilance, traditionally associated more with postmarketing activities, is now increasingly applied throughout the life cycle of a drug, making premarketing and postmarketing activities a continuum (Hartford *et al*., 2006).

The ICH E2E guideline recommends that company pharmacovigilance experts get involved early in product development. Planning consists of the 'safety specification', which reflects the status of safety issues being followed during development and includes review of

nonclinical as well as clinical data, and the 'pharmacovigilance plan', which is based on the safety specification and describes actions for safety concerns identified.

The most common methods of postmarketing drug surveillance are described below.

4.1.1.1 Spontaneous Reporting

Much valuable safety information may be gleaned by the reporting of 'spontaneous' adverse events from routine clinical usage of a drug. Reports may be either from the consumer directly to the pharmaceutical company (commonly in the USA) or from a healthcare professional. Pharmaceutical companies have an obligation to submit an initial report on life-threatening and unexpected serious adverse events, received in this manner, to regulatory authorities within a given time frame (usually within 15 days of receipt). Clarification, obtained from a request for further information regarding concomitant disease, medication and outcome, may be submitted later in order to complete the overall assessment. In the UK, the additional mechanism of the 'Yellow Card' scheme (administered by the Medicines and Healthcare Products Regulatory Agency (MHRA) encourages voluntary reporting by healthcare professionals and patients of all suspected reactions to new drugs (defined as the first year of a drug's licence; 'black triangle' designation), and serious or unusual reactions to established drugs. Reports number over 20 000 per year (MHRA, 2007). However, it is estimated that only 10% of serious reactions and 2–4% of nonserious reactions are reported in this way. In contrast, in France and other countries physicians have a legal obligation to report to pharmacovigilance centres. The WHO also administers a scheme (Programme for International Drug Monitoring) encompassing 86 countries (WHO, 2009). Reporting from these schemes may be influenced by many factors including drug promotion, time on the market and adverse publicity. A balanced picture of a drug's safety may not necessarily be obtained, but this method is particularly useful in detecting signals worthy of further study.

4.1.1.2 Clinical Trials

Development trials may be regarded as potentially artificial situations because of limitations on the types of patients entered and concurrent medications, defined dosage, duration of treatment and the use of comparators, including placebo. Nevertheless, clinical trials may provide useful information. During the course of clinical trials (whether premarketing or postmarketing), pharmaceutical companies have an obligation to report all serious adverse events (fatal, life-threatening, disabling/incapacitating and those causing or prolonging hospitalization or congenital abnormalities or birth defects) to regulatory authorities (European Commission, 2001; ICH, 2002; 2008). In general marketed usage, a wider spectrum of patients may receive a drug, occasionally even for an unlicensed (i.e. unproven/untested, so-called 'off-label') indication and at higher doses and for longer periods. Previously unrecognized or unpredictable drug toxicity may also occur from such usage.

In many countries, there are legal requirements for pharmaceutical companies to submit periodic safety update reports (PSURs) to regulatory authorities on any new safety information which comes to light after a drug is marketed; correspondingly CIOMS introduced a development safety update report (DSUR) for the premarketing phase (EMEA, 2005; Klepper, 2004). However, there are rarely any formal requests for large-scale pharmacovigilance studies. Countries such as the UK and USA may request postmarketing surveillance studies (PMS), particularly for drugs of a new class and for those where potentially significant but relatively infrequent adverse events have been seen (e.g. hepatic disturbance) in the development phase. Such large-scale, company-sponsored studies, involving many thousands of patients, may report a multitude of adverse events which are often difficult to interpret even when the studies are well designed. Indeed, it has often been considered that PMS can only give bad news about a new drug. However, with careful interpretation, such studies can yield useful safety information which will assist the passage of the drug into more widespread clinical usage.

Phase 4 clinical trials which are well controlled may yield useful safety information, in the same manner as development trials.

4.1.1.3 Safety Assessment of Marketed Medicines (SAMM)

This is distinct from Phase 4 studies as it involves primarily noninterventional studies in which a drug is prescribed in the usual way by the patient's physician. Their aim is to collect safety data from routine clinical use. Safety assessment of marketed medicines (SAMM) studies involving any form of intervention (e.g. randomization and nonroutine investigations) are subject to normal clinical trials ethics and regulatory requirements. They should have a protocol or study plan including precise objectives, stating whether the study is hypothesis testing (investigating known or putative safety issues) or generating (identifying previously unrecognized safety issues). SAMM studies are conducted by pharmaceutical companies, are approved, and are sometimes required by regulatory authorities (e.g. MHRA), as a condition of granting a product licence. Such studies should not be conducted for promotional purposes. Different types of study may be conducted. They include observational cohort studies, case—control studies and case surveillance. Results of these studies are presented to regulatory bodies and are usually published. Reported adverse events from these are included in the PSUR. The various different types of study are described below.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat046
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.1.1.3.1 Observational Cohort Studies

Patients who are about to receive a prescribed drug are identified and followed prospectively, whereby certain conditions apply:

1. The study population should reflect the population expected to receive the drug in normal clinical practice and is subject to the stipulated contraindications in the prescribing information.
2. The decision to prescribe the drug should have been made on clinical grounds before the patient is entered into the study.
3. The product is supplied by the family physician and not by the pharmaceutical company.
4. A control group of patients with the same condition should generally be prescribed an alternative therapy.
5. The physician reports adverse events during routine, rather than specially arranged consultations.

A special type of cohort study, commonly used in the UK since 1982 by the Drug Safety Research Trust, is where the patient is identified by the prescription (prescription event monitoring (PEM)) (Drug Safety Research Unit, 2009). General Practitioners are, after an interval of six months, sent a questionnaire requesting information on 'events', that is, new diagnoses, deterioration or improvement in a condition, any suspected adverse drug reaction or any other significant finding, including cessation of treatment and subsequent follow-up details. The results for one drug can be compared with those for other drugs subjected to this scrutiny.

Many general practices in the UK have computerized databases and there are many computerized healthcare systems (e.g. Kaiser-Permanente and Medicaid in the USA). These databases can be used either to investigate in greater detail previously identified clinical conditions that are suspected of being drug related (e.g. human insulin is associated with hypoglycaemia without warning) or to identify all patients on a specific drug or with a condition and follow them up to determine what clinical events subsequently occur. The latter is effectively an 'electronic' cohort study.

4.1.1.3.2 Case—Control Studies

These are hypothesis-testing, retrospective studies comparing the history of drug exposure of patients experiencing a disease or event with control patients without the disease or event. These studies have been employed to study associations between thromboembolism and oral contraceptives, endometrial cancer and hormone replacement therapy, and upper gastrointestinal haemorrhage and nonsteroidal anti-inflammatory drugs.

4.1.1.3.3 Case Surveillance

These are again retrospective studies looking at patients with diseases or events that are likely to be related, and ascertaining drug exposure.

In conclusion, each method has advantages and disadvantages both in terms of ease of use, reliability and cost. The principal benefit is that otherwise unidentified associations can be detected by virtue of the population approach that these techniques employ.

4.1.2 Toxicovigilance

While drug surveillance schemes provide useful information on pharmaceuticals in 'normal use', they cover by their very nature only a very limited number of chemicals. There is a need to collect and review data related to drugs in overdose situations as well as to the vast range of nonpharmaceutical chemicals which people are exposed to at work or in their everyday lives. Such information can be collected from various sources, such as statistics on mortality and morbidity, and accident surveillance schemes.

Official statistics can provide overall numbers for deaths and hospital admissions and are useful for trend analysis, but they do not provide detailed clinical and toxicological information. Furthermore, the nature and extent of data collection varies enormously between countries, and international comparisons are therefore extremely difficult. Accident surveillance schemes have been developed to facilitate health education and to monitor product safety. In the UK, for example, the Home Accident Surveillance Scheme administered by the Royal Society for the Prevention of Accidents (ROSPA, 2008) monitors home and leisure accidents. However, experience has shown that suspected poisoning accounts for only 3–4% of such accidents, and that, while overtly dangerous products can be identified, little information is collected from which to assess toxic effects and dose response (Volans *et al.*, 1991). A special situation exists in the case of pesticide exposure. The UK Health and Safety Executive runs a scheme which allows pesticide operators, as well as members of the general public, to report incidents relating to pesticide use. The data thus collected are evaluated by a panel of experts who decide, on the basis of the available information, whether the alleged health effect is likely to have been caused by the exposure (Health and Safety Executive, 2007). In addition, companies in the UK are required to submit immediately any new information on potentially dangerous effects of a product on human or animal health, ground water or the environment. The Pesticide Safety Directorate (PSD) publishes an annual survey of human health incidents report to companies each year (PSD—Pesticide Safety Directorate, 2008). This lists the active ingredient, symptoms, description of the incidents and the actions taken by the company.

The most important source of data on toxicovigilance comes from poison control centres (PCCs). Such centres exist now in many countries, and their primary role is the provision of advice on potential risks and management of cases of suspected poisoning and toxicological emergencies. This advice is usually given by telephone, in many cases on a 24-hour basis, either to healthcare professionals or members of the general public. In order to be able to give accurate information, the PCC must receive details of the incident, patient information, the time course of symptoms and any treatment already given. This information has enormous potential as a source of human toxicology information, and, increasingly, PCCs see it as their role to collect and evaluate such data for the purpose of health surveillance and promotion. As with other surveillance schemes, there are limitations in the way the data are collected and analysed, principally because of the lack of standardization of systems used to obtain and record information from the caller. In the recent past, some of the PCCs have developed Internet-based information systems (NPIS, 2008; RIVM, 2008; TOXINZ, 2008). However, while these systems are of proven efficacy with regard to delivering information, they are less suitable to collect data on human poisoning due to their lack of personal interaction.

However, efforts are being made at a national and supranational level to improve the systems of toxicovigilance. In the USA all PCCs accredited by the American Association of Poison Control Centers provide annually an agreed set of data on their incident-related activities that is reported in the National Poison Data System (NPDS) (Bronstein *et al*., 2008). Data from 60 PCCs are automatically uploaded via the Internet to a central server at least once per hour, thus enabling 'real-time' toxicosurveillance. This database can be searched according to product, circumstances of exposure, therapy, type and severity of effect and medical outcome. The data thus obtained can be used for further analysis. For example, in 2007 there were approximately 2.4 million exposure cases of which more than 1.2 million occurred in children younger than six years. Of the total number of exposures 0.7% experienced a major outcome, and there were 1415 (0.1%) fatalities. The most commonly implicated substance categories were analgesics, cosmetics (including personal care products) and household cleaning substances. The low hazard factors (sum of major and fatal outcomes per number of exposures) indicate that frequent exposure does not necessarily imply toxicity. Pharmaceutical preparations accounted for most of the fatalities, with sedatives/hypnotics/antipsychotics being the most frequent cause.

Many European countries require their PCCs to provide annual reports. Under the auspices of the European Association of Poison Control Centres and Clinical Toxicologists efforts are being made towards a better harmonization of data collection. In conjunction with the European Commission and the IPCS, a standardized scheme (poisoning severity score) for grading the severity of poisoning has been developed and has been in use for 10 years (Persson *et al*., 1998). Initial application of the scoring system has shown that it is helpful in accurately assessing the initial clinical severity and the likelihood of further deterioration. Furthermore, it helps in deciding which enquiries to refer to a clinical toxicologist (Casey *et al*., 1998).

One of the aims of the IPCS is to encourage countries to establish PCCs, and it has published a policy overview and technical guidance on PCC organization and management (WHO, 1997). These guidelines recommend the establishment of internationally agreed mechanisms for the collection, validation and analysis of data relating to poisonings. The IPCS has for a number of years developed a poison centre information system (Meredith and Haines, 1996). This 'INTOX' system is particularly aimed at helping developing countries to establish their own poison information services, and contains a large volume of product and treatment information (*www.intox.org*). At the same time the comprehensive incident recording facilities of the system help to foster standardization and integration of data collection and reporting not only across centres but also across countries.

4.2 Use of Chemicals as Therapeutic Agents

Chemicals have been used as therapeutics throughout history. Arsenic in its naturally occurring disulphide form was recommended by Hippocrates and Galen for treating ulcers, and cautery of tumours by arsenic salts was practised by Avicenna in the tenth century. Potassium arsenite solution (Fowler's solution) was used extensively for treating numerous ailments, including until recently in some treatments of leukaemia (Sollmann, 1957). Similarly, mercury ointments were used by Arab physicians from the tenth century. From around 1500 onwards, the use of mercury salts or vapour was standard treatment for syphilis (though it is a matter of debate whether more patients died from the disease or the treatment). The diuretic potential of mercury has been known at least since the seventeenth century, and mercurial diuretics were used as late as the mid 1970s.

The reason why therapeutic use of chemicals is of interest for toxicologists is because of the first-hand, often extensive human information which becomes available when a chemical is taken through the stages of pharmaceutical development. There are three principal reasons why a chemical may become of interest for such development.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.2.1 Incidental Discovery of Therapeutic Potential

Nitroglycerin (glycerol trinitrate) was discovered in 1847 and incorporated by Alfred Nobel into a major component of dynamite in 1867. Effects from occupational exposure were first described by Darlington (1890) as throbbing headaches, breathing difficulties, drowsiness, weakness and vomiting. These effects are due to the pharmacological action of nitroglycerin on the smooth muscle, where it produces relaxation.

The ability of organic nitrates to relieve anginal pain was discovered in 1867 by Lauder Brunton, who noticed that amyl nitrite caused marked flushing, tachycardia and a fall in blood pressure when its vapour was inhaled (cited in Rang and Dale, 1987). It was soon realized that the symptoms caused by nitroglycerin were due to the same action as that of amyl nitrite, and it was found to be just as effective in angina. It is still widely used but because of its short action other organic nitrates have been developed, the most commonly available being isosorbide dinitrate or mononitrate and pentaerythritol tetranitrate.

4.2.2 Therapeutic Use as a Direct Consequence of the Known Properties of the Chemical

Treatment of human vector-borne parasitic disease relies heavily on the use of insecticides. DDT (dichlorodiphenyl-trichloroethane) was the first major chemical to be used with spectacular success by American troops during the Second World War in malaria vector control and against other insect pests (Smith, 2001). During the 1940s and 1950s it became an important element of public health campaigns, until concerns over its persistence in the human body and the environment, as well as the development of insect resistance led to restriction of usage and an eventual ban in many countries. However, because of its cost-effectiveness and relatively low acute toxicity, DDT remains an important vector control agent in many parts of the world (IPCS—International Programme on Chemical Safety, 1979). The widespread use of DDT prompted many investigations into possible health effects, including oral, dermal, inhalation and bioaccumulation volunteer studies at doses up to 1500 mg (for a summary see Smith, 2001). Apart from its antiparasitic use, DDT was also studied for a possible bilirubin-reducing effect in selected patients with jaundice (Thompson *et al*., 1969) at doses up to 3 mg kg^{-1} day^{-1} for six months. There were no side effects in this study, nor were there any when DDT was used as an antidote in phenobarbital intoxication as a single dose of 5000 mg (Rappolt, 1970).

The products nowadays used in vector parasitic control fall into different chemical categories, mainly organochlorines, organophosphates and pyrethroids. Lindane, malathion and permethrin are effective against scabies while malathion and permethrin are recommended for head lice.

4.2.3 Use as a Therapeutic Adjuvant

Many chemicals are used as coformulants in medicinal preparations. For example, propylene glycol is used as a solvent in parenteral preparations, either on its own or in combination with ethanol. The chemically related diethylene glycol, an industrial solvent and antifreeze, was used in 1937 to prepare a liquid formulation of the newly introduced sulfanilamide antibiotic. The resulting death of over 100 people had profound consequences for the licensing of drugs in the USA, leading to new legislation which stipulated the requirements for data submission to the Food and Drug Administration (Wax, 1995). Unfortunately, there have been at least six other mass poisonings with analgesic elixirs containing diethylene glycol in South Africa, India, Nigeria, Bangladesh, Haiti and Panama, resulting in the death of several hundred patients, the majority of them children (Wax, 1996; Barr *et al*., 2007; Schier *et al*., 2008). In each case, the cheaper diethylene glycol appears to have been substituted for the more expensive propylene glycol or glycerol.

Chlorofluorocarbons (CFCs) are still widely used as refrigerants, propellants, degreasers, fire extinguishers and industrial cleaning agents. Human health effects such as cardiac arrhythmias and even fatalities from asphyxiation have been described at high concentrations (McGee *et al*., 1990). On the other hand, CFCs are used as propellants in metered-dose inhalers prescribed for the treatment of asthma. Doses dispensed from these devices contain typically between 50 and 100 mg of CFCs, the most common ones being trichlorofluoromethane (FC-11), dichlorodifluoromethane (FC-12) and dichlorotetrafluoroethane (FC-14) (Pierce *et al*., 1991).

4.3 Exposure and Health Surveys

Human studies of chemical exposure are at their most powerful if they include adequate information on both exposure and health effects. Such an ideal is rarely achieved; most studies concerned with exposure measurement look at relatively low levels of exposure over short periods, which are unlikely to result in short-term health effects. Conversely, most epidemiological studies looking at health effects from chemical exposure suffer from a lack of quantifiable exposure information, especially where there is a long latency period between exposure and onset of illness (see **Essentials of Epidemiology for Toxicologists**).

Exposure and health surveys can in theory be carried out wherever there is a likelihood of exposure occurring,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

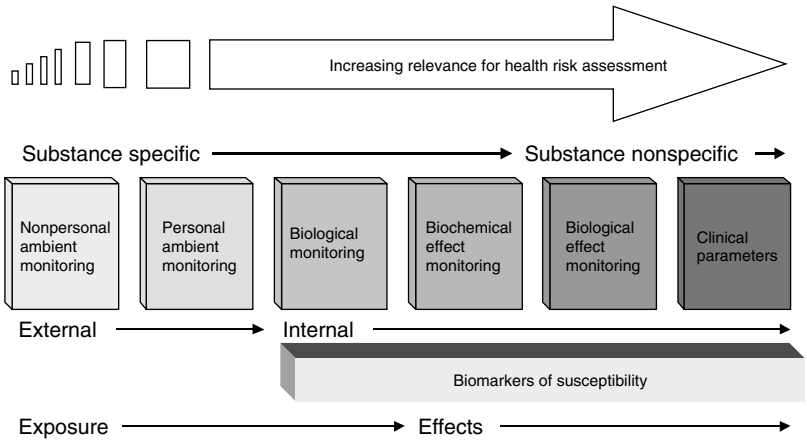

Figure 1 Monitoring techniques as part of the exposure-disease continuum. (Reproduced with permission from ECETOC. © 2005.)

including environmental exposure of the general public. In practice, it is mainly the surveillance of occupationally exposed workers which is likely to yield substantive information on the link between chemical exposure and health effects (see **Occupational Toxicology**). Exposure and health surveys are useful either as components of risk assessment or risk management. The former takes place ideally before people are exposed to the chemical in question, the latter is part of an ongoing process to safeguard the health of the individual who may be exposed.

4.3.1 Methods for Exposure Assessment

Exposure can be determined by means of nonpersonal ambient monitoring or personal monitoring, the latter being further categorized into personal external monitoring and variants of biomonitoring (**Figure 1**). The choice of a method depends principally on the purpose of the investigation, the chemical involved, the conditions at the workplace and the resources available.

Nonpersonal ambient monitoring is designed to assess the concentration of chemicals either as particulate, gas or vapour in the workplace air. It is achieved by installing collection devices containing filters or other absorptive material (e.g. activated charcoal, silica gel) which can subsequently be analysed. The high sampling volume means that very low levels of detection can be achieved (Schlatter, 1992). This method is particularly suitable for process checks and to monitor engineering controls designed to minimize exposure.

Personal ambient monitoring is usually carried out to assess inhalation exposure. The distribution of a nongaseous chemical depends largely on the physicochemical properties of the particle or droplet. In terms of inhalation risk assessment, two categories of airborne particulates are usually considered; the inhalable fraction (the mass fraction which is inhaled through the nose and mouth) can for sampling purposes be considered to be of a size below 100 µm. The respirable fraction (the mass fraction which penetrates into the unciliated airways) is considered to be below 15 µm (International Organization for Standardization, 1995). The collection devices are attached to work clothing in the vicinity of the breathing zone and are connected to personal sampling pumps.

The contamination of workers' skin and clothing can be measured using a variable number of multilayered gauze patches attached to defined areas of the body. However, because of the nonuniformity of dermal exposure, whole body monitoring using clothing which acts as sampling medium has been proposed as an alternative (Chester, 2001). This has the advantage that the capture and retention properties of normal work clothing are mimicked as closely as possible.

Biomonitoring is a general term comprising a number of subcategories (ECETOC, 2005 and **Figure 1**):

1. **Biological monitoring:** This method analyses for biomarkers of exposure designed to provide a measure of internal dose or body burden. It can be defined as measurement of a chemical or its metabolites in the body fluids of exposed persons, and conversion to an equivalent absorbed dose of the chemical based on a knowledge of its human metabolism and pharmacokinetics (Woollen, 1993). Examples include the determination of metals (e.g. mercury, arsenic or lead) in blood or urine, the determination of unchanged substances (e.g. PCBs (polychlorinated biphenyls), dioxins or benzene) in adipose tissue, milk, urine or blood, the determination of specific metabolites of a chemical (e.g. s-phenylmercapturic acid as a metabolite of benzene) in urine, or volatile compounds (unchanged substances or metabolites) in exhaled breath.
2. **Biochemical effect monitoring:** While also being a measure of exposure, the biomarker reflects the effective dose of a chemical, usually a potentially genotoxic substance, by measuring its reaction

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat046
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

product with an endogenous macromolecule indicating that the chemical was not only bioactive but also was absorbed into the body and reached the tissues (hence: tissue dose). Examples are the determination of adducts of a specific chemical (e.g. ethylene oxide or polycyclic aromatic hydrocarbons) to DNA or a protein, such as albumin or haemoglobin.

3. **Biological effect monitoring:** This measures early and often reversible biological effects, which do not necessarily lead to specific health effects. Because the effect may be influenced by various physiological and environmental factors unrelated to chemical exposure, most methods of biological effect monitoring are intrinsically nonspecific. Examples include measurements of acetyl cholinesterase activity in blood, zinc protoporphyrin, sister chromatid exchanges and other chromosomal aberrations, and microproteinuria.
4. **Clinical parameters (biomarkers of disease):** These are an expression of (beginning) disease. Some parameters assessed in biological effect monitoring may also be used in clinical practice and form a continuum from a reversible biological to a clinically relevant effect. For example albuminuria may be used in biological effect monitoring (microalbuminuria) as a biomarker of early renal function effects but it is also used as a clinical parameter, for instance to assess renal function impairment in diabetics.

Biomarkers are influenced by factors such as lifestyle and physiology, including genotype and phenotype. The term 'biomarker of susceptibility' refers to indicators of an inherent or acquired ability of an organism to respond to exposure to a specific substance, for instance through the expression of certain isoforms of cytochrome P450, glutathione transferases or *N*-acetyltransferases. In addition, factors such as iron status, nutritional status, and so on, may also be regarded as biomarkers of susceptibility. In contrast to the other biomarkers they reflect potential differences in uptake and metabolism of chemicals between individuals and, consequently, potential differences in health risks. Biomarkers of susceptibility may, like lifestyle factors, such as smoking and drinking behaviour, explain differences in biomarker results between individuals with identical exposure profiles (Angerer *et al*., 2004).

Recent developments in molecular biology have raised the possibility of using 'omics' technologies in the study of biomarkers, for example:

- In proteomics, new mass spectrometric (MS) techniques such as analysis of the single combined spectra extracted from full-scan MS data may allow the detection and structural characterization of chemical adducts on proteins (Brock *et al*., 2007).
- Differences in biological responses to exposure to hazardous airborne substances between children and adults have been studied using genome-wide gene expression profiles in peripheral blood of children in regions with different levels of air pollution (Van Leeuwen *et al*., 2008).
- The use of molecular spectroscopic approaches that capture environmental and selected genomic influences is now being used to investigate the connections between phenotype variation and disease risk factors (Nicholson *et al*., 2008).

4.3.2 Worker Exposure and Health Surveys

With hundreds of thousands of chemicals in production and use, it is clearly neither possible nor desirable to establish a human database for all of them, since the vast majority pose no appreciable risk to humans. Human data should therefore be obtained in a systematic, priority-based way with an emphasis on those chemicals which are most likely to lead to adverse health effects as a result of their intrinsic hazard *and* the likely human exposure.

Surveys of occupationally exposed populations can be of considerable benefit in the risk assessment process, particularly when a considerable amount of human use experience data has accumulated (see **Occupational Toxicology**). In addition, health surveys may help to refine assessment factors for the calculation of acceptable risk, particularly where there are questions about the applicability of animal data at high doses to the human use conditions which may involve exposure at doses several orders of magnitude lower than encountered in animal studies.

The registration and regulation of pesticides probably involves the most sophisticated risk assessment process outside the pharmaceutical area. This is not surprising given that pesticides are designed to have an effect on biological systems leading to the control or destruction of rodents, weeds, insects or fungi. Most countries operate regulatory systems, with the best known existing in the USA (EPA, 2002) and the European Union (SANCO European Commission Health and Consumer Protection Directorate General, 2008). Internationally, the Food and Agriculture Organization (FAO) and the WHO carry out toxicological evaluations of pesticides (Joint Meeting on Pesticide Residues (JMPR)) for the purpose of setting acceptable daily intakes (ADIs) (IPCS—International Programme on Chemical Safety, 2008).

It has been proposed to take a tiered approach to the generation and use of human data for the purpose of pesticide operator risk assessment (Henderson *et al*., 1993; OECD, 1997). This is shown schematically in **Figure 2**. Each tier involves the comparison of an exposure data set with the appropriate NOAEL (no observed

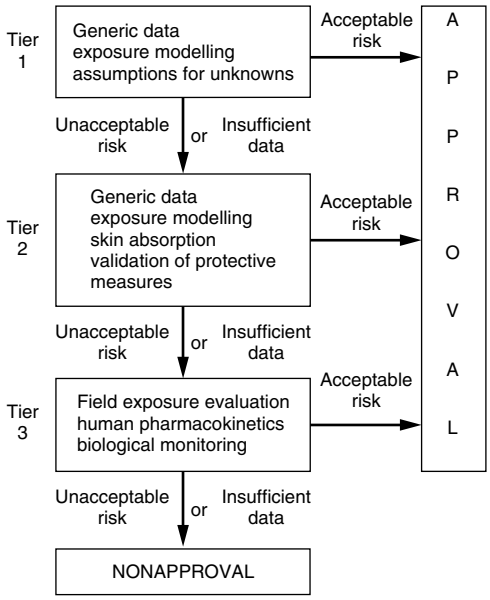

Figure 2 Three-tiered approach for the assessment of worker exposure in a risk assessment procedure for registration of a pesticide. Requirement of actual human data (field exposure evaluation, biological monitoring) depends on whether the calculated exposure shows an acceptable risk when considering the toxicology profile of the compound. (OECD, 1997, modified and reproduced by permission of OECD.)

adverse effect level—usually obtained from animal toxicology studies) and applying an assessment or safety factor to account for uncertainties when extrapolating from animal data to human exposure, as well as interindividual differences in human response.

The first tier in the risk assessment process would typically involve the use of generic databases which allow model calculations for the likely exposure level (Van Hemmen, 1993). The source and type of data used should be clearly identified and the database or model used must be validated and applied correctly. At this stage, very conservative assumptions are used (e.g. no protective equipment, 100% skin absorption). In the second tier the data set is refined, for example using actual skin absorption data (animal or human *in vitro*) and building in factors to account for personal protection. The third tier involves the generation of actual human data. These could be exposure measurements (Chester, 1993) or, ideally, biological monitoring backed by human pharmacokinetic information (Woollen, 1993). If the risk assessment still indicates excessive exposure, further risk mitigation factors may be considered to reduce the absorbed dose to an acceptable level.

Chemically-induced occupational illnesses are prevented by the control of exposure to chemical hazards in the workplace. Sometimes this needs to be supplemented by surveillance of the people potentially exposed to chemicals at work. It is important that such surveillance is fully integrated in the risk management process (Tordoir and Maroni, 1994). If this is not the case the surveillance will be out of focus and neither effective nor efficient. Some of the basic principles which should be followed are:

1. The surveillance should give information over and above that already available.
2. It should provide information which will assist in evaluating control measures.
3. If individual (biological) monitoring is involved, there must be an appropriate sampling strategy and analytical technique, preferably involving noninvasive sampling.
4. There must be clear criteria for interpreting the results.
5. There must be adequate consultation with employees, including feedback of the results.
6. Appropriate action is taken as a result of the surveillance, and its effectiveness is evaluated.

Medical examinations form an important part of occupational health programmes (see **Occupational Toxicology**). The content and frequency must depend on the results of the risk assessment process. In particular, the content of medical examinations should be related to the identified health hazards and to the characteristics of chemical exposure, while the frequency of periodical examinations should be determined on the basis of the magnitude of risk to human health and the natural course of the relevant adverse health effects (Tordoir and Maroni, 1994). Any surveillance programme involving clinical care must contain appropriate safeguards for the participating individuals. Employees should be aware of the possible consequences of surveillance, and individual medical records should be kept confidential. Before disclosing such information the individual's consent needs to be obtained. However, as a result of surveillance employees may be transferred to a job that entails less exposure to a particular hazard, and this should be explained clearly to the participants in a programme at the outset. It is also important that surveillance programmes are not used to discriminate against specific employee groups (e.g. women or older workers).

Any occupational surveillance programme is critically dependent on the quality of data recording and retention. The records should document data relevant to individual workers, they should be able to identify health trends and priority areas for action, fulfil legal requirements, and enable future epidemiological studies to be carried out. It is important to keep records for long enough periods, for example, in the case of exposure to ionizing radiation 60 years is recommended.

The main items of information that are useful for future studies may be considered under a prioritization system

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat046

of data recorded along the following lines (Cooke *et al*., 1999):

1. A basic data set aimed primarily at identification of subjects, employment and exposure to potentially hazardous substances. The latter should include as much information as possible about job profile, employment dates and sites, as well as all available information on chemical exposure, in particular any available monitoring data.
2. Data which frequently prove desirable in epidemiological studies and which could be available or recorded at medical interviews and examinations, such as information about previous employments, ethnicity, residence abroad, recreational activities and hobbies.
3. Medical (clinical) data where it is considered useful or advisable to carry out a full clinical examination. These may include detailed histories, medical examinations and laboratory tests.

It is recognized that ideal data records are rarely, if ever, available. Furthermore, data records may not follow the individual if they change their employer. Nevertheless, analysis of data records may be the only way to identify health effects from chemicals with long latency periods between exposure and the occurrence of illness.

4.3.3 Surveys in the General Population

Historically, (bio)monitoring has mainly been used in occupational settings, for example for surveys, and also as a research tool to study uptake and metabolism of chemicals to help with the assessment of health risks. However, due to rapid technical developments, biomonitoring is increasingly being used to study environmental exposure. In recent years many countries around the world have established environmental biomonitoring programmes that report representative values of selected xenobiotics in nonoccupationally exposed populations. These programmes complement a range of other biomonitoring programmes that study levels of chemicals in the environment, such as in drinking water, food, fish and other biota and air. One population group of particular interest in many programmes is children.

A coordinated approach to human biomonitoring in Europe has been initiated under the European Environment and Health Strategy. In a pilot project a number of work packages were completed, such as establishment of an electronic inventory of human biomonitoring activities, drafting of various guidelines, consideration of ethical issues and work on the utility and sensitivity of biomarkers (ESBIO—Expert Team to Support Biomonitoring in Europe, 2007). Projects at member state level have included biomonitoring studies, for example in Germany (Pesch *et al*., 2002), Poland (Jakubowski and Trzcinka-Ochocka, 2005) and France (Huel *et al*., 2002). A number of related research activities and projects have also been set up at European level, in particular through the EU Framework Programmes, for example ChildrenGenoNetwork (2008), AIRNET (2008), Plutocracy (2008), MENDOS (2008) and BIOMONECS (2008).

In the USA, the third National Report on Human Exposure to Environmental Chemicals has recently been published (CDC, 2005), providing part of an ongoing assessment of the exposure of the US population to selected environmental chemicals using biomonitoring. The report provides data for 148 chemicals, including metals, polycyclic aromatic hydrocarbons, dioxins and dioxin-like substances, PCBs, phthalates, phyto-oestrogens, organochlorine and organophosphate pesticides and pyrethroids. This report was based on measurements taken from selected participants in the National Health and Nutrition Examination Survey (NHANES), which is undertaken serially to collect data on the health and nutrition status of the US population. Trends in the levels of chemicals are reported where these chemicals were also measured in earlier reports. Results are interpreted with reference to the ranges of concentrations found in the population studied. In some instances, results are also interpreted against reference values.

With regard to existing information it is useful and important to differentiate between *research projects*, which aim at the generation or the improvement of knowledge on the causal links between environmental factors and health by hypothesis generation and testing, and *survey projects*, which aim at periodic measurements to produce information on the prevalence of exposure to environmental agents. Survey projects may be used in the public health arena with a view to developing and evaluating policies designed to protect the health of the general population.

4.4 Human Volunteer Studies

Human studies are commonplace in drug development. New chemical entities are taken through the stages of safety and efficacy testing, the first one usually involving the administration of a single dose to volunteers (Phase I testing). In contrast, there is very little information on human pharmacokinetics and toxicity for the majority of nonpharmaceutical chemicals. However, such information can be very useful, in some cases even essential, for the risk assessment process. While the previously mentioned types of studies can all make a very valuable contribution to the understanding of the effects of chemicals in humans, they almost invariably suffer from a lack of control regarding exposure. In contrast, human volunteer studies give information on health effects in relation to well-defined exposures.

4.4.1 The Controversy over Human Volunteer Studies

The underlying principles and international guidelines on ethical aspects of research involving human subjects have already been extensively discussed (see above). Historically, safe exposure levels for chemicals were established through experience of safety in use. For less overtly toxic compounds it may have taken a long time to recognize the link between exposure and harmful effects. Even when this was achieved, certain effects may have been tolerated as an occupational hazard if the benefit from use was seen to be substantial. Increasing awareness of the effects of chemical exposure has gradually led to the introduction of regulations covering the control of chemical exposure in the workplace. Biological monitoring has been established as a cornerstone of exposure surveillance (see above), but it requires an understanding of human metabolism and pharmacokinetics (Wilks *et al*., 1993). A second line of argument concerns the use of human volunteer studies for the purpose of reduction, refinement or replacement of animal studies (Volans *et al*., 1991). This is of particular importance in areas where public opinion is increasingly reluctant to accept animal testing for basic safety assessments. A typical example would be testing for topical effects of cosmetics, personal care and household products.

Some types of human volunteer studies, in particular those with pesticides, have attracted considerable controversy in recent years. In the USA, the Food Quality Protection Act of 1996 introduced the concept of an additional uncertainty factor of up to 10 into the risk assessment process for pesticides, to account for the possible increased sensitivity of infants and children (EPA, 2009). A number of dosing studies with volunteers were subsequently submitted to the agency with the intent of providing human data which would allow reduction of the existing intraspecies uncertainty factor. The resulting protracted and intensely polarized debate has been summarized in detail elsewhere (NRC Committee on the Use of Third Party Toxicity Research, 2004). Some scientists, environmental and other activist groups challenged the ethical and scientific validity of the studies, contending among other things that people should not be put at risk for the purpose of reducing the stringency of regulatory standards (Lockwood, 2004; Oleskey *et al*., 2004; Sass and Needleman, 2004; Needleman *et al*., 2005; Krimsky and Simoncelli, 2007). Other scientists and industry groups argued that the human dosing studies were needed to ensure the scientific quality and accuracy of the EPA's safety evaluations and that they had been, and could be, conducted ethically (Charnley and Patterson, 2003; Chart *et al*., 2004; McAllister, 2004; Tobia *et al*., 2004; Resnik and Portier, 2005). In response to the controversy, the EPA commissioned the National Academy of Sciences to provide advice on whether, and under what circumstances, the agency should accept and consider intentional human dosing studies. The National Research Council committee which considered this question recommended that such studies should be conducted and considered for regulatory purposes only if all of the following conditions were met (NRC Committee on the Use of Third Party Toxicity Research, 2004):

- The study is necessary and scientifically valid—that is, it addresses an important regulatory question that cannot be answered with animal studies or nondosing human studies, and has been designed, conducted and reported in a manner that ensures the study will be adequate scientifically to answer the question.
- The societal benefits of the study outweigh any anticipated risks to participants.
- Intentional human dosing studies that are to be used only to improve the accuracy of a reference dose (RfD), and that otherwise provide no health or environmental benefit, can be justified only when there is reasonable certainty that participants will experience no adverse effects.
- All of the recognized ethical standards and procedures for protecting the interests of study participants are observed, including equitable selection and recruitment of participants, informed consent and independent review of the scientific and ethical merits of the study by an IRB or its foreign equivalent.

On the basis of this advice the EPA issued a final rule in 2006 which established the framework under which data from intentional human dosing studies would be considered in future (EPA, 2006). The rule gives details of the many difficult questions the agency had to struggle with and the reasons for its decision. The final rule categorically prohibits any EPA-funded research, or the consideration of other ('third party') research involving intentional exposure of pregnant women and children. It also extends the federal policy which governs protection of human subjects in research ('Common Rule') to other intentional exposure studies involving nonpregnant adults intended to be submitted to EPA under the pesticide laws. Furthermore, it requires protocols for such studies to be submitted to the EPA before the research is started, and it establishes an independent Human Studies Review Board to review new research proposals and research reports intended to contribute to decision making.

In Europe, the regulatory framework concerning authorization and use of pesticides is governed by European Union legislation. In Annex II, Part A, Point 5.9 of Council Directive 91/414/EEC of 15 July 1991 on the placing of plant protection products (PPPs) on the market, it is stated that '... Data and information relevant to the effects of human exposure, where available, are of particular value, in confirming the validity of extrapolations made and conclusions reached with respect to target organs, dose—response relationships

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and the reversibility of toxic effects. Such data can be generated following accidental or occupational exposure' (Commission of the European Communities, 1991). Furthermore, in an opinion expressed by the Scientific Committee on Plants, it was stated that 'Human data are most useful because they provide reassurance on the extrapolation process' (SCP—Scientific Committee on Plants, 2002). However, the Scientific Committee went on to note that 'apart from ethical issues, studies conducted in humans may have limitations (e.g. reduced number of subjects, the use of only one sex, the possibility of studying only selected end points). The Committee stresses that human data should be used in the context of the entire toxicological profile of the PPP under consideration.' The latest draft guidance document on the setting and application of acceptable operator exposure levels (AOELs) describes the intended restrictions concerning the use of human data as follows: 'Toxicological studies conducted in humans with the purpose of determining a human No Observed Effect Level of an active substance have not been and will not be used *per se* to derive regulatory limit values (such as an ADI, an AOEL or an Acute Reference Dose) for the substance. Rather, such studies if they are scientifically and ethically valid, will be evaluated and used as supplementary information to confirm the validity of regulatory limit values which will continue to be derived from extrapolations from appropriate studies in laboratory model species' (SANCO European Commission Health and Consumer Protection Directorate General, 2006). The document goes on to say that if appropriate scientifically valid and ethically generated human data are available which show that humans are more sensitive and which would lead to a lower AOEL value, these data should take precedence over animal data. Significantly, no such provision has been made for the reverse case, that is, human data showing decreased sensitivity. This position has been criticized by the European Food Standard Authority's Panel on Plant Protection Products and their Residues (PPR), who stated in an opinion on an earlier draft of the guidance document that 'the results of tests involving humans when ethically and scientifically acceptable should be used to derive reference values, including AOELs, and not be considered simply supportive of reference values derived from animal data. However, this position should not be interpreted as condoning the injudicious study of human subjects involving deliberate or intentional exposure' (PPR, 2006). It appears, nevertheless, that the opinion of this scientific advisory body may not find its way into legislation, in particular the revision of the PPP directive 91/414/EEC. The latest proposal by the European Commission repeats on a number of occasions the point made in the draft AOEL guidance document, that deliberate human administration studies should not be used to determine a human No Observed Effect Level of an active substance, and explicitly states in Article 4: 'In relation to human health, no data collected on humans shall be used to lower the safety margins resulting from tests or studies on animals' (Commission of the European Communities, 2006).

In contrast, the World Health Organization has considered human data in the context of chemical risk assessment for many years through the IPCS. Regarding human volunteer studies, the IPCS concluded that such studies have contributed particularly to our understanding of kinetics and to the development of air quality guidelines and standards for traditional pollutants (IPCS—International Programme on Chemical Safety, 1999). The 1998 Joint Meeting of the FAO Panel of Experts on Pesticide Residues in Food and the Environment, and the WHO Core Assessment Group discussed the use of data from biomedical testing involving human subjects in hazard evaluation (JMPR, 1998). The meeting concluded that in order for human studies to be considered in the hazard evaluation of a pesticide, it must be shown that they were conducted in accordance with principles such as those expressed in the Declaration of Helsinki or equivalent statements. Studies should be designed with sufficient rigour and robustness to ensure their applicability to diverse populations. Therefore, the study design should include a sufficient number of subjects of both sexes (to be determined, in part, on the basis of the effects to be evaluated, to account for inherent normal variability and to ensure adequate statistical rigour). The subjects should be adults, and any females should not be pregnant. Provided that studies could be shown to be scientifically sound and to adhere to appropriate ethical guidelines, the meeting agreed to make continued use of them in future evaluations.

4.4.2 Preliminary Safety Data

An assessment of the risk to volunteers participating in any study involving the administration of drugs or chemicals can only be made on the basis of available hazard information on the compound. There is a trend within the pharmaceutical industry to study new chemical entities in humans increasingly early in the development. However, a recent life-threatening adverse event in a Phase I clinical trial has demonstrated that unforeseen human reactions to novel products can occur even in the presence of drug safety information which does not indicate any specific risk (Suntharalingam *et al*., 2006). In this case, six healthy male volunteers were given a recombinant anti-CD28 monoclonal antibody in a clinical trials facility. Within 90 minutes of receiving a single intravenous dose of the drug, all volunteers experienced inflammatory reactions of an increasing severity and became critically ill over the following 12–16 hours with pulmonary infiltrates and lung injury, renal failure and disseminated intravascular coagulation. They were transferred to an intensive care unit where they received intensive cardiopulmonary support including dialysis,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

high-dose methylprednisolone and an anti-interleukin-2 receptor antagonist antibody. Despite the severity of the cytokine release syndrome, all six patients survived although two required intensive organ support for 8 and 16 days, respectively. A subsequent investigation by the MHRA concluded that the adverse incidents did not involve errors in the manufacture of the antibody or in its formulation, dilution or administration to trial participants (MHRA, 2006). In the MHRA's opinion an 'unpredicted biological action of the drug in humans' was the most likely cause of the severe adverse reactions in the trial participants, despite apparently adequate preclinical testing. The report highlights the important scientific and medical issues raised by the incident, in particular those concerning the potential risks associated with this type of drug and how to make the transition from preclinical testing to trials in humans. However, an editorial accompanying the publication of the event concluded that while it is important to do whatever is necessary to minimize risk, it is not possible to prevent all such events in future, and rare and idiosyncratic adverse events should not put an end to medical progress (Drazen, 2006).

Human dosing studies with a nonpharmaceutical are almost invariably carried out comparatively late, for example in the case of pesticides when data on operator exposure are required. This means that there will be substantially more toxicity information available than that which is required for a Phase I single oral dosing study in drug development. The WHO/FAO Expert Panel of the Joint Meeting on Pesticide Residues has suggested that the entire standard toxicological database in the appropriate animal species to establish the ADI should be available (JMPR, 1998). The benefit of this situation in the case of the pesticide is that a risk assessment for humans will be improved as more toxicity information becomes available. On the other hand, there may be a tendency to overemphasize adverse effects occurring in chronic and lifetime studies in animals at high dose levels, which may have little or no relevance for possible effects expected from a single low dose administered to volunteers. A minimum toxicity dataset has therefore been suggested which should be available before considering a human volunteer study with nonpharmaceutical chemicals (Wilks and Woollen, 1994). This would, of course, need to be adjusted depending on the type of study and the chemical in question, but for a single oral dosing study it should contain at least the following, carried out according to OECD guidelines:

1. *In vitro* and *in vivo* tests of genotoxicity.
2. Acute oral toxicity tests in one rodent and one nonrodent species.
3. Subchronic (90 days) toxicity in one rodent and one nonrodent species.
4. Balance and biotransformation studies in one species.
5. Assessment of fertility in a single generation study.
6. Teratology in one species (in case of participation of female volunteers).

Particular attention should be given to the results of short-term tests which are most relevant to a single exposure of humans. For a single dose dermal study additional information would be required on:

1. Acute dermal toxicity in one rodent species.
2. Percutaneous absorption, either using animal *in vivo* or human skin *in vitro* data.

In addition to any toxicological information, human experience in use should be considered whenever possible.

4.4.3 Types of Human Volunteer Studies

Two principal types of human volunteer studies with nonpharmaceutical chemicals need to be distinguished. There are studies which look at an adverse or toxic effect as the outcome measurement. The second type involves the administration of chemicals to study their metabolic fate and pharmacokinetic behaviour.

4.4.3.1 Effect Studies

The term 'minimal risk' in human volunteer studies has already been discussed, and this is of paramount importance when considering effect studies. It therefore follows that the study of adverse or toxic effects in volunteers can only be justified on the assumption that no lasting damage will occur. In practice, this restricts such studies to acute and inherently reversible changes at dose levels which people are likely to encounter at their workplace or in the general environment. For example, the acute neurobehavioural effects of solvents have been studied in volunteers at exposures around permitted occupational exposure limits (Iregren and Gamberale, 1990). Such studies include the effects of exercise and alcohol as modifiers of the CNS effects of solvents. Another example is the study of sensory effects of pyrethroid insecticides. Synthetic pyrethroids have the potential to induce transient, fully reversible paraesthesia (variously described as tingling, burning or numbness) in exposed skin of susceptible individuals (LeQuesne *et al*., 1980). The underlying mechanisms of this effect, as well as the potential for therapy, have been studied using human volunteers (Flannigan and Tucker, 1985; Flannigan *et al*., 1985).

Organophosphorus insecticides have been tested in volunteer studies for their potential to inhibit cholinesterase (ChE) activity as a biochemical marker of exposure long before the present controversy regarding such studies (see above). Oral administration of malathion at doses up to 16 mg person^{-1} day^{-1} for up to 47 days had no significant effect on either

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat046
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

plasma or red cell ChE activity, and the volunteers remained asymptomatic (Moeller and Rider, 1962). Parathion-methyl has been studied in a whole series of volunteer studies, with oral doses between 1 and 22 mg person^{-1} day^{-1} producing no significant effect on plasma or red cell ChE (for a summary see Rider *et al*., 1969). A dose of 30 mg person^{-1} day^{-1}, or approximately 0.4–0.5 mg kg^{-1} day^{-1} showed a maximal mean red cell ChE depression of 37%, thus being defined as the level of minimal incipient toxicity for parathion-methyl (Rider *et al*., 1971). In studies designed to test the safety of dichlorvos as a disinsectant of aircraft, 15 volunteers were intermittently exposed to a concentration of 0.5 mg m^{-3} for five hours per night, four nights per week over two weeks (Rasmussen *et al*., 1963). There was no effect on red cell ChE activity, but a gradual reduction of plasma ChE with the lowest single plasma value observed being 34% of normal. No clinical signs were seen, and detailed studies of visual performance, complex reaction time, neurological function and airways resistance showed no abnormalities.

The largest number of effect studies is carried out in the testing of consumer products for topical irritancy and sensitization. It is now recognized that the standard animal tests, such as the Draize skin and eye irritation tests (Draize *et al*., 1944; Draize, 1959) frequently overpredict the severity of effects occurring in humans (Freeberg *et al*., 1984; Nixon *et al*., 1975). With regard to eye effects, volunteer studies have been employed to establish the threshold of effects seen with mild to moderate irritants (Freeberg *et al*., 1986). This has shown that a modification of the Draize test using a lower instillation volume is more representative of human effects. For the predictive testing of skin irritancy a human four-hour patch test has been developed (Basketter *et al*., 1994; Dykes *et al*., 1995; York *et al*., 1995). It has been proposed to use this test as an alternative to the Draize test for the classification and labelling of substances and preparations (York *et al*., 1996).

4.4.3.2 Metabolism and Pharmacokinetic Studies

These types of studies have two main purposes. The first is the identification of metabolic pathways and target metabolites which can subsequently be used in biological monitoring studies at the workplace or in the general population. Second, in order to interpret the results of biological monitoring studies and extrapolate back from the excretion of a metabolite to exposure to the parent compound, a detailed knowledge about the human pharmacokinetics of the compound is required. When a compound is administered to humans for the first time it is prudent to carry out a pilot study with a single volunteer. This serves several purposes. It provides assurance that adverse reactions are unlikely (particularly relevant since the events surrounding the Phase I trial of a novel monoclonal antibody in 2006, see above), confirms whether the dose is adequate in terms of analytical sensitivity, provides material for the improvement of analytical methods, and allows the sample collection times to be optimized. For the main study, it may be desirable to study more than one dose level, and, where dermal or inhalation uptake is important, more than one route of administration.

For example, the pyrethroid insecticide cypermethrin was administered to volunteers as a single oral and dermal dose (Woollen *et al*., 1992). Urine was collected for 120 hours after dosing and analysed for the metabolites *cis*- and *trans*-3-(2,2-dichlorovinyl)-2,2-dimethylcyclopropane carboxylic acid (DCVA), 3-phenoxybenzoic acid (3PBA) and 3-(4-hydroxyphenoxy)benzoic acid (4OH3PBA). Following oral dosing, the ratio of *trans*- to *cis*-DCVA metabolites was approximately 2 : 1, and similar amounts of DCVA and PBA (3PBA + 4OH3PBA) metabolites were excreted. In contrast, in the dermal study the ratio of *trans*- to *cis*-DCVA metabolites excreted in urine was approximately 1 : 1, and the total amount of PBA metabolites recovered was four times higher than the total amount of DCVA metabolites. In comparison, the metabolite excretion profiles in a field worker exposure study involving hand-held spraying were consistent with a predominance of absorption by the oral rather than the dermal route, since the ratios of *trans*- to *cis*-DCVA were usually close to 2 : 1 and similar amounts of DCVA and PBA metabolites were excreted in urine (Wilks *et al*., 1993). These data illustrate route-specific metabolism of cypermethrin that may not have been predicted from animal studies, as well as the importance of both oral and dermal volunteer studies and the usefulness of measuring multiple metabolites. The results could be used to provide indicators of the main route of absorption during occupational exposure, thus allowing better targeting of safety advice and protective measures.

Di-2-ethylhexyladipate (DEHA) is a plasticizer which is added to PVC to produce 'cling film' type food wrappings. DEHA can migrate into foods, particularly those with a high fat content, and the maximum likely daily intake has been estimated to be around 8 mg day^{-1} (MAFF, 1990). An oral human volunteer study was carried out using deuterium-labelled compound to distinguish between metabolites derived from the test substance and background levels (Loftus *et al*., 1993). The most abundant metabolite found was 2-ethyl hexanoic acid (EHA), whereas mono-2-ethylhexyl adipate, the major metabolite found in a primate study at a 100-fold higher dose level, was not found. This example illustrates a potential problem in risk assessment. Certain metabolic pathways may become overloaded at higher doses and bring other pathways into operation. Consequently there will be some uncertainty about comparisons between animal toxicology studies at

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat046
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

high dose levels and human volunteer studies at much lower doses. Follow-up biological studies were carried out using EHA as a biological marker in 24 hour urine samples from 112 individuals from five geographic locations in the UK. Estimates of daily intake of DEHA showed a skewed distribution with a median value of 2.7 mg (Loftus *et al*., 1994).

5 CONCLUDING REMARKS

The use of toxicity data from human studies is still very much the domain of pharmaceutical safety assessment, but the benefits of the collection of human data are now recognized in other areas, most notably those involving exposure to industrial chemicals and pesticides, as well as the safety assessment of consumer products. This chapter has looked at the main sources of human data in toxicity assessment, in particular for nonpharmaceutical chemicals. They all have their unique advantages and limitations, and no single type of human study is able to answer all questions.

Case reports often contain a high level of detailed and verified exposure and give a rare insight into dose–response relationships. In the case of adverse reaction reporting they also allow an estimate of the likelihood of adverse effects occurring. Their main limitation is that they are reactive, often retrospective and rely on the individual effort of clinicians or relatively few data collection systems, for example those of PCCs and the pharmaceutical industry.

In the case of human therapeutic use of chemicals, the systematic use of human data normally seen with pharmaceuticals applies through a combination of volunteer studies and adverse data reporting. However, this is only applicable to a small number of chemicals.

Exposure studies and health surveillance provide invaluable information on presence or absence of effects from long-term exposure to chemicals in the workplace or environment. However, they can be time consuming and expensive, and the link between exposure and effect may be difficult to verify, particularly for retrospective studies.

Human volunteer studies with nonpharmaceutical chemicals have the advantage of well-characterized exposure combined with information on the pharmacokinetic behaviour and/or effects of the compound. Nevertheless, outside the area of consumer products their usefulness is limited by ethical concerns and scientific challenges such as study design and small study populations. It is hoped that the present controversy surrounding some aspects of volunteer studies can be resolved through rational, scientific debate involving all stakeholders.

In the end, it is not so much the type of human study which will determine the ultimate usefulness of the data generated, but the rigorous application of established scientific principles. For the reasons discussed in this chapter, it is neither feasible nor desirable that human studies will replace experimental toxicology, but the two should be complementary. The danger is that toxicologists will continue to do experiments and epidemiologists will continue to collect data, but they fail to constructively interact with each other (Wilks *et al*., 1996). As observed by Sir Richard Doll, most occupational hazards of cancer have been discovered as a result of clinical intuition or epidemiological observation. However, most could have been avoided if modern laboratory techniques had been employed to test the substances used before men and women were exposed to them in an industrial environment (Doll, 1984).

Quality Assurance in Toxicology Studies

J. Rodney Pateman

CONTENTS

1 INTRODUCTION

The concept of any quality-related controls in respect of scientific research can at first seem nonsensical. The very nature of research, including toxicology, is to discover hitherto unknown and sometimes unexpected information: if a study generates the first information in the field, against what measures can it be assessed for quality, and what would be the purpose of such assessment?

Some of these issues become clear when a distinction is made between regulatory and nonregulatory toxicology. The purpose of regulatory toxicology is to provide information to government agencies, such that they can make sound decisions as to the precautions necessary to protect against dangerous properties of a chemical substance. The dangers may relate to human or animal health, or to the environment, and may be mitigated by limitations on the amount of material permitted on the market, limiting the scope or manner of the use of the material, or advice and warnings as to precautions during use (such as protective clothing, hazard labelling, etc.). The reports of the studies on which these regulatory decisions are based must be reliable, or else dangerous material may be inadequately controlled with potentially disastrous consequences. For these reasons, such work must be done within a statutory legal framework.

However, historically (and in some ways paradoxically), it was fundamental research that was first subject to quality control. Such work is generally published in the scientific press, and the process of publication almost invariably includes a process of peer review. Then, when published, other workers in the field attempt to verify and extend the original observations. This process, although retrospective, serves to control overenthusiasm in the original authors, enhance the authenticity of the observation, if it can be replicated by others, and allow the work to fade away if it cannot. These processes continue today, but their retrospective nature and protracted timescale can allow considerable waste of resource and exposure to risk, until the feedback mechanisms take effect.

More immediate assurance of the integrity of toxicological work would clearly be of advantage, and this need was vividly illustrated by the nature of some regulatory studies submitted to the US Food and Drug Administration (FDA), during the mid-1960s. The story is an interesting one, but the full telling is for another place. In essence, a chance observation of an anomaly between submitted dossiers by one of the FDA data integrity assessors led to a major investigation of the whole of the American regulatory testing business (US Food and Drug Administration, 1976). The original anomaly arose from error, oversight and endemic sloppiness in the testing laboratory, but the wider investigation revealed spectacular scientific fraud in some other organizations. Studies had not been conducted properly, or, in some cases, the work had not been done at all and 'results' were simply made up. There was a general lack of proper management and supervisory control, including poor data review, inadequate training and inappropriate

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat049

equipment; combined with a tendency to under- or over-report to satisfy the perceived preference of the sponsor company. This all culminated in hundreds of instances in which it was considered that false statements had been made to the US Government agencies. Custodial sentences were imposed on the main players in the fraud, but a significant improvement in general control and quality was needed if the FDA were to reach proper decisions in future, and provide adequate protection for the populace. There was no choice: regulatory toxicology, subject to inherent commercial pressures as it inevitably will be, had to be brought to heel. Following a several-million-dollar investigation lasting over two years, the FDA published legislation for regulatory toxicology (US Food and Drug Administration, 1978) that demanded specific standards and controls. This was 'Good Laboratory Practice' (GLP). Although this US Federal Regulation directly affected US laboratories and did not extend beyond US territory, any foreign company submitting data to the FDA was also required to meet the same standards and attest to so doing, in writing; otherwise the FDA would not consider the submission.

2 GOOD LABORATORY PRACTICE

The FDA GLP regulations were designed to ensure that data presented to the Administration was sound and reliable, and so prevent a recurrence of the earlier problems. Given the nature, impact and extent of those problems (people were in jail and test laboratories had ceased business), the requirements were accepted by the US pharmaceutical industry relatively easily. Once this ground had been broken, other authorities followed. In 1983 the US Environmental Protection Agency published almost identical legislation, as did authorities around the world, notably in Japan, the Netherlands and the UK. Aware that a plethora of slightly different national GLP regulations might constitute a multifaceted barrier to trade, the Organisation for Economic Cooperation and Development (OECD) developed generic *Principles on Good Laboratory Practice* (OECD, 1998), which the agencies of all OECD member countries agreed to accept. The list of countries agreeing to accept the common standard is shown in **Table 1**, and this gives an indication of the power of this MAD (Mutual Acceptance of Data) agreement. This is essentially the situation today: although laboratories undertaking regulatory studies must comply with their domestic GLP legislation, the domestic law is invariably based on the OECD principles and is accepted, not only by OECD member countries, but by many others as well. As the number of OECD member countries grows and the new members are seen to meet the necessary standards, the extent of mutual acceptance of toxicology data also expands. Within each country, government-appointed inspectors visit laboratory premises and observe work in progress, examine records and reports, interview staff and monitor compliance with GLP laws. The outcomes of such inspections are widely available, so that the authorities can reject work from unsatisfactory laboratories, wherever in the world they may be based.

Table 1 Countries Mutually Accepting GLP Data Under the OECD Scheme (January 2008)

Argentina[a]	Australia	Austria

United Kingdom	United States	

[a]Provisional adherents.
[b]Observer status.
[c]Non-OECD member countries mutually accepted as adherent to OECD GLP.

What do the GLP Principles or Regulations demand? The requirements cover the way in which regulatory studies are planned, performed, monitored, recorded, reported and archived. For a full and authoritative account of these six elements the reader is referred to the text of the *OECD Principles* (or national GLP statute), but the official wording is sometimes vague, thereby permitting a variety of interpretations of detail by nations, even by individual inspectors. The basis of each of these six elements will be addressed here, but this account should not be the sole source of information for those intending to implement a GLP system. Read the rules, and speak to the relevant inspectorate. In the experience of the author, a constructive and helpful dialogue can often be had.

3 GLP REQUIREMENTS

3.1 Study Planning

Each individual study must be the subject of a written plan, agreed between those sponsoring the work and the individual responsible for coordinating the study events. In GLP terms, the latter person is styled 'study director'. Although a laboratory may employ several individuals in this role, at any one time there must be only one study director per study, acting as the single point of study coordination and control. The purpose of the plan is to ensure that no one involved is in any

doubt as to the nature and extent of the study: one of the contributory causes of the error and oversight in the 1960s. This plan (or protocol) was initially perceived as one of the most difficult aspects to achieve in a scientific environment, because the future course of a study may depend on results obtained to date. However, regulatory studies are usually well defined, with clear end points and internationally agreed methodology. Plans for such studies can be prepared, sometimes by pasting the variables, such as the identity of the item under test, study schedule, and so on into the text of a standard method. Component technical procedures need not be specified in detail if they can be standardized in other documents held by the laboratory. These are defined as standard operating procedures (SOPs), and cover routine operations, such as use and calibration of equipment, preparation of reagents, animal husbandry, laboratory cleaning and so on. The regulation requires that the following points are addressed in each study plan—although addressing the issue might simply amount to stating that the item is not relevant to the particular study.

- Descriptive title
- Statement of purpose
- Identity of test item and any reference item
- Identification of the sponsor
- Location of test laboratory(ies)
- Identification of the study director
- Identification of any principal investigator(s) and their areas of responsibility
- Dated approval of the plan by the study director
- Proposed dates for starting and completing the study
- Reference to any relevant published test guideline
- Justification for the choice of test system
- Relevant characterization of the test system
- Method/route of administration of the test item to the test system, and justification for the choice
- Dose or concentration to be used, frequency or duration of application
- Experimental design, chronology, materials, methods and conditions
- Type and frequency of analysis, observations, measurements and examination.

Once agreed between the study sponsor and the laboratory, the plan is fixed and authorized by the dated signature of the study director. For such a document to be effective as an instrument of control on the scope and conduct of the study, the plan must be made available to all technical staff.

The plan may take on a significant level of complexity when several disciplines are required to work in harmony on a study, such as veterinarians, analytical and clinical chemists, pathologists and statisticians, and if some aspect of the study is located in another company or facility, especially if that location is in another country speaking a different language, the communication and drafting skills of the study director are tested indeed. In such cases, he/she may call on the services of one or more local GLP-compliant peers, styled 'principal investigators'. The extent of any such assistance is of course defined in advance in the study plan, and it is self-evident that principal investigators must maintain excellent contact with the study director, if the latter is to retain his/her position as a single point of study coordination.

The proposed study must be entered on the laboratory's 'master schedule' of studies. Historically a paper ledger, but nowadays usually a computerized database, this schedule displays the study identifier, study director, material under test, test type and key dates, often with other information useful to the laboratory in the management of work. The schedule must be kept current as the work proceeds, so providing a clear picture of the extent of work done, planned or in progress. The GLP purpose, however, relates to the quality monitoring of the test facility—as described later.

3.2 Study Performance

Each study must follow its study plan and the relevant SOPs, but the legislators recognized that toxicology studies do not always run on fixed tracks, and that changes of direction may be necessary as a result of emerging information. Such changes might include changes to dose levels, the addition (or removal) of observation time-points or appointment of a replacement study director. In some cases, it may be necessary to terminate a study early. Whatever the change from the originally approved plan, it must be formalized in a written amendment to the study plan, approved by the dated signature of the study director and distributed to all holders of the original document. The study may then proceed according to the plan as amended. In the course of a study there may be several such amendments, and to ensure that there is no doubt about the sequence of events, all must be sequentially numbered.

Life in the toxicology laboratory can suffer the same vicissitudes as anywhere else. The study that follows the plan (as amended) exactly, from start to finish, is relatively rare. A timed observation may be a few minutes late, controlled temperature may temporarily exceed defined limits, a proportion of samples or specimens may be lost in processing, specified equipment may cease functioning and be replaced. The list of potential deviations from plan or from SOP is endless, and few can be anticipated in an amendment. In this situation, GLP requires that the deviation is acknowledged in writing by the study director, and an assessment made of its impact. Clearly, the impact may range from negligible, to invalidation of the study; the purpose of formal documentation of deviations is to ensure that the individual best placed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat049
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to perceive the widest consequences to the study (the study director), makes the most appropriate decision and is seen so to do.

Regulatory toxicology studies often involve the use of living test systems: animals, plants, cell cultures, bacteria. The reliability of the study may be compromised if the test population is diseased or not homogenous, so GLP requires that the source, strain and health of the test species are known. However impeccable the source, a period of quarantined acclimatization to laboratory conditions should be allowed, during which any latent disease may be manifest—rather than appear as a complicating factor or possible effect of treatment during the study. In the case of microorganisms or cell lines, specific tests may be necessary to verify the expected characteristics and lack of contamination. In each case, the choice of the test system must be justified in writing to minimize the risk of deliberate or accidental selection of an insensitive species, potentially resulting in serious underestimation of toxicity.

The study environment must be appropriate to the health of the species and assure a stable and protected platform for the study. The health of rodents supplied with adequate diet and water can be indicated by behavioural observation and weight gain: unicellular plants in log phase of growth are generally considered healthy. As test systems, both must be protected from external interference; allegedly, the ability of field mice to come and go in the rodent house did not help the integrity of one early study! Granada Television's 'World in Action' called 'Tried Untested'(Granada Television, 1981).

GLP requires equal attention to the integrity of the test item (substance or material under test). The study director must be sure that the test item is stable for the duration of the study, and will not degrade as the work proceeds—otherwise the test results may be misleading as to the toxicity of the item provided for test. Similarly, if it is necessary to administer the substance as a preparation in vehicle (water, oil, feed, etc.), tests must be done to assure the stability, homogeneity and achieved concentration of the preparation.

Substances are often much less stable in vehicle than as the supplied chemical, especially in liquid formulation, so the same concerns about the identity of the chemical causing any effects on the study apply as for the stability of the test item itself. Homogeneity is a concern in dietary mixtures and liquid suspensions, since it is necessary to ensure that all test subjects receive the specified dose (another early problem related to inadequate mixing of a test item in feed. Animals could have eaten the feed, but ignored the lumps of chemical).

An assessment of achieved concentration is required to verify the accuracy of the preparation process. Should any one of these aspects not be assured, it may be difficult for the study director to state, with confidence, that the effects observed related to the specified dose of the specified substance.

Weak, contaminated, inappropriate or expired reagents may also be a source of misleading results. The GLP regulations require that all reagent containers show the identity of the contents, storage conditions and expiry date, and, not unreasonably, state that expired reagents should not be used.

Equipment used in studies must be reliable and fit for purpose. Proper cleaning and maintenance to minimize the risk of breakdown, and calibration of measuring equipment against traceable standards may seem self-evident, but GLP requires, not only that this is done, but that it is seen to be done. Inspection, cleaning and calibration logs for many instruments are therefore mandatory, and the scheme for scheduling and recording these assessments must be described in SOPs. All this information relating to the status of equipment must be readily available to users, for as we shall see later, the users of measuring equipment are required to put their names to the results. The increasing use of computerized systems in regulatory studies has presented new facets to the equipment aspects of GLP compliance, in which extensive validation work may be required to demonstrate that systems perform as required—and continue to do so, following any modification or upgrade. (Here I should emphasize the word 'required'—it is not necessary to demonstrate that systems perform at their peak, or to manufacturer's specification; the needs of the individual laboratory must be determined, then the system must be assessed against those needs). Clear documentation of the laboratory's needs, the actions required to test system performance against those needs, the execution of those actions, the outcome of those actions and final management approval of the system as fit for use will all be required for a claim of GLP compliance.

Possibly the most significant contributors to the reliability of a study and its report are the personnel involved in the work—not just technical staff in the laboratory, but managers, data processors, maintenance engineers, clerical workers, animal husbandry staff, quality monitors and so on. GLP requires that all these staff are aware of their responsibilities and are appropriately qualified, trained, experienced and competent—although the determination of 'appropriately' and assessment of competence are left to facility management. Nevertheless, documentation such as job descriptions, curricula vitae (CVs—résumés) and records of training must be maintained and kept current.

All samples or specimens arising from the study and data records, whether paper-based or digital, must carry a unique study identifier. All raw data (records of original observations and activities, i.e. primary data) must be made promptly, legibly, accurately and directly, and be dated and initialled by the staff making the entry (see later). Electronic signatures and dates are acceptable, so long as they are as secure, and as legally valid as their

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat049
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

handwritten equivalents. Changes to data are acceptable, so long as any change is itself signed, dated and carries a written explanation. These requirements arose from work in which data appeared to have been provided retrospectively by persons unknown, or in which records had been changed for no apparent good reason but, suspiciously, resulted in a better outcome for the study. Nowadays, the dates and signatures allow cross-reference to the competence records, so that it can be demonstrated, at any time in the future, that the persons making the observations and records were deemed competent by management, at the time that the work was done.

3.3 Study Monitoring

For toxicologists, perhaps one of the most bizarre concepts was that their work should be monitored, not for technical excellence, but for compliance with GLP; and not by their peers, but by an independent quality assurance (QA) function, reporting to management. Often seen initially as a group of interfering (and ignorant) nit-pickers, asking naïve questions and easily misdirected by scientific argument, this group of people not only picked over the data records and reports arising from studies, but they also intruded into laboratories to observe the toxicologist at work.

The background to this requirement justified the intrusion. The FDA investigation had revealed that some work reported to government agencies had been misreported, fraudulently manipulated or manufactured. Although the FDA had considered placing an Agency investigator in each facility to ensure integrity, this was over-burdensome (financially, at least) and the requirement was dropped in favour of an internal quality assurance unit (QAU). This unit monitors and evaluates all regulatory studies, but its purpose is to report outcomes to management. Management is ultimately responsible for the standards within a facility, including GLP compliance; the QAU acts as a management agent providing the information upon which management may take appropriate corrective and preventive action. For this reason, the members of the QAU report directly to management, and cannot be placed organizationally within any technical department working on regulatory studies. (There are exceptions for very small organizations, but these are uncommon and require very careful justification).

This principle of independence extends to the QA tasks themselves. Self-inspection is neither ideal nor particularly effective, and QA must take care not to become embroiled in technical procedure. In making their observations on quality and compliance, QA should not become part of the processes they are monitoring; they should be the metaphorical 'fly on the wall'. Although the subject of QA monitoring of study reports will be addressed later, one of the most likely ways for this principle to fail is when QA of study reports drifts into quality control (QC), so it is worth expanding somewhat on this danger now.

In principle, the study director's team should produce a draft study report that is perfect in all respects; then QA confirm to management that the system has worked well. In the real world of course, even the best draft will doubtless contain some transcription errors, typographical errors, ambiguity or obscurity—even though it may meet the requirements for a generally full and accurate account. The training and psychology of most QA auditors will not allow them to ignore presentational glitches—and why should it? The auditor, as much as the scientist, has an interest in the general quality of the report, the only part of the study that most people will see. So the auditor will bring the study director's attention to ambiguous phraseology, incorrect numerology and typographical fumbles. All well and good, but as this process is repeated in report after report, the study director may begin to rely on the QA process to pick up any errors, to the extent that the draft is no longer proofed before submitting it to QA scrutiny. Presto! Quality control, part of management's role of *ensuring* quality, is transferred to the *assurance* function; QA has become an integral part of the process and is on the brink of disqualifying itself as an independent GLP QA unit.

Over almost three decades, the scope of QAU activity has expanded into advisory roles, and the skills of the individuals within the QAU are often of value in customer contact and in assessing matters other than GLP compliance. When planning their work, many QAUs now use fairly sophisticated risk-analysis techniques, but the fundamental activity, required by legislation, is unchanged. They are required to inspect regulatory studies in progress, and to audit the reports emanating from those studies.

3.3.1 Study Inspection

All study QA inspection work is designed to assess the level of compliance: with the GLP regulations, with the plan for the study (protocol) and with the company's written procedures. Aspects of compliance that cannot easily be associated with a specific study may well be inspected separately on a facility basis; such aspects might include the operation of storage areas, maintenance of the SOP system, staff competence review procedures and cleaning or husbandry.

To ensure that all regulatory work in the facility is covered by the internal monitoring scheme, the QA inspectors will refer to the laboratory's master schedule of studies. From this, the inspectors are able to determine the type of each study, identify the study director and see when each study starts and ends. In this way, QA can ensure that an appropriate level of monitoring is applied to every piece of work intended for regulatory submission.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat049
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

During some early inspections, it was not uncommon for technicians to attempt to demonstrate their skill by performing tasks as speedily as possible. Unfortunately for them, QA were less concerned about the rate of pipetting, instead concentrating on whether the volume and identity of the material being dispensed agreed with the study plan, whether the containers were properly labelled, and the extent to which cross-contamination was controlled. Of course, excess speed can be associated with lack of care so technical enthusiasm often backfired, resulting in even closer scrutiny!

Further, there may have been a tendency for scientific managers to wheel out their best technicians for inspection, or QA inspectors could have been excused for thinking they had wandered onto the *Marie Celeste* when entering a laboratory for an arranged inspection. Such displays will be rare in an organization with well-established GLP and QA systems, and the QA inspector will be recognized as an essential and normal element of the study infrastructure. Study staff will recognize that the QA inspections lend credence to their work through independent observation of normal practice, and they act no differently whether QA are present or not.

The QA role is to assess compliance with written standards, not to make judgements on scientific merit. It is for management to decide, on receipt of the report from QA, whether (for example) an SOP should be updated to reflect better practice, or whether technical staff should be disciplined for failing to follow the official procedure—or both.

Quality control traps, similar to those mentioned previously for the audit of study reports, may be found in relation to the QA role in study inspection. The QA inspector that checks that all the sample labels are correct before the technical staff proceed does *their* job for them. QA should be concerned with assessing systems and processes, not directly checking every last item; QA should ask themselves whether there is evidence that someone else has checked every last item. Of course, there are circumstances in which a QA inspector must interfere: if a technician has picked up the wrong syringe and is just about to dose an animal with an incorrect material, it would be inappropriate for the inspector to silently observe the error, then write a report to management about it. And there is no harm in pleasantries such as holding a door or passing a towel—so long as the inspector does not lose sight of the potential danger of involvement.

3.3.2 Study Report Audit

In most QA units, the majority of effort goes into report audit, and the master schedule of studies is often used to identify study reports that are imminently available for attention, and so manage workloads. In essence, the audit procedure is intended to provide assurance to management that reports of toxicology studies are complete (all the study events are addressed; no actions or outcomes are suppressed), true (all the described events and outcomes are supported by study records), the study followed the plan (no planned activities omitted and no extra activities included) and that the report addresses all the required elements listed in the GLP Regulations. Usually, the review also includes an assessment of data quality, and an assessment of 'internal consistency'—that is, tables of individual data, group means or summary tables, graphical representations, textual accounts, summaries and conclusions are all in logical agreement. It is not difficult to see how such minute scrutiny can drift into quality control or issues of presentation!

To perform such an audit, QA must have access, not only to the draft report, but also to all the study records and supporting information. This will include the study protocol, records of study activities and results, receipt, characterization, dispensing, formulation and analysis of the substance under test; receipt, characterization and health records of the test species; environmental control, data processing; relevant correspondence, and so on, in whatever form (handwritten or machine output paper documents, computer databases, electronic files, photographs, chart output, specialist reports, dictation tapes, microscope slides, etc.). Records of reagent preparation, instrument calibration and staff competence may also be called for. The access to this material is direct and by right, not by gift of the study management. For example, QA staff will have personal, (normally read-only) access to computer data, rather than relying on the study staff to supply a printout.

The QA auditor's role is not executive. Although some detected errors may appear to be typographical in origin or easily and plainly corrected ('three samples' should be 'four samples'), the auditor should at most propose a change to the report, for ratification or rejection by the study director. For anomalies that are less clear-cut ('the reported result does not seem to be obtained using the equation specified in the SOP'), the auditor should neither recalculate the result according to the equation, nor assume that an alternative equation is relevant on this occasion. In all cases, the auditor should aim to display the anomaly and the study director should assess the issue, then make any appropriate correction to the report or explanation in the data, simply indicating to QA that the audit observation is accepted and resolved, or rejected.

From time to time, but hopefully rarely, the QA audit will reveal such a fundamental error that the study is invalid (say, an incorrect material had been tested or a key reagent was past its expiry date). In such a case the auditor will notify the study director immediately and not persist with the audit of that study. Much more commonly, subject to slight correction, study reports will be approved for issue and a Statement of Quality Assurance, listing the occasions on which the study

was monitored and audited, will be signed by a QA representative.

3.3.3 External Monitoring

The company QA unit serving a toxicology laboratory will be very familiar with the processes and procedures in that laboratory, and will therefore be well placed to detect anomalies (and, with experience of individual technicians, even predict them!). However, despite the best intentions, over-familiarity with a single environment can restrict the auditor's ability to perceive; and in any case, the opinion of an internal auditor employed by the toxicology facility (directly or indirectly) will have limited influence on government regulatory bodies. Greater assurance is obtained by occasional monitoring at a higher (and even more independent) level, by government-appointed national GLP monitoring authorities.

Administratively, these government inspectorates occupy various positions in the national framework. In some cases, inspectors are associated with the regulatory bodies themselves, for example in the USA, Japan and Switzerland, in which each ministry has its own inspectors. In the Netherlands and the UK, a single inspectorate within the Department of Health monitors GLP compliance on behalf of all agencies. Elsewhere, autonomous or quasi-autonomous organizations may be accredited to inspect on behalf of government.

Whatever the legal framework, the GLP monitoring authorities of OECD countries make inspection visits to facilities wishing to enter the GLP programme; then annual, biennial or three-yearly short-notice routine surveillance inspections of GLP-registered test facilities, as well as extra inspections in relation to specific issues (for-cause). These inspections assess all aspects of facility operation in respect of GLP compliance, often using high-level documents such as site plans and master schedules to determine whether the facility has the capability to perform all the reported work. Inspection observations are reported to the laboratory management, who must indicate that appropriate action has been taken or is intended in respect of each reported deficiency. The inspectors generally reserve the right to verify such statements, but the final outcome results in the laboratory continuing on the list of compliant facilities, or removal. The current list of UK compliant facilities is maintained on the Medicines and Healthcare Producers Regulatory Agency (MHRA) web site (MHRA, 2008). The national GLP authority is also required to report the overall outcome to the OECD (and within the European Union (EU), to the European Commission). There is therefore considerable pressure on the test facilities to maintain their compliance status, since the report of the national authority to OECD is the basis of Mutual Acceptance of Data between OECD countries.

3.4 Study Recording

GLP addresses some features of the way in which study events and outcomes are recorded. Data should be recorded directly, promptly and legibly, entries should be signed and dated and any changes to the record must leave the original clear, be explained and themselves be signed and dated. Why?

The problems discovered in the 1970s included many data entries that had been obliterated and rewritten, without apparent justification, and which aroused the suspicion of the FDA review team. The laboratory managers were, in the main, unable to account for the changes. On judicial enquiry, it further transpired that other data had been entered after the study had finished, not by the study technicians, and clearly not at a time when the recorded observations could have been made.

Signing and dating by the technicians responsible for recording the data allows verification that these personnel were competent to make the observations (by reference to training and competence records) and indicates that the records were made at a time that the observations could have been made. To a large extent, these signatures and dates also limit the possibility of fraudulent generation of data purporting to reflect contemporaneous observations, since any such entries will be relatively easy to detect. Similarly, signatures and dates associated with changes to the records provide clarity, and associated with the explanation or justification and the ability to see the original entry, assurance that the change was made for good reason. This was not a new concept, but a new application; consider the process for correcting a written error on a bank cheque.

Prompt and direct recording is required to reduce transcription errors and enhance credibility. Observations committed to memory for later documentation must carry a degree of suspicion: 'It must have been number 21 that was immobile yesterday, because it's immobile today—or was it number 23 yesterday?'. The requirement for direct recording relates to the GLP definition of 'raw data'. These are not just unprocessed, unadjusted or uncorrected individual records, but the earliest records of events, observations or decisions. An interim note on a scrap of paper, which is destroyed after the information is later rewritten into the formal record, is not acceptable. The scrap of paper was the raw data: the only record that was not potentially open to mistranscription. It should have been retained—and signed and dated!

Identical requirements apply when data is captured and retained by a computer system. The person responsible must be identified (usually carried into the record from the user log-on information along with the date—and often the time), and changes must be written to the database in such a way that the new entry (with its new user id and date) logically overrides the original, but does not physically overwrite it. The ability of such a system to maintain a clear, complete audit trail covering possibly

multiple levels of correction to a variety of types of data will be an essential element of system validation.

Original data may therefore take many forms, and the same data type may not be in the same form between laboratories. Paper records are used by almost all laboratories, even if only as backup in case of computer failure. Other forms might include photographs, sound recordings, machine printout as charts or tally-rolls, specimens, microscope slides, optical or magnetic discs, determined solely by data capture mechanisms. The list of possibilities is endless, the key issue is whether is this is the original, retainable record.

3.5 Study Reporting

The GLP Regulations require a full, written account of every study. The study director is responsible for the report and for signing a statement to indicate the extent to which the study complies with the Regulations. A properly designed and executed study in a well-managed facility will have few if any deviations from GLP, but the intent of the statement is to highlight any significant or systematic failures to comply. The occasional administrative error—such as a single missing signature in the data—would not constitute non-ompliance, but the routine omission of signatures by an individual, or throughout one section of the data, would do so. This is an area requiring judgement by the study director, often following advice from the QA department, but noncompliance does not necessarily imply that the study is not reliable. It is the responsibility of the study director to declare such shortcomings, and for the receiving authorities to make judgements on their impact.

The study director must consider his/her statement of compliance very carefully. In the UK, there are specific legal penalties (financial and custodial) for making, copying, holding or supplying a false 'Good Laboratory Practice Instrument' with the purpose of inducing a regulatory authority to accept it as genuine. The definition of such instruments includes the study director's statement, required in every report.

The previously mentioned signed statement of quality assurance monitoring for the study is also a required element. Other elements specified in the Regulation are:

- A descriptive title
- Identification of the test item by code or name (IUPAC, CAS number, biological parameters, etc.)
- Identification of any reference item
- Characterization of the test item including purity, stability, and homogeneity
- Name and address of the study sponsor
- Name and address of any test facilities and test sites involved
- Name and address of the study director
- Name and address of any principal investigators and the phase of the study delegated, if applicable
- Name and address of scientists having contributed reports to the final report
- Experimental starting and completion dates
- Description of methods and materials used
- Reference to OECD test guidelines or other test guidelines or methods
- A summary of results
- All information and data required in the study plan
- A presentation of the results, including calculations and determinations of statistical significance
- An evaluation and discussion of the results and, where appropriate, conclusions
- The location where the study plan, samples of test and reference items, specimens, raw data and the final report are to be stored.

In the event that a published report requires amendment for any reason, the amendment must be done in the form of an addendum, justifying the correction and clearly identifying the area affected. This parallels the principles of correction to data entries and amendment to study plans, that is, formal, justified, signed and dated documentation that does not obscure the original.

3.6 Study Archiving

A major difficulty encountered in the 1970 investigations was the absence of complete records. Whether the records had never been generated, or had been destroyed during normal housekeeping, simply mislaid or were deliberately hidden will never be known. Whatever the reason, significant parts of the data for many studies were not available, and therefore it was not possible for the FDA investigators to fully reconstruct the study events. As the events could not be reconstructed, there was no way of assessing whether or not the events were well controlled and accurately represented in the study reports. Therefore, the GLPs specify that all records supporting the study should be retained in secure archives.

The archive need not resemble a bank vault. GLP does not describe the physical nature of the archive, it simply specifies what is to be achieved. The size of an archive facility is wholly at management discretion, and will depend on the amount and type of material to be retained. The archive may be a building, a series of rooms, a single dedicated room, one or more filing cabinets or a desk drawer. It is the way that such facilities are operated and the assurance they provide that meets GLP standards, not the physical scale.

The archive must be 'secure'. Risks to security range from the accidental, through negligence to malice, and may originate with persons or nature. GLP defines some

DOI: 10.1002/9780470744307.gat049
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

minimum features for security arrangements, but every company must assess the potential risks to its archive, and then incorporate policies, controls, protection and detection to the extent necessary in each individual case.

Company management is responsible for establishing GLP archive arrangements, for appointing a person in charge and for the safekeeping of the materials. This responsibility is critical. The archive must not be open to those that manage the studies or generate the data; this is a necessary security feature since it separates the keeping of the material from those who might be considered to have most interest in interfering with it.

Access to the archive area must be limited to the management-appointed archive staff, and the area must be secured whenever these are not present. Other persons may have legitimate reasons for access, such as maintenance engineers, government inspectors, potential sponsors or QA personnel, but archive staff should control all such visits by remaining present and keeping a record of the event.

The design and positioning of the archive should protect against leakage or other water damage, fire, seismic disturbance, malicious incursion and, in the case of magnetic records, dust and electromagnetic flux. Although many risks may be minimized by design, it will not be possible to eliminate them completely, so it will be necessary to monitor the storage areas. In any case, monitoring can demonstrate the effectiveness of the precautions.

If special storage temperatures are necessary (say for some types of specimens), the operating temperatures of fridges and freezers should be monitored and recorded, just as for any other such equipment in the laboratory areas. Infestation control may also be appropriate.

Although it is not a strict GLP requirement, many GLP-compliant facilities generate backup copies of archived material, and retain them in a separate location. In the case of paper or electronic media, this is particularly easy (in some respects too easy, since a plethora of copies may confuse the identity of the original or erode concern for its integrity). However, such measures can significantly enhance the security of the archived materials.

The named individual in charge of the archive (the 'archivist'), should have at least one named assistant so that the archive is routinely accessible for reference. Archive staff may have other responsibilities, but crucially, must not be involved in any way with the generation of GLP material to be archived.

Just like any other GLP area, the archive must be operated according to SOPs. These SOPs should address all archive procedures, including receipt, storage and eventual disposal of materials, as well as environmental control, staff training and emergency measures.

The whole point of a GLP archive is that the material must be readily available for authorized inspection. This has implications for the organization and indexing of materials whilst in storage. It also requires a formal system, whereby material can be brought out of storage for review, without compromising its integrity. Management is responsible for authorizing any access, which should be seen as a normal aspect of a working archive; technical staff, managers, quality assurance and clerks compiling registration dossiers will all have genuine need to refer to previous records.

GLP does not require that materials be retained forever, so the collection may be reviewed at intervals to allow the removal of unwanted material. Most national GLP regulations state that study material should be retained for a period relating to the notification, submission or registration of the material under test. Some national authorities define exact retention times, such as US EPA and Switzerland (10 years) or Germany (15 years). It can be difficult to establish the point at which material that is not specific to a particular study is no longer required, such as equipment calibration records or staff training records. Many companies retain such items indefinitely.

Even prior to their temporal retention limit, GLP allows disposal of specimens that cannot sustain evaluation, so specimens that are likely to have a limited life in storage may be assessed from time to time and any that have deteriorated beyond use may be removed.

In common with all other areas of a GLP facility, records should be retained for all archive activities, such as movement of records, training and competence reviews of staff and the dates and circumstances of visits by anyone else and the whole operation should be subject to regular review by QA.

3.6.1 Archive Contents

Any item that relates to the conduct of GLP work should be retained. This simple statement belies the variety of material that will encompass not only the study plan, amendments, data (in all its forms), specimens, correspondence and final report of every study, but all supporting material. This will include items such as personnel records, historical SOPs, equipment calibration and maintenance records, environmental controls, performance or validity checks on test systems, test item and test system receipt and distribution information, animal health and husbandry records, reagent preparation logs, quality monitoring records, master schedule of studies, the list is almost endless.

At management discretion, the archive may also retain other records, such as those from non-GLP areas, financial data, business contracts, submission dossiers and so on. However, to avoid compromising the integrity of GLP materials, identical standards of control and archive management must apply to this material as to GLP data.

3.7 GLP Today

The basic requirements of GLP have not changed for decades. However, the adverbial nature of the requirements has allowed their application to study designs not originally envisaged. These encompass the increasing variety of nonanimal, *in vitro* or *ex vivo* alternative toxicology testing strategies without recourse to separate legislation or extended facility accreditation; although OECD has produced a guidance document (OECD, 2004) on the application of GLP principles to *in vitro* studies, the guidance can all be derived from the basic GLP principles. In the same way, GLP has extended successfully into areas such as agricultural field work, determination of physicochemical properties, subatomic spectroscopy analysis, direct capture and reporting with computerized systems and studies with biological test items.

Currently, several government agencies are beginning to take account of risk in their programmes of GLP monitoring, such that facilities with a long history of satisfactory inspection, performing standard, noncritical work may be inspected with less frequency or rigour than those with large volumes of immediately preclinical work. There is a growing body of interpretative advice published by national monitoring authorities (a reflection of the imprecise language of the OECD principles, and unfortunately not always enjoying international harmony in either scope or content). The frequency with which GLP deviations are found remains apparently high, even in facilities categorized as low risk. However, the high incidence of shortcomings generally relates to administrative matters, which in all conscience do not impact directly on the integrity of studies. This is often true even in the case of shortcomings categorized as 'major' deviations by the inspectorate, since even a major deviation (such as a lack of characterization information on the item under test) does not result in a misleading outcome so long as the circumstances are clearly reported.

4 NONREGULATORY TOXICOLOGY

Although there is no legal obligation for quality systems in nonregulatory toxicology, the inclusion of quality-based controls can be of significant benefit. In the early days of GLP, much was made of the cost to industry of implementation, but the passage of time has shown that early detection and resolution of issues can avoid very costly cumulative error. The same is likely to be true in nonregulatory work, whether in research or judicial process. The financial cost of pursuing a line of research arising from a miscalculation in an earlier result, or of a team of coworkers attempting to develop a discovery whilst misunderstanding the original procedure, could be great indeed. The cost of miscarriage of justice arising from erroneous conclusions presented in court could be devastating, not only to those wrongly convicted and their families/employees, but to the reputation of the legal system and the scientific community as a whole, not to mention the effect on society when the guilty are not brought to book. Sadly, science often has a poor reputation with the general population nowadays, possibly because scientific opinion has too small a voice when competing with politicians and the mass media.

For all the above reasons, any aspect of toxicology would be well advised to instigate some form of quality control. If further encouragement is needed, ask any investigator whether they would be confident that they could repeat an observation they made five years ago, and obtain the same result (within experimental error, or course!). Would they stake their career on it? Aren't they, in effect, doing just that anyway? What is it about the human condition, that allows us to repeat a rushed piece of work 'properly' but resists doing it 'properly' in the first place?

The value of quality systems in nonregulatory toxicology is recognized by organizations such as the International Association of Forensic Toxicologists, the British Association of Research Quality Assurance, the American Academy of Forensic Sciences and the European Society for Toxicological and Forensic Chemistry. All of these organizations have produced guidelines or standards to help enhance the status of nonregulatory toxicology—and minimize the occurrence of unreliable data and the bad publicity that inevitably follows. Poor practice will out, eventually, as an American State Patrol toxicology laboratory discovered. A panel of District Court judges ruled in 2008 that the laboratory's alcohol analyses should not be admitted in trials, because they were so unreliable. The problems included selective reporting and rejection of results, mix-ups in sample identity and malfunctioning software. As a result, the judges wrote, there was the possibility that 'the innocent may be wrongly convicted and the guilty may go free'. This related to the determination of a common, small hydrocarbon in body fluids. If this cannot be done reliably, what of more complex techniques such as DNA analysis or screening of athletes for performance-enhancing substances? Errors in forensic toxicology may not directly affect such a potentially worldwide population as inappropriate marketing permits for chemicals, but they do have significant influence on the outcome of judicial process. Any defined quality system will enhance the authority and credibility of results, assisting juries and disciplinary panels with their conclusions and helping assure the population at large that judgements are soundly based.

Much common ground exists between the various statements, policies and codes with respect to scientific quality. For example, the contractual agreement required between funding bodies such as the Biotechnology and Biological Sciences Research Council, Department for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat049

Environment, Rood and Rural Affairs (DEFRA), Food Standards Agency (FSA) and the Natural Environment Research Council and their contractors, (Joint Code of Practice for Research), covers the same major elements as ISO 9000, national accreditation schemes such as United Kingdom Accreditation Service (UKAS) and GLP. Such commonality surely indicates the fundamental nature of the benefit of the component requirements. Detailed mechanisms differ: some schemes accredit specific techniques, others relate to management systems under which a laboratory operates. Some schemes involve regular interlaboratory comparisons of standard samples to assure that test sensitivity is similar (and therefore more likely to be fundamentally accurate); most involve external and internal audit. Documented calibration of measuring instrumentation traceable to national standards is routine, as are documented validation exercises to demonstrate that computerized systems do, in fact, do what the toxicologists require and expect of them.

Take the inevitable bureaucracy out of these systems, and you are left with common-sense, fundamental precautions. Where there is no statutory requirement to implement a formal system, toxicological investigations of any type carry increased credence if they can be associated with a demonstrable quality scheme, however basic. This can give comfort and confidence to governments, the judiciary, toxicological researchers and the public in general.

Quality research—done by knowledgeable people, thought through, with all circumstances clearly documented, all observations accurately recorded and reported in an unbiased manner and double-checked—isn't that a concise summary of the requirements for regulatory toxicology? Toxicologists owe it to themselves, their profession, society and science to do no less.
