Aminoglycoside-induced HC death occurs in a distinct pattern. In the organ of Corti, in line with the pattern of hearing loss, HCs in the basal (high-frequency) coil are affected first, damage spreading progressively apicalwards with time and with increasing dosage. OHCs are more sensitive than IHCs (**Figure 4F, G**). IHCs do not usually appear to die until all the OHCs in their immediate vicinity are lost (**Figure 4E, I, J**). IHCs in mice are particularly resistant to damage. IHCs can persist for months after there has been complete loss of all OHCs (Taylor *et al*., 2008). The reasons for the apparent differential sensitivity between OHCs and IHCs are not yet known, but the delay before IHCs are affected may suggest that their loss is a secondary event that occurs as a consequence of OHC loss, and is unrelated to the initial ototoxic events (Taylor *et al*., 2008). Following death of the IHCs, the spiral ganglion neurons which innervate them begin to die (Hawkins and Johnsson, 1981; Wersäll, 1981). This is probably because survival of the innervation requires neurotrophic factors derived from the IHCs, identified as NT-3 (neurotrophin 3) and BDNF (brain-derived neurotrophic factor) (Ylikoski *et al*., 1993; Ernfors *et al*., 1995), as well as continuing stimulation (normally provided by IHC activity). Perfusion of neurotrophic factors into the cochlea following aminoglycoside administration has been shown to prevent loss of the auditory neurons (Ernfors *et al*., 1996).

The death of each HC is accompanied by expansion of the supporting cells around them to close the lesion and effect tissue repair (Forge, 1985; Raphael and Altschuler, 1991; Li *et al*., 1995; Meiteles and Raphael, 1994). Supporting cells are not usually affected by aminoglycosides (or other ototoxins). Following the initial lesion closure by expansion of the supporting cells (**Figure 4F, G**), reorganization of the sensory epithelium may continue for some time after HC loss, and ultimately the crest of cells that normally constitutes the organ of Corti becomes replaced by an apparently simple cuboidal-like epithelium across the basilar membrane (**Figure 4H, K**). It is not at present clear whether this arises from de-differentiation of those supporting cells that normally surround the HCs in the intact organ of Corti, or their replacement by some other cell type. The pattern of HC loss observed following aminoglycoside exposure—OHC death spreading from base to apex with delayed IHC death—is also seen in many other pathologies in which HC death occurs, including *cis*-DDP ototoxicity (Laurell and Bagger-Sjoback, 1991a; Kaltenbach *et al*., 1997), ageing (Wright *et al*., 1987), as a consequence of the effects of various different genetic mutations that are associated with deafness (Steel and Kros, 2001; Boettger *et al*., 2002; Cohen-Salmon *et al*., 2002; Rozengurt *et al*., 2003) and even with noise, where effects on HCs at a location that relates to the frequency of the damaging sound are accompanied by a base–apex spread along the organ of Corti, of initially OHC death and then of IHC (Wang *et al*., 2002).

In the vestibular system aminoglycoside-induced HC loss is seen initially in the central regions of the epithelia, that is, at the crests of the saddle-shaped cristae and across the 'striola' along the middle of utricular and saccular maculae; HC loss then spreading progressively towards the peripheries (Lindemann, 1969). There is also differential susceptibility among the vestibular organs; in an individual subject, cristae show greater HC loss than the utricle, which in turn shows more extensive damage than the saccule (Wersäll, 1981). This differential susceptibility conforms to a differential uptake of aminoglycoside between the two HC types; immunohistochemistry has shown preferential uptake of gentamicin into the Type 1 HCs (Lyford-Pike *et al*., 2007). The Type 1 HCs predominate on those regions where damage is initiated and are thought to be more susceptible to aminoglycoside-induced damage than the Type 2 vestibular HCs. It is of note that the Type 1 HCs have an exclusively afferent innervation and other similarities to cochlear IHCs, but are the more susceptible of the two vestibular HC types, whereas the more resistant Type 2 HCs have a direct efferent innervation resembling OHCs, the more susceptible HC type in the cochlea. This implies that the HC innervation patterns do not have an influence upon susceptibility of HCs to the toxic effects of aminoglycosides.

Unlike the organ of Corti, where lost HCs are not replaced, there is some evidence for regeneration of HCs in the mammalian utricle (Forge *et al*., 1993; 1998; Lopez *et al*., 1997), but the extent to which this occurs is limited, and only a proportion of the lost HCs may be replaced by new ones (Forge *et al*., 1998). Regeneration of HCs is extensive and can lead to complete recovery of damaged sensory epithelia in birds and other nonmammalian vertebrates (Stone *et al*., 1998; Cotanche, 1999; Taylor and Forge, 2005). The replacement HCs derive from the supporting cell population, which is unaffected by injuries that kill HCs, through initiation of cell division amongst the supporting cells that is stimulated by loss of the HCs (Stone *et al*., 1998; Cotanche, 1999), and/or through direct nonmitotic transdifferentiation, or 'phenotypic conversion' of supporting cells into HCs (Li and Forge, 1997; Taylor and Forge, 2005).

5.3.1.3 Mechanisms of Toxicity

The susceptibility of all HC types in all vertebrate classes emphasizes that HCs are specific targets of the aminoglycosides, and studies using radioactively or fluorescently labelled aminoglycosides administered to animals have shown that the drug is indeed taken up specifically into HCs in the mammalian cochlea (Hiel *et al*., 1992; 1993). The common feature of all HCs is the transduction apparatus at their apical poles (Hudspeth, 1989; Bryant *et al*., 2005). Direct application of aminoglycoside to explant cultures of the organ of Corti from neonatal mice,

in which the transduction mechanism works normally, though the HCs are not fully mature, (Geleoc and Holt, 2003) results in blockage of the transduction channel (Marcotti *et al*., 2005). Blocking of the transduction channels by aminoglycoside has also been observed in the lateral line systems of fish and amphibians *in vivo* (Kroese and van den Bercken, 1982), and in bullfrog vestibular HCs *in vitro* (Kroese *et al*., 1989). Indeed aminoglycosides are one of the few known blockers of the HC transduction channel, the molecular characteristics of which are currently unknown. Further evidence that an interaction of aminoglycoside with the transduction channel is a crucial element in determining both the cellular selectivity of the response and the progression of injury is demonstrated by the resistance to aminoglycosides of HCs in a strain of mutant mouse with a defect in an unconventional myosin, myosin VIIa (Richardson *et al*., 1997). Myosin VIIa localizes to the apical ends of HCs in both the auditory and vestibular organs in all vertebrates (Hasson *et al*., 1997), and the mutant mice show disorganized hair bundles at their apical ends (Self *et al*., 1998). HCs in organotypic cultures of the organ of Corti prepared from homozygous mutant animals were unaffected by exposure to aminoglycoside, and radiolabelled drug did not enter the cells, which remained undamaged. In contrast in cultures prepared from the heterozygous littermates, the drug entered HCs, but not supporting cells, and killed them (Richardson *et al*., 1997). Myosin VIIa has been found to play an important role in the operation of the gating elements, such as the tip-link, that regulate the opening of the transduction channel in response to sound stimulation (Kros *et al*., 2002). In HCs in which myosin VIIa is defective, opening of the transduction channels is impeded, so that the channels are normally closed, and open only with extreme deflections of the hair bundle (the equivalent of very loud sounds). Since the transduction channels are closed in the HCs in these mutant animals, the failure of entry of aminoglycoside suggests that the drug enters the HC via the transduction channel. Studies of the entry of the styryl fluorescent dye FM1-43 into HCs (Gale *et al*., 2001) support this contention. FM1-43 is of similar size to aminoglycoside (molecular weight of FM1-43 is 452, of kanamycin is 484), is of a similar, elongated shape, and like aminoglycosides FM1-43 is a cation. It is taken up specifically into HCs after short exposures of explant cultures and *in vivo* after systemic application (Meyers *et al*., 2003; Taylor *et al*., 2008). It enters through the transduction channel (Gale *et al*., 2001; Meyers *et al*., 2003; Marcotti *et al*., 2005) and it blocks aminoglycoside entry, protecting HCs from the drug-induced damage (Gale *et al*., 2001). Entry of aminoglycoside from endolymph across the HC's apical membrane has also been inferred from the presence of immunolabelled gentamicin in vesicles in the apical cytoplasm of chicken HCs shortly after the end of a course of systemic drug treatment (Hashino *et al*., 1997). Entry via the transduction channels could explain the faster and greater uptake of aminoglycoside into OHCs in the basal cochlear coil in comparison with those at the apex, that has been observed following systemic application of radioactively labelled gentamicin (Hiel *et al*., 1992; 1993). There are differences in the probability of the open state of the transduction channels that match the differential uptake; in OHCs in the basal coil the probability of transduction channel opening is 50%, but the open-state probabilities decrease towards the cochlear apex (Russell and Kossl, 1992). IHC transduction channels have a 5% open-state probability. However, in explant cultures of the early postnatal mouse organ of Corti directly exposed to radioactively labelled gentamicin, radiolabelling, which is confined only to the HCs, is almost as intense in IHCs as it is in OHCs, indicating entry of drug into both HC types; but IHC are not killed by the aminoglycoside when OHC are (Richardson *et al*., 1997). Furthermore, it is not clear that there are differences between vestibular HC types and across the vestibular sensory epithelia in transduction-channel-open probability that match the differential HC loss observed in those organs. Nor is it easy to explain in terms of transduction-channel-open probability the differential vulnerability of HCs along the cochlea in response to nonchemical damaging agents, such as noise and ageing, in a pattern similar to that of aminoglycosides. Thus, while an affinity between aminoglycosides and the HC transduction channel that enables the drug to enter through that channel could account for HC specificity in all vertebrate classes, other, or additional, factors are likely to be important for the toxicity.

A second molecular mechanism proposed to explain the damage to HCs caused by aminoglycosides is a specific, irreversible interaction of the drugs with the cell membrane phospholipid, phosphatidylinositol-4,5-bisphosphate, (PIP_2) (Schacht, 1986). PIP_2 is located on the cytosolic side of the plasma membrane and, thus, would be accessible only after entry into the cell. The inner ear, neural tissue and the kidney (the tissues susceptible to aminoglycoside toxicity) show a much more active metabolism of phosphoinositides than do other tissues such as the liver or lung, and it has been demonstrated *in vivo* that neomycin inhibits the turnover of phosphoinositides in both the kidney and the inner ear. Furthermore the interactions of the aminoglycosides with lipid bilayers containing PIP_2 produce alterations in bilayer conformation that are unique in comparison with those that occur with other anionic phospholipids, indicating a specific interaction (Forge *et al*., 1989). In addition, changes in the surface pressure of monomolecular films formed of different phospholipids on addition of aminoglycoside have indicated not only a specific binding of the drug to PIP_2, but that the strength of binding of different aminoglycosides matches the rank order of ototoxic potencies (Schacht and Weiner, 1986). That is, neomycin induces

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the greatest change in surface pressure, indicating the strongest interaction, with other aminoglycosides inducing relatively lower changes in parallel with their relative cochleotoxic potencies. Aminoglycosides such as neamine and spectinomycin which are not ototoxic (nor nephrotoxic) and do not cause injury to HCs (Kotecha and Richardson, 1994) do not appear to interact with PIP_2 as assessed in monomolecular films (Schacht and Weiner, 1986).

However, binding of aminoglycoside to PIP_2 does not of itself explain how the HC is killed. It has been shown that following systemic administration, gentamicin can remain inside HCs for as long as 11 months without injury ensuing (Dulon *et al*., 1993). Isolation of the undamaged organ of Corti and its maintenance in short-term culture has revealed that differential sensitivity to damage of HCs along the organ of Corti is inherent in the tissue even in the absence of any specific extraneous potentially damaging agent (Sha *et al*., 2001a). Upon isolation of strips of organ of Corti, OHCs from the basal coil die within two to three hours in maintenance medium, but those at the apex can survive for more than six hours. IHCs survive for more prolonged periods, and supporting cells for up to 24 hours. The survival of basal coil OHCs can, however, be enhanced by addition to the maintenance medium of free radical scavengers, including *N*-acetylcysteine, salicylate and glutathione (Sha *et al*., 2001a). This supports the hypothesis that one trigger for HC death is the production of excess free radicals, and indicates that basal coil HCs are more susceptible to such damage than those at the apex. In line with this notion, the levels of glutathione, one of the natural cellular free radical scavenger systems, are higher in HCs at the cochlear apex than in those at the base (Sha *et al*., 2001a). Previous work (Hoffman *et al*., 1988) had shown that depletion of glutathione by administration of buthionine sulfoxamine rendered the cochlea very sensitive to ototoxic damage, and the sulfhydryl-containing radioprotectant, WR 2721, provided some protection against kanamycin-induced ototoxicity in the guinea pig (Pierson and Moller, 1981). In agreement with these earlier suggestions, coadministration of glutathione with aminoglycoside attenuates both the histopathological and functional consequences of aminoglycoside injury in guinea pigs (Garetz *et al*., 1994), though this is most effective in nutritionally deficient animals (Lautermann *et al*., 1997). Aminoglycoside-induced HC death is also markedly reduced in transgenic mice that overexpress superoxide dismutase 1, one of the enzymes involved in detoxifying free radicals in cells (Sha *et al*., 2001b). The release of free radicals in the inner ear coincident with aminoglycoside treatment has been observed in both chick HCs after gentamicin exposure (Hirose *et al*., 1997) and the mammalian organ of Corti after kanamycin administration (Takayama *et al*., 1997), and the products of free radical damage can be localized by immunohistochemistry to HCs during the early stages of the progression of injury following chronic kanamycin treatment in mice (Jiang *et al*., 2005). These observations provide further support for a role of free radicals in the ototoxic action of aminoglycoside.

Aminoglycosides can chelate iron (Fe^{3+}) (Priuska and Schacht, 1995; Priuska *et al*., 1998), the iron–aminoglycoside complex becoming a source of free radicals, and the iron–aminoglycoside complex may be an initiator of the HC death (see Forge and Schacht, 2000 for review). In the presence of an electron donor, Fe^{3+} can be converted to Fe^{2+}, with subsequent generation of the hydroxyl radical ($OH^{\bullet}$), regeneration of Fe^{3+} and then successive cycling through the same pathway generating further toxic $OH^{\bullet}$ radicals (the Fenton reaction; Evans and Halliwell, 1999). Arachidonic acid has been identified as a preferred electron donor (Priuska *et al*., 1998), and arachidonic acid is one of the fatty acids of which PIP_2 is composed. Therefore, the strong binding that occurs between aminoglycosides and PIP_2 may be a significant factor in the generation of the ototoxic response as the drug–phosopholipid interaction would bring the aminoglycoside in close proximity with arachidonic acid (Sha and Schacht, 1997). Supplemental iron has been shown to enhance aminoglyocoside ototoxicity *in vivo* (Conlon and Smith, 1998). More significantly, coadministration of iron chelators with aminoglycoside can completely prevent aminoglycoside-induced ototoxicity *in vivo* in guinea pigs, preserving both the HCs and auditory function in the cochlea (Song and Schacht, 1996; Song *et al*., 1997) and HCs in the vestibular organs (Song *et al*., 1998; Forge and Li, 2000). Deferoxamine (DFO) provides significant attenuation of the ototoxicity in vestibular organs (Forge and Li, 2000), but complete protection of cochlear HCs is afforded by 2,3-dihyroxybenzoate in combination with mannitol (Song *et al*., 1997; 1998). Interestingly, salicylate (aspirin), which was shown from *in vitro* experiments to enhance survival of HCs in short-term culture (Sha *et al*., 2001a), is a monohydroxybenzoate. It has both iron-chelating and free radical-scavenging properties and, as discussed in the preceding section, is able to enter cochlear perilymph rapidly and thus, crucially, to be available in the right place potentially to be effective in protecting HCs. It has been shown to ameliorate HC loss and hearing impairment when coadministered with aminoglycoside in animal models (Sha and Schacht, 1999). A preliminary clinical trial undertaken in China has now proven the principle of using salicylate as a therapeutic intervention to protect against aminoglycoside ototoxicity in clinical conditions (Sha *et al*., 2006). In a group of about 400 patients prescribed daily gentamicin for two weeks for a variety of ailments, the coadministration of three aspirin tablets three times a day (a total dose of salicylate below that which induces the temporary hearing impairment discussed in the previous section)

reduced the incidence of a clinically significant hearing loss from 13% in the group of patients who received only gentamicin to 3% in those who also received the aspirin.

Free radicals are one initiator of programmed cell death leading to apoptosis (Hockenberry *et al*., 1993; Evans and Halliwell, 1999). There is considerable evidence that aminoglycosides cause death of HCs by inducing apoptosis (Forge, 1985; Forge and Li, 2000; Forge and Schacht, 2000; Jiang *et al*., 2006). The morphological characteristics of cells undergoing apoptosis have been observed in cochlear HCs of guinea pigs affected by gentamicin (Forge, 1985) and mice affected by kanamycin (Jiang *et al*., 2006; Taylor *et al*., 2008), and in vestibular HCs following systemic gentamicin treatment (Li *et al*., 1995). In explant cultures, both of the mammalian (Forge and Li, 2000) and avian (Matsui *et al*., 2002; 2003) utricular maculae, incubation in pan-caspase inhibitors prevented gentamicin-induced HC death. Inhibitors of the *c-Jun-N-terminal kinase* (JNK) cell stress pathway also attenuated cochlear HC loss not only in explant cultures exposed to gentamicin (Pirvola *et al*., 2000), but also *in vivo* following continuous delivery of the inhibitor from osmotic pumps to the perilymphatic space in neomycin-treated animals (Wang *et al*., 2003). These results implicate the classical caspase-dependent apoptotic pathway triggered by intracellular stress factors that initiate the intrinsic cell death pathway in the HC death (Forge and Van De Water, 2008). Detection of the activation of caspase-3, the principle effector of apoptosis, in aminoglycoside-damaged avian cochlear and vestibular HCs in explant culture, and of the activated initiator capsase-9 in mammalian and avian vestibular organs, supports that conclusion (Matsui *et al*., 2003; Cunningham *et al*., 2002). Activated caspase-3 has also been identified in the kanamycin-damaged organ of Corti in conditions that result in rapid loss of all OHC (Taylor *et al*., 2008), but other work has indicated that the cell death pathways in damaged HCs following chronic treatment protocols which resemble the more usual clinical conditions of aminoglycoside use may be more variable (Jiang *et al*., 2006). There was no indication of activation of caspase-3 but evidence of the involvement of non-caspase-dependent apoptotic pathways. This increasingly detailed understanding of the programmed cell death pathways that are activated, and how they are triggered, is leading to investigation of a variety of procedures for preventing aminoglycoside-induced damage (Rybak and Whitworth, 2005). Such therapies may have wider value since apoptosis triggered in response to excess free radical production is now thought to be a common mechanism of HC death in a variety of conditions (Rybak and Whitworth, 2005; Lynch and Kil, 2005).

5.3.1.4 *Effects of Aminoglycosides on the Stria Vascularis*

Although HCs are the primary site of aminoglycoside action, there is evidence that the stria vascularis also is affected in the initial stages of the response of the cochlea to these drugs. In experimental studies, in animals immediately following the end of a course of aminoglycoside treatment alterations to the stria can be seen at the same time as the earliest effects in the organ of Corti are apparent (Forge and Fradis, 1985), and a decrease in the volume of the stria vascularis in human temporal bones obtained within two weeks of aminoglycoside treatment has been observed (Kusunoki *et al*., 2004). However, as both the organ of Corti and stria show drug-induced abnormalities at these earliest stages, it is not possible to determine the relative chronology of these events, or whether effects in the stria and the organ of Corti are related or occur independently. The lateral wall of the cochlea has been shown to contain a high level of PIP_2, higher in fact than that of the organ of Corti (Schacht, 1986) and, thus, it is possible that the stria may be directly susceptible to the drugs if, as discussed above, this phospholipid serves as the target for aminoglycoside action. There is no direct evidence for an interaction between aminoglycosides and strial tissues, but the use of Texas Red-tagged gentamicin has shown that the aminoglycoside enters strial marginal cells as rapidly as it does into HCs (Dai and Steyger, 2008).

The observed decrease in thickness of the stria is due to an atrophy almost exclusively of marginal cells (Forge *et al*., 1987). Some cells are lost by a process which shows morphological attributes of apoptosis, but the majority of marginal cells remain, but with much reduced volume. Such alteration might be expected to affect EP and the ionic profile of endolymph, but EP appears to be maintained at close to normal levels for up to 4 weeks after the end of aminoglycoside treatment, and is only slightly reduced 12 weeks after treatment when there is significant decrease in strial thickness (Hellier *et al*., 2002). Thus the functional consequences of the effects of aminoglycoside ototoxicity on the stria are not clear. Obviously, the reorganization in the organ of Corti resulting from the loss of HCs and their replacement by supporting cells that occurs following aminoglycoside treatment will have profound effects on cochlear physiology. This might be expected to influence the activity of the stria, but as yet there is no indication of whether and how there might be an inter-relationship between effects in the stria and in the organ of Corti.

Interestingly the changes to the stria and a coincident lack of effect on EP that occur with aminoglycosides are similar to those seen with ageing in a gerbil model (Schulte and Schmeidt, 1992). Here there is significant thinning of the stria, but EP is little affected until the stria is less than one-third its normal volume, when there is a catastrophic loss of EP. These results might suggest that there is significant redundancy in the stria; EP and

organ of Corti activity can be maintained even when there has been considerable strial injury. Thus, it may be that the stria can sustain injury for some time without a noticeable effect on auditory function, but in this 'compromised' state it might be less able to resist further insults. Consequently a sudden loss of auditory function might ensue in conditions which would otherwise not be expected to cause hearing loss.

5.3.2 cis-Platinum

cis-Platinum (*cis*-DDP), is used to treat various tumours of soft tissue. Like the aminoglycosides, it is nephrotoxic as well as ototoxic (reviewed in Rybak *et al*., 2007). Some audiometric studies have reported that 75–100% of patients suffer some degree of hearing impairment. *cis*-DDP induces a progressive loss of HCs, the extent of which correlates with the dose of drug administered (Hoeve *et al*., 1988). This occurs following repeated injections of relatively low drug doses (1 mg kg^{-1} daily) administered by intramuscular, intraperitoneal or subcutaneous routes, and after a single, large intravenous dose (10–12 mg kg^{-1}) (Laurell and Engstrom, 1989; Laurell and Bagger-Sjoback, 1991a; Laurell and Bagger-Sjoback, 1991b). The pattern of HC damage in the cochlea also resembles that of the aminoglycosides; the first (innermost) row of OHCs is the first to show damage, followed by the second and third rows, and HCs in the basal coil of the cochlea are preferentially affected with damage spreading progressively apicalwards (Laurell and Bagger-Sjoback, 1991a; Laurell and Bagger-Sjoback, 1991b). As with aminoglycosides, the IHCs appear to be relatively resistant to damage following *cis*-DDP administration (Kaltenbach *et al*., 1997). These histopathological findings correlate with assessment of auditory function in both animals and patients, which show an initial high-frequency hearing loss measured by ABR, and suppression of OAEs indicating an effect on OHCs (Sie and Norton, 1997; Allen *et al*., 1998). However, the amplitudes of the CAP and ABR are reduced to a greater extent than is CM, which has revealed that *cis*-DDP may have direct effects upon the spiral ganglion cells themselves (van Ruijven *et al*., 2005), and effects in the stria vascularis are also apparent. Differing dosing regimes may influence which tissue is most affected (Rybak *et al*., 2007). *cis*-DDP also causes HC loss from the vestibular organs in a manner similar to that resulting from aminoglycosides (Wright and Schaefer, 1982; Cunningham, 2006).

There have been very few studies of the pharmacokinetics of *cis*-DDP in the inner ear or of the mechanisms by which it is taken up into cells. It has been reported (McAlpine and Johnstone, 1990) that a rapid deterioration in the auditory nerve response threshold is produced when *cis*-DDP is present in the scala media at concentrations of about 5 μM, but no effect is apparent with perilymphatic perfusion at drug concentrations of less than 3 mM. This suggests that one possible site of the drug action is at the apical end of the HCs. *cis*-DDP has been shown to be able to block transduction currents in isolated HCs from chicken (Kimitsuki *et al*., 1993), and from the characteristics of the response to a single systemic administration in guinea pigs a similar conclusion has been drawn. Thus, it may be that like aminoglycosides an affinity of *cis*-DDP for the HC transduction channel may underlie specific action upon HCs, but there is no conclusive evidence for this.

Nevertheless, it is now clear that the cytotoxicity of *cis*-DDP upon HCs results from the action of free radicals (Rybak *et al*., 2007). *cis*-DDP ototoxicity correlates with a decrease in cochlear glutathione and significant decrease in the activity of glutathione peroxidase, glutathione reductase and superoxide dismutase in cochlear tissues (Ravi *et al*., 1995). Why this occurs is not altogether clear, though it may be due to direct binding of *cis*-DDP to enzymes through the sulfhydryl groups, or *cis*-DDP-dependent depletion of essential cofactors (Rybak *et al*., 2007). This interference with antioxidant systems in the cochlea may lead to accumulation of free radicals and the consequent death of the HCs. Ototoxic doses of *cis*-DDP also lead to the up-regulation of NOX3, a particular isoform of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase that is normally highly expressed in the inner ear. The activity of this enzyme naturally produces reactive oxygen species (ROS), but upon exposure to *cis*-DDP, significant enhancement of superoxide was observed and this has been shown to occur in cochlear tissue (Mukherjea *et al*., 2006). The formation of hydrogen peroxide (H_2O_2) from superoxide radicals has been observed in cochlear tissue (Dehne *et al*., 2001), and H_2O_2 can be converted to $OH^{\bullet}$, which reacts with fatty acids to form 4-hydroxynonenal (Evans and Halliwell, 1999). Superoxide also reacts with nitric oxide to form peroxynitrite, which upon reaction with proteins forms nitrotyrosine (Evans and Halliwell, 1999). Immunohistochemistry has identified 4-hydoxynonenal, but not nitrotyrosine in HCs of *cis*-DDP-treated animals (Lee *et al*., 2004), indicating that generation of $OH^{\bullet}$ may have a critical role in *cis*-DDP-induced death of HCs.

In support of the conclusion that generation of excessive free radicals follows from the effects of *cis*-DDP in the cochlea, agents such as (+)-methionine and 4-methylbenzoic acid, which enable maintenance of glutathione levels or preserve the activity of associated enzyme systems, are highly effective in preventing the ototoxic effects of *cis*-DDP *in vivo* (Campbell *et al*., 1996; Rybak *et al*., 1995). Furthermore, these agents also prevent the HC loss that normally follows from direct exposure to the drug in organotypic cultures of neonatal organs of Corti (Kopke *et al*., 1997). This organotypic culture system also proved of value to screen a range of antioxidant molecules to identify those that are effective in preventing *cis*-DDP ototoxicity. More detailed discussions of agents that are being investigated for their

value on preventing *cis*-DDP-induced HC death can be found elsewhere (Rybak and Whitworth, 2005; Rybak *et al*., 2007).

5.3.2.1 Effects of cis-Platinum on the Stria Vascularis

cis-DDP causes a decline in EP, indicating an action in the stria, and has been reported to cause strial atrophy, but the effects appear to vary depending upon the dose of drug administered (Laurell and Engstrom, 1989; Klis *et al*., 2000). Following a single, large intravenous dose ($10-12.5\,mg\ kg^{-1}$), EP begins to decline within one day and becomes permanently lost in parallel with the loss of HCs that also ensues. However, with lower doses of the drug given repeatedly (e.g. daily injections of about $2\,mg\ kg^{-1}$ for 10–14 days) by subcutaneous or intramuscular routes, EP does not show any immediate alteration. Ultimately, strial atrophy develops several days or weeks after the end of the chronic treatment. The contrasting responses to the different dosing regimens suggest that effects in the stria and in the organ of Corti are independent of each other and that the stria may be less susceptible to damage from *cis*-DDP than are the OHCs. Immunolabelling for platinated DNA, that results from interaction of *cis*-DDP with DNA, in cochleae from animals treated with ototoxic levels of the drug, has shown positive labelling in the marginal cells in the stria vascularis and in some fibrocytes of the spiral ligament (van Ruijven *et al*., 2005). The identification of TUNEL (terminal-dUTP-nicek end labelling)-positive nuclei (Alam *et al*., 2000) and of activated caspase-3 (Watanabe *et al*., 2003) in marginal cells indicates that *cis*-DDP triggers apoptosis in these cells. The TUNEL-positive cells were present in all three turns of the cochlea in *cis*-DDP treated animals, even when the HC damage was confined to the basal coil. This again suggests the stria vascularis as a separate target of action from the organ of Corti. Free radical damage is the likely cause of cell death in the stria vascularis, but unlike the organ of Corti, there is some evidence that nitrotyrosine as well as 4-hydoxynonenal are generated during *cis*-DDP intoxication of the stria, potentially pointing to some difference in the toxic action in the two tissues. Apoptosis is also evident amongst spiral ligament fibrocytes in cell culture when exposed to *cis*-DDP (Liang *et al*., 2005). This was shown to be a consequence of block of the large conductance potassium (BK) channels in those cells by the drug. However, whether this occurs *in vivo* has not been verified.

5.3.2.2 Effects upon the Spiral Ganglion Neurons

Electrophysiological assessment of sound-evoked responses (CM and CAP) following *cis*-DDP administration has shown that there can be large elevations of CAP thresholds concomitant with relatively small elevations in CM threshold (van Ruijven *et al*., 2004). Since IHCs appear to be intact, these discrepancies suggest an effect at the level of the auditory nerve. Detachment of the myelin sheaths from Type 1 spiral ganglion cells (those that innervate IHCs) has been observed and appears to progressively increase in extent in parallel with loss of OHCs. This suggests that the injuries to the HCs and to spiral ganglion cells are separate phenomena.

5.3.3 Trimethyltin (TMT)

TMT is quite extensively used in a number of industries and is a known neurotoxic agent, but it has been shown to have direct ototoxic effects at doses far lower than those which are neurotoxic (Fechter *et al*., 1986; 1992). Studies in rats and guinea pigs (Crofton *et al*., 1990; Clerici *et al*., 1991; Hoeffding and Fechter, 1991) have shown that it produces effects in the cochlea generally similar to the 'classical' pattern as identified with aminoglycosides and *cis*-DDP; that is, hearing loss beginning at high frequencies which correlates with a loss of OHCs in the basal coil and spreading towards lower frequencies with time.

However, unlike the drugs, TMT rapidly produces pronounced effects after a single intraperitoneal injection. A profound decrease in CAP across all frequencies tested occurs within 30 minutes of injection, and depression of CM, indicative of effects at the OHCs, occurs within 6 hours (Fechter *et al*., 1992). The CAP recovers across much of the lower and middle frequency range with time (Hoeffding and Fechter, 1991), but high-frequency hearing loss persists and OHCs in the basal coil die. These observations indicate that TMT rapidly enters perilymph, gaining access to the HCs and their innervation, and that it acts at the perilymphatic side of the organ of Corti. They also suggest that TMT has two separate sites of action; first, an acute, reversible effect on afferent neurotransmission at the IHCs, noted from the effect on CAP, along the entire cochlea; second, an ultimately fatal effect on OHCs.

That TMT has direct effects on OHCs has been demonstrated in studies with isolated cells (Clerici *et al*., 1993), studies which provide a good illustration of how a direct interaction of a putative ototoxin with a presumed cochlear target can be performed relatively quickly. At concentrations between $30\,\mu M$ and $1\,mM$, TMT caused a dose-dependent shortening of the HCs that was not reversed during a 30 minute TMT-free rinse. Such an effect *in vivo* would result in changes in the micromechanical responses of the organ of Corti to sound and a decrease in auditory sensitivity. TMT also disrupted the lateral plasma membrane of many OHCs. Subsequent studies have shown that incubation of isolated OHCs with TMT leads to release of Ca^{2+} from intracellular stores (Liu and Fechter, 1996), although whether this is a result of direct interference of TMT with calcium

sequestration, or an indirect effect deriving from more generalized damage, is not clear.

5.3.3.1 Effects of TMT on the Stria Vascularis

Following TMT administration, the stria vascularis becomes reduced in thickness, strial capillary diameter increases but the density of radiating arterioles and collecting venules decreases (Fechter and Carlisle, 1990). These changes, observed six weeks after TMT treatment, are most marked in the middle and apical cochlear turns, whereas OHC loss at this time is most marked in the basal coil. It has therefore been suggested that the effects in the stria are separate from those in the organ of Corti, although EP has not been measured during the acute phase following TMT administration. TMT is thought to uncouple oxidative phosphorylation. Since the strial activity is dependent upon a high level of oxidative metabolism, these effects on the stria may be a consequence of this activity (Fechter and Carlisle, 1990).

5.3.4 Organic Solvents

Exposure to high concentrations of organic solvents induces acute, reversible narcosis and neurotoxicity, but the possibility of ototoxic damage was initially recognized from the unusally high number of workers in the chemical industry who showed a hearing loss, and from case reports of hearing deficits in solvent abusers (Morata *et al*., 1994). The effects of solvents may be exacerbated by concurrent exposure to high noise levels, or the converse; noise-induced hearing loss may become more pronounced with concomitant exposure to certain solvents, thus presenting a significant occupational hazard (Morata and Lemasters, 1995; Morata, 1998). Vestibular dysfunction may also follow exposure to organic solvents (Morata *et al*., 1995) but there is evidence that this results from specific effects on vestibulo-oculomotor pathways in the vestibulocerebellum rather than from effects in the inner ear (Morata *et al*., 1995). This would be classified as neurotoxicity rather than ototoxicity according to the definitions used in this chapter.

A number of different aromatic solvents have been implicated in ototoxicity (Morata *et al*., 1994), and in a comparative study of 21 different solvents, conducted in rats, 8 were identified as ototoxic: toluene, *p*-xylene, ethylbenzene, *n*-propyl benzene, styrene, α-methylstyrene, *trans*-β-methylstyrene and allylbenzene (Gagnaire and Langlais, 2005). Trichloro ethylene has also been reported to be ototoxic (Crofton *et al*., 1994; Fechter *et al*., 1998). The features of the ototoxicity caused by all of these agents are similar and are exemplified by the effects of toluene. Specific cochleotoxic effects of toluene were first observed in studies in rats exposed by inhalation (Pryor *et al*., 1984). ABR and behavioural audiometry revealed auditory deficits after repeated exposure to high doses for periods of 2–16 weeks. Similar results were subsequently obtained after subcutaneous administration. Concomitant with the the occurrence of permanent hearing loss, OHCs are lost (Pryor *et al*., 1984; Campo *et al*., 1997). Suppression of OAEs by toluene confirms the OHCs as a site of injury *in vivo* (Johnson and Canlon, 1994a). However, unlike the majority of ototoxins discussed above, the characteristic features of damage caused by toluene are: (i) it is the mid-frequency ranges of hearing that are affected rather than the high frequencies (Johnson and Canlon, 1994a; Crofton *et al*., 1994), which coincides with HC loss in the middle and apical turns of the organ of Corti (Johnson and Canlon, 1994b; Campo *et al*., 1997); and (ii) damage spreads from the third (outermost) row of OHCs inwards to involve subsequently the second and maybe the first row of OHCs, the reverse of the pattern of damage seen with aminoglycosides (although, as with the aminoglycosides, the IHCs are spared) (Campo *et al*., 1997). Additionally, the supporting cells, especially the third (outermost) row of Deiters' cells, are affected (Campo *et al*., 1997). These features are characteristic of all the solvents implicated in ototoxicity (Crofton *et al*., 1994; Fechter *et al*., 1998; Gagnaire and Langlais, 2005; Campo and Maguin, 2007). The cell bodies of the afferent neurons may also be a target of trichloroethylene (Fechter *et al*., 1998). However, there are species differences in ototoxic susceptibility to solvents. While rats have proved to be sensitive, organic solvents do not cause damage in the inner ears of guinea pigs (Campo and Lataye, 1993; Fechter, 1993; Lataye *et al*., 2003) or chinchillas (Davis *et al*., 2002). This obviously raises questions about the use of particular species of animals as models for the likely conditions in humans. However, it has been argued that the way solvents are distributed and metabolized in rats is similar to the human and thus that these animals are an appropriate model (Campo and Maguin, 2007).

Since organic solvents are minimally water soluble, their distribution in the inner ear is unlikely to be determined by entry into the fluid spaces. It is their distribution in the tissue that is significant. The pattern of damage across the organ of Corti, from outside to in, has suggested that the solvents reach the inner ear from the vasculature of the stria vascularis or the spiral prominence region just below it and then pass through the tissues to the organ of Corti (Campo *et al*., 2001; Campo and Maguin, 2007). The cuboidal cells of the outer sulcus, the epithelial cells that connect the epithelia of the lateral wall to the organ of Corti along the basilar membrane (**Figure 1**) may be a major transport route (Campo *et al*., 2001). Upon reaching the organ of Corti, the supporting cells of the organ of Corti, the Hensen's cells that form the outer ridge of the sensory epithelium and the Deiters' cells that surround the HCs, may then become injured. Deiters' cells, in particular those in the outermost row,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

have been reported to be the most vulnerable cells in the organ of Corti following styrene administration (Chen *et al*., 2007a). The supporting cells are involved in the reuptake of K^+ from around the HCs, and damage to these cells may therefore result in excessive K^+ levels around the OHC that would lead to their death. The effects of the solvents may be upon the membranes of the supporting cells and of the HCs themselves. Loss of membrane integrity and cell swelling, perhaps as a consequence of membrane damage, have been described as early events in the progression of damage in the organ of Corti, and it has been contended that the principle mode of cell death in the organ of Corti is necrosis (Campo and Maguin, 2007). However, the death of Deiters' cells that occurs following styrene administration was reported to be apoptotic and to be triggered through both the intrinsic intracellular stress pathway as well as through the cell death receptor pathway (Chen *et al*., 2007a).

However, why damage is initiated in the middle-frequency region of the cochlea is not clear. In this regard it is perhaps of note that the stria vascularis in the middle and apical cochlear turns is affected by TMT (Fechter and Carlisle, 1990), perhaps indicating some characteristic of the vascular pathways and blood flow that may influence solvent distribution.

5.3.5 Other Ototoxic Agents

Good evidence for the ototoxicity of many of the other drugs listed in **Table 1** is relatively sparse. Vancomycin has been reported to cause transient hearing loss and/or tinnitus, but many of these clinical reports derive from cases in which it has been used in combination with other potentially ototoxic drugs. The few experimental studies which have been performed suggest no loss of HCs or permanent hearing impairment from systemic administration of polypeptide antibiotics even at very high doses (Brummett, 1993). Viomycin has been reported to be predominantly vestibulotoxic following chronic treatment regimes (Daly and Cohen, 1965; Nakayama *et al*., 1991), and animal studies have confirmed that, after repeated systemic injections of relatively high doses, viomycin causes HC death in the vestibular sensory organs in a pattern similar to that seen with aminoglycosides (Kanda and Igarashi, 1969). Chloramphenicol has been shown to cause irreversible hearing loss following infusion into the middle ear cavity in animals (Morizono and Johnstone, 1975), presumably gaining access to the perilymph following uptake across the round window membrane, but clinical reports of hearing loss following use of chloramphenicol are rare. Polymyxin B, when perfused through the perilymphatic spaces, caused an almost immediate decline in CM followed shortly after by a decline in EP, suggesting separate effects on both the organ of Corti and the stria vascularis (Komiya and Tachibana, 1990). However, the rarity of clinical reports in which an ototoxic effect can be attributed directly to polymyxin B suggests the use of this antibiotic does not present a significant risk to the inner ear. Desferrioxamine (deferoxamine mesylate; DFO) binds iron and is used in patients with β-thalassaemia to remove excess iron from the serum. In support of iron chelation as a means to ameliorate aminoglycoside toxicity, in cultured explants of inner ear sensory epithelia, DFO attenuates aminoglycoside-induced HC loss (Forge and Li, 2000). However, repeated high-dose systemic administration of DFO to patients has been reported to cause high-frequency hearing loss in about 20–40% of those receiving long-term therapy (Olivieri *et al*., 1986; Chiodo *et al*., 1997; Karimi *et al*., 2002). In experimental studies in birds, high-dose chronic treatment with DFO produced HC loss in the high-frequency region of the auditory organ in a pattern similar to that caused by gentamicin (Ryals *et al*., 1997), suggesting DFO may kill HCs in a pattern similar to that caused by aminoglycosides. On the other hand, other clinical studies failed to identify a direct ototoxic effect of DFO (Masala *et al*., 1988; Cohen *et al*., 1990), and experimental studies with a mammalian model (chinchilla) could find no effects on cochlear physiology following long-term systemic treatment (Shirane and Harrison, 1987). The reasons for these apparent discrepancies have not been resolved. Differences between experimental models may derive from the differences in susceptibility between species, known to be the case for aminoglycosides (Forge and Schacht, 2000), and differing treatment regimes and/or patient groups may account for differences in clinical reports (Porter *et al*., 1989; Karimi *et al*., 2002).

The reports of ototoxicity following the use of other agents listed in **Table 1** are often anecdotal, and there are no rigorous, well-controlled clinical studies or experimental studies in animal models to confirm and define the ototoxic effects.

5.3.6 Ototoxic Interactions

Both epidemiological studies of the incidence of hearing loss in man and experimental studies in animals have indicated that noise exposure in conjunction with an ototoxic agent may cause more extensive damage than with either agent alone. This is true for noise combined not only with organic solvents (Morata *et al*., 1994; Morata, 1998) as pointed out above, but also noise and aminoglycosides (Brummett and Fox, 1992). Indeed, exposures under conditions in which neither noise nor the aminoglycoside alone would be expected to cause damage can result in marked auditory impairment and HC loss when the two agents are presented together. It has been observed that animals reared in a sound-attenuated room do not take up gentamicin as extensively as animals raised in the environment of a normal animal facility (Hayashida *et al*., 1989). This could result from increased uptake through the transduction channel; in the presence

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat066
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of sound stimulation, transduction channels will be in the open state more frequently, thereby enabling increased entry of the aminoglycoside than would be the case in a quiet environment. With increased sound exposure this effect will be enhanced. Thus, with exposure to noise, aminoglycoside uptake to a 'critical' level necessary to cause HC death would be reached more quickly. High sound pressure levels also lead to the generation of a variety of free radical species (Yamashita *et al*., 2004; Henderson *et al*., 1999). In combination with those produced by the interaction of aminoglycoside with cochlear tissues, levels of free radicals exceeding those with which the natural free radical scavenger systems can normally deal may be achieved more quickly than when either agent is presented alone. However, there have been no systematic studies of the mechanisms by which these combined exposures exert their synergistic effects.

Clinical experience and animal studies have also shown that coadministration of a single dose of loop diuretic with a single systemic administration of aminoglycoside, neither of which alone would cause HC loss, produces significant cochlear damage (Brummett, 1981a). All aminoglycoside antibiotics have been found to interact with the loop diuretics (Brummett, 1981a), as has *cis*-platinum (Brummett, 1981b). Administration of an intravenous or intraperitoneal dose of ethacrynic acid, frusemide or bumetanide shortly before or shortly after a single, nonototoxic dose of kanamycin rapidly produces depression of cochlear function which is permanent and associated with extensive HC destruction in guinea pigs or mice (West *et al*., 1973; Brummett *et al*., 1975; Prieve and Yanz, 1984). In mice, subcutaneous injection of kanamycin followed after about 40 minutes (the time of peak plasma levels of the kanamycin after subcutaneous injection (Wu *et al*., 2001)) with a single intraperitoneal injection of bumetanide causes almost complete loss of all OHC within 48 hours of the injections (Taylor *et al*., 2008). The stria vascularis is also affected, becoming progressively thinner through loss of marginal cells. This protocol has provided a model for examining cochlear pathologies in mice, which are particularly resistant to the effects of many agents that cause cochlear damage. The effects of the interaction are generally confined to the cochlea; no significant loss of HCs is apparent in the vestibular system which appears to remain unaffected even at prolonged periods of time after all OHC have been lost from the organ of Corti (McFadden *et al*., 2002; Taylor *et al*., 2008).

Ethacrynic acid markedly increases the penetration of aminoglycosides into endolymph (Tran Ba Huy *et al*., 1983a) and enhances uptake of gentamicin into cochlear HCs (Dai and Steyger, 2008). Bumetanide also enhances the uptake of FM1-43 into cochlear HCs (Taylor *et al*., 2008). The potentiation of cochleotoxicity following systemic administration of both agents therefore likely arises because the diuretic enhances uptake of the aminoglycoside from the systemic circulation into endolymph. It is perhaps noteworthy that the interaction is only manifest when the time between administration of the two agents is relatively short, that is, the diuretic is administered no more than one hour before or two hours after the aminoglycoside (Brummett, 1981a) and that the vestibular system is not affected following the combined administration of single doses of these drugs. The time scale covers the time over which EP is significantly reduced by the diuretic. The reduction in EP to negative values from the normally high positive potential may encourage entry of the cationic aminoglycoside (and FM1-43, or potentially *cis*-DDP) into endolymph. Since there is no equivalent of EP in the vestibular system and the diuretic does not cause a reduction of the positive diffusion potential of the vestibular endolymph, enhancement of aminoglycoside uptake into vestibular HCs would not occur. In line with the absence of HC loss in the vestibular system with combined diuretic–aminoglycoside treatment, FM1-43 uptake into vestibular HCs is not enhanced by coadministration of diuretic (Taylor *et al*., 2008). However, the combination may have also have effects additional to those of either drug alone. Mulheran and Harpur (1998) found that adminstration of a diuretic–aminoglycoside combination quite rapidly caused a significant increase in the CAP threshold without there being adverse effects on either EP or CM. This may suggest that the primary site of action of the two drugs in combination is on the inner HC and/or the afferent synapse.

5.4 Closing Considerations

The inner ear is histologically complex, with a variety of different tissue types serving a diverse range of activities necessary to maintain the optimal physiological environment for detection and transduction of sensory information. All of these are potential targets of ototoxic agents. It should be noted that at the threshold of hearing the deflections of the hair bundles that produce HC responses are of the order of 0.4 nm, within the range of atomic dimensions. Given this level of sensitivity it is surprising how relatively few are the agents that cause significant functional impairment in the inner ear. Although the primary effect of several agents is to cause HC death, damage to other tissues may also occur. Atrophy of the stria vascularis, mainly as a consequence of death and atrophy of marginal cells, is observed as a consequence of the effects of aminoglycosides and of *cis*-platinum, and with noise and ageing, both of which cause HC loss, there is associated loss of a particular subpopulation of spiral ligament fibrocytes (Hequembourg and Liberman, 2001; Wang *et al*., 2002). While the effects of *cis*-platinum on the stria vascularis

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

appear to be direct and independent of effects on HCs, with other damaging agents the extent to which the initiation and progression of HC loss is related to damage to other cochlear tissues, or vice versa, is not clear. Damage to the stria vascularis or spiral ligament is likely to affect cochlear homeostasis, which will have adverse effects on HCs. This might be expected to contribute to the characteristics of the hearing impairment resulting from exposure to other ototoxins, noise or ageing. This emphasizes the potential importance of analysing the entire cochlea rather than only the sensory epithelium to determine the possible cause of an observed hearing impairment or in assessing the ototoxic potential of any chemical agent.

Cardiac Toxicology

Lalita A. Bharadwaj

CONTENTS

1 INTRODUCTION

One of the most important organ systems required for maintaining homeostasis in the human body is the cardiovascular system. The cardiovascular system is the transport system of the human body and its functions are to deliver oxygen, nutrients and other substances to cells and to remove waste products of cellular metabolism. The cardiovascular system is composed of three basic components: the heart, the blood vessels and the blood. The heart weighs less than one pound in an adult, is the size of a fist, lies obliquely in the mediastinum and serves as a pump imparting pressure to blood, thereby establishing a pressure gradient that is required for blood to flow to the tissues of the human body. The blood vessels serve as the passageways through which blood is distributed from the heart to all parts of the body. Blood vessels also redirect blood back to the heart and form a closed-circuit circulatory system. Finally, the blood, the third component of the cardiovascular system, serves as the transport medium within which nutrients, oxygen and waste products are dissolved or suspended. Numerous control mechanisms regulate and integrate the diverse functions and component parts of the cardiovascular system, so that blood is supplied to body areas according to tissue-specific needs. These essential control mechanisms ensure a constant internal homeostatic environment that surrounds each body cell, regardless of differing demands for nutrients or removal of waste products. The normal functioning of the cardiovascular system is essential for life. Toxicity to the component parts of the cardiovascular system can lead to devastating irreparable damage to the normal functioning of all systems of the human body. Toxicity can also result in sudden death due to cardiac arrest.

Diseases of the cardiovascular system are the main cause of death in the UK and Canada and account for approximately 200 000 and 75 000 deaths each year, respectively (British Heart Foundation, 2006; British Heart Foundation Promotion Research Group, 2005; Heart and Stroke Foundation of Canada, 2004). Diseases of the cardiovascular system are associated with dysfunction of the component parts of the cardiovascular system; namely the heart, the blood vessels of the heart and body, and the blood. Currently the main forms of cardiovascular disease (CVD) are divided into coronary heart disease (CHD) and stroke. About half (48%) of all CVD deaths are associated with CHD and approximately one quarter with stroke. CVD not only affects the elderly, but is also the third leading cause of premature death under the age of 75. In 2006, CVD resulted in just over 53 000 premature deaths in the UK alone (British Heart Foundation, 2006).

Extensive clinical and statistical studies have identified several factors that increase the risk of CVD. The major risk factors contributing to the high prevalence rate of CVD in Canada and the UK are associated with behavioural risk factors. Behavioural risk factors are considered factors in one's personal life that can be eliminated or reduced through lifestyle or behavioural changes (World Health Organization, 2002; Sanderson *et al*., 2009). Some behavioural risk factors include: smoking, physical inactivity, high blood pressure, dyslipidaemias, obesity and diabetes. Although the risk of CVD is primarily associated with lifestyle factors, there are several factors that contribute to an increased risk of CVD that cannot be controlled. These include age, gender, family history and ethnicity. More recently there has been a growing interest in the role of low-level chronic exposure to environmental pollutants in the cause of CVD. Environmental factors are considered key determinants of CVD. Although lifestyle choices, such as smoking, diet and exercise, are viewed as major environmental influences, the contribution of pollutants and environmental chemicals is less clear. There is a growing body of research evidence that suggests that exposure to pollutants and chemicals could elevate the risk of CVD (O'Toole *et al*., 2008). Epidemiological studies report that exposure to fine particles present in ambient air is associated with an increase in cardiovascular mortality and statistically significant relationships between particulate air pollution and ischaemic heart disease, arrhythmias and heart failure have been reported (Puett *et al*., 2008).

It has been known for decades that certain chemicals; both industrial and pharmaceutical, can specifically affect the cardiovascular system. Chemicals that target the heart are classed as cardiotoxins and will be specifically discussed in this chapter. Cardiotoxins exert their effects on the heart both directly and indirectly. The degree of their effects on the heart is mainly associated with dosage and exposure period (Wu, 2008). Cardiotoxins can induce functional or structural effects on the heart. Chemicals can produce functional alterations in the heart by affecting its normal physiological function. For example, cardiotoxic chemicals may alter the normal pumping action of the heart by inducing arrhythmias. Cardiotoxins can selectively induce structural damage to the heart by altering its cellular components. Cardiotoxins may affect the architectural structure of the heart through direct alterations of the myocardial cells. Structural toxicants may directly affect the cardiomyocyte membrane integrity, ion transport and energy supply systems. In general, cardiotoxicity results as a secondary consequence of pharmaceutical/industrial chemical overdoses. Functional alterations in the heart can occur after a single exposure or they may last only during the exposure period to the cardiotoxic compound. More permanent structural and functional changes result as side effects, after administration of an overdose or as a result of the initiation of an inflammatory response following repeated long-term exposures.

A few well-known cardiotoxic agents are chemically classed as plant- and animal-derived toxins, heavy metals, aliphatic alcohols and hydrocarbons, aldehydes, gases (CO), carcinogens and pharmaceutical agents utilized in the treatment of cancer, high blood pressure (antihypertensive drugs), arrhythmias and depression (tricyclic antidepressants), and anaesthetics (such as bupivacaine and halogenated hydrocarbon anaesthetics). Environmental pollutants, including particulate matter, polyaromatic hydrocarbons and metals are suspected to be associated with CVD; however, the contribution of environmental contaminant exposures to CVD is still incompletely understood.

In summary, cardiotoxins lead to the development of heart muscle damage and eventually result in the loss of normal heart function. The heart becomes weaker and is not as efficient in pumping and therefore circulating blood; the main function of the heart. Cardiotoxins affect the normal function of the heart through a number of indirect and direct mechanisms that result in biochemical and electrophysiological alterations. Direct toxic effects include those where the cardiomyocyte is directly affected. These effects on the cardiomyocyte include alterations in the plasma membranes ability for ion transport, and the ability of the cardiomyocyte to generate force and energy. Generally, chemicals influence the electrical and contractile properties of the heart. Chemicals may affect the heart through their effects on heart rate (chronotropic), conductivity (dromotropic), excitability (bathmotropic) or contractility (ionotropic). Indirect damage can occur as a result of the cardiomyocytes' sensitivity to hypoxia, and loss of homeostatic mechanisms of the body responsible for acid–base and electrolyte balance. In general, chemicals can depress oxygen uptake and interfere with cardiac energy metabolism (carbon monoxide), interfere with normal calcium homeostasis and interfere

with cardiac contraction and impulse conduction (metals, β-adrenergic agents), induce direct damage, resulting in myocardial necrosis (antihypertensives), produce cardiac arrhythmias (respiratory tract irritants) and interfere with nucleic acid synthesis (anticancer agents). The mechanisms of cardiotoxicity are complex and differ substantially amongst the classes of chemicals known to induce cardiotoxicity. In this chapter, several cardiotoxic chemicals will be overviewed, along with their mechanisms of toxicity.

2 OVERVIEW OF THE HEART

2.1 Structure and Function of the Heart

The heart is composed of three layers: the pericardium, the myocardium and the endocardium (**Figure 1**). The pericardium is a double-walled membranous sac that encloses the heart. It acts as a physical barrier, anchors the heart in the mediastinum and protects the heart from infection and inflammation arising from the pleural cavity and lungs. The myocardium is composed of cardiac muscle. Cardiomyocytes, the cells of the cardiac muscle are composed of long, narrow fibres that contain bundles of longitudinally arranged myofibrils, a nucleus, superabundance of mitochondria, sarcoplasmic reticulum (SR) and a plasma membrane or sarcolemma that encloses the cell. Cardiomyocytes, due to their unique features and arrangement in the myocardium, are able to transmit action potentials quickly from cell to cell and maintain high levels of energy synthesis to maintain blood pressure and the regular pumping action of the heart; essential for the circulation of nutrients and gases to the cells of the human body. There are two specialized types of cardiac muscle cells. A majority of cardiac cells that make up the myocardium are contractile cells. These cells perform the mechanical work of imparting pressure to blood for circulation through the body. The cardiac muscle is divided into two separate networks, one atrial and one ventricular. Within these networks, the cardiomyocytes are in close physical contact through transverse thickenings of the sarcolemma or intercalated discs. These discs function to allow action potentials to pass from cell to cell very rapidly and efficiently, thus each network, atria and ventricles, contract as one functional unit. There is no direct physical contact between atrial and ventricular myocardium, thus a specialized conduction system is present to facilitate and coordinate the electrical excitation from the atria to the ventricles to ensure synchronization between atrial and ventricular pumping, and a normal heart rate.

There are a small number of cardiac cells, autorhythmic cells, that do not contract, but are specialized for initiating and conducting action potentials. These cells are responsible for the excitation and contraction of the contractile cells of the myocardium. They are found in specific locations in the myocardium called nodes. These include the sinoatrial node (SAN) and atrioventricular node (AVN), the AV bundle (bundle of His) and the Purkinje fibres. The third and final layer, the endocardium, is the internal lining of the myocardium and is comprised of connective tissue. The endocardium is continuous with the lining of the endothelium that lines the blood vessels of the circulatory system of the body and thus creates a continuous closed-circuit system.

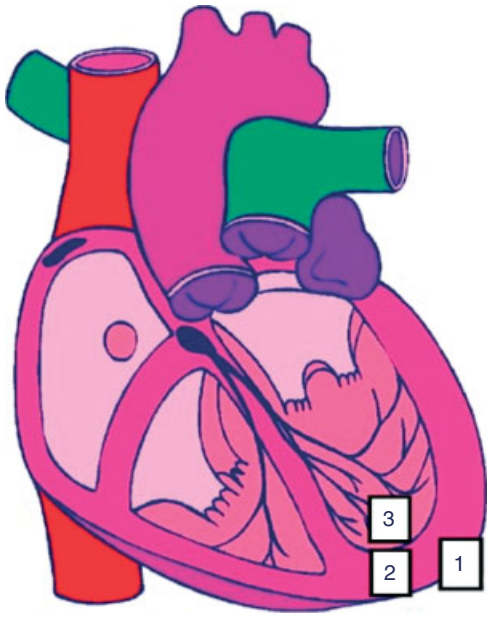

Figure 1 Wall of the heart. This section of the heart shows the (1) pericardium, (2) the myocardium and (3) the endocardium. (Reproduced with permission from John Ross, © 1999.)

2.2 Blood Flow Through the Heart

The heart is the centre of the cardiovascular system. Generally, the cardiovascular system is divided into two separate vascular loops. These include the pulmonary circulation, which carries blood between the heart and the lungs, and the systemic circulation, which carries blood between the heart and organ systems.

The heart is divided into right and left halves and is composed of four chambers; the right and left atria, and right and left ventricles (**Figure 2**). The atrial and ventricular chambers of the heart are separated by electrically nonconductive fibrous tissue. These chambers are essential in facilitating the movement of blood from the heart to the body. The right heart chambers pump deoxygenated blood through the pulmonary

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat067

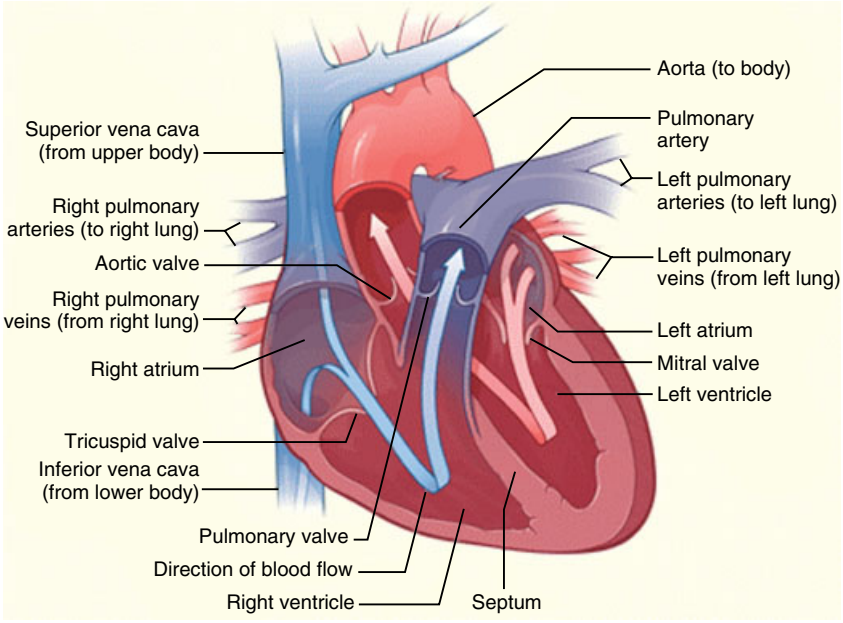

Figure 2 Chambers of the heart. The heart has four chambers: the left atrium, the right atrium, the right ventricle and the left ventricle. During diastole, blood flows into the atria, atrioventricular valves are pushed open and blood begins to fill the ventricles. Atrial systole ejects blood remaining in the atria out into the ventricles. During ventricular systole, the ventricles contract, pushing blood out through semilunar valves into the pulmonary artery (right ventricle) and the aorta (left ventricle). (From *http://www.nhlbi.nih.gov/ . . . /arr/arr_howheartwork.html*.) (Reproduced from U.S. Department of Health and Human Services.)

circulation and the left heart pumps blood through the systemic circulation. The right heart generally consists of structures located on the right side of the heart. These include the right atrium, AV valve (tricuspid valve) and ventricle, the pulmonary semilunar valve and the pulmonary artery. The left heart consists of the pulmonary vein, left atrium, AV valve (mitral valve) and ventricle, the semilunar aortic valve and the aorta.

The opening and closing of valves, controlled by the blood pressure changes in the heart chambers, and the contraction and relaxation of the myocardium control the movement of blood through the heart. During relaxation of the myocardium, or diastole, deoxygenated blood continuously flows through the great venous vessels (inferior and superior vena cava) and the coronary sinus to the right atrium, and oxygenated blood flows from the pulmonary veins into the left atrium. During diastole, blood passively flows from the atria into the ventricles through the opened AV valves, and ventricular pressure rises above atrial pressure, resulting in the closure of the AV valves. During contraction of the myocardium, or systole, ventricular pressure rises above arterial pressure, the semilunar valves open and blood is forced from the ventricles into their respective arteries.

2.3 The Normal Heart Rate

The continuous pumping (beating) action of the heart is a result of the rhythmic contraction (systole) and relaxation (diastole) of the myocardium of the heart wall. In a normal adult the heart beats an average of about 70 beats per minute. The continuous rhythmic beating of the myocardium is highly dependent upon the transmission of electrical impulses or cardiac action potentials through the cardiac muscle. Heart rate can be altered by changes in autonomic nervous system activity. For example, increased parasympathetic activity can slow the heart rate below normal resting (bradycardia is defined as a resting heart rate below 60 beats per minute) and an increased sympathetic activity will augment the heart rate above normal (tachycardia is defined as a heart rate of above 180 beats per minute). Cardiac muscle is capable of generating action potentials without nervous stimulation as a result of specialized cardiac muscle that is part of the heart's specialized conduction system. A complete heartbeat, or cardiac cycle, consists of the contraction (systole) and relaxation (diastole) of both atria and ventricles.

3 THE CONDUCTION SYSTEM

The conduction system is composed of specialized muscle tissue that generates and distributes electrical impulses that stimulate cardiac muscle to contract (**Figure 3**). These include the SAN, a small specialized region in the right atrial wall located near the opening of the superior vena cava; the AVN, a small bundle of specialized cardiac muscle cells located at the base of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

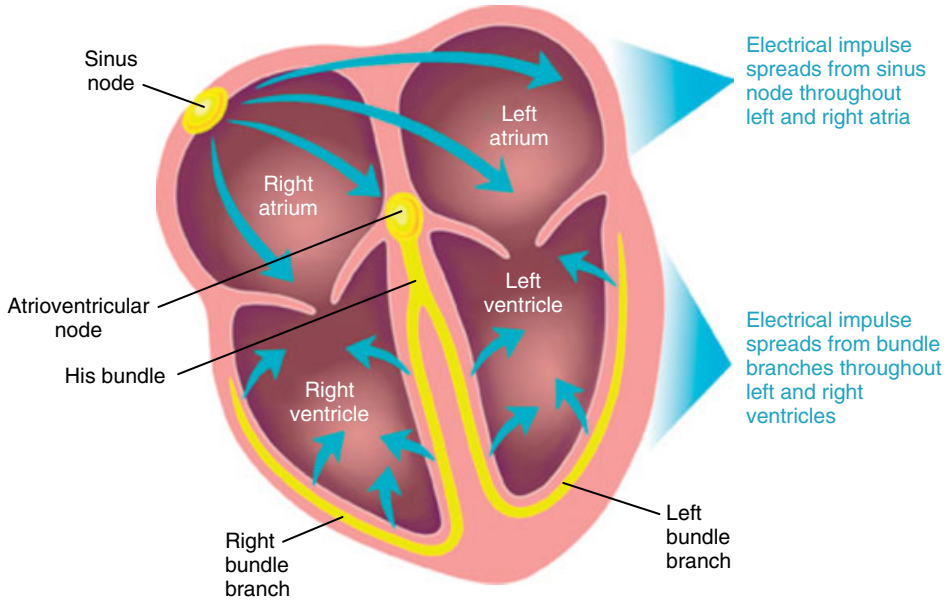

Figure 3 Specialized cardiac muscle cells in the wall of the heart rapidly conduct an electrical impulse throughout the myocardium. Signals are initiated at the pacemaker (sinoatrial node; SAN) and spread to the rest of the atrial myocardium and to the atrioventricular node. The AVN then initiates signals that are conducted throughout the ventricles by way of the bundle of His and Purkinje fibres. (From *http://www.bioen.utah.edu/faculty/sri/Lab8_humancardiovascular.htm*.) (Reproduced with permission from Marquette Electronics, © 2006.)

the right atrium just above the junction of the atria and ventricles; the AV bundle (bundle of His), a tract of specialized cells that originates at the AVN and enters the interventricular septum, where it divides to form the right and left bundle branches, and travels down the septum to the tip of the ventricular chambers and back towards the atria along the outer walls; the Purkinje fibres, small fibres that emerge from the bundle branches and pass into the myocardium of the ventricles.

The sinoatrial node, also known as the pacemaker sets the basic pace for the heart rate, generating about 100–110 action potentials per minute. The average pace of an adult heart is approximately 72 beats per minute. The SAN is under vagal control at rest. Vagal tone brings the resting heart rate down to the normal rate of 60–72 beats per minute. The SAN generates action potentials faster than other components of the conduction system and therefore sets the beating rhythm of the heart. Once the SA node initiates an action potential, the impulse spreads quickly over both atria and causes them to contract (P wave on an electrocardiogram (ECG)). The action potential originating in the SAN is transmitted from the atria to the ventricular myocardium through fibres travelling to the AVN. The action potential is then transmitted to the bundle of His, the left and right bundle branches and finally to the Purkinje fibres of the heart wall to result in contraction of the ventricular muscle (QRS wave on an ECG).

Chemicals may disturb the conduction system of the heart and lead to alterations in heart rate, cardiac impulse origin and conduction velocity. Arrhythmias (dysrhythmias) or deviations from 'normal sinus rhythm' may manifest as a change in heart rate (tachycardia or bradycardia), a disturbance in impulse formation or conduction (AV block) or as premature contractions arising from areas within the heart and outside the normal conduction sequence, as a result of augmented excitability and/or re-entry excitation. In summary, alterations in the conduction system can manifest as dysfunctions in heart rate (chronotropic) contractility (inotropy), conductivity (dromotropy) excitability/irritability (bathmotropy) and in the ability of the heart to relax (lusitropy).

4 THE CARDIAC ACTION POTENTIAL

Movement of ions into and out of the cell creates an electrical difference across the cell membrane called the membrane potential. The resting membrane potential of non-nodal myocardial cells is between −80 and −90 mV. These include the atrial and ventricular myocytes, and the Purkinje cells of the heart. The resting membrane potential of the SAN and AVN are between −50 and −60 mV and −60 and −70 mV respectively. During depolarization, the inside of the cell becomes less negatively charged. The various phases of the cardiac action potential are related to changes in the permeability of the cell membrane to ions, primarily to sodium and potassium. Typically, normal myocardial cell depolarization and repolarization occurs in four phases.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat067
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

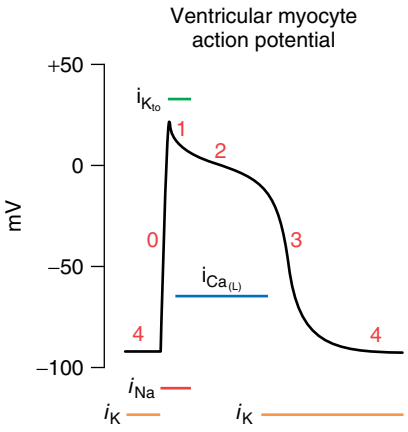

Figure 4 Ventricular action potential. Cardiac contractile cells remain at a resting membrane potential of −90 mV until excited. The rising phase of the action potential is caused by fast sodium influx and the falling phase by a fast potassium efflux. The plateau phase of the action potential results from a slow influx of calcium coupled with a marked decrease in potassium permeability. (Image obtained from Cardiovascular Physiology Concepts, Dr. Richard E Klabunde, PhD at *http://www.cvphysiology.com/Arrhythmias/A004.htm*.) (Reproduced with permission from Klabunde, © 2008.)

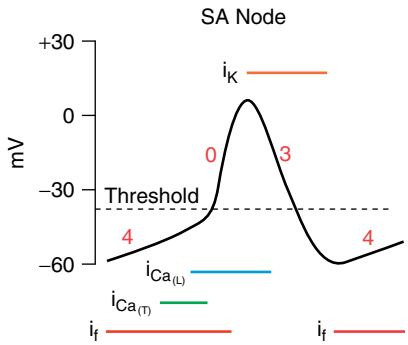

Figure 5 Nodal action potential. The membrane potential of cardiac autorhythmic cells does not remain constant between action potentials. Following an action potential, the membrane slowly depolarizes to a threshold as a result of inactivation of potassium channels, followed by the opening of transient calcium channels. At the same time, less potassium is leaving the cells and sodium continues to leak into the cell, and the cell slowly depolarizes to the threshold. Once the threshold is reached, longer-lasting L-type calcium channels open. There is a rapid influx of calcium, resulting in the initiation of an action potential. The fall back to resting membrane potential results from rapid potassium efflux upon activation of the potassium channels. (Figure obtained from Cardiovascular Physiology Concepts Richard E. Klabunde, PhD *http://www.cvphysiology.com/Arrhythmias/A004.htm*.) (Reproduced with permission from Klabunde, © 2008.)

Phase 4 of the non-nodal myocardial cells (**Figure 4**) represents the resting membrane potential of the cells. The resting membrane potential is maintained during this phase because of the movement of potassium ions through potassium channels. In Phase 4, positive potassium (K^+) ions are moving out of the cell, making the membrane potential more negative inside. At the same time there is no movement of sodium (Na^+) or calcium (Ca^{2+}) into or out of the cell. This is primarily due to the closure of fast sodium channels and (L-type) slow calcium channels. When non-nodal myocardial cells are rapidly depolarized to their threshold voltage of about −70 mV, there is a rapid depolarization (Phase 0) that is caused by an inwardly directed movement of Na^+ into the cell. This occurs through the opening of fast Na^+-channels on the sarcolemma. At the same time, potassium channels close and movement of K^+ out of the cell ceases. Therefore, the membrane potential moves towards a more positive value and away from its resting membrane potential of −80 to −90 mV.

Phase 1 represents an initial repolarization that is of short duration and is caused by the outward movement of K^+. This movement is primarily due to the opening of a unique K^+ channel located in the myocardial membrane. At approximately the same time as K^+ is moving outward, and when the membrane potential has depolarized to approximately −40 mV, slow Ca^{2+} channels open, calcium moves into the cells and Phase 2 or the plateau of the action potential results. Repolarization, or Phase 3, of the myocardial action potential occurs when the movement of K^+ out of the cell increases due to complete opening of the K^+ channels and closing of the Ca^{2+} channels.

In summary, the action potential in nonpacemaker cells of the myocardium is primarily determined by the changes in fast Na^+, slow Ca^{2+} and K^+ channels and the movement of these ions across the sarcolemma.

Cells within the SAN and the AVN are characterized as having no true resting potential and have the ability to generate regular, spontaneous action potentials. Nodal action potentials, unlike non-nodal myocardial cells, are divided into three phases (Phases 4, 0 and 3) (**Figure 5**). Phase 4 of the action potential in these cells is considered the phase of spontaneous depolarization (pacemaker potential) or the period where an action potential is triggered once the membrane potential reaches a threshold between −40 and −30 mV. Phase 4, starts when the membrane potential is about −60 mV. At this membrane potential, slow Na^+ channels are open and there is a slow inward movement of Na^+ into the cell. Additionally, during Phase 4 there is a slow decline in the outward movement of K^+, as the K^+ channels, responsible for Phase 3 or repolarization, continue to close. This fall in K^+ conductance (gK^+) also contributes to the ability

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat067
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

for spontaneous depolarization. The slow inward movement of Na^+ causes the membrane potential to begin to spontaneously depolarize resulting in the initiation of Phase 4 of the pacemaker action potential. Phase 0 is the depolarization phase of the action potential. The depolarizing current in these myocardial cells is primarily a result of the movement of Ca^{2+} through slow Ca^{2+} channels. The movement of Na^+ through fast Na^+ channels is responsible for the depolarization of the nonpacemaker myocytes of the heart. In fact, there are no fast Na^+ channels operating in nodal cells. As a result these cells depolarize more slowly and pacemaker action potentials are sometimes referred to as 'slow-response' action potentials. Phase 0, when depolarization begins and the membrane potential reaches approximately -50 mV, the transient or T-type Ca^{2+} channels open and Ca^{2+} moves into the cells. The movement of Ca^{2+} into the cells results in movement of the membrane potential to a more positive value. As the membrane continues to depolarize and moves towards a more positive, value, a second Ca^{2+} channel opens. Opening of this channel occurs around a membrane potential of -40 mV. These Ca^{2+} channels are called the long-lasting or L-Type Ca^{2+} channels. The L-Type channels open and result in the movement of more Ca^{2+} into the cell until the action potential threshold is reached (usually between -40 and -30 mV). Thus, Phase 0 or depolarization in nodal tissue is primarily caused by an increased Ca^{2+} conductance (gCa^{2+}) through the L-type Ca^{2+} channels that begin to open towards the end of Phase 4. The movement of Ca^{2+} through the L-type Ca^{2+} channels is not rapid, and thus the rate of depolarization (slope of Phase 0) is much slower than that found in other cardiac cells (e.g. the nonpacemaker cells, the atrial and ventricular myocytes, and the Purkinje cells). Phase 3, or repolarization, follows phase 0. The movement back towards the resting membrane potential in Phase 3 is a result of the movement of K^+ ions out of the cell. Once the cell is completely repolarized at a membrane potential of about -60 mV, the cycle is spontaneously repeated. Phase 3 or repolarization occurs as K^+ channels open (increased conductance, gK^+). This results in an increasing outward-directed, hyperpolarizing K^+ current. At the same time, the L-type Ca^{2+} channels close, gCa^{2+} decreases and the inward depolarizing Ca^{2+} currents diminish, resulting in the re-establishment of the resting membrane potential.

The normal initiation and propagation of myocardial action potentials is essential for the proper functioning of the heart. Alterations in ion movements, membrane potential or transmission of cardiac action potentials through the heart muscle can lead to severe disturbances in the normal cardiac rhythm and contractile ability of the heart. It is well characterized that some chemical agents cause disturbances in the normal formation and conduction of cardiac action potentials by their alteration of normal ionic gradients and fluxes across the membrane of cardiomyoctes. For example, some metals, such as barium, affect the normal formation of cardiac action potentials. Barium, because of its charge (2^+), can carry currents across the membrane in place of calcium ions, thus reducing the normal resting membrane potential of the cell. When the resting membrane potential is reduced or modified to a more positive value, the cells are more likely to have an increased automaticity. Due to a reduction in resting membrane potential, the cell is more readily excitable and will depolarize prior to its normal time course. This results in a premature impulse formation and contraction of myocardial cells, resulting in both alterations in normal heart rate (or arrhythmias) and contraction.

Antiarrhythmic drugs are known to alter the conduction of action potentials in non-nodal tissue of the heart. These drugs block the specific ion channels important in the normal generation of action potentials in non-nodal tissue. Sodium-channel blockers, such as quinidine, can inactivate the fast sodium channels and reduce the rate of depolarization (decrease the slope of phase 0) of non-nodal tissue, thus reducing the propagation rate of the action potential, and slowing conduction and ultimately contraction of the heart. Calcium-channel blockers, such as verapamil and diltiazem, affect Phase 2 of the action potential. Verapamil blocks the slow inward calcium current, an action that decreases the concentration of intracellular calcium and thus contractile activity of the heart decreases. Potassium-channel blockers delay Phase 3, or repolarization, by blocking the potassium channels. When the action potential of a cardiac cell fails to return to the resting level along its normal timeframe, a second action potential may arise (early after depolarization). In this case, where repolarization is delayed, a second depolarization may occur prematurely, and this can lead to premature contractions of the heart and altered heart rhythms ultimately affecting the blood supply to the systemic and pulmonary circulations, and oxygen to the body tissues.

Chemicals may also alter impulse conduction in nodal tissue. Chemicals, such as cardiac glycosides, may delay the propagation of electrical impulses in the conduction tissue of the heart. For example, digitalis glycosides will increase the refractory period in the AVN and thus decrease impulse conduction in this section of the conduction system. If the effect is severe enough, conduction will be blocked at the AVN. Chemicals may also modify the sensitivity of the conduction system to endogenous agents. For example, halogenated hydrocarbons, such as chloroform, have been shown to sensitize the heart to the effects of catecholamines and sympathomimetic agents. Thus, in the case of a previous exposure to halogenated hydrocarbons, the normal catecholamine effects (increased heart rate, force of contraction) are exaggerated at lower internal concentrations. Additionally, as the catecholamine dosage is increased, there is risk for the development of rhythm

(tachycardia) and contraction (premature contractions) dysfunctions.

5 EXCITATION–CONTRACTION COUPLING

Excitation–contraction coupling (ECC) is the process whereby a cardiac action potential triggers a myocyte to contract. When a myocyte is depolarized by an action potential, calcium ions enter the cell, through L-type calcium channels located on the sarcolemma, during Phase 2 of the action potential. Calcium triggers a subsequent release of stored calcium from the SR through calcium-release channels. The intracellular calcium concentration is increased. Free intracellular calcium binds to a protein, troponin-C (TN-C), which is part of a regulatory complex attached to thin contractile filaments (actin myofilaments). The binding of calcium to TN-C induces a conformational change in the regulatory complex and a site on actin is exposed and able to bind to the myosin head of the thick contractile filament. This binding results in the hydrolysis of adenosine triphosphate (ATP), which supplies energy for a conformational change to occur in the actin–myosin complex, resulting in cross-bridge cycling (actin and myosin filaments slide past each) and contraction of the cardiomyocyte. Cross-bridge cycling occurs as long as the cytosolic calcium remains elevated. At the end of Phase 2, calcium entry into the cell slows and calcium is sequestered by the SR by an ATP-dependent calcium pump (sarcoendoplasmic reticulum calcium-ATPase), thus lowering the cytosolic calcium concentration; actin-myosin interaction stops and the myocardial cell relaxes.

Contraction of the myocardium is highly dependent on the availability of ATP and calcium. Mechanisms that enhance the concentration of cytosolic calcium increase the amount of ATP hydrolysed and the force generated by the actin and myosin interactions, as well as the velocity of shortening. Physiologically, cytosolic calcium concentrations are influenced primarily by β-adrenergic stimulation. β-adrenergic stimulation increases the force and shortening velocity of contraction (i.e. positive inotropy) and increases the rate of relaxation (i.e. positive lusitropy). Mechanisms that alter ATP availability will also impact the normal contraction of the myocardial cell.

Chemical agents can alter the force of myocardial contraction by affecting any of the steps involved in the ECC process. Generally, agents that alter intracellular calcium levels interfere with the autonomic nervous system control of the heart, alter metabolic processes for energy production/utilization, oxygen and nutrient delivery and the process of ECC will impact the force of myocardial contraction. Additionally, disturbances in the integrity of the myocardial cell membrane, ion movements and membrane-bound enzyme activity will alter the propagation and duration of the myocardial action potential and thus alter contractile strength. Alterations in the normal function of myofilaments of the conduction system will also alter contraction, leading to alterations in force and development.

6 THE NORMAL ELECTROCARDIOGRAM

Electrical impulse transmission through the conduction system generates currents that can be detected on the surface of the skin and recorded using an electrocardiograph. The recording of the sum of all cardiac potentials (a full cardiac cycle) is called an electrocardiogram or ECG (**Figure 6**). This type of recording is performed to evaluate symptoms of heart disease, to detect abnormalities in heart rate or conduction and to evaluate effectiveness and side effects of therapeutic agents. There are three very distinct waves recorded during each cardiac cycle. The first is called the P wave and it represents atrial depolarization. The atria contract a fraction of a second after the P wave begins. The second wave, called the QRS wave or complex represents the sum of all ventricular muscle cell depolarization. This wave begins as a downward deflection, then continues as an upward triangular wave and finishes as a downward wave. The ventricles undergo contraction shortly after the QRS complex begins. The third wave, the T wave indicates ventricular repolarization.

There are several intervals and segments on the ECG and they provide information on the rate of conduction. The PR interval, measured from the beginning of the P wave to the beginning of the QRS wave, is a measure of the conduction time from the beginning of atrial excitation to the beginning of ventricular excitation or the time necessary for impulses to be transmitted from the SA node through the atrium, AVN and His–Purkinje system. The PR interval normally ranges from 0.12 to 0.2 seconds. The ST segment represents the time during which the ventricles are contracting and emptying. The QT interval lasts approximately 0.4 seconds and is sometimes referred to as the electrical systole of the ventricles. The TP interval represents the time when the heart is in diastole and ventricular filling is taking place.

7 CARDIOTOXIC CHEMICALS

Chemicals known to induce cardiotoxicity can be classed chemically or by therapeutic usage. Aliphatic alcohols, aldehydes, glycols, halogenated alkanes, heavy metals and biotoxins, as well as cardiovascular, central nervous system and chemotherapeutic agents have all been identified as cardiotoxic chemicals. Cardiotoxicity is highly

dependent on dose, route magnitude, and frequency and duration of exposure. Cardiotoxicants can be placed into the basic categories of pharmaceuticals, industrial chemicals and natural products. Pharmaceuticals with cardiotoxic action include antineoplastic, anaesthetics, psychotropics and antibiotics. In general, pharmaceutical cardiotoxic effects are seen only when the dose exceeds the therapeutic range.

Many pharmaceutical agents have been withdrawn from the market or severely restricted to specific indications because of unexpected adverse events, including fatalities. Cardiac abnormalities are one of the major causes of withdrawal of drugs or restriction in their labelling. Among these unintended effects, drug-induced arrhythmogenic death is the most dramatic. In 2004, rofecoxib (Vioxx), a nonsteroidal anti-inflammatory drug marketed by Merck & Co. to treat osteoarthritis and chronic pain was withdrawn due to concerns about increased risk of heart attack and stroke associated with long-term high-dosage use. The mechanism proposed to be associated with rofecoxib cardiotoxicity was the suppression of prostacyclin, a vasodilator and anticlotting agent.

Cisapride (Propulsid), a gastrointestinal pharmaceutical used to treat nocturnal heartburn as well as a variety of other gastrointestinal disorders was withdrawn in 2000, due to its association with acquired long QT syndrome and ventricular arrhythmias. The cardiotoxic effects were suspected to be due to blockade of one or more types of K^+ channel currents in the human heart, resulting in dysrhythmias and cardiac arrest. Commonly known pharmaceutical agents that alter heart function will be discussed in the following section.

8 PHARMACEUTICAL AGENTS

8.1 Chemotherapeutic Drugs

Chemotherapeutic drugs are used in the treatment of malignant tumours. They include anthracyclines such as doxorubicin and daunorubicin and alkylating agents. The anthracycline class is the best known of the chemotherapeutic agents that cause cardiotoxicity. Alkylating agents such as cyclophosphamide, ifosfamide, cisplatin, carmustine, busulfan, chlormethine and mitomycin have also been associated with cardiotoxicity.

Anthracycline antibiotics such as doxorubicin (i.e. adriamycin) and daunorubicin are some of the most effective chemotherapeutic agents used in the treatment of cancer and have been used for over 30 years. These drugs are used effectively in the treatment of leukaemias, lymphomas and adenocardinomas. However, the utility of these pharmaceuticals is limited by cumulative, dose-related, progressive myocardial damage that eventually leads to congestive heart failure (CHF) (Shan *et al.*, 1996). The incidence of anthracycline-induced heart failure represents approximately 1% of patients with

advanced heart failure due to ventricular systolic dysfunction (Praga *et al*., 1979). A number of risk factors may predispose a person to cardiotoxicty under chemotherapy. These are cumulative dose (anthracyclines, mitomycin); total dose administered during a day or a course of treatment (cyclophosphamide, ifosfamide); rate of administration (anthracyclines, fluorouracil); schedule of administration (anthracyclines) and other factors, such as age, gender and history of pre-existing cardiovascular disorders (Von Hoff *et al*., 1979). Anthracyclines are well-known cardiotoxins and are known to induce arrhythmias, left ventricular failure and cardiomyopathy following long-term usage (Lenaz and Page, 1976).

Anthracycline-induced cardiotoxicity has been classified into three distinct types. First, acute or subacute injury can occur immediately after treatment. This rare form of cardiotoxicity may cause transient arrhythmias, a pericardial/myocardial inflammatory syndrome or acute failure of the left ventricle. Second, anthracyclines can induce chronic cardiotoxicity resulting in cardiomyopathy (Ferrans, 1978; Von Hoff *et al*., 1977; Bristow *et al*., 1978a; Friedman *et al*., 1978; Haq *et al*., 1985). This is a more common form of damage and is considered the most important. Chronic anthracycline-induced cardiomyopathy characteristically presents within one year of treatment. In a series of more than 3900 patients treated with anthracycline, Von Hoff *et al*. (1977) noted that CHF secondary to anthracycline-induced chronic cardiomyopathy occurred 0–231 days after the completion of anthracycline therapy. Finally, late-onset anthracycline cardiotoxicity may manifest years to decades after anthracycline treatment and is increasingly being recognized, causing late-onset ventricular dysfunction and arrhythmias (Schwartz *et al*., 1987).

Acute and subacute cardiac toxicity, which occur immediately after a single dose of an anthracycline or a course of anthracycline therapy, are uncommon under current treatment protocols. However, several distinct, early cardiotoxic effects of anthracyclines have been described. First, electrophysiologic abnormalities may result in nonspecific ST and T-wave changes, decreased QRS voltage and prolongation of the QT interval. Sinus tachycardia is the most common rhythm disturbance, but arrhythmias, including ventricular, supraventricular and junctional tachycardias, AV and bundle-branch block have been reported (Steinberg *et al*., 1987; Lenaz and Page, 1976; Ferrans, 1978; Von Hoff *et al*., 1977; Bristow *et al*., 1978a).

The incidence of CHF secondary to doxorubicin (anthracycline)-induced cardiomyopathy depends on the cumulative dose of the drug. At total doses of less than $400\,mg\,m^{-2}$ body surface area, the incidence of CHF is approximately 0.14%; and this incidence increases to 7% at doses of $550\,mg\,m^{-2}$ body surface area and to 18% at doses of $700\,mg\,m^{-2}$ body surface area (Von Hoff *et al*., 1979). The rapid increase in clinical toxicity observed at doses greater than $550\,mg\,m^{-2}$ body surface area has made a 550 mg dose the empiric limiting dose for doxorubicin-induced cardiotoxicity (Von Hoff *et al*., 1979; Praga *et al*., 1979). Doses in excess of $1000\,mg\,m^{-2}$ body surface area can be well tolerated by some patients (Henderson *et al*., 1989; Bristow *et al*., 1978a), however appreciable decreases in left ventricular ejection fraction have been documented at doses as low as $300\,mg\,m^{-2}$ body surface area (Bristow *et al*., 1978a; Cortes *et al*., 1975). Histopathologic changes characteristic of doxorubicin-induced cardiotoxicity have been observed at doses as low as $183\,mg\,m^{-2}$ body surface area, which is one third less than the conventional limiting dose. In general, a substantial proportion of patients will experience anthracycline-induced cardiac damage while receiving standard treatment regimens, whereas others can tolerate cumulative doses twice as large as the conventional limiting dose (Friedman *et al*., 1978). Age remains a significant risk factor to anthracycline cardiotoxicity, with patients older than 65 years having triple the risk of doxorubicin-related CHF compared with younger patients at the same cumulative dose (Von Hoff *et al*., 1979).

It is hypothesized that the toxicity of anthracyclines is associated with oxidative stress, loss of mitochondrial integrity, disrupted calcium homeostasis and altered gene expression leading to apoptosis (Doroshow, 1983; 1991; Dorowshow *et al*., 1980; Ito *et al*., 1990; Rajagopalan *et al*., 1988). Anthracycline-induced cardiac injury has been based upon studies in animals and cell cultures. Although anthracycline-induced injury appears to be multifactorial, a common denominator among most of the proposed mechanisms is cellular damage mediated by reactive oxygen species. However, it is not clear why this mechanism would be preferential to inducing cardiotoxic effects.

Anthracyclines have been shown to induce membrane damage via lipid peroxidation in all tissues, including the heart (Doroshow, 1983). The formation of ROS is induced by the quinone moiety of anthracyclines; however, oxidative stress is also known to occur via induction of nitric oxide synthase, leading to nitric oxide and peroxynitrite formation. This latter mechanism of oxidative stress has been linked to nitration and inactivation of key enzymes in the heart that include myofibrillar creatine kinase, which is a critical energetic controller of cardiomyocyte contractility. Myofibrillar creatine kinase has been demonstrated to be a particularly sensitive target of peroxynitrite-induced nitration and inactivation. Anthracyclines are also known to cause impairment of membrane binding, assembly and enzymatic activity of mitochondrial creatine kinase, although the consequences of this impairment are not clear (Olson *et al*., 1974; Kusuoka *et al*., 1991; Holmberg and Williams, 1990).

In the heart, like other tissue, anthracyclines intercalate into nucleic acids, causing suppression of

DNA, RNA and protein synthesis. Some transcriptional regulatory proteins that appear important for regulation of cardiac-specific genes appear particularly susceptible to anthracyclines. Myocyte cell death by both apoptosis and necrosis has also been implicated in anthracycline-induced cardiotoxicity. It is proposed that a net loss of cells' apoptotic and necrotic mechanisms contributes to its cardiotoxicity and heart failure. Recently *in vivo* studies have demonstrated that anthracyclines have a selective inhibition of cardiac muscle gene expression for actin, troponin, myosin light-chain 2 and the M isoform of creatine kinase *in vivo*. Other suspected theories for anthracycline-induced myocardial damage include free-radical-mediated myocardial injury (Doroshow, 1983; Rajagopalan *et al*., 1988), myocyte damage from calcium overload (Holmberg and Williams, 1990), disturbances in myocardial adrenergic function (Wakasugi *et al*., 1992), release of vasoactive amines (Bristow *et al*., 1983) and cellular toxicity from metabolites of anthracycline therapeutics, such as doxorubicin.

Anthracyclines also induce changes in adrenergic function and impart abnormalities in Ca^{2+} handling, both of which are critical components in the regulation of cardiac function. Down-regulation of myocardial β-adrenergic receptors, resulting in adrenergic dysfunction, has also been demonstrated in anthracycline-induced ventricular dysfunction (Tong *et al*., 1991; Robison and Giri, 1986; Fujita *et al*., 1991). However, the extent to which each of these mechanisms contributes to the dose-dependent heart failure in anthracycline-treated patients remains somewhat controversial.

It has also been hypothesized that proinflammatory cytokines may be directly relevant to anthracycline -induced cardiac injury. Recent reports have indicated that circulating proinflammatory cytokines may be linked to anthracycline-induced ventricular dysfunction and cardiomyopathy (Ehrke *et al*., 1986). Doxorubicin has been shown to induce the release of tumour necrosis factor from macrophages and of interleukin-2 from monocytes (Shi *et al*., 1993).

In summary, the cause of anthracycline-induced cardiotoxicity is multifactorial; however, a large body of evidence points to two major mechanisms: calcium overload and free-radical-mediated myocyte damage. Increased oxygen-radical activity generated through the semiquinone moiety of the doxorubicin molecule can cause lipid peroxidation and cell injury. Additionally, anthracycline-induced intracellular calcium overload may also lead to myocyte death. Doxorubicin has been shown to activate the calcium-release channel across the SR and causes calcium influx into the myocyte. Free-radical-induced cell-membrane damage has been demonstrated with calcium influx, suggesting that these two cellular mechanisms of anthracycline-induced cardiotoxic may be linked.

8.2 Digitalis Glycosides

Cardiac glycosides have been used for centuries as therapeutic agents for the treatment of heart diseases and are one of the most commonly described cardiac drugs. Cardiac glycosides, known as a class of digitalis, are widely used in the pharmaceutical treatment of CHF and atrial tachyarrhythmias (The Digitalis Investigation Group, 1997). Digitalis derivatives are found in several plants, including oleander, foxglove and lily of the valley. Digoxin and other cardiac glycosides exert their effects on myocardial contractility through their effects on ion homeostasis.

In patients with heart failure, cardiac glycosides exert a positive inotropic effect by indirectly increasing intracellular calcium levels through inhibiting the plasma membrane Na^+-K^+ ATPase. This inhibition results in an increase in intracellular sodium, which in turn inhibits Na^+/Ca^{2+} exchange and ultimately leads to an increase in calcium levels and a positive inotropic effect. The therapeutic index of digitalis is narrow and thus patients are susceptible to arrhythmias in cases where the therapeutic window is compromised. Although digoxin-induced arrhythmias are a common clinical issue in patients being treated for heart disease, the underlying cellular mechanisms of these arrhythmias are yet to be elucidated.

There are several theories that have been proposed regarding the arrhythmic effects of digoxin. The toxic arrhythmogenic effects of cardiac glycosides are said to be due to a combination of direct and indirect effects on the myocardium (Kemmerer, 2008). It is proposed that digoxin induces arrhythmias by causing oscillatory fluctuations in cardiac resting membrane potential. It is proposed that digoxin increases the rate and amount of Ca^{2+}-induced calcium release from the cardiac SR vesicles (McGarry and Williams, 1993) and as a result induces an oscillatory fluctuation in cardiac resting membrane potential, an increase in myocardial automaticity and ultimately the development of cardiac arrhythmias. Both systolic and diastolic intracellular calcium concentrations increase during digitalis-induced arrhythmias leading to the notion that calcium overload contributes to the overall arrhythmogenic effects of digitalis. It is believed that spontaneous cycles of calcium release and reuptake ensue resulting in afterdepolarizations (abnormal depolarizations of cardiac myocytes that interrupt Phases 2, 3 or 4 of the cardiac action potential and lead to cardiac arrhythmias) and aftercontractions (Hauptman and Kelly, 1999).

There is some evidence to suggest that increased cardiac sympathetic activity is involved in digitalis-induced cardiotoxicity. Experimental studies demonstrate that stimulation of central α-adrenoceptors depresses cardiotoxicity (Chen *et al*., 1991; Thomas and Stephen, 1991), whereas β-adrenoceptor blockers (Mest *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat067
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1995; Nakanishi *et al*., 1992) can reduce these arrhythmias. Other proposed mechanisms of toxicity include the involvement of nitric oxide (Altug *et al*., 1999), cyclo-oxygenase products (Mest *et al*., 1981; Moffat *et al*., 1986; 1987), ROS (Schlieper and Tawfik, 1987; Ark *et al*., 1999; Tian *et al*., 2003) and magnesium (Kafiluddi *et al*., 1989).

In summary, digitalis glycosides alter the normal contractile and rhythmic function of the heart. They alter impulse formation and conduction through their effect on ion homeostasis. Cardiac glycosides indirectly increase intracellular calcium levels through inhibition of the plasma membrane Na^+-K^+ ATPase resulting in a positive inotropy. Additionally the magnitude of the resting membrane potential is reduced and in myocardial automaticity is increased, leading to increased susceptibility for arrhythmias.

8.3 Antiarrhythmic Drugs

Antiarrhythmic drugs affect the heart by directly or indirectly altering membrane ion conductance across the membrane of the myocardial cell. Antiarrhythmic drugs such as the fast Na^+-channel blockers (Class I), which include lidocaine, procainamide, quinidine and phenytoin impair intraventricular conduction. These agents can be responsible for life-threatening arrhythmias after either an accidental intravenous administration or enhanced absorption from an injection site. Accidental intravenous injection in humans or experimental injection in laboratory animals has been shown to result in a variety of cardiac tachyarrhythmias, including the common occurrence of ventricular fibrillation. The mechanisms by which Class I antiarrhythmics produce cardiac rhythm disturbances are incompletely characterized, but have been assumed to result from excessive blockade of Na^+ channels. However, interactions with Ca^{2+} channels, K^+ channels and SR-associated calcium channels, as well as many other ion channels and enzymes have been demonstrated (MacMahon *et al*., 1988; Hondeghem and Katzung, 1977; Bolger *et al*., 1987; Castle, 1990; Kindler *et al*., 1999; Tovey *et al*., 1998). Any of these actions on membrane-associated ion channels could potentially trigger arrhythmias and account for cardiotoxicity.

8.4 Tricyclic Antidepressants

Cyclic antidepressants have been used in the treatment of major depression since the late 1950s. Currently, cyclic antidepressants are also utilized in the treatment of chronic pain syndromes and for migraines. Cyclic antidepressants were identified to have a low threshold for toxicity following reports of overdose shortly after their use in the 1950s. Although in the past 10 years, the prescription of cyclic antidepressants has declined significantly with the arrival of selective serotonin reuptake inhibitors (SSRIs), they remain second only to analgesics as the most common drugs implicated in overdose fatalities. The most commonly prescribed cyclic antidepressants include the following: amitriptyline, desipramine, imipramine, nortriptyline, doxepin and clomipramine (Hong *et al*., 1974; Coull *et al*., 1970; Curry *et al*., 1971).

Significant adverse effects are generally seen at doses of greater than $20\,mg\,kg^{-1}\,d^{-1}$, in aged patients with pre-existing heart disease, and in situations where drug administration is uncontrolled long term (Freeman *et al*., 1969; Rasmussen, 1965). The toxic effects of cyclic antidepressants are primarily related to the pharmacologic effects of these drugs (Cairncross and Gershon, 1962). Cyclic antidepressants exhibit a number of pharmacologic effects that include anticholinergic and antihistamine activity, α-adrenergic blockade, inhibition of norepinephrine and serotonin reuptake and blockade of fast sodium channels in myocardial cells, resulting in quinidine-like effects on the heart (Robinson, 1965; Williams and Sherter, 1971; Rosenbaum *et al*., 1969; Sacks *et al*., 1968). The most serious adverse effects of cyclic antidepressant toxicity are due to central nervous system effects and cardiovascular instability. Depressed mental status is generally caused by the antihistamine and anticholinergic properties of cyclic antidepressants. Life-threatening cardiovascular complications are due to impaired conduction from fast sodium-channel blockade. The impairment decreases the slope of Phase 0 depolarization, widens the QRS complex, and prolongs the PR and QT intervals, resulting in alterations in cardiac conduction. Impaired cardiac conduction may lead to heart block and unstable ventricular arrhythmias or asystole. Cyclic antidepressants have also been shown to directly depress myocardial contractility and induce profound hypotension, due to vasodilatation from direct α-adrenergic blockade in serious poisoning situations.

8.5 Antihistamines

Antihistamines are the most widely used drugs in the treatment of allergic reactions of all kinds. Their main action is to counter the effects of histamine, one of the chemicals released in the body when there is an allergic reaction. The antihistamine drugs, known as H1 blockers, block the action of histamine on certain receptors, known as H1 receptors. Several clinically useful drugs (such as chlophenamine (formally chlorpheniramine), brompheniramine, triprolidine, hydroxyzine and diphenhydramine), able to antagonize the effects of histamine at the level of the H1 receptor, were developed in the late 1940s and early 1950s.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat067
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Following the development and success of these early antihistamines (first-generation antihistamines), hundreds of new antihistamine drugs (second-generation antihistamines) were synthesized and marketed with outstanding success. The more recently introduced antihistamines include: acrivastine, astemizole, cetirizine, ebastine, levocarbastine, loratadine, fexofenadine, ketotifen and oxatomide. These second-generation antihistamine drugs had improved selectivity for histamine receptors and lack sedative effects (Taglialatela *et al*., 2000).

Despite the enormous therapeutic effects of these drugs (both first- and second-generation antihistamines) in the treatment of allergies, in the mid 1980s several reports appeared in the literature indicating the occurrence of cardiotoxicity after the administration of astemizole or terfenadine, two of the most successful second-generation antihistamines on the market (Soldovieri *et al*., 2008). Astemizole and terfenadine were withdrawn from the market in several countries because they caused the rare occurrence of *torsades de pointes* (TdPs) (Paakkari, 2002). TdPs is a potentially fatal polymorphic ventricular arrhythmia that occurs in the setting of a marked prolongation of the QT interval either in patients taking intentional or accidental overdoses of these two antihistamines or in insubjects with predisposing CVD (Taglialatela *et al*., 2000). The metabolic products of astemizole, desmethyl astemizole and norastemizole are cardiotoxic, whereas fexofenadine, the active metabolite of terfenadine is devoid of cardiotoxicity. Terfenadine and astemizole were shown to cause a prolonged QT-interval in the ECG (Paakkari, 2002). This effect was soon demonstrated to be associated with an impaired repolarization of cardiomyocytes due to a selective blockade of cardiac potassium currents (Paakkari, 2002; Soldovieri *et al*., 2008).

8.6 Aliphatic Alcohols

Ethanol consumption has been associated with a variety of CVD. In the 1950s evidence began to emerge to suggest that alcohol has a direct toxic effect on the myocardium. Over the last 25 years research has been conducted to characterize the cardiotoxicity associated with alcohol consumption and it is now well recognized that the heart is a primary target for the damaging effects of excessive ethanol consumption (Urbano-Marquez *et al*., 1989). Upon autopsy, individuals who have consumed excessive amounts of alcohol have been observed to have cardiac enlargement, often with thickened regions of the endocardium and other pathological and histological symptoms of heart failure, such as interstitial fibrosis, hypertrophy and atrophy of myocytes, together with focal regions of myocardial necrosis (Teragaki *et al*., 1993). Alcohol use has been shown to have numerous effects on the cardiovascular system. It has been associated with arrhythmias, heart failure, cardiomyopathy, hypertension and stroke. The most prevalent form of alcoholic heart disease is cardiomyopathy, which is characterized by depressed cardiac output, reduced myocardial contractility and dilation of all four chambers of the heart (Richardson *et al*., 1986). Alcoholic cardiomyopathy develops primarily after prolonged periods of sustained and daily heavy drinking, generally exceeding a period of 10 years.

Ethanol has been shown to induce structural changes that often precede functional alterations in the heart. An increase in left ventricular mass is a common structural change that often precedes contractile alterations. Impairment of cardiac function appears to develop incrementally with increasing ethanol consumption until overt alcoholic cardiomyopathy manifests itself. Progression to cardiomyopathy is associated with substantial ventricular and atrial dilation, as well as mitral valve regurgitation, which may be associated with ethanol-induced papillary muscle insufficiency (Teragaki *et al*., 1993; Nakanishi *et al*., 1990). Ethanol is also known to cause rhythm effects of the heart and there are a number of abnormalities that may be associated with resulting arrhythmias seen in alcoholics. Alcoholics often have atrial dysrhythmias and these may be attributed to effects on conduction times and increases in action potential refractory periods (Teragaki *et al*., 1993; Regan, 1978).

Reports on the short-term effects of ethanol ingestion are somewhat contradictory. Some studies indicate that acute ethanol ingestion induces a direct negative inotropic and chronotropic effect on the myocardium (Thomas *et al*., 1994). However, others have reported no change or enhancement of rhythm and contractility. The most common observation following acute ethanol ingestion is a modest increase in heart rate, which is assumed to be a secondary consequence of the action of ethanol on autonomic regulation of the heart (Patel *et al*., 1997). Acute ethanol intake has been shown to increase systolic time in healthy volunteers. Under conditions of autonomic blockade, increases in systolic times are said to be associated with reduced myocardial contractility and blood ethanol levels of approximately $110\,\mathrm{mg\,dl^{-1}}$ (or 20 mM) (Ahmed *et al*., 1973; Child *et al*., 1979).

Investigations into the cellular mechanisms of the acute ethanol affects on contractile function have been mainly based on experiments in animal models. *In vivo* experimentation on the effects of ethanol on cardiac contractility, in animals as well as in humans, is complicated due to the indirect effects ethanol has on other elements of the cardiovascular system. However, a number of studies in dogs have demonstrated that ethanol, at blood levels between $70–310\,\mathrm{mg\,dl^{-1}}$, causes decreased contractile function (Mendoza *et al*., 1971). The acute effect of ethanol is more pronounced under conditions of autonomic blockade (Child *et al*., 1979). *In vitro* investigations of acute ethanol affects on isolated cardiac muscle

preparations have indicated that ethanol concentrations of 20–200 mM depress cardiac contractility (Hirota *et al*., 1976). Ethanol concentrations of 70 mM have been shown to decrease the rate and tension development in rats, ferrets and canines and in human foetal cardiac muscle preparations (Gimeno *et al*., 1961; Kobayashi *et al*., 1979; Richards *et al*., 1989). Animal studies have linked acute ethanol exposure with direct negative inotropic effects on the heart and these appear to be independent of the neuronal and vascular effects of ethanol.

There are several theories that have emerged regarding the mechanisms of reduced contractile function following acute ethanol exposures. These include the interference of ECC. A number of steps in the ECC have been proposed as targets of ethanol action. These include the ion channels that are responsible for the generation and conduction of action potentials, the release of stored Ca^{2+} from the SR required for contraction, the resequestration of stored Ca^{2+} for myocardial relaxation and finally the activation of contractile proteins by Ca^{2+} (Richards *et al*., 1989; Thomas *et al*., 1991).

The effects of chronic alcohol consumption on cardiac function have been examined in a variety of animal models. These include the rat, mouse, dog, turkey and rhesus monkey. Structural, metabolic and functional alterations in cardiac function have been observed in experimental animal studies of chronic ethanol exposure. Experimental studies of chronic ethanol intake in animals have demonstrated structural abnormalities of the heart. The effects observed include a characteristic increased ratio of heart weight to body weight, pronounced left ventricular dilation, reduction in the total number of myocytes comprising the left ventricle, distention of the mitochondrial matrix, swelling of the SR and T-tubules, dehiscence of intercalated discs, disruption of the myofibrillar structure and accumulation of lipid droplets (Segel *et al*., 1975; Thomas *et al*., 1980; Bing, 1982). Chronic ethanol feeding in animal studies has also demonstrated an influence on the metabolic processes of the heart. The most pronounced effect demonstrated is on the capacity of the myocyte for oxidative metabolism. Numerous studies have reported a reduced efficiency of mitochondrial oxidative phosphorylation (Bing, 1982). It has been reported that the reduced oxidative metabolism of heart mitochondria is associated with a reduction in fatty acid oxidation and increase in triglyceride deposition in the heart tissue (Bing, 1982). In addition, ethanol metabolites have been shown to affect cardiac contractile function. The best characterized of these metabolites is acetaldehyde, which has been demonstrated to decrease action potential duration in Purkinje fibres, inhibit Na^+/K^+-ATPase activity in sarcolemma and enhance catecholamine release at concentrations of >0.4 mM (Sorrell and Tuma, 1987).

Ethanol metabolites, such as fatty acid ethyl esters, that are a result of nonoxidative ethanol metabolism, have been shown to accumulate in the hearts of ethanol-fed animals (Lange, 1991). These metabolites have been suggested to disrupt sarcolemma functions. A variety of long-term ethanol feeding studies in animals have demonstrated clear and consistent depressive effects on cardiac contraction and increase in the vulnerability of the heart to fibrillation following acute ethanol administration.

In summary, ethanol has acute negative inotropic effects on the heart, which are mediated by direct action on the cardiac muscle. Some theories have arisen in regard to the mechanisms of cardiotoxity induced by acute ethanol exposures, but the alteration of intracellular calcium seems to stand out as a major mechanism for cardiac dysfunction following acute exposures. The chronic effects of long-term frequent episodes of ethanol consumption on cardiac function is assumed to be a result of the cumulative effects of the cardiac actions of this agent ultimately leading to degeneration of contractile function and cardiomyopathy. The mechanism of cardiac damage produced by chronic alcohol exposure remains unclear. However, several theories have arisen based on clinical and experimental evidence derived from human and animal studies. Proposed mechanisms of toxicity include: the generation of toxic metabolites, interference with normal metabolic processes, alterations in mitochondrial structure, alteration in calcium metabolism and glutathione content, inhibition of protein synthesis, fatty acid ester accumulation, inhibition of calcium–myofilament interactions and disruption of cell membrane structure.

8.7 Hydrocarbons

A variety of hydrocarbons, with and without halogen substitution, have long been known to sensitize the heart to adrenaline-induced arrhythmias (Himmel, 2008; Hermann and Vial, 1935; Garb and Chenoweth, 1948; Hays, 1972; Reinhardt *et al*., 1973). For example, chlorofluorocarbons (CFCs) have been demonstrated to produce ventricular arrhythmias. CFC exposure studies in dogs have demonstrated the ability of this hydrocarbon to sensitize the myocardium to exogenous adrenaline. Reinhardt *et al*. (1971) exposed dogs to varying concentrations of CFC-12 for periods of 0.5–10 minutes and found that a concentration of CFC-12 in air of 250 g m^{-3} (5%) sensitized the heart to an intravenous dose of adrenaline (8 µg (kg body weight)$^{-1}$). Similar findings were observed in rabbit exposure studies; however, the arrhythmogenic thresholds of CFCs are known to be dependent upon the animal species and concentration of exogenous adrenaline (Lessard and Paulet, 1986).

The arrhythmogenic potency of CFCs, derived through inhalation studies, has been shown to be dependent on the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat067
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

degree of fluorination. It has been shown that as fluorination increases within a homologous series of CFCs, the arrythmogenic potency decreases. For example, for the chlorofluoromethanes, the arrhythmogenic potency of CFC-11 seems to be greater than that of CFC-12. A similar pattern has been observed in fully halogenated ethanes (CFC-113 > CCF-114 > CFC-115) (Reinhardt *et al*., 1971; 1973; Clark and Tinston, 1972a; 1972b; Wills, 1972). Through animal studies it appears that a critical blood level of CFC is needed to cause cardiac sensitization. It has been hypothesized that differences in cardiac sensitization among various CFCs may reflect differences in absorption characteristics rather than mechanisms of action at the molecular level (Jack, 1971; Taylor *et al*., 1971; Clark and Tinston, 1972a; Azar *et al*., 1973). Similarities in the lowest venous blood concentrations associated with cardiac sensitization in various animal studies suggest that these CFCs act in a similar and nonspecific manner in causing arrhythmias. This hypothesis is somewhat supported by basic similarities in cardiac sensitization caused by these and other halo-substituted hydrocarbons.

Inhalational exposure studies in animals have demonstrated mixed results regarding the effects of CFCs on heart rate. Through these numerous studies it appears that any observed changes induced by an inhalational exposure to CFC is highly dependent on the use of anaesthetic in experimental design, the CFCs, CFC concentration and animal species. For example, inhalation of CFC-12 in a gas mixture given to anaesthetized animals has been reported to cause bradycardia in mice (Aviado and Belej, 1974), rats (Doherty and Aviado, 1975) and dogs (Flowers and Horan, 1972). No change in heart rate has been observed in monkeys (Belej *et al*., 1974), rats (Friedman *et al*., 1973; Watanabe and Aviado, 1975) and cats (Harris *et al*., 1971). However, tachycardia has been induced in anaesthetized monkeys and unanaesthetized rats (Aviado and Smith, 1975; Watanabe and Aviado, 1975).

Chlorofluorocarbon gases may exert their effects on cardiac rhythm in two ways; directly on the myocardium and indirectly through sensitization of the ventricular myocardium to endogenous catecholamines (Taylor *et al*., 1971; Aviado and Belej, 1974). The latter theory is consistent with the blocking of CFC-induced arrhythmias by propranolol. Electrophysiological analysis of CFC-induced effects on different cardiac cells indicates that arrhythmias are a result of nonspecific impairment of the membrane properties and notably the inhibition of transmembrane ionic currents (Lessard and Paulet, 1985; 1986).

Several investigators have attempted to determine if CFCs affect oxidative phosphorylation. However, the CFCs, CFC-12 and CFC-114 were shown not to affect oxygen consumption or oxidative phosphorylation in mitochondria isolated from the liver, lung, brain, heart or kidney of exposed rats (Griffin *et al*., 1972). Subsequent *in vitro* studies conducted with liver and heart mitochondria supported the *in vivo* findings, also indicating no effects on either oxidation or phosphorylation (Griffin *et al*., 1972).

In summary, hydrocarbons have long been known to sensitize the heart to adrenaline-induced arrhythmias; however, the mechanisms of action are not well elucidated, fully investigated and understood. Further studies are required to determine the exact mechanisms of action, although it is proposed that hydrocarbons, halogenated or not, seem to induce cardiac sensitization through a similar mechanism of action.

8.8 Volatile Substance Abuse

Volatile substance abuse (VSA), referred to as glue sniffing, inhalant abuse, solvent abuse, is the deliberate inhalation of volatile substance for the purposes of achieving intoxication, has been reported in many part of the world and occurs most commonly in adolescents, individuals living in remote and rural communities, and in individuals whose occupations provide access to these substances (Flanagan and Ives, 1994). Solvents from contact adhesives, including toluene and gasoline, in addition to halogenated solvents and volatile organic hydrocarbons (aliphatic hydrocarbons, alkyl halides, alkyl nitrites, aromatic hydrocarbons, ethers and ketones), such as those present in cigarette-lighter refills, aerosol propellants, halocarbon fire extinguishers and inhalational anaesthetics are chemical agents that are utilized by volatile substance abusers (Flanagan and Ives, 1994; Linden, 1990). In the UK, the most common types of substance abused today are butane lighter fuel and aerosol inhalers (Harris, 2006). There are also a large number of deaths annually occurring in the UK as a result of VSA. Substances that are inhaled for the purpose of recreational self-intoxication have the ability to cause asphyxia, arrhythmias, cardiovascular depression, neurological dysfunction and mucosal, pulmonary and skin irritation following acute exposures. The major risk following acute poisoning is sudden death. Arrhythmias leading to cardiac arrest are thought to be the major causes of sudden death in cases of acute poisoning. Like CFCs, the aliphatic hydrocarbons found in solvents utilized by solvent abusers can sensitize the myocardium to the effects of catecholamines, which can then predispose exposed individuals to tachydysrhythmias, which can result in syncope or sudden death.

Deaths occurring from VSA can be classified as a result of either direct or indirect toxic mechanisms (Harris, 2006). Direct toxic effects are thought to account for over half of all VSA-associated deaths in the UK and are thought to be associated with mechanisms related to

cardiac arrhythmia, vagal inhibition, respiratory depression and anoxia (Shepard, 1989).

Cardiac arrhythmia is considered the most common cause of direct death in individuals who are termed solvent abusers (Harris, 2006). Cardiac arrhythmias arise due to the process of cardiac sensitization. Inhaled volatile compounds sensitize the myocardium to the effects of circulating catecholamines. Intravenous administration of epinephrine, in attempted emergency resuscitations, has been associated with cardiac arrest in VSA users admitted to emergency wards (Lawrence, 1987).

8.9 Metals

Human exposures to heavy metals have been associated with a variety of diseases, including cardiovascular disorders. Cadmium, lead, arsenic, cobalt, manganese, nickel and barium have all been associated with CVD.

Arsenic is an environmental toxicant, which has been used by physicians for more than 2000 years to treat diseases ranging from cancer to syphilis and tuberculosis. Arsenic trioxide has also been shown to be clinically effective in treating acute promyelocytic leukaemia. However, its use clinically has been restricted due to its cardiotoxic effects (Freeman, 2007). Arsenic is also an element found in multiple compounds commonly encountered in the environment. Human exposure to inorganic and organic arsenicals can occur from a variety of sources, including occupational, medical and environmental (Lee and Fraumeni, 1969; Watanabe *et al*., 2004; Westervelt *et al*., 2001). Whether exposure occurs from medical therapy (as with the use of arsenic trioxide in cancer treatment) or accidental malicious acute poisoning, the cardiac effects of high-level acute arsenic exposure are well documented (Westervelt *et al*., 2001; Hall and Harruff, 1989; Little *et al*., 1990). Arsenic exposure is associated with direct myocardial injury, cardiac arrhythmias and cardiomyopathy (Benowitz, 1992; Goldsmith and From, 1980). Arsenic trioxide has been shown to cause QT prolongation, TdPs and sudden death. The exact mechanism by which arsenic trioxide causes myocardial toxicity remains unclear, although it is believed that arsenic produces extensive organ damage by combining with protein thiol groups. Earlier reports predicted that oxidative stress might play a crucial role in cardiac and vascular abnormalities in different types of CVDs (Haidara *et al*., 2006; Dhalla *et al*., 2000; Bashir *et al*., 2006). Emerging research also indicates that apoptosis of terminally differentiated cardiomyocytes may contribute to the development of myocardial infarction (MI) and CHF. Apoptosis is known to play an important role in the pathogenesis of a variety of CVDs, however, the role in acute and chronic myocyte loss associated with arsenic exposures remains to be fully elucidated.

Excessive amounts of cobalt are known to be cardiotoxic. Congestive cardiomyopathy has been reported in people who drank large quantities of beer to which cobalt had been added as a foam stabilizer (Morin and Daniel, 1967; Kesteloot *et al*., 1968; Sullivan *et al*., 1969) and in those receiving oral cobalt therapy (Manifold *et al*., 1978). Although cobalt exposure is associated with cardiotoxicity, the mechanism for this toxicity remains unclear.

Cobalt given as a daily subcutaneous injection of cobalt chloride for eight days at doses of 1, 5, 20 and 50 mg $(\text{kg bw})^{-1}$, produced a marked and dose-dependent accumulation of cobalt in the myocardium and a decrease in manganese-superoxide dismutase. Myocardial acute cobalt cardiotoxicity may involve a reduction of intrinsic scavengers resulting in an increased vulnerability to oxygen free-radical toxicity. Cobalt cardiotoxicity may also be attributed to its antagonistic action towards the Ca^{2+} ion, as well as its ability to form complexes with macromolecules. Cobalt interacts with sulfhydryl groups to impair thiol-enzyme activities (Alexander, 1972). In a dog model, cobalt myocardial toxicity was characterized by vacuolation and loss of myofibres (Sandusky *et al*., 1981a) with histochemical evidence of severe mitochondrial damage (Sandusky *et al*., 1981b). The effects observed were hypothesized to be related to cobalt–thiol group interaction resulting in citric acid cycle malfunction (Jarvis *et al*., 1992) and a decrease in myocardial energetics.

Lead exposure has also been associated with an increased incidence of CHD, stroke, peripheral arterial disease (Schober *et al*., 2006; Lustberg and Silbergeld, 2002; Menke *et al*., 2006; Navas-Acien *et al*., 2004) and with cardiovascular function abnormalities, such as left ventricular hypertrophy and alterations in cardiac rhythm (Cheng *et al*., 1998; Schwartz, 1991). The link between low-level lead exposure and hypertension has been intensively studied for many years and an association between blood pressure, increases risk of atherosclerosis and cardiovascular mortality has been reported (Rossi, 2008; Patrick, 2006). Animal studies support the possibility that lead exposure promotes hypertension and accelerates CVD. Chronic treatment of rats with low levels of lead in the drinking water has been shown to elevate blood pressure (Marques *et al*., 2001). This increase in blood pressure has been linked to the ability of lead metal to increase ROS generation, to inactivate nitric oxide synthase and to a decrease in nitric oxide.

Like lead, cadmium has also been shown to increase atherosclerosis in animal models (Subramanyam *et al*., 1992; Revis *et al*., 1981) and environmental exposure to cadmium has been suggested to be particularly toxic to heart and blood vessels, in part because of the ability of cadmium to increase free-radical generation. Overall, metals that diminish antioxidant defences or increase radical production could increase the risk of CVD.

9 AIR POLLUTION

Environmental factors are considered key determinants of CVD. Although lifestyle choices, such as smoking, diet and exercise are viewed as major environmental influences, the contribution of pollutants and environmental chemicals is less clear. Accumulating evidence suggests that exposure to air pollutants and chemicals in ambient air could elevate the risk of CVD. One only has to look back at history to remember the sudden rise in mortality rates and the estimated 4000 premature deaths that resulted in 1952 as a result of the great smog in London, England. In December 1952 on days 7 and 8, smoke and sulphur dioxide concentrations rose from 0.49 to 4.46 mg m^{-3} and 0.41 to 3.83 mg m^{-3} respectively. It was estimated that 4000 deaths had occurred as a result of the great smog and the main causes for these deaths were associated with respiratory disease and CVD. Respiratory diseases such as emphysema and bronchitis were reported to account for approximately 59% of the deaths recorded during the time of the great smog. CVD was reported to account for approximately 22% of the deaths recorded. Many current epidemiological studies report that exposure to fine particles present in ambient air is associated with an increase in cardiovascular mortality (Yang and Omaye, 2009; Puett *et al*., 2008; Simkhovick *et al*., 2008). Statistically significant relationships between particulate air pollution and ischaemic heart disease, arrhythmias and heart failure have been reported. An elevated risk for acute MI (Lanki *et al*., 2006; Peters *et al*., 2001) and cardiorespiratory symptoms (de Hartog *et al*., 2003) has been reported in relation to air pollution. Animal studies show that exposure to ambient air particles increases peripheral thrombosis and atherosclerotic lesion formation. Exposures to arsenic, lead, cadmium, pollutant gases, solvents and pesticides have also been linked to increased incidence of CVD. Mechanistically, these effects have been attributed to changes in the synthesis or reactivity of nitric oxide that may be caused by environmental oxidants or increased endogenous production of reactive oxygen species. Alveolar inflammation induced by particles may either directly or via oxidative stress lead to systemic inflammation with increased levels of blood coagulability, progression of atherosclerosis and destabilization or even rupture of vulnerable plaques, resulting in acute ischaemic events (Brook *et al*., 2004; Seaton *et al*., 1995) and myocardial infarct.

However, future studies are required to identify the contribution of individual pollutants, as well as mixtures to specific aspects of CVD and myocardial injury. Additionally, the underlying physiological and molecular mechanisms of cardiotoxicity associated with exposures to environmental contaminants need to be further elucidated.

10 CONCLUSIONS

Impaired pump function is the common end point of cardiotoxicity. Toxicity generally results due to an injury to the heart muscle and/or an alteration in the conduction system of the heart, leading to electrical disturbances that result in arrhythmias. The myocardium is very vulnerable to damage as it has no regenerative capacity and injury to the myocardium can occur as a result of indirect and direct toxic mechanisms. Some general mechanisms of injury to the myocardium of the heart include interference with ion homeostasis (Na^+, K^+, Ca^{2+}), damage through altered or insufficient blood supply to the heart muscle, oxidative stress, as a result of ischaemia/reperfusion injury, organellar dysfunction, as a result of lack of ionic homeostasis, alterations of metabolism and mitochondrial injury.

Alterations in ion channels can occur as a result of a primary alteration in ion channels, signalling or calcium-handling proteins, structural changes in the myocytes or extracellular matrix and changes in the activity of the neurohumoral system. Inhibition of Na^+/K^+-ATPase leads to an increase in intracellular calcium and a decrease in conduction velocity; Na^+-channel blockade decreases conduction velocity, K^+-channel blockage decreases repolarization and Ca^{2+}-channel blockade (L-type channel, calcium release) can lead to a decrease in AV conduction.

Pro-oxidant/antioxidant balance determines the degree of myocardial oxidative stress. Lipid peroxidation can impair the sarcolemma, cause mitochondrial and SR dysfunction and alter calcium homeostasis. These oxidative effects contribute to arrhythmias, myocardial stunning and myocyte death.

Cytotoxic calcium overload caused by SR dysfunction, sarcolemmal injury, Na^+/K^+-ATPase inactivation or sympathetic activation is another common mechanism of cardiotoxicity. It results in the breakdown of high-energy phosphates, blebbing of plasma membrane, activation of Ca^{2+}-dependent phospholipases and neutral proteases, Ca^{2+}-activated DNA fragmentation and Ca^{2+} activation on oncocytic and apoptotic cell death. Apoptosis predominates soon after toxicant-induced injury and is a prominent feature in heart failure. Overall, cardiotoxicity occurs as a result of affects on biochemical, structural and functional abnormalities induced by overexposure to cardiotoxic agents.

Hepatotoxicity

Richard H. Hinton, Paul Grasso and Timothy C. Marrs

CONTENTS

1 INTRODUCTION

The liver has many metabolic roles and is, accordingly, affected by a very large number of xenobiotics. However, the liver also has an immense capacity for self-repair, so that the majority of lesions observed in the liver reverse rapidly on cessation of treatment. Nevertheless the liver's defences can be overwhelmed. Liver failure from paracetamol (acetaminophen) overdose is familiar to most clinical toxicologists, whereas repeated liver damage, for example from ethanol, may lead to cirrhosis. Also, while primary liver cancer is rare in Western Europe and North America, it is common in other parts of the world. Non-dose-dependent side effects on the liver affecting up to 5% of patients are common with many classes of drug and may be sufficiently severe to require cessation of treatment. Hence understanding hepatotoxicity is vital to both clinical and academic toxicologists.

In any discussion of hepatotoxicity, it is necessary to remember Paracelsus' dictum that it is the dose that makes the poison. One of the major roles of the liver is to protect the body against naturally occurring toxins present in, for example, plants, or produced by the body's own intestinal flora. Exposure to small amounts of such materials results in changes in the liver which permit efficient removal of the toxin. These changes are called adaptive because they do not compromise the ability of the liver to perform its other vital functions. As the dose of the compound is increased there may come a point when other functions are compromised and this is defined as the toxic phase of the response. However, before considering this and other aspects of the action of chemicals on the liver, it is necessary to discuss briefly the structure and metabolic roles of the liver.

2 ANATOMY AND PHYSIOLOGY OF THE LIVER

The liver is a large organ making up about 3.5% of the body weight of an adult rat or 2% of the body weight of an adult human. The overall shape of the liver differs markedly between species. In rats and mice, the liver is divided into several distinct lobes; the human liver, on the other hand, is divided into two rather poorly differentiated lobes. The liver lies immediately under the diaphragm, is covered in a thin capsule and is supported mechanically by attachments to the diaphragm and by the blood vessels. The liver has a complex blood supply. Approximately 80% of the blood is derived from the portal vein (PV). This drains the stomach, duodenum, small intestine and colon. The remaining 20% of the blood supply comes from the hepatic artery. Blood leaves the liver by the very short hepatic veins which join the ascending vena cava. The liver acts as an exocrine gland, secreting bile. This bile is conducted down the extrahepatic bile duct (BD) into the intestine. In the majority of mammalian species, but not in the rat, a portion of the bile secreted from

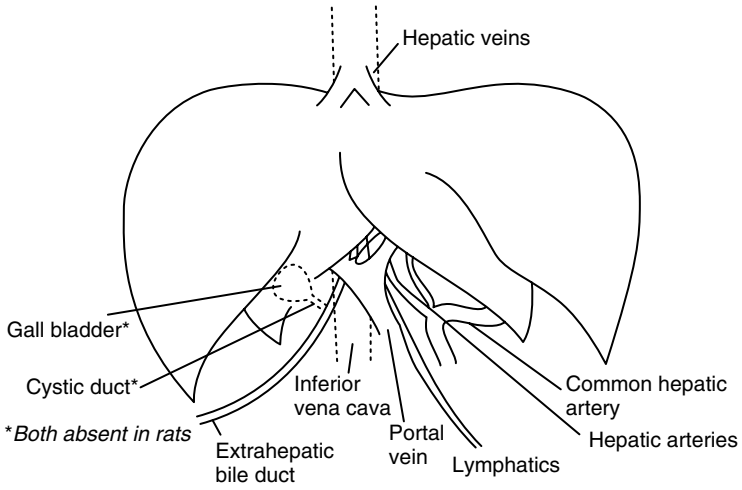

Figure 1 Diagram showing the blood supply to the liver and the drainage of bile and lymph.

the liver is stored and concentrated in the gall bladder, a blind-ended sac attached to the BD. As will be seen later in this chapter, the organization of the bulk of the liver substance, the parenchyma, means that no lymph is formed in most of the liver. Lymph is, however, formed in the connective tissues of the portal tracts and is drained by a duct which connects with the lymphatics that drain the intestine and from there it passes to the thoracic duct. The PV, hepatic artery, extrahepatic BD and the major lymphatics all enter the liver substance at a single point, the porta hepatis. The hepatic veins, however, leave at different points, the number and location of which vary with the species. These various connections are summarized in **Figure 1**.

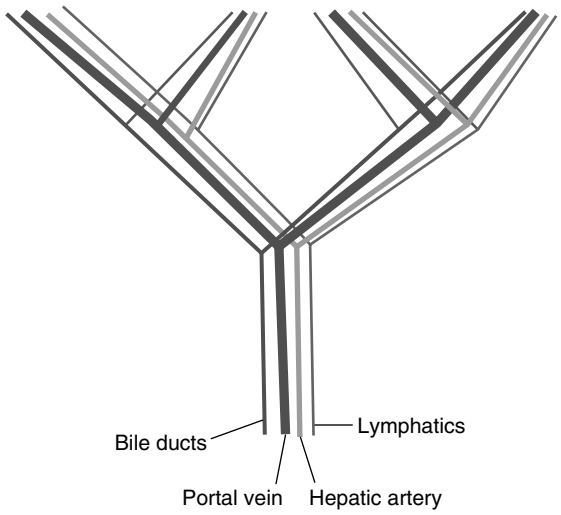

Figure 2 Diagram showing branching of the portal tree within the liver substance. Note that even the smallest branches contain branches of all four types of vessel.

2.1 Organization of Vessels and Nerves within the Liver

As mentioned in the last section, the PV, the hepatic artery, the extrahepatic BD and the major liver lymphatics enter the liver together at the porta hepatis. Once within the liver, the vessels branch to form the portal tree (**Figure 2**). At all branch points there is bifurcation of all types of vessel. This has two consequences. First, all branches of the portal tree, from the largest to the smallest, contain all four types of vessel (**Figure 3**). Second, there are few anastomoses between vessels. Hence any blockage of a branch of the hepatic artery, which provides oxygenated blood to the liver, will result in destruction of an area of the liver (hepatic infarct), blockage of a branch of the PV will result in a similar lesion known as a pseudo-infarct or Zahn's infarct, which is distinguished by atrophic cells, whereas blockage of a branch of the BD will result in local cholestasis. Hepatic infarcts and pseudo-infarcts are normally associated with thrombosis at distant sites and are rare in experimental animals, although, as discussed in a later section, local cholestasis may play a role in BD proliferation, but this is purely speculative.

The organization of vessels within the portal tract is more complex than is apparent at first sight. As will be seen from **Figure 3**, each portal tract contains a single branch of the PV and of the hepatic artery, but may contain several BDs of varying diameter, and several lymphatics. Each BD is surrounded by a group of blood vessels termed the peribiliary plexus which are supplied from the hepatic artery and which will eventually drain into the PV. This is shown in **Figure 4**. The result is a 'contraflow' system which is assumed to be concerned with the resorption of nutrients lost into the bile, although this is also a matter for speculation (Jones *et al*., 1980). Also, bile acids absorbed by cholangiocytes recycle via

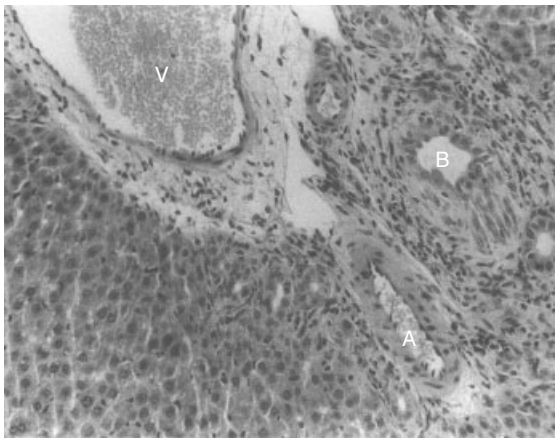

Figure 3 Light micrograph of a middle-sized branch of the portal tree showing branches of the portal vein (V) and the hepatic artery (A) and several bile ducts (B) of various size. The lymphatics are not shown, as these small, thin-walled vessels cannot be identified with any certainty under the light microscope.

Figure 4 Scanning electron micrograph of a corrosion cast of the peribiliary plexus of inner blood capillaries and outer venules in the rabbit. the peribiliary plexus back to hepatocytes for resecretion into bile (Xia *et al*., 2006). In some species, such as humans and rats, the BDs themselves branch, often forming blind-ended pouches (Yamamoto *et al*., 1985) which may be involved in bile storage and modification.

As the portal tree divides, the vessels gradually become smaller. From the smallest veins (terminal hepatic venules), small vessels bud off and pass to the

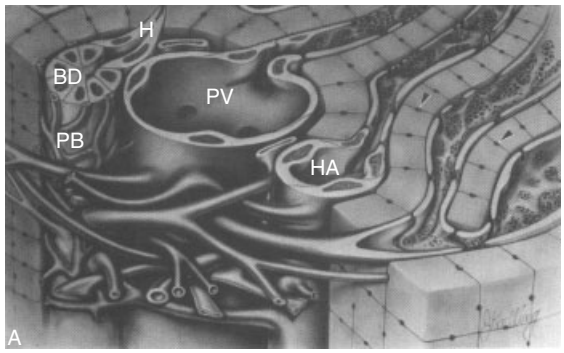

Figure 5 Diagram showing the principal features of a portal canal and connections to the parenchyma. Portal veins (PVs) and hepatic arteries (HAs) empty either directly or via small branch vessels. Bile duct (BD) lining cells contact hepatocytes directly, the junction zone being termed the canal of Hering (H). (Reproduced from Jones, *et al*, 1980. © Springer.)

edge of the portal tract, discharging their blood into the capillaries, which, in the liver, are termed sinusoids (**Figure 5**). Similar branches probably arise from the terminal hepatic arterioles, but a part of the flow from the hepatic artery is believed to pass through the peribiliary plexus before reaching the parenchyma. As is discussed below (Section 2.3.1.1), bile is first formed by discharge into channels between hepatocytes, these channels being called bile canaliculi (BC). These empty directly into BDs, as shown in **Figure 5**. Lymphatic vessels are only found within the portal tracts and around the larger branches of the hepatic veins, so that no connections with the parenchyma are necessary.

The liver is only lightly innervated, and the success of liver transplants shows that innervation is not necessary for liver function. Most fibres are unmyelinated and form part of the autonomic nervous system. It is generally assumed that these fibres, which run in the portal tracts up to their smallest branches, are involved in the regulation of blood flow and possibly of bile flow (Ballantyne, 1978). However, small fibres have been found in the parenchyma contacting hepatocytes (Friedman, 1982) and, because hepatocytes are electrically coupled through the gap junctions, it is reasonable to assume that all hepatocytes may be influenced by signals from the sympathetic nervous system, although the effect of this is obscure.

2.2 Organization of the Hepatic Parenchyma

The bulk of the liver is composed of a single type of cell, the hepatocyte. These are assembled into sheets (sometimes termed muralia), each a single cell thick, which

bifurcate and fuse to give a most complex network. Through this network run the liver capillaries, termed sinusoids. Between cells within the wall run small branching channels called bile canaliculi (**Figure 6**). The relationship between these vessels is shown schematically in **Figure 7**.

The liver sinusoids are lined by endothelial cells. Unlike the endothelia of normal capillaries, these cells do not form a continuous barrier, but are penetrated by fenestrations (**Figures 8** and **9**), which allow a free exchange of proteins between the blood within the sinusoids and the space of Disse (perisinusoidal space), which lies between the endothelial cell and the hepatocyte. There is no distinct basement membrane in the undamaged liver, but some collagen fibres are present and the scant extracellular matrix which is laid down by Ito cells appears to play a role in signalling in the liver and may be rapidly expanded on liver injury (Bissell, 1998). Within the sinusoids are Kupffer cells, fixed macrophages which form attachments both to the walls of the endothelial cell and, by means of processes pushed through the fenestrations, to the hepatocytes. The principal role of the Kupffer cells is to remove particulate material which may have been absorbed from the intestine, and their position and structure, particularly the numerous processes which may extend right across sinusoids, are adapted to this role.

As blood enters the parenchyma from the portal tract and is drained through branches of the hepatic vein, hepatocytes lying close to portal tracts receive blood with a much higher oxygen content than hepatocytes lying close to the central veins. This is in turn reflected in differences in function and a marked variation in sensitivity to certain toxins. It is thus unfortunate that there is no generally agreed system for naming the different zones. The two most common nomenclatures

are shown in **Figure 10**. Neither is ideal for toxicologists. A concept of cylinders (circles in thin section) encircling the portal tract to define a periportal area and branches of the hepatic vein to define a centrilobular area corresponds most closely with the distributions of lesions within the liver (**Figure 11**) and with differences in oxygen tension.

2.3 Structure and Function of the Different Types of Cell in the Liver

2.3.1 Hepatocytes

2.3.1.1 Structure of Hepatocytes

Hepatocytes (**Figure 12**) form approximately 90% of the volume of the liver parenchyma, but are only 60% of the total cell number. They are large cells, approximately cuboidal in shape. The nucleus or nuclei (in rats about half the cells are binucleate diploid cells, the remainder being mostly mononucleate tetraploids) is normally placed centrally; markedly eccentric nuclei are only seen in severely damaged cells. Approximately 20% of the cytoplasm consists of mitochondria, which are actually not spheres or blunt cylinders, as they appear in thin section, but long and often branching tubular structures. Scattered amongst the mitochondria are peroxisomes which normally form only 2% of the volume of the cytoplasm. Normal rat liver peroxisomes can be identified by the crystalloid core, which consists of uric acid oxidase, but this is absent from primates, including humans. Hepatocytes contain a highly developed endoplasmic reticulum which, as usual, is continuous with the outer nuclear membrane. In rodent liver, rough-surfaced endoplasmic reticulum elements may either be wrapped around mitochondria, an arrangement especially associated with periportal cells, or arranged in small stacks, an arrangement characteristic of cells in the centrilobular region. At high magnifications it is seen that the ribosomes are arranged with great regularity along most rough endoplasmic reticulum (RER) elements. Partial loss of ribosomes (RER degranulation), leading to a 'moth-eaten' appearance, is an early sign of hepatotoxicity.

While the RER consists predominantly of sheets of membrane, which, on ultrathin sectioning, gives the characteristic paired membranes, the smooth-surfaced endoplasmic reticulum is predominantly arranged as tubules which, on sectioning, give small circles of ellipses of membrane which are often difficult to identify. In well-fed animals, smooth-surfaced endoplasmic reticulum is largely associated with deposits of the storage polysaccharide glycogen. On treatment with many chemicals, the smooth endoplasmic reticulum proliferates with, in extreme cases, masses accumulating in the centre of the cell marginalizing other organelles.

The Golgi apparatus in hepatocytes is small and, in undamaged cells, invariably located close to the bile canaliculus. The stack of membranous sacs (dictyosomes) of the Golgi apparatus is, however, merely the centre of a much more complex series of membranes (**Figure 13**). The central sacs are connected to a complex of membranous tubules which interleave with elements of the smooth endoplasmic reticulum. Closely associated with the Golgi apparatus in function are the membranes of the late endosome compartment, where proteins taken up by endocytosis are sorted. The final stages of sorting preceding exocytosis also appear to be associated with 'extreme trans-Golgi' elements or trans-Golgi network, which do not form part of the main membrane stack. The Golgi apparatus also forms the centre for a system of microtubules which act as 'railroads' for transferring vesicles to or from the sinusoidal surface of the cell. The lysosomes are believed to bind to this network because in normal hepatocytes they are always located close to the

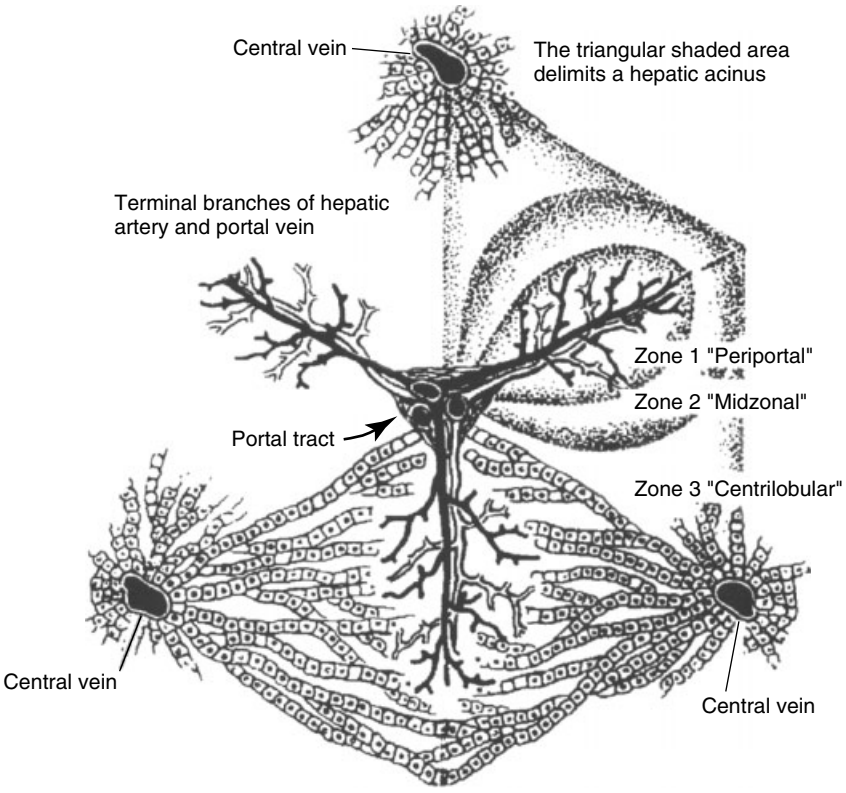

Figure 10 Diagram of the simple liver acinus, small terminal branches of the hepatic artery and portal vein branch from the portal tract. These deliver blood into sinusoids which drain into the central vein. Zone 1 (also known as the periportal zone) receives well-oxygenated blood and nutrient-rich blood from the portal tracts. As the blood passes through the parenchyma, both nutrient and oxygen concentrations fall (Zone 2 or mid-zonal area), being lowest around the central veins (Zone 3 or centrilobular zone). Adapted from Ham (1974).

Golgi apparatus. The plasma membrane of the hepatocytes is divided into two domains. As mentioned above, bile is discharged into small channels between hepatocytes, the BC (**Figure 12**). At the edge of the BC the membranes of the hepatocytes are sealed together by tight junctions, which almost entirely prevent the passage of both soluble and membrane-bound proteins into or out of the bile canaliculus by diffusion between the cells. Close to the BC are the intermediate junctions (zonula adherens), which provide an anchoring point for actin microfilaments, some of which are organized to form a contractile belt around the bile canaliculus (the terminal web). Away from the bile canaliculus the cells are joined by 'spot welds' formed by desmosomes. These act as anchorage points for the intermediate filaments of cytokeratin which cross the cell, giving it mechanical strength and which also anchor the nucleus in place.

2.3.1.2 Functions of Hepatocytes

Hepatocytes have many functions. The liver serves both as an exocrine and an endocrine gland. The exocrine secretion of the liver is bile. The formation of bile is a complex topic (Burwen *et al*., 1992; Crawford, 1996). The critical factor in bile formation is the secretion of bile acids and bile salts, detergents important for the emulsification of fat in the intestine (Stamp and Jenkins, 2008). It should be noted that bile acids are highly bioactive compounds, for example genotoxicity has been reported in some cases (Hardie, 2008).

Of the other major components of bile, water appears to enter passively across the tight junctions whereas phospholipids and cholesterol are extracted from the bile canalicular membrane by the detergent action of the bile salts. In some species, such as rat and dog, IgA antibodies are secreted into bile by a process involving uptake of the IgA at the sinusoidal surface of the cell, sorting in the endosome compartments and release into bile by exocytosis. Bile also has an excretory function. Conjugates, both of endogenous materials such as bilirubin and hormones, and of xenobiotics, are secreted into bile in a process that will be described later in this section. There is also, as mentioned earlier, a slow discharge of lysosomes into bile.

The liver, in its second role as an endocrine gland, secretes almost all the major proteins of plasma with the exception of the immunoglobulins. In addition, the liver plays a central role in lipid metabolism, taking up chylomicron remnants in the blood from the intestine and repackaging this and newly synthesized lipid with a new group of proteins to form very low density lipoprotein

Price.)

(VLDL) particles, which are then exported from the liver. The transport of proteins through the exocytic pathway is especially sensitive to change in intracellular ATP. This is reflected in the accumulation of fat in the damaged liver and in the fall in plasma proteins and disturbances in blood clotting that follow long-standing liver damage.

In addition to forming the bulk of the plasma proteins, the liver is also responsible for their recycling. Most proteins in plasma are glycoproteins, possessing a terminal sialic acid on their sugar side chains. Removal of this sialic acid exposes a galactose residue, which binds avidly to a receptor on the hepatocyte plasma membrane. Following binding, the proteins are taken up by endocytosis and transferred to lysosomes for digestion. Nonglycosylated plasma proteins, such as albumin, are taken up by using other, less well-characterized receptors. The liver is also responsible for recycling old red blood cells, this task being carried out principally by Kupffer cells. Aged red blood cells are recognized because the removal of sialic acid residues from their cell surface glycoproteins reveals galactose residues, which are recognized by a receptor. Following binding, the cells are taken up by phagocytosis and their proteins digested. The haem residues are passed to hepatocytes for reuse or degradation.

In addition to these roles, the liver acts as the centre of intermediary metabolism in the body. The role of the liver in the metabolism of exogenous lipid has already been discussed. In addition, the liver provides a central store of sugar, in the form of glycogen, and is also a major site for the conversion of sugars to lipids and for conversion of amino acids to sugars and lipids. This may have marked consequences. For example, in rats, the metabolic demands of 8 result in a 30% increase in liver weight, exacerbating the toxicity of liver-enlarging agents, such as butylated hydroxytoluene (BHT) (McFarlane *et al*., 1997). In addition, the liver is the main, or in the case of humans almost the sole, site of *de novo* cholesterol synthesis. The result is that liver damage can cause marked disturbances in endocrine function, for example liver cirrhosis results in feminization in men and masculinization in women (Johnston and Alberti, 1985). See review by Foresta *et al*. (2008).

The final function of the liver is in the modification and excretion of a variety of hydrophobic compounds. These reactions involve both endogenous body constituents, such as haem or steroids, and nutrients absorbed with the diet or produced by the body's own microflora. In general, the physiological role of the reactions is to prepare the compounds for excretion. The enzymes

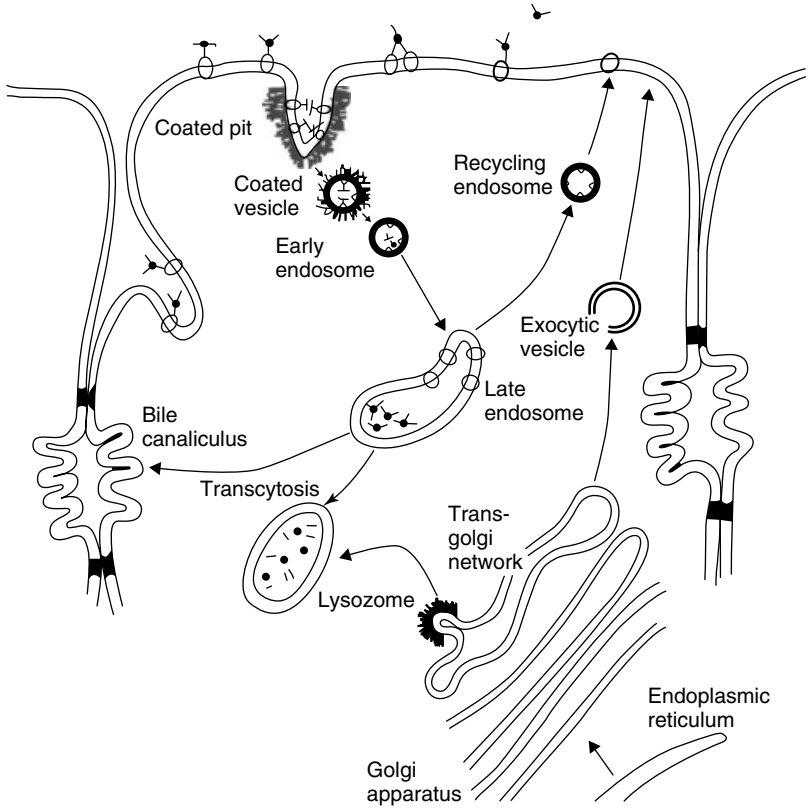

Figure 13 Scheme showing the relationship between the central stack of the Golgi apparatus and associated elements.

involved are conventionally divided into two groups (see **Biotransformation of Xenobiotics**). Phase 1 reactions involve chemical modification of the reactant, most often by oxidation, whereas Phase 2 reactions are biosynthetic, generally involving conjugation with a hydrophilic moiety such as glucuronic acid, sulfate or glutathione. Under most circumstances, the role of these enzymes is protective and results in the removal of potentially harmful materials from the body. However, under some circumstances, the metabolites are markedly more toxic than the parent compound.

By far the most important group of enzymes involved in Phase 1 reactions are the cytochromes P450 (CYPs). These are a large group of enzymes which catalyse a wide variety of reactions (**Table 1**).

The cytochromes P450 are classified into families and subfamilies according to their amino acid sequences, for example CYP 4A1 is the first member of subfamily A of family 4. There is, however, only limited correlation between the classification of the cytochromes P450 and their substrate specificities (**Table 2**), and while there are structural analogies between the P450s of different mammalian species it is unclear how far these correlate with the function of the enzymes (Ioannides, 1996; Lewis and Ito, 2008). The number of isoforms of cytochrome P450 is very large. Some are present constitutively, whereas others are only synthesized in response to inducing agents. Thus the response of animal populations to a xenobiotic may be altered by prior exposure to other chemicals and the situation is further complicated by the fact that outbred populations, such as humans, may show considerable genetic polymorphism. See review by Guengerich (2002).

Although there are several other Phase 1 drug-metabolizing enzymes in the liver, there is little evidence that they play a significant role in the pathogenesis of liver damage. Again, although the liver is the principal location of the Phase 2 drug-metabolizing enzymes listed in **Table 3**, these reactions generally remain, 'as intended', purely protective; the metabolism of aromatic amines (see later) is a notable exception. It should be noted, however, that there are marked variations in levels of Phase 2 enzymes between species of animals and even among individuals (**Table 4**) and that this may result in major differences in toxicity. For example, the chromone FPL 52757 (a candidate antiasthmatic drug) is markedly hepatotoxic in the dog and mildly hepatotoxic to some individual humans, but has no effect on other species because it is not detoxified by N-acetylation; it causes BD necrosis (Eason *et al*., 1982; 1990).

Many of the materials metabolized in the liver are excreted into the bile. In addition, bile contains bile acids and bile salts, present in the bile, play a vital role in digestion Secretion of bile salts from the liver and

absorption from the intestine comprise the enterohepatic circulation of bile acids. Understanding of the mechanisms by which these compounds enter bile has advanced markedly and dedicated bile-salt transporters in hepatocytes and enterocytes are responsible for the unidirectional transport of bile salts in the enterohepatic cycle (Steiger and Meier, 1998; Pellicoro and Faber, 2007; Stamp and Jenkins, 2008). In the hepatocytes, selection occurs both at the sinusoidal surface of the cell and at the bile canalicular surface. Bile acids are specifically taken up at the sinusoidal surface of the cell by the sodium taurocholate cotransporter. Organic anions may also be transported by nonspecific sodium-independent 'organic anion transport protein(s)'. The driving force for these has not been established. Monoanionic bile acids are secreted into bile by the ATP-dependent 'bile-salt efflux pump', whereas dianionic bile salts, glutathione conjugates and at least some glucuronic acid conjugates are transported into bile by the rather broad-specificity MDR (multiple drug resistance) transporters, again using ATP as energy source. Transfer is also mediated by the related MRPs (multidrug resistance-associated proteins). There would appear to be at least six of these in the human genome, but not all have been fully characterized (see reviews by Alrefai and Gill, 2007; Kosters and Karpen, 2008).

2.3.2 Sinusoid Endothelial Cells

The smallest blood vessels in the liver, the sinusoids, are lined by endothelial cells specialized in structure to assist in the liver's major roles of removal of waste materials from the blood and of blood formation. In the majority of tissues, the capillaries form a continuous barrier preventing blood components from coming directly into contact with the cells of the tissue. However, in the

Table 2 Specificities of major isoforms of cytochrome P450 showing the preferred substrate conformations (clearly a wider range of compounds can be metabolized than are specified here)

Isoform	Preferred substrate
1A1	Polyaromatic hydrocarbons
1A2	Polyaromatic hydrocarbons with amine substituents, multiringed heterocyclic aromatic compounds
2B	V-shaped molecules with one or more nonfused aromatic rings
2D	Similar to 2B but with a basic nitrogen at a specific distance and orientation from an aromatic ring
2E	Small molecules, not necessarily planar
3A	Large molecules, not necessarily planar, some show cross-specificity with 1A1 and 2B
4A	Carboxylic acids and their esters, usually with one or two unfused aromatic rings at a certain distance from the carboxylate group

Guengerich (2002) should be consulted for further details.

live, the endothelial cells which line the smallest blood vessels are pierced by fenestrations about 100 nm in diameter, sometimes called sieve plates (**Figure 8**), which allow all components of the plasma, but not blood cells, to make direct contact with the hepatocytes. It is for this reason that the smallest blood vessels in the liver are termed sinusoids, not capillaries. Apart from the possession of sieve plates, the sinusoidal endothelial cells present few features of interest to toxicologists. As with other endothelial cells, there would appear to be active uptake of material by pinocytosis, but the nature of the materials absorbed is not known. The cells contain only small numbers of mitochondria and the endoplasmic reticulum is not well developed. The Golgi apparatus and the lysosomal system account for a considerably greater proportion of the cell volume than in hepatocytes. It is believed that sinusoid endothelial cells play an important part in cell–cell communication: these cells are active in the secretion of cytokines, eicosanoids (i.e. prostanoids and leukotrienes), endothelin-1 and nitric oxide (Kawada, 1997; Kmieć, 2001).

2.3.3 Kupffer Cells

Kupffer cells are fixed macrophages which are found within the sinusoids (**Figures 8** and **9**). They are attached both to the endothelial cells and, via processes extending through the fenestrations in the endothelial cells, to hepatocytes. Like all macrophages, Kupffer cells are actively phagocytic, removing particulate material, such as bacteria or bacterial fragments (endotoxins), which may have entered the blood from the intestine. Kupffer cells are also largely responsible for the recycling of old red blood cells and cooperate with hepatocytes in the metabolism of haem. The structure of Kupffer cells is similar to that of other macrophages. Phagolysosomes are prominent and numerous filamentous elements are present. There are a fair number of mitochondria, but the endoplasmic reticulum is poorly developed and consists mainly of rough-surfaced elements.

It is becoming increasingly evident that, in addition to their protective role, Kupffer cells have other roles (Laskin *et al*., 2001). Kupffer cells are heavily involved in the signalling systems of the liver and, like other macrophages, Kupffer cells secrete a range of cytokines. Some of these, such as IL-1, are principally concerned with signalling to the immune system, but others, such as tumour necrosis factor (TNF)-α, act on hepatocytes and other cells; in this case IL-6 induces synthesis of the protective acute-phase proteins (Scotte *et al*., 1996) while TNF-α, at low concentrations, causes hepatocytes to prepare for division (Webber *et al*., 1998), but causes apoptosis of hepatocytes at high concentrations (Kunstle *et al*., 1997). In addition, Kupffer cells and endothelial cells are the major source of the mitotic inhibitory factor,

Table 3 Phase 2 drug metabolizing enzymes

Reaction	Substrates
Glucuronidation	*O*-Glucuronides formed from alcohols, carboxylic acids, unsaturated ketones, hydroxylamines *N*-Glucuronides formed from carbamates, arylamines, aliphatic tertiary amines, sulfonamides *S*-Glucuronides from aryl thiols and dithiocarbamic acids *C*-Glucuronides from 1,3-dicarbonyl systems
Sulfation	Only *O*-sulfates are formed; phenols, catechols, hydroxylamines, steroids are substrates
Methylation	Aliphatic and aromatic amines, *N*-heterocycles, mono- and polyhydric phenols, sulfydryl-containing compounds
Acetylation	Many including aromatic primary amines, hydrazines, hydrazides, sulfonides and certain primary aliphatic amines
Amino acids	Carboxylic acid residues including arylacetic acids, aromatic carboxylic acids, aryl-substituted and bile acids. The amino acid(s) employed varies with species
Glutathione	Enzymic substitution reactions with alkyl, aryl and aralkyl halides. Enzymic addition reactions with alkenes, aryl and alkyl epoxides. Nonenzymic addition reactions with many free radicals and reactive intermediates

transforming growth factor (TGF)-β, although when stressed, for example in the late stages of liver repair, production is predominantly in hepatocytes (Bissell *et al*., 1995). This may also be true with other cytokines. In addition, as discussed below, interchange of signals between Kupffer cells and Ito cells is believed to play an important role in liver fibrosis. See review by Tiegs (2007).

2.3.4 Hepatic Stellate Cells (Ito Cells)

Hepatic stellate cells, also known as Ito cells, are found tucked in between hepatocytes. Their structure and functions have been reviewed by Kawada (1997), Hautekeete and Geerts (1997) and Senoo (2004). Hepatic stellate cells are modified fibroblasts, one of whose roles in the undamaged liver is to maintain the sparse extracellular matrix of the space of Disse and to store vitamin A. Hepatic stellate cells are small cells compared with hepatocytes. The 'fat' droplets, which are their most prominent feature, contain a 40% solution of vitamin A in triglyceride. Hepatic stellate cells play pivotal roles in vitamin A homeostasis. These cells express, on their cell surface, specific receptors for retinol-binding protein, a binding protein which is specific for retinol: the cells take up the complex comprising retinol and for retinol-binding protein by receptor-mediated endocytosis (Senoo *et al*., 2007). Stellate cells have a well-developed RER and Golgi apparatus and are the source for hepatocytes growth factor (HGF), which is one of the two major mitogens which act on hepatocytes. Their most prominent role in liver damage, however, is when they differentiate into myofibroblast-like cells and actively form Type 1 collagen and secrete TGF-β. The transition between the two states of the cell is regulated by a network of signals coming from Kupffer cells, damaged hepatocytes, endothelial cells, platelets and inflammatory cells. It is thus clear that hepatic stellate cells play an important role in the development of liver diseases, in particular those which involve fibrosis (see Henderson and Forbes, 2008).

2.3.5 Other Cell Types of the Liver

Most biochemical tests are carried out on liver homogenates and, when interpreting these, one must bear in mind that blood vessels make up about 5% of the hepatic parenchyma so that blood plasma and cells may contribute significantly when measurements are made on the homogenates. Furthermore, even the normal liver in experimental animals generally shows some small inflammatory foci and these may increase greatly in treated animals, again emphasizing the necessity for biochemical studies on poorly characterized hepatotoxins to be accompanied by histological examination of the tissue. Blood cells and inflammatory cells cannot, however, be thought of as normal components of the liver. There is, however, a final cell type, the pit cell, whose status is less clear. Pit cells are rarely observed, although there are about 500 000 per gram of rat liver (Wisse *et al*., 1989). These cells are located on, or embedded in, the endothelial lining and possess numbers of small granules. Isolated pit cells have natural killer (NK) activity (i.e. they recognize and kill tumour cells *in vitro*) and morphologically they resemble a population of NK cells, the large granular lymphocytes in the blood, although the two populations do not seem to be identical. Cells considered morphologically to be pit cells probably include a proportion of NK T cells. The morphology and function of pit cells has been reviewed (Nakatani *et al*., 2004).

2.4 Development of the Liver

2.4.1 The Embryonic Liver

The liver develops as a fused pair of diverticulae of the foregut. Clusters of cells grow from this into a mesenchymal stroma in which has developed a plexus of small blood vessels. The intimate relationship between blood vessels and hepatocytes is thus established from the very origins of the organ. Throughout foetal life, the liver consists of sheets of hepatocytes two cells thick, unlike the single cell muralia found in adult life. The development of the blood supply to the foetal liver is extremely complex (MacSween and Scothorne, 1987). The development of the ductular system is equally complicated, but is of more relevance to toxicologists. BC between hepatocytes are seen very early in development. The BDs themselves develop much later. It has been suggested (MacSween and Scothorne, 1987) that BD lining cells differentiate from immature hepatocytes through contact with the connective tissue of the developing portal tracts,

whereas mature hepatocytes differentiate from cells in contact with the vascular endothelium and with the sparse collagenous framework which these lay down. This view is supported by some direct explantation experiments (Shiojiri, 1984).

Hepatocytes in the developing liver are highly differentiated and are functional, producing plasma proteins. Drug-metabolizing enzymes are inducible, although the constitutive expression is small. In addition to its adult role, the liver takes on a second temporary role as the main organ for haematopoiesis. Cells deriving from the yolk sac settle in the liver and rapidly dominate the histological picture (**Figure 14**) (McGrath and Palis, 2008). All cell lineages are represented, although erythropoietic activity is dominant (Moore and Johnson, 1976). In humans, the role of the liver as the major haematopoietic organ passes to the bone marrow in the fifth month of gestation, but in rats and mice this change occurs in the first three weeks after birth.

2.4.2 Changes in the Liver with Age

There are only minor structural or ultrastructural changes in the liver after birth. The proportion of connective tissue increases to accommodate the increasing weight of the organ. In rats, blood flow through the liver diminishes over the first 12 months of life (Van Bezooijen, 1984). In addition, there is a marked increase in BD hyperplasia with age in the rat, possibly as a consequence of spontaneous infections. In both humans and experimental animals the 'age pigment' lipofuscin, which is thought to represent lysosomes filled with an indigestible material consisting largely of peroxidized lipid, accumulates in hepatocytes in later life. There is also a marked increase in nuclear ploidy and in the number of binucleate cells which occur in mice and, to a lesser extent, in some strains of rats (Johnston *et al*., 1968; Grice and Burek, 1984). In mice, ageing animals show significant numbers of hexadecaploid nuclei. Of much more significance to toxicologists are significant metabolic alterations, especially in the enzymes which metabolize xenobiotics.

As noted in the previous section in connection with the embryo/foetus, the liver of a newborn rat is underdeveloped and, in particular, has much less drug-metabolizing capacity than normal liver. Different drug-metabolizing enzymes develop at different rates (Ioannides, 1996). Cytochromes P450 IA develop before birth, reach maximum activity before weaning (three weeks) and decline thereafter (Lum *et al*., 1985). Total cytochrome P450 and the amount of mRNA for the phenobarbital-inducible isoenzymes CYP 2B1, 2B2, 2C3 and 3A1 reach adult levels approximately three weeks after birth and then stabilize (Omiecinski *et al*., 1990). However, the activity of benzphetamine N-demethylase, which is markedly inducible by phenobarbital, does not stabilize in rats until the animals are over seven weeks of age (Lum *et al*., 1985). It is unclear whether this is due to other, unidentified, late-developing isoforms of cytochrome P450 catalysing this reaction or to age-dependent variations in the half-life of the P450 proteins.

In addition to changes in the constitutive expression of genes for drug-metabolizing enzymes, there are also changes in their inducibility. Many, but not all isoforms of cytochrome P450 are inducible in the foetal rat (Marie and Cresteil, 1989). Following birth there are also marked changes in inducibility. The phenobarbital-induced form (CYP 2B2) is highly inducible two weeks after birth (Giachelli and Omiecinski, 1987), but the degree of inducibility declines later, as constitutive expression increases. The main methylcholanthrene-inducible P450 isoforms (CYP 1A) show high constitutive expression early in life, but later this constitutive expression declines and the inducibility increases (Ioannides and Parke, 1990).

Changes in hepatic enzyme levels also occur in the ageing animal. Both constitutive expression of drug-metabolizing enzymes and their inducibility decline with age (Schmucker and Wang, 1981). Superoxide dismutase and catalase activity also decrease (Mote *et al*., 1990) and there is a reduced response to peroxisome proliferators (Hinton *et al*., 1986). The hyperplasia which is so marked in young rats treated with phenobarbital or peroxisome proliferators is much reduced in the ageing animal (Schmucker and Wang, 1981; Hinton *et al*., 1986). There is thus, in ageing animals, a generalized decrease in the capacity of the liver both to metabolize xenobiotics and to protect itself against damaging

products of metabolism such as superoxide free radicals.

2.5 Adaptive Changes in the Liver

Because of its many roles, the liver is continuously changing and this affects even its histological appearance. Glycogen is stored following meals and used at night. Fat accumulates transiently and drug-metabolizing enzymes, alter depending on the composition of the diet. In the small animals normally used in toxicology studies even the size of the liver shows significant variation. For example, a 'normal' rat, mouse or chicken liver is significantly larger than that of their germ-free counterparts (Gordon, 1959). Accordingly, it is necessary, before considering the action of hepatotoxins, to identify the changes in the liver that occur naturally in the course of an animal's life.

One would not expect major changes in bile secretion in the normal life of an animal. Changes in the synthesis of plasma proteins will occur following haemorrhage and, more importantly for toxicologists, as a result of inflammation in any part of the body. In the former case there is a compensatory increase in the synthesis of normal blood proteins. In the latter case a reaction termed the 'acute-phase response' occurs, and the liver synthesizes and secretes into the plasma a distinct range of proteins, the acute-phase respondents, some of which are barely detectable in normal plasma (Kushner, 1982), in addition to the normal plasma proteins. A prominent feature of acute-phase reaction is the alteration of gene expression in hepatocytes (Fulop, 2007). The intermediary metabolism in the liver is affected by pancreatic, adrenal, pituitary, thyroidal and sex hormones, among others (Van Thiel, 1982). The interactions are extremely complex and result in, *inter alia,* the establishment of marked diurnal rhythms (Belanger, 1988; Feuers and Scheving, 1988). This emphasizes the need for strict standardization of conditions in toxicological studies. Generally, however, although hormones at natural levels will not cause morphological change in the liver apart from affecting glycogen content, marked changes are found in the liver during lactation. In rats the weight of the organ increases by over 30% and this is associated with a marked increase in lipogenesis (Williamson, 1980).

The most marked changes in the liver occur in response to xenobiotics. The ranges of variety may seem bewildering, but some logic is appearing. Inducible genes in eukaryotes are controlled by regulatory elements which may lie either before or after the coding area. Transcription of the genes occurs when regulatory protein molecules bind to these sequences. Each gene will normally have a range of regulatory elements and interactions may be positive or negative. Induction of enzymes to metabolize small hydrophobic molecules usually involves binding of the inducing agent to the regulatory protein. This produces a conformational change which permits the protein to bind to DNA, initiating transcription. Thus a single control element may control several genes. The response of the rat liver to agents, such as clofibrate, which induce peroxisome proliferation, typifies this phenomenon. These agents induce a range of enzymes (Mannaerts and van Veldhoven, 1993), including the group responsible for fatty-acid oxidation in the peroxisomes, cytosolic epoxide hydrolase, cytochromes P450 of the 4A family, especially CYP 4A1 and bilirubin-glucuronyl transferase (Magdalou *et al*., 1993), in addition to a range of other enzymes associated with lipid metabolism (it will be noted that these together form a tool kit for degrading and excreting peroxidized fatty acids). These enzymes are induced in parallel. In addition to increasing the metabolic capacity of the existing cells, there is also a burst of cell division, which may result in a doubling of the liver weight. The fundamental process is transactivation of nuclear receptors, typified by peroxisome proliferation associated receptor-α (PPAR-α) (Rettie and Kelly, 2008). These effects all appear to be caused by binding of the inducing agent to PPAR-α, which then binds to the appropriate genes; there are significant species differences in this process (Johnson *et al*., 2002) (see also Section 3.2.5.2.3). The situation as regards inducers of microsomal enzymes can be complicated. Two receptors appear to be specialized for binding to xenobiotics. Best understood is the aryl hydrocarbon (Ah) receptor. Compounds which bind to this induce CYP 1A1 and a range of other enzymes, and are associated both with hepatic injury and immunotoxicity (Whitlock, 1999; Moorthy, 2008). It is interesting to note, however, that the increased activity of CYP 1A2 caused by Ahs is not due to changes in transcription, but is probably associated with increased stability of the mRNA (Kawajiri and Hayashi, 1996). Less well understood are the receptors by which other classes of xenobiotic-metabolizing cytochromes P450 are induced. In the case of CYP 2E1, regulation may affect the translation of the gene, the half-life of the mRNA and the half-life of the protein, although, in the case of xenobiotics, regulation appears to occur at the post-translational level (Ronis *et al*., 1996). The CYP 2B subfamily and the CYP 3 family of cytochromes P450 are both regulated at the transcriptional level. A possible receptor regulating the induction of at least some of the CYP 3 family has been identified (Kliewer *et al*., 1998). Like the PPARs, thyroid hormone, vitamin D and retinoic acid receptors (Lemberger *et al*., 1996), this pregnane X receptor binds to DNA only after forming a heterodimer with the retinoid X receptor. With regard to the regulation of the CYP 2B subfamily, the structural diversity of xenobiotics displaying CYP 2B-inducing ability, the apparent lack of clearly defined structure–activity relationships within certain structural classes and the absence

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of enantioselectivity in the induction process makes it difficult to rationalize the existence of a receptor for this induction process, however it is now thought that the constitutive active receptor (constitutive androstane orphan nuclear receptor) (CAR) is involved in the regulation of CYP 2B (Guengerich, 2002; Corcos and Berthou, 2008). A number of factors are responsible for activating transcription of the genes coding for CYP 2A proteins, including hepatocyte nuclear factor 4, octomer transcription factor 1 and others (see Raunio *et al*., 2008). Nuclear receptors regulating CYPs have been reviewed (Yoshinari *et al*., 2008).

It is thus clear that regulation of the enzymes involved in metabolism is extremely complicated. It is clear that there may be regulation both of transcription and of the rate of degradation both of mRNAs and of the proteins. It would seem almost certain, as with PPAR-α, that the other receptors will induce not single enzymes, but 'tool kits', including both Phase 1 and Phase 2 metabolizing enzymes; certainly coordinated induction is seen. In addition, while compounds which bind to the PPARs are sufficiently different in structure from other xenobiotics for there to be little cross-reaction with other receptors, it would seem that microsome inducers can often bind to more than one receptor. Thus, for example, phenobarbital, which is a strong inducer of the CYP 2B subfamily, also induces, albeit weakly, the CYP 3A subfamily. This complexity, coupled with the differences between species, means that the accurate prediction of induction and of routes of metabolism will remain impossible for some period of time.

2.5.1 Adaptive Changes and Regulatory Toxicology

Liver hypertrophy raises a problem in risk assessment undertaken by regulators in that it is necessary to consider whether a pure adaptive change should be considered adverse. If it is considered that such changes are not adverse, it is necessary to define adaptive changes. The Joint FAO/WHO Meeting on Pesticide Residues (JMPR) concluded that no single effect is generally sufficient to support a determination that liver hypertrophy is adaptive or adverse and that it would be needful to look at morphology, clinical chemistry and other end points to decide (FAO/WHO, 2006). (See also Andrew, 2005.)

3 LIVER TOXICITY

3.1 Diagnosis of Toxic Changes in the Liver

Diagnosis of liver damage depends principally on the gross pathology and on histological examination of the tissue.

Gross pathology is often neglected, especially in research laboratories. For those laboratories doing work intended for submission to regulatory authorities, the data to be gathered at necropsy will usually be specified in guidelines and will almost always include the liver weight. The most common changes observed are liver enlargement, which can, of course, be confirmed by weighing the liver, and changes in colour. The most common of these changes is when the liver assumes a fawny colour and feels greasy on cutting. These changes are generally associated with accumulation of fat in the liver and may be confirmed by examining frozen sections stained with specific stains for neutral fats such as Oil Red O. In humans and to a lesser extent in large experimental animals, ultrasound imaging has proved invaluable in the diagnosis of large-scale changes in the liver architecture, but these techniques are much less useful in small animals such as rats. The significance of liver enlargement is discussed later in this chapter. Other changes that may be seen at necropsy include masses, which may be single or multiple, and haemorrhage.

There is no single guide to the histopathology of the livers of experimental animals and it is usually necessary to consult both textbooks of general pathology, such as that by McGee *et al*. (1992) and Majno and Joris (2004), descriptive texts, such as that by Greaves (1990), and atlases, such as that by Gopinath *et al*. (1987). Special stains may be useful in the diagnosis of some types of liver damage. Loss of glycogen and certain types of fat accumulation are useful early indicators of liver damage and may be confirmed by staining with the periodic acid Schiff technique and with Oil Red O, respectively. Pigmented inclusions may be characterized by stains for iron (Perls' Prussian Blue) and lipofuscin (Schmorl's stain). The initial stages of fibrosis may require confirmation with a reticulin stain. Mallory bodies are eosinophilic inclusions characteristic of human alcoholic liver disease and a number of other conditions which predispose to cirrhosis; they are now known to consist of bundles of intermediate filaments. There is, however, no connection between these and the development of cirrhosis in experimental animals. Mallory bodies are found, for example, in the livers of mice treated with griseofulvin, colchicine or dieldrin (Meierhenry *et al*., 1981; Stumptner *et al*., 2001; Zatloukal *et al*., 2007) and should probably be regarded simply as a marker of hepatocellular damage.

Electron microscopy frequently provides the earliest indications of toxic changes in hepatocytes, degranulation and vacuolation of the RER being a particularly useful indicator. The electron microscope is also invaluable in detecting proliferation of smooth endoplasmic reticulum, peroxisomes and mitochondria, although minor changes in these organelles should not, in themselves, be taken as indicators of hepatotoxicity. Mitochondrial damage is also readily detected under the electron microscope, but careful comparison with control sections is needed as these organelles are exquisitely sensitive to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

post-mortem change. Comprehensive guides to ultrastructural pathology has been produced by Ghadially (1982) and Cheville (2009). However, electron microscopy is now little used outside of research laboratories because of the time needed for tissue preparation and section cutting, and the difficulties in interpreting micrographs of anisotropic tissues such as the liver.

Biochemical tests are much less valuable for the diagnosis of liver damage, although biochemical studies on the liver itself may be invaluable in determining the mechanism of change. In particular, increases in drug-metabolizing enzymes do not, in themselves, indicate damage to the liver. A fall in hepatic glucose-6-phosphatase activity, which parallels a reduction in glycogen, or in reduced glutathione indicates stress on the liver. ATP levels can be used to quantify acute toxic stress, but are not useful in subacute or chronic studies.

Whereas measurement of enzymes and other proteins in blood is important in the diagnosis of human liver disease, such measurements have limited value in work with small laboratory animals. In general, the same enzymes are measured in studies on experimental animals as are measured for the diagnosis of liver disease in humans. It should be noted that γ-glutamyl transpeptidase is a poor marker for cholestasis in rat, whereas secretory IgA and free secretory component provide excellent markers in rats, but do not change in humans (see also **Clinical Chemistry in Toxicity Testing: Scope and Methods**).

3.2 Action of Toxins on the Liver

In 1964, a review of experimental toxic injury to the liver by Rouiller attempted to draw up a comprehensive list of hepatotoxins (Rouiller, 1964). Even then this list covered nine published pages. Advances in our knowledge of the deleterious effects of natural and synthetic chemicals make compilation of a similar list impossible within the bounds of a book such as this. Accordingly, it is necessary to group hepatotoxins. Pathologists have grouped toxins according to the part of the lobule affected (i.e. centrilobular, midzonal and periportal), but, as will be seen, this may differ between species. Ideally toxins should be grouped according to their mechanism of action, but this is often not understood. We have accordingly adopted a hybrid system grouping toxins which do not require metabolic activation by mechanism of action, but discussing toxins which require metabolic activation as a group.

3.2.1 Acute Hepatotoxicity

In 1979, the US Public Health service issued guidelines for the detection of the hepatotoxicity of drugs and chemicals (Davidson *et al*., 1979). In the guidelines, hepatic lesions were divided into two groups. Type I lesions are 'predictable, dose and time dependent, occurring in most, if not all, subjects exposed to appropriate doses of the causative chemical; the lesions are usually readily reproducible in animals'. Type II lesions are 'unpredictable, dose and time independent, occurring sporadically and often becoming apparent only after monitoring a large number of exposed individuals; the lesions are not usually reproducible in animals'. Fortunately, it is unusual for Type I lesions to affect humans except in serious accidents or deliberate ingestion. However, Type II lesions occur with a large number of pharmaceutical agents. We shall, therefore, deal first with the sporadic hepatotoxicity observed in humans before we consider the effects likely to be observed both in humans and in experimental animals.

3.2.1.1 Sporadic Hepatotoxicity in Humans

Drug-induced liver effects are major impediments to the introduction of new drugs into clinical use and are major causes of drug withdrawal (Antoine *et al*., 2008). Hepatic side effects are observed following treatment with a large number of drugs spanning all therapeutic classes, as well as with other xenobiotics. There would appear to be two distinct lesions. The first, and more common, is intrahepatic cholestasis. This is especially associated with phenothiazines, for example chlorpromazine (van Ommen and Brown, 1955), but is also found in many other classes of drug (see also Section 3.2.10). The presenting symptom is generally jaundice with elevation of serum aminotransferases. The incidence varies markedly between compounds. Liver biopsies show portal-tract inflammation, sometimes with a high eosinophil count, which suggests some involvement of the immune system. The condition reverses rapidly when the compound is withdrawn. Much more serious are compounds, such as halothane, which, very occasionally, induce symptoms resembling those of viral hepatitis. In this case there is massive damage, which may be fatal, and cases have been reported since the early 1960s (Inman and Mushin, 1974). The cause is thought to be a hypersensitivity reaction against a conjugate of the drug with a hepatocellular protein (Neuberger, 1998). Even if the acute lesion is not lethal, chronic damage may ensue, although generally the condition does ameliorate with time.

3.2.1.2 Toxins and Requiring Activation by Specific Enzymes

3.2.1.2.1 Agents Affecting Lipid and Lipoprotein Metabolism

The role of the liver in detoxifying potentially dangerous chemicals requires that hepatocytes have an exceptional capacity to take up xenobiotics. When one remembers the numerous metabolic roles of the liver it is not surprising that it is affected by inhibitors of the basic pathways of metabolism, particularly those affecting lipid

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

metabolism. As has been mentioned earlier, the liver plays a central role in fat metabolism, both repackaging dietary lipid from the intestine for use by peripheral tissues and engaging in the synthesis *de novo* of fatty acids from sugars and amino acids. It would seem that these processes are especially sensitive to metabolic changes, because accumulation of large droplets of fat in the liver (steatosis) is amongst the most common signs of acute hepatotoxicity (see review by Postic and Girard, 2008).

It should be noted that fat accumulation in the liver does not always indicate liver damage. Following partial hepatectomy there is a massive importation of fat into the liver, but there is no evidence of hepatocyte misfunction (Bucher and Malt, 1971). In rats fed high-fat diets (Ashworth *et al*., 1961) or made hyperphagic by hormonal manipulation (Meyer and Hartoft, 1960), and in rats treated with the peroxisome proliferators discussed later, fat generally accumulates in numerous small droplets, an exception being the perfluorinated fatty acids, where lipid accumulates in the midzonal area of the lobule.

While the 'metabolic fat' discussed in the previous paragraph accumulates in small droplets and is principally found in the periportal zone, the action of hepatotoxins often results in accumulation of lipid in large droplets and principally in the centrilobular zone. It is clear that there is more than one mechanism for accumulation of fat in the liver but it seems likely that interference in the formation of VLDL particles plays a major role (Zimmerman, 1978). The protein synthesis inhibitor cicloheximide (cycloheximide) induces the development of a fatty liver that is correlated with loss of apoprotein B, which forms the core of the VLDL particle (Mori, 1983; Janero *et al*., 1984; Gibbons *et al*., 2004). In animals treated with ethionine, which decreases hepatic ATP levels, apparently by sequestering adenine (Okazaki *et al*., 1968), the lipoprotein particles are found in the endoplasmic reticulum, but not in the Golgi apparatus (Mori, 1983). Transfer from the endoplasmic reticulum to the Golgi apparatus is known to be exceptionally sensitive to low ATP levels (Farquehar and Palade, 1981). Colchicine interferes even further along the export pathway, causing depolymerization of the microtubule network that guides secretory vesicles from the Golgi apparatus to the plasma membrane (Mori, 1983). It would appear that many other toxins also cause steatosis by interfering with lipoprotein metabolism. Puromycin, like cicloheximide, is an inhibitor of protein synthesis. A similar mechanism was proposed for tetracycline toxicity but later work suggests interference in the assembly of lipoprotein particles (Deboyser *et al*., 1989). Choline deficiency, treatment with orotic acid and administration of phosphorus also inhibit the release of VLDL particles, by mechanisms that are not fully understood.

Inhibition of lipoprotein export is, of course, only one mechanism responsible for accumulation of fat in the liver. Fat accumulation is also caused by necrogenic toxins, such as carbon tetrachloride (see later). Fat accumulation also occurs in animals treated with valproic acid (Olson *et al*., 1987) and, at high doses, with perfluorodecanoic acid and related compounds (Borges *et al*., 1993). In these cases, fat accumulation appears to result from inhibition of fatty-acid oxidation. Fat accumulation also occurs in the human liver following alcohol abuse, but the mechanism remains obscure (Andrews and Snyder, 1991).

3.2.1.2.2 Effects on Lysosomes

Compounds may affect lysosomes in two ways. First, indigestible material may reach lysosomes and accumulate there, causing enlargement and interference in cellular function. Second, compounds may cross the lysosomal membrane and be trapped as a result of the difference in pH between lysosomes and the cytoplasm. The former route is rarely a major problem for toxicologists. Up to 5% of liver lysosomes are discharged into the bile each day (Godfrey *et al*., 1981) so, in general in the liver, materials do not accumulate in lysosomes. However, it would appear that there are circumstances in which fusion of lysosomes with the bile canalicular membrane is prevented and enormously enlarged lysosomes may accumulate in patients with haemochromatosis, Wilson's disease and the various lysosomal disorders (Watts, 1986). It would also appear that spontaneous changes may occur, because in ageing animals, including humans, lipofuscin granules, lysosomal residual bodies containing material with the staining properties of polymerized, peroxidized lipid, accumulate and this process may be accelerated in experimental animals by treatment with 'peroxisome proliferators' (Hinton *et al*., 1986) and with an imidazole antifungal drug (Nishikawa *et al*., 1984). Enlargement and labilization of hepatocyte lysosomes has also been observed in rats treated with the food dye Neutral Red (Abraham *et al*., 1967), although the mechanism of action has not been determined. Accumulation of material in the lysosomes of Kupffer cells may result in reticuloendothelial blockade and even in cell death (see later).

The acidity of the interior of lysosomes is below pH 5, whereas the cytosol is essentially neutral, having a pH of 7.2. As a result, weak bases may be trapped in lysosomes. Taking, as an example, a simple amine with a pK of 8.2: at pH 7.2, 10% of the molecules of this material will be in the nonionized form and therefore capable of dissolving in phospholipid membranes. Such a material may diffuse across the lysosomal membrane but, at the pH of the interior of the lysosome, less than 0.1% of the compound will be in the nonionized form, effectively trapping it within the lysosome. Such weak bases accumulate in lysosomes and, as they concentrate, water enters the lysosomes to maintain an osmotic balance, resulting in a marked distention of these organelles. The type of compound here is monensin (an ionophore antibiotic), which has

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

been much used in cell biology experiments, but similar effects will be produced by any compound with a p*K* between 7 and 9.5. Damage by this mechanism requires a high concentration of the compound and, because of the other biological activities of amines, this type of lysosomotrophy is rarely a practical problem, although some such effect may contribute to the antimalarial effects of quinine derivatives (Abraham *et al*., 1967).

3.2.1.2.3 Other Metabolic Inhibitors

Although the principal symptom of the action of many direct hepatotoxins affects fat metabolism, there are numerous exceptions. Galactosamine, for example, is capable of mimicking galactose to the extent that it is converted into uridine diphosphate (UDP)-galactosamine, but the galactosamine cannot be donated to glycoproteins. Thus uridine is effectively sequestered and the resulting depletion of UTP- and uridine triphosphate (UDP)-sugars has major metabolic consequences. Depending on the dose, the result is either acute hepatitis (with poor recovery) or chronic hepatitis and cirrhosis (Medline *et al*., 1970). Other compounds affect different systems. Phalloidin, a fungal toxin found on lupin products, prevents the depolymerization of fungal microfilaments. This results, by mechanisms that remain uncertain, in cholestasis, biliary hyperplasia, centrilobular hepatocellular necrosis and cirrhosis (Read, 1985; Peterson, 1990). The fungal toxin, phomopsin, is directly cytotoxic, but also interferes with cell division, preventing normal liver repair (Kelly, 1985). Another group of compounds, exemplified by griseofulvin, 3,5-diethoxycarbonyl-l,4-dihydrocollidine, inhibit ferrochelatase, resulting in an increase in porphyrin deposits (De Matteis *et al*., 1987; De Matteis and Marks, 1996). Similar deposits are seen in the livers of animals treated with hexachlorobenzene (a fungicide banned globally under the Stockholm Convention on persistent organic pollutants) and the antiarthritic agent 3-[2(2,4,6-trimethylphenyl)thiothyl]-4-methylsydnone (Greaves, 1990; McNamee and Marks, 1996), and in humans with a hereditary deficiency of ferrochelatase (Bloomer, 1988). On the basis of studies in mice, Sinclair *et al*. (2000) concluded that CYP 1A2 was essential in the processes leading to hexachlorobenzene-induced uroporphyria. Alteration in the metabolism of porphyrins is also implicated in the toxicity of metals, including lead and arsenic (see **Haematology and Toxicology** and the next section).

3.2.2 Hepatotoxicity of Metals, Near Metals and Their Compounds

Several metals are toxic to the liver. In some cases this is a reflection of their general toxicity. High doses of a number of transition metals result in liver damage, possibly from redox cycling. The effects of copper are especially notable. Liver damage from excess copper has been reported in experimental animals, domestic animals and in humans (Stokinger, 1981). Sheep are particularly susceptible (Kelly, 1985). Wilson's disease (Sternlieb and Scheinberg, 1985), a hereditary condition in humans probably involving a defect in the transfer of copper from hepatic lysosomes to bile, produces all the symptoms of copper intoxication. Bedlington terriers also show a hereditary disease with symptoms of copper intoxication, which probably involves a defect in copper excretion (Su, 1982).

Other transition elements are capable of causing liver damage. Salts of iron, cobalt and mercury cause liver damage in experimental animals under extreme conditions and, as with copper, hereditary human diseases, notably haemochromatosis, cause symptoms of iron intoxication at normal dietary levels (Powell, 1985). In general, however, the liver is less susceptible to transition-metal toxicity than other tissues, such as the kidneys. This is not because sulphur-binding metals such as copper, zinc, gold, bismuth and mercury do not reach the liver, but because the metals induce binding proteins, called metallothioneins, which sequester the metals resulting in their inactivation and, in the case of the liver, exit from the tissue (Ham, 1986).

Several of the less common metals and semimetals are hepatotoxins. Beryllium may induce granulomatous lesions in the liver, although its main toxic action is directed against the lung (Stokinger, 1981). Arsenic and its compounds induce hepatocellular damage, indicated by fatty change, particularly in the centrilobular zone. Electron microscopy showed vesicularization of the endoplasmic reticulum and intracellular damage indicated by an increase in autophagosomes (Ishinishi *et al*., 1980) and mitochondrial swelling (Fowler *et al*., 1977). Biochemical studies suggest that interference in the assembly of haemoproteins and redox cycling consequent on the release of free haem may contribute to the toxicity (Albores *et al*., 1989). Fatty liver is also induced by antimony administration (Stokinger, 1981).

Lanthanides cause hepatic changes (Arvela, 1979), although this is of limited practical importance as these elements are not well-absorbed by the gut. The lighter members of the series localize to the liver and, in large amounts, induce a fatty liver, whereas the heavier elements show less preference for the liver and cause focal necrosis without fatty change. Electron microscopy shows changes in the nuclei and the endoplasmic reticulum after treatment with the lighter lanthanides, but there is much less indication of systematic morphological changes after administration of the heavier elements in the series. The similarity in ionic radius of calcium and the lanthanides, first pointed out by Lettvin *et al*. (1964), suggests a possible mechanism of toxicity. There are, indeed, effects of lanthanides on other tissues, which can be directly related to calcium antagonism but, as discussed by Arvela (1979), there are many other interactions which may explain the hepatotoxicity. It is of interest, for example, that hepatic damage caused by

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

praseodymium is antagonized by silybin, an agent which also antagonizes the RNA-polymerase inhibiting toxins phalloidin and α-amanitin (Tuchweber *et al*., 1976). In addition to these effects some lanthanides affect Kupffer-cell function (see later).

The metalloid selenium is both an essential nutrient (it is a component of the active site of enzymes, *inter alia* glutathione peroxidase and thioredoxin reductase) and a potential toxicant. Excess doses of selenium cause liver atrophy, necrosis and haemorrhages in both experimental (Rouiller, 1964) and farm animals (Hogberg and Alexander, 1986), although liver effects are not particularly prominent in humans (ATSDR, 2009). In general, selenites are more toxic than selenates or selenium salts (see review by Alexander, 2007).

3.2.3 Toxins Requiring Metabolic Activation

In **Biotransformation of Xenobiotics**, Timbrell and Marrs point out that, in a number of cases, metabolism of a xenobiotic increases rather than reduces the toxicity. As the liver is the major site for xenobiotic metabolism, damage by 'active metabolites' plays an important role in chemically induced liver damage: thus even in 1964, Rouiller was able to list over 100 chemicals capable of causing acute or subacute damage to the liver. Since that time, many more chemicals capable of causing liver damage have been identified, but there is no agreement on their classification. The major reason why our understanding of acute hepatotoxicity is so poor, in spite of the efforts which have been made, is the sheer number of the parameters which have to be considered. These factors will include the identity and localization of the enzymes which produce the active metabolite, the nature and stability of the active metabolite, and secondary effects either due to 'message-passing' between liver cells or direct effects on cells other than hepatocytes.

3.2.3.1 Enzymes Involved in the Formation of Active Metabolites

It is a commonplace among toxicologists to say that chemical warfare is nothing new—plants and fungi have been engaged in it for millenia. Accordingly, animals have evolved very elaborate defence systems to detoxify xenobiotics and coevolution of plants and animals has resulted in significant differences in species; for example, the cat family, which are obligate carnivores, are notoriously deficient in some detoxication systems (see **Biotransformation of Xenobiotics**). As has already been mentioned, the highest concentration of xenobiotic-metabolizing enzymes is in the liver. Human liver contains numerous isoforms of cytochrome P450 and many isoforms of glutathione-S-transferase (Vermeulen, 1996). It is noteworthy that the spectrum of cytochromes P450 in human liver differs markedly from the spectrum found in rats. In addition, there may be marked differences between individuals. Thus poor metabolism of certain drugs is associated with polymorphism in isoforms of cytochrome P450 (CYP 1A2, CYP 2C18, CYP 2D6 and CYP 3A5), while it has been suggested that the 40% of the population which are deficient in the μ forms of glutathione-S-transferase may be more susceptible to certain carcinogens and an increased incidence of lung cancer has, indeed, been reported (Vermeulen, 1996). Hence, to summarize, we can state that: (i) xenobiotic-metabolizing enzymes differ both between individuals and between species and (ii) compounds may often be metabolized by more than one route (e.g. testosterone may be hydroxylated at several positions depending on which isoform of cytochrome P450 is involved). Hence variations in the balance of xenobiotic-metabolizing enzymes between species and between individuals may result in differences in the generation of active metabolites and hence in damage to the liver.

Although the majority of 'active metabolites' are formed by the action of isoforms of cytochrome P450, other enzymes may be involved. Probably the most important here are the glutathione-S-transferases and glucuronyl-, sulfo- and acetyltransferases. These enzymes are generally considered as protective, but metabolism of certain halogenated hydrocarbons, such as 1,2-dibromobenzene may result in the formation of the extremely reactive episulfonium ions which may enter the nucleus and bind to DNA (**Figure 15**). It should be noted that, in this case, the normal assumption that cytochromes P450 make toxic metabolites and glutathione-S-transferases destroy them is reversed, as dibromobenzene may also be metabolized by the cytochromes P450, especially CYP 2E1, to the stable bromoacetic acid. The toxicity of dibromobenzene will hence be modulated upwards by inducers of glutathione-S-transferase and downwards by inducers of CYP 2E1. Likewise, formation of glucuronate, sulfate or acetate conjugates is normally a final step in preparing a compound for excretion, but, in the case of certain aromatic amines, the hydroxylamine formed by the action of a cytochrome P450 is stable, but the conjugates are unstable and potent alkylating agents (see **Toxicokinetics of Xenobiotic and Metabolite Distribution and Excretion**). It must be stressed, however, that these are the exceptions that prove the rule; in general, active metabolites are formed by the cytochromes P450 and detoxified by glutathione-S-transferases.

3.2.3.1.1 Differences between Areas of the Liver Lobule

Generally, hepatotoxins have their principal effects on a particular portion of the liver lobule. In the majority of cases, damage is found principally in the centrilobular zone, but the effect of certain toxins, exemplified by allyl alcohol, is on the periportal hepatocytes. There are three reasons for these differences. First, there is the change in oxygen tension across the lobule; second,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

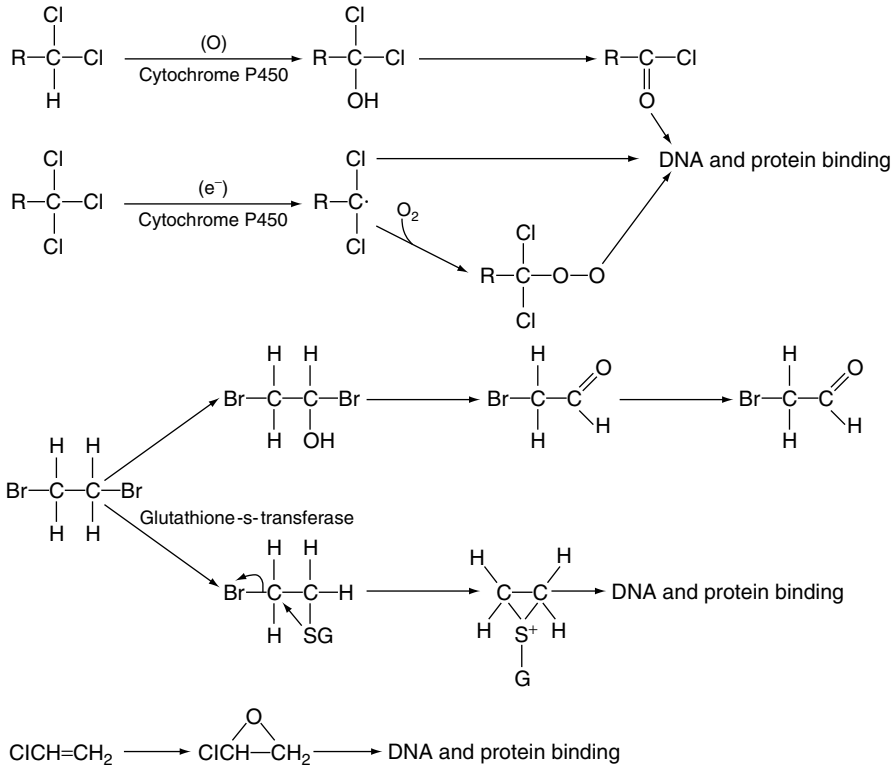

Figure 15 Scheme for the oxidation of haloalkanes and haloalkenes.

the enzymes involved in xenobiotic metabolism are not evenly distributed, for example in the absence of inducing agents most cytochromes P450 are located in the centrilobular zone of the liver; and also, when oxygen tension is low, the cytochromes P450 may catalyse reductive reactions, and these are responsible, for example, for the reduction of azo dyes and for the activation of the cytotoxic agents adriamycin and mitomycin C (Vermeulen, 1996). The factors discussed in the last paragraph mean that the majority of toxins which require metabolic activation, affect the centrilobular hepatocytes more than the periportal cells. However, there are exceptions to this rule. First, metabolism may not involve the cytochromes P450. Thus, for example, allyl alcohol is metabolized by oxidation to acrolein by alcohol dehydrogenase, and this reaction occurs more readily in regions of high oxygen tension leading to periportal toxicity. In other cases the reasons for zonal differences in toxicity are less clear. For example, the pyrrolizidine alkaloid retrorsine causes centrilobular necrosis in rats, mice and guinea pigs, periportal necrosis in hamsters and focal necrosis in chickens and monkeys (White *et al.*, 1973).

In addition to interspecies variation affecting the site of liver damage, alterations may also be seen if pretreatment has resulted in induction of a particular isoenzyme or group of isoenzymes. It is, of course, obvious that induction of an isoform of P450 which generates active metabolites will enhance toxicity, while induction of an alternative path of metabolism is likely to be protective and that the contrary will be the case with inhibitors. However, sometimes pretreatment with a substrate for the isoform responsible for producing the active metabolite may be protective. An example here is that a small dose of carbon tetrachloride protects against a subsequent larger dose, the reason being that the carbon tetrachloride is acting as a 'suicide substrate', the metabolite bonding to, and inactivating, the enzyme. This will reduce the liver's ability to metabolize the subsequent dose, hence less active metabolite will be formed and there will be less damage.

In addition to altering the amount of damage, preinduction may also affect the localization of damage, a phenomenon called 'floating necrosis'. This is exemplified by the action of the sesquiterpenoid, ngaione. This produces midzonal lesions in untreated rats, periportal lesions in rats treated with phenobarbitone and centrilobular lesions in rats pretreated with inhibitors of cytochrome P450 (Kelly, 1985). In a similar way, the effects of cocaine in the uninduced rat are centrilobular, but may be shifted by induction to be midzonal and even to the periportal zone (Powell *et al.*, 1991). The reason is unknown, but two factors appear to contribute to this phenomenon. First, while cytochromes P450 in uninduced rats are concentrated in the centrilobular zone, after induction, the distribution becomes more even and there may even be accumulation in the periportal area. Second, the fact that necrosis is seen in a band rather than across the lobule suggests that, in these cases, optimum

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

formation of the toxic metabolite occurs preferentially in an oxygenated zone, provided that the concentration of the appropriate cytochrome P450 is sufficiently high.

3.2.3.1.2 The Nature of the Active Metabolite

The active metabolites formed in the liver will vary in their reactivity and this will, in turn, determine the type of damage which occurs. This is true even where the active metabolite is a free radical. It is frequently assumed that these are the 'mad axemen' of the intracellular world, but in fact the free radical most commonly formed in the body, the superoxide radical, is too weak to cause lipid peroxidation (it can, however, be transformed to the hydroxyl radical, which most certainly can). Inversely correlated with the reactivity of the active metabolite will be its half-life. For example, 1-aminobenzotriazole is metabolized by a range of cytochromes P450 and produces a metabolite which reacts with the P450 molecule itself, inactivating the enzyme, and this phenomenon extends to organs other than the liver (Knickle and Bend, 1992). There is, however, practically no damage to the liver, probably because there is no significant release from the enzyme. In the case of carbon tetrachloride, the free radical produced by its metabolism does bind to and destroy the cytochromes P450 to some extent. However, it is also released from the enzyme, causing severe damage to the interior of the cell. The metabolite is, however, too short lived to enter the nucleus in significant amounts and hence there is no genotoxicity (see review by Weber *et al*., 2003). Mutagenic carcinogens such as dimethylnitrosamine, on the other hand, both cause cytoplasmic damage and enter the nucleus, binding to the DNA. Finally, the active metabolites produced from the pyrrolizidone alkaloids are so long lived that they not only damage the vasculature of the liver, but also pass to the lungs, causing damage there (WHO, 1988). Hence the damage which an active metabolite causes will be determined both by its reactivity, in particular whether it is potent enough to cause lipid peroxidation or bind to DNA, and also by its half-life in the environment of the cell interior

3.2.3.1.3 Influence of Nonhepatocytes

It has long been known that the body's response to tissue damage involves, not only the damaged cells themselves, but also other cell types, but details of the message-passing system operating in the liver remain obscure. The best characterized example of cooperation is between Kupffer cells and hepatocytes. Here it has been shown that interference in Kupffer cells by administration of gadolinium chloride reduces the liver damage caused by carbon tetrachloride (Edwards *et al*., 1993), paracetamol (acetaminophen) (Laskin, 1989), cadmium (Kayama *et al*., 1995) and allyl alcohol (Przybocki *et al*., 1992), while activation of Kupffer cells enhances the toxicity of carbon tetrachloride (Sipes *et al*., 1989). The mechanism by which the Kupffer cells influence hepatocytes is not known. Kupffer cells are known to produce TNF-α and TGF-β, both of which are capable of inducing apoptosis in hepatocytes and, given the liver's powers of regeneration and the risk of damage to DNA in severe cell injury, it would seem logical that damaged cells should be removed and, indeed, an increase in apoptotic cells has been reported in damaged livers (Gopinath *et al*., 1987). However, El-Hassan *et al*. (2003) have shown that, while inhibitors of caspases (proteases involved in apoptosis) inhibit the later stages of paracetamol toxicity, the relationship between hepatocyte damage and apoptosis is not simple. Marked cell–cell interactions are observed first in liver enlargement, where HGF, one of the major hepatocyte mitogens, is secreted by stellate cells, while fibrosis in the liver is controlled by a message-passing system involving hepatic stellate cells and Kupffer cells. It is also clear that sinusoid endothelial cells are also involved in message passing, but the nature and toxicological implications of this remain obscure.

3.2.4 Chronic Damage to the Liver

3.2.4.1 Fibrosis Including Cirrhosis

Repair of the liver parenchyma normally occurs by regeneration. However, repeated injury, for example by alcohol abuse in humans or repeated carbon tetrachloride administration in experimental animals, may eventually cause fibrotic changes in the parenchyma. In addition, repair by fibrosis may be observed in the small spontaneous granulomatous lesions observed in laboratory rats and in similar lesions induced by highly immunogenic materials, such as bacterial cell walls or pig intestinal alkaline phosphatase (PAP) (Dijkhuis *et al*., 1989). There is strong immunohistochemical evidence that the fibroblast-like cells in small PAP-induced granulomas are derived from stellate cells (Dijkhuis *et al*., 1989). Fat stellate cells synthesize collagen and proliferate when stimulated by factors derived from Kupffer cells (Zerbe and Gresner, 1988) and it is extremely likely that these cells will be stimulated in viral infections or by foreign carbohydrates or proteins. Repair by fibrosis may also be observed following administration of single doses of certain compounds, notably the pyrrolizidine alkaloids (WHO, 1988), which cause livestock poisoning worldwide, one plant responsible being common or tansy ragwort (*Senecio jacobaea*). Comfrey (*Symphytum officinale* L.) is a source of exposure in man. The reason why pyrrolizidine alkaloids induce fibrosis is unknown, but, as discussed earlier, the acute effect of these compounds is a haemorrhagic necrosis associated with damage to branches of the hepatic vein, changes frequently described in farm animals, including horses, and in humans (e.g. Dimande *et al*., 2007) (see also Section 3.2.3.1.1 and COT, 2008). Damage associated with blood clots is normally repaired by fibrosis in extrahepatic tissues and it is possible that this is also

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the case in the liver; it has also been suggested that the fibrosis is related to the biotransformation of alkaloids by hepatic microsomal enzymes (Stickel and Seitz, 2000).

It is also not clear why repeated insults to the liver by carbon tetrachloride, ethanol and other compounds result in repair by fibrosis. It could be that fibrosis requires that the repeat insult should occur before the earlier damage is fully repaired. In the early stages of injury to hepatocytes, fibrosis is observed together with an increase in reticulin fibres in the space of Disse. This in turn is associated with metaplasia of the hepatic stellate cells to a myofibroblast morphology.

There would thus appear to be two factors which may contribute to the development of further fibrotic change on continued insult. First, it appears that the sparse reticulin network in the space of Disse plays the role of a basement membrane in guiding liver regeneration and changes to these reticulin fibres associated with collapse of the parenchyma may prevent repair by regeneration. Second, as proliferation of all cells depends on secretion of growth factors from neighbouring cells, changes in the secretion of these factors or in the sensitivity of the target cells may change the balance between regeneration of hepatocytes, and proliferation and transformation of fat-storing cells. Thus, for example, the transformation of stellate cells to myofibroblasts is controlled by, amongst other things, factors secreted by Kupffer cells and hepatocytes, while the myofibroblasts secrete TGF-β, a negative growth factor for hepatocytes (Hautekeete and Geerts, 1997; Bissell, 1998). This is controlled by the bone-morphogenetic protein (BMP)-7, an important antagonist of the actions TGF-β (Gressner *et al*., 2008). It is important to stress the word balance; repair by regeneration continues in parallel with development of fibrosis and plays a critical role in the development of the cirrhosis.

The processes which lead from fibrosis to cirrhosis are much better understood (McGee *et al*., 1992; Bataller and Brenner, 2005; Friedman, 2008). With continued bouts of cell death and fibrous repair, the fibrous septa extend and form links between adjacent central veins, and between portal tracts and central veins. Capillaries develop in these tracts and enlarge to form veins, allowing blood to flow directly from the portal tract to the central vein, thereby bypassing the parenchyma. This results in further cell death followed by further fibrous repair. The condition is self-sustaining and the liver is reorganized into nodules of cells separated by connective tissue septa. The circulation in the nodules is highly disturbed so that foci of cell loss alternate with areas of regeneration. Overall, however, there is a progressive loss of liver substance leading finally to hepatic failure and death.

3.2.5 Hepatocarcinogenesis

Primary liver cancer of humans is not particularly common in North America or Europe, but it is much more common in east and southeast Asia and sub-Saharan Africa, amongst the aetiological factors being alcohol and aflatoxins (Kew, 2002; Gomaa *et al*., 2008). Hepatocellular adenomas and carcinomas are frequently observed in experimental animal studies. These tumours may be induced both by genotoxic and nongenotoxic agents. Furthermore, any treatment which causes chronic hepatocellular damage or which results in a persistent increase in the size of the liver is likely to promote the action of a genotoxic carcinogen and, in fact, many of these regimens will actually increase the incidence of liver cancer on their own. In the past there has been much emphasis on determining whether particular chemicals are genotoxic. Protocols using a combination of several promoters, such as that described by Moslen *et al*. (1985), have been devised to increase the sensitivity of assays for liver carcinogenesis. Emphasis has also been placed on the role of promoters (Ames *et al*., 1987; Cohen and Ellwein, 1991).

The stages in the development of liver cancer appear to be the same in spontaneous tumours and in tumours induced by genotoxic and nongenotoxic carcinogens. The first detectable changes are the development of foci of altered cells (Pitot, 1990). These are small groups of cells, sometimes visible using conventional staining techniques, but generally only detectable by histochemical techniques. The early foci are extremely heterogeneous in their enzyme composition. These early foci do not appear committed to tumour development and, under some experimental conditions (see later), may regress completely. It is nevertheless thought that some foci of altered cells do progress to the second stage of liver carcinogenesis, the development of distinct hyperplastic foci that compress the surrounding tissue. Small hyperplastic foci can, again, reverse completely, but larger foci develop into adenomas and, in some cases, carcinomas. The morphology of liver carcinomas is very varied, but tumours induced by nongenotoxic agents generally remain well differentiated, even in metastases, while those induced by the more potent genotoxins may be very anaplastic.

The incidence of cancer in the liver, as in many other tissues, is influenced by many factors (see above). Conventionally, discussion is divided between considerations of initiators, that is compounds where a single treatment is sufficient to start the processes which lead to cancer, and promoters, compounds not carcinogenic on their own, but which increase the incidence of cancer following treatment with an initiator. This is simplistic when applied to the liver because the classic hepatic 'promoters' are almost all carcinogens in their own right when administered to mice over a lifetime. We consider the compounds under two major headings: compounds which appear to act as direct mutagens and 'nongenotoxic' carcinogens, which in turn are split into compounds which cause chronic liver damage and compounds which cause persistent liver enlargement. It should be noted,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

however, that both classes of nongenotoxic hepatocarcinogen strongly promote the action of genotoxic agents and theoretical considerations suggest that the enlarged or damaged liver which results from the action of nongenotoxic hepatocarcinogens may be especially susceptible to the action of genotoxic agents.

3.2.5.1 Mutagenic Hepatocarcinogens

Examples of aromatic amines which increase the incidence of cancer in humans and experimental animals are given in **Table 5**. The majority of the compounds contain two aromatic rings; aromatic amines with a single ring either do not increase cancer incidence or are very weak carcinogens. It is also noted that there is a marked interspecies variation in the target organ, with liver cancer generally being found only in mice. The mechanism of action (King *et al*., 1988) appears to involve N-oxidation by cytochromes CYP 1Al and CYP 1A2 to form the corresponding hydroxylamine. Once formed, these can yield the reactive nitrenium ion at an acidic pH or by oxidation (**Figure 16**). Alternatively, there may be further metabolism to form the *N*-hydroxy sulfate or *N*-hydroxy acetyl derivatives. Spontaneous decomposition of these again results in the formation of nitrenium ions, and of DNA and protein adducts. Acetylation or sulfation appears an absolute requirement in the case of N-acetylated or N-arylated amines. It is likely that the greater potency of the polycyclic aromatic amines, and their derivatives, as carcinogens results from their ability to facilitate the formation of nitrenium ions by derealization of its excess electrons. It should be noted that the cytochromes P450 which oxidize aromatic amines have marked structural specificity (Williams and Weisburger, 1991). For example, 1- and 3-acetylaminofluorene are not carcinogenic, unlike 2-acetylaminofluorene. The three corresponding hydroxylamines are equally carcinogenic. The difference arises because the liver is unable to metabolize the 1- and 3-isomers. As there are marked interindividual variations in the human population in the ability to N-hydroxylate arylamines, it would seem likely that there will be equally marked differences in sensitivity to these compounds.

Nitro analogues of carcinogenic aromatic amines also lead to tumour formation (Williams and Weisburger, 1991). These compounds may be reduced by rather weakly active mammalian enzymes and by gut bacteria to hydroxylamines, which can then be further metabolized as described in the previous paragraph. As the nitro reductases are much less specific than the cytochromes P450 which oxidize aromatic amines, it appears possible that these compounds may be more widely toxic. In practice, this does not seem to be the case. Whereas 1-hydroxyaminonaphthalene is carcinogenic, 1-nitronaphthalene is not, presumably because the rate of reduction of the nitro group to the carcinogenic hydroxylamine is much lower than the rate of reduction of the hydroxylamine to an amino group. 1-Naphthylamine is not oxidized by CYP 1Al and so there can be no re-formation of the hydroxylamine, whose steady-state concentration is therefore extremely low. However, the effects of equivalent nitroaryl and aminoaryl compounds may sometimes be very different: 2,4-diaminotoluene is a potent carcinogen, whereas 2,6-diaminotoluene is consistently negative (Cunningham *et al*., 1991). 2,6-Dinitrotoluene is, however, a much more potent carcinogen than 2,4-dinitrotoluene (King *et al*., 1988). As discussed earlier, part of the explanation may lie in the fact that 2,4-diaminotoluene is a potent hepatotoxin

and hence increases cancer incidence by a nongenotoxic mechanism. All in all, the varying toxicities of aromatic amines and nitro compounds show the difficulty of predicting toxicity from chemical structures, even when the metabolic pathways linking the compounds are well understood.

Aromatic azo compounds can be divided into two distinct groups (Williams and Weisburger, 1991). In the first group are simple compounds consisting of two aromatic groups joined together by an azo bond. These compounds include hepatocarcinogens such as dimethylaminoazobenzene (Butter Yellow) (IARC, 1975a). Carcinogens in this group have an amino group attached to one of the aromatic rings and are metabolized in exactly the same way as the amines described above. The azo group bridging the two rings allows efficient delocalization of the electrons in the nitrenium ion. The carcinogenicity of these compounds is influenced by two factors. First, the azo bond may be reduced, yielding noncarcinogenic or very weakly carcinogenic monocyclic aromatic amines. Second, compounds containing polar constituents such as sulfonic acid residues, are usually not carcinogenic.

Complex azo dyes consist of polycyclic structures generally linked by more than one azo group. With the simple azo dyes, the reductive splitting of the azo group is a detoxification reaction and simple monocyclic amines are released, but with the complex materials, the same reaction releases polycyclic aromatic amines which, as seen earlier, may be potent carcinogens affecting both the liver and other tissues.

The *N*-nitroso compounds of interest to toxicologists are derivatives of secondary amines, amides or ureas; *N*-nitroso derivatives of primary amines are not stable. They are readily formed in the digestive tract by the reaction of a secondary amine with nitrite, which is formed in the body from nitric oxide. *N*-Nitroso compounds are almost all potent carcinogens. The target organ, however, differs between species and between compounds. Nitroso derivatives of alkylureas, alkyl amides and esters are exceedingly potent carcinogens, but normally the liver is not the major target organ. These unstable compounds decompose spontaneously, yielding alkylating agents, on contact with aqueous solutions, especially of a neutral or alkaline pH. *N*-Nitroso derivatives of linear secondary amines such as dimethylnitrosamine or of cyclic amines such as morpholine require metabolism and are thus much more likely to affect the liver. Such *N*-nitrosamines are activated by hydroxylation on a carbon adjacent to the nitrogen (**Figure 17**). This results in cleavage of the carbon–nitrogen bond yielding first a diazonium and then a carbonium ion, both of which are potent alkylating agents. Although such metabolism is theoretically possible for all *N*-nitrosamines in the livers of all species, there is, as already mentioned, a marked variation in sensitivity. Discussion of the reasons for these differences may be found in monographs by Bartsch *et al*. (1987) and O'Neill *et al*. (1991).

Metabolism of dialkylhydrazines can yield products identical to those produced by *N*-nitrosamines (**Figure 17**). As substituted hydrazines are more uncommon than secondary amines both in nature and in industry, much less is known about their toxicity. However, there are indications that there is likely to be the same variation in target organ as with the *N*-nitrosamines (Williams and Weisburger, 1991). Probably the most important compound in this class is cycasin, a compound found in cycad flour. Cycasin is the glucoside of methylazoxymethanol: the glucose is removed by bacterial hydrolysis in the gut, releasing methylazooxymethane, a powerful carcinogen affecting the liver, kidney and intestinal tract (Williams and Weisburger, 1991).

It is generally assumed that toxins are, in some way, unnatural compounds. This is certainly not the case. There are few direct benefits to plants or fungi

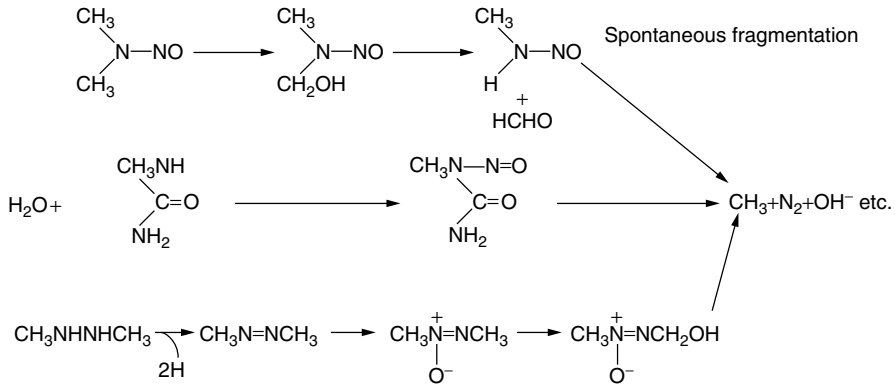

Figure 17 Scheme for the metabolism of *N*-nitrosamines and dialkylhydrazines.

in being eaten, with the result that both groups have developed chemical deterrents. Many of these compounds are very potent hepatotoxins (**Table 6**). These materials are commonly complex polycyclic hydrocarbons with a wide variety of substituents and there are few common features apart from their ability to be metabolized to electrophiles. The mechanisms by which they cause liver damage and liver cancer are the same as the synthetic chemicals discussed earlier. The more potent hepatotoxins were considered in some detail by Kelly (1985) and structure–activity relationships in general were discussed by Ashby and Tennant (1988).

3.2.5.2 Nonmutagenic Hepatocarcinogens

A considerable number of the chemicals which increase the incidence of tumours in the liver give no evidence for mutagenicity in either prokaryotic (Ashby and Tennant, 1988; Ashby *et al*., 1989) or eukaryotic (Williams *et al*., 1989) tests. The mechanism by which they increase cancer incidence is not known. On initial examination most fall into four distinct groups, namely agents which cause chronic damage to the liver, agents which cause proliferation of peroxisomes, agents which cause proliferation of smooth endoplasmic reticulum, and possibly agents which cause proliferation of mitochondria. However, as discussed at the end of this section, it is possible that, with three of the groups, the underlying superficial dissimilarities belie an underlying connection: persistent enlargement of the liver (Grasso and Hinton, 1991). The first group, however, is mechanistically distinct.

3.2.5.2.1 Agents Causing Chronic Liver Damage

There is a close association between chronic tissue damage and the induction of cancer (Butterworth *et al*., 1991; Grasso *et al*., 1991). Eschenbrenner and Miller (1945) showed that chloroform increased liver cancer at doses which were hepatotoxic, but not at lower doses.

Table 6 Natural products that show marked hepatotoxicity

Chemical	Chemical class	Source species	Action
Methylazoxymethanol	Aglycone of glycoside	Cycadales (plants)	Alkylating agents
Ngaione	Furanosesquiterpenoid	Myoporaceae (plants)	Zonal necrosis
Trematoxin	Glycoside	Ulmaceae (plants)	Periportal necrosis
Aflatoxins	Bisfuranocoumarins	*Aspergillus* (fungi)	Alkylating agents
Phomopsin	Not characterized	Moulds on *Lupinus* spp.	Mitotic arrest
Sporidesmin	Not characterized	Moulds on dead ryegrass	Cholestasis
'Many compounds'	Pyrrolizidine alkaloids	Many plants	Alkylating agents Cirrhosis Endothelial damage[a]
Lantadenes (identical to Icterogenin)	Triterpenes	*Lantana camera* *Lippia rehmanni*	Cell enlargement Cholestasis

These plant and fungal products have been responsible for widespread loss of cattle and, especially, sheep. The list is intended to demonstrate the range of sources and effects on the liver and is in no way exhaustive. In particular it should be noted that where soil contains abnormal amounts of trace components such as selenium there may be marked concentrations in growing plants and resultant toxicity.
[a]Petasitenine also induces endothelial cell tumours.
Kelly (1985).

More recently, the link between cell proliferation and carcinogenesis has been emphasized by Klaunig *et al*. (1986), who demonstrated that rats treated with chloroform by gavage or in the drinking water showed the same very small amount of DNA binding, but liver damage only developed in rats treated by gavage and it was only these animals which developed tumours. In an earlier paper (Grasso and Hinton, 1991), references were cited showing an association between liver damage and tumour induction in animals treated with carbon tetrachloride, tetrachloroethylene, 1,1,2,2-tetrachlorethane or paracetamol (acetaminophen), all agents known to be nonmutagenic. Ethionine should probably be added to this group (Farber, 1963). Selenium is another possible member of this class of carcinogen (IARC, 1975b) (see review by Rayman, 2005). At nontoxic doses, selenium has anticarcinogenic properties (Combs and Clark, 1997; Yu *et al*., 1997; Burns *et al*., 2008), but, as noted earlier, selenium is markedly hepatotoxic at high doses and at these doses tumours have been observed (Fishbein, 1987).

3.2.5.2.2 Compounds Causing Mitochondrial Proliferation

Methapyriline and certain close analogues (Reznik-Schuller and Lijinsky, 1981) cause marked proliferation of mitochondria, liver enlargement in short-term studies and cancer in the longer term. The effects seem to be specific to rats (see Copple *et al*., 1992). It is of interest that other close analogues of methapyriline cause peroxisome proliferation (Reznik-Schuller and Lijinsky, 1982). Although methapyriline is negative in most *in vivo* and *in vitro* mutagenicity tests, there is binding to cell proteins and suppression of mitochondrial protein and DNA synthesis (Lijinsky and Muschik, 1982; Copple *et al*., 1992). It has been shown that there is a sustained increase in the rate of cell division (Cunningham *et al*., 1995), suggesting that these compounds should be classified as inducers causing sustained damage to the liver.

3.2.5.2.3 Compounds Causing Peroxisome Proliferation

Proliferation of peroxisomes in the liver of rats and mice treated with a number of lipid-lowering drugs was noted in the 1960s, but it was only in the early 1980s, when a connection with increased cancer incidence was noted (Cohen and Grasso, 1981; Reddy and Lalwani, 1984), that much interest was taken in these compounds. Since then compounds in this group have been extensively studied. The results have been extensively surveyed by the European Chemical Industry Ecology and Toxicology Centre (ECETOC, 1992) and in books edited by Gibson and Lake (1993) and Reddy *et al*. (1996). The phenomenon of induction of peroxisome proliferation extends to compounds other than antilipidaemic drugs, including phthalate esters of branched-chain alcohols, typified by di-(2-ethylhexyl)phthalate (DEHP) (Howarth *et al*., 2001), and the herbicide dicamba (Espandiari *et al*., 1995).

Although there are marked variations in potency between different peroxisome proliferators, the development of hepatic changes are remarkably uniform. There are major species differences in the response to peroxisome proliferators (Gonzalez and Shah, 2008). Thus marked peroxisome proliferation is only found in old-world rodents (family Muridae). There are marked differences even within this family, with rats and mice responding much more vigorously than hamsters. It is unlikely that other species are totally nonresponsive. The most potent peroxisome proliferators are reported to have some effect on rhesus monkeys (Lalwani *et al*., 1985), but xenobiotic-induced peroxisome proliferation is not generally seen in humans; however, marginal effects have been reported for some fibrate hypolipidaemic agents such as clofibrate and cyprofibrate (Hinton and Grasso, 2000). Humans express much less PPAR-α, which is required for peroxisome proliferation, than mice (see reviews by Green, 1995; Lake, 1995; Klaunig *et al*., 2003). It is reasonable, however, to conclude that peroxisome proliferation is probably metabolically important to rats and mice, but is vestigial outside this family of animals. Neither animal studies nor exceedingly comprehensive epidemiological surveys (Committee of Principal Investigators, 1978) in human populations have given any evidence that these materials increase cancer incidence in species where peroxisome proliferation is not observed and it is generally believed that any marked peroxisome proliferation is predictive of a carcinogenic potential in rodents, but that this does not automatically indicate a hazard to humans.

Several studies have been carried out on the development of hepatic changes in rats treated with peroxisome proliferators (Mitchell *et al*., 1985; Price *et al*., 1986; ECETOC, 1992). These changes appear to be mediated by binding of the compounds to specific nuclear receptor(s) (Green, 1993; Reddy and Chu, 1996; Espandiari *et al*., 1998) (see also **Nongenotoxic or Epigenetic Carcinogenesis**). The earliest change is an accumulation of small lipid droplets similar to those found in hyperphagia which are possibly associated with alterations in fatty-acid metabolism (Mitchell *et al*., 1986). Messenger RNAs for a specific cytochrome P450, CYP 4A1, and for the peroxisomal proteins (Milton *et al*., 1990) accumulate within a few hours of treatment. Consequent on these changes are a burst of cell division, which occurs two to three days after first administration of diets, and the accumulation of specialized peroxisomes lacking a uricase-rich core, smooth endoplasmic reticulum and a specific, cytosolic, epoxide hydrolase (Meijer and de Pierre, 1987). Peroxisome proliferators are further discussed in **Toxicity of Peroxisome Proliferators**.

In Section 2.5, the distinction was made between adaptive and toxic changes. It is likely that the changes mentioned above are essentially adaptive, permitting, for example, oxidation of peroxidized fatty acids. Treatment

for one month or more results in changes clearly indicative of toxicity, namely the accumulation of enlarged lysosomes filled with material with the staining properties of lipofuscin and, at least in some cases, an increase in cell turnover (Price *et al*., 1986; Cattley *et al*., 1987). Dose–response experiments suggest that with each compound there is a distinct threshold for these latter effects, suggesting they represent the result of some form of metabolic overload. More prolonged treatment results in the development of foci of altered cells. These foci differ from those formed spontaneously or in response to microsomal inducers such as phenobarbital in that they lack γ-glutamyl transpeptidase and foetal-type glutathione-S-transferase activity (Rao *et al*., 1982; Sato, 1989). These foci and at least some of the hyperplastic nodules which develop on more prolonged treatment reverse on withdrawal of the compound (Mompon *et al*., 1987), but if treatment is continued, well differentiated hepatocellular carcinomas appear, which occasionally show metastases, particularly to the lungs. The mechanism of carcinogenesis is not fully understood, but is generally believed to be associated with liver enlargement rather than oxidative stress (Belury *et al*., 1998; also see below).

3.2.5.2.4 Compounds Inducing Microsomal Oxidases

Whereas compounds causing proliferation of peroxisomes may be treated as a single group, this is not the case for compounds which induce microsomal enzymes. Furthermore, there has been considerable controversy about the mechanism of carcinogenesis by certain compounds, such as the food dye safrole, which are potent inducers of microsomal oxidases, but are also weakly mutagenic in certain *in vitro* tests. In the following discussion we will attempt to group the compounds, but the classification is very tentative.

First, it should be noted that phenobarbital (IARC, 1987) and other compounds, such as BHT (Inai *et al*., 1988), which induce cytochrome CYP 2B isoforms almost invariably increase the incidence of liver cancer in mice when administered at high doses. These compounds all cause massive liver enlargement, are potent promoters of the action of genotoxic carcinogens, and give negative results in both *in vivo* and *in vitro* mutagenicity tests. In general, these compounds do not increase cancer incidence in species other than mice, although Rossi *et al*. (1977) did report an increase in rats following three years administration of phenobarbital. It is generally believed that with this group of compounds an increase in liver tumours in mice alone does not indicate any risk to humans. This attitude is supported by studies showing high spontaneous rates of initiation of proto-oncogenes in the livers of strains of mice susceptible to liver cancer (Anderson *et al*., 1992).

At first sight, the polyhalogenated aromatic and alicyclic hydrocarbons would appear to form a second, group but, in fact, these compounds fall into two or more distinct subclasses. The first group is formed by TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) and the planar polychlorinated biphenyls (PCBs) and polybrominated biphenyls (PBBs) and related compounds. These induce a group of enzymes, controlled by the Ah locus, which induce cytochrome CYP 1Al and 1A2 (Nebert and Gonzalez, 1987). These compounds increase the fat in the liver and cause alterations in the RER, changes which are not observed with the nonplanar PCBs, which are phenobarbital-type inducers (Kohli *et al*., 1979). TCDD, PCBs and PBBs all increase the incidence of liver cancer (IARC, 1987). It is of interest that another group of inducers which act on the Ah locus, the polycyclic aromatic hydrocarbons, neither affect liver size nor cause any increase in liver tumours, although they are potent carcinogens.

The second group of halogenated hydrocarbons which increase the incidence of liver tumours are heavily substituted alicyclic compounds. The following have been assessed as hepatocarcinogens (IARC, 1979a; IARC, 1987): 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), 2,4,6-trichlorophenoxyacetic acid (2,4,6-T) (obsolete herbicides), aldrin/dieldrin, mirex, photomirex, chlordecone hydrate, lindane, chlordane and toxaphene (organochlorine insecticides). These compounds induce a poorly characterized spectrum of cytochrome P450s. They also produce massive liver enlargement and it is of interest that, whereas α-,β-,γ- and δ-hexachlorocyclohexane were all effective inducers of cytochromes P450, only the γ-isomer (lindane) was a hepatocarcinogen in mice (FAO/WHO, 2003), and that it is by far the most potent in causing liver enlargement (Grasso and Hinton, 1991). There is generally little liver damage apart from some accumulation of fat, although in mice treated with dieldrin, Mallory bodies accumulate in the cytoplasm (Meierhenry *et al*., 1981).

With two hepatocarcinogens, the food dyes Ponceau MX (Grasso and Gray, 1977) and safrole (Crampton *et al*., 1977), the increase in microsomal enzymes reverses on prolonged administration of the compound. Electron microscopic examination, however, shows continued proliferation of the endoplasmic reticulum (ER) and enlargement of lysosomes. Such 'hyperplastic, hypoactive' ER has also been observed in rats treated with dieldrin, but not in mice treated with the same material (Tennekes *et al*., 1979) and it is likely that the carcinogenicity of Ponceau MX and safrole is attributable to other factors (see IARC, 1976 for a review of the carcinogenicity of safrole).

There is no evidence for a direct mechanistic relationship between induction of microsomal oxidases and development of cancer. A common feature to all the compounds discussed in this section is continued liver enlargement with little liver damage. This is also observed with other groups of nongenotoxic hepatocarcinogens and will be discussed later. It should also

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be noted that most of the compounds discussed in this section are only weak carcinogens when administered on their own, but all are potent promoters of the action of genotoxic carcinogens.

3.2.5.2.5 Hormones

Certain types of combined oral contraceptive appear to increase very slightly, but significantly, the risk of cancer incidence in human patients (IARC, 1987). The tumours produced are typical of those induced by nonmutagenic hepatocarcinogens in experimental animals being normally benign, well differentiated and, in some cases, they appear to regress on cessation of treatment (Klatskin, 1977). In animal trials, increases in liver tumours have been observed with ethinyloestradiol, the progestins, ethynodiol diacetate, norethisterone and norethynodrel, as well as various oestrogen–progestin combinations (IARC, 1979b), but there is no evidence for mutagenicity. Several oestrogens are capable of promoting the action of mutagenic carcinogens (IARC 1979b). The best-characterized hormone which induces liver cancer is the synthetic progestin cyproterone acetate. This increases the incidence of liver tumours both in mice and in rats (Tucker *et al*., 1996). The actions of cyproterone acetate have been studied extensively by Schulte-Hermann and his colleagues (see Grasl-Kraupp *et al*., 1998). This agent is a potent inducer of the CYP 3A subfamily of cytochromes and causes marked liver enlargement. There is some evidence that human liver cells have the capacity to activate cyproterone acetate to genotoxic intermediates (Kasper, 2001; Brambilla and Martelli, 2002).

3.2.5.2.6 Other Compounds or Treatments

The incidence of liver cancer, like that of other tumours, in rodents is affected by diet. Increased incidences have been found in rats induced to eat a hypercaloric diet, whereas the incidence of tumours falls when food intake is restricted (Cheney *et al*., 1983; Pollard and Luckert, 1989). The incidence of liver tumours is also increased in rats receiving a choline-deficient diet (Mikol *et al*., 1983). The increase is not caused by the associated liver damage, as an increase in hepatic tumours is also found in rats following transient choline deficiency in early life (Ghosal *et al*., 1987). Choline deficiency results in hypomethylation of DNA (Wainfen *et al*., 1989). DNA methylation is important for maintaining the accuracy of postsynthetic repair and cell differentiation, and it is thought that DNA hypomethylation, in itself, increases the risk of cancer (Rogers, 1995).

3.2.5.3 Liver Enlargement and Liver Remodelling by Apoptosis and Carcinogenesis

Although it was believed in the early 1980s that all carcinogens acted directly on the cell's genome, by the end of that decade it had become generally accepted that there were carcinogens which did not cause mutations in short-term prokaryotic or eukaryotic test systems, and that these fell into two major groups: agents which caused persistent tissue damage and those which produced tissue enlargement without causing a sustained increase in the rate of cell division (Grasso *et al*., 1991; Hildebrand *et al*., 1991). Into the latter group fell, not only xenobiotics, but also a considerable number of hormones, for example thyroid adenomas are found when there is sustained elevation of thyroid-stimulating hormone (TSH), pancreatic acinar cell cancer when there is elevation of cholecystokinin, and carcinoid tumours when there is persistent elevation of gastrin. The response of the liver to inducers of microsomal and peroxisomal enzymes resembles the responses induced by the trophic hormones. There is a burst of cell division which is complete by about three days of the initiation of treatment. Enlargement of the postmitotic cells results in the tissue weight continuing to rise for a few more days, but then tissue weight stabilizes and the half-life of the cells returns to its normal value.

In normal circumstances, the liver weight is carefully controlled and, if it falls, due to toxic damage or to surgical removal of some of the liver, it rapidly returns to its original value. It is thus clear that the body is able to measure accurately the liver weight (or more precisely the liver: body-weight ratio) and induce mitosis or apoptosis to make any suitable adjustments. It was thus felt that the compounds which cause liver enlargement worked by affecting this control mechanism so that, in the presence of the compound, liver weight was controlled at a higher value than normal, but when the compound was withdrawn, the control point reverted to its normal value. Unfortunately, more recent studies suggest that this simple and elegant hypothesis is incorrect.

The control of liver regeneration following partial hepatectomy has been reviewed by Michalopoulos (2007). Repair of the liver following partial hepatectomy follows a similar time course to chemically induced liver enlargement. There is a rapid shift of hepatocytes from G_0 to G_1, DNA synthesis in hepatocytes peaks at around 24 hours and mitosis at around two days. Although the signalling pathways leading to cell division are not known for certain, it would appear that TNF-α plays an important part in the process. Levels of this cytokine rise within minutes of partial hepatectomy. TNF-α induces IL-6. This would appear to play a vital role in regeneration as liver regeneration is inhibited in IL-6 knockout mice. TNF-α *in vitro* can induce synthesis of the HGF in stellate cells and also of the nuclear factor CCAAT/enhancer binding protein β (C/EBPβ). HGF is a paracrine mitogen acting on hepatocytes, and could be the proximate effector of cell division. Obviously there have to be factors which stop further cell division when the liver cell number has been restored. Expression of IL-10, which down-regulates TNF-α, occurs soon after partial hepatectomy, while synthesis of TGF-β, which

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat068
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

inhibits hepatocyte division, begins about 24 hours after partial hepatectomy.

It has already been mentioned that the time course for hepatocyte DNA synthesis and replication is similar in liver repair and in chemically induced enlargement. However, when liver enlargement is induced by cyproterone acetate or nafenopin, there is no increase in expression of the 'first early' genes *c-myc*, *c-fos* and *c-jun*, although there is following partial hepatectomy or induction of liver enlargement by lead nitrate or ethylene dibromide (Coni *et al*., 1993). Further, when liver enlargement is induced by cyproterone acetate, there are no changes in C/EBPα or β, whereas both change following partial hepatectomy (Skrtic *et al*., 1997). Other authors report no increases in mRNA for TNF-α, TGF-α or HGF following treatment with a peroxisome proliferator (Ohmura *et al*., 1996), and no increase in TGF-β or its receptors in rats treated with the peroxisome proliferator, nafenopin, or with cyproterone acetate (Grasl-Kraupp *et al*., 1998), although Jirtle *et al*. (1991) reported a sustained increase in TGF-β in rats treated with phenobarbital and Oberhammer *et al*. (1996) reported an increase following treatment with cyproterone acetate at doses sufficiently high to induce apoptosis. It would therefore seem that, whereas the time courses of cell division and DNA synthesis in repair and chemically induced liver enlargement are similar, there are fundamental differences in mechanism and there may also be differences between the effects of different classes of inducer.

These differences between the control of liver enlargement and of liver repair emphasize that the enlarged liver is in an abnormal state. In the enlarged liver a continued drive to cell division is balanced by an antimitotic mechanism, which, in the past, was believed to come from the action of TGF-β. It is generally believed that tumours induced by genotoxic carcinogens arise from mutations in genes involved in the transduction of positive growth factors, such as *H-ras*. However, in the enlarged liver there is a second group of genes involved, those which stop the chemically induced cell division. The importance of these genes is shown by the fact that the preneoplastic lesions may be totally removed by apoptosis when treatment ceases. The influence of the negative growth factors is also emphasized by the increased rate of apoptosis in preneoplastic and neoplastic lesions (Grasl-Kraupp *et al*., 1998). It would thus seem likely that, as discussed by Andersen *et al*. (1995), the increased rate of liver cancer in rats treated with agents which cause liver enlargement is due to mutation in the genes which limit cell division which allows clones of cells to divide, and that these cells differ from normal hepatocytes in some way, as they are selectively removed when the liver remodels after withdrawal of the compound from the diet (Schulte-Hermann *et al*., 1995).

3.2.6 Toxic Damage to Sinusoid Endothelial Cells

Sinusoid endothelial cells may be damaged by direct-acting liver toxins or as a result of the release of toxic metabolites from neighbouring hepatocytes. The destruction of sinusoid endothelial cells will cause haemorrhage or, if there is also damage to hepatocytes, haemorrhagic necrosis. There are few toxins which appear to act directly on the endothelium. Sinusoidal endothelial cells do, however, appear to be affected by allyl formate earlier than any other cell types (Haenni, 1964), and light microscopic studies suggest a similar lesion may be produced by urethane (Doljanski and Rosin, 1944) and alloxan (du Bois, 1954). Pyrrolizidine alkaloids cause destruction of the endothelial cells of sinusoids and branches of the hepatic vein, apparently due to a metabolite produced in the hepatocytes (WHO, 1988). In this case, the damage to endothelial cells is clear because of the effects on the venous endothelium, but it is likely that similar, but milder, 'by-stander' damage will occur with other toxins. Certain genotoxic carcinogens, such as thioacetamide and Butter Yellow cause enlargement and hyperactivity of endothelial cells (Simon and Rouiller, 1963).

The numbers of tumours arising from endothelial cells (angiosarcomas) can be increased by certain compounds. The most notable of these is vinyl chloride, which, in animals, produces a range of tumours, including angiosarcomas, especially in the liver. In humans, exposure to vinyl chloride is associated with an increase in a range of tumours, in addition to hepatic angiosarcomas (IARC, 1987). Vinyl chloride is a potent mutagen and it is not known why exposure should be associated with this particular tumour. Vinyl chloride is metabolized in hepatocytes by P450 isoenzymes which, as discussed earlier, gives rise to products with protein- and DNA-binding capacity that are detoxified by glutathione. There is no obvious reason why the sinusoid endothelial cells should be the targets, although evidence now points to action involving the formation of genomic DNA adducts (see **Nongenotoxic or Epigenetic Carcinogenesis**).

Angiosarcoma in humans has also been associated with exposure to arsenic (Lander *et al*., 1975). Most early effects of arsenic are, however, on hepatocytes and these have been discussed earlier. Angiosarcomas have also been found in patients treated with colloidal thorium dioxide (thorotrast) which was, at one stage, employed as an X-ray contrast medium (Swarm, 1967) and is probably associated with accumulation of the radioactive material in the neighbouring Kupffer cells (discussed in the next section).

3.2.7 Toxic Damage to Kupffer Cells

Particulate material taken up by Kupffer cells that is not digestible by lysosomal enzymes may be retained in the liver for very long periods. If the material is radioactive

Table 7 Compounds that cause bile duct necrosis and bile duct proliferation without hepatocellular damage

Compound	Species	Reference
α-Naphthyl isothiocyanate	Rats, mice	Goldfarb *et al*. (1962)
Sporidesmin	Sheep[a]	Kelly (1985)
FPL 52757	Dogs[b]	Eason *et al*. (1982)
Dibutyltin	Rats, mice[c]	Barnes and Magee (1958)
Arsenic (III) or (V) compounds[d]	Rats, dogs	Byron *et al*. (1967), Ishinishi *et al*. (1980)
Tilidine fumarate	Rats	McGuire *et al*. (1986)
Oxamniquine	Rats[e]	Gregory *et al*. (1983)
Methylenedianiline	Rats	Kanz *et al*. (1992)

[a]Direct injection of the alkaloid into rabbit gall bladder also produces a lesion (Worker, 1960).
[b]Bile duct damage in rats may be produced by retrograde infusion (Eason *et al*., 1982).
[c]Development of the lesion probably depends on interaction with pancreatic enzymes (W. N. Aldridge, personal communication).
[d]Arsenic (III) and (V) compounds also induce damage to hepatocytes in the centrilobular area.
[e]Not dogs, mice or hamsters and probably (Chvedoff *et al*., 1984) not humans.

this may have serious consequences. Colloidal thorium dioxide (thorotrast) was used as an X-ray contrast medium up to 1945. Thorium is radioactive, emitting alpha particles. Patients exposed to thorotrast retained thorium in the liver for many years and have developed a range of tumours both in the liver and at other sites of accumulation. Liver tumours have included tumours arising from hepatocytes (hepatomas), from BD lining cells (cholangiomas) and from endothelial cells (angiosarcomas) (Swarm, 1967). Uptake of 'indigestible' material may also result in loss of Kupffer-cell function and reticuloendothelial blockade, for example gadolinium chloride (Bouma and Smit, 1989), dextran sulfate (Laskin, 1989) and carrageenen (Abraham *et al*., 1972) are taken up by Kupffer cells and inhibit their function.

Kupffer cells may also modulate the effects of xenobiotics on hepatocytes. This may occur through processing of the toxin; for example, it appears that the uptake of colloidal beryllium into Kupffer cells and the subsequent release of the free ion play a significant role in the toxicity of this metal (Skilleter, 1987). Alternatively, the interaction may be complex; for example, inactivation of Kupffer cells attenuates the toxicity of paracetamol (acetaminophen) (Laskin, 1989) and of allyl alcohol (Przybocki *et al*., 1992), whereas activation of Kupffer cells enhances the toxicity of carbon tetrachloride (Sipes *et al*., 1989). In the brain, much of the damage following ischaemic injury results from the secondary effects mediated through glial cells and it is interesting to speculate that inappropriate release of mediators from Kupffer cells may, likewise, exacerbate hepatic damage.

3.2.8 Toxic Damage to Bile Duct Lining Cells

A small number of compounds are specifically toxic to the BD lining cells (**Tables 7** and **8**). This does not appear to be due to a special susceptibility of these cells to the action of the toxin, but rather to the concentration of compounds as they pass down the biliary tree. Toxic changes are, therefore, normally confined to middle- and large-sized ducts. In two cases, the mycotoxin, sporidesmin (Mortimer, 1963; Kelly, 1985), and the antiasthmatic, FPL 52757 (Eason *et al*., 1982), toxicity is due to the parent compound. However, with other compounds, such as α-naphthyl isothiocyanate (ANIT), the actual toxin is a metabolite produced by the hepatocytes (Horky *et al*., 1971; Connolly *et al*., 1988b). The pattern of change is consistent with a toxin, possibly a glutathione conjugate (Carpenter-Deyo *et al*., 1991) escaping from the BDs and, indeed, electron microscopy shows opening of the tight junctions between BD lining cells (Connolly *et al*., 1988a). In addition to damage to the BD lining cells there is also marked portal oedema and haemorrhage, presumably from damage to the small

Table 8 Compounds that cause damage to hepatocytes and bile duct proliferation

Compound	Reference
Ethionine	Farber (1963)
Tannic acid	Korpassy (1961)
Thioacetamide	Ambrose *et al*. (1949)
Flectol H	Panner and Packer (1961)
Allyl alcohol and allyl formate	Haenni (1964)
Butter Yellow[a]	Buyssens (1962)
Pyrrolizidine alkaloids	WHO (1988)
Stilbamidine	Seager and Castelnuovo (1947)
Aflatoxin A_1	Busby and Wogan (1984)
Coumarin[a]	Evans *et al*. (1989)

[a]These compounds increase the incidence of cholangiocarcinoma in rats.

blood vessels of the peribiliary plexus. In mice there is destruction of the gall bladder epithelium (Connolly *et al*., 1988b). Acute lesions heal rapidly; in rats total biliary necrosis produced by ANIT resolves within seven days with restoration of the normal architecture (Plaa and Priestley, 1976). Chronic treatment with such agents will lead to lethal liver failure if the dose is sufficient to prevent repair of the vessels, but if repair is possible, BD proliferation occurs.

Some di- and trialkyltin salts also cause BD damage, an example being di-*n*-butyltin dichloride (Merkord *et al*., 2001). The lesion is only found in species in which there are anastomoses between the BD and the pancreatic ducts (WHO, 1990), and mainly consists of an ascending cholangitis that affects initially the extrahepatic portion of the BD (Barnes and Magee, 1958). The mechanism of damage is not understood.

Arsenical compounds (III or VI) produce centrilobular damage to hepatocytes and damage to the biliary tree. The organic arsenical candidate chemical-warfare agent, dichloro(2-chlorovinyl)arsine (lewisite) has been observed to produce changes in the liver and epithelial necrosis (and even transmural necrosis) of the gall bladder in experimental animals (Inns *et al*., 1988; Inns and Rice, 1993; Marrs and Maynard, 2007).

3.2.9 Bile Duct Proliferation

3.2.9.1 Idiopathic or Infectious

It should be noted that spontaneous BD proliferation occurs in hamsters and in many strains of rat in the second year of life (Greaves, 1990), and that BD changes, up to and including cholangiocarcinoma, are sometimes observed in ageing dogs and cats (Kelly, 1985). The lesions cannot be distinguished from those consequential on BD damage described in the next section. Marked BD proliferation may follow infection with certain liver flukes, such as *Fasciola hepatica*, which may infest the BDs. It is believed that the changes following such infestations result from damage to the duct by the parasite (Kelly, 1985) and hence have a similar pathogenesis to the lesions described in the next section.

3.2.9.2 Consequences of Bile Duct Damage

Repeated exposure to toxins affecting the BDs results in marked proliferation. With chronic treatment, the initial damage caused by the toxin resolves by fibrosis. After a short time, heavily vascularized immature connective tissue is seen between the ducts. The BDs are embedded in dense connective tissue. Histochemical staining shows that the blood vessels of the peribiliary plexus no longer abut directly on to the basement membrane of the duct, but are separated from it by a ring of connective tissue (Kelly *et al*., 1991). It would seem that development of this type of BD proliferation involves two processes. First, the process exemplifies the 'rule' that acute injuries tend to heal by regeneration, but that chronic injuries heal by fibrosis. However, the proliferation of ducts and the separation of the vulnerable blood vessels from the ducts suggest that this is an adaptive change that increases the ability of the liver to excrete cytotoxic materials into the bile.

3.2.9.3 Proliferation Associated with Periportal Damage

Hyperplasia of the BDs and ductules occurs with a number of hepatotoxins, including ethionine, tannic acid, thioacetamide, allyl formate, 4-dimethylaminoazo benzene (Butter Yellow), lasiocarpine and stilbamidine. With these compounds, unlike the materials discussed in the previous section, damage to BDs appears proportional to the degree of hepatocellular damage (Rouiller, 1964). In other cases, exemplified by the antioxidant BHT, a very mild BD proliferation is observed at doses below those required to cause frank periportal necrosis (Powell *et al*., 1986). In some cases BD proliferation with these agents resembles that described in the previous section, namely well-defined BDs often surrounded by fairly dense connective tissue, grouped within distinct portal tracts. In other cases a different pattern is observed. In the minimal lesion, small BDs with little associated connective tissue appear to grow into the parenchyma. With other agents (Fausto *et al*., 1987), exemplified by the hepatocarcinogens ethionine, 2-acetylaminofluorene and 3′-methyl-4-dimethyl aminoazobenzene, the proliferating cells no longer form distinct ducts, but are found as strings of so-called oval cells. These have now been isolated and found to be a mixed population, a portion of which are committed BD lining cells, while others have the potential to differentiate into either hepatocytes or BD lining cells (Fausto, 1990). It is thought possible that these cells, which possibly arise from a small population of stem cells present in the normal liver, are associated with the process of carcinogenesis (Fausto, 1990). An increased prevalence of BD proliferation and portal sclerosis were noted in female rats in the mid- and high-dose 80 ppm after 52 and 104 weeks of treatment with fentin (triphenyltin), a fungicide (FAO/WHO, 1992). Cyhexatin (tricyclohexylhydroxystannane), an acaricide, produced BD hyperplasia in both sexes in a two year feeding study in rats (FAO/WHO, 1979). The relationship between these lesions and those seen with alkyl tins is unclear.

3.2.10 Cholestasis

The word cholestasis means simply the absence of bile flow and covers several distinct pathological conditions. Firstly, there is mechanical obstruction of the extrahepatic duct from either gall stones (cholelithiasis) or external pressure, for example carcinoma of the head of the pancreas. Secondly, there is obstruction of intrahepatic BDs, normally as a result of inflammation. Finally, there exist changes in hepatocytes, which may interfere

with the initial secretion of bile into the BC, either by inhibiting the secretion of bile acids and bile salts (the fluid component of bile enters by passive diffusion) or by altering the permeability of the tight junctions which prevent materials passed into the bile canaliculus from returning to the plasma. In experimental animals, treatment with agents causing biliary obstruction results in proliferation of BDs and focal necrosis in the liver parenchyma. Treatment with cholestatic agents which affect hepatocytes, on the other hand, does not generally cause damage to hepatocytes or BD lining cells, although bile plugs may be observed in BC and ducts.

The most common form of gall stone is composed of cholesterol and calcium salts, often arranged in alternating layers (Karran *et al*., 1985; Thomas, 2008). Pigment stones also occur, especially in Asiatic countries, and consist largely of salts of bilirubin (Leuschner *et al*., 1994). The two types of stone are thought to form by different mechanisms. Biliary cholesterol is dissolved in the interior of mixed micelles formed by phospholipids, and bile acids and salts. Normal human bile is technically supersaturated in cholesterol, but this does not normally crystallize. It is thought that crystallization may be provoked by the formation of nucleation centres, short-term fluctuations in cholesterol secretion and changes in the stability of bile micelles with changes in bile salt composition (Heaton, 1985). Formation of pigment stones is associated with infection of the biliary tree: the β-glucuronidase secreted abundantly by bacteria such as *Escherichia coli* breaks down bilirubin glucuronides and causes precipitation of free bilirubin (Karran *et al*., 1985). There is probably a threshold to this process, as normal bile contains an inhibitor of β-glucuronidase (Godfrey *et al*., 1981). Cholelithiasis is not normally associated with the administration of xenobiotics, but an increase in gall stones has been reported in patients treated with clofibrate and possibly similar drugs (Committee of Principal Investigators, 1978; Backes *et al*., 2007).

The normal cause of intrahepatic biliary obstruction in experimental animals is damage to BD lining cells. Compounds causing such damage have been considered earlier. There are, however, a few materials which appear to cause intrahepatic obstruction by a distinctive mechanism. Geeldikkop is a photosensitizing disease of sheep in South Africa and there have been similar reports from other countries, including Australia (Glastonbury *et al*., 2008). Geeldikkop appears to result from an interaction between sporidesmin (a mycotoxin) and a component of puncture vine (*Tribulus terrestis*) and the BD becomes blocked with crystalline material of unknown composition (Kelly, 1985). Similar crystals have been observed in sheep intoxicated by other phytotoxins. It has been suggested that the spontaneous BD proliferation observed in some strains of ageing mice may also be associated with obstruction by a crystalloid material (Lewis, 1984). Treatment of rats with benzofuran also causes symptoms of intrahepatic cholestasis but, in this case, there is no evidence of damage to the BD (Connelly, 1988). At autopsy, gross dilation of the extrahepatic BD was noted and it would appear possible that spasm of the sphincter of Oddi may play a role in inducing cholestasis with this material.

Whereas intrahepatic obstructive jaundice is a relatively minor problem in experimental animals, it is a major problem in clinical practice in humans (Read, 1985). The condition was described in the early 1950s with chlorpromazine (van Ommen and Brown, 1955), and the response to phenothiazines is typical of this lesion (see also Section 3.2.1.1). This adverse effect is confined to a small minority of patients who may show marked hypersensitivity. Patients affected are jaundiced, and liver biopsies show portal tract inflammation, sometimes with a high eosinophil content, and some damage to hepatocytes. An immunological mechanism has long been suspected, but cannot be proven. It is of interest that BD lining cells are a major target in autoimmune disease and that, following liver transplantation, the BDs are especially liable to rejection (Welsh and Male, 1989). Investigation of these conditions has been hampered by the fact that, even after immunological manipulation, it has proved impossible to reproduce the condition in experimental animals.

As mentioned earlier, the formation of bile is a complex process and it is therefore not surprising that there are many classes of compound that induce intrahepatic cholestasis by interference with bile secretion (Oelberg and Lester, 1986; Kukongviriyapan and Stacey, 1991; Plaa, 1991). The classic agents, in this case, are anabolic and contraceptive steroids. The mechanism of action of these compounds remains obscure. There is a lag phase of approximately 12 hours before the establishment of cholestasis. There are some indications for both interference in the uptake of bile acids into hepatocytes and for alterations in membranes which might affect tight-junction structure. It remains unclear how far the mechanism of cholestasis by steroids correlates with the mechanism of cholestasis by D-ring glucuronide conjugates of oestrogens or testosterone. Unlike the parent steroids, the effect of these compounds is immediate and clearly dose dependent. In this case there is evidence for a direct competition with bile acids at the bile canalicular plasma membrane.

In addition to steroids and their glucuronides, many other classes of compound induce cholestasis at the canalicular level. The monohydroxy bile acid, lithocholate, has a cholestatic effect, probably after conjugation with taurine. Studies show that taurolithocholate inhibits taurocholate uptake into hepatocytes (Schwenk *et al*., 1977), but cytological examination of the livers of treated animals shows dilation of the Golgi apparatus and loss of microvilli from BC, which would appear

to be independent events. The reason why the immunosuppressive drug ciclosporin (cyclosporin A) can induce cholestasis is equally obscure, but this may be related to inhibition of transport of bile acids (Kukongviriyapan and Stacey, 1991). Cholestasis following the intake of manganese is observed in both humans and experimental animals. It has been demonstrated that the mechanism requires interaction of manganese and bilirubin at the bile canalicular membrane, but why, given that bilirubin excretion is responsible for only a tiny proportion of bile flow, this should result in cholestasis remains obscure. A mechanism involving hydroxy-3-methylglutaryl coenzyme A reductase and cholesterol 7α-hydroxylase has been proposed (Akoume *et al*., 2003; Goering, 2003).

The compounds mentioned in the last few paragraphs are only a small proportion of those capable of causing cholestasis through their action on hepatocytes. As the compounds described are 'the best understood' it will be clear how limited is our present knowledge of the mechanisms of cholestasis at the canalicular level, despite the availability of animal models. It is to be hoped that the development of *in vitro* techniques, such as the use of hepatocyte doublets and microanalytical techniques may assist solution of these problems in the future. Xenobiotic-induced cholestasis has been reviewed (Mohi-ud-din and Lewis, 2004).

The reduction of bile flow is a serious toxicological problem, but an increase in bile flow (choleresis) is without any serious consequences. Passage of water into bile appears to occur by passive diffusion across the tight junctions between hepatocytes. Normally this is governed by the rate of secretion of bile acids and bile salts. The administration of large doses of compounds whose metabolites are excreted into bile will result in an increase in bile flow and, often, dilation of BC. On their own, these are changes without long-term implications.

ACKNOWLEDGEMENTS

The authors are grateful to past and present colleagues, and especially to Professor L. J. King, Dr. S. Cottrell, Dr. C. Ioannides, Dr. D. Lewis, Dr. C. Powell and Dr. J. Fowler for advice on specialized points, and to Dr. S. C. Price, Dr. S. Singh and Miss D. Chescoe for provision of electron micrographs.

Toxicology of the Exocrine Pancreas

John R. Foster

CONTENTS

1 INTRODUCTION

The exocrine pancreas is a medium-sized organ lying below the stomach and attached, via mesenteric connective tissue, between the duodenum and the spleen. It has a primary function in the production and secretion of digestive enzymes, under neurohormonal control, into the small intestine via a complex, anastomosing, ductal system which empties into the duodenum, either in combination with the common bile duct, as in man and the rat, or, in species such as the pig, as a separate system each of which opens into the duodenum via a separate duct. Approximately 60% of the human population possesses an additional, accessory pancreatic duct, which empties directly into the duodenum without fusing with the bile duct.

The possession of extremely large amounts of digestive enzymes requires safety measures to avoid their premature activation within the organ and consequential autodigestion, but anatomical variances, disturbances of metabolism and secretion in both the pancreas and the liver, and in particular unfavourable lifestyle choices, such as alcoholism, can rapidly induce life-threatening disease in the organ.

DOI: 10.1002/9780470744307.gat069
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In the context of toxicology, changes, which in other organ systems would lead to adaptation, can rapidly progress to wholesale organ failure and death in the pancreas.

Clinical and experimental evidence suggests that the physiology and function of the exocrine pancreas intimately determines its vulnerability. A complete understanding of the features of the organ that make it susceptible to toxicity requires an appreciation of the evolutionary and anatomical links between the pancreas, the gastrointestinal tract and the liver.

Because of the potentially vast scope of this chapter, the bibliography largely relates to the section on toxicology. Individual references on other aspects of pancreatic disease can be found in alternative reviews on the pancreas (Cano *et al*., 2007; Howat and Sarles, 1979; Go *et al*., 1993); monographs on pancreatitis (Grigorescu and Grigorescu, 2005; Behrman and Fowler, 2007; Lee and Enns, 2007; DiMagno and DiMagno, 2006; Nair and Lawler, 2007; Talukdar *et al*., 2006; Braganza, 1991; Kingsnorth, 1996) and pancreatic cancer (Koorstra *et al*., 2008; Hart *et al*., 2008; Moossa, 1980; Scarpelli *et al*., 1987; Hezel *et al*., 2006), and in the journal series *Current Opinion in Gastroenterology* (Braganza, 1990; Fernandez-Zapico *et al*., 2003; Weber and Adler, 2003).

2 NORMAL PANCREAS

2.1 Embryology/Phylogeny

The mammalian arrangement of the hepatopancreatoduodenal complex is a relatively recent phylogenetic development compared to that of the drug-metabolizing enzyme systems (**Figure 1**).

The pancreas develops through two evaginations of the foregut endoderm during the fifth week of gestation in man. It is ventral, initially bilobed, and grows out from the lateral aspect of the hepatic bud. Duct systems appear in each outgrowth by the sixth week and open into the gut tube. By the seventh week the duodenum rotates to become a retroperitoneal organ. The two rudimentary glands of the pancreas then fuse, so that the dorsal bud forms the bulk of the gland while the ventral bud forms the inferior aspect of the 'head' and the uncinate process.

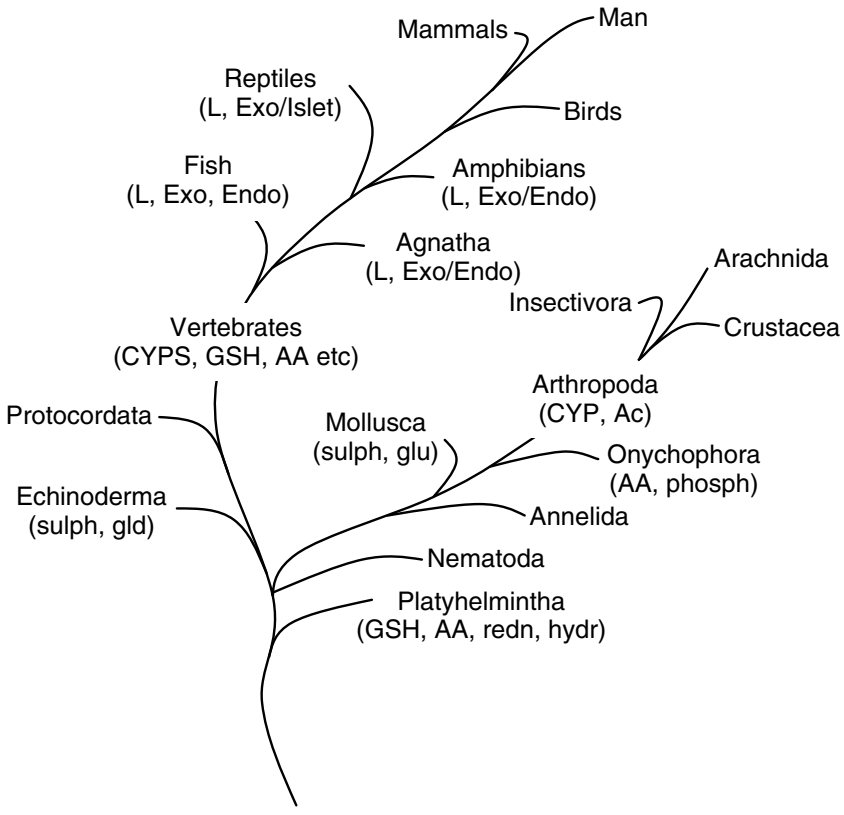

Figure 1 Phylogenetic tree showing that xenobiotic enzymes were present in animals well before the components of the liver and pancreas separated. Conjugating reactions with glutathione (GSH), amino acids (AA), sulfate (sulph), glucose (glu) and glucuronic acid (gld). Primitive degradation reactions are present with reduction (redn), and hydrolysis (hydr); cytochrome P450 dependent oxidation (CYPs) and acetylation (Ac). L = liver; Exo = exocrine pancreas; Endo = endocrine pancreas; Islet = islet arrangement. (Reproduced with permission from Braganza, 1991. © Manchester University Press.)

The duct of the larger dorsal bud (duct of Santorini) opens directly into the gut through a tiny orifice on the minor duodenal papilla; while, a fraction distally, the major papilla is the entry point for the joint bile duct and duct of the ventral pancreas (duct of Wirsung). In 10–80% of humans these two ducts may fuse into a common channel, the ampulla of Vater; smooth muscle surrounding the lower end of each duct, and of the ampulla, forms the sphincter of Oddi. During the seventh week of gestation the duct systems of the pancreas fuse, and the section of dorsal duct between the site of fusion and the minor duodenal papilla usually withers away. In approximately 5% of individuals fusion fails to occur and gland drainage relies largely on Santorini's duct. This condition in man, 'pancreas divisum', is recognizable by endoscopic retrograde cholangiopancreatography (ERCP).

Pancreatic acini, the secretory units, bud off the distal-most cells of the elongating duct system. A lobular arrangement is seen in man in the fourth month and acinar cells are functional a month later, as shown by abundant rough endoplasmic reticulum (RER) and the development of zymogen (enzyme precursor) granules. As morphological differentiation occurs so does the transcription and translation of those genes involved in the production of the digestive pancreatic enzymes. Prior to the appearance of zymogen granules (ZGs), very small amounts of carboxypeptidase, amylase and chymotrypsin can be detected within the gland, but as ZGs appear morphologically during development there is a surge in the transcription of the messenger RNA (mRNA), followed by the appearance of large amounts of the protein, for all of these digestive enzymes within the organ. In man, therefore, enzyme secretion begins in the 26th week of gestation, coincident with the emergence of the trypsinogen activator, enterokinase, in the duodenum.

Endocrine cells are present as single cells within the ductal epithelium from which they undergo extensive proliferation, and during the last trimester they begin to organize into islet-like clusters and undergo additional remodelling and maturation after birth before assuming the adult islet arrangement (Habener *et al*., 2005).

2.2 Applied Anatomy

The pancreas lies deep in the upper abdomen, usually in a transverse plane at the level of the first lumbar vertebra. The pancreas in man has a head, a neck, body and a tail. The hepatic portal vein is formed posterior to the neck of the pancreas by the union of the superior mesenteric and splenic veins (**Figure 2**). The pancreatic head lies within the curve of the duodenum and is usually seen encompassing the lower part of the common bile duct. The body and tail extend to the left, across the vertebral column and the tail ends at the spleen. The body lies superior to the duodenal-jejunal flexure.

In laboratory animals the organ is more diffuse, but the rough divisions can still be made out. The gland is surrounded by a thin condensation of retroperitoneal connective tissue and no definite capsule can generally be made out, as is seen in other abdominal organs.

The pancreatic duct begins in the tail and runs towards the head region where it fuses with the bile duct before emptying into the second part of the duodenum at the greater duodenal papilla. A second, accessory pancreatic duct drains part of the head which empties separately into

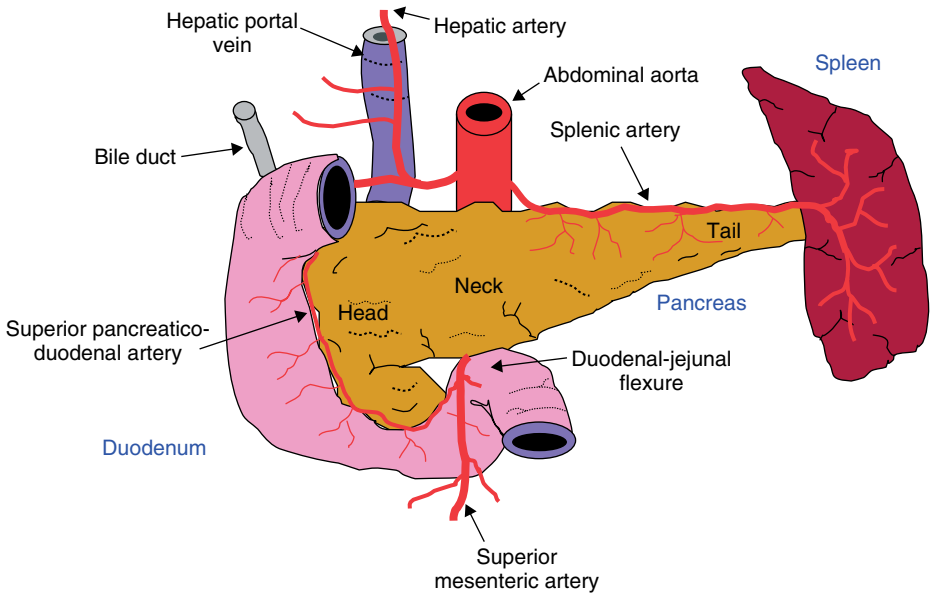

Figure 2 Anatomical relationship between the pancreas, the spleen and the duodenum showing the major blood vessels.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat069
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the duodenum proximal to the greater duodenal papilla. The exocrine pancreatic secretions flow from the tail towards the head before emptying into the duodenum.

The pancreas is closely related to a number of important blood vessels: behind it lie the aorta, the inferior vena cava, the superior mesenteric artery and the portal vein; along its upper border are the hepatic and splenic arteries. The pancreatic head receives its blood supply via the anterior and posterior superior pancreaticoduodenal arteries (from the hepatic artery via the gastroduodenal artery) and by the anterior and posterior inferior pancreaticoduodenal arteries (from the superior mesenteric). The remainder of the organ is supplied by branches of the splenic artery. Venous drainage is into the hepatic portal vein. Lymphatics on the surface of the pancreas lead into a complex system of lymph nodes.

The pancreas has extrinsic and intrinsic innervation and autonomic control is critical in regulating exocrine secretion. Parasympathetic innervation is effected via the vagal nerves, which act upon ganglion cells within the pancreas. These neurones in the ganglia are capsaicin-sensitive and contain substance P, calcitonin-gene-related peptide and low levels of norepinephrine and dopamine (Love *et al*., 2007; Buijs *et al*., 2001) and they lie within the connective tissue being most abundant in the head and neck regions. The ganglion cells are also innervated by the axons from the enteropancreatic neurones of the stomach and duodenum allowing local reflux control by the gastrointestinal tract, which almost certainly signals the mechanical and physicochemical states of the stomach and proximal small intestine to coordinate pancreatic secretion (Noble and Liddle, 2005). In contrast to the pancreatic ganglia, pancreatic duct cells have been shown to contain large amounts of epinephrine and 5-hydroxytryptophan, and moderate amounts of norepinephrine (noradrenaline) and dopamine (Yi *et al*., 2004). Pancreatic enzyme secretion is thought to be under the control of cholecystokinin (CCK) and serotonin and the vago-vagal reflex activating the cholinergic post-ganglionic neurons of the pancreas. Evidence suggests that at least for CCK in man, regulation occurs via the vagal cholinergic pathway rather than it acting directly on the ganglia cells, which were found not to express functional CCK receptors (Owyang and Logsdon, 2004).

2.3 Microanatomy

The exocrine pancreas is a lobular, compound tubuloalveolar gland with the lobes being separated by thin connective tissue that is continuous with that surrounding the outside of the gland. A variable proportion of the gland's blood supply passes directly to pancreatic islets and hormone-enriched blood may then enter acinar lobules before draining into veins. An insular-acinar 'portal' circulation would favour zonality of pancreatic exocrine function, in the same way as the simple hepatic acinus describes a microcirculatory functional unit in the liver. This concept would rationalize the higher levels of pancreatic enzymes in 'peri-insular acini', which display changes associated with hyperactivity. The acini are irregular oval or elongated glands comprised of a single layer of pyramidal-shaped cells with the apex of the pyramid defining the lumina of the acini while the broad base of each cell lies on a basement membrane and sparse connective tissue stroma (**Figure 3A**). The nucleus lies at the base of each acinar epithelial cell surrounded by abundant RER (**Figure 3B**). The ZGs are arranged at the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

apex of each cell and appear as black oval bodies by electron microscopy.

The apical cytoplasm of the acinar cells is packed with large round ZGs (0.8–1 μm in diameter), which appear eosinophilic, in contrast to the RER, which appears basophilic, in haematoxylin and eosin-stained histological sections. Pancreatic duct cells can be seen as flattened cells with pale cytoplasm and while the larger ducts are totally lined with these cells, the beginning of the duct system can be observed where small intercalated ducts are half lined by acinar cells and half by clearly designated ductular epithelial cells.

2.4 Structure–Function Relationships

The RER manufactures intramembranous digestive, and lysosomal, enzymes. The luminal plasma membrane projects microvilli consisting of bundles of microfilaments containing actin, myosin, tropomyosin, β-actinin and villin. The microvilli are anchored to a terminal web, an extension of the inner leaflet of the plasma membrane. Freeze-fracture studies show that the bulk of ZGs are located near the apical plasma membrane in readiness for exocytosis, but also that vesicles impinge against the basolateral membrane of the acinar cell, apparently for discharge directly into the interstitial space.

Ductal cells are equipped to secrete a bicarbonate-rich fluid: they have abundant mitochondria, immunostainable carbonic anhydrase activity in the cytoplasm and a generous amount of the cystic fibrosis transmembrane regulator (CFTR) protein at the luminal domain. The 'fuzzy coat' lining ductal epithelium is caused by mucus secreted by interspersed cells.

2.5 Acinar Cell

2.5.1 Enzyme Synthesis and Growth Regulation

In addition to the reference sources mentioned above, useful information can also be obtained from the reviews by Johnson (1987), Musa (1989) and Case (1990). High rates of amino acid influx in the rat pancreas are mediated by at least four transporters in the basolateral membrane, while amino acid efflux is mediated by at least two further transporters and activated by transexchange with extracellular amino acids. Diet and endocrine status are among many factors that interact to alter enzyme synthesis profiles. Recent work in rats shows that at least some of those changes are brought about by signal transduction mechanisms akin to those involved when the regulated secretory pathway is activated by occupancy of specific plasma membrane receptors.

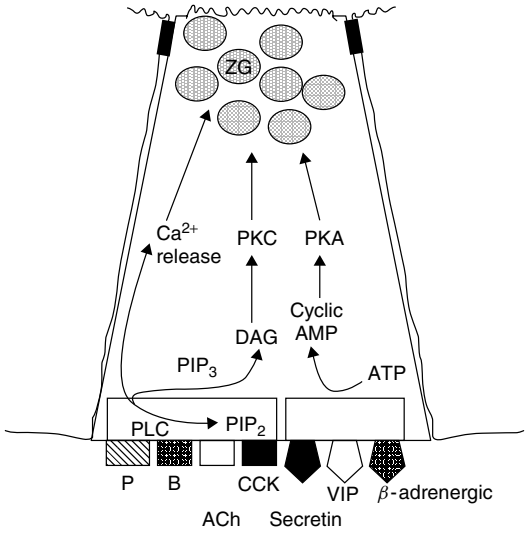

Figure 4 Plasma membrane receptors and intracellular chemical messengers involved in signal transduction by the regulated secretory pathway in the acinar cell. ZG: Zymogen granule; PKC: protein kinase C; PKA: protein kinase A; DAG: diacylglycerols; PIP_3: inositol 1,5-triphosphate; PIP_2: Inositol 4,5-bisphophate; AMP: andenosine monophosphate; ATP: adenosine triphosphate; PLC: phospholipase C; P: pirenzepine receptor; B: the PAF receptor antagonist drug, BN52021; CCK: cholecystokinin; VIP: vasoactive intestinal peptide; ACh: acetylcholine.

These membrane receptors fall into two main classes (**Figure 4**), of which one mainly accommodates secretin and VIP (vasoactive intestinal peptide) and the other accommodates mainly CCK (cholecystokinin-pancreozymin) and acetylcholine (ACh). The CCK receptor has high affinity (K_d for CCK-8, 65 pM) and low affinity (K_d, 15 nM) subtypes. Synthetic CCK receptor antagonists include glutamic acid derivatives (e.g. CR-1392, CR-1409, CR-1505 from Rotta Research Laboratories, Milan, Italy), benzodiazepine derivatives (e.g. L-364, 718 from Merck, Sharp & Dohme Research Laboratories, West Point, Pennsylvania, USA) and a series of CCK analogues. The acinar cell membrane also has receptors for somatostatin, insulin, epidermal growth factor, platelet-activating factor (PAF) (Nigam *et al*., 1996) and pirenzepine (low affinity, M2B subtype). Occupation of the CCK-type receptor increases the synthesis of several proteolytic enzymes, acting preferentially via increased cytoplasmic Ca^{2+}.

Hyperthyroidism extends the effect to include heightened synthesis of amylase and lipase. Occupation of the secretin-type receptor increases lipase synthesis by causing activation of adenylate cyclase (AC), which generates cyclic adenosine monophosphate (AMP) from adenosine triphosphate (ATP).

Not surprisingly, factors that stimulate pancreatic enzyme synthesis and secretion also promote pancreatic growth, but it is not known whether these three

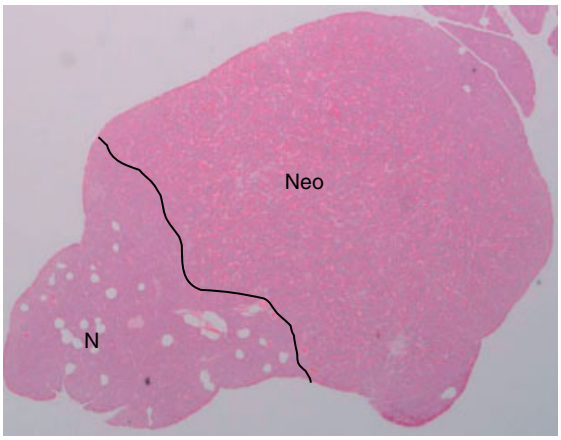

Figure 5 Light micrograph of pancreas from rat given a trypsin inhibitor for 12 months. The line shows the margin of the neoplastic nodule on the right hand side (Neo) from the normal pancreas (N) on the left. Magnification × 63.

effects are regulated via a common messenger, or whether enzyme discharge triggers synthesis and subsequent hypertrophy [enlargement of the cell] and/or hyperplasia (cell proliferation). Growth can be induced by administering CCK (or similar peptides such as caerulein) to rats, or by promoting its endogenous release by lowering the level of pancreatic proteases in the small intestinal lumen. This can be done by feeding with soya flour, which contains trypsin inhibitors, treatment with a synthetic inhibitor of serine proteases, such as Camostate, or by pancreatoduodenal diversion. The relevance of this feedback loop in humans is questionable, however. Pancreatic growth can also be evoked by hormones (glucocorticoids, insulin, epidermal growth factor), the bile-salt-binding resin cholestyramine, occlusion of the main pancreatic duct, pancreatic trauma and dietary deprivation of essential amino acids followed by free access. Chronic induction of exocrine pancreatic growth in rodents has been shown to result in the development of benign pancreatic exocrine tumours (**Figure 5**).

2.5.2 Regulated Secretory Pathway

Proteins synthesized in the RER are transported vectorially to the cisternal space through signalling transport sequences. Thereafter transport is believed to follow the ZG packaging and exocytosis model, in which lysosomal and food digestion enzymes are largely separated from each other in different, membrane-bound, compartments. As in other secretory cells, signal transduction is accomplished through a system of intracellular messengers (**Figure 4**). Occupation of the CCK-type receptor leads, via a G-protein (guanine nucleotide-binding protein), to activation of phospholipase C (PLC) producing inositol 1,5-triphosphate (PIP_3) and diacylglycerols (DAG from precursor inositol 4,5-bisphosphate (PIP_2), preferentially. Those chemical messengers mobilize Ca^{2+}, probably from the RER, or activate protein kinase C (PKC), respectively (**Figure 4**). The rise in cytosolic Ca^{2+} activates calmodulin (CAM) and thereby protein kinase (PK), and phosphatase (PP). Studies suggest that biological free radicals and free radical oxidation products (FROPs) provide a further network of intracellular signal transducers in a variety of secretory cells (Remacle *et al*., 1995). Examples of such reactive species include the nitric oxide radical, derived from arginine (Moncada *et al*., 1991), and derivatives of lipid oxidation, such as 4-hydroxynonenal, isoprostanes, isoleukotrienes and the lysophospholipid PAF (Nigam *et al*., 1996).

The methylation of membrane phospholipids, by transfer of methyl groups from methionine via sulfadenosyl methionine (SAMe) also seems to be important for signal transduction in a variety of cells. Thus, it has been shown that the binding of catecholamine to its receptor activates methyl transferases, resulting in methylation of phosphatidylethanolamine to generate phosphatidylcholine. In the process, membrane fluidity increases, allowing lateral mobility of the β-adrenergic receptor, so that it can interact with a G-protein coupling factor and AC to generate cyclic AMP, as in **Figure 4**. *In vitro* studies also showed that when SAMe was present in the incubation medium, treatment with PLC was accompanied by a methylating-enzyme-facilitated flip-flop realignment of membrane phospholipids with increased membrane fluidity. The potential application of these findings to signal transduction in the acinar cell is unknown.

It is also not known exactly how ZGs are shunted to the apical plasma membrane, but regulated exocytosis involves fusion of the granules with the apical plasma membrane mediated by opposing membrane complexes of soluble *N*-ethylmaleimide-sensitive fusion-protein attachment protein receptor (SNARE) proteins, for example, syntaxins (Weiss *et al*., 2008). In acinar cells syntaxin is present on the apical membrane and enters the ZG during exocytosis. The SNARE protein VAMP8/endobrevin was found to be enriched on the membrane of ZGs, and VAMP8 knockout mice contained approximately three times as many ZGs than control acinar cells (Wang *et al*., 2004). It also seems probable that microtubule/myosin phosphorylation is involved in the process and that membrane proteins in the ZGs, apical membranes or both are necessary for the fusion event, and that G-proteins, other Ca^{2+} dependent proteins and probably also CFTR (Trezise *et al*., 1992; Kopelman *et al*., 1995) interact to facilitate enzyme discharge. It is also apparent that free thiol groups, and as yet uncharacterized protein thiols, play critical roles in exocytosis, in a process that involves the formation, and maintenance, of an exocytosis transmembrane pore (Braganza and Chaloner, 1995; Weiss *et al*., 2008).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Considering the potentially lethal cocktail of proteases contained within the acinar cells, the pancreas has evolved systems to prevent premature activation of its contained enzymes and autodigestion. The most potent enzymes (proteolytic, phospholipase A_2) are synthesized as precursor enzymes or zymogens, which require hydrolysis in order for activation to occur. The proenzymes are constrained within membrane-enclosed granules, while the enzyme activators tend to be located in other organs, for example, the trypsinogen activator, enterokinase is located in the duodenum. In addition, a low-molecular-weight trypsin inhibitor, the pancreatic secretory trypsin inhibitor-1 (PSTI-1), is cosecreted within the ZG and can trap as much as 20% of potential trypsin activity (Bartelt *et al*., 1977), and should any trypsin become prematurely activated within the gland, it quickly activates an inhibitor-resistant protease, mesotrypsin, which in turn inactivates trypsinogen and other zymogens to help curtail the activation cascade (Szmola *et al*., 2003).

2.5.3 Nonregulated Secretory Pathway

There is evidence for a constitutive, nonregulated facility for protein discharge from acinar cells through pathways that seem to be preferentially located in the basolateral membrane, and that lead directly into the interstitium and bloodstream (**Figure 6**). As a backup mechanism, plasma contains safeguards against premature activation of pancreatic proteases that enter via the 'endocrine' route. These include the α_1 protease inhibitor (α_1PI) whose primary function is to protect against leucocyte-derived elastase (Karnaukhova *et al*., 2007) and which completely inactivates proteases and also binds to proelastase.

2.6 Ductal Cells

2.6.1 Bicarbonate Secretion

Secretin and VIP are the main stimuli of ductal bicarbonate secretion, although other agonists, notably CCK, can potentiate their action. Signal transduction involves cyclic AMP acting in concert with CFTR to increase the open probability of a chloride channel on the luminal plasma membrane. The active secretion of bicarbonate into the duct system results from the coordinated action of a chloride/bicarbonate exchange protein spanning the luminal membrane, an intracellular carbonic anhydrase, which generates carbonic acid from carbon dioxide that has diffused into the cell, and three proteins in the basal plasma membrane (sodium–potassium exchanger, hydrogen sodium antiporter, potassium channel) (Szucs *et al*., 2006). Sodium appears to enter

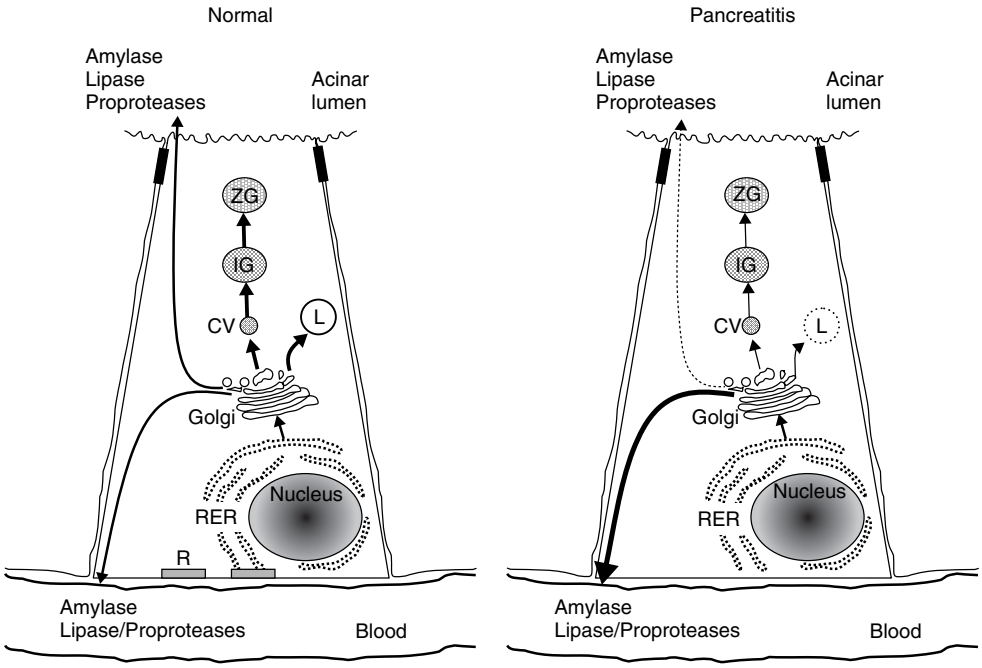

Figure 6 Nonregulated vesicular pathway into the interstitium via the basolateral membrane: a minor secretion route in the normal acinar cell (Arvan and Castle, 1987), but seemingly used preferentially in pancreatitis. the duct via the intercellular fluid and through the spaces between the ductal epithelial cells.

2.6.2 Mucus Secretion

Different cells secrete highly sulfated mucin, weakly sulfated neutral mucin, sialomucin or sulfomucin, and, following mucin synthesis, glycosylation occurs in the Golgi apparatus. Thereafter glycoproteins are packaged into granules and propelled along microtubules for exocytosis. Cholinergic agonists and prostaglandins are secretagogues for mucus secretion, while bile salts may owe their effectiveness to a local response mediated by receptors on the cell surface.

2.7 Pancreatic Juice

2.7.1 Phases of Secretion

Interdigestive secretion varies with the phases of upper gastrointestinal motility. The digestive pattern is evoked by food, hormonal and neural stimuli. The coordination between secretion and motility may help to protect the intestinal lining from irritation by pancreatobiliary secretions and to ensure that duodenal pressure does not exceed that in the pancreatic duct.

2.7.2 Composition of Pancreatic Juice

The human pancreas secretes between 0.7 and 2.5 l of pancreatic juice each day, which has a pH of 7.5–8.8 and which is isotonic with serum. Its bicarbonate concentration rises with flow rate to a maximum of 130–150 mmol l^{-1} at a rate of 300 ml h^{-1}. The sum of bicarbonate and chloride is constant at around 154 mmol l^{-1}. Sodium is the principal cation (139–143 mmol l^{-1}), and the concentration of calcium varies between 2.2 and 4.6 mmol l^{-1}. Digestive enzymes account for most of the high protein content, 4.8–5.3 g l^{-1}, while traces of albumin, globulin and mucoprotein account for the remainder. There are more than 20 different enzymes, including inactive precursors of serine proteases (three forms of trypsinogen, two of chymotrypsinogen, two of proelastase and kallikreinogen) and exopeptidases (four forms of procarboxypeptidase, and prophospholipase A2) and lipase, colipase, cholesterol ester hydrolase, amylase, RNase and DNase. The concentration of lipids is very low, 5.2 mg l^{-1}. Other constituents include lysosomal enzymes, lactoferrin and a 'pancreatic stone protein (PSP)', that is, nowadays called lithostatin, which helps to solubilize calcium and has bacteriostatic potential (Weiss *et al*., 2008).

3 EXOCRINE PANCREAS: TARGET FOR TOXICITY FROM DRUGS AND CHEMICALS

3.1 Chemicals in Non-Neoplastic Pancreatic Disease: Human

3.1.1 Acute Pancreatitis

Table 1 is a compilation reviewing the evidence linking exposure to drugs and chemicals with pancreatic disease. It is largely taken from the textbook by Braganza (1991), but updated with the more recent reviews on the subject by Badalov *et al*. (2007), Dhir *et al*. (2007) and Trivedi and Pitchumoni (2005), along with more recent information from case reports uncovered by computer-assisted searches. The interpretation of a proposed link with chemical exposure is frequently confounded by the presence of concurrent disease and the pancreatic lesion, for example, the connection between azathioprine, Crohn's disease and pancreatitis, and the three-way relationship between HIV infection, pancreatic lesions and treatment with pentamidine or didanosine (Schwartz and Brandt, 1989). It can be difficult to unravel the interaction between pancreatic ischaemia-reperfusion injury and the toxicity, to pancreatic acinar cells, of drugs such as cyclosporin A. There is evidence that this drug accelerates pancreatic acinar cell injury in caerulein-treated rats (Hirano *et al*., 1991) although it was also shown to decrease the severity of pancreatitis in a rat model most probably through its anti-inflammatory effect in inhibiting neutrophil infiltration into the damaged pancreas (Scott *et al*., 1992).

Table 2 is an attempt to clarify the underlying principles governing drug-induced acute pancreatitis, in the absence of a confounding influence, from pharmacological properties (Smith, 1973; Bowman and Rand, 1980; Schenkman and Kupfer, 1982; Halliwell and Gutteridge, 1985; Hodson and Levi, 1987), by analogy with drug toxicity in the liver (Plaa and Hewitt, 1982; Timbrell, 1982; Cohen, 1986). Evidence exists for the presence of drug-metabolizing activity within the pancreas of animals (Scarpelli, 1989) and enzymic activation is one likely mechanisms in the genesis of some forms of acute pancreatitis. This analysis has been forced in some way, while appreciating that any single agent can potentially injure the pancreas in more than one way, as exemplified by the toxicity of ethanol. The role of ethanol in the development of chronic pancreatitis is discussed in the next section.

With regard to injury from bioactivated drug metabolites, a case report of methyldopa-associated severe acute pancreatitis, affecting ectopic as well as entopic pancreas, is described, that defies any alternate explanations other than the generation of toxic metabolites of the drug

Table 2 Possible mechanisms of drug toxicity in human acute pancreatitis

Mechanism	Drugs
Impeded protein synthesis/transport/secretion	Alcohol, L-asparaginase, azathioprine, caerulein/CCK, calcium infusion, cobalt chloride, colchicines, corticosteroids, cytosine-Ara, didanosine, DL-ethionine, 6-mercaptopurine, pentamidine, phenylalanine, puromycin, sulfonamides, tetracycline, theophyline, vinblastine.
Cytochrome P450 induction	Alcohol, corticosteroids, isoniazid, meprobromate, rifampicin, valproic acid.
Toxic metabolites via cytochrome P450	Alcohol, azathioprine, indomethacin, isoniazid, methyldopa, metronidazole, nitrofurantoin, oestrogens, paracetamol, sulindac, valproic acid.
Toxic metabolites via other route	Chlrorthiazide, chlorthalidone, ethacrynic acid, procainamide, sulfonamides.
Increased triglycerides	Alcohol, β-blockers, corticosteroids, isoretinoin, oestrogens.
Impeded drainage	Alcohol, dextropropoxyphene, diphenoxylate.
Haptene formation	Alcohol, 5-aminosalicylic acid, isoniazid, cyclosporin, procainamide, sulfonamides.
No clues	Amphetamine, cholestyramine, cimetidine, clonidine, cyproheptidine, diazoxide, enalapril, histamine, phenformin, salicylates, warfarin.

(Bembow, 1988). The principles of pharmacogenetics (Idle and Smith, 1979) could explain why the most persuasive case reports linking frusemide (furosemide) and pancreatitis involved American Negroes (Buchanan and Cane, 1977), while other negroid races have been reported to possess higher intrinsic levels of certain cytochromes P450. Prior induction of cytochromes P450 by an extrinsic agent, such as grapefruit juice or St John's wort can be equally important in determining the toxicity or otherwise of a drug metabolically activated within the liver or pancreas (Azuma *et al*., 1998; Lee *et al*., 2006). This connection is recognized in

the case of paracetamol (acetaminophen)-, or carbon tetrachloride-associated acute liver toxicity. Reports on drug or chemically related acute pancreatitis sometimes mention alcohol, but seldom, if ever, whether the patient was a smoker or whether the diet contained substantial amounts of C18 : 2 fatty acids. Antioxidant status is also generally not reported in these case histories. Finally a case report that has a bearing on the pathogenesis and treatment of drug-induced pancreatic damage is worth discussing. This report concerned a man who died within 12 hours of consuming a large amount of theophylline, and who showed all the neurological manifestations ascribed to blockade of adenosine receptors (Burgan *et al*., 1982). The authors concluded that he did not have pancreatitis at autopsy because there was no histological evidence of inflammation. His blood amylase level was 10 times the upper limit of normal five hours after tablet ingestion and had doubled within the next three hours, increments that typically accompany the pancreastasis phase of experimental pancreatitis. Blockade of adenosine receptors on plasma membranes of pancreatic acinar cells (Yamagishi, 1986) would be expected to compromise cell stores of SAMe and ATP (**Figure 7**).

There are several case reports of acute pancreatitis after intentional or accidental exposure to organophosphate insecticides in children (Weizman and Sofer, 1992) and adults following inhalation (Hsiao *et al*., 1996) or cutaneous exposure (Marsh *et al*., 1988), with agreement that excessive cholinergic stimulation of pancreatic acinar cells is the damaging mechanism (**Table 3**).

There are several reported associations between inhaled chemicals and the induction of pancreatitis, including dimethylformamide (Chary, 1974), pentachlorophenol (as part of a wood preservative which also contained zinc naphthanate) (Cooper and MacCaulay, 1982) and trichloroethylene, volatile petrochemical products and diesel/petrol exhaust fumes (Braganza *et al*., 1986). It is recognized that many aliphatic/halogenated hydrocarbons undergo bioactivation, and hence that prior enzyme induction has the potential to magnify any tissue damage (Sato *et al*., 1980; Strubelt, 1980; Plaa and Hewitt, 1982; Koop *et al*., 1985). As little as 30 g alcohol may thus precipitate an attack of pancreatitis some 10 hours later, following exposure to metabolically activated chemicals in the home or work environment. A genuine link between inhaled hydrocarbons and acute pancreatitis would rationalize the observation that postoperative pancreatitis, after halogenated hydrocarbon anaesthetics, occurred even when the operation was nowhere near the gland (Howat and Sarles, 1979; Go *et al*., 1993).

3.1.2 Chronic Pancreatitis

Alcoholism, cyanogenic glycosides, drugs such as azathioprine, oestrogens and sodium valproate, and high fat/protein diets are among the accepted environmental risk factors. Unfortunately there is no reproducible animal model of alcoholic pancreatitis and hence detailed investigation of the aetiology still remains to be achieved. The current dogma for the human disease is that there is no threshold for alcoholic toxicity to the human pancreas and that among patients with chronic pancreatitis, 'the logarithm of risk increases linearly in terms of the mean amount of alcohol consumed each day' (Howat and Sarles, 1979). A major problem has been the difficulty in providing laboratory animals with a nutritionally balanced diet while ethanol is administered (Go *et al.*, 1993). When this is accomplished, biochemical changes akin to those in alcoholics with or without chronic pancreatitis do occur after some 12 months, for example, increased amounts of pancreatic zymogens with increased fusion between zymogen and lysosomal compartments (Singh, 1992). The introduction of the rat gastric infusion model (Horn and Tsukamoto, 1993) has made it easier to dissociate the effects of alcohol from those of high fat intake, the former leading to hypogranulation and apoptosis of pancreatic acinar cells with additional dietary fat exaggerating the effects. The combination also affected the way in which the pancreas subsequently responded to CCK, inhibiting the binding of the hormone to receptors and reducing the pancreatic secretory response. At least in the rat, CCK is a major mitogen for the exocrine pancreas and interference with its action could inhibit regeneration of pancreatic cells following an insult.

While not diminishing the usefulness of these animal studies they have limited applicability to the clinical situation since they are unable to take into account the complex lifestyle and generally inadequate dietary intake that alcoholics engage in where it is known that protein intake and smoking are significant risk factors in the development of alcoholic pancreatitis (Howat and Sarles, 1979).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Ethanol is largely metabolized by cytosolic dehydrogenases, but protracted exposure brings the microsomal cytochrome P450 2E1 system into play. The dehydrogenase pathway generates fatty acid ethyl esters while the cytochrome P450 pathway generates ethinyl radicals and reactive oxygen species (ROS). Both systems lead to the production of the highly toxic acetaldehyde metabolite. Acetaldehyde has been shown to inhibit mitochondrial function and to form adducts with constituents of the cytoskeleton that could jeopardize secretion, provoke a reversal in secretory polarity and/or form adducts with constituents of the plasma membrane to generate chemotactins (Lieber, 1988; Werner *et al*., 1997; Israel, 1997). These effects would be compounded by changes in CCK-receptor binding and ethanol-induced hypertriglyceridaemia (**Table 2**).

In the case of alcoholic hepatotoxicity, the emphasis has shifted away from mitochondrial damage and on to cytochrome P450 2E1-mediated production of reactive intermediates from drugs/chemicals to which an individual is simultaneously exposed. This mechanism is attractive for alcoholic damage to the exocrine pancreas also, not least because it could rationalize the resistance to ketosis when patients become diabetic, because ketones would be more rapidly processed. Computer-assisted discriminant analysis of factors contributing to accelerated theophylline clearance in patients from Manchester, UK (Acheson *et al*., 1989) identified cigarette usage as the major influence, with a contribution from dietary protein and other factors, irrespective of whether or not the patients were alcoholic.

In regard to nonalcoholic disease, it is interesting to note that many of the drugs, incriminated in chronic pancreatitis, can be metabolized to reactive intermediates. Furthermore, recent studies of European patients suggest an aetiological connection between regular inhalation of volatile chemicals, usually in the occupational environment, and chronic pancreatitis in nonalcoholics (Dossing *et al*., 1985), as well as in exalcoholics (Braganza *et al*., 1986). Those chemicals included paints, solvents and thinners, diesel/petrol fumes, degreasing agents and dyes. The connection was confirmed in a large case-control study in Manchester, UK (McNamee *et al*., 1994). A similar range of chemicals emerged in several patients with nongallstone recurrent acute pancreatitis or pancreatic cancer (Kemppainen and Puolakkainen, 2007) (**Figure 8**).

An animal model of pancreatitis has been achieved by feeding young Syrian hamsters for six months with a corn-oil-enriched diet, supplemented with either β-naphthoflavone or phenobarbital, to induce cytochromes P450 1 or P450 2, respectively. The hepatobiliary and pancreatic changes associated with chronic pancreatitis were reproduced in this model and high concentrations of FROPs were found in bile, with excess deposits of lipofuscin and pancreatic lipoatrophy. These results are consistent with a chronic elevation of ROS accompanying the development of pancreatitis (Rutishauser *et al*., 1995). The hamster was chosen for these experiments because of their high intrinsic rate of drug metabolism and because this species is peculiarly vulnerable to pancreatic carcinogenesis by nitrosamines that require bioactivation for genotoxicity (see below).

With regard to tropical, nonalcoholic, chronic pancreatitis as is seen in the Far East, it has for long been accepted that hydrogen cyanide released from the dietary staple cassava (manioc, tapioca) is a major determinant. Cassava contains the cyanogenic glycosides, linamirin (2-((-D-glucopyranosyl-oxy)isobutyronitrile)) and lotaustralin (methyl linamirin). However, the acute administration of hydrogen cyanide to rats results in death from respiratory failure and diabetes, but not in chronic pancreatitis. It has been suggested that, based upon the findings of damage to other organs in an experimental setting, a possible alternative explanation for this disease residing in a non-cyanide-generating chemical in cassava (Ballantyne, 1987). This hypothesis is supported by reports that in rats, another plant nitrile, 1-cyano-2-hydroxy 3-butene(nitrile), caused biphasic changes akin to those found in human tropical pancreatitis, namely, early hypersecretion of pancreatic juice and bile followed by loss of pancreatic nonprotein thiols and ZGs, with vacuolation of the acinar cell cytoplasm and inflammatory oedema (Maher *et al*., 1991). Further, it has been shown that subtle differences in nitrile structure spared the pancreas, but caused liver and kidney damage (Wallig *et al*., 1988). The dissociation between the changes due to reduced protein intake and those due to the nitrile, and the additive effect when these problems coexisted, was demonstrated in another study which confirmed that the pancreatic acinar cell was the primary target, despite descriptions of mucin-choked ducts in the human disease (Geldof *et al*., 1992).

One area where such changes in the ductal system have been described is in Madras in southern India, where chronic pancreatitis is relatively common (Mohan *et al*., 2003). A study of xenobiotic exposures among these people revealed that many patients with chronic pancreatitis were in regular close contact with smoke (from firewood, vehicle emissions or cigarettes) and petrochemical products, especially kerosene fumes, from lamps or cookers (Braganza *et al*., 1990). These links, if validated by case-control studies, could rationalize cardiomyopathy in those patients, considering that similar effects

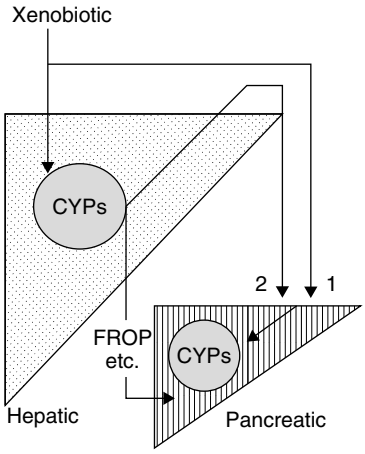

Figure 9 Possible routes of pancreatic injury from toxic metabolites of drugs/chemicals. See text for discussion. (Reproduced with permission from Braganza, 1991. © Manchester University Press.)

accompany kerosene toxicity in experimental animals (Rai and Singh, 1980), and also the decline in disease incidence in Kerala, India, in the past few years in line with increasing electrification. Although there are no reports of kerosene metabolism by the pancreas, studies of the liver strongly suggest the generation of highly toxic metabolites (Starek and Kaminski, 1982), including acrolein. The regular use of C18:2 fatty acids in cooking oil (linseed, peanut) would facilitate prior enzyme induction, as would any polycyclic aromatic hydrocarbons in smoke, and in situations of malnutrition where antioxidant content would be suboptimal, tissue damage could occur from exposure to nitriles or kerosene.

We thus conclude that the template for chronic pancreatitis in **Figure 9** accommodates many of the experimental and clinical observations to date, not least the low prior antioxidant status in some African communities, where chronic pancreatitis is endemic (Segal, 1998; Segal *et al*., 1995). A number of reports on dietary insufficiencies now endorse the oxidative stress philosophy behind the development of chronic pancreatitis (Wesson *et al*., 2008; Mishra, 2007; Merentie *et al*., 2007; Schoenberg *et al*., 1995).

3.1.3 Experimental Non-Neoplastic Injury

Individual references are given in **Table 4**. Some agents (asterisked) generate toxic metabolites, including oxygen radicals, organic intermediates or both. It is unclear why excess corn oil in the diet can, of its own, cause cytochromes P450 1 induction in hepatocytes of Syrian hamsters after six months, but this is associated with an increase in hepatic lipid peroxidation and spotty pancreatic lipoatrophy (Rutishauser *et al*., 1995). The degree of enzyme induction was similar to that achieved

following phenobarbitone or ß-naphthoflavone given with a low-corn-oil diet in these experiments, and those reported by others (Scarpelli, 1989).

The pancreas seems to be much more sensitive than the liver to damage from some toxic metabolites, judging by studies with carbon tetrachloride. where 0.07 g per 100 g body weight was sufficient to induce pancreatic lesions, while considerably higher doses were needed to induce hepatic injury. The pancreatic lesions occurring were reported to be similar to those of human chronic pancreatitis (Veghelyi *et al*., 1950a), except that features compatible with enzyme induction (**Table 5**) were lacking. Differences in the distribution of pancreatic cirrhosis nodules in different glands were ascribed to possible differences in blood supply (Veghelyi *et al*., 1950a; Veghelyi and Kemeny, 1962), which in turn could reflect variations in islet-acinar 'portal' circulation, especially now that certain cells in pancreatic islets have been shown to contain easily inducible cytochromes P450 (**Figure 10**).

The changes in the pancreas brought about by the long-term administration of hypolipidaemic agents are especially interesting because, in similarity to the effects seen after dietary methionine deprivation followed by refeeding, acinar cells metamorphose into fully functional hepatocytes (Rao *et al*., 1986). Not only do these findings underline the common ancestral lineage of the liver and pancreas from the evolving foregut (Braganza, 1986; 1988a), but they also show that repair mechanisms, after any form of toxic insult in either tissue can potentially result in its conversion to the alternate cell type (Rao *et al*., 1986; 1989). When pancreatic injury is caused by interference with protein synthesis, it is hardly likely that antioxidants will find use in prophylaxis or treatment. However, where a reactive intermediate is involved, glutathione (GSH) precursors and/or vitamin C could be useful.

4 CHEMICALS IN CANCER OF THE PANCREAS

4.1 Human Pancreatic Cancer

Cigarette smoke has the clearest association with the development of human pancreatic cancer. It is recognized that each intake of cigarette smoke delivers approximately 1015 free radicals in the gas phase (e.g. oxides of nitrogen) and 1014 free radicals in the tar phase (e.g. from benzo[a]pyrene) (Lu *et al*., 2008). Smoke contains large numbers of toxic chemicals, but it also has two main classes of potentially genotoxic chemicals—polycyclic aromatic hydrocarbons (Freudenthal and Jones, 1976; Coggins and Gaworski, 2008) and nitrosamines (Lijinsky, 1987; Bacsik *et al*., 2007), and several potential epigenetic agents (Williams, 1984; Upham *et al*., 2008), including catechols and phenolic compounds.

Several occupations, and linked chemical exposures, have been implicated in the development of pancreatic cancer (**Table 6**), but for each positive epidemiological study there are several others that do not support a connection (Alguacil *et al*., 2003; Bond *et al*., 1985; Hanis *et al*., 1982; Hotz *et al*., 1990; Rushton and

Alderson, 1981; Clapp, 2006). In their review Pietri and Clavel (1991) concluded that despite these reservations there does appear to be a significant risk from the chemical and petroleum industries.

The fractionation of petroleum gives rise to many of the substances associated with pancreatic cancer (**Table 6**). This process yields natural gas (C1–2), used for fuel and in the chemical industry; liquefied or bottled gas (C3–4), used as fuel gas for the synthesis of rubber compounds and in the petrochemical industry; petroleum ether (C4–5), for solvents and as an anaesthetic; gasolines (C6–l0) in cleaning fluids, solvents and for refining stock; kerosenes (C5–l6), used as jet, tractor and gas turbo-fuels, and in lamps and stoves in underdeveloped countries; gas-oil (C9–l6), used as diesel or furnace oil; lubricating stocks (C > 17), for white oils, lubricating oils and greases; waxes (C > 20), for ceiling wax and bottoms (C > 20), used as heavy fuel oil, road oil and asphalt. Suspicion that chronic pancreatitis in tropical zones may increase the risk for pancreatic cancer (Balakrishnan, 1987) would be rationalized if smoke and kerosene fumes were to be involved, and the mutagenicity of airborne particles from a kerosene heater has been demonstrated (Yamanaka and Maruoka, 1984). Similarly, it is not difficult to see why chronic pancreatitis in temperate zones may be a forerunner of pancreatic cancer, since aliphatic/aromatic halogenated hydrocarbons in solvents, degreasing agents, paint thinners and so on, seem to be involved in each condition (**Figure 11**) (McNamee *et al*., 1994). These hydrocarbons, whose potential genotoxicity is recognized (Schwartz and Brandt, 1989), are ubiquitous (Aviado *et al*., 1976; Nicholson and Moore, 1979) in the polluted atmosphere of industrialized and traffic-congested cities.

Other suspected risk factors for pancreatic cancer could be rationalized through promotion of cytochromes P450 activity. Thus, the increased susceptibility of American blacks may be due to a higher intrinsic level of certain cytochromes P450 (Idle and Smith, 1979). The interaction between genetic and environmental factors

influencing cytochromes P450 may explain the occurrence of pancreatic cancer in siblings and kindreds with hereditary chronic pancreatitis. It would also rationalize the report of pancreatic cancer in a chemical worker and his son who were exposed to vinyl chloride and other substances (Reiner *et al*., 1977). The association between high-fat diets and pancreatic cancer may reflect the steady increase in consumption of polyunsaturated fatty acids (PUFA), especially C18:2, in corn-oil by Western societies in the past 50 years (Hollander and Tarnawski, 1986). Continued suspicion that alcohol may be a risk factor is understandable now that its inducing effect on cytochrome P450 2E1 is appreciated. It is hardly surprising that these potential interactions could not be dissected out in the study relating expression of different pancreatic cytochromes P450 (**Figure 10**) and exposure to xenobiotics (Foster *et al*., 1993). Failure or inability to document prior exposure to enzyme inducers or antioxidant status could also explain discrepant results concerning chemicals and human pancreatic cancer in some studies (Li *et al*., 1969; Hoar and Pell, 1981; Mack and Paganini-Hill, 1981; Gold *et al*., 1985).

4.2 Experimental Pancreatic Cancer

The inhalation route of xenobiotic entry, which may be very relevant to the pathogenesis of human pancreatitis and also pancreatic cancer, has only rarely been used in experimental studies in laboratory animals. One such study (Malley *et al*., 1995) used the 1,1-dichloro-2,2,2-trifluoroethane, a potential substitute for the ozone-depleting hydrocarbons, and showed the induction of exocrine pancreatic cancer when given by inhalation exposure to rats for two years. This compound led to the development of acinar cell adenomas at dose levels down to 300 ppm in males, while also inducing acinar hyperplasia, but not neoplasia, in females. It was also found to be a potent hypolipidaemic agent and peroxisome proliferator in rodent liver. Although the relationship between this hepatic effect and the pancreatic lesions was unclear, several other compounds in the class of hypolipidaemic agents, for example, nafenopin and clofibrate (Reddy and Rao, 1977; Longnecker, 1983), also induce the development of pancreatic cancer in the rat.

Experimental studies on the development of pancreatic cancer have largely focussed on a ductal phenotype tumour as produced by the nitrosamine, *N*-nitroso-bis-(2-hydroxy-propyl) amine (BHP), in hamsters (Go *et al*., 1993; Pour and Lawson, 1984), and an acinar phenotype tumour from *O*-diazoacetyl-L-serine, azaserine, in rats (Mäkinen *et al*., 1998; Longnecker *et al*., 1984) (**Table 7**). Transgenic mouse models have also been described involving either an elastase enhancer/promote–SV40 T-antigen construct (Ornitz *et al*., 1987), or an elastase enhancer/promoter–myc oncogene construct (Sandgren *et al*., 1990). The former has an acinar phenotype, while the latter may have a ductal or mixed phenotype.

The spectrum of cancer precursor lesions in the BOP and azaserine models includes multiple neoplasias and neoplastic precursor lesions. They generally show the full spectrum of lesions from the atypical acinar cell focus, consisting of cells with increased nuclear size, prominent nucleoli, increased mitotic index, cytoplasmic

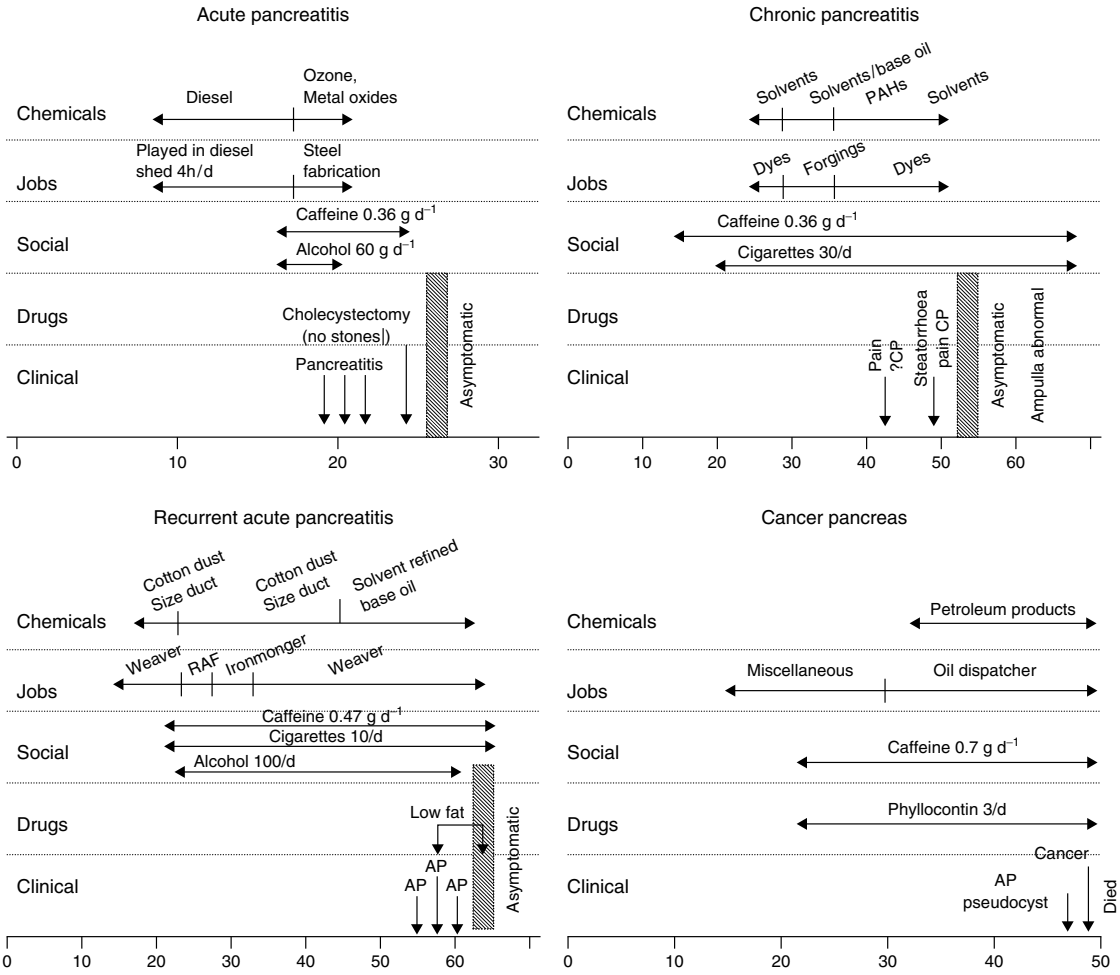

Figure 11 Examples of xenobiotic exposure histories in four patients in Manchester, UK. RAF = Period in the UK Royal Air Force; AP = acute pancreatitis; CP = chronic pancreatitis. The numbers on the x axis are years.

basophilia and reduced zymogen content, the atypical acinar cell nodule, similar in all respects to the focus except for its larger size, the acinar cell adenoma with size more than 3 mm and a tendency to capsule formation, the cystic ductal complex with one or more luminal spaces lined by flattened epithelium containing some cells that possess ZGs, the tubular ductal complex with small lumina and finally, carcinoma-*in-situ*. The last three lesions and papillary hyperplasia are characteristic of BOP-induced lesions in hamsters, whereas the first three are typical of cancer in rats following exposure to many carcinogens (Go *et al*., 1993).

Several oxidized derivatives of dipropylnitrosamine (**Figure 12**) can produce pancreatic cancer in hamsters, but BOP is the most pancreas-specific and carcinogenic potency lies in the order MOP (*N*-nitrosomethyl-2-oxopropylamine) > BOP > HPOP (*N*-nitroso-bis-2-(hydroxypropyl)-2-oxopropyl)amine) > BHP (*N*-nitroso-bis-2-hydroxypropylamine) (**Table 7**). HPOP exists as a tautomeric mixture of the open chain and cyclic forms (**Figure 12**). It is not surprising therefore that the cyclic form, *N*-nitroso-2,6-dimethylmorpholine (NDMM), which is a derivative of morpholine, also has carcinogenic potential. It resembles the endocrine cell toxin streptozotocin, which may help to rationalize the variable effects on exocrine cancer yield when this drug is given along with BOP. Structure–activity relationships have been defined for these nitrosamines (Moossa, 1980; Pour and Lawson, 1984). Thus, the presence of a keto or hydroxy group in the α-position on an aliphatic chain proved to be a prerequisite for pancreatic carcinogenicity, while the addition of a second α-group increased activity and specificity for the pancreas. The replacement of a 2-oxo chain with a methyl group diminished pancreas specificity, as did prolongation of the aliphatic chain, while carboxylation at the 3-position was associated with a complete loss of toxicity to the pancreas. HPOP and MOP seem to be more proximate carcinogens, but the ultimate carcinogen is unclear. The bulk of BOP metabolism occurs in the liver by a microsomal cytochrome-P450-dependent system, and to a much lesser extent by a cytosolic system, which utilizes NADH or NADPH (Boux *et al*., 1983). There is agreement that

substantially less BOP is metabolized in the pancreas, and that exocrine cell cytosol may be the predominant site, with little (Kokkinakis and Scarpelli, 1989) or no (Boux *et al*., 1983) contribution from microsomes.

These data suggest that carcinogenic metabolites produced in the liver may enter the gland by way of the bloodstream, and in certain circumstances through bile reflux (Ruckert *et al*., 1981). This concept, which has also been proposed for human pancreatic disease (Braganza, 1986; 1988a), is supported by the greater damage to pancreatic DNA after *in vivo* treatment of animals with BOP and MOP than occurs following *in vitro* incubation of isolated pancreatic cells (Curphey *et al*., 1987), and the observation that interruption of the hepatic blood supply reduced the DNA-damaging effect of MOP *in vivo* (Schaeffer *et al*., 1984). The DNA-damaging effects were accompanied by a 14-fold increase in GSH and 19-fold increase in oxidized glutathione (GSSG) in the pancreas after BOP treatment (Toyooka *et al*., 1989). BOP was found to damage DNA in cells isolated from the whole pancreas, hence largely acinar, in doses as low as $0.5\,\mu g\,ml^{-1}$ (Levin *et al*., 1984), while HPOP was marginally less potent.

Damage to duct cells was substantially higher than to acinar cells when these were examined separately (Lawson and Nagel, 1988) and DNA repair efficiency was also much lower in ductal cells. Several specific methylated and hydroxypropylated DNA bases were identified after BOP and HPOP treatment. However, levels of O6-methyl guanine best reflected their relative carcinogenic potency (Kokkinakis and Scarpelli, 1989); while O6 and N7-alkyl guanine adducts persisted much longer in ductal than acinar cells (Bax *et al*., 1990).

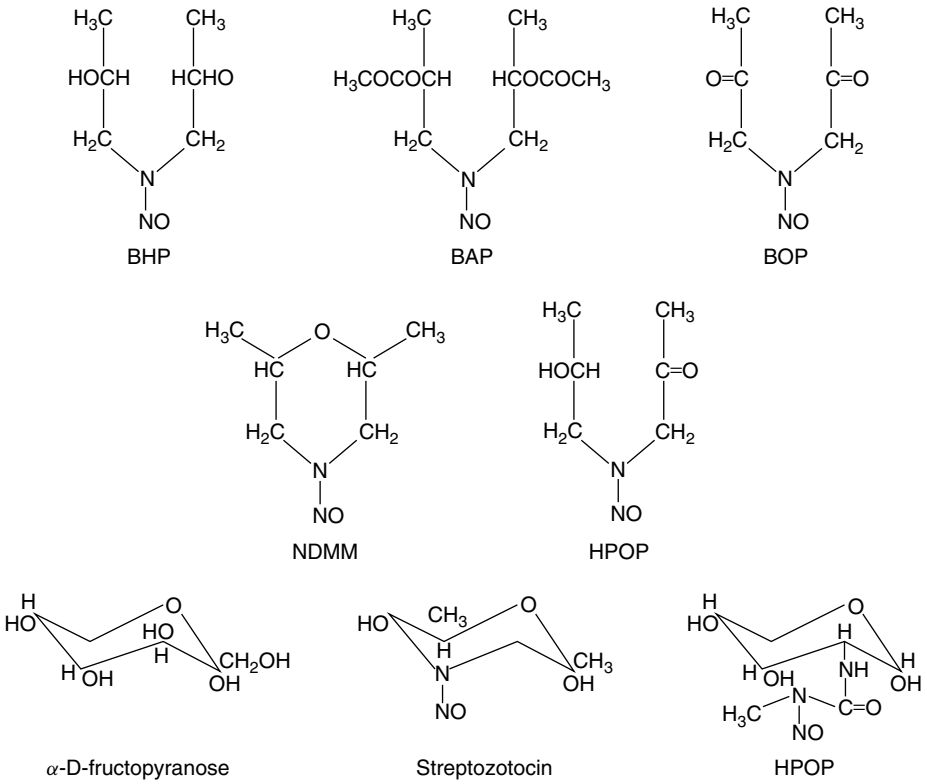

Figure 12 Chemical structures of some oxidized derivatives of dipropylnitrosamine and, for comparison, chemical structure of islet cell toxins such as streptozotocin. For abbreviations see **Table 8**.

Mutagenicity does not seem to have been tested via liver fractions. Studies of pancreatic S-9 fractions from control and polychlorinated-biphenyl-induced hamsters showed mutagenicity in strain TA100 by BOP and HPOP but not by NDMM or BHP (Mori *et al*., 1986). NDMM was mutagenic in a study with strain TA1535 as detector (Scarpelli *et al*., 1980); and use of Chinese hamster V79 cells as target showed that BOP was a more potent mutagen than HPOP (Mangino *et al*., 1985). However, carcinogenic or mutagenic potential was not reflected in protein synthesis, which was unchanged by BOP treatment (Zucker *et al*., 1988). Finally, it is noteworthy that treatment of pregnant animals with BOP caused a different spectrum of tumours in maternal and foetal tissues (Pour, 1986).

Azaserine (**Figure 13**) produces precursor lesions of the acinar phenotype in rats. As in the case of BOP, this carcinogen requires metabolic activation, but seemingly via a pyridoxal-dependent reaction yielding diazoacetate. The structurally similar 6-diazo-5-oxo-L-norleucine (DON) was found to be considerably less effective (Lilja *et al*., 1981). Metabolic activation of azaserine results in N7-carboxymethylguanine, in addition to the more usual O6 guanine adduct (Go *et al*., 1993) and the degree of pancreatic DNA damage is the same in *in vitro* as is seen *in vivo*, indicating that it is the pancreas itself that is metabolically activating the chemical and that another organ, such as the liver, is not required for carcinogenic activation (Curphey *et al*., 1987).

From the information in **Table 7**, it is clear that the species specificity of BOP and azaserine is best explained in terms of differences in pancreatic DNA damage/repair efficiency. With regard to ductal versus acinar phenotype, the facts are consistent with the hypothesis that the acinar cell may be the cell of origin for tumour induction in both species (Moore *et al*., 1983), but that species-dependent factors influence subsequent development so that the tumour acquires features of duct cells in hamsters, but retains acinar cell features in rats. **Tables 8** and **9** summarize information regarding other pancreatic carcinogens.

There is considerable literature evidence for promotion of pancreatic cancer by many factors including hormones (Skett, 1987) and dietary factors, and the gender of rats, whether or not neutered, and sex hormone replacement therapy have been shown to influence the development of azaserine-induced pancreatic cancers and precursor lesions (Longnecker and Sumi, 1990). Diets rich in soya flour have been shown to result in the development of exocrine pancreatic cancers in rats after two years (McGuiness *et al*., 1980), and an 8–10-fold stimulation in DNA synthesis was observed within as little as 48 hours (Woutersen *et al*., 1991). This effect was tracked down to the ability of soya-rich flour to inhibit trypsin in the small intestine, resulting in the feedback release of

excess CCK that leads to hypertrophy and subsequently hyperplasia of the pancreatic exocrine tissue (Kato *et al*., 1994). Enrichment of the diet with corn oil achieved a similar outcome in rats (Dowling *et al*., 1987).

When a single injection of azaserine was given at the start of a 15-month experiment to compare the modifying effect of low fat intake, 5% corn oil, and high fat intake, 25% corn oil, the number of atypical acidophilic acinar cell foci increased from 472 per pancreas to 963 respectively, with a fivefold increase in adenomas and a sixfold increase in microcarcinomas in the high-fat group (Woutersen *et al*., 1991). High-corn-oil diet had a similar impact on the course of nitrosamine-induced carcinogenesis in hamsters (Go *et al*., 1993). It is not known exactly how corn oil facilitates pancreatic carcinogenesis, and factors such as the heightened release of CCK from the small intestine and direct induction of cytochrome P450 1 isoenzymes have been proposed as playing a significant role in promoting initiated cells.

Another area that cannot be covered in detail in the current review concerns the burgeoning literature on the influence of dietary antioxidant composition and experimental cancer. This is potentially of great importance,

not least because antioxidants, such as pyrrolidine dithiocarbamate (PDTC) and vitamin E have been shown to enhance the antitumour efficacy of chemotherapeutic agents such as 5-fluoruracil and doxorubicin (Kastan, 1997).

4.3 Drug-Metabolizing Enzymes

The function of the drug-metabolizing system within the organs of the body, but particularly within the liver has been covered in detail in earlier chapters of this textbook. However, it is pertinent to review some of the key features that impact on the pancreas being a target for metabolically activated drugs and industrial chemicals. Briefly, the system acts to convert lipophilic chemical species that easily traverse membranes, into more polar, hydrophilic derivatives that are more easily eliminated from cells and from the body as a whole. The process is usually described in two phases and while in Phase I, an electrophilic group is inserted into the drug or chemical molecule, during Phase II the substituent group is conjugated with an amino acid, the tripeptide GSH or glucuronic acid, for example, which allows excretion via either the biliary tract or the urinary system. The various enzymes involved are collectively termed drug-metabolizing enzymes, but, in fact, they metabolize a wide range of xenobiotics and also endogenous intermediaries such as sterols, prostaglandins, bile acids, bilirubin, cholesterol and so on. The terminal component of the Phase I system, cytochrome P450, exists in multiple molecular forms that are classified by gene families (numbered 1–21), then subfamilies (A–E) and finally individual genes (numbered 1–13) (Nebert *et al*., 1987; Guengerich, 1989). It is widely recognized that the intrinsic level, and inducibility, of certain isoenzymes is genetically determined (Idle and Smith, 1979).

Studies of hepatocytes show that a xenobiotic traverses the plasma membrane along pathways shared by bilirubin and other organic anions, such as bromosulfophthalein (BSP) and, likewise, is transported by GSH-S-transferase B to the smooth endoplasmic reticulum for Phase I reactions. The ingredients are oxygen, NADPH, the flavoprotein NADPH cytochrome P450 oxidoreductase, the haemoprotein cytochrome P450, membrane phospholipids (Wade, 1986) and the trace element selenium (Correia and Burk, 1976). Phospholipids are vital because they hold substrate—enzyme complexes in optimal configuration, while stabilizing the active site region of the cytochrome. On insertion of activated oxygen into the lipophilic substrate, a hydroxylated polar metabolite is generally produced, which dissociates and

moves into the aqueous environment of the cell where, if required, it becomes more polar through conjugation with GSH, glucuronic acid, sulfate, bile acids and so on. Polarity, size and charge are just some of the characteristics that determine the route of excretion, whether into bile or urine (Smith, 1973).

4.4 Pancreatic Drug-Metabolizing Enzymes

The contribution of drug-metabolizing enzymes in extrahepatic tissues in general, and in the pancreas in particular, to the overall disposition of xenobiotics *in vivo* is considered to be small, even in those organs where enzyme induction is known to occur, such as the lung and kidney. Nevertheless, drug metabolism in extrahepatic sites may be toxicologically very significant (reviewed in Braganza, 1991; Go *et al*., 2005; Pavek and Dvorak, 2008). Pancreatic cytochromes P450 are known to exist in adults of many species and their distribution within acini or ducts varies between different animal species (Baron *et al*., 1983). Pancreatic mono-oxygenases are also inducible in animals and in man (Weisburger, 2002; Weibkin *et al*., 1984; Foster *et al*., 1993). Immunohistochemical methods seem to be more effective in demonstrating these drug-metabolizing systems in the healthy pancreas than the measurement of enzyme activities, possibly due to the heterogeneous nature of the tissue and the discontinuous distribution of the enzymes concerned (Norton *et al*., 1995; Anderson *et al*., 1997).

4.5 Enzyme Induction is a Double-edged Tool

It is paradoxical that a defence reaction, enzyme induction, may have deleterious consequences. This threat arises because the cellular load of oxygen radicals inevitably increases when an increased metabolic load is placed on an organ, and more importantly because certain chemicals undergo bioactivation to highly toxic species, so that prior enzyme induction amplifies the risk of tissue damage. If antioxidants are simultaneously denied, through dietary manipulation, the risk increases further. Selenium deprivation causes newly synthesized haem to be directed, and hence lost, down the bilirubin pathway, instead of being incorporated into cytochrome P450 (Correia and Burk, 1976). It is noteworthy that not all cytochrome-P450-inducers are primarily metabolized by that system. Thus, alcohol is largely metabolized via cytosolic dehydrogenases, and cytochrome P450 2E1 assists only when intake increases substantially over long periods (Go *et al*., 2005). However, even small doses of alcohol are potent inducers of that subfamily, so that they increase the yield of, and hence potential damage from, reactive intermediates of chemicals to which the individual may be simultaneously exposed and which are processed by the same system (Sato *et al*., 1980; Strubelt, 1980; Koop *et al*., 1985). Such potentially competing chemicals include nitrosamines, paracetamol (acetaminophen) oestrogens, ketones, and aliphatic and halogenated hydrocarbons.

4.6 Pancreatic Disease: Casualty of Detoxification

4.6.1 Evidence Linking Enzyme Induction in the Liver and the Pancreas

Table 5 summarizes observations in patients from Manchester, UK, which are collectively best interpreted as indicating liver, as well as pancreatic, enzyme induction and include aspects that have been discussed in previous reviews (Uden *et al*., 1990a; Braganza, 1986; 1988b; 1991; 1996). Although attractive as a hypothesis, there is little direct support for the idea that genetic polymorphism may underlie susceptibility to chronic pancreatitis among alcoholics, even though a polymorphism in the *SPINK1* gene has been associated with a threefold increased risk of developing alcoholic chronic pancreatitis (Hanck *et al*., 2003; Liddle, 2006) and although pharmacogenetic studies showed no differences between patients and controls with regard to debrisoquine hydroxylation status (P450 2 subfamily) (Acheson, 1988), there has been reported a link between a polymorphism in the UDP glucuronosyltransferase (UGT1A7) gene and increasing risk for both pancreatic cancer and chronic pancreatitis (Ockenga *et al*., 2003). Since this enzyme is concerned with Phase 2 drug metabolism it is highly likely that drug exposure in such patients might lead to a compromised elimination profile and subsequent toxicity. DNA analysis indicated that the genotypes of GSH-S-transferase T1 and M1, or cytochrome P450 2E1 did not influence disease susceptibility (Frenzer *et al*., 1997; Yang *et al*., 2001).

Pharmacokinetic studies have been more informative. They showed a modest increase in antipyrine clearance (P450 2 subfamily), but unequivocal increase in theophylline clearance (P450 1 subfamily) (Acheson *et al*., 1989; Braganza, 1996). These conclusions applied to most, if not all patients, with chronic pancreatitis, some 50% with gallstone-related acute pancreatitis, the majority with recurrent (nongallstone) acute pancreatitis, and the few with pancreatic cancer who reported relatively early. Increased theophylline clearance was also found in patients with nonalcoholic chronic pancreatitis

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat069

at Madras, South India (Chaloner *et al*., 1990). However, the clearance values in those patients were much lower than in the Manchester patients, which underlined the need to consider antioxidant status, rather than enzyme induction alone.

Ultrastructural studies from Europe showed an increase in the volume density of smooth endoplasmic reticulum in hepatocytes (Soames *et al*., 1988) and in the volume density of both rough and smooth endoplasmic reticulum in pancreatic acinar cells (Tasso *et al*., 1973) in patients with chronic pancreatitis. Immunocytochemistry of surgically obtained tissue fragments, using a panel of monospecific antibodies against different cytochromes P450, provided evidence of enzyme induction (Foster *et al*., 1993).

A few other studies have been published on immunohistochemical localization of drug-metabolizing enzymes in the normal human pancreas (McManus *et al*., 1987; Sasano and Sasano, 1988) but not, to our knowledge, in the diseased gland.

4.6.2 Evidence for Oxidative Stress in Liver and Pancreas

Table 5 also summarizes observations pointing to oxidative stress in liver and pancreas of British patients with chronic pancreatitis. Recent studies give clear evidence of heightened free radical activity in African patients with alcoholic disease (Gut *et al*., 1994) in whom iron overload could not be incriminated (Segal *et al*., 1996).

4.6.3 Evidence for Micronutrient Antioxidant Insufficiency

Three sets of observations suggested that a lack of dietary antioxidants may be relevant to the pathogenesis of the disease. In patients admitted with acute-on-chronic pancreatitis there is frequently a rapid, early-phase, disappearance of injected bromosulfthalein (BSP), together with high levels of bilirubin in secretin-stimulated bile. Additionally a high lactoferrin content of pancreatic juice can also be observed, especially in tropical, nonalcoholic, pancreatitis. The first two findings are reminiscent of those that accompany enzyme induction in selenium-deficient animals (Correia and Burk, 1976; Diplock, 1984) while the third reminds us that lactoferrin has appreciable antioxidant potential (Braganza and Worthington, 1995).

Home dietary inventories in patients with idiopathic chronic pancreatitis, who had not changed their diets or lifestyles between attacks, revealed significantly lower intakes of selenium and vitamin C than in age, and gender-matched, controls. Female patients also ingested lower amounts of many other antioxidants (**Figure 14**). Selenium was the best discriminator overall, and consideration of this factor, alongside theophylline clearance, a marker of cytochrome P450 1 induction, gave a discriminant line (**Figure 15**) to separate data from controls (with higher intakes of selenium for any given level of theophylline clearance) and chronic pancreatitis patients (Rose *et al*., 1986). Data from patients with acute pancreatitis were in the borderline zone. A similar demarcation emerged when blood 9,11 LA' and selenium concentrations replaced theophylline clearance and selenium intake, respectively, in a discriminant analysis (Uden *et al*., 1988; 1992), which suggested that this trace element may help to curb the isomerization pathway of free radical attack on lipids.

When these studies were extended to include a group of enzyme-induced controls, that is, patients with epilepsy on treatment with anticonvulsant drugs, the lower intakes of methionine and vitamin C emerged as the key factors in identifying patients with chronic pancreatitis (Uden *et al*., 1988). These findings strongly suggested the potential importance of reactive intermediates from xenobiotics in the development of chronic pancreatitis, compared with ROS in several animal models of acute pancreatitis and in their human counterparts (**Table 3**). GSH is a major defence against reactive electrophilic chemical species and the rate-limiting component for its synthesis, cysteine, draws on the essential amino acid methionine for its source (**Figure 7** and **Figure 16**). A previous study from Sweden had implicated a breakdown in the methionine trans-sulfuration pathway in patients admitted with an alcohol-induced exacerbation of chronic pancreatitis (Martensson and Bolin, 1986).

In a clinical trial where the diet was supplemented with essential nutrients, the combination of delivered methionine, as a precursor for GSH, along with vitamin C and selenium as GSH refurbishers (Uden *et al*., 1990b; Braganza, 1991) was shown to be effective in reducing symptoms of recurrent acute pancreatitis. SAMe was ineffective on its own, or when combined with β-carotene and selenium (Bilton *et al*., 1994). It is also interesting to note a recent report that in families with hereditary chronic pancreatitis, vulnerable members are earmarked by their poor antioxidant status, and antioxidant supplements to bolster GSH ameliorated symptoms (Prasad *et al*., 1996). Along the same lines, there is persuasive evidence to support the concept that a deficiency in pancreatic GSH is involved in tropical chronic pancreatitis and that the gland may be damaged by the concurrent ingestion of cyanogenic glycosides (Wallig *et al*., 1988).

These observations find parallels in animal studies, where selenium deficiency caused dilatation of the RER in pancreatic acinar cells, followed by cell differentiation and replacement fibrosis, as was also caused by a deficiency of zinc (Go *et al*., 1993). Copper deficiency, too, tended to result in damage to the acinar cells selectively, causing them to transdifferentiate into hepatocyte-like cells when the normal diet was resumed some eight

weeks later (Rao *et al*., 1988). The effects of experimental methionine deficiency were shown to vary with degree of deficiency and duration. Hence, when administered carbon tetrachloride, a mild protracted deficiency resulted in pancreatic fibrosis (Veghelyi *et al*., 1950a; Veghelyi and Kemeny, 1962), whereas a more severe deficiency accelerated frank toxicity (Veghelyi *et al*., 1950a) causing vacuolation of pancreatic acinar cells and cystic dilatation of acini, while profound deficiency, along with dietary choline depletion, resulted in haemorrhagic pancreatic necrosis (HPN) (Rao *et al*., 1976).

4.6.4 Integrated Scheme

The control of the symptoms of pancreatitis by antioxidant supplementation is powerful evidence that the aberrations seen may be linked to disease pathogenesis. **Figure 9** integrates the three sets of aetiological factors—cytochromes P450 inducers, factors decreasing micronutrient antioxidant availability, xenobiotic sources of reactive intermediates—into a template for the pathogenesis of chronic pancreatitis.

Further, it seems that the gland can be damaged from reactive intermediates generated *de novo* through induced pancreatic cytochromes P450, and also from stable metabolites that are generated via induced hepatic cytochromes P450, if they entered the gland in refluxed bile or in the bloodstream (**Figure 8**). This deduction finds echoes in experimental pancreatic carcinogenesis (see below).

5 ABNORMAL PANCREAS: OBSERVATIONS AND TRADITIONAL INTERPRETATIONS IN MAN

5.1 Diseases and Definitions

Acute pancreatitis, chronic pancreatitis and pancreatic cancer are the main acquired diseases of the exocrine pancreas in man. The gland is affected in kwashiorkor and by the ageing process, it can be damaged *in utero* in the congenital disease, cystic fibrosis, and is involved in the inherited metal storage diseases, haemochromatosis and Wilson's disease (Klöppel and Heitz, 1984; Braganza, 1991; 1992).

Pancreatitis, inflammation of the exocrine pancreas, usually manifests in man as a severe attack of upper abdominal pain accompanied by a sharp rise in blood levels of pancreatic enzymes. Spontaneous and rapid resolution follows in some 60% of patients, but other patients develop a local complication, commonly a pseudocyst, or deteriorate with multiple organ dysfunction syndrome (MODS). The death rate of around 20% has

not changed in the past 20 years. About half of the deaths occur within the first week, while the remainder die during the second week when the devitalized pancreatic bed becomes overrun by colonic bacteria (Braganza and Chaloner, 1995).

Pancreatitis may strike a gland that was previously normal and will return to normal when, and if, it recovers from the active lesions of oedema and/or haemorrhage and/or necrosis. The term 'acute pancreatitis' describes this situation and the same term is applied if recovery is complete following future attacks (**Figure 16**). Alternatively the attack, or recurrence, may occur against a background of chronic destruction, in which case the pathology is proof, after the superimposed lesions of active damage, and associated abdominal pain, which punctuate the clinical course of the disease, have healed.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat069
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The term 'chronic pancreatitis' describes this development. The established disease has the characteristic triad of steatorrhoea, intraductal calculi and diabetes (Külling *et al*., 2003). It is noteworthy that pancreatic cancer may present with, or be complicated by, acute or chronic pancreatitis, while the chronic pancreatitis-like lesions of cystic fibrosis occasionally manifest as a painful attack.

Chronic pancreatitis is damaging and, although it does not usually result in death directly, reduces lifespan from associated problems such as diabetes and maldigestion. The cardinal problem in pancreatic cancer is the long presymptomatic period of tumour growth. Death follows within six months of the first symptom in most patients; hence mortality statistics give incidence, as well as prevalence rates. Between 1940 and 1980 the age-adjusted death rate from pancreatic cancer doubled in the UK, trebled in the USA and quadrupled in Japan, but there has been a levelling off in mortality rate thereafter.

5.2 Acute Pancreatitis

5.2.1 Aetiological Factors

Gallstones are the overriding risk factor. They are present in some 50% of acute pancreatitis patients in the USA and Europe, but in a much higher proportion in South America, and in more than 75% of patients over the age of 80 years, irrespective of geography (Frossard *et al*., 2008). The composition of gallstones varies widely, from almost pure cholesterol stones through to almost pure pigment stones (Braganza, 1988a). The 'migrating gallstone theory' regards transient obstruction to drainage of pancreatic fluid, when a tiny gallstone migrates from bile duct into the duodenum, as the cause of acute pancreatitis (**Table 3**). This explanation is supported by the ease with which oedematous pancreatitis is produced experimentally when the pancreatic duct is clamped transiently, and even more easily when secretin is simultaneously infused.

Certain agents seem to initiate the human disease by compromising the pancreatic microcirculation, while others may do so by interfering with the metabolism of the acinar cell. Experimental models are available to simulate these situations (**Table 3**). The acinar-ignition route of clinical pancreatitis leading to a severe outcome is nicely mimicked when young mice are reared on a diet that deprives them of the essential fatty acid, choline, and the essential sulphur amino acid, methionine, (CDE dietary model).

The following conditions may damage the pancreas by more than one route, sequentially or concurrently: an alcoholic debauch (which increases duodenal and sphincter pressure while also affecting the metabolism of pancreatic acinar cells), cardiopulmonary bypass surgery (which could compromise the pancreatic microcirculation, but also involve prolonged exposure to volatile anaesthetics which might be the true precipitant), combined pancreas-renal transplantation (when the same considerations apply with the additional possibility of drug-mediated toxicity) and pancreatic hyperstimulation, as may occur following exposure to the insecticide diazinon, or the bite of a scorpion (which not only increases ductal pressure but also alters acinar cell metabolism).

5.2.2 Pathophysiology and Progression of Acute Pancreatitis

It is generally assumed that an attack of pancreatitis represents autodigestion of the pancreas by its prematurely activated enzymes, notably elastase and phospholipase A2. The finding of these enzymes in the pancreas or ascitic fluid of animals with established HPN, or of 'activation peptides', released from trypsinogen and other precursor enzymes, in urine from animals and patients with severe disease, has been accepted as proof of this philosophy. A popular theory for premature activation of trypsinogen in patients with gallstone pancreatitis is depicted in **Figure 17**. However, it fails to explain why the experimental transpancreatic passage of bile, via an intestinal loop for many months, results in the complete activation of pancreatic enzymes, but not HPN. Another theory revolves around bacterial toxins present in infected bile or duodenal fluid, but once again definitive evidence of infection is lacking at the time of presentation in most patients. Proposals to overcome these objections include activation of trypsinogen by lysosomal cathepsin B, or altered calcium compartmentalization in pancreatic acinar cells.

Upon recovery, 'tubular complexes' appear within the pancreas. These represent dedifferentiated acini—also termed redifferentiated, transdifferentiated, retrodifferentiated or phenotypically modulated acini (Bockman, 1995). These complexes disappear in oedematous pancreatitis, but in HPN they persist until the acini are completely effaced.

5.3 Chronic Pancreatitis

5.3.1 Aetiological Factors

This subject has been extensively reviewed recently (Nair and Lawler, 2007; Behrman and Fowler, 2007; DiMagno and DiMagno, 2006; Talukdar *et al*., 2006). In developed countries the disease is regarded as synonymous with alcoholism (Apte and Wilson, 2003; Hanck *et al*., 2003; Sand *et al*., 2007), yet alcohol on its own is a weak risk factor, with some 17 years of drinking more than 150 g alcohol daily usually preceding the first symptom, such that the peak age at presentation is in the third or fourth decade. The paradox remains that a few patients report

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat069
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

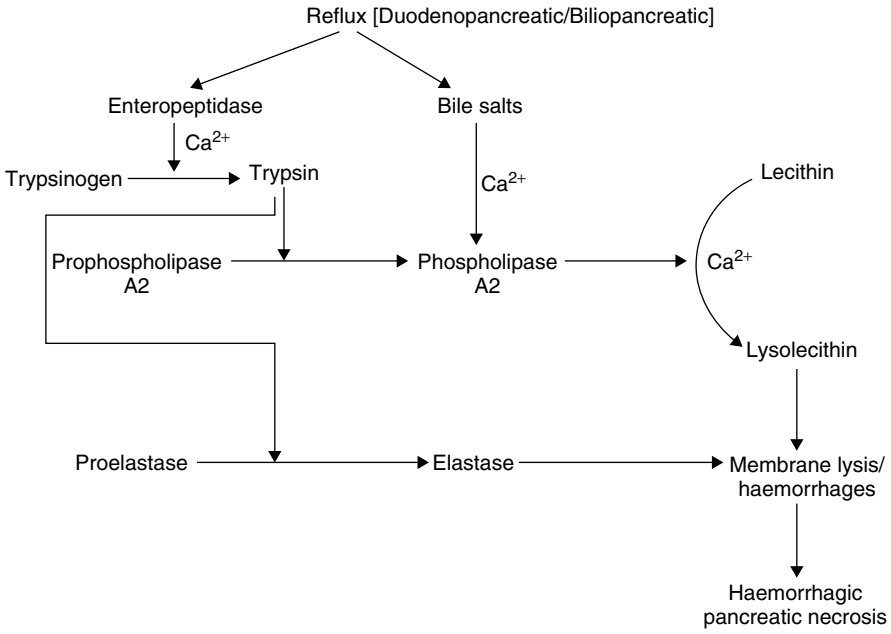

Figure 17 Traditional explanation for gallstone related pancreatitis.

with the disease after drinking less than 50 g alcohol daily for less than two years, which is said to indicate that there is no threshold for alcohol toxicity to the pancreas and/or that certain individuals are genetically predisposed (Hanck *et al*., 2003) and/or that pancreatic injury reflects the sum of toxicities from alcohol, cigarette smoke and diets that either contain too much or too little fat and protein (Sand *et al*., 2007; Oruc and Whitcomb, 2004). In Brazil, it is claimed that 100% of patients have alcoholic disease, whereas only 45% of cases in Manchester, UK, fall into this category when it is defined as the consumption of more than 50 g of ethanol per day for 12 months preceding the first symptom.

Hyperparathyroidism, surgery, chronic renal failure, renal transplantation, inflammatory bowel disease, endoscopic retrograde cholangiopancreatography and exposure to certain drugs/chemicals are other accepted risk factors, but the interaction is not straightforward. In contrast, the autosomal recessive disease cystic fibrosis is the surest cause of chronic pancreatitis.

Another inherited condition, transmitted in an autosomal dominant pattern with incomplete penetrance, is rare but well documented. Several siblings may be affected and the first symptoms occur in childhood, with 20% of patients going on to develop pancreatic cancer. In this group a mutation in the cationic trypsinogen gene at locus 7q35 has been identified recently and it has been suggested that resistance to proteolysis of trypsin underlies the vulnerability to developing chronic pancreatitis (Whitcomb *et al*., 1996). There is no ready explanation when the disease develops in family members without an ancestral history, or when it follows the alcoholic pattern in one member and is idiopathic in another.

The same disease, but with much higher prevalence, familial clustering, presentation in the first decade and accelerated course to pancreatic calculi and diabetes, is found in several countries of tropical zones, for example, southern India (Balakrishnan, 1987) where it is known as 'tropical calcific pancreatitis'. These peculiarities suggest the disease-promoting effect of indigenous genetic and environmental factors (Braganza, 1991). There is a good geographic match between the distribution of the disease and the growth/consumption of cassava (tapioca, manioc), which contains cyanogenic glycosides, which led to the hydrogen cyanide toxicity theory, namely, that there is inadequate detoxification of this poison in malnourished people because of low dietary protein and hence low sulphur amino acid intake. The main problems with this attractive theory are that certain populations who subsist on cassava do not develop chronic pancreatitis, that among residents of the tropical belt who do, there are many who have not consumed cyanogenic foods in excess, and that, whereas some patients develop the full-blown disease, others have insulin-requiring diabetes, but without calcific chronic pancreatitis. More recently a link has been made to a mutation in the serine protease inhibitor, Kazal type 1 (*SPINK1*) gene that encodes for an inhibitor of intrapancreatic trypsin activity (Bhatia *et al*., 2002).

Various animal models for alcoholic pancreatitis have been introduced over the last 20 years and they have proved valuable in helping to understand critical factors and mechanisms of the human condition (Oruc and Whitcomb, 2004). They generally fall into one of two camps, the Lieber and DeCarli (1986) model and the Tsukamoto *et al*. (1988) model. Whereas the former uses alcohol added to a nutritionally defined liquid diet

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat069
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and where alcohol exposure is discontinuous, the latter uses catheters implanted into the stomach to permit a continuous infusion of, and hence exposure to, ethanol plus liquid diet. Neither model is accurate in its depiction of the mode of exposure in the human population, but each has produced the morphological characteristics of chronic ethanol-induced pancreatitis.

A rat model with many of the characteristic features of chronic pancreatitis in man was developed in the rat (Puig-Divi *et al*., 1996) using an intraductal injection of trinitrobenzene sulfonic acid, which is reported to reproduce both the morphological changes seen in the pancreas together with the hallmark 'pain' observed during the onset and progression of the human disease (Winston *et al*., 2005). Animal models generally vary in their similarity to the clinical presentation and progression of the human form of chronic pancreatitis and while some will mimic the histological picture of fibrosis and tubular complexes, similar to that of the human disease, more natural methods of producing the disease, showing the full clinical spectrum, including abdominal pain, pancreatic failure and vascular and gastrointestinal complications, have not generally been reproduced (Hirschfield and Gimson, 2007). On the other hand various simplified animal models can be instructive for helping to dissect this complex syndrome and build a more realistic understanding of the disease in man.

5.3.2 Pathophysiology and Progression of Chronic Pancreatitis

The classical mode of presentation of chronic pancreatitis is with an attack of acute pancreatitis, followed by further attacks (**Figure 6**), with a steady erosion of exocrine secretory capacity, although the rate of progress is unpredictable and varies between patients. Most of them develop background pain of increasing intensity but this is multifactorial, with inflammatory oedema and irritation of nociceptive nerve endings in the interstitium being prominent components. Viable acinar cells may be a prerequisite, in that pancreatic pain tends to disappear when more than 90% of acini are lost. There is a correlation between chronic pancreatitis and the future development of pancreatic cancer (Lowenfels *et al*., 1993; Hart *et al*., 2008).

Between attacks, secretory profiles initially show increased amounts of pancreatic proteins, including lysosomal enzymes, but there is a reversal in the normal 2:1 ratio of cationic to anionic trypsinogen in patients who go on to develop pancreatic calculi. Later secretory changes include an increase in lactoferrin and mucoprotein in the pancreatic secretion. The nidus of a calculus has been shown to consist of shed cells around which protein fibrils, calcium, mucin and lactoferrin aggregate to form a matrix for deposition of calcite (calcium carbonate). As time goes by, there is a steady reduction in both protein and bicarbonate secretion, and with each attack of pancreatitis, increasing groups of acini die. Tissue lysis and remodelling is facilitated by activation of prourokinase at the plasma membrane aspect of acinar cells (Freiss *et al*., 1997), with overexpression of transforming growth factors and activation of the epidermal growth factor receptor. Alongside these changes, acinar cells dedifferentiate to form tubular complexes before they are finally replaced by fibrous tissue. Islets may show nesidioblastosis (hyperactivity), even when patients are frankly diabetic.

Because the earliest abnormality seen in chronic pancreatitis at the light microscopic level is the ductal protein plug, because ducts become more distorted over time, and ductal calculi and strictures may develop, ductal elements are traditionally regarded as the focus and ductal obstruction as the cause of the disease. The ductal theory is undermined by the discovery of free anastomoses between the lumina of the pancreatic ducts and the acini. Nevertheless, a possible role for bile reflux in initiating ductal strictures in the 'head' of the gland is suggested by the rare histological finding of bile pigment throughout the duct system or sequestered within the pancreatic parenchyma (Braganza, 1986; Sandilands *et al*., 1990).

5.4 Cancer of the Pancreas

5.4.1 Aetiological Factors

Established risk factors include old age, high fat/protein diets, genetic predisposition and tobacco smoke, with the latter estimated to be responsible for >30% of all cases in the UK (Oliveira-Cunha *et al*., 2008; Hart *et al*., 2008). A series of reports suggests that exposure to certain volatile industrial chemicals may also be involved. Alcoholism remains under suspicion as a risk factor. Familial background of pancreatic cancer is suggested by the susceptibility of American Negroes and the occurrence of the disease in siblings, kindreds with hereditary chronic pancreatitis, and patients with ataxia telangiectasia.

5.4.2 Pathophysiology and Progression of Pancreatic Cancer

Pancreatic ductal cells are generally regarded as being the source of most human pancreatic cancers, but there is some evidence that acini can undergo metaplasia to tubular/ductal complexes and these cells may be the true progenitor in a number of cases (Bockman, 1995). Most tumours in man lie in the 'head' of the gland, a predilection that is not entirely explained by its relatively greater amount of ductal epithelium. It has been

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

suggested that reflux of a biliary carcinogen or procarcinogen directly, or via the duodenum, into the pancreatic duct may explain this propensity. A tumour developing in the head of the pancreas can rapidly obstruct the pancreatic and/or common bile duct and accelerate any pancreatic damage through partial blockage of pancreatic outflow following neurohormonal stimulation. Pain, diabetes and weight loss are commonly associated with pancreatic cancer, as is recurrent thrombosis of peripancreatic and systemic veins and the expression of tissue-type plasminogen activator in the plasma membrane of cancer cells has been described and may be a compensatory phenomenon (Steven and Al-Ahmad, 1984).

Orthotopic models of human pancreatic cancer, whereby a human pancreatic cancer cell line is implanted at, or near to, the pancreas of severe combined immunodeficient mice have provided excellent systems for assessing novel chemotherapeutic agents against the disease (Céspedes *et al*., 2006), but have probably provided little additional information about the natural history and progression of pancreatic cancer.

Cultured human pancreatic explants have also provided a tool to study certain aspects of the human disease. Biochemical studies have shown the DNA-damaging effects of certain nitrosamines, and formaldehyde, on the pancreatic cells, while immunohistochemical studies indicate the persistence of O6-methyl guanine in target cell nuclei after treatment with alkylating nitrosamines.

Acquisition of the cancer phenotype involves activation of oncogenes and, in the case of the pancreas, the c-K-ras oncogene seems to be preferentially activated by mutation at codon 12 in >90% of cases in the UK (Oliveira-Cunha *et al*., 2008; Agbunag and Bar-Sagi, 2004), with very high incidences of inactivation of thep16/RB1 (>90% of cases), p53 (~75%), DPC4 (55%) and BRCA2 tumour-suppressor genes (Jimeno and Hidalgo, 2006; Wenger *et al*., 1999; Lebedeva *et al*., 2006; Hruban *et al*., 2000). Oncogenes, in turn, cause increased expression of receptors for growth factors on plasma membranes of cells, leading to activation of the growth-promoting ornithine pathway. Other characteristic features include loss of certain cell surface proteins and increased expression of others, notably a plasminogen activator-like protease, along with increased expression of an intracellular multidrug-resistance (MDR) gene product P-glycoprotein (Goldstein *et al*., 1989), and an early increase in the ratio of lysosomal to digestive hydrolases in pancreatic juice.

Studies of experimentally induced pancreatic carcinogenesis have proved invaluable in understanding the evolution of human pancreatic cancer (Moossa, 1980; Scarpelli *et al*., 1987; Go *et al*., 1993). As with most induced cancers, a multistep evolutionary pattern is accepted (Hirst and Balmain, 2004). Genotoxic agents, whether chemical, virus or other, damage nucleophilic oxygen, as well as the nitrogen atoms of the DNA bases. The most reactive groups in DNA are the N-7 of guanine and N-3 and N-7 of adenine. DNA damage is generally rapidly repaired by specific enzymes, but multiple 'hits', epigenetic agents (tumour promoters) and genetically determined defects in DNA repair, are just some of many factors that favour conversion of a DNA lesion to a mutation.

6 PANCREAS: TARGET FOR OXYGEN RADICAL TOXICITY

6.1 Oxidative Stress in Experimental Acute Pancreatitis

6.1.1 Oedematous Pancreatitis

Time-course analysis of experimental models shows that whatever the inciting agent or its route of attack may be (**Table 3**), and whether the disease pursues a self-limiting or life-threatening pattern, the pivotal problem is a metabolic blockade to exocytosis, that follows close on the heels of a burst of free radical activity. Inflammation is a secondary event, so 'pancreastasis' is a better descriptor than pancreatitis for the earliest metabolic aberration (Braganza, 1988a; 1988b; 1990; 1991; Braganza and Chaloner, 1995).

The early events following induction of pancreatitis in most models can be rationalized as an attempt by the cell to get rid of pent-up secretions and to combat oxidative stress:

1. The normal secretory products of the gland are rerouted via the basolateral membrane, draining off into the lymphatics and into the bloodstream.
2. There is excessive fusion of the lysosomal and zymogen compartments, demonstrable as cytoplasmic vacuoles by microscopy, and within these spaces trypsinogen is activated by cathepsin B en route to its complete degradation and without any spill-over into the systemic circuit, as can be tracked by analysing urine for 'activation peptides' (Leach *et al*., 1992).
3. The cell switches off its synthesis of elastase, instead showing up-regulation of stress-activated PK with over-expression of mob-1 and mcp-1 chemokine genes (Grady *et al*., 1996; 1997) and a particular brand of acute phase protein that has bacteriostatic potential, the pancreatitis-associated protein (McKie *et al*., 1996). The changes seen in chemokine gene expression, implicate nuclear factor κ B (NFκB), released from its precursor peptide

by the burst of free-radical activity (Schreck and Baeuerle, 1991).

There is little doubt regarding the initiating burst of oxidant damage, and it has been directly demonstrated by chemiluminescence measurements in a model of hyperstimulation and by electron spin resonance spectroscopy in the CDE dietary model. Further, pretreatment with superoxide dismutase and catalase confers protection in several models, whereas the administration of oxidizing agents caused a sharp reduction in pancreatic secretion in the isolated perfused pancreas preparation (Braganza, 1991; Kingsnorth, 1996). However, the precise source of the free-radical burst in pancreatic acinar cells is unclear, as is the precise cause of the exocytosis blockade.

In theory, there are many ways in which oxidative stress might interfere with exocytosis (van der Vliet and Bast, 1992): by activating guanylate cyclase and altering the balance between G- and Gs-proteins), by interfering with microtubular transport systems and actin, by reducing membrane fluidity through production of 9,11-lauric acid, by attacking vulnerable enzymes in the methionine trans-sulfation pathway and thereby reducing membrane phospholipid methylation (**Figure 7**). It may be that different mechanisms operate in different animal models. However, observations in the CDE dietary model, viewed alongside more recent observations in caerulein-induced pancreatitis (Luthin and Grendell, 1994), suggest that interference in the methionine trans-sulfation pathway may be the critical factor. Studies of hepatocytes treated with DL-ethionine show that this analogue follows the metabolic pathway of the natural amino acid methionine, but does not readily donate its ethyl group in the way that SAMe donates its methyl group; the adenine moiety is thus trapped, depleting cells of ATP and jeopardizing protein and PIP_3 synthesis. The additional deprivation of the choline would remove the choline-betaine pathway that contributes to the limited capacity to resynthesize methionine from homocysteine.

6.1.2 Free Radicals Do Not Rationalize Haemorrhagic Pancreatic Necrosis

The zymogens of human pancreatic proteases (Guyan *et al*., 1988), and also phospholipase A2, are not activated, nor is pancreatic trypsin inhibitor destroyed, upon exposure to high doses of the primary or secondary metabolites of oxygen. Hence, it is very unlikely that oxygen free radicals directly activate pancreatic zymogens to initiate HPN. Instead, many observations suggest that activated phagocytes may be the primary source of elastase and phospholipase A2 in HPN (Braganza, 1988b), and also the main cause of MODS, through frustrated phagocytosis coupled with premature immunosuppression (Braganza, 1988b; 1991; Rinderknecht, 1988; Braganza and Chaloner, 1995). In this scheme (**Figure 6**), the discharge into the pancreatic interstitium of FROPs, together with PAF and tumour necrosis factor (TNF), produced in excess by the injured acinar cell, are envisaged as causing the early degranulation of mast cells (Hollender *et al*., 1983) with early activation of the endothelium. PAF, initially from the acinar cell and then from the mast cell, seems to serve as a second relay station, such that neutrophils are bombarded and respond aberrantly. These enzymes, together with chemokines, hypochlorous acid (HOCl), complement factors and kinins, flood the bloodstream and can be detected as a consequence.

The amplitude of the initial free-radical burst did not distinguish between mild and severe disease in animal models. Hallmarks of severe disease are an unremitting blockade of exocytosis, the presence of irritant material, such as bile salts or cell casts (**Table 3**), death of injured cells by necrosis rather than apoptosis, hordes of neutrophils, truncation of capillaries with platelet thrombi and premature immunosuppression (Braganza, 1988b). In this highly proinflammatory, procoagulant state, trypsinogen and pancreatic phospholipase A2 are ignited, most probably by way of plasmin and thrombin.

6.2 Oxidative Stress in Human Acute Pancreatitis

6.2.1 Pancreastasis and Phagocyte-Activation Sequence

Prospective studies, in situations where pancreatitis is expected, collectively confirm that the template for the evolution of acute pancreatitis shown in **Figure 16** is applicable to the human disease. Thus, ERCP causes pancreatitis by the ductal ignition route (Kemppainen *et al*., 1997; Messmann *et al*., 1997), pancreas transplantation (Büsing *et al*., 1993), coronary artery bypass grafting (Fernandéz del Castillo *et al*., 1991) and aortic aneurysm repair (Gullo *et al*., 1996) exemplify ischaemia-reperfusion injury to the pancreas, and haemolytic uraemic syndrome and Reye's syndrome offer the opportunity to study pancreatitis from metabolic derangements in the acinar cell (Durie *et al*., 1985) (**Table 3**).

The early burst in free-radical activity is suggested by the ultrastructural findings in pancreatic acinar cells during the ischaemic phase of pancreas transplantation. The exocytosis blockade with reversal in secretory polarity is also clearly demonstrated in pancreas transplants. The presymptomatic increase in trypsinogen with appearance of trypsin-inhibitor complexes some 48 hours later were striking findings in children with the stated metabolic problems. This sequence was accelerated in patients undergoing ERCP, when trypsinogen peaked at six hours with trypsin/antitrypsin complexes notable at

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat069

24 hours and rising. Finally, studies of ERCP pancreatitis indicated an increase in interleukin-6 beginning one hour after the procedure and increasing to maximal levels after 24–48 hours, with the elicited increase in C-reactive protein evident from 12 hours and peaking at 72 hours.

In day to day practice, the time lag between first symptoms and diagnosis of acute pancreatitis usually exceeds 15 hours and may be as long as 72 hours. At this stage, admission blood samples show clear evidence of oxidative stress with marked depletion of several antioxidants, notably plasma GSH, ascorbate and selenium, but with preservation of red cell GSH and ATP levels. From the earliest sampling point there are high concentrations in plasma of neutrophil elastase-α_1PI complexes, markedly higher in patients who go on to have a severe outcome. By 48 hours this subgroup shows evidence of inappropriate trypsinogen activation from the presence of anionic trypsin-inhibitor complexes in serum, the activation peptide of trypsinogen and especially of carboxypeptidase B in urine (Gudgeon *et al*., 1990; Kemppainen *et al*., 1997; Appelros *et al*., 1998). Phospholipase A2 profiles show an early increase in the synovial-type isoenzyme and the pancreatic isoenzyme mimic from certain phagocytes (Kingsnorth, 1996), with the later appearance of the indigenous pancreatic isoform. It is now accepted that acute pancreatitis epitomizes the systemic inflammatory response syndrome (SIRS), the natural progression of which is death from MODS (**Figure 16**) (Braganza and Chaloner, 1995).

Whereas daily treatment with *N*-acetylcysteine, in a handful of patients with MODS undergoing haemodialysis, produced dramatic results (Braganza, 1991), in a second study *N*-acetylcysteine, together with another GSH precursor, SAMe, had no impact in all-comers, when treatment was restricted to the first 24 hours in a controlled trial (Sharer *et al*., 1995). Similarly, enthusiastic early reports of the benefit of a PAF antagonist (Kingsnorth, 1996) are now more muted with the realization that the drug is most useful if given within the first six hours to patients who might appear only moderately ill. Treatment with the PAF antagonist (lexipafant) was associated with lower blood concentrations of interleukin-8 than in the untreated group, but without any reduction in plasma concentration of neutrophil elastase-α_1PI complexes. Therefore the benefit from lexipafant may have stemmed from its antioxidant function, in that partially oxidized lipid fragments such as isoleukotrienes and isoprostanes exert their toxic effect via the PAF receptor (Nigam *et al*., 1996).

6.2.2 Recurrent (Nongallstone) Pancreatitis

If a burst of free-radical activity underlies an isolated attack of pancreatitis, then it seems reasonable to assume that further bursts underlie successive attacks (**Figure 18**). These are predictable in patients with a congenital deficiency of the enzyme lipoprotein lipase, in whom high levels of triglycerides, of the order of $20-100\,\mu mol\,l^{-1}$, are the rule. Attacks typically begin in childhood. Many patients are characterized as recurrent acute pancreatitis with normal exocrine secretory capacity between attacks, but a few may develop chronic pancreatitis with a steady reduction in exocrine secretory reserve and increasing background pain (**Figure 18**). Daily oral administration of an antioxidant combination, including methionine as a precursor for GSH, along with vitamin C and selenium as GSH refurbishers has been shown to prevent exacerbations of pancreatitis in these patients. The successful formulation also contained vitamin E and β-carotene but blood antioxidant profiles before and after supplementation showed that levels of the lipid antioxidants were in the high-normal range pretreatment, whereas the concentration of GSH in red cells and levels of GSH, vitamin C and selenium in plasma/serum were subnormal pretreatment and normalized thereafter (Heaney *et al*., 1999).

6.2.3 Oxidative Stress in Other Pancreatic Diseases

With regard to the development of pancreatitis in patients with cystic fibrosis, a significantly higher frequency of a mutation in one copy of the CFTR gene has been found in patients with chronic pancreatitis than among unrelated partners of patients with cystic fibrosis in the absence of chronic pancreatitis (Quesnel *et al*., 1998). Furthermore the highest frequency of the mutation was found among nonalcoholic pancreatitis. It was also shown that CFTR is present in pancreatic acini and that the normal CFTR protein is involved in vesicle trafficking and macromolecule targeting, over and above its role in ion transport (Quesnel *et al*., 1998). Loss of the normal function of CFTR protein in cystic fibrosis has the potential to prevent exocytosis, setting in motion the train of events leading to chronic pancreatitis and, further, that in cystic fibrosis carriers, the smaller quota of wild-type protein makes them more vulnerable to oxidative stress from unquantifiable xenobiotic exposures, for example, through passive smoking (Childers *et al*., 2007). There is some evidence that frustrated phagocytosis may contribute to the lung injury seen in cystic fibrosis, when neutrophil-derived oxidants wipe out the α_1PI shield in the airways (Bilton, 1992; Vandivier *et al*., 2006; Morris *et al*., 2005).

Oxidative stress has been documented in kwashiorkor (Golden and Ramdath, 1987; Dreosti, 1991) and seems to represent the combined effects of poor dietary antioxidant intake coupled with increased free-radical load from infective agents, dietary/atmospheric contaminants, strong ultraviolet rays and other sources. Iron-catalysed free-radical production plays an important part in the tissue injury of haemochromatosis and it is likely that copper-catalysed reactions are similarly involved in

Wilson's disease (Langner and Denk, 2004; Kitzberger *et al*., 2005).

6.3 Summary: Target for Toxicity

An overriding goal of laboratory animal studies, in all aspects of toxicology, is to relate any adverse findings with drugs and chemicals to a possible risk to man after either intentional or accidental exposure. It is now clear that the expression of toxicity *in vivo* depends not upon broad similarities between species, but rather upon specific absorption, excretion, pharmacological and metabolic properties of the animal and/or the compound in question, over and above the question of dose. The concentrations and efficiencies of xenobiotic activating and detoxifying enzyme systems differ markedly between outwardly healthy laboratory animals and man (Anderson *et al*., 1997). In many cases the differences are quantitative rather than absolute (Garner *et al*., 1984) with human tissues generally showing lower amounts of activating enzyme systems (Foster *et al*., 1993).

In terms of the pancreas, the physiological control of function in rodents and man is similar in some respects, but not in others (Longnecker, 2004). The species factor is extremely important and while there is clear evidence of feedback control on CCK release by dietary components in the rat, this is a hotly debated issue in man. In contrast the hamster may be closer to man than the rat in regard to drug-metabolism studies, because of the high intrinsic rate of drug metabolism which rationalize the ease with which ductal adenocarcinomas, so similar to human pancreatic cancer, develop upon exposure to certain nitrosamines. Recent reports of rat pancreatic cancer, including a ductal phenotype lesion from a tobacco-specific nitrosamine (Rivenson *et al*., 1988; Pour and Rivenson, 1989; Hoffman *et al*., 1991; Adsay *et al*., 2000) are of particular interest because of the strong link between cigarette smoking and the human disease, and also because of the recent finding of aromatic amine and nitro aromatic hydrocarbon-adducts in eight among 29 DNA samples from organ donors (Anderson *et al*., 1997). It is unlikely to be a coincidence that many of the drugs and chemicals incriminated/suspected in the aetiology of exocrine pancreatic disease require bioactivation for their toxicity. The paradox that the pancreas bears the brunt of injury in chronic pancreatitis, even though the liver is clearly involved (**Table 5**), may result from a much greater endowment of GSH and other detoxification systems in the liver. It may also be that smoking provides an inhalation exposure route that would optimize the pancreas, with its rich arterial blood supply, being exposed to any noxious chemicals present in the smoke.

Observations in patients with alcoholic chronic pancreatitis have shown that overt signs of liver damage may be delayed for a decade after the first symptom of pancreatic damage (Howat and Sarles, 1979). Involvement of liver cytochromes P450 in the pancreatic cancer setting may explain why hepatic metastases are often present at the time of clinical presentation in pancreatic cancer in man. The spectrum of pancreatic injury inducible by the same toxin, for example, DL-ethionine or ethanol, underlines the need to consider dose, species, confounding factors and a multiplicity of potential tissue-damaging agents, including products of activated phagocytes and the immune response. Finally, the mystery of ketone resistance in diabetics with chronic pancreatitis, especially in tropical zones, may be resolved if induced cytochromes P450 2E are implicated, as this isoenzyme family seems to be important in processing ketones.

7 HORIZONS

The bulk of information presented in this chapter suggests that the regulated secretory pathway in pancreatic acinar cells is exquisitely sensitive to oxidative stress, and that this vulnerability plays a major part in each of the acquired pancreatic diseases (Braganza, 1991). There are clues as to the pathogenesis of oxidative stress in these diseases as well as in certain congenital diseases (**Table 10**) (Braganza, 1991). The predominance of cytochromes P-450 as a source of excessive free-radical activity should not come as a surprise when one considers that this is a very primitive acquisition in phylogenetic terms (**Figure 1**). Hence, evidence of chemical damage to pancreatic acinar cells in lower vertebrates, for example, the toxicity of weed killers in teleosts, or diesel oil in trout (**Table 4**), should not be disregarded as irrelevant to human pancreatic disease. The similarity in patterns of pancreatic damage from toxic metabolites or antioxidant deficiency, for example, vacuolation of cytoplasm and dilated endoplamsic reticulum on exposure to many toxins, as well as from isolated trace metal deficiency, or production of'pancreatic hepatocytes' by a particular regimen of BOP treatment or copper deficiency, can be reconciled with the realization that each manoeuvre would precipitate oxidative stress. These factors can probably be considered as components of disease aetiology (Rothman, 1986), insofar as pancreatic disease is concerned (**Table 10**). The inhalation route may be especially important with regard to the second and third components, while the first component has implications for treatment and, more importantly, for prophylaxis.

ACKNOWLEDGEMENTS

I would like to thank Mrs. Sandra Roe of the Medical Illustrations Department at the Manchester Royal Infirmary for preparing the original figures on both of the previous two editions. Finally I would like to acknowledge the one person without whom this chapter could not have been written, Dr. Joan M Braganza, who I understand is enjoying her retirement in the bosom of her family. I trust that I haven't done her an injustice in the changes that I have made to her original manuscript.

Skeletal Muscle Toxicology

M. Alexander Kenaston, Ellen M. Abramson, Matthew E. Pfeiffer and Edward M. Mills

CONTENTS

1 INTRODUCTION

Skeletal muscle is the workhorse for all voluntary movements of limbs and tissues, and accounts for approximately 45% of body weight in adult males (~35% in females). Humans have approximately 630 skeletal muscles. Skeletal muscle is also the most metabolically demanding tissue in the body and uses roughly half of all the energy consumed. Given these properties, muscle toxicity (myotoxicity) and dysfunction can result in a variety of detrimental metabolic disturbances and even life-threatening sequelae for the patient. Because of its broad clinical coverage and significance, myotoxicity induced by environmental (poisons, drugs and microgravity) and endogenous (hormones, temperature) insults has been the subject of intensive research interest for decades. Insights gained from experimental and clinical research in skeletal muscle toxicology have contributed

greatly to the understanding of normal muscle physiology, and to the clinical management of drug-induced and idiopathic myopathy syndromes. However, skeletal muscle toxicology has received comparatively little attention in textbooks of toxicology.

The enigmatic adage *form follows function* is particularly suited to skeletal muscle. Muscle cells are designed to contract and relax in a homeostatic process to enable coordinated, purposeful movements such as walking or winking, and the manipulation of external objects. During embryonic development, multinucleated skeletal muscle fibres arise from the fusion and differentiation of multiple skeletal muscle stem cell precursors or myoblasts into elongated, cylindrical muscle fibres (a single muscle fibre = myocyte) specialized for contraction. A single muscle is composed of multiple parallel muscle fibres ranging in diameter from 10 to 100 μm, and up to several centimeters in length. Within myocytes, intracellular contractile elements, referred to as myofibrils, contain highly structured thick actin and thin myosin filaments. Upon excitation by motor neurons at the neuromuscular junction, an influx of extracellular Ca^{2+} and concomitant accumulation of intracellular Ca^{2+} from endoplasmic reticulum (ER; 'sarcoplasmic reticulum' (SR)) stores in the muscle fibre results in a complex series of molecular events that culminate in the rearrangement of the thick and thin filaments and a shortening, or contraction, of the fibre.

The unique architecture, the major role of Ca^{2+} for contraction, and the great metabolic demands of skeletal muscle endow its sensitivity to damage by toxins and in many cases underlie the multiorgan systemic sequelae of muscle pathology (myopathy). To be discussed in more detail below, skeletal muscle-mediated damage to distant organs most prominently involves myoglobinaemia induced by the release of myoglobin from necrotic oxidative myocytes with leaky outer membranes. Because of the size of skeletal muscle, even a small amount of myotoxicity per total muscle mass can result in clinically significant myoglobinaemia and resultant toxicity to renal glomeruli. Drugs, hormones or poisons that induce myopathies can be subdivided into two main categories: (i) agents that induce skeletal muscle breakdown, or *rhabdomyolysis* (*rhabdomyo* = striped muscle; *lysis* = breakdown), and (ii) agents that induce contractile dysfunction or failure. Because contractile toxicities result largely from xenobiotic-induced damage to peripheral and/or central neuronal components of movement control and only indirectly affect muscle, this chapter will be focussed on agents that directly induce damage to skeletal muscle structure and function, and mechanisms of action if known. However, it should be noted that skeletal muscle toxicity secondary to neurotoxicity is an important contributor to diverse skeletal muscle pathologies, as proper innervation of muscle by motor neurons is essential for both the development and growth of muscle, and also in the maintenance of skeletal muscle architecture and function. In this chapter, we will review essential concepts dealing with skeletal muscle toxicology and will provide an overview of experimental methodologies, clinical markers and management of muscle intoxication and pathology. Finally, we will survey the diverse range of skeletal muscle toxins and their mechanisms of action, with a particular emphasis on pharmacogenetic considerations where appropriate.

2 OVERVIEW OF SKELETAL MUSCLE STRUCTURE AND PHYSIOLOGY

2.1 Normal Muscle Development and Anatomy

Myoblasts are mononucleated primitive myocyte precursors that are committed to terminal differentiation into large, cylindrical, multinucleated skeletal myocytes referred to commonly as 'myotubes'. *In vivo,* complete myoblast differentiation requires innervation by a motor neuron. Once innervated, developing myotubes rapidly increase the expression of contractile proteins, or myofibrils, that mediate the shortening of the muscle fibre in response to neuronal excitation. Another feature of innervation-induced maturation is the development of distinct sets of muscle fibre types distinguished primarily on the basis of their metabolic profiles. In this regard, these fibre types are determined by the kind of innervating lower motor neuron and can be distinguished by colour—some are deep red, some are white. As will be discussed below, the red fibres are highly oxidative, slow to contract and have high endurance, whereas the white fibres are more glycolytic, contract rapidly and are more easily exhausted. From a clinical toxicology perspective, agents that induce damage to red fibres can lead to more multiorgan pathologies than those that damage white fibres because of the high concentration of myoglobin in red fibres. As will be discussed in more detail throughout this chapter, myoglobinaemia is arguably the most life-threatening complication of skeletal muscle intoxication by drugs, hormones and poisons.

Skeletal muscles are connected to the skeleton with thick fibrous tendons, and typically span joints to function in a lever motion with the attached bones. A single skeletal muscle is composed of many fibre bundles referred to as fascicles, and is encased in an outermost layer of connective tissue called the fascia, or epimysium, which forms the tendons at the ends of the muscle. Inside the fascia, fascicles are similarly bundled together with an internal layer of connective tissue, the perimysium. Each individual fibre within a fascicle comprises a single elongated multinucleated myocyte. Muscles contain between 10 000 and 1 million individual

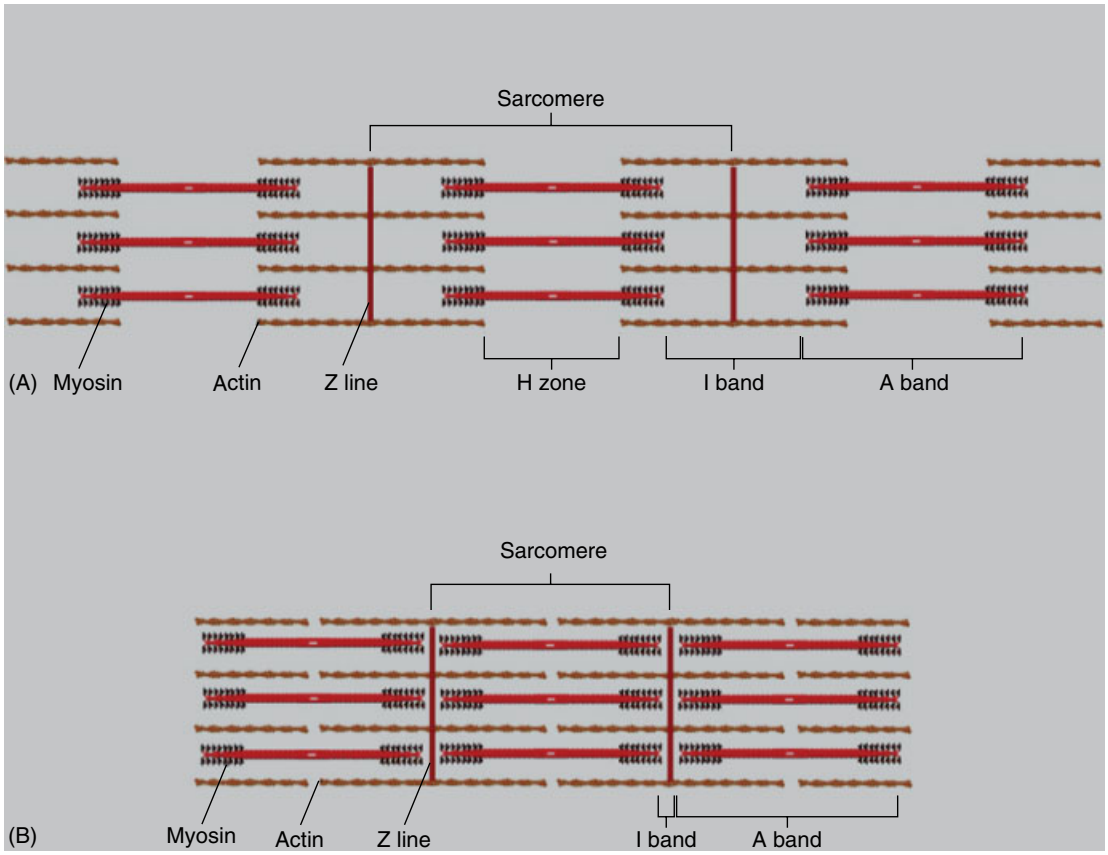

Figure 1 Structural organization of myofibre contractile filaments. (A) Relaxed muscle; (B) contracted muscle.

muscle fibres, each of which contains numerous myofibrils, the intracellular contractile elements comprising 80% of the volume of muscle cells. Myofibrils are long, cylindrical structures approximately 1 μm in diameter, and span the entire length of the muscle. Each myofibril is composed of the thin actin and thick myosin filaments that essentially slide together to mediate contraction in response to a rise in intracellular calcium (Sherwood, 2007). As depicted in **Figure 1**, these filaments exhibit a partially overlapping arrangement that give skeletal muscle its unique appearance. Using electron microscopy to observe a single myofibril reveals a patterned structure with alternating bands of light (I band) and dark (A band) that are perpendicular to the long axis of the fibre. The I bands are the portions of thin actin filaments that do not overlap with the thick myosin filaments, whereas the A bands consist of the overlapping portions of actin and myosin filaments. At the junctions of the A and I bands, the outer plasma membrane of the muscle fibre extends into the fibre interior forming the transverse tubule (T tubule) system that is critical for propagating contractile signals efficiently throughout the muscle fibres. This banding pattern is what gives skeletal muscle its striped or 'striated' appearance. Hence the term 'striated muscle' was coined. Within each I band is a dark-appearing line perpendicular to the fibres, referred to as a 'Z line'. It is that portion of the myofibre in between two Z lines that defines the sarcomere, the smallest functional unit of muscle capable of contraction. These structural features of a myofibril are summarized in **Figure 1**.

2.2 Fibre Types

Skeletal muscle fibres can be subdivided into three main classes: slow and fast oxidative fibres (Type I and IIa, respectively), and fast glycolytic (Type IIb). Fast glycolytic fibres exhibit nearly 10-fold faster contraction rates compared to slow oxidative fibres. Thus, these contractile elements are also termed 'fast twitch'. No skeletal muscle in the body is composed of one fibre type, but different muscles contain different proportions of fibre types. As summarized in **Figure 2**, oxidative fibres are so named for their large dependence on mitochondrial oxidative phosphorylation for adenosine-5′-triphosphate (ATP) production, whereas glycolytic fibres rely most on glycolysis for ATP synthesis. Not surprisingly, glycolytic fibres contain relatively few mitochondria, but oxidative muscle fibres have an abundance of these organelles. Mitochondria in skeletal muscle fibres lie in the intracellular spaces between myofibrils, along with glycogen, a source of

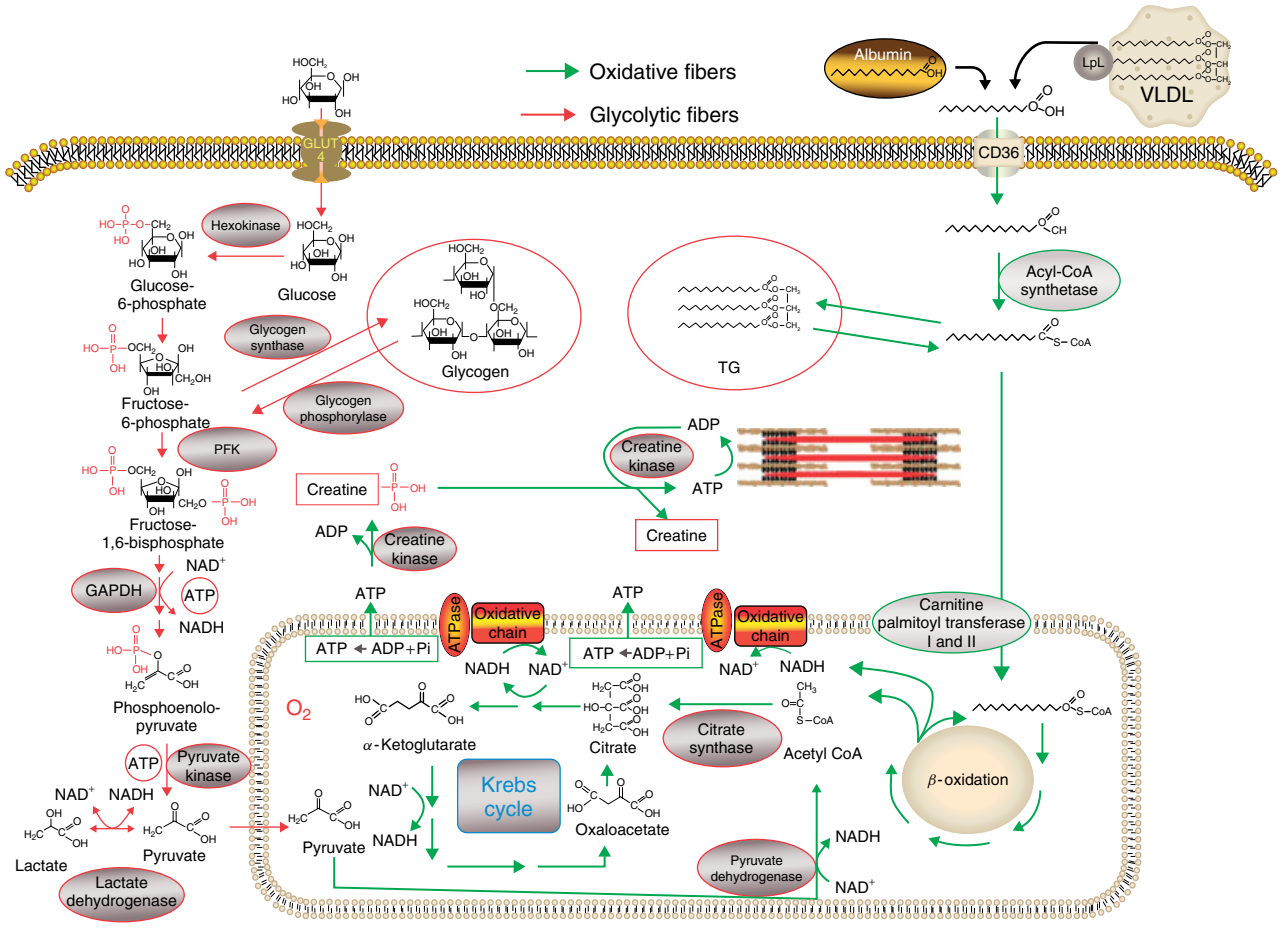

Figure 2 Glucose, fatty acid and energy metabolism in skeletal muscle. Glycolytic and oxidative muscle fibres have the alternative primary energy substrates of glucose (red arrows) and fatty acids (green arrows), respectively. Extracellular glucose enters the cell through plasma membrane glucose transporters (GLUTs) and is subsequently phosphorylated by hexokinase. After conversion to fructose and then pyruvate, it is transported into mitochondria for entry into the Krebs' cycle as acetyl CoA. Alternatively, glucose can be stored as the polysaccharide glycogen. Fatty acids are carried in the bloodstream via binding proteins such as albumin or as constituents of lipoproteins. Free fatty acids enter myocytes through plasma-membrane fatty acid transporters such as CD36, and translocate to the mitochondria after carnitine attachment via the carnitine palmitoyl transferase system. Through β-oxidation, free fatty acids are metabolized to acetyl CoA and oxidized during the Krebs' cycle. Free fatty acids that accumulate within the cell can also be stored as triglycerides (TGs). ATP that is produced through oxidative phosphorylation is exported into the cytosol where it is used to drive muscle contraction or can alternatively be stored as phosphocreatine. Abbreviations used: PFK—phosphofructokinase; GAPDH—glyceraldehyde-3-phosphate dehydrogenase; ATP—adenosine-5′-triphosphate; ADP—adenosine diphosphate; LpL—lipoprotein lipase; VLDL—very low-density lipoprotein; NAD+/NADH— nicotinamide adenine dinucleotide.

stored glucose for ATP synthesis. Oxidative fibres also contain high myoglobin concentrations as a strategy to maximize oxygen uptake from the bloodstream for its delivery to mitochondria for ATP production. This property endows oxidative fibres with their red colour. In contrast, glycolytic fibres have low myoglobin levels, and their colour is pale/white. Because oxidative fibres can generate several fold more ATP per molecule of glucose compared to fast fibres they are more suited for endurance work, and fatigue at a slower rate compared to glycolytic fibres.

2.3 The Neuromuscular Junction and Excitable Membranes

The membrane systems of muscle are highly specialized for muscle contraction. The outer plasma membrane makes physical contacts with motor neuron axon terminals, is electrically excitable and encloses multiple myofibrils. As mentioned above, protrusions of plasma membrane into the muscle fibre occurring at regularly spaced intervals (at each sarcomere) by T tubules

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

efficiently propagate nervous impulses to muscle fibres deep within the muscle. When a central command for voluntary movement is coordinated by movement centres in the brain (basal ganglia, cortex and cerebellum), it is delivered via spinal and motor neuronal efferents to a muscle via action potentials that are propagated along the motor neuron axon terminals, leading to the vesicular release of the neurotransmitter acetylcholine (ACh). The specialized connections between nerve and skeletal muscle, referred to as neuromuscular junctions, are composed of axon terminals of motor neurons, and the motor end plate, the region of the sarcolemma that interacts with the motor neuron. A single motor neuron innervates a single motor end plate. High concentrations of acetylcholine receptors (AChRs) localized to the end plate are made possible by the increased surface area created by deep folds or fenestrations in the end plate plasma membrane. Binding of ACh to AChR on the end plate leads to the influx of Na^+ into and efflux of K^+ from the intracellular compartment of the muscle fibre. As the result of large amounts of Na^+ entry and the increased positive charge, ion flux thereby changes the resting electrical potential across the plasma membrane of the muscle fibre from the resting state at -80 mV, to a depolarized state at -15 mV. With sufficient nerve impulses and complex integration, the release of ACh and membrane depolarization at the contact points across the fibre will be propagated as an electrical signal and penetrate deep into the muscle via the T tubule membranes. It is this event, the depolarization of the plasma membrane and T tubule system, that initiates the contractile process (Rhoades and Pflanzer, 1989). Termination of the neural component of muscle contraction is regulated mainly by the enzyme acetylcholinesterase (AchE), which degrades ACh in the neuromuscular junction. Agents that induce motor neuronal death or block neuromuscular synaptic transmission lead to paralysis and loss primarily of Type II fibres; on the other hand, agents that induce excessive neuronal firing at neuromuscular junctions, or those that induce membrane damage that renders skeletal muscles leaky to sodium and potassium, can profoundly enhance muscle contractile responses and lead to sustained, painful and toxic muscle contractions or tetanus, some cases of which can be followed by neurotransmitter depletion and fatigue, and even death. **Table 1** outlines the major effects of neuromuscular junction perturbation by biologic or chemical toxins.

2.4 The Sarcoplasmic Reticulum and the Molecular Mechanism of Muscle Contraction

At the heart of both the contractile response and many, if not most, skeletal muscle toxicities is the intracellular second messenger calcium. The plasma membrane and its series of interconnected T tubule membranes are in close proximity to a specialized intracellular membrane structure, the sarcoplasmic reticulum, which is a form of endoplasmic reticulum. The ER of nonmyocytes and the SR of myocytes is a major intracellular storage depot for calcium. Release of stored calcium from the SR into the myocyte cytoplasm (sarcoplasm) is the fundamental link between neuronal excitation of the muscle and contraction. Similarly, dysregulation of calcium movement across the SR membrane is the mechanistic basis for skeletal muscle toxicity induced by a vast array of drugs and toxins. Agents that induce calcium handling abnormalities comprise the largest and most diverse group of compounds associated with skeletal muscle toxicity and pathology. As shown in **Figures 1** and **2**, at each junction of the A and I bands of the filaments within the myocyte or muscle fibre, the plasma membrane protrudes into the muscle forming the T tubule. The T

Table 1 Agents that alter myoneural transmission

	Source	Mechanism of action and symptoms of exposure
Neuromuscular blockers that induce paralysis		
Alpha toxins	Snake venoms	Inhibition of ACh receptors. Weakness, fatigue, paralysis, respiratory failure, death
Botulinum toxin	*Clostridium botulinum*	Blockade of vesicular ACh release. Weakness, respiratory failure, death
β bungarotoxin	Snake venoms	Blockade of vesicular ACh release. Mild muscle weakness
Neuromuscular stimulants that induce hypercontraction or spasm		
Alpha latrotoxin	Black Widow spider	Induces a pore in the myocyte membrane that is permeable to Na^+ and K^+, leading to membrane depolarization. Initial effects are muscle spasms followed by depletion of ACh, respiratory failure and death
Organophosphate	Pesticides, chemical warfare agents	Inhibition of acetylcholinesterase. Seizures, neuropathy, weakness, respiratory failure, death

tubule extends into the interior of the muscle, perpendicularly to the filaments. Since the plasma and T tubule membranes are continuous, excitation by motor impulses at the neuromuscular junctions leads to action potentials across these membranes, and the activation of membrane protein voltage-gated calcium channels (VGCCs). Via mechanisms that are not completely understood, it is primarily the activation of the VGCCs in the plasma membrane which leads to the opening of the SR Ca^{2+} channel commonly known as the ryanodine receptor (RyR). The plant toxin ryanodine binds to RyR and locks it in an open conformation. Many of the VGCC in the sarcoplasm physically interact with VGCC in the plasma membrane in regions of the SR that come in close proximity to the outer plasma membrane or T tubule membrane. Upon activation of a sufficient number of RyR by activated VGCC, RyR not in close association with VGCC also open, and calcium stored in the SR is released into the cytosol or sarcoplasm, where it activates the sliding filament mechanism of muscle contraction wherein the actin and myosin filaments slide along each other in a manner that shortens the sarcomere in an ATP-dependent reaction. Contraction is terminated by the reuptake of Ca^{2+} from the sarcoplasm back into the SR via the ATP-dependent calcium pump sarcoplasmic/endoplasmic reticulum Ca^{2+} ATPase (SERCA). As will be discussed below in the next section, the RyR is probably the most widely studied molecule in skeletal muscle toxicology. Mutations in the gene encoding RyR in humans predispose individuals to hyperthermia and skeletal muscle breakdown induced by volatile anaesthetics. This sometimes-fatal condition, commonly referred to as malignant hyperthermia (MH), is one of the first-described 'toxicogenetic' disorders where toxicity requires a genetic mutation. A summary of the molecular mechanisms of calcium-induced muscle contraction and calcium homeostasis in a muscle fibre sarcomere is depicted in **Figure 3**.

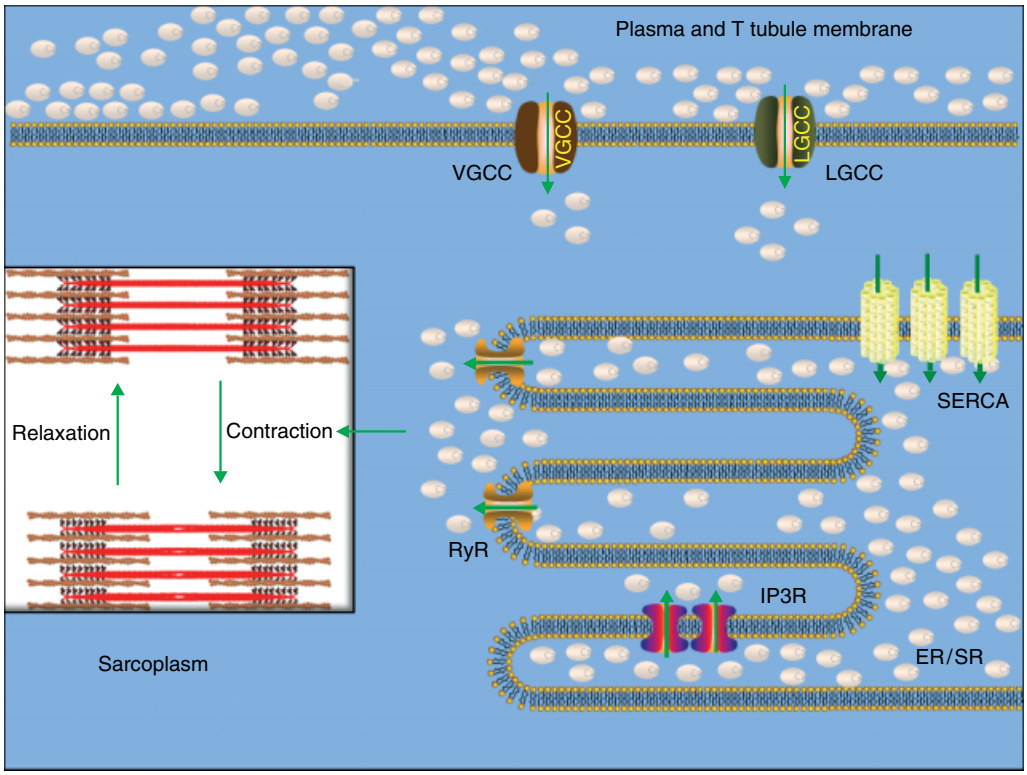

Figure 3 The role of calcium in muscle contraction. The ryanodine receptor (RyR) is an intracellular calcium transporter situated within the membrane of the sarcoplasmic reticulum (SR), similar to the inositol triphosphate receptor (IP3R) found in the endoplasmic reticulum (ER) of some cells. The sarcoplasmic reticulum is a specialized reservoir for calcium storage within muscle cells. Voltage-gated (VGCC) or ligand-gated calcium channels (LGCCs) initially allow extracellular calcium ions to enter the cell cytosol. These receptors are present on transverse tubules (T tubules), which are invaginations of the plasma membrane that come into contact with the SR. Because these ion channels are in close proximity to RyR/IP3R receptors on the SR/ER, a robust positive-feedback cascade is initiated. The small rise in cytosolic Ca^{2+} levels causes activation of the RyR receptor in a calcium-activated calcium release mechanism. Calcium stores from the SR/ER are liberated, rapidly increasing cytosolic Ca^{2+} concentrations and initiating muscle contraction. Calcium ions then re-enter the ER/SR through the sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA).

3 Laboratory Methods (*In Vivo* and *In Vitro*) for Investigating Skeletal Muscle Injury, and Biomonitors for Skeletal Muscle Toxicity

3.1 Introduction

The body of research on skeletal muscle diseases, particularly responses to toxic insults, has markedly advanced in the preceding 30 years. As such, the battery of tests available to the clinician and the number of research protocols available to the scientist have grown as well. Biochemical tests used to evaluate serum samples for skeletal muscle enzymes are readily available in most clinical laboratories. Many healthcare institutions and research facilities have dedicated electrophysiology laboratories capable of assessing contractile and conduction abnormalities. Histological analyses using light microscopy, electron microscopy and immunohistochemistry are well-established techniques for evaluating muscle biopsy samples. The isolation of intact skeletal muscles for tissue culture or myocyte isolation is a routine practice in research laboratories. In addition, numerous animal models of skeletal muscle-relevant disease states have been developed for better understanding pathophysiologic mechanisms of muscle injury and disease.

3.2 Biochemical Evaluation

Established protocols exist for the management of emergency myopathies that develop acutely and require immediate diagnosis and intervention. The cornerstone of identification and treatment of many myopathies is the array of biochemical tests which are used to gauge muscle injury through evaluation of venous blood flow. The most appropriate candidates for assessment of myopathy are enzymes that are usually confined to the intramyofibrillar space. The presence of large quantities of these enzymes in the systemic vasculature indicates that a substantial injury to the skeletal muscle has occurred. Many enzymes, including lactate dehydrogenase (LDH), aspartate transaminase (AST) and alanine transaminase (ALT), can be elevated after damage to skeletal muscle (Haschek and Rousseaux, 1998). However, the best marker of skeletal muscle injury is creatine kinase (CK). Although CK, like many other enzymes, can be elevated with a variety of disorders, it is possible to differentiate the affected area through exclusion of alternative sources. CK catalyses a reversible enzymatic reaction that liberates a phosphate group from phosphocreatine and thereby provides an essential energy reservoir for the production of ATP within myocytes. The Oliver–Rosalki method for estimating enzyme activity utilizes the reverse CK reaction of ATP synthesis from creatine phosphate and adenosine diphosphate (ADP) (Rosalki, 1967; McPherson and Pincus, 2006). Second and third reactions are used to generate glucose-6-phosphate and nicotinamide adenine dinucleotide (NADH), respectively. The NADH produced is subsequently measured as the indicator of CK levels. Enzyme measurements are typically expressed in units of activity per litre or per millilitre, with the normal range being $30–200\,\mu l^{-1}$ (Daniels, 2002; McPherson and Pincus, 2006; Barohn, 2008). The test for CK activity does have some limitations due to its short plasma half-life, making it possible for a patient with active myopathy to have relatively normal levels of plasma CK. This is discussed in further detail in section 4 'Clinical Management of Skeletal Muscle Toxicity (Especially Rhabdomyolysis)'.

In addition to the CK assay discussed above (i.e. total CK), a more-specific test can be performed to better determine the origin of the released enzyme. The mature CK protein contains a combination of two different subunits which have been found to be tissue-specific in their expression, 'M' for muscle and 'B' for brain. Therefore, three CK isoenzymes exist; CK-MM is primarily expressed in skeletal muscle, CK-MB is found predominantly in cardiac tissue, and CK-BB is found in brain and intestines (Haschek and Rousseaux, 1998; McPherson and Pincus, 2006; Barohn, 2008). Typically, in order to differentiate between different CK isoenzymes, an immunoassay approach is employed. This strategy is useful in assessing total CK, followed by the specific isoenzyme contribution to the total CK measurement. First, the total CK enzyme activity is measured, followed by the addition of antibodies specific to the CK-M subunit. By binding to the 'M' enzyme subunits, these antibodies would theoretically abolish the enzyme activity of the CK-MM isoenzyme and decrease the activity of CK-MB by half (Barohn, 2008). This technique also has its limitations, as unexpected aberrations in CK isoenzymes do occur. For instance, CK-MB can be elevated in patients with skeletal muscle myopathy that do not have an injury to cardiac tissue (Kiely *et al*., 2000). Other immunoassays, such as the detection of skeletal troponin I (sTnI), are being explored for their utility in diagnosing skeletal muscle-specific injury (Simpson *et al*., 2005). sTnI exists as two isoforms, ssTnI and fsTnI, which are produced in slow twitch and fast twitch fibres, respectively. This detection method has not been developed into a commercial assay for implementation in clinical laboratories.

Another specific marker for skeletal muscle injury is the haem-containing protein, myoglobin. Perhaps most importantly, myoglobin can have a direct toxic effect on the kidneys (see 'Clinical Management of Skeletal Muscle Toxicity section, below). The detection

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of myoglobin is highly time dependent because it is efficiently cleared from the plasma (Beetham, 2000). Therefore, it is more appropriate to measure urine myoglobin, which is usually first evident as a urine colour change from yellow to dark red/brown. Drastically elevated myoglobinuria represents a condition that requires immediate treatment intervention because of the possibility of acute renal failure (ARF). The most rapid test is a qualitative assessment using inexpensive urine test strips. A urine sample is applied to a test strip containing hydrogen peroxide and the tetramethylbenzidine colour reagent. After interaction with the peroxidase activity of the haem in haemoglobin or myoglobin, the reagent will produce a detectable change in colour (McPherson and Pincus, 2006). One confounding factor to interpreting the qualitative test results is that haemoglobin will also be detected (in addition to myoglobin). Therefore, these findings must be considered in the context of other results such as urine erythrocytes and serum CK. A positive urine myoglobin test, together with absent urine erythrocytes and a high serum CK is indicative of skeletal muscle injury. An alternative procedure uses immunoassay techniques to identify and quantify myoglobin in urine. Although there is a small degree of interference from haemoglobin, this test is much more specific for myoglobin (McPherson and Pincus, 2006).

3.3 Electrophysiological Evaluation

Exposure to xenobiotics can induce changes in the contractility and nerve conduction of skeletal muscles. One tool to investigate these alterations is electromyography (EMG), which evaluates the electrical activity of the muscles by comparing amplitude, number and duration of impulses (Acosta *et al*., 1997). Primarily, this technique is employed in order to determine if symptoms are myogenic or neurogenic (Daniels, 2002). Two superficial or needle electrodes are used. The patient is then asked to either contract or relax a given muscle or muscle group. The trained electrophysiologist can make determinations on the nature of the pathology by comparing the spontaneous and voluntary electrical potentials. Nerve conduction studies and needle EMG studies can also be conducted using skeletal muscle tissue obtained through a needle or punch biopsy (Barohn, 2008).

3.4 Microscopic Evaluation

Several groups have published protocols for the microscopic evaluation of skeletal muscle toxicity in animals (Ownby *et al*., 1976; Suarez-Kurtz and Eastwood, 1981; Melo and Ownby, 1996). After exposure of the organism to a toxin, the muscles are harvested and fixed in glutaraldehyde, dehydrated in acetone, and embedded in a resin such as paraffin. Sections are then obtained using an ultramicrotome in either a longitudinal or cross-section depending on the desired perspective. The sections can then be stained with azure II, methylene blue, trypan blue or haematoxylin and eosin for visualization. As the slides are reviewed under a light microscope, abnormal findings such as presence of vacuoles, aggregation of cells, amorphous appearances, cell necrosis and cell oncosis (death by cell swelling) are noteworthy. Muscle biopsies from human patients are used for microscopic examination. Typical findings during myopathy are central nuclei, hypertrophic fibres, split fibres, degenerating fibres and regenerating fibres (Barohn, 2008). Inflammatory myopathies in particular are characterized by infiltrates of mononuclear cells in the connective tissue of the epimysium and perimysium (Barohn, 2008). Immunohistochemistry and electron microscopy for prepared tissue samples can also easily be performed. Histochemistry can be employed in order to identify a particular protein using immunostaining. Scanning and transmission electron micrographs have been used to visualize autophagic vacuoles and morphology of intracellular organelles, respectively.

3.5 Tissue and Cell Culture

The utility of *in vitro* tests for skeletal muscle toxicity has been well documented. Experimental systems exist to transiently maintain a muscle tissue explant (i.e. *ex vivo*) or grow a confluent monolayer of contracting, differentiated myotubes (*in vitro*). Extraction of an *ex vivo* tissue sample can consist of an entire muscle group, muscle strip or single cell preparation. Maintaining a tissue in culture requires immersion in a temperature-controlled media bath which will closely replicate the endogenous conditions *in vivo* (Acosta *et al*., 1997). Of particular importance are the nutrient and oxygen demands of the tissue. The tissues are usually superfused with a modified Krebs buffer which is maintained at 37 °C, pH 7.4 and has been supplemented with glucose, sodium, potassium, calcium, magnesium and chloride ions to recapitulate their physiologic concentrations (Melo and Ownby, 1996). This system has many advantages, including ease of modification of the constituents of the perfusate, and convenient serial sampling of the perfusate. Because the oxygen-carrying capacity of perfusion media is unknown, some researchers have supplemented the buffers with haemoglobin. Another limitation of the system is the uncertainty of the penetration of oxygen and nutrients into the interior of the tissue explants. Creating thin cross-sections of muscle or treatment with detergents at low concentration (e.g. Triton X-100 0.1%) are strategies to increase access of nutrients to the intramyocellular compartment. The greatest obstacle to the use of tissue

explants is the rather temporary cell viability that is achieved.

Cultured myocyte systems to evaluate toxicity have been widely used since first being introduced in the 1970s (Wenzel *et al*., 1970). The two most commonly used cell lines, C2C12 and L6, were both developed by Yaffe and colleagues from mouse and rat, respectively (Yaffe, 1973; Yaffe and Saxel, 1977). Cells are also routinely isolated from human muscle biopsies (Sarabia *et al*., 1990). Isolation of myoblasts requires separation from the other cells of the skeletal muscle such as myotubes, myofibroblasts, erythrocytes and leukocytes. Isolation protocols utilize the ability of cells other than myoblasts to adhere to cell culture vessels (Acosta *et al*., 1997). After a series of digestions by proteases and/or collagenases, the homogenate can be filtered to isolate intact cells, which can then be washed and retrieved by centrifugation. After plating in a cell culture vessel, the supernatant can be moved to a new vessel at predetermined time points in order to isolate a particular cell variety. Myoblasts are usually the last cells to attach and are easy to distinguish from myofibroblasts via light microscopy. Myoblasts can be induced to differentiate into mature myotubes by changing their growth media (usually Dulbecco's Modified Eagle Medium with 10% foetal bovine serum) to media containing 2% equine serum. The differentiating cells will form multinucleated myotubes that have characteristic changes in their protein expression patterns and have the ability to contract. Cultured myocyte systems can be immortalized through viral transduction to create a renewable cell line that can be cryogenically preserved. This homogenous system is also useful because it can be used to study a specific cell type without the potentially confounding presence of others. Similarly to *ex vivo* tissues, serial sampling of the media is accomplished easily. The major disadvantage and criticism of cultured myocyte systems is that they fail to duplicate the *in vivo* environment in all aspects, making extrapolation of results difficult (Haschek and Rousseaux, 1998).

3.6 Animal Models

Numerous experimental models exist to recapitulate human disease states in animals. Gross examination of skeletal muscle should be performed at necropsy with particular emphasis on the presence of lesions and alterations in size, shape, consistency and colour of the tissue (Haschek and Rousseaux, 1998). Animal models exist for genetic disorders (e.g. glycogen storage disease, MH), toxin-induced myopathies (e.g. rhabdomyolysis, critical illness myopathy), as well as neuropathies (Gonzalez *et al*., 1998; Chander *et al*., 2003; Rich and Pinter, 2003; Rucker *et al*., 2004). The vast majority of skeletal muscle myopathy models are in the mouse or rat; however some researchers have used rabbits for studying rhabdomyolysis, inclusion body myositis and botulinum-induced toxicity (Piepmeier *et al*., 1995; Gonzalez *et al*., 1998; Chen *et al*., 2008). The ability of the researcher in controlling the experimental conditions and interpreting the data in the context of human disease is critical with the use of animal models.

4 CLINICAL MANAGEMENT OF SKELETAL MUSCLE TOXICITY

4.1 Introduction

The aetiology of skeletal muscle toxicity has a diverse set of possible mechanical, molecular, biochemical, genetic or pharmacological origins (reviewed in Guis *et al*., 2003). However, there are many similarities in the clinical and laboratory findings between different types of skeletal muscle toxicities. The hallmark finding of skeletal muscle toxicities tends to be disruption of the sarcolemmal membrane surrounding myofibrils. This determination is traditionally not made by visualizing sarcolemmal rupture via microscopy or histology, but rather by assessing serum levels of intracellular myocyte proteins. The disruption of this membrane can lead to pain, electrolyte disturbances, abnormal muscle function and muscle cell lysis. Potentially more serious complications include muscle necrosis, renal failure, shock and even death. Skeletal muscle toxicities can present as syndromes with an inconsistent array of symptoms, making assessment and diagnosis particularly challenging. The clinician treating these disorders must be experienced with musculoskeletal examination, associated diagnostic observations and medical management of the patient.

4.2 Clinical Presentation

The most important and obvious clinical symptom of myopathy is muscle pain and/or weakness, which is seen in the majority of skeletal muscle toxicities. Also, unlike electrolyte disturbances and laboratory test deviations, these symptoms can be easily assessed by the clinician or reported by the patient. The principal patient report will be pain or tenderness in the affected area. The area in question can be a muscle group or compartment or a more focal region. The most frequently affected areas are the extremities and lower back (Finnish Medical Society, 2007).

Assessment of a patient with musculoskeletal symptoms begins with a medical history and basic physical examination which includes a test for muscle pain

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and muscle strength/muscle weakness (Barohn, 2008). Joints, bones, tendons and muscles should be individually palpated to isolate the painful area. Determining the origin of the pain can assist the clinician in differentiating between neurological and musculoskeletal pain. A typical musculoskeletal examination would also include passive and active range of motion for affected muscle groups. In addition, a motor and sensory neurological examination should also be performed. Techniques for neurological examination include isolating the involved nerve group (e.g. deep versus superficial reflexes, fasciculations and cranial nerves). Motor and sensory deficits that follow a pattern consistent with myopathy rather than neuropathy should be identified.

The clinical presentation of a patient with musculoskeletal toxicities can be deceivingly similar to other metabolic, nervous system or genetic disorders. Differential diagnosis is a crucial part of the initial patient assessment. The patient assessment should be focussed on excluding other possible causes of symptoms such as traumatic injuries (e.g. crush injuries), bacterial infections, heatstroke, genetic disorders (e.g. CPT (carnitine palmitoyl transferase) deficiency) and autoimmune diseases (e.g. Guillain-Barré syndrome).

4.3 Diagnostic Observations

In addition to the physical findings mentioned above, clinical laboratory tests can be used to support the diagnosis of skeletal muscle injury. As mentioned previously, loss of integrity of the sarcolemmal membrane is a cardinal feature of myopathies. This results in release of the cellular contents, which can then be detected in the systemic blood flow. In addition to serum indicators, histological examination of muscle biopsies can provide valuable evidence needed for diagnosis.

The most appropriate and most sensitive indicator of skeletal muscle injury is a test for CK, also known as phosphocreatine kinase or creatine phosphokinase. Creatinine kinase is an enzyme involved in supplying the muscle with phosphate needed to make energy as ATP. Myosin uses ATP to travel along actin filaments and contract muscles. The energy pool devoted to this process is stored as phosphocreatine, which can then be rapidly liberated by CK to generate ATP when needed. This enzyme is found in the cytoplasm and mitochondria of cells in skeletal and heart tissue. Certain isoenzymes, such as CK-MB are most highly expressed in the heart, and therefore a ratio of total CK to CK-MB is used to differentiate between skeletal muscle versus cardiac muscle injury. Serum CK levels are expressed in units of enzyme activity over litres of blood (U l^{-1}). The basal levels of serum CK are negligible (30–200 U l^{-1}); therefore elevated levels are sensitive indicators of muscle damage. CK levels that are five-fold higher than the normal range are indicative of the most severe form of myolysis: rhabdomyolysis. Serum CK level is also useful for monitoring muscle injuries because it has a predictable clearance from the systemic blood flow, provided normal renal function is present. Onset of elevated CK levels is 12 hours following muscle injury, while peak levels can occur 24–36 hours postinsult. The levels usually decline within three to five days if the muscle injury has resolved. Failure of the CK levels to return to baseline indicates a continuing myopathic condition. A serum CK level greater than 5000 U l^{-1} can indicate impending or current renal failure, although other tests such as serum or urine myoglobin may be more useful for that purpose (Ward, 1988).

Myoglobin is a monomeric haem protein with high binding affinity for oxygen. It is the protein that gives meat its red colour. Although structurally related to haemoglobin, it is only present within muscle cells and therefore a useful marker for muscle injury. Serum levels of myoglobin are less useful than serum CK because the half-life is only approximately 1–3 hours and can therefore lead to false negatives if not collected at the appropriate time (Beetham, 2000; Barohn, 2008). However, myoglobin excreted through the kidneys will colour the urine dark red and is therefore more easily detected. Presence of urine myoglobin can be assumed in a patient with haematuria whose urine tests negative for red blood cells using conventional urine test strips. Confirmation is performed either microscopically by a urine myoglobin assay or via electrophoresis and radioimmunoassay.

During muscle injury that results in cell lysis, chemicals such as phosphates, potassium and urine acid are released in addition to proteins (e.g. CK and myoglobin) (Haschek and Rousseaux, 1998). Electrolyte disturbances are a common finding in skeletal muscle toxicities. Elevations in phosphates, potassium and uric acid are most frequently seen. This can result in severe acidosis, especially in the presence of concomitant renal failure. Damage to myocytes also causes release of sarcoplasmic calcium stores, creating precipitates in the cytosol in addition to lowering the serum calcium level. If severe, the hyperkalaemia and hypocalcaemia can cause cardiovascular complications such as arrhythmias.

Specialized tests such as EMG and histology are sometimes used to confirm diagnoses as well as exclude other potential conditions. EMG findings are typically unremarkable, because they primarily evaluate conduction problems. Muscle biopsies may be taken and subjected to electron microscopy, immunohistochemistry and, potentially, genetic studies. Muscle biopsy samples from patients with severe myopathy may show an irregular distribution of myocytes or necrotic areas of cell death.

Rhabdomyolysis is important to mention independently of other conditions of skeletal muscle damage because it is relatively common and one of the most

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

severe forms of myopathy. Rhabdomyolysis is characterized by a triad of symptoms; myasthenia/myalgia, elevated serum CK levels and myoglobinuria (Ward, 1988; Beetham, 2000; Barohn, 2008). As swelling accumulates at the site of muscle injury, systemic hypovolaemia and a rise in blood pressure is seen. Although all forms of skeletal muscle toxicity involve some cellular damage, rhabdomyolysis is defined by the release of toxic intramyocellular substances into the bloodstream. The most severe complication of rhabdomyolysis is renal failure caused by acute tubular necrosis (ATN) (Finnish Medical Society, 2007). The release of myoglobin from damaged skeletal muscle quickly exceeds the capacity of serum binding proteins to carry it. The kidneys will begin to clear the myoglobin once its concentration exceeds $230\,mg\,l^{-1}$ (about three times basal levels) (Coco and Klasner, 2004). Acidosis caused by release of phosphate, potassium and uric acid can cause the myoglobin to dissociate into globulin and the iron haem protein ferrihaemate, usually below pH 5.6. Ferrihaemate is a direct toxin for the renal tubular epithelium, in addition to causing myoglobin casts which precipitate within the kidney and cause obstruction. Subsequently, renal failure, shock and disseminated intravascular coagulation are all potential outcomes with rhabdomyolysis.

4.4 Clinical Management of Symptoms

The goals in managing a patient with myopathy are to determine and remove the initial cause of the injury, ensure hydration and correct electrolyte imbalances (Better and Stein, 1990). The fluid balance within the myocytes as well as between the associated musculoskeletal compartments and the systemic vasculature must be corrected with intravenous fluid administration. Hydration with isotonic fluids such as normal saline should begin as early as possible. By diluting elevated electrolytes and myoglobin, aggressive hydration can ameliorate metabolic acidosis and assist in alkalinization of the urine (Coco and Klasner, 2004). Urine alkalinization via administration of intravenous sodium bicarbonate can be used to prevent renal cast formation by titrating urine pH to 6.5. Its use should be carefully monitored as it can exacerbate hypocalcaemia. The osmotic diuretic mannitol can also be used to cause dieresis which may be effective in raising urine pH (Brown *et al*., 2004). Urine output should be carefully monitored using a Foley catheter, in addition to urine pH levels and acid-base status (Bertorini, 1997).

The most common electrolyte disturbances seen in myopathies are hypocalcaemia, hyperkalaemia and hyperphosphataemia. The hypocalcaemia initially is due to sequestration of calcium within the myocytes; however, in later stages of myopathy liberation of that pool can cause increases of systemic calcium and subsequent hypercalcaemia. Hypocalcaemia can be left untreated unless cardiac arrhythmias or seizures are present. The patient should, however, be carefully monitored for late-stage hypercalcaemia (Coco and Klasner, 2004). Hyperkalaemia can be treated by shifting plasma potassium into the intracellular compartment. This can be accomplished by coadministration of glucose and insulin, using inhaled β-agonists, or potassium exchange resins such as Kayexalate (sodium polystyrene sulfonate) (Brown *et al*., 2004). Hyperphosphataemia is usually treated by hydration and dieresis. Conditions resistant to appropriate interventions such as severe anuric renal failure, persistent electrolyte abnormalities or metabolic acidosis may require dialysis (Brown *et al*., 2004).

5 MYOTOXIC AGENTS AND THEIR MECHANISMS OF ACTION

5.1 Overview

The most common expression of drug-induced direct muscle toxicity is rhabdomyolysis, a diffuse, noninflammatory breakdown of skeletal muscle. In most cases, the precise mechanisms of xenobiotic or hormone-induced skeletal muscle breakdown are poorly defined, but it is apparent that mitochondrial dysfunction, energy (ATP) depletion and disruption of ionic gradients (e.g. calcium, protons, potassium, sodium) underlie the vast majority of myopathic responses. No matter the upstream intracellular toxic signalling events, agents that induce rhabdomyolysis ultimately cause sarcolemmal breakdown leading to the spilling of the intracellular contents of myocytes into the bloodstream. As to be discussed in further detail below, serum levels of intracellular skeletal muscle enzymes such as CK and myoglobin are useful quantitative markers of muscle damage both in clinical cases and in experimental animal models of muscle toxicities. In addition, accumulation of myoglobin in the bloodstream (myoglobinaemia) is a major cause of renal failure and death induced by skeletal muscle toxins. Interestingly, a diverse array of compounds induce parallel muscle breakdown and hyperthermia. From a clinical perspective, the most common myotoxicities are associated with exposures to agents that also induce concomitant hyperthermia. From a biological viewpoint, information gleaned from understanding the mechanisms of thermoregulatory myotoxins may shed light on a mystery in human biology, dealing with the mechanisms by which the body generates heat, and the role of muscle in thermogenesis.

5.2 Hyperthermia-Inducing Rhabdomyolytic Agents

Skeletal muscle fibres are especially sensitive to destruction by a pathologic rise in body temperature. Given its metabolic prominence, skeletal muscle is also a main site for heat production in the human body, but the extent to which hyperthermia and skeletal muscle breakdown are causally related, or rather are epiphenomena, is unclear. One of the least understood aspects of human metabolic physiology involves the actual mechanism(s) and cellular sources of heat generation in response to physiologic inducers such as bacterial toxins for fever, or in response to hyperthermia-inducing agents such as amphetamines, serotonin reuptake inhibitors (antidepressants) and levothyroxine, to name a few. Not all agents that induce rhabdomyolysis induce hyperthermia. Interestingly though, most if not all compounds, including physiologic bacteria-derived fever mediators capable of raising body temperature, universally share a common capacity to induce rhabdomyolysis. Accumulating evidence from studies on two main muscle poisons, volatile anaesthetics and amphetamine-type drugs, implies a causal link between thermogenic mechanisms and rhabdomyolysis. These links are based upon the identification of hyperthermia mediators RyR (the target of volatile anaesthetics) and uncoupling protein 3 (UCP3, the target of amphetamines), both of which regulate thermogenic ionic cycles (see below) and are enriched in skeletal myocytes. **Table 2** includes a list of agents that induce concomitant hyperthermia and rhabdomyolysis, along with those agents that induce myopathic responses independently of effects on body temperature.

5.3 Skeletal Muscle in Temperature Homeostasis and Drug-Induced Hyperthermia Syndromes

Body temperature in warm-blooded animals is regulated by a complex and highly orchestrated series of central neuronal and peripheral physiologic mediators, and is integrated mainly by the hypothalamus in the brain. Brain neurotransmitters serotonin, norepinephrine and dopamine are the primary mediators of temperature regulatory neurotransmission, with serotonin being the most important. Prothermogenic changes in the levels of these central hypothalamic neurotransmitters in thermoregulatory neurons in the hypothalamus lead to activation of the peripheral sympathetic nervous system and the release of norepinephrine, the primary thermogenic neurotransmitter, at peripheral organ sites and into the bloodstream. Norepinephrine interactions with α adrenergic receptors in cutaneous vessels lead to heat conservation by vasoconstriction. Interactions of norepinephrine with the β_3 adrenergic receptor lead to metabolic heat production, though the mechanisms and tissue sites are not well

Table 2 Agents that induce myopathic responses

Major agent-class/syndrome	Drug subtypes/examples
Co-inducers of rhabdomyolysis and hyperthermia	
Bacterial pyrogens (fever)	Lipopolysaccharides, endotoxin
Adrenergic agents (indirect mitochondrial uncouplers)	Phenylethylamines including amphetamine, methamphetamine, 3,4-methylenedioxymethamphetamine (MDMA); cocaine, monoamine oxidase inhibitors
Direct mitochondrial uncouplers	Salicylates, pentachlorophenol, dinitrophenol
Neuroleptic malignant syndrome	Serotonin-increasing drugs such as tricyclic antidepressants; dopamine modulators such as olanzapine, metoclopramide, promethazine
Anticholinergic hyperthermia	Plant 'belladonna' alkaloids, antispasmodics, antiulcer drugs, acetylcholine receptor antagonists
Malignant hyperthermia	Volatile anaesthetics, depolarizing muscle relaxants
Serotonin syndrome	Hallucinogens, serotonin reuptake inhibitors
Thyrotoxicosis	Thyroid hormone, levothyroxine
Inducers of myopathies not associated with hyperthermia	
Endocrine disrupters	Anabolic steroids, dexamethasone, vitamin D, parathyroid hormone dysregulation, growth hormone intoxication
Lipid-lowering compounds	Statin drugs, fibrate analogues, niacin
Alcohol intoxication	Acute and chronic alcohol ingestion
Lysosomal disrupting agents	Chloroquine, amiodarone
Potassium-disrupting agents	AChE inhibitors, diuretics
Microtubule-disrupting agents	Colchicine, vincristine, phalloidin
Neuromuscular blockers	AChE inhibitors

defined. In human and animal studies, infusion of norepinephrine into isolated brown adipose tissues (BATs) and skeletal muscle induces thermogenesis (Astrup *et al*., 1984; Astrup, 1986). Thus, it is likely in humans, which lack BAT, that the sympathetic nervous system activates thermogenic mechanisms in muscle (Astrup *et al*., 1984). In addition, the precise molecular mechanisms for the selective sensitivity of muscle to undergo breakdown in response to body heat accumulation are unclear. Hyperthermia is distinguished aetiologically from fever by its lack of regulation, or rather, its escape from normal temperature regulatory mechanisms. Fever, on the other hand, is not generally myotoxic, and involves a more moderate and highly regulated rise in body temperature in response to infection.

The sum inefficiency of all metabolic reactions in the body generates a sufficient amount of heat to keep the body warm at neutral ambient temperatures (~25 °C). This type of heat production is referred to as *obligatory thermogenesis*. On the other hand, inducible metabolic reactions are required to raise body temperature in response to cold exposure, infection or thermoregulatory toxins. In this type of *facultative* thermogenesis, as will be discussed below in more detail, three metabolic mechanisms have been identified that are able to generate sufficient heat to rapidly raise body temperature: (i) exercise or skeletal muscle contraction (shivering, tetany); (ii) futile proton cycling in mitochondria; and (iii) futile RyR-induced calcium cycling in the SR. Each of these processes, when overactive, is associated with significant skeletal muscle damage and morbidity in humans.

5.4 Thermogenic Mechanisms Involving Futile Ionic (Ca^{2+}, H^{+}) Cycling

Facultative thermogenesis in man is poorly understood, but in most, if not all types of significant heat production in cells, the futile transport and flux of ions such as calcium and protons is the main thermogenic mechanism. The term *futile* is meant not to imply that ionic flux is meaningless. Rather, the active, energy-requiring transport of protons out of the mitochondrial matrix during oxidative phosphorylation, and the pumping of calcium ions into the SR, are processes that are seemingly 'wasted' by the leak or passive diffusion of these ions back into the respective cellular compartments from where they were originally pumped. Of these, only proton cycling and leak in mitochondria is established as the physiologic generator of heat production in the cells of endothermic organisms. Futile calcium cycling, as discussed in more detail below, is only thought to contribute to pathologic thermogenesis induced in the pharmacogenetic syndrome MH.

In rodents and hibernating mammals, the two organs established to generate sufficient heat for the quick increase of body temperature are skeletal muscle and BAT. One view of skeletal muscle thermogenesis, at least in a physiologic sense, is that shivering accounts for its main capacity to generate heat and participate in body temperature regulation. However, shivering is only short lived during infective-fever-associated thermogenesis, and many toxic thermogenic responses, including those induced by mitochondrial uncouplers (e.g. dinitrophenol), serotonin reuptake inhibitors, amphetamines and thyroid hormone (TH) excess do not involve a significant shivering component, and therefore appear to involve heat-producing mechanisms apart from contraction. Contraction-independent heat production in skeletal muscle can be invoked by diverse compounds, suggesting the capacity for similar mechanisms to exist for physiologic functions. Unlike shivering or contraction-induced heat production, BAT thermogenesis doesn't involve work by cells *per se,* but rather employs a futile cycle of mitochondrial proton flux to convert energy stored in mitochondria to heat. Essentially, much like the heat produced by short-circuiting an electrical device (e.g. automobile battery), proton leak short-circuits the pH and proton gradient across the inner mitochondrial membrane and generates heat. Unlike white fat, BAT is a mitochondria-rich fat tissue, and is established as the thermogenic mediator of cold-adaptation thermogenesis in some mammals. Mitochondrial uncoupling protein 1 (UCP1), localized to the inner mitochondrial membrane of brown adipocytes, is the molecular mediator of BAT-induced heat production (Nicholls and Rial 1999). The proton gradient provides the energy necessary for ATP production by the F1/F0 ATPase. As protons are released into the mitochondrial matrix, by flowing through the proton pore formed by the ATPase, the energy released from proton flux along its concentration gradient is consumed for the phosphorylation of ADP to ATP. In contrast, proton leak induced by UCPs uncouples this proton gradient from ATP synthesis through the provision of an alternate pathway for proton entry into the mitochondrial matrix. However, since proton-leak-generated energy is not linked to another energy-consuming process, the energy is released as heat. The 'futile cycle' component of mitochondrial uncoupling involves the continuous pumping of protons from the matrix to the inner membrane space for the creation of the mitochondrial electron-transport proton gradient, followed by the successive leak of these protons back into the matrix. Much like the excessive and thermogenic cycling of calcium into and out of the SR that accounts for malignant hyperthermia (to be discussed below), UCP-induced heat production involves a thermogenic futile cycle of proton extrusion from, and leak back into, the mitochondrial matrix.

One challenge to our understanding of human thermoregulation is that adult humans, like most large

animals, have minimal amounts of BAT, and no similar physiologic thermogenic mechanism in humans has been identified. Thus, human BAT depots are regarded as thermogenically irrelevant due to the small aggregate size of the tissue in man. In 1997 it was discovered that human skeletal muscle is enriched in UCP3, a UCP1 homologue linked to skeletal muscle thermogenesis and toxicities in experimental animal models (Vidal-Puig *et al*., 1997; Mills *et al*., 2003). Consistent with the idea that humans may have evolved a similar pathway of thermoregulation in muscle as for the BAT of rodents, sympathetic nervous system stimulants activate skeletal muscle thermogenesis and shut down brown fat thermogenesis (Rusyniak *et al*., 2008). Likewise, a recent series of reports demonstrated that certain of the substituted amphetamines induced hyperthermia and rhabdomyolysis through the activation of UCP3, a skeletal muscle-enriched proton leak regulator. UCP3-null mice were shown to be almost completely resistant to a range of thermogenic doses of the amphetamine 3,4-methylenedioxymethamphetamine (MDMA, Ecstasy), and MDMA failed in these studies to induce lethality in UCP3-null mice at doses that were lethal to wild-type mice and can induce rhabdomyolysis and death in humans (Mills *et al*., 2003). Similarly, rats administered β adrenergic inhibitors designed to inhibit the activation of upstream signalling pathways regulating UCP3 activity were protected from rhabdomyolysis induced by amphetamine-type psychostimulants (Sprague *et al*., 2004a; 2005). More work is needed to understand the relationships between UCP3 and diverse other myotoxic responses, and the mechanisms by which some drugs elicit UCP3 activation in skeletal muscle. However, excessive uncoupling of mitochondrial ATP synthesis and thermogenesis in skeletal muscle resulting from UCP3 activation appears to be critical for both the thermogenic and myotoxic responses to all amphetamine drugs, and therefore represents a new target for the development of strategies of intervention and treatment for certain skeletal muscle toxicities. **Figure 4** provides an overview of proton cycling in mitochondria and its relationships to thermogenesis and oxidative phosphorylation.

The mitochondrial electron transport chain is energized by the intake of fuel substrates derived from food and their oxidation (combustion) in the mitochondrial matrix to liberate electrons used in the oxidation and reduction of mitochondrial respiratory complexes I–IV in the inner mitochondrial membrane. Electrons passed from fuel substrates to electron donors NADH and FADH2 (flavin adenine dinucleotide) are passed from complexes I and II, respectively, to complex III and on to complex IV by the membrane redox carrier coenzyme Q (CoQ) and the soluble protein, cytochrome C. Electrons at complex IV are passed to molecular oxygen to form water (oxygen consumption). As electrons pass along complexes I, III and IV, conformational changes lead to the pumping of protons from the matrix to the inner membrane space. These protons can flux back into the matrix via the F1/F0 ATPase, where the energy from proton flux is consumed for ATP production. Alternatively, protons can 'leak' back into the matrix by UCP activation. Since this process isn't coupled to an energy consuming reaction, the energy from proton flux is liberated as heat. This is the most significant thermogenic mechanism in warm-blooded animals, and in experimental models

is associated with amphetamine-induced muscle breakdown and hyperthermia by the skeletal muscle-enriched UCP3.

5.5 Rhabdomyolytic Agents that Induce Hyperthermia

5.5.1 Volatile Anaesthetics: Inducers of the Pharmacogenetic Syndrome, Malignant Hyperthermia

Halogenated anaesthetic drugs and muscle relaxants, including all gaseous anaesthetics, and the neuromuscular-blocking skeletal muscle relaxant succinylcholine, induce a rare, genetically mediated autosomal dominant syndrome of skeletal muscle-derived hyperpyrexia referred to as malignant hyperthermia (MH) (Stowell, 2008). MH is a highly lethal condition that is caused by skeletal muscle heat production and leads to diffuse necrotic skeletal myocyte death and leakage of muscle-derived ions, myoglobin and CK into the bloodstream. Hyperthermia induced during MH is associated with intravascular coagulation and pulmonary oedema, and myoglobinaemia efficiently damages renal glomeruli, leading to renal failure. In many cases, renal failure and hyperthermia precipitate multiorgan failure and death. In this toxic syndrome, it appears that the loss of intramyocyte levels of ATP, heat accumulation and high levels of intracellular calcium combine to form a triad of toxicities that culminate in the loss of sarcolemmal integrity and the release of myoglobin from necrotic muscle fibres.

Though several mutations are linked to MH susceptibility, the most important loci are found in the RyR of the sarcoplasmic reticulum (Girard *et al*., 2008). MH susceptibility mutations are generally associated with an increased extracellular calcium-induced intracellular calcium release response from the SR that is unmasked when patients are administered MH-triggering agents such as general anaesthetics or muscle relaxants. In these cases, the genetic lesion and drug administration causes excessive RyR-dependent calcium cycling across the SR membrane. This ionic flux is thought to give rise to the excessive skeletal muscle thermogenesis associated with MH syndrome, and the overwhelming of the body's thermoregulatory homeostatic mechanisms, and hyperthermia. Moreover, because MH is generally caused by myocyte calcium accumulation, intoxication is also associated with profound muscle contraction, which is both thermogenic and metabolically exhaustive to the muscle (ATP depletion) as well as the rest of the body. MH syndrome can easily usurp oxygen from the rest of the body, and combined with hyperthermia and rhabdomyolysis is a highly life-threatening toxic response associated with multiorgan failure, disseminated intravascular coagulation, coma and death. Parenteral administration of the RyR inhibitor dantrolene is the only approved treatment for MH (Kobayashi *et al*., 2005). Combined with screening for susceptibility mutations and the avoidance of anaesthesia in susceptible individuals, the use of dantrolene has dramatically decreased the overall mortality rates from MH worldwide from near 80% in the 1960s to roughly 10% today.

During an MH event, excess calcium in the cytoplasm leads to ATP-dependent activation of SERCA pumps to limit excess toxic calcium accumulation in the cytosol of myocytes. ATP is also consumed during the high-calcium-induced contractile responses of skeletal muscle during MH. Thus, hyperthermia, ATP depletion and oxygen consumption each likely contributes to generalized necrotic skeletal muscle breakdown during MH. MH is associated with a significant release of intracellular constituents including myoglobin into the bloodstream, and can rapidly induce kidney and other multiorgan failures, and death, without rapid interventions. Common agents which cause or exacerbate RyR-dependent malignant hyperthermia include the plant-derived alkaloid ryanodine, halothane, 4-chloro-*m*-cresol, caffeine and succinyl choline.

5.5.2 Sympathomimetic Drugs (Amphetamines, Cocaine)

The abuse of sympathomimetic drugs such as MDMA (Ecstasy) and methamphetamine (METH) has steadily increased worldwide into what was cited by the United Nations in a 2003 report as a worldwide 'public health crisis'. The two most dangerous side effects of exposure to these psychostimulant drugs are hyperthermia and rhabdomyolysis. Sequelae of intoxication downstream of muscle breakdown and hyperthermia include, as in MH cases, myoglobinaemia, myoglobinuria, ARF and disseminated intravascular coagulation. However, because sympathomimetics mimic the actions of sympathetic nervous system catecholamine neurotransmitters, norepinephrine and epinephrine, their toxic actions also include increased vasoconstriction and heart rate. These effects can lead to increased blood pressure and adverse myocardial events. Most importantly for skeletal muscle, hyperthermia in the setting of vasoconstriction can lead to a double-edged sword of heat accumulation and muscle ischaemia (reduced blood flow). Amphetamines increase metabolic heat production (through mitochondrial uncoupling and proton flux) and block heat dissipation by constricting vessels, decreasing both muscle perfusion and heat dissipation from cutaneous vessels.

Not surprisingly, given the clinical similarities and outcomes, it has long, and erroneously, been assumed that all disorders of skeletal myotoxicity that are associated with hyperthermia are due to MH mechanisms (Girard

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and Urwyler, 2007). Biophysical mechanisms of thermogenesis, and therefore skeletal muscle breakdown, do appear to be similar in cases of amphetamine toxicity to MH-induced rhabdomyolysis and toxic calcium cycling. Recent evidence indicates that the core mechanisms in sympathomimetic-induced skeletal muscle breakdown also involve ionic cycling. However, MDMA- and METH-induced thermogenesis appears to employ mitochondrial proton leak rather than sarcoplasmic calcium flux (Sprague *et al*., 2003; 2004b). A recent report showed that dantrolene, the RyR inhibitor that blocks RyR-induced calcium flux and is a treatment for MH, fails to affect MDMA hyperthermia in rodents (Rusyniak *et al*., 2004). On the other hand, as mentioned above, mice deficient in skeletal muscle-enriched UCP3 fail to mount a significant thermogenic response to MDMA in experimental conditions, and are protected from MDMA-induced death (Mills *et al*., 2003). In contrast to MH, where anaesthetics appear to have direct-acting effects on the sarcoplasmic reticulum RyR molecule, activation of proton leak by UCPs in MDMA intoxication appears instead to be indirect (Sprague *et al*., 2003). MDMA initiates thermoregulatory derangements and ultimately skeletal muscle breakdown downstream of its activation of norepinephrine-activated β_3 adrenergic receptors, localized to diverse tissues in the periphery. In rodents, MDMA induces a massive increase in plasma norepinephrine that precedes the onset of hyperthermia and skeletal muscle breakdown and renal failure (Mills *et al*., 2004). If β_3 adrenergic receptors are antagonized with the β_3 adrenergic receptor-antagonist, carvedilol (used in cardiovascular medicine), MDMA hyperthermia and rhabdomyolysis are effectively prevented and fully reversed. β_3 adrenergic receptors liberate UCP, activating free fatty acids most importantly in fat and muscle cells, and evidence points to a mechanism involving these intracellular fatty acid messengers in the pathology of MDMA-induced hyperthermia. What aren't clear are the precise locations (either white fat cells or skeletal myocytes, or both) of the β adrenergic receptors most significant in the myotoxicity induced by amphetamines, and the precise mechanisms wherein the free fatty acids are coupled to mitochondrial UCP3 activation. What is clear is that β_3 adrenergic receptors, free fatty acids, and most importantly mitochondrial UCP3 and proton flux distinguish MDMA-induced hyperthermia and rhabdomyolysis from calcium-mediated, anaesthesia-induced MH rhabdomyolytic syndromes.

5.5.3 Thyroid Hormone Intoxication

The most important endocrine regulator of body temperature is thyroid hormone, which acts by binding to intracellular steroid/TH receptor transcription factors and activating the gene expression of a plethora of metabolic regulatory genes in cells. The endogenous thyroid hormones, thyroxine (T4) and triiodothyronine (T3), regulate numerous biological pathways that control the overall metabolism of carbohydrates, proteins and fats, as well as the distribution and regulation of other endocrine hormones. Due to the prominent role THs play within the body, changes in their levels are capable of causing a wide variety of symptoms and health problems, namely related to metabolism. When thyroid tissue becomes over-stimulated due to antibody-mediated autoimmune reactions (Graves' disease), cancer or an imbalance of thyroid stimulating hormone, supraphysiologic and toxic concentrations of T3, T4 or both are released into the bloodstream. This hyperthyroid state induces weight loss, arrhythmias and dyspnoea, but can often lead to thyrotoxic myopathies and hyperthermia (Ramsay, 1966; Engel, 1972). Like other myopathies, the initial symptom of thyrotoxic myopathy involves muscle weakness, and the symptoms of frank thyrotoxicosis (a severe form of hyperthyroidism that is acutely life threatening) include rhabdomyolysis and severe body heat accumulation. Weakness can occur gradually and usually appears in the shoulders, neck and hips. If not reported, weakness can sometimes spread to the eyes and throat, potentially impairing speaking, breathing and vision (Puvanendran *et al*., 1979). If left untreated, chronic and acute cases can result in permanent muscle fibre damage and possibly rhabdomyolysis (Alshekhlee *et al*., 2002). Evidence suggests that it is the TH-induced up-regulation of metabolic respiration, β-oxidation and protein degradation that often leads to the muscle weakness and eventual muscle breakdown/atrophy associated with hyperthyroidism (Bennett and Huston, 1984; Celsing *et al*., 1986; Fukui *et al*., 2001). Muscle biopsies have also revealed an alteration in muscle fibre type from Type 1 oxidative slow-twitch fibres to Type 2 glycolytic fibres. This is attributed to the up-regulation of genes, such as the myosin heavy-chain gene, transcribed by the thyroid nuclear hormone receptor (Olson *et al*., 1991). Interestingly, one of the metabolic proteins induced strongly by thyroid hormones is the thermogenic UCP3, the target of MDMA-induced hyperthermia and rhabdomyolysis (Bouillaud *et al*., 2001). Hyperthyroidism has been shown to lead to dramatically enhanced MDMA thermogenesis, and hypothyroidism leads to a loss of hyperthermia induced by MDMA, and a loss of UCP3 expression (Sprague *et al*., 2003). Though the molecular mechanisms still remain to be fully elucidated for a variety of thermogenic rhabdomyolytic syndromes, interesting links are being established between UCP3 and a variety of myotoxic thermal dysfunction-inducing agents.

There have also been reports linking TH dysregulation to the muscle disorder known as periodic paralysis. Periodic paralysis is considered a genetic disease, occurring predominantly in Asian ethnicities (Okinaka *et al*., 1957; Crane, 1960; McFadzean and Yeung, 1967). This syndrome is characterized by recurring and temporary

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

muscle fatigue due to malfunctions in potassium channels resulting in hyperkalaemia (Tinker and Vannatta, 1987; Kung, 2006). This channelopathy is triggered by high-carbohydrate diets, stress and starvation. Not only does hyperthyroidism affect overall metabolism, but it is also known to increase the activity of sodium/potassium ATPases, which contributes to hyperkalaemia and inhibited muscle contraction (Lin and Akera, 1978; Lam *et al*., 1989; Chan *et al*., 1991). Once a patient becomes euthyroid through drug treatment or thyroidectomy, periodic paralysis ceases to occur.

5.6 Myopathic Agents Not Associated with Significant Induction of Hyperthermia

5.6.1 Endocrine Disrupters

- **Growth hormone:** One of the most common syndromes associated with the pituitary gland is acromegaly, a disease wherein an individual produces excess growth hormone. It is often the result of a pituitary adenoma, but more recently has been associated with growth hormone abuse by bodybuilders. This condition causes skeletal muscle hypertrophy in both Type I and Type II muscle fibres. Myolysis has been confirmed by elevations in serum creatinine kinase (Wolf *et al*., 1978). Actinomyosin ATPase levels are reduced and membrane excitability is also decreased; this commonly results in myofibrillary vacuolization, apoptosis and tissue degeneration (Ruff and Weissmann, 1988; Frustaci *et al*., 1999). The exact mechanism by which this occurs remains unclear, but it is believed to involve nitric oxide (Sacca *et al*., 2003).
- **Corticosteroid intoxication and deficiency:** Corticosteroids are steroid hormones synthesized in the adrenal cortex that are essential regulators of immune, stress and inflammatory responses, and also play fundamental roles in metabolic and catabolic reactions throughout the body. Corticosteroids are generally subdivided into two classes: glucocorticoids and mineralocorticoids. Glucocorticoid hormones such as cortisol modify lipid, carbohydrate and protein metabolism to promote energy storage and stress responses. They also play roles in preventing inflammation by reducing cytokine production and secretion, as well as inducing apoptosis of cytokine-producing cells. Mineralocorticoids, the most common being aldosterone, control electrolyte and water homeostasis by modifying sodium retention in the kidney nephron. Consistent with their metabolic functions, excessive or high-dose corticosteroid use often causes a generalized metabolic shift towards energy storage in patients. This is evident by fat redistribution to the trunk in affected individuals. Corticosteroid myopathy is typically localized to the extremities with the legs being the preferential site for progressive weakness and muscle wasting, with only rare cases of myalgia. This corticosteroid-induced atrophy is marked by CK elevation and rhabdomyolysis primarily in Type II fibres (Dekhuijzen and Decramer, 1992; Fernandez-Sola *et al*., 1993).

Glucocorticoids have been demonstrated to increase cytoplasmic protease activity in skeletal muscle, which increases the rate of muscle damage as well as inhibiting repair mechanisms (Lang *et al*., 2001b). This effect is potentiated by glutamine synthetase, the major enzyme that produces glutamine from glutamate. Under conditions of high circulating glucocorticoid levels, intramuscular glutamine levels drop initially, resulting in decreased protein synthesis. This effect is followed by enhanced function of glutamine synthetase, which activates catabolic pathways and further exacerbates proteolysis (Shoji *et al*., 1974; Max *et al*., 1988).

Clinical manifestations of corticosteroid deficiency-induced myopathy are often observed in patients suffering from Addison's disease, a condition involving insufficient hormone secretion of the adrenal gland. In these patients, muscle biopsy and CK levels appeared normal, but they displayed a pronounced weakness with occasional paralysis (Ruff and Weissmann, 1988). These effects were found to be caused by impaired carbohydrate metabolism and alterations in serum electrolytes, especially hyperkalaemia (Van Dellen and Purnell, 1969).

5.6.2 Acetylcholinesterase Inhibitors

As mentioned above, ACh is the major neurotransmitter that drives skeletal muscle movement in response to peripheral nervous system (PNS) stimulation. In the PNS, ACh is released by neurons at neuromuscular junctions, resulting in the opening of ligand-gated Na^+ channels, depolarization, calcium-induced sarcoplasmic release of calcium and, finally, muscle contraction. After neuronal firing and release of ACh at the junction, ACh is rapidly metabolized by AChEs. AChE inhibitors (AChE-Is) are compounds that inhibit this enzyme. Common AChE-Is include venoms, pesticides and drugs to combat Alzheimer's disease and myasthenia gravis.

The progression of acute AChE-I poisoning has been well studied in humans. Initially, involuntary fasciculation is observed, followed by weakness, myalgia, rhabdomyolysis, and finally the development of subjunctional necrotic lesions, with Type I fibres being preferentially affected (Laskowski *et al*., 1977; Gupta *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1986). As is commonly observed during rhabdomyolysis, serum CK levels are increased, and myocyte ATP levels are decreased (Gupta and Dettbarn, 1987). In cells, AChE-I toxicity is expressed as mitochondrial swelling, vacuolization, sarcomeric hypercontraction, myofilament breakdown and Z-band fragmentation. Necrosis induced by AChE-I toxicity was observed to originate near the muscle endplate; it is postulated that this effect is initiated by hyperstimulation and increased contractile activity of individual fibres (Gupta *et al*., 1987). This would lead to the rapid consumption of ATP stores, which may in turn exacerbate calcium release from sarcoplasmic Ca^{2+} stores, resulting in the activation of PLA_2 (phospholipase A_2) and Ca^{2+}-activated proteases, causing aberrant signalling and the degradation of macromolecules necessary for cell structure and function.

Treatments for AChE-I poisoning include AChR antagonists such as atropine, AChE phosphorylating/activating drugs such as pyridine-2-aldoxime methyl chloride (2-PAM), and in extreme cases anti-AChE receptor antibodies are administered to block ACh binding (Laskowski *et al*., 1977; Patterson *et al*., 1988).

5.6.3 Amiodarone

Amiodarone is a controversial antiarrhythmic agent that is used for the acute treatment of sudden arrhythmias, or is administered chronically to suppress existing arrhythmic conditions. It has a relatively long half-life and has been found to preferentially accumulate in muscle tissues (Patterson *et al*., 1988). It is considered a class III antiarrhythmic agent as its primary mechanism of action is to prolong Phase 3 of the cardiac action potential. This activity is most likely an effect of amiodarone blocking potassium export channels, which in turn stalls membrane repolarization.

Despite the fact that the most common complications associated with amiodarone are neuropathic in nature, skeletal muscle myopathies are also common. The majority of myopathies resulting from amiodarone administration typically arise when it is used in conjunction with other drugs, especially those of the statin family. Amiodarone myopathies are generally mild and are most commonly described as progressive and persistent muscle weakness similar to myasthenia gravis. This weakness is believed to be due to decreased depolarization in muscle fibres, and therefore the diminished capacity for contraction. There is typically no myolysis associated with amiodarone treatment. Amiodarone is structurally similar to, and also loosely mimics, thyroid hormone in its ability to bind the nuclear thyroid receptor (Franklyn *et al*., 1985). Though the mechanisms for myopathic effects are not clear, it is likely that its activity in the regulation of TH receptors may account for at least some of its effects on skeletal muscle.

5.6.4 Amphiphilic Drug Myopathy

Amphiphilic drugs contain both hydrophilic and hydrophobic regions. Many drugs included in this category are psychotropic compounds such as chlorphentermine, chlorcyclizine, l-chloro-amitriptyline, triparanol, quinacrine (Mepacrine), iprindole or imipramine, as well as chloroquine (CQ), hydroxychloroquine (HCQ) and doxorubicin (Drenckhahn and Lullmann-Rauch, 1979; Kuncl and Wiggins, 1988). Myopathies caused by these drugs generally present as muscle tissue restructuring as denoted by fibre branching and subfibre clustering. Increased vacuolization and myofibrillary necrosis have also been associated with amphiphilic compounds (Drenckhahn and Lullmann-Rauch, 1979). The two regions of these drugs have discrete mechanisms by which they promote myotoxicity. The nonpolar hydrophobic regions insert into myofibre membranes and induce permeabilization leading to electrolyte and osmotic imbalances, and ultimately, necrotic death of the muscle fibre. In contrast, the polar hydrophilic regions of amphiphilic toxins tend to interact with lysosomes in muscle cells where they cause perturbations in lysosomal pH. The core of lysosomes is generally maintained at a pH of 4.5, which is necessary for the proper function of the digestive enzymes that mediate lysosomal functions. Changes in intralysosomal pH inactivate these enzymes and prevent lysosomal degradation and recycling of cellular macromolecules such as lipids, proteins and carbohydrates. Lysosomal dysfunction leads to mucolipidosis, a condition characterized by the intracellular accumulation of waste and debris in myocyte vacuoles (Plante *et al*., 2008). This vacuolization impedes cellular function and myofibrillary contraction.

5.6.5 Emetine

So named, emetine is a potent 'emetic' drug that is often used clinically for the removal of harmful substances from the stomach, and is often abused by bulimic patents for weight control. Emetine is an alkaloid that acts by irritating the gastric mucosa. This in turn leads to stimulation of the medullary chemoreceptor trigger zone (CTZ), likely via serotonin signalling. The CTZ communicates with the area postrema, which then signals the induction of vomiting. While acute use is considered safe, chronic administration of emetine has been linked to several complications, the most common of which are cardiac and skeletal muscle myopathies.

Researchers have discovered that in rats, chronic dosing of emetine caused severe muscle atrophy, with decreases in muscle weight and contraction strength. While atrophy was most common in Type II fibres, decreases in myofibrillar ATPase and NADH tetrazolium

reductase were also shown in all three fibre types, indicating muscle injury. These animals also showed occasional necrotic and splitting fibres, and it was determined that these effects were not due to neuromuscular aberrations (Blasco *et al*., 1976).

Similar research also indicated that much of this atrophy could be due to apoptosis and autophagy. Chronically dosed rats showed progressive ultrastructural abnormalities in their muscle tissues much like in the above findings. Myofibrillar changes observed included rod formation, Z-line streaming, contractile clumping, myofilament loss and mitochondrial degeneration. It was also found that these myofibres showed extensive vacuolization, membrane proliferation, sarcoplasmic abnormalities and increased lysosomal activities, which are indicative of autophagy (Bindoff and Cullen, 1978; Stam and van Crevel, 1989).

Findings made using immunological cell lines revealed that emetine treatment induced phosphatidylserine exposure, DNA fragmentation and mitochondrial depolarization. It was also shown that emetine resulted in the activation of caspase-3, -9 and -8, but that these effects could be prevented by either over-expressing Bcl-2 or knocking-out caspase-8. These data indicate that if emetine is causing apoptosis in muscle cells, it is most likely through the mitochondrial pathway (Moller and Wink, 2007). Emetine-induced myopathy is reversible upon discontinuation of the drug, and no other treatment exists for emetine poisoning.

5.6.6 Ethanol Myopathy

Ethanol was initially implicated in muscle injury in the early 1800s, and the injurious effects of ethanol on skeletal muscle occur after both acute and chronic exposure (Hed *et al*., 1962; Pittman and Decker, 1971). Acute ethanol myopathy generally occurs after bouts of excessive, or binge, drinking. Chronic ethanol-induced myopathy may occur when lower doses are administered long term (Pittman and Decker, 1971). Symptoms of these conditions are often observed as generalized muscle pain, swelling, rhabdomyolysis, cramping or noninflammatory atrophy. Ethanol, myopathies are commonly associated with or potentiated by degrees of malnutrition and dehydration (Fahlgren *et al*., 1957; Haller and Drachman, 1980). As with many myopathies, those induced by ethanol are diagnosed by elevated levels of serum CK and myoglobinuria. Alcohol myopathy is considered a multifactorial disease state and is often accompanied by other conditions including vitamin deficiency, electrolyte imbalance, metabolic derangement, endocrinopathy, oxidative stress, gene dysregulation and altered signal transduction (Urbano-Marquez and Fernandez-Sola, 2004).

5.6.7 Acute Alcohol Myopathies

Acute alcohol myopathies preferentially affect Type I (slow-twitch) fibres (Haller, 1985). Tissue analysis revealed myofibrillar necrosis, irregularities in sarcomeric banding patterns, mitochondrial disruption and increased cellular vacuolization (Hed *et al*., 1955; Klinkerfuss *et al*., 1967; Martinez *et al*., 1973; Martin *et al*., 1982). Since acute ethanol myopathies are associated with large doses of alcohol, membrane disruption is a major contributor of the disease state. While ethanol exposure does not affect the stoichiometry of membrane components, it does directly alter the fluidity of membranes, especially those of the SR. Ethanol causes the acyl chains of membrane phospholipids to become disordered, and may even trigger dissociation of cholesterol from the membrane during extended exposure (Goldstein and Chin, 1981; Ferguson *et al*., 1984). Under more extreme conditions cell lysis may occur along with inflammatory responses (Preedy *et al*., 1989). Increased membrane fluidity is also in part mediated by the disruption of ion transport mechanisms for sodium, potassium and calcium, resulting in a decrease in the cellular resting state potential (Blachley *et al*., 1985). In addition, acute ethanol exposure increases passive calcium permeability in the SR, which is a probable cause of the negative muscle inotropic effects observed in cases of ethanol intoxication (Ohnishi, 1985).

Several metabolic effects have also been associated with acute alcohol myopathies. These effects include a decrease in glucose uptake and utilization, glycogen depletion, excess lactate production, and increased gluconeogenesis and glycolytic activities (Perkoff, 1971; Hed *et al*., 1977; Chui *et al*., 1978; Cook *et al*., 1988; Peters *et al*., 1996). Protein metabolism has not been well studied in the acute condition, but some reports show that protein synthesis is decreased along with amino acid transport (Rubin, 1979; Rubin and Rottenberg, 1982). Effects on mitochondria include structural derangements, uncoupled oxidative phosphorylation and decreased levels of Ca^{2+} ATPase in myofibres (Lange and Sobel, 1983; Martin *et al*., 1984). Hypokalaemic myopathies have been observed after acute alcohol abuse and generally present as weakness or periodic paralysis. They are thought to be derived from ischaemia induced by vasoconstriction. This condition is exacerbated by exercise (Knochel and Schlein, 1972). Acute ethanol use has also been linked to alterations in gene expression, which could contribute to the development of myopathies. Gene microarrays performed on rats treated with ethanol showed altered expression of over 400 genes (Shankar *et al*., 2006). Genes with altered expression included those involved in metabolism, apoptosis and gene expression.

5.6.8 Chronic Alcohol Myopathies

Unlike acute alcohol myopathies, chronic consumption of ethanol typically affects Type II (fast-twitch) fibres (Lang *et al*., 1999a). Roughly 50% of high-dose alcohol abusers develop a skeletal myopathy (Estruch *et al*., 1993). Gradual muscle atrophy is the most pronounced metabolic aberration found in chronic alcohol abusers (Lang *et al*., 1999b). This muscle wasting is typically described by a decrease in fibre size, but not fibre number (Peters *et al*., 1985). The metabolic effects of ethanol may be mediated either directly through alterations in membrane fluidity or receptor binding, or indirectly through the generation of secondary mediators such as inflammatory cytokines, stress hormones and reactive oxygen species (ROS).

Skeletal muscle comprises 40% of human body weight and acts as a considerable site for protein synthesis and storage. Chronic ethanol consumption has been shown repeatedly to impair protein synthesis in muscle, particularly that of myofibrillar proteins (Lang *et al*., 1999b; Reilly *et al*., 2000). The eukaryotic initiation factors (eIFs) are responsible for binding of t-RNA (transfer RNA) to the 40 S ribosomal subunit to form the 43 S preinitiation complex. Alcohol does not appear to directly alter the abundance or modification of these complexes (Lang *et al*., 2001a). It does however appear to impair the activity of the mammalian target of rapamycin (mTOR), a key regulatory kinase in many signal transduction pathways. One of the functions described for mTOR is the phosphorylation and inactivation of the eIF-4E binding protein (4E-BP1), which functions to sequester eIF-4E (Gingras *et al*., 2001). Insulin-like growth factor-1 receptor (IGFR-1) also mediates protein synthesis by phosphorylating ribosomal protein S6. Decreased IGFR-1 activation has been observed in skeletal muscle preparations from chronic alcohol users (Kumar *et al*., 2002). Mitochondrial metabolism is also altered in patients presenting with chronic ethanol myopathies. In particular, β-oxidation of fatty acids is markedly decreased (Lange and Sobel, 1983). Even though Type II fibres are more heavily reliant on glucose, and not fats (and mitochondrial respiration) for ATP production, these factors may potentiate the disease state by inhibiting energy production required for muscle repair and function.

ROS have also been implicated in alcoholic myopathy. ROS are most commonly generated in the mitochondrion as a by-product of oxidative phosphorylation where electrons that pass along the respiratory complexes slip away and react with molecular oxygen, forming partially reduced oxygen species. Since ethanol has been shown to damage mitochondria, it is likely that this is the cause of increased ROS generation observed after alcohol exposure. ROS, such as superoxide and hydrogen peroxide, indiscriminately damage cellular macromolecules such as DNA, RNA, lipids and proteins and extensive damage has been shown to induce apoptosis. Rats fed ethanol showed a marked increase in antioxidant enzymes, a sign of increased oxidative stress.

Chronic alcohol consumption has been shown to induce apoptotic death in several cell types including Type II muscle fibres (Fernandez-Sola *et al*., 1996; Narula *et al*., 1996; Brooks, 2000; Kelkar *et al*., 2002). Ethanol may trigger both the intrinsic (mitochondrial) and extrinsic (death receptor-mediated) apoptotic pathways (Molina *et al*., 2003). The extrinsic pathway is most likely activated by the up-regulation of the Fas receptor, while activation of the intrinsic pathway is probably caused by either mitochondrial damage, altered gene expression or by disrupting calcium concentrations (Narula *et al*., 1996; Trump and Berezesky, 1996; Lu *et al*., 2002). Ethanol-induced mitochondrial membrane damage causes the release of cytochrome C, a major constituent of the apoptosis-promoting apoptosome complex, which is responsible for activating caspase-3, the cell's major effector caspase. Increased intracellular calcium levels have also been implicated in release of cytochrome C from mitochondria via opening of the mitochondrial permeability transition pore by the voltage-dependent anion channel (VDAC). Levels of proapoptotic genes such as *BAX* are also up-regulated in alcoholic myopathies (Narula *et al*., 1996). Cytosolic Bax translocates to the mitochondrion where it facilitates VDAC opening. These findings indicate that both acute and chronic ethanol myolysis and atrophy are multifactorial disease states with several molecular mechanisms contributing to the apoptotic and necrotic loss of myocytes and cellular dysfunction.

5.6.9 Potassium-Based Myopathies

Potassium is an important electrolyte that plays several important roles in the muscle, the primary of which is to maintain membrane potential and aid in the membrane depolarization process. Myopathy may result under conditions of either hyperkalaemia or hypokalaemia, and appears to affect both Type I and Type II fibres equally (Brumback *et al*., 1995).

- **Hyperkalaemia:** Increased circulating potassium may be caused by dietary overabundance, potassium-sparing diuretics, nonsteroidal anti-inflammatory drugs (NSAIDs) and ACE (angiotensin -converting enzyme) inhibitors (Knecht *et al*., 1985). Excess serum potassium leads to membrane depolarization, which activates membrane sodium channels, resulting in the influx of extracellular sodium, but not enough to propagate a membrane potential, causing these channels to become intractable. Without proper Na^+ channel function, the threshold required for mounting an action potential increases, which prevents further depolarization. The most common clinical symptom of hyperkalaemia is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

generalized muscle weakness, with bicarbonate therapy being the most common treatment. Bicarbonate serves to increase serum Na^+ concentration, which then reactivates Na^+ channels and motor function.

- **Hypokalaemia:** Circulating potassium levels may be decreased due to dietary insufficiency, heavy fluid loss or the loop diuretic, furosemide. Pathology of the condition often presents as myalgia and cramping, with paralysis, tetany and rhabdomyolysis in more severe cases. Diminished potassium levels cause skeletal muscle membrane hyperpolarization due to the inability of cells to import sufficient potassium to restore membrane potential to a 'normal' resting state. The consequence of these actions is a reduced response to stimulus, which may lead to atrophy under chronic conditions (Mastaglia, 1982). Treatment typically consists of potassium supplementation and treatment or discontinuation of the aforementioned causes.

5.7 Lipid-Lowering Drugs

5.7.1 Statins

Statin drugs are among the most widely prescribed drugs worldwide. Statins are a group of 3-hydroxy -3-methylglutaryl coenzyme A reductase (HMG CoA reductase) inhibitors, considered the most effective lipid-lowering drugs on the market. They function by blocking the first, rate-limiting enzymatic step during *de novo* cholesterol biosynthesis, thus preventing the generation of mevalonate. Inhibition of cholesterol synthesis results in the activation of proteases which cleave the membrane-bound sterol regulatory element binding protein, leading to its translocation to the nucleus and the up-regulation of a variety of proteins/enzymes, including the LDL (low-density lipoprotein) receptor. The increase of LDL receptors on the liver membrane results in the subsequent binding and clearance of both LDL and VLDL, and decreased circulating LDL and VLDL cholesterol levels. The major side effect of statins, however, is the tendency to develop myopathic symptoms and, in extreme cases (7.8% of patients), rhabdomyolysis and consequently kidney failure. Less severe myopathies involve muscle pain and muscle weakness and do not involve a significant rise in CK levels (Paoletti *et al*., 2002; Dirks and Jones, 2006).

While the mechanism for muscle toxicity is not fully understood, the more extreme cases of myopathy and rhabdomyolysis are often due to combination therapies with drugs such as fibrates, cyclosporine A and niacin (Boger, 2001; Hodel, 2002). These agents inhibit the drug metabolizing enzyme cytochrome P450 3A4 (CYP3A4), the protein responsible for the breakdown of the majority of statin drugs. This causes the statins to remain in the bloodstream longer, thus altering their pharmacokinetic and pharmacodynamic properties related to absorption, distribution, metabolism and excretion of the drug (Paoletti *et al*., 2002). Current research shows that statins are capable of inducing apoptosis in a variety of cell lines including vascular smooth muscle cells, and skeletal myoblasts and myotubes (Blanco-Colio *et al*., 2002; Johnson *et al*., 2004; Erl, 2005). Myocyte apoptosis is a likely contributor to the myopathic side effects of statins. Interestingly, inhibition of enzymes downstream of the HMG CoA reductase in the cholesterol biosynthetic pathway, such as squalene synthase, fails to induce apoptosis, suggesting it is not depletion of cholesterol itself that is resulting in the induction of apoptosis. Studies suggest that statin-induced apoptosis is, rather, linked to an alternative mevalonate metabolic pathway related to the synthesis of isoprenoids (Guijarro *et al*., 1998; Laufs and Liao, 2003). Isoprenoids are important lipid moieties required for both ubiquinone biosynthesis and for the post-translational modifications of the membrane-associated proteins Rho, Ras and Rac—key players in cell fate decisions involving cell growth and death. Treatment with statins does not alter ubiquinone levels but does affect the isoprenylation, farnesylation or geranylgeranylation of Rho and Ras in L6 muscle cells and vascular smooth muscle cells, thus altering their ability to translocate to the plasma membrane and be activated (Johnson *et al*., 2004; Matzno *et al*., 2005). This inhibition of Rho and Ras is also associated with an increase in intracellular calcium that causes the activation of calpains, triggering the translocation of the proapoptotic protein Bax to the mitochondria, and the activation of the mitochondrial death pathway via caspase-9 and caspase-3 (Sacher *et al*., 2005).

5.7.2 Fibrates

Fibrate derivatives, while less effective than statins at lowering LDL, are also considered hyperlipidaemic agents for their ability to raise HDL (high-density lipoprotein) and lower triglyceride (TG) levels (Duriez, 2003). The mechanism by which fibrates treat hyperlipidaemia is attributed to their ability to act agonists for peroxisome proliferator-activated receptors (PPARs), specifically PPARα (Matzno *et al*., 2006). PPAR isoforms belong to the nuclear hormone receptor superfamily, and their activation results in the up-regulation of a variety of lipid metabolism genes. While the fibrate derivative, gemfibrozil, has been the only fibrate reportedly associated with causing rhabdomyolysis, all the fibrates are capable of causing some muscle toxicity resulting in palpitation-induced muscle pain, cramps, myalgia and weakness. When used in combination with statins, risk

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of more severe induction of rhabdomyolysis is reported (Guis *et al*., 2003). As mentioned above, combination therapies with fibrates and statins lead to drug metabolism issues, as each drug class is metabolized by CYP3A4, and each drug class can induce myopathic responses upon monotherapeutic use. Likewise, drugs such as cyclosporine A, which inhibit CYP34A, could also lead to dangerous myopathic symptoms when used together with fibrates. Less clear are the mechanisms by which fibrates induce myolysis when administered alone. Recent studies show treatment of L6 rat skeletal myoblasts with clofibrate caused apoptosis in a dose-dependent manner within 24 hours (Matzno *et al*., 2006). Clofibrate is one of the more traditionally prescribed hyperlipidaemic agents and is broken down to the free acid derivative clofibric acid. Treatment of L6 rat skeletal myoblasts resulted in the rapid release of calcium from the SR followed by the extended elevation of calcium levels due to the influx of extracellular calcium. This triggers the cleavage and activation of caspase-12 in a calpain-independent manner. Activation of caspase-12 leads to the activation of caspases-9 and -3 and the induction of DNA fragmentation and apoptosis (Matzno *et al*., 2006). The ability of clofibrate to induce apoptosis by a slightly different mechanism than statin-induced apoptosis supports the higher risk of skeletal myopathy when the two drugs are used in concert; however several mechanistic questions remain unclear that could provide safer combination drug therapies in the future.

Because mechanisms of myopathic muscle cell death induced by statins remain to be further elucidated, still no treatment exists that allows patients sensitive to statin-myopathy to persist in receiving statin therapy should a clinically significant myopathic response occur. Unfortunately for these patients, especially given the great effectiveness of these agents in the treatment of hyperlipidaemia and the prevention of cardiovascular events, the only way to treat statin myopathy is via cessation of the drug treatment.

5.7.3 Niacin

Another commonly prescribed lipid-lowering agent associated with rare myopathies is niacin (nicotinic acid/vitamin B_3). Like statins and fibrates, niacin prevents the production of VLDL and lowers overall cholesterol secretion from the liver while sparing cardioprotective HDL levels (Gharavi *et al*., 1994). Very few cases of myopathy have been reported in patients using niacin alone, and in those rare cases the mild symptoms ceased once drug administration was stopped. In contrast, more severe cases of myotoxicity have been attributed to the coadministration of niacin with either fibrates or statins. Excessive consumption of alcohol while taking niacin may also predispose a patient to more extreme myopathies (Ballantyne *et al*., 2003; Bays and McGovern, 2003).

5.8 Lysosomal/Vacuolar Myopathies

5.8.1 Chloroquine/Hydroxychloroquine

CQ and its hydroxylated version, HCQ are widely used as antimalarial agents and in the treatment of connective tissue diseases such as rheumatoid arthritis. These agents rarely induce myopathy alone, but in combination with other drugs can elicit muscle and nerve toxicities. Termination of CQ or HCQ treatment will usually result in the reversal of muscle toxicity (Richards, 1998; Stein *et al*., 2000). Most cases of CQ- or HCQ-induced myopathy are referred to as lysosomal or vacuolar myopathies due to the accumulation of lysosomal vacuoles within the skeletal muscle. Initial signs of CQ myopathy are easily confused with the disease symptoms themselves, including weakness in the proximal limbs and areflexia. CK levels are usually normal and lysosomal myopathic symptoms usually do not present themselves until 6 months to even 10 years later (Estes *et al*., 1987; Sghirlanzoni *et al*., 1988). While the myotoxic mechanisms remain largely undefined, CQ and HCQ are cationic, amphiphilic compounds with long half-lives that appear to affect the autophagy pathway and subsequent protein degradation. Research has also shown in rat models that treatment with CQ causes an increase in the activity of lysosomal proteolytic enzymes such as cathepsins and acid hydrolases (Tagerud *et al*., 1986; Sugita *et al*., 1987).

5.9 Microtubule Disrupting Agents

5.9.1 Colchicine

Colchicine continues to be the standard long-term treatment for gout. It is also used to treat other diseases such as primary biliary cirrhosis, amyloidosis and Mediterranean fever (Chattopadhyay *et al*., 2001). Colchicine is able to treat gout due to its ability to block the formation of uric acid crystal deposits by inhibiting the synthesis of lactic acid. Colchicine is also a microtubule disrupting agent that binds to tubulin and prevents microtubule polymerization. This property has generated some interest in the use of colchicine as a potential chemotherapeutic agent due to the necessity for microtubules in the creation of the mitotic spindle required for the completion of mitotic cell division. However, there is currently no means of preventing the toxic effects on nontumorigenic cells. Colchicine induces vacuolar myopathy, indicated by the accumulation of lysosomal and autophagic vacuoles within the non-necrotic muscle fibres. Likewise, colchicine has also been found to inhibit endosomal/lysosomal trafficking in a variety of cell lines. Microtubules play a critical role in developing skeletal muscle by directing and securing AChRs (Kuncl

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat070
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 2003). Thus, scientists have been interested in defining the mechanisms by which colchicines disrupt the microtubule-dependent receptor trafficking process. Several studies have recently determined that colchicine inhibits AChR exocytosis, providing a likely explanation by which colchicine disrupts ACh signalling and induces muscle weakness and skeletal muscle myopathy (Kuncl *et al*., 2003).

5.9.2 Vincristine

Another microtubule disrupting agent, vincristine, is often used as an antineoplastic drug. The main side effect associated with vincristine treatment is axonal peripheral neuropathy; however, myopathy can also occur (Sieb and Gillessen, 2003). Similar to colchicines, accumulation of lysosomes and autophagosomes is often observed in vincristine-treated skeletal muscle fibres. Due to the smaller amount of vincristine-induced myopathy research, it has yet to be determined if the same inhibition of exocytosis as seen with colchicine treatment also occurs with vincristine treatment (Bradley *et al*., 1970).

5.10 Mitochondrial Myopathies

5.10.1 Zidovudine (AZT)

Patients infected with human immunodeficiency virus (HIV) are often more susceptible to myopathy due to a variety of disease- and treatment-related reasons. Approximately 20% of patients treated with the nucleoside reverse transcriptase inhibitor, zidovudine, displayed myopathic symptoms such as myalgia, fatigue, overall muscular weakness and elevated CK levels, and duration and dose of treatment can also dictate the occurrence and severity of symptoms. Zidovudine helps to treat HIV infection by substituting for the viral reverse transcriptase. Unfortunately, that also makes zidovudine a good substitute for the mitochondrial DNA polymerase γ, thereby disrupting replication of mitochondrial DNA, which leads to a decrease in the mitochondrial respiratory proteins and subsequent mitochondrial dysfunction (Gold *et al*., 1990; Dalakas *et al*., 1994). Both muscle biopsies and experiments in cultured human muscle cells revealed vacuolization, lipid accumulation, aberrant cristae and ragged-red fibres often associated with abnormal mitochondria and myopathy (Masini *et al*., 1999). It is often difficult to differentiate between HIV-induced myopathy, T cell-mediated inflammatory myopathy, and the mitochondrial myopathy induced due to zidovudine treatment; however, discontinuation of zidovudine treatment or L-carnitine supplementation can sometimes result in an almost full reversal of symptoms (Gold *et al*., 1990; Dalakas *et al*., 1994; Masini *et al*., 1999).

5.11 Necrotic Myopathy/Other

5.11.1 Venom

Envenomation by a variety of species, from snakes and insects to fish and mushrooms, is known to cause mild-to-severe myotoxicity. Snakes can be categorized into two main groups. The elapids (cobras and coral snakes), which reside mainly within Africa and Southern Asia contain venom that causes neurotoxicity. The viperids (rattle snakes, water moccasins and copper heads), on the other hand, inhabit North and South America, and their venom is known to cause necrotic myopathy, including the more severe compartment syndrome, rhabdomyolysis and myoglobinuria. Viperid venom contains a variety of components that promote the spreading of the venom, as well as digestive enzymes including phospholipase A_2 and other specific myotoxins capable of acting both locally and systemically. A combination of necrotic and intact fibres can be visualized in the muscle biopsies of snake-bite victims (Rossi *et al*., 1989; Mebs and Ownby, 1990; Bush and Jansen, 1995; Jolles *et al*., 1998; Spiller and Bosse, 2003).

Insect venom can also cause myotoxicity distant from the wound. Most insect bites and stings cause very little myopathy; however, certain arthropod's venom can elicit severe reactions in the body including rhabdomyolysis and, in rare cases, death. Arachnids (spiders and scorpions) such as the brown recluse, the redbacked spider and the mouse spider, often exert more neurotoxic effects on their victims; still general muscle aches and acute rhabdomyolysis along with some necrotic lesions have been described in some cases (Gala and Katelaris, 1992; Muller, 1993). The most severe cases usually involve the honey bee or larger attacks by the Africanized honey bee. Multiple stings from wasps can also induce mild rhabdomyolysis (Franca *et al*., 1994; Vetter *et al*., 1999). What is not clear is whether these intoxications result in direct muscle injury by chemical components in the venoms, or rather are secondary to fevers produced during the acute immunologic reactions to venom exposure.

Eating certain vegetation or animals can also result in skeletal muscle toxicity. The mushroom known as *Amarita phalloides* contains the myotoxin phalloidin that binds directly to tubulin and prevents microtubule polymerization. Phalloidin is often conjugated to fluorochrome molecules and used to visualize microtubules in cell culture experiments (Westendorf, 1999). Ingestion of certain types of fish has also triggered rhabdomyolysis. This condition is referred to as Haff disease. The first described cases of Haff (*Haff* is the German word for lagoon) disease occurred around the Baltic Sea. Other fish that have since been found to cause Haff disease are the tropical blue humphead parrot fish and the buffalo fish found in the USA (Buchholz *et al*., 2000). Although the

Table 3 Summary of rhabdomyolytic agents and their mechanistic and clinical properties

Type of myopathy	Cause	Mechanism	Signs and symptoms	Clinical and diagnostic findings
Necrotic	Lipid lowering drugs: statins, fibrates and niacin	Statins: inhibit the synthesis of isoprenoids, disrupting Rho and Ras pathways leading to apoptosis Fibrates: cause elevated levels of calcium and the activation of calpains and caspase-12 leading to apoptosis Niacin: affect the metabolism of fibrates and statins when coadministered Co-treatment of fibrates, statins and niacin with one another as well as cyclosporine A or alcohol inhibits cytochrome P450 (CYP34A) preventing the proper metabolism and excretion of the drug	Muscle pain/ weakness/cramps, rhabdomyolysis, renal failure	Elevated CK levels, Myoglobinuria
	Venom: snakes and insects	Venom contains combination of digestive enzymes and muscle-specific toxins	Pain, compartment syndrome, rhabdomyolysis, myoglobinuria	Combination of necrotic and intact muscle fibres. Elevated CK levels in more severe cases
	Corticosteroid excess	Increases cytoplasmic protease activity in skeletal muscle and inhibits glutamine synthesis, reducing protein synthesis	Muscle weakness/wasting, rhabdomyolysis, occasional myalgia	Elevated CK levels, atrophy of Type II fibres, lowered intramuscular glutamine levels, fat redistribution to lower extremities
	Alcohol abuse, acute/chronic	Acute: overall dehydration and malnutrition. Disrupts phospholipid membranes and other metabolic pathways; hypokalaemia due to vasoconstriction, altered gene expression	Muscle pain/swelling/ cramping, rhabdomyolysis	Elevated CK levels, myoglobinuria, necrotic Type I fibres with irregular sarcomeric banding, irregular mitochondria, vacuolization
		Chronic: impairs protein synthesis (e.g. myofibrillar protein), impairs mTOR function and damages mitochondria, resulting in increased apoptosis	Muscle wasting, gradual muscle fibre atrophy, rhabdomyolysis	Elevated CK levels, decrease in Type II fibre size, elevated ROS levels, decreased IGFR-1 activity, myoglobinuria
	Opiates	Unknown	Rhabdomyolysis, compartment syndrome, renal failure	Myoglobinuria, necrotic muscle fibres (see focal myopathy)
	Amphetamines (MDMA)	Increase in norepinephrine, increased mitochondrial uncoupling	Rhabdomyolysis, compartment syndrome, renal failure	Elevated CK levels, myoglobinuria, increased levels of free fatty acids, elevated temperature

Table 3 (*continued*)

Type of myopathy	Cause	Mechanism	Signs and symptoms	Clinical and diagnostic findings
Lysosomal/ vacuolar	Amphiphilic drugs: chloroquine/ hydroxychloro-quine, amiodarone	Hydrophobic region: disrupts myofibre membrane causing electrolyte/osmotic imbalance Hydrophilic region: interacts with lysosomes disrupting protein and lipid degradation. Accumulation of vacuoles impedes further cell function and muscle contraction	Proximal muscle weakness, rhabdomyolysis	Accumulation of lysosomal and autophagic vacuoles within muscle fibres. CK levels normal
Potassium-based	Hyperkalaemia (caused by diuretics, NSAIDs and ACE inhibitors)	Excess serum potassium results in membrane depolarization without the ability to repolarize	Generalized muscle weakness	Atrophy of Type I and Type II fibres
	Hypokalaemia (caused by dietary insufficiency or extreme dehydration)	Causes skeletal muscle membrane hyperpolarization. Reduced response to stimulus	Myalgia, cramping, periodic paralysis, tetany, rhabdomyolysis	Atrophy of Type I and Type II fibres. Elevated CK levels
Antimicrotubular	Colchicine and vincristine (can also be considered lyso-somal/vacuolar myopathies)	Stably bind to tubulin preventing microtubule polymerization. Disrupt microtubule-dependent receptor trafficking. Possibly alter acetylcholine signalling	Proximal muscle weakness	Accumulation of lysosomal and autophagic vacuoles within muscle fibres
	Amarita phalloides phalloidin	Binds directly to tubulin and prevents microtubule polymerization		
Mitochondrial	Zidovudine	Disrupts the mitochondrial DNA polymerase γ causing a decrease in mitochondrial proteins, leading to mitochondrial dysfunction	Myalgia, fatigue, overall muscle weakness, rhabdomyolysis	Muscle biopsies reveal vacuolization, lipid accumulation, ragged-red fibres, abnormal mitochondria with aberrant cristae
Endocrine	Thyroid	Hyper: up-regulates metabolic respiration, β- oxidation and protein degradation. Altered gene expression (myosin heavy-chain), increased activity of Na/K ATPase.	Muscle weakness of shoulder neck and hips, permanent muscle fibre damage, rhabdomyolysis, periodic paralysis	Alteration in muscle fibre type in favour of more Type II glycolytic fibres
		Hypo: alters metabolic processes, effects β-adrenergic receptors and catecholamine expression	Severe muscle cramps/spasms/ weakness	Atrophy of fast-twitch Type II fibres and increase in slow-twitch Type I fibres
	Parathyroid/Vitamin D disorders	Both hyperparathyroidism and Vitamin D intoxication cause desensitization of calcium-regulated proteins (e.g. troponin).	Muscle fatigue	Elevated calcium levels

Table 3 (*continued*)

Type of myopathy	Cause	Mechanism	Signs and symptoms	Clinical and diagnostic findings
		Both hypoparathyroidism and Vitamin D deficiency prevent efficient calcium reabsorption (hypocalcaemia). Effects calcium-regulated neurotransmission and muscle contraction	Muscle cramps and tetany, pain and tingling in the face, legs, hands and feet	Low serum calcium levels
	Pituitary (acromegaly)	Excessive production of growth hormones altering gene expression and resulting in skeletal muscle hypertrophy	Rhabdomyolysis	Hypertrophy of both Type I and Type II fibres; mild increase in CK levels, vacuolization within fibres, elevated NO levels
Other	Acetylcholinesterase inhibitors	Causes hyperstimulation and increased activity of individual fibres resulting in the rapid consumption of ATP stores and excess calcium leading to aberrant signalling, protein degradation and induction of apoptosis	Involuntary fasciculation, muscle weakness, myalgia, rhabdomyolysis	Increase in CK levels, decrease in cellular ATP levels, mitochondrial swelling, sarcomeric supercontraction, vacuolization, Z-band fragmentation
	Emetine	Induces apoptosis	Severe muscle atrophy/ weakness, decrease in muscle weight and contraction strength, rhabdomyolysis	Atrophy of Type II fibres, decrease in myofibrillar ATPase and NADH tetrazolium in all three fibres; occasional necrotic fibres, mitochondrial degeneration, vacuolization, sarcoplasmic abnormalities, increased autophagy and lysosomal activity
	Food poisoning: quail (hemlock poisoning), fish (Haff disease)	Unclear	Rhabdomyolysis, acute renal failure	Myoglobinuria
	Focal	Chronic intramuscular injections	Muscle pain, abscess formation, rhabdomyolysis	Focal necrosis. Mild elevation in CK Levels

toxin and mechanism of poisoning from these fish are still uncertain, other fish- borne illnesses are thought to be due to the fish's ingestion of ciguatoxin, a toxin emitted by coral reefs (Gillespie *et al*., 1986; Stommel *et al*. 1991). Similarly, consumption of quail has also led to cases of rhabdomyolysis and myoglobinuria, but similar to Haff disease, the origin of the myotoxic compounds is dietary. European migratory quail which reside primarily in Mediterranean countries feed on seeds from the hemlock plant (*Conium maculatum*). Hemlock plants contain the neurotoxin coniine. When consumed by humans and some livestock this can cause a breakdown of the PNS and is frequently associated with rhabdomyolysis and ARF (Rizzi *et al*., 1991; Papadimitriou *et al*., 1996).

5.11.2 Opiates

Derived from the opium poppy (*Papaver somniferum*), opiates include all the alkaloid narcotics morphine, codeine, thebaine and papaverine, as well as synthetic derivatives heroin and hydrocodone that elicit their main effects from the central nervous system (Aggrawal, 1995). Morphine and codeine are often utilized for medical/anaesthetic purposes, but are still considered highly addictive and lethal. The semisynthetic opiate, heroin, derived from morphine, due to its abuse as a recreational drug is often linked with the more severe opiate-induced side effects (Aggrawal, 1995). Heroin is typically taken intravenously, and the medical problems are typically more neurological in nature; however there have been rare cases of heroin-induced myopathies such as rhabdomyolysis and compartment syndrome followed by renal failure (Vitris *et al*., 1991; Sahni *et al*., 2008). Heroin-associated myopathies have also been described when users inject the drug intramuscularly, however it is still unclear whether muscle damage arises from general focal myopathy or the toxic effects of the adulterants in the injection solution (Weber *et al*., 2000). Studies have shown that injection of pure heroin into the soleus muscle of rats causes myopathic changes and necrosis (Pena *et al*., 1990; 1993).

5.12 Endocrine Myopathies

5.12.1 Hypothyroidism

Hypothyroidism involves the deficiency of circulating levels of thyroid hormone, and is most often caused by the loss of TH synthesis secondary to iodine deficiency. Like the over-production of thyroid hormone, the lack of TH can also result in myopathic symptoms (Martin *et al*., 1994; Kisakol *et al*., 2003). However, TH deficiencies affect muscles differently from hyperthyroidism. Patients often experience severe muscle cramps and spasms secondary to fibre type switching. Hypothyroidism can lead to atrophy of fast-twitch fibres and increased expression of slow-twitch fibres (Modi, 2000). TH deficiency leads to decreased expression of β adrenergic receptors and levels of neurotransmitter catecholamines (adrenaline), and these events can contribute to muscle weakness (Monzani *et al*., 1997). Treatment of hypothyroidism with levothyroxine generally leads to complete cessation of myopathic events, and full recovery.

5.12.2 Vitamin D Intoxication

Vitamin D is a prohormone produced in the skin upon exposure to sunlight. It is converted to its active form, calcitriol within the liver and kidneys and binds the vitamin D receptor (VDR) (Jones *et al*., 1998). When activated, VDR acts as a transcription factor that up-regulates the expression of transport proteins such as TRPV6 and calbindin, which promote the reabsorption of calcium within the intestines (Bouillon *et al*., 2008). Vitamin D intoxication is rare; only excessive exposure to certain rodenticides has been demonstrated to induce vitamin D toxicity. Vitamin D intoxication does not directly target muscle tissue, but can sometimes lead to myopathic symptoms secondary to changes in circulating calcium levels (Vieth, 1990).

5.12.3 Hypoparathyroidism

Hypoparathyroidism occurs when the parathyroid glands are lost due to autoimmune disorders or surgical removal. The reduction in parathyroid hormone (PTH) leads to hypocalcaemia, a potentially lethal condition characterized by low circulating levels of calcium. Myopathic symptoms are common, and include muscle cramps and tetany. Other symptoms such as pain and tingling in the face, legs, hands and feet are due to a combination of neuropathy and myopathy linked to both calcium-regulated neurotransmission at neuromuscular junctions, and calcium-regulated muscle contraction (Yamaguchi *et al*., 1987; Barber *et al*., 2001). Intravenous calcium is typically administered in severe cases. Vitamin D_3 supplementation, as well as the synthetic PTH drug, teriparatide can be used to treat hypoparathyroidism.

Table 3 summarizes rhabdomyolytic agents and provides details on the mechanism of action, clinical presentation and diagnostic findings for each.

Cartilage and Bone as Target Tissues for Toxic Materials

Alan B.G. Lansdown

CONTENTS

1 INTRODUCTION

Cartilage and bone are not commonly regarded as sites of toxic action by environmental chemicals, food additives or drugs. They develop from anlages in the primitive mesenchyme to become highly organized and complex tissues providing a structural framework for the body, and functional rigidity with attachments for musculoskeletal action. In their developmental state and in adulthood, both tissues are metabolically active and subject to age-related structural variations determined by genetically regulated patterns of mitosis and differentiation, hormonal action and nutrition (Urist *et al*., 1968; Dunnill *et al*., 1967). Developmental profiles involving programmed sequences of cell proliferation, migration and functional differentiation are subject to natural cell loss (apoptosis) and numerous biochemical changes, with each event being potentially vulnerable to chemical or physical insults (Exton-Smith *et al*., 1969). For the toxicologist, it is essential that cartilage, and more importantly bone, should not be considered in isolation, but as integral parts of the body with key roles in mineral homeostasis.

Cartilage and bone are specialized connective tissues composed of cells (chondrocytes and osteocytes respectively) embedded in intercellular matrices permeated by a network of collagen fibres (Jackson, 1970; Williams and Warwick, 1980; Davies, 1998). The two tissues become anatomically and functionally distinct and differ greatly in their cytological profiles, physical properties, vascularization, growth, and regeneration patterns following injury. Whereas cartilage predominates in early stages of skeletogenesis in all mammals, much of this chondroskeleton becomes ossified with advancing age to be replaced by bone (Owen, 1970). Intrinsic factors, physiological changes or toxicological interventions at this stage may lead to aberrations in growth and functional capacity in later development (Pappas, 1968). In adulthood, residual cartilage persists in the articular surfaces of long bones, intervertebral discs, costal regions, nasal cartilages, the xiphoid protuberance of the sternum, larynx and trachea, and certain elements of the skull. These tissues become specialized to fulfil functional roles: hyaline cartilage, white collagen-rich fibrocartilage and yellow elastic fibrocartilage are recognized. To an anatomist, white fibrocartilage and yellow fibrocartilage

are more specific, distinct and stable than hyaline cartilage which is subject to wide variations in composition and age-related changes (Williams and Warwick, 1980).

Cartilaginous elements in the axial (vertebral) and appendicular skeletal regions of the early skeleton are largely ossified and replaced by bone as maturation progresses. The modulation of this process is not fully appreciated but can be expected to involve hormonal changes, up-regulation of cytokines and growth factors and genetically programmed sequences involving apoptosis and cell death. Multinucleate osteoclast cells of reticuloendothelial origin are central to this process and in regulation of mineral homeostasis. Osteoclasts found in close association with bony surfaces are characterized by numerous lysosomal inclusions with an array of hydrolytic and proteolytic enzymes including acid phosphatase and cathepsin D involved in cartilage breakdown and in the remodelling of articular and other cartilages, and regulation of mineral homeostasis later in life (Weston *et al*., 1969). Impairment of lysosomal physiology or inactivation of lysosomal hydrolases by pathological or toxicological influences is a potential cause for teratogenesis and skeletal abnormality (Beck and Lloyd, 1963). Muscular action and movement is critical in developmental stages of articular cartilages, such that agents evoking musculoskeletal or neuromuscular paralysis at critical phases in prenatal development impair specialization and subsequent joint development (Drachman and Sokoloff, 1966). Cartilages in the larynx and trachea should be included in the present discussion under hyaline cartilage, but other than age-related metastatic mineralization, these tissues are rarely implicated as sites for toxic action.

Bones of the axial and appendicular skeletons preformed in cartilage are correctly termed 'endochondrial' bones to distinguish them from certain elements of the vault of the skull (e.g. frontal, parietal, occipital bones) which develop from osteoblasts differentiating as mesenchymal condensations in the suprachondral regions of the primitive chondrocranium. These 'membrane' bones ossify and anastomose, ultimately replacing the cartilaginous elements of the chondrocranium. This means that in skull development, any hereditary or toxic influence acting to deform the chondrocranium or impair the osteogenesis or movement of the membrane bones will have an adverse effect on skull development, resulting in such conditions as craniorachischisis, exencephaly, anencephaly and persistent fontanelles (Kokich *et al*., 1982).

Correctly, dentine in teeth is included in a discussion of the toxic effects of xenobiotic agents in bone. Dentine resembles bone in its mineral content (up to 70% calcium hydroxyapatite by weight), but it is structurally different and mechanisms controlling its morphogenesis are distinct (Fitzgerald, 1969). Dentine is more stable than compact bone and resistant to toxic change (Moss, 1968), but theoretically any toxic material impairing collagen or hydroxyapatite biosynthesis in early odontoblast differentiation is a potential cause for abnormal tooth development and dental decay (Rogers, 1967). Dentine is vulnerable to certain bone-seeking ions like cadmium and strontium which interact with and displace calcium from the hydroxyapatite matrix.

Mineral nutrition and hormonal regulation are of fundamental importance in the early development and functional maturation in cartilage and bone. Structural development in the mammalian skeleton is a function of genetical factors, maternal nutrition and health, and conditions in the microenvironment (pO_2, temperature, pressure, etc.). Additionally, cation and anion balances (notably calcium : phosphate ratios) are highly relevant in developing bone, ossification, maintenance of functional rigidity, and repair following injury. Ionic balances between calcium and zinc, magnesium and calcium, and magnesium and iron are relevant in tissue function (Lansdown, 1995). Nutrition is an imprecise science and cellular demands for vitamins, fats, carbohydrates, amino acids (proteins), minerals and electrolytes differ greatly according to the age, sex and state of health of an individual. Inherent metabolic inhibitors or toxic factors impairing the availability of key nutrients are potential causes for deformity in cartilage, bone and other tissues (Rao and Knapka, 1998; Ionnides, 1998). Accumulating biochemical evidence points to the role of metal ion carrier proteins including metallothionein, calmodulin and caeruloplasmin in the metabolism and regulation of mineral elements in the mammalian body and their transport to target tissues following gastrointestinal absorption (Lansdown, 2002a; 2002b; Lansdown *et al*., 2007). The bivalent metal ions are highly inter-reactive in metabolic systems, and excess of one ion is liable to impair availability of another through competitive ionic binding at carrier protein or cell membrane receptors.

Toxicological studies conducted as a mandatory part of most safety evaluation programmes commonly use rodent species as predictive models. Although the biology, physiology and pathology of the rat differ greatly from the human, its predictive value for agents liable to be hazardous in humans is recognized (Rhodes, 1999). It is noteworthy that whereas the human skeleton develops to maturity and is then subject only to normal homeostatic events related to mineral metabolism, the rat skeleton continues to grow throughout most of an animal's life and is appreciably more sensitive to hormonal changes, or pathophysiological responses to idiopathic or toxic agents. Active osteogenesis persists in the metaphyseal growth plates of major long bones until about 12 months of age (or 30–50% of expected lifespan) according to strain and nutritional sufficiency. Nevertheless, a large proportion of current knowledge on cartilage and bone physiology has been derived from experimental studies in the rat, and the rat has been the choice species in unravelling the complexities of toxic action in these tissues.

2 DEVELOPMENT, STRUCTURE AND FUNCTION

2.1 Prenatal Growth

Cartilage and bone in the mammalian skeleton have a common origin in the mesenchyme of the early embryo (Owen, 1970; Hall, 1970). From early studies by Maximow, Maureen Owen (1970) proposed the paradigm of a small pool of pluripotent cells emerging in primitive mesenchyme with a capacity to differentiate along predetermined pathways (**Figure 1**). Under the influence of ill-defined indigenous factors, these 'stem cells' give rise to all connective tissues, including chondroblastic and osteoblastic progenitor cell lines which undergo defined differentiation patterns.

Growth factors are variously implicated as 'messengers' in tissue proliferation, and repair. Recombinant DNA technology has allowed isolation of these peptides in a pure form, thereby permitting analysis of amino acid sequences, appreciation of their specific action in undifferentiated tissue, and their modulation of morphogenic sequences in regeneration and repair (Roberts *et al*., 1990). Further, whilst major macromolecules synthesized in early primordia of both cartilage and bone are possibly similar, the relative concentrations of glycosaminoglycans, water and other constituents vary greatly as tissues develop under the influence of different and specific control mechanisms and the nature of the surrounding 'medium' (Urist *et al*., 1968; Jackson, 1970). As tissues age, so their sensitivity to growth factors and intrinsic regulators change. Whilst negative-feedback mechanisms and growth factors are widely implicated in the normal homeostasis in the skin and epithelial tissues and their responses to injury, their contribution in skeleton genesis is entirely speculative (Scarano and Augusti-Tocco, 1967).

The cartilaginous phase in endochondrial bone development provides a template for subsequent ossification patterns and the ultimate configuration of limb bones, ribs, vertebrae and some bones of the skull. Development in endochondrial bones is viewed as a progressive and overlapping three step sequence involving:

1. Chondrogenesis—involving differentiation of chondroblasts, initial synthesis of cartilage matrix and collagen fibres.
2. Maturation and hypertrophy of cartilage, differentiation of a perichondral sheath, infiltration of osteoclasts (chondroclasts) leading to cartilage breakdown, differentiation of osteoblasts in association with vascular tissue.
3. Maturation of osteoblasts, deposition of calcium hydroxyapatite and formation of actively ossifying trabeculate bone. Cartilage becomes eliminated (other than at metaphyseal growth plate zones and at articular surfaces.

Growth profiles in typical endochondrial bones (e.g. tibia or femur) are illustrated in **Figure 2**. From early condensations of chondroblasts in presumptive mid-shaft or diaphyseal zones (**Figure 3**), subsequent growth extends proximally and distally, with the appearance of three cytologically and behaviourally distinct regions:

1. The central or diaphyseal region comprising a cuff of actively ossifying tissue with an advanced degeneration of cartilage, and marrow cavity differentiation.
2. Terminal (proximal and distal) epiphyseal regions composed of mature cartilage permeated by vascular channels with foci of osteoblast infiltration and early mineralization.
3. Metaphyseal growth plate regions separating the diaphyseal and epiphyseal zones of ossification/mineralization (**Figure 4**).

Collagen is an essential feature of growing bone and functional maturation of perichondral and periosteal sheaths, such that inherited, nutritional or toxic defects in collagen fibre crosslinking are a cause of deformity.

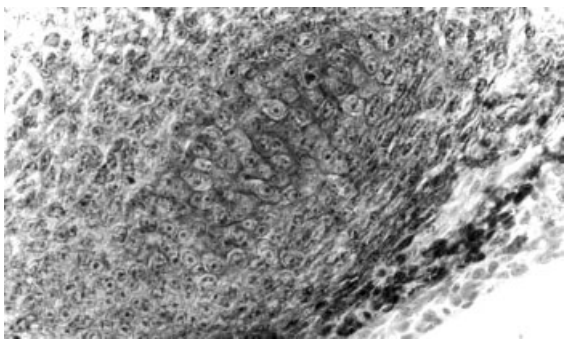

Figure 3 Early development of diaphyseal cartilage of a long bone, with secretion of chondroitin sulfate matrix. Ill defined contours and lack of fibrous perichondral tissues. ×40 objective.

Growth in the diaphyseal cuff becomes robust with increased mineralization on the surface but with further deposition of osteoid and bony trabeculae on internal or endosteal surfaces lining the marrow cavity (**Figure 5**). Ossification in epiphyseal regions is characterized by infiltration by vascular tissues, hypertrophy and lysis of cartilage matrix and fusion of centres of mineralization. The part played by infiltrating vascular tissues in the resorption of cartilage in the appearance of foci of mineralization in epiphyseal regions is controversial. Whilst blood vessels are essential in mineral nutrition at sites of ossification, circumstantial evidence suggests that vascular tissues *per se* may be involved in cartilage degeneration.

Ossification in periosteal and endosteal surfaces of the diaphysis and in epiphyseal regions is active through the latter part of foetal life and persists well into the postnatal period. On the other hand, growth, differentiation and mineralization persist in the metaphyseal plate regions through until adulthood with ossifying cartilage columns remaining vulnerable to wide-ranging physiological and toxic factors (**Figure 6**). This is illustrated by abnormalities in the long bones in young sheep presenting with pathological changes in metaphyseal chondrocytes and bizarre patterns of ossification and mineralization (**Figure 7**) (Duffell *et al*., 1985). The aetiology of these abnormalities is unknown, but irradiation, manganese deficiency and infection may have been implicated. In this case, there was a tendency for the metaphyseal

plate to separate from the epiphyses. The limbs of these animals were dystrophic and the undefined condition was fatal.

Whilst the developmental pattern of membrane bones is well documented, the action or interaction of exogenous or indigenous factors in the differentiation of osteoblasts and tissue modelling is largely unclear. It is tempting to implicate chemotactic gradients, oxygen tensions, cell-to-cell contacts, cytokines and growth factors, all of which are implicated in tissue repair and morphogenesis (Hall, 1967; Owen, 1970; Slavin, 1996; Kingsnorth and Slavin, 1991). Membrane bones of the skull are largely immature at birth. They are separated by mesenchyme, and vulnerable to a wide variety of conditions affecting general growth and movement, mineral balances and deficiencies, and aberrant tissue inter-relationships. In the human baby, closure of the membranous spaces or fontanelles between the major skull bones is incomplete at birth, but continued growth, expansion and ossification of surrounding membrane bones normally leads to full closure within the first year of postnatal life (Ford, 1956). Deformities are commonly documented in teratological studies, particularly where individuals are exposed to deforming agents like hypervitaminosis A in early-to-mid pregnancy (Kalter, 1968). The literature is replete with reports of spontaneous, idiopathic or chemically induced exencephaly, cleft palate and anencephaly, but mechanisms are still equivocal.

2.2 Collagen and Elastic Tissue

Collagens are the most prevalent proteins in animal tissues (Davies, 1998). They are essential components of all connective tissues including bone and cartilage and are obligatory in the normal structure of intercellular matrices (Miller and Gay, 1992). The density and distribution patterns of collagens vary widely throughout the body according to the tissue and its location, age and physiological function (Davies, 1998). Thirteen types of collagen are recognized, of which eight (Types I, II, V, VI, IX, X, XI and XII) are found to a greater or lesser extent in hyaline cartilage and/or bone. The structure and biochemical constitution of at least five of the fibre-forming collagens in bone and other connective tissues have been elucidated, but this information is likely to be valid for all other molecular species of collagens (Grant and Jackson, 1976; Prockop *et al*., 1976; Bailey, 1978; Herring, 1968). The major collagen type in cartilage is collagen II, other collagens, I and III, are typically prevalent in the dermis and vascular tissues, and Type IV in basement membranes (Jackson, 1970). Collagenesis is modulated by growth factors and cytokines and is vulnerable to genetical abnormalities, environmental toxins, and nutritional factors leading to imbalances in the enzyme cofactors copper, ferrous iron and manganese (Bailey, 1978; Phillips and Wenstrup, 1992).

Collagens are extracellular polysaccharide α-chains held in the form of a triple helix by covalent bonds and intermolecular linkages which can be broken by heat or chemical denaturing agents. Proline and lysine residues are hydroxylated in the triple helix domain in defining the final structure of collagen fibres, and assays of either provide suitable assays for collagenesis in normal growth and tissue maturation, as well as markers for metabolic disease and defective repair systems following injury (Firschein, 1967; 1969; Öberg *et al*., 1969). Proline estimation is a suitable marker for changes more associated with mineralization and bone repair (Shtacher and Firschein, 1967). Glycine is present in collagen molecules and is repeated at a one-in-three sequence between constituent amino acids of chain sequences. In rare inherited conditions like osteogenesis imperfecta, where cysteine substitutes for glycine in collagenesis, bones are fragile, collagen chains do not intertwine, and dense packing characteristic of normal bone is absent (Davies, 1998). In normal chondrogenesis, specific proline and lysine residues are hydroxylated by the copper-containing enzymes prolyl oxylase and lysyl oxidase, which also depend upon ferrous iron, ascorbic acid, molecular oxygen and α-ketoglutaric acid as cofactors. Further, glycolysation of hydroxylysine and synthesis of various collagen types require manganese-dependant transferases. These transferases are bound to the rough endoplasmic reticulum, and hydroxylation commences on nascent polysaccharide chains attached to membrane-bound ribosomes. Glycolysation involving galactosyl and glucosyl transferases is a further process integral to collagen formation and maturation.

Elastin is a component of the so-called yellow fibroelastic cartilages of the ear and laryngeal cartilages (Cox and Peacock, 1977). Like collagen, elastin synthesis involves the cupro-enzymes—lysyl oxidase and prolyl oxylase; but according to Partridge (1962; 1966), the reactions in elastin formation are 'more complete'. The histogenesis of elastin is a two-stage process involving an initial deposition of glycoprotein framework followed by impregnation (Bailey, 1978; Davidson *et al*., 1992). Collagen and elastin are vulnerable to copper-deficiency conditions and agents like the lathyrogens (β-aminopropionitrile) which inhibit lysyl and prolyl oxidases (Lenaers *et al*., 1971).

2.3 Dentine

Dentine forming the major component of teeth is a hard, avascular tissue composed largely of crystalline hydroxyapatite, water and calcium phosphates. Human dentine consists of 72–75% inorganic matter, 2% organic (including 0.08% by weight of hexosamine and equivalent amounts of glucosamine and galactosamine) and 5% water (Clark *et al*., 1965; Herring, 1968). Unlike bone, which is subject to remodelling and age-related changes, dentine is a stable structure. Tooth enamel contains a high mineral content (96% hydroxyapatite). Both tissues are robust and resistant to toxic changes except in cases of severe calcium or vitamin D deficiency, abnormal parathyroid function or xenobiotic agents acting to displace calcium or zinc. Although documentation is limited, it is expected that as in bone, the hydroxyapatite moiety in dentine and enamel will bind

bone-seeking metals including lead and the radioactive isotopes of strontium (^{89,90}Sr) (Curzon and Spector, 1980; Johnson *et al*., 1970). The extent to which tooth or enamel provides a reservoir from which toxic metals are released into the circulation is not well documented.

Fluoride is commonly regarded as being important in the health and stability of teeth. Dentifrices containing fluoride are widely marketed as a nutritional supplement for care of teeth and gums (Mellberg and Ripa, 1983; Mason, 2000). The World Health Organization 1994 recognized that use of fluoridated dental cream made a major contribution in the dramatic decline in dental caries in the developing world. Today, the so-called anticavity dentifrices contain fluoride salts at 1000–1500 ppm (Mason, 2000).

2.4 Bone

Bone is a rigid form of connective tissue with a major role in mineral homeostasis in the body. Three principle cell types are found in mature bone—osteoblasts and osteocytes of mesodermal origin, and osteoclasts derived from reticuloendothelial precursors. Osteoblasts are primarily responsible for bone growth, including synthesis of bone matrix, osteoid, and maintenance of bone mass. They differentiate in perichondral, endochondral or intramembranous regions but predominate in metaphyseal plate regions during phases of active bone growth. Osteocytes, on the other hand, are functionally mature bone cells with limited mitotic capacity but some potential to secrete matrix (Marcus, 1987; Osdoby *et al*., 1987). Osteoclasts are rich in hydrolytic enzymes and serve the dual role of resorbing bone and recirculating bone minerals in bone remodelling (Stevenson and Evans, 1981). Osteoblasts are embedded in an organic matrix which is impregnated with 'bone salts' (also referred to as 'lime salts') including calcium, zinc, magnesium, chloride, phosphate, hydroxyl, fluoride, citrate and carbonate, which confer hardness and rigidity (Biltz and Pellegrino, 1969). Bone structure and mineral metabolism is modulated by circulating concentrations of Ca^{2+}, Mg^{2+}, phosphate and vitamin D (D_3), and hormonal interactions involving oestrogens, parathyroid hormone, calcitonins and growth hormone.

A precise knowledge of the normal constituents of bone, their variations with age, sex and racial variation is an important basis for appreciating pathological changes attributable to disease, physiological influences and toxicological action. Mammalian bone is a complex of organic materials, mineral salts and water; wide interspecies variations exist; individual species display certain distinguishing chemical characteristics (Biltz and Pellegrino, 1969). Water is a major constituent of bone and a reciprocal relationship exists between the water content of the tissue and the level of mineralization. Analytical studies have shown that the 'average dry bone' of mammals comprises of 93.75% by weight of organic and inorganic material and 6.25% 'crystalline' water (Biltz and Pellegrino, 1969). Robinson and Elliot (1957; 1958) analysed dog bone and reported 13 volumes per cent of crystalline water, 38% organic and 49% mineral salts. As noted above, collagen fibres are an essential constituent of bone matrix, but unlike some other collagens, bone collagens tend to be more stable in the presence of denaturing agents and are resistant to swelling in the presence of acids, possibly reflecting a higher level of fibrillar crosslinking.

Calcium and phosphate are the principle minerals in normal bone growth and mineralization. Experimental studies in growing rat bone illustrate that Ca : P ratios are critical in the mineralization process, but vary according to the age of the tissue and the metabolic state of osteoblasts (Bernhardt *et al*., 1969). Phosphate levels are higher during the active growth phase, whereas increased calcium is a feature of the mineralization process. Magnesium is an essential element in bone growth and a major constituent of bony tissue, but is well known to interact with and suppress calcium in many systems including gastrointestinal absorption and in metal carrier protein-mediated metabolic processes (Lansdown, 2002a). Clark and Bélanger (1967) demonstrated a complex inter-relationship between magnesium, calcium and phosphate in dietary studies in rats, supporting the view that magnesium modulates calcium homeostasis in bone development. They presented evidence showing that bone is capable of sequestering relatively large amounts of Mg^{2+} and can enhance bone calcium and phosphate balances. Histological studies revealed that animals with the highest calcium phosphate balance and reduced bone ash (i.e. those fed 0.5 or 1.0% magnesium) had abnormal bone structure with pathological changes involving epiphyseal cartilages, diaphyseal osteocytes and matrix indicative of osteolytic change. Since magnesium is a 'surface-limited ion' its increase in bone concentration may be explained largely by absorption to the surface of hydroxyapatite crystals, but some ion is possibly absorbed within the crystal matrix. Ossification and hydroxyapatite synthesis was inhibited in metaphyseal growth plate regions.

Oestrogens are well known causes of increased bone mineral turnover and accelerated trabecular bone loss in women and natural or artificial menopause (Fentiman *et al*., 1989). The anti-oestrogenic therapeutic, tamoxiphen, prescribed for treating advanced breast cancer, is without significant effect in bone density or calcium balance (Fentiman *et al*., 1989). Calcitonin (thyrocalcitonin), a hormone secreted by C cells of the thyroid, acts to protect mature bone against resorption and has a major therapeutic role in treating human conditions

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat071
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

including Paget's disease, osteoporosis and other disorders of calcium metabolism (Hosking, 1985; De Deuxchaisnes, 1983). Oestrogens possibly exert a protective influence against lathyrogenic agents, which, as discussed below, impair collagenesis and elastic tissue formation and are a cause of skeletal abnormalities, but the mechanisms are unclear (Simmons *et al*., 1965; Berntsen, 1968).

The structure and chemical composition of bone matrix in mammals and birds has been subject to extensive electron-microscopic, microchemical and *in vitro* analysis in the past 40 years (Moss, 1968; Herring, 1968). Bowness (1968) reviewed the role of ground substance in mineralization and proposed a conjectural model stressing the importance of mucopolysaccharides as inducers and modulators for calcium deposition. Although chondroitin sulfate inhibited mineralization in preosseous cartilage, his experiments demonstrated a rapid increase in synthesis of sulfated mucopolysaccharides and mucoprotein macromolecules in the vicinity of areas of active endochondrial calcification (and possibly other calcifying areas). These intercellular polysaccharide–protein complexes possibly provide a medium for the preferential accumulation of calcium in relation to sodium, potassium and magnesium; even so they retain a relatively low level of phosphate. Phosphate accumulates more in fibrous tissue compartments of the intercellular space and in cellular compartments in the form of organic and inorganic salts. Early evidence suggests that calcium accumulates in preosseous cartilage possibly as a preliminary to mineralization (Bonucci, 1969; Herring, 1970). Whilst differences exist in the structure and chemical composition of bone according to age, sex, nutrition and health status within a species, the observations are compatible with and reveal a structural complex involving glycoproteins, acidic lipids, peptides with a potential role in nucleation, and ion transport in active mineralization (Herring, 1970).

X-ray diffraction and ultrastructural studies show that the amorphous and crystalline mineral salts of mature bone contain calcium hydroxyapatite $Ca_5(PO_4)_3OH$ (or more commonly shown as two molecules $Ca_{10}(PO_4)_6(OH)_2$ as the largest single component). Taylor *et al*. (2000) have used inelastic neutron scattering (INS) spectroscopy to determine the complex molecular structure of calcium hydroxyapatite. INS is especially sensitive to 'vibrations of groups with hydrogen' to resolve the substitutions at the hydroxyl group site in bone, and the authors have shown that the extracellular matrix of bone comprises largely calcium hydroxyapatite as an extracellular protein, but emphasize that the composition of this mineral is controversial. In their conjectural model, the hydroxyapatite crystal viewed in the a–b plane and observed along the c-axis shows hydroxyl moieties lying in a channel formed by calcium ions at the intersection of four unit cells; Taylor *et al*. (2000) discussed the capacity of carbonate ions to substitute hydroxyl groups which, in ox bone at least, occurs at a rate of approximately 60%. Importantly, these authors point out that the sensitivity of the INS technique opens up new possibilities in monitoring changes in the composition of bone due to ageing and pathological conditions (including osteoporosis), presumably including those attributable to binding of xenobiotic ions like lead, aluminium and ^{89,90}strontium.

Calcium hydroxyapatite has been subjected to numerous biochemical studies, and the ability of organic diphosphates, fructose biphosphate, pyrophosphate, imidodiphosphate and 3-phosphoglycerate to inhibit the conversion of amorphous calcium phosphate into the apatite complex has been extensively examined, and putative mechanisms of action evaluated (Fleisch *et al*., 1969; Williams and Sallis, 1979). These chemical studies suggest that strong inhibitors require at least one phosphate group and another acidic group (phosphate or carboxylic acid group) at some other position. Phosphonoformate and phosphocitrate were thus shown to be powerful inhibitors of calcium hydroxyapatite synthesis, probably through their profound ability to chelate Ca^{2+}.

Calcium hydroxyapatite crystals in normal human bone are needle-like, with their long axes lying parallel to fibres of the collagen network, but the precise relationship between the two is unclear. Uncertainty exists also regarding the positioning and interaction of chloride, citrate, carbonate and fluoride ions in normal bone and their availability to bind xenobiotic ions like lead, radium and other 'bone-seeking cations'. The role of strontium in human nutrition and bone development and physiology and development is equivocal, but its capacity to interact with and displace calcium in skeletal tissues is well documented (Lansdown *et al*., 1972; Sutton *et al*., 1970; Colvin *et al*., 1972).

3 NUTRITIONAL ASPECTS OF SKELETAL DEVELOPMENT

Cartilage and bone develop through prenatal and postnatal life in keeping with the growth and maturation of the body, with differentiation patterns subject to interaction between genetical factors, hormones and nutritional factors (Underwood and Mertz, 1987; National Research Council, 1995). In each case, histological profiles and chemical composition of the tissues are consistent with age, sex, hormonal status, and the overall state of health and nutrition of the body (Visco *et al*., 1991; Dunnill *et al*., 1967). Radioisotope studies using L-phenylalanine, L-leucine, ^{35}S-labelled chondroitin sulfate and ^{75}Se-salts have variously been employed in experimental and *in vitro* studies to monitor growth and patterns of mucopolysaccharide, mucoprotein and protein synthesis. They serve as a measure of growth rates under normal and

DOI: 10.1002/9780470744307.gat071
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

pathological (toxic) conditions (Campo *et al*., 1967). With advancing skeletal maturity, bone consolidates to achieve a more compact structure with metabolically active regions persisting in the highly vascular periosteal and endosteal regions where osteoblasts and osteoclasts regulate mineral accumulation and mobilization. ^{14}C-proline and ^{48}Calcium are available as indicators of collagen formation and bone metabolism respectively (Firschein and Miller, 1966).

Many toxic materials or clinical situations capable of influencing growth patterns in cartilage or bone in perinatal or postnatal development act through impairing the availability of essential nutrients (notably minerals) or by inhibiting essential biosynthetic events through impairment of enzyme systems, particularly those like lysyl oxidase which depend on metal cofactors (Kagan and Li, 2003; Kosonen *et al*., 1997). Whilst nutritional requirements and recommendations are published for humans and some experimental species, variations reflect the date of the study and current opinion. Nutritional factors as potential causes of impaired growth and development in cartilage and bone are summarized as follows:

- general and severe malnutrition (e.g. kwashiorkor, marasmus, major protein-energy insufficiency)
- deficiency in one or more key nutrients (e.g. calcium, zinc, copper)
- nutrient imbalances (excess of one nutrient inhibits essential metabolic events dependant upon others)
- dietary materials with minimal or dubious nutrient value which impair uptake and metabolism of key nutrients.

Nutritional requirements vary according to the developmental state of the tissue and biosynthetic events in progress at the time (**Table 1**). Calcium, zinc, magnesium, vitamin A and phosphate have a major role in bone structure and function throughout life, whereas silicon, sulphur-containing amino acids and micronutrients are of greater importance in early active growth phases and in differentiation (Food and Drug Administration, 1997; Carlisle, (1982; 1988); Lansdown and Williams, 2007). In each case, recognised nutrients fulfil Underwood's (1977) criteria, namely that each is necessary for one or more key physiological or biochemical events in development and maintenance of structure and function.

Whereas defects in growth resulting from nutrient deficiencies in adulthood can in many cases be rectified by dietary correction or hormonal supplementation (Talmage, 1969; Stevenson and Evans, 1981), defects involving impaired mineral metabolism occurring in prenatal and postnatal growth are unlikely to be corrected by nutrient supplementation later in life. Minerals like calcium, zinc, magnesium and phosphate exist in bone in stable or structural forms or as labile moieties from which they may be mobilized to compensate for mineral deficiencies in other tissues through parathyroid action (Talmage, 1969).

3.1 Proteins and Amino Acids

Protein-calorie malnutrition presents major public health problems in many technically underdeveloped parts of the world, and conditions of marasmus and kwashiorkor are well documented. When general malnutrition or undernutrition is imposed during pregnancy, protein becomes a limiting nutrient, implying that close similarities exist between the effects of malnutrition and protein deficiency states (Hurley, 1977). Severe long-term deficiencies are common causes of fatality, whereas lesser levels of chronic protein or key amino acid deprivation are more likely to evoke growth retardation and defects in the maturation and function of tissues developing at the time (Apgar and Everett, 1991). The brain is particularly susceptible to malnutrition and nutrient deficiencies. Numerous studies are available discussing the complications of marasmus as a clinical cause of muscular wasting, and retardation in postnatal growth and development (Scrimshaw, 1974; Scrimshaw and Behar, 1961).

The role of chronic protein deficiency in the aetiology and pathogenesis of kwashiorkor-related conditions is incompletely characterized, and animal models are not entirely satisfactory in researching the biochemical changes of severe protein deficiency in children (Scrimshaw and Young, 1976). Enwonwu and Sreenby (1970) studied biochemical changes in rats fed low dietary protein (0.5%) for up to 12 weeks and demonstrated body weight loss, subcutaneous oedema, fatty liver and atrophy in spleen and pancreas similar to that seen in kwashiorkor children. Serum analyses showed significant depression in levels of essential and nonessential amino acids, including those with key roles in cartilage and bone growth, but no skeletal abnormalities were reported. The absorptive properties of the intestinal mucosa are initially increased to accommodate dietary protein deprivation, but later there was an onset of body weight loss, degenerative changes and atrophy (Worthington and Boatman, 1974). Guinea pigs which were considered to be a good representation of malnourished children, also showed severe growth retardation without involvement of skeletal tissues following low protein diets for three to four weeks (Enwonwu, 1973). In contrast, when pregnant mice were infected with a pancreatotropic strain of *Coxsackie virus B*, severe exocrine pancreatic insufficiency lead to impaired dietary protein utilization; offspring were severely growth retarded and exhibited skeletal malformations and abnormal ossification patterns (Lansdown, (1976a; 1976b)).

Table 1 Major nutrients in growth and development of mammalian bone and cartilage

Nutrient	Biological function	Deficiency	Excess
Vitamin A	Mucopolysaccharide synthesis	Cartilaginous deformity, impaired ossification	Cleft palate, multiple skeletal deformities
Vitamin C	Maintains intercellular matrices in cartilage, bone and teeth; modulates mineral absorption and metabolism; collagen synthesis	Degenerative changes in tissues, mineral deficiency	—
Vitamin D (D_3)	Modulates growth and mineral content of bone, promotes calcium uptake and metabolism	Defects in mineralization in bone and teeth	—
Calcium	Bone cartilage growth and structural integrity	Defects in mineralization and skeletal rigidity, osteoporosis	Hypercalcaemia, metastatic mineralization in soft tissues
Zinc	Mitotic activity, enzyme cofactor	Impaired growth and survival	Minimal
Copper	Mitotic activity, crosslinking in collagenesis and elastic tissue formation	Impaired growth and structural deformities linked to collagen disorder	Neurological abnormalities and muscular pathology
Magnesium	Enzyme cofactor, mitochondrial function, calcium metabolism	Increased mineralization, impaired growth	Mineral imbalance
Iron	Enzyme cofactor, mineral absorption, oxygen/energy metabolism	Impaired growth and survival	Mineral imbalance
Manganese	Enzyme cofactor in cartilage development	—	—
Silicon	Collagenesis, glycosaminoglycan synthesis in matrices	Structural weakness	Not known
Phosphate	Growth and maturation in cartilage, mineralization in bone and teeth	Impaired skeletal growth and structural weakness	—
Sulfate	Mucopolysaccharide synthesis in cartilage and bone matrices	Impaired skeletal growth, defects in ossification	—
Chloride	Mineralization	Mineralization defects	—
Fluoride	Bind to hydroxyapatite, stabilizes bone structure and strength	Reduced bone and tooth resistance to degeneration	—
Protein/amino acid	General growth and development in all tissues of cartilage, bone and teeth	Stunting and delayed growth	—
Oxygen	Mineralization	Reduced bone structure	—

Numerous clinical reports illustrate how protein and/or calorie insufficiency leads to structural defects in ossifying elements of the skull and appendicular skeleton in human babies. Impaired collagen synthesis is a frequent complication (Frandson *et al*., 1954; Reddy *et al*., 1972; Krishnamachari and Iyengar, 1975). Frequently, damage induced in late prenatal or early postnatal stages is irreversible and catch-up growth does not occur even when protein-sufficient diets with growth hormone supplement are provided (Toews and Lee, 1975). On occasions, protein insufficiency may not be the principle cause of skeletal abnormality, but human babies exposed to malnutrition or other forms of growth retardation *in utero* fail to achieve catch-up growth in prenatal life even where nutrient levels are optimal (Dickerson and Hughes, 1972).

Herring (1968) discusses in detail the chemical composition of cartilage, dentine and bone matrix, with specific reference to collagen, protein-polysaccharides, glycoproteins, lipids and peptides. Analysis of the fibrillar structure of collagen and the amino acid composition of tropo-collagen chains and the intermolecular and intramolecular crosslinking has enabled a clearer vision of the amino acid sequences and their relative importance in molecular stability and physiological significance. Protein-polysaccharides of bone and

Table 2 Variations in amino acid composition of galactosaminoglycan and mucoproteins of bovine scapular cartilage (residues per 1000)

Amino acid	Resting cartilage	Transforming zone	Ossifying zone
Cysteic acid	11.8	14.2	9.8
Aspartic acid	94.7	82.6	92.0
Threonine	47.3	42.7	46.0
Serine	47.3	51.3	49.1
Glutamic acid	124.2	136.7	113.5
Proline	100.6	82.6	73.6
Glycine	112.4	125.3	14.3
Alanine	112.4	114.0	17.4
Valine	65.1	68.4	79.8
Isoleucine	35.1	37.0	39.9
Leucine	71.0	74.1	89.0
Phenylalanine	29.6	28.5	39.9
Lysine	35.5	42.7	61.3
Histidine	59.2	59.8	55.2
Arginine	53.3	39.9	39.9

From Lindenbaum and Kuettner (1967).

cartilage are deemed to be highly heterogeneous with regard to the protein : polysaccharide ratios. Interest is also shown in the role of glycoproteins in bone and connective tissue development, and in Herring's (1968) opinion, concentrations are much higher than at one time thought. Further, amino acid concentrations of protein-polysaccharide complexes differ in cartilage according to its level of proliferative activity or onset of ossification (**Table 2**). Sulphur-containing cysteine is relevant in mucopolysaccharide synthesis and production of cartilage and bone matrix (Simmons, 1968). Experimentally, uptake of ^{35}S in murine long bone provided an accurate assessment of growth and mucopolysaccharide synthesis and revealed daily rhythms. It is also clear that deficiency in key amino acids can be as damaging as more generalized patterns of protein deficiency (Zamenhof *et al*., 1974; Hurley, 1977).

The relative importance of individual amino acids in cartilage and bone development has been examined in experimental studies with diets lacking lysine, proline, and so on (Hurley, 1977). Experimental studies have commonly demonstrated that deficiency in one or more key amino acids at vulnerable stages in development is a cause of severe growth retardation and decreased viability, without obvious effects on skeletal development. However, administration of the specific leucine antagonist—hypoglycine A—to pregnant rats did lead to syndactyly, and defects in skull ossification (Persaud and Kaplan, 1970). Ethionine is an antagonist for methionine, and prenatal exposures lead to a marked reduction in general body development and bone growth (Lee *et al*., 1955). On the other hand, excesses in single amino acids can be detrimental to foetal development; mostly the effects are manifest in terms of retarded growth and reduced foetal survival, with skeletal abnormalities reflecting growth retardation rather than actual pathological changes in chondrogenesis or ossification.

3.2 Vitamins

Excesses and deficiencies of vitamins A, C and D, niacin, folic acid and riboflavin are well-documented causes of structural deformities and pathological changes in prenatal or postnatal skeletal growth. Teratological studies illustrate how specific inhibitors including 6-aminonicotinamide, galactoflavin, α-methylpteroylglutamate and 5-bromo-2-deoxyuridine impair prenatal growth and viability, with reduction in skeletal ossification and abnormal skeletal patterns. Deficiencies in key vitamins or administration of specific vitamin inhibitors in experimental studies have commonly been related to a generalized pattern of deformities including cleft palate, defective ossification in the vault of the skull, micrognathia and impaired ossification in long bones (Chamberlain and Nelson, 1963; Hurley, 1977).

Vitamin A (retinol/retinoic acid) is an essential nutrient in all higher animals and correct levels are critical in normal epithelial cell growth and foetal development (Kalter, 1968; Maden, 1998). It is an example of an essential nutrient which is teratogenic if present at suboptimal or supraoptimal concentrations. In developing and adult mammals, vitamin A analogues interact with nuclear receptors including steroid and thyroid hormone receptors. These vitamin A receptors are involved in up-regulating gene transcription factors including genes modulating cell growth and differentiation in prenatal growth. Excess vitamin A affects mesenchymal tissue

specifically and has variously been associated with abnormalities in cell proliferation, cell migration and differentiation leading to chondrodystrophies in cephalic and axial bones with manifestations of craniorachischisis, anencephaly and spina bifida (Marin-Padilla, 1966; Kochhar, 1968; Morriss and Steele, 1974). Cellular shrinkage and oedema formation were observed. The ossifying elements of the skull appear to be particularly vulnerable to injury (Cohlen, 1953; Masi *et al*., 1966; Giraud, 1968; Kalter, 1968; Morriss, 1972). Excesses of vitamin A and related retinoids led to degenerative changes through their action in labilizing lysosomal enzymes (notably hydrolases and phosphatases) in developing tissues (Goodman *et al*., 1974).

Research on retinoids has thrown light on their action in remodelling of bone, including an activation of osteoid resorption through enhanced osteoclastic activity leading to metastatic mineralization (Cunliffe and Miller, 1984). Turton *et al*. (1985) demonstrated that bone exposed to retinoid compounds exhibited greater radiolucency and showed a reduction in diaphyseal width and increased tendency to fracture. Histological sections revealed increased osteoclastic activity, reduced osteoid in mid-shaft regions, but increased mineral deposition in endosteal regions and in zones of ossification in hyperplastic chondrocyte columns of the metaphysic (Teelmann, 1989). Other changes including osteocytosis, hyperostosis and ossifying spondylitis have been recorded in response to retinoid toxicity (Clark, 1970; Cho *et al*., 1975; Mahtle and Berger, 1982).

Vitamin D (or its metabolically active form, D_3), 1,25-dihydroxycholecalciferol, exhibits a major role in the uptake and mobilization of calcium and phosphate in bone and other tissues (Ornoy *et al*., 1968; 1969; Talmage, 1969). It may function as a trophic hormone in calcium uptake by up-regulating the genetically determined calcium-binding proteins, calcium channels, membrane receptor sites and cell membrane permeability to the trace metals zinc, magnesium and iron, all of which are known to interact with calcium-binding receptors (Friedlander *et al*., 1977; Cole *et al*., 1999; Lansdown, 2002a). Calcium uptake in the intestine is a relatively inefficient process in which only about 30% reaches the systemic circulation. In normal individuals, calcium absorption is proportional to 'available calcium' in the circulation and free binding sites on the calcium-binding proteins (calbindin, calmodulin, S-100 proteins, etc.). Vitamin D_3 controls the reversible calcium–calbindin complex and transfer of Ca^{2+} to the Ca^{2+}-Mg^{2+}-ATPase pump for transfer to the peripheral circulation. Vitamin D_3 may mimic the action of parathyroid hormone in regulating extracellular calcium through calcium-sensing receptors (CaSRs) and act synergistically with it (Goldhaber, 1963). Mutations in CaSR genes are implicated in familial hypercalcaemia and hypocalcaemia. Either condition is a potential cause for abnormalities in cartilage and bone formation. Thus hypocalcaemia resulting from low vitamin levels is a cause of rickets in children and retarded bone growth affecting long bones, skull bones and costal cartilages and bone (Sevastikoglou *et al*., 1970). Hypophosphataemia is additionally a cause of impaired mineralization and pathological changes in regions of active bone/cartilage growth. Tooth formation and structure is at risk of demineralization (Rosen *et al*., 1974). The influence of vitamin D_3 on parathyroid hormone secretion is equivocal, but activation of enzymes including alkaline phosphatase and citrate metabolism may be involved (Sevastikoglou *et al*., 1970). High levels of systemic vitamin D or D_3 are toxic and may lead to demineralization of bone and the withdrawal of 'lime salts' (Carlsson, 1952). Additionally, hypervitaminosis D accentuates magnesium uptake (Ornoy *et al*., 1968). Calcitonin suppresses calcium mobilization from bone in cases of hypervitaminosis D or parathyroid hormone and is a recognized therapy for Padget's disease characterized by an up-regulation of osteoclasts and accelerated bone resorption (Siris *et al*., 1980).

Vitamin C (ascorbate) may not exert a direct influence on the development or physiological function of cartilage or bone, but is necessary for the intestinal absorption of several trace metal nutrients upon which those tissues depend. Thus, iron uptake relies on adequate dietary sources of vitamin C, and in cases of hypovitaminosis, resulting anaemias are associated with indolent skin wounds, impaired carriage and metabolism of oxygen radicals, impaired mitochondrial respiration in growing and repairing tissues, dyscollagenesis and wide-ranging conditions reflecting oxygen deficiency (Lansdown, 2001).

3.3 Minerals

Underwood (1977) identified at least 21 minerals as trace elements and essential nutrients in the mammalian body. Most exhibit a role in the structural integrity or physiological function of cartilage and bone, and deficiency symptoms are documented. With the exception of calcium and phosphate, minimal effective concentrations for normal healthy tissue at any age are normally low, but may vary according to the age, the developmental state of the tissues and the state of health of the individual. Calcium, zinc, magnesium, copper, silicon, iron, manganese, chloride, fluoride, sulfate and phosphates are variously implicated in the growth, structure, homeostasis and physiological function of cartilage and bone. Additionally, elements including lead, silver, strontium and aluminium with no recognized trace metal

status, are occasionally located in bone bound structurally or covalently within hydroxyapatite crystals. As in the skin and related tissues, metal ions interact; they compete for receptor sites in the gastrointestinal mucosa, and competitive binding occurs on metal ion carrier proteins in the circulation and in growing and metabolically active tissues (Lansdown, 1995). The importance and biological implications of cahederins, calmodulins and S-100 proteins in calcium metabolism, and metallothioneins in zinc and copper uptake and mobilization have been reviewed (Lansdown, 2002a; 2002b; Lansdown *et al*., 1999; 2007). Imbalances between elements of nutritional importance, and interaction with xenobiotic ions (including radioactive and stable forms) are significant causes of structural deformity in growing bone and impairment of normal homeostatic mechanisms in adult tissues (Lansdown, 1995). The clinical and experimental implication of strontium, aluminium, lead, beryllium and iron in calcium metabolism and manifestation of rachitogenic changes is discussed below.

3.3.1 Calcium and Phosphate

Calcium uptake and mineralization in bone is influenced by excess concentrations of the anions fluoride, phosphate and phosphonates (Clark and Bélanger, 1967) Many studies have been conducted to evaluate the influence of changes in calcium–phosphate balance in growing bone and to demonstrate that whereas low phosphate favours mineralization, high phosphate suppresses calcium uptake and hydroxyapatite binding, leading to increased mobilization of labile calcium and osteoporotic symptoms (**Figure 8**) (Spencer *et al*., 1975). In a similar way, polyphosphonates and diphosphates impair calcium hydroxyapatite formation leading to structural damage in the bone matrix (Francis, 1969; Cram *et al*., 1971). Fleisch *et al*. (1975) suggested that pyrophosphates and ATPase in calcifying calf cartilages may modulate Ca^{2+} and mineralization in cartilage matrix vehicles and function as a physiological regulator of calcium homeostasis. In contrast, fluoride is probably beneficial in improving the structure and physicochemical properties of the calcium hydroxyapatite in bone and teeth, possibly through enhancing calcium binding. Shambaugh and Petrovic (1968) showed that although increased fluoride did not increase the overall dimensions of major long bones it did improve their flexibility and tensile strength. The mechanisms are presently unclear.

According to Capen (1999), the sensitivity of the parathyroid chief cells to calcium appears not to be fixed but may change during development and ageing and in response to disease processes. In this case, the negative feedback system regulating release of calcium from skeletal tissues breaks down and is influenced by circulating levels of vitamin D, adrenergic catecholamines and phosphate (Wongsurawat and Ambrecht, 1987). Additionally, urinary phosphate excretion is significantly higher in older rats compared to young adult animals fed equal dietary phosphate (Lee *et al*., 1984).

Numerous alkaloids and environmental chemicals show an ability to bind calcium in biological systems, occasionally with toxic or functional implications in bone or cartilage. Thus, alizarin dye from the madder plant (*Rubia tinctorum*), found in Mediterranean regions, binds calcium and can provide a useful nontoxic marker for bone growth and development in experimental studies (**Figure 9**). Steckoll *et al*. (1971) described red-stained bones of human skeletons recovered from archaeological sites in Qumran near the Dead Sea where madder is used as a vegetable food. The dye

selectively stained osteogenic parts of the skeleton (especially the medullary cavity) and other sites of calcium deposition. Purified calcein preparation (DCAF) and tetracycline are also absorbed by bone and provide useful markers for bone growth in experimental studies (Rahn and Perrin, 1970; Rasmussen, 1975). Unlike the relatively nontoxic plant dyes, tetracycline is associated with toxic effects in embryonic and adult tissues (Rolle, 1967). Skeletogenic toxicity is manifest through increased uptake of calcium in osteoplastic and osteogenic tissues leading to premature ossification. In cultured bone explants tetracycline was shown to depress collagenesis by inhibiting proline uptake and proto-collagen formation, possibly through a competitive interaction of ferrous iron in the oxidation process (Halme *et al*., 1969). Alternatively, impairment of the cupro-enzymes, lysyl hydroxylase or prolyl hydroxylase, is involved. In teratological studies, tetracycline and other antibiotics binding or otherwise impairing the metabolism of calcium cause skeletal abnormalities with delayed ossification in rats dosed in early to mid gestation (Filippi and Mela, 1957a; 1957b; Murphy, 1965; Lejour-Jeanty, 1966). Deformities involved also included skull bones, cleft palate and long bones.

3.3.2 Strontium

Strontium is an enigma in human and animal nutrition and its role as a trace element in the mammalian body with a possible action as an enzyme cofactor or structural component in mineralization in bone is equivocal. Although early studies suggested that strontium might have a trace metal value in modulating early mineralization in bone (Johnson, 1973; Johnson *et al*., 1970), this is not substantiated. Chemically, strontium is similar to calcium and interacts with it in several biological systems, notably at receptor sites on cell membranes, carrier proteins and hydroxyapatite (Rygh, 1949; Harrison *et al*., 1959; Baud *et al*., 1968; Treffitt and Sutton, 1969). In bone, strontium fixation on bony surfaces occurs initially by a physicochemical process involving ionic exchange followed by progressive diffusion of the Sr^{2+} into the hydroxyapatite crystal structure (Harrison *et al*., 1959). This process may be modulated by dietary phosphate which favours calcium uptake (Colvin *et al*., 1967), but results of X-ray diffraction and extraction studies indicate that strontium substitutes *iso*morphically for calcium in hydroxyapatite and forms a complex tentatively identified as—$Sr_6H_3(PO_4)_5 \cdot 2H_2O$. In teeth, calcium and strontium exhibit a reciprocal relationship in enamel but with incisor areas highest in calcium.

Although hydroxyapatite possibly discriminates against strontium (Rygh, 1949), experimental evidence suggests that it is absorbed against a concentration gradient and that the rate of uptake reflects the Ca : Sr balance in tissue fluids; calcium : strontium ratios in bone resembling serum concentrations. Experimental studies also suggest that strontium can substitute for calcium in adult and foetal bone without obvious pathological change other than a change in tissue mass (Johnson, 1973; Lansdown, 1969). However, high dietary strontium levels are potentially toxic and have been shown to inhibit body growth leading to reduced bone and tooth ash (Johnson, 1973; Curzon and Spector, 1980; 1981). In severe cases, excessive strontium is a documented cause of 'strontium rickets', which may involve a deactivation of vitamin D (or its active form D_3) or competitive binding of calcium receptors, leading to calcium displacement and impaired mineralization. Strontium is known to suppress calcium-binding proteins and gastrointestinal absorption and is a further recognized cause of skeletal pathology and congenital bone deformity (Colvin *et al*., 1972). Strontium is absorbed by tooth surface enamel from soluble salts in drinking water, but there is conflicting evidence implicating it as a cause of dental caries or other pathological changes (Curzon and Spector, 1980).

Greater toxicological problems derive from exposure to radioactive strontium ($^{89,90}Sr$) where the radioactive emissions are the primary cause of skeletal dysgenesis. Herring (1969) emphasized that whereas many isotopes, including ^{90}Sr, locate in sites of active mineralization, ^{90}yttrium as a breakdown product of ^{90}Sr concentrates particularly on the surface of bone where ion exchange is active and where osteoblastic and osteoclastic activity is dormant. Other radioisotopes, including the bone seeking metals americium and plutonium, also concentrate in resorbing and resting bone surfaces but tend to be endosteal rather than periosteal in distribution (Vaughan, 1956). Radioactive emissions of bone-seeking elements including americium, plutonium, radium, yttrium and thorium are also potential causes of abnormal bone formation and mineral metabolism (Priest *et al*., 1983). Yttrium and thorium have been identified causes of impaired sialoprotein synthesis as a potential route to aberrant mineralization in bone (Williams and Peacocke, 1965). Radioisotopes of these and some other metals displace calcium and are a potential cause of degenerative and neoplastic changes, but in each case the pathology is largely attributable to the β-emissions rather than the mere displacement of the calcium ion, or disturbances in homeostatic mechanisms. Carcinogenicity is a recognized hazard following exposure to strontium and several other radioactive nuclides.

3.3.3 Zinc, Copper and Magnesium

Zinc and copper are essential trace minerals necessary for many key biochemical events maintaining health throughout life (Ma and Betts, 2000). Magnesium is present in all living cells but highest concentrations are found in bone ($1100\,\mu g\,g^{-1}$ tissue in normal human adult) (Schroeder *et al*., 1969). These elements are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat071
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

active biochemically and form structural components or cofactors for a large number of enzymic reactions involved in tissue morphogenesis and homeostasis. Zinc and copper are similar in induction and binding to metallothionein I and II carrier proteins, which modulate their uptake and intercellular distribution patterns (Lansdown, 2002a). Magnesium readily forms complexes with, and acts as an activator or catalyst for, a large number of enzymic reactions, notably those involved in the phosphorylation of ATP and oxidative phosphorylation (Wacker and Parisi, 1968). In cartilage and bone biology, magnesium and calcium interact, such that magnesium acts as a modulator of calcium uptake, tissue binding and excretion (Clark, 1969). Calcium–magnesium balances are central in controlling mineral homeostasis in bone.

Zinc is essential as a constituent or cofactor in more than 70 metalloenzyme systems including matrix metalloproteinases, alkaline phosphatase, RNases and DNases, involved in the development and maintenance of cartilage and bone (Lansdown *et al*., 2007). Hypozincaemias resulting from the chelating action of histidine, phytate, plant fibres, cyclohexamide or actinomycin D are potential causes of impaired bone growth and mineralization (Yamaguchi and Takahashi, 1983; Yamaguchi and Yamaguchi, 1986). Epidemiological studies by Prasad, of children in Middle Eastern countries fed high levels of plant fibre and phytates in vegetables, have shown that severe zinc deficiency syndromes were manifest as profound body growth retardation and tissue maturation, with defects in many organ systems including bone (Prasad, 1978; Lansdown *et al*., 2007). Cadmium, lead and alcohol in the diet reduce intestinal absorption and availability of zinc, and lead to symptoms of hypozincaemia (Yamaguchi and Yamaguchi, 1986; Eckhardt *et al*., 1981).

Copper is present at very low levels in living cells but is best recognized for its role as a cofactor in the metalloenzymes lysyl and prolyl oxidases involved in the crosslinking of collagen fibres, cytochrome oxidase, dopamine hydroxylase, superoxide dismutase and enzymes related to ferrous iron metabolism. It is bound in albumin complexes in the circulation, and more particularly to the specific carrier protein, caeruloplasmin. Copper deficiencies in early chondrogenesis leading to impaired development of the collagen-rich perichrondral sheath are a cause of impaired ossification and subsequent bone development. Copper deficiency leads to an excess of soluble collagen (Lansdown, 1995). Menkes' syndrome is a rare lethal mutation characterized by an inability to absorb or metabolize copper. It is a known cause of multiple defects of which neurological changes, epidermal changes and 'kinky hair' syndrome, vascular damage and impaired skeletogenesis are documented. Excessive copper is toxic in early development in the brain and liver but may be alleviated by the chelating agent penicillamine. Penicillamine has been examined as a potential antifibrotic therapeutic on account of its ability to block reactive aldehydes in collagen crosslinking (Nimni, 1980).

Collagen and elastic tissue crosslinking are inhibited by lathyrogenic agents including β-aminopropionitrile and α-amino acetonitrile, isolated from food plants (e.g. *Lathyrus odorata*). These lathyrogens are documented causes of mandibular, tooth and other skeletal abnormalities in cattle and experimental animals (Lenaers *et al*., 1971; Ohshima *et al*., 1989; Keles *et al*., 2005). Lathyrogenic agents have been shown experimentally to evoke a wide range of skeletal abnormalities including periodontal defects, mechanical strength of mandibles and long bones, mid-facial bone structure and calcium content in bone ash (Bar and Hurwitz, 1974; Kemm, 1975; Ohshima *et al*., 1989; Keles *et al*., 2005). They selectively impair the action of copper-dependant lysyl and prolyl oxidases leading to dyscollagenesis (Herring, 1968). As in states of dietary copper deficiency, the process may be modulated by growth factors, and cytokines, as seems to be the case in wound healing (Davidson *et al*., 1992). Resulting collagens are thermally unstable in the triple helix configuration and are subject to increased turnover; proline analogues investigated therapeutically in the treatment of fibrotic conditions can also be expected to impair collagen and elastic tissue formation in preosseous cartilage and synthesis and repair of fibroelastic cartilages.

3.3.4 Manganese

Manganese is a minor trace element important in chondrogenesis and bone development, and in the mineralization of otoliths in the middle ear (Tsai and Everson, 1967; Gamble *et al*., 1971). Manganese acts as a cofactor in phosphorylases and phosphotransferases involved in mucopolysaccharide synthesis in chondrogenesis. Structural deformities, poor growth and abnormalities in otolith formation are tell-tale features of manganese deficiency (Leach and Muenster, 1962). Recent views suggest that these symptoms reflect changes in circulating cholesterol and glucose concentrations. Other deficiency signs including reproductive failure, depressed growth and anaemia are nonspecific (Greger, 1999). Skeletal deformities in manganese deficiency are permanent but Greger suggests that there is an urgent need to identify accurate markers for manganese status. Serum manganese concentration with lymphocyte manganese-dependant superoxide dismutase and possibly serum arginase activity may be suitable for monitoring manganese deficiency, whereas neurofunctional tests with brain MRI scans are available to detect excessive or toxic exposure to the metal. Neurological symptoms are an occasional

DOI: 10.1002/9780470744307.gat071
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

health risk in workers consuming manganese fumes occupationally.

In veterinary medicine, dietary manganese deficiency is associated with a condition known as 'perosis' in long bones. Affected tissues exhibit a diaphyseal thickening, possibly as a result of increased alkaline phosphatase activity (Wolbach and Hegsted, 1953; Leach *et al*., 1969). It is unclear to what extent manganese impairs calcium or zinc metabolism in this malformation. Investigative studies in deformed sheep identified pathological abnormalities in the columns of hyperplastic cartilages and ossifying metaphyses of limb bones (**Figure 7**) (Duffell *et al*., 1985). The changes resembled those associated with manganese deficiency, but this was not established. Earlier, manganese deficiency was suspected as a contributory cause of a skeletal deformity in turkeys, the so-called 'TY-65' syndrome in which young turkeys presented with abnormalities in the metaphyseal plate region of major long bones (Wise *et al*., 1973).

4 TOXIC DAMAGE IN CARTILAGE AND BONE

A xenobiotic material may invoke structural damage and functional changes in cartilage and bone at any stage from early differentiation through to old age. The type and severity of the damage will be a reflection of the nature of the toxic insult, the vulnerability of the target tissue or cell at the time of exposure, and the genetical susceptibility of the tissue. In the prenatal and perinatal periods, developing tissue in any organ is appreciably more susceptible to injury than in adulthood, and at a time of high biosynthetic activity, tissue differentiation and mitotic activity and differentiation (Lansdown, 1987). Thus toxic action and manifestations of structural and physiological damage in prenatal life commonly reflect impaired growth and cellular interaction in differentiation, incomplete or defective macromolecular syntheses in intercellular matrices (including collagenesis and elastic tissue formation), abnormal morphogenic tissue movements and defective intertissue relationships. The status of maternal health and nutrition has a major bearing on foetal development, such that any condition, chemical exposure, microbiological infection or physical insult (anoxia, X-irradiation, hyperthermia, etc.) in/on the mother is a potential cause of foetal abnormality, substandard postnatal growth and reduced survival.

Skeletal tissues become vulnerable to a different range of toxic changes in postnatal life as mitotic activity and postmitotic cell migration and morphogenic events diminish and as the tissues of appendicular and axial structures achieve their expected adult proportions. At this stage, we consider:

1. Functional change
   (a) impairment in the regulatory mechanisms for bone as a physiological source of minerals (Ca, Zn, Mg, etc.)
   (b) obstruction in the ability of bone matrix to absorb xenobiotic ions thereby protecting vulnerable soft tissues
   (c) reduction in the capacity of tissues to repair following fracture or other injury
2. Pathological damage
   (a) impairment in vascular function → tissue death, nutritional deficiency
   (b) osteoporosis, osteodystrophy → bone weakness, vulnerability to fracture
   (c) metastatic mineralization in cartilages → osteoarthritis
   (d) mutagenic change → bone/cartilage carcinogenesis.

In each case the severity of tissue response is influenced by genetical factors, hormonal changes (oestrogens, parathyroid), nutrition (phosphates, vitamins D, C) and general metabolic health.

A wide range of environmental chemicals, agrochemicals and drugs have a capacity to influence cartilage and bone at one or more stages, leading to transitory or irreversible damage. Unlike soft tissues, including liver and kidney, where minor changes in structure and function of adult tissues are readily detected by serum enzyme changes, secretion and excretion patterns, subtle changes in skeletal morphology are less readily appreciated other than through biopsy with chemical analyses, or X-radiography. In toxicological studies, it is now common practice to examine key bones for histological changes after nine months (subacute) or two years (chronic) (Lansdown, 1987). Where, on the rare occasions manifestations of damage are detected, they may result from direct action of a test material on metabolically active chondrocytes, osteocytes or cells of the periosteum or endosteal surfaces. Alternatively, they may result by an indirect means, namely through the action of drugs, pharmacological or toxic agents on vascular pathways, nerve conduction and neuromuscular activity, which have a bearing on the health and function of musculoskeletal tissues.

5 TERATOGENIC MECHANISMS IN SKELETAL DYSGENESIS

Skeletal abnormalities are commonly reported in teratological studies. Virtually every teratogen having a direct or indirect influence on prenatal or perinatal body growth is a noted cause of defective skeletal development. This is illustrated by personal studies on salicylates, bone-seeking minerals, anaesthetic gases and infections

in pregnancy. Principle mechanisms of skeletal deformity and/or pathological changes involving cartilage or bone include:

1. Impaired differentiation and function of chondrocytes.
2. Abnormal cartilage formation and maturation; defective formation of ground substance (glycosaminoglycan) of bone matrix.
3. Impaired function and regulation of osteoclasts and their degradative enzymes.
4. Abnormalities in mineralization and ossification.
5. Impairments in physiology and general body growth in the foetus/embryo.
6. Impairments in maternal health leading to abnormalities in the intrauterine environment (an indirect effect).

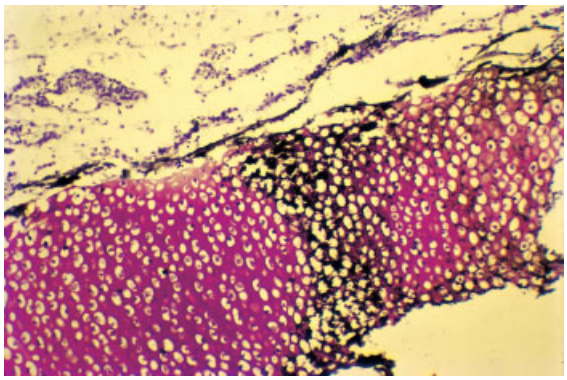

Figure 10 Aberrant ossification patterns in the femur of a rat foetus (12 days gestation) following maternal exposure to sodium salicylate, illustrating impaired cartilage and chondrocyte hypertrophy. Note disorganized perichondrium (×10 objective, toluidine blue and silver impregnation).

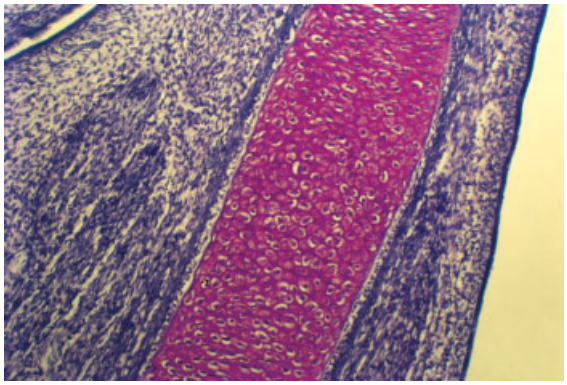

Figure 11 Normal preosseous cartilage in the rat femur after 10 days gestation (×10 objective, toluidine blue).

Putative teratogens including chemical, physiological or biological (bacteria, viruses, etc.) may exhibit site-specific effects or multifocal sites of toxic action. Manifestations of toxic action vary according to species, time and duration of exposure and genetic factors (as in induction of cleft palate). Cleft palate, as frequently described in teratological literature, has a complex aetiology and may be associated with cleft lip (Shah and Halperin, 1982). In human babies with orofacial clefts, isolated cleft lip and isolated cleft palate each account for approximately 20–30% of cases, with the remaining 50% being represented by combined cleft lip and cleft palate. Certain strains of mice are particularly susceptible to spontaneous cleft palate, a feature which has been used to advantage in studying the genetical sensitivity to cortisone teratogenicity (Loevy, 1962; Pinsky and Di George, 1965).

Patterns of structural deformity in endochondrial bones are illustrated by reference to site-specific teratogens like salicylates and cadmium with known biochemical action on cartilage matrix (Lansdown, 1969; 1970; Foulton *et al*., 2000; Larsson and Piscator, 1971). Experimental studies demonstrate that such toxins impair the biosynthesis of chondroitin sulfate and other mucopolysaccharides through blocking sulfation patterns, and are potential causes of abnormal development and maturation in long bones of the limbs, vertebrae and ribs (**Figure 10**).

The chondrogenic phase of all long bones is characterized by elaboration of an intercellular matrix composed largely of mucopolysaccharides like chondroitin sulfate. These mucopolysaccharides exhibit a metachromatic staining reaction in response to toluidine blue and related dyes; the intensity of the metachromasia serving as a guide to the maturity and normality of the cartilage (**Figure 11**) (Lansdown, 1968). In normal chondrogenesis, cellular maturation in mid-shaft regions is associated with more intense metachromasia and hypertrophy of chondroblasts. As site-specific teratogens, salicylates impair the sulfation of polysaccharides leading to defective cartilage matrix and subsequent osteogenic phases. Thus in experimental studies, foetal rats exposed to high maternal doses of sodium salicylate exhibited major abnormalities involving limb bones, ribs, vertebrae and skull bones. In each case cartilage matrix showed reduced staining and abnormal ossification patterns (Lansdown, 1970).

Cadmium, on the other hand, concentrates more in cranial regions of exposed rat foetuses, leading to cleft lip and facial deformities (Holmberg and Ferm, 1969). Preosseous cartilage was abnormal and impaired growth led to abnormal fusions and mesenchymal derangement (Mulvihill *et al*., 1970). Cadmium is severely cytotoxic and induces inflammatory changes, but its principle biochemical effect is the induction and binding of metallothioneins, thereby impairing the zinc and copper-dependent events (Margoshes and Vallee, 1957). Cadmium is known to evoke vascular hypertension and is commonly regarded as an antimetabolite in biological systems (Schroeder *et al*., 1967). Vitamin A (retinoates,

EDTA (ethylenediaminetetraacetic acid)) and penicillamine are other causes of cartilage abnormalities and defects in mineralization (Shah, 1979; Hendrickx and Binkerd, 1979).

It is customary in teratological studies to demonstrate patterns of ossification in foetal skeletons using the red dye alizarin red, which binds calcium hydroxyapatite in skeletal tissues (**Figure 9**). Although the underlying mechanisms for deformity may not be known, skeletal preparations stained with alizarin red dye allow appreciation of such features as:

1. the extent of ossification in the various elements of the skeleton—limbs, vertebrae, ribs, skull
2. presence of abnormal centres of ossification
3. absence of centres of ossification
4. abnormal fusions and sutures.

Whereas retarded prenatal development is frequently a consequence of impaired maternal health, abnormal fusions, deletions and growth of additional vertebrae, ribs and digits can be attributed to deviations in intercellular contact or other defects within the skeletal blastema modulated by genetic or idiopathic factors (Lansdown, 1976a). Rodent and rabbit species commonly used in laboratory studies show a strain-related incidence of structural abnormalities in bone (Lansdown, 1987). Thus the mouse is of limited value in view of its known susceptibility to cleft palate (Loevy, 1962). The incidence of 'spontaneous' abnormalities in rabbits is slightly higher than in rodent strains, but in view of its susceptibility to known human teratogens like thalidomide, this is not considered to be a major disadvantage (Gibson *et al*., 1966; Stadler *et al*., 1983; Lansdown, 1987).

Pathologically, materials capable of inducing specific structural abnormalities in cartilage or bone through prenatal exposure may act during initial transformation of mesenchymal cells in the early blastema (the induction phase), elaboration and synthesis of chondroitin sulfate in the cartilage matrix (preosseous phase), or during the differentiation of osteoblasts and mineralization in mid-shaft and endochondral sites (osseous phase). Once centres of ossification become established, teratogenic agents may influence subsequent skeletal growth through toxic action in metaphyseal growth plates, impaired chondroblastic action (impaired breakdown of preosseous cartilage matrix) or defective mineralization patterns. Impairment in the induction phase of chondrogenesis in long bones and vertebrae is a common cause of limb and spinal deformity. Defects in the ossification of membrane bones of the skull are commonly associated with impaired closure of fontanelles or other forms of craniofacial abnormality (Kokich *et al*., 1982).

The highly toxic alkylating agent, nitrogen mustard, is an illustration of a teratogen that targets mesenchymal cells (Sweeney and Watterson, 1969; Salzgeber, 1979). It is a cause of mutagenic damage, mitotic inhibition and necrosis in preosseous cartilage, leading to severe deformities in limb bones, vertebrae and rib cage.

Hypoxia is an acknowledged cause for circulatory disturbances leading to oedema, imbalances in anion–cation distribution, and changes in sugar, lactate and free amino acid concentrations in the developing embryo/foetus (Grabowski, 1966). Oxygen tension in the induction phase of early development is critical in osteoblast differentiation (Hall, 1967). Calcium is absorbed more readily by chondroblasts, which in due course hypertrophy and undergo premature mineralization. Other illustrations of materials that impair oxygen balances in early bone formation include trypan blue dye, dinitrophenol, lactate and calcium chloride (Grabowski, 1964; Kaplan and Johnson, 1968). Whilst mechanisms of subcellular action differ, vascular changes, rarefaction of proliferating cell populations, blisters and local oedema through hypervitaminosis A, bis-azo dyes and nutritional deficiency of linoleic or pantothenic acids are recorded causes of impaired oxygen metabolism leading to skeletal abnormalities in experimental animals or human babies (Marin-Padilla, 1966; Turbow, 1966; Morriss and Steele, 1974; Sandor and Amels, 1975).

Mucopolysaccharide synthesis is a target for several bone-seeking teratogenic agents, including hypervitaminosis A, salicylates and cortisone, although mechanisms differ. Vitamin A possibly acts by impairing the sulfation of polysaccharides (Wolbach, 1947; Fell and Mellanby, 1952; Wolf and Varandani, 1960; Pasternak and Thomas, 1968). Experimental studies suggest a strong relationship between the concentration of vitamin A and the developmental sensitivity and genotype of the tissue (Kochhar, 1967; Nolen, 1969; Robens, 1970; Biddle and Fraser, 1976). Biochemical and teratological studies demonstrate that salicylates also impair chondrogenesis and osteogenesis, acting by inhibiting key enzymes involved in the sulfation of polysaccharides, and advancing the hypertrophy of cartilage matrix (Whitehouse and Bostrom, 1961; Larsson and Bostrom, 1965; Grisolia *et al*., 1968; McArthur and Smith, 1969; Somogyi *et al*., 1969). Foetal deformities in pregnant rats exposed to high levels of sodium salicylate or salicylic acid in early- to mid-gestation are related closely to the concentration of salicylate, the gestational age of the foetus and genotype (Warkany and Takacs, 1959; Larsson *et al*., 1963; Ericksson, 1971). Abnormal cartilage in long bones and vertebrae were shown histologically to lead to impaired ossification (**Figure 12**) (Lansdown, 1970). In older foetuses, high salicylate has been associated with excess ossification with occasional metastatic mineralization, possibly resulting from an inhibition of oxidative phosphorylation (Whitehouse, 1963; Cotty and Harris, 1968). Deformed human babies have been reported in mothers consuming high levels of aspirin during pregnancy, but where the doses were at suicidal levels (British

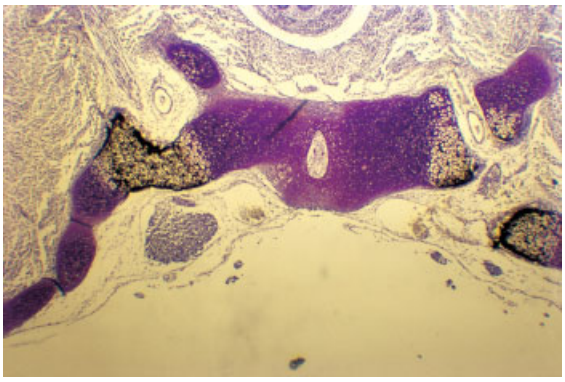

Figure 12 Chondrodystrophy associated with abnormal ossification in the mid-dorsal region of a 13-day rat foetus exposed to high levels of sodium salicylate *in utero* (×2.5 objective, toluidine blue and silver impregnation).

Medical Journal, 1963; Jackson, 1948). A further illustration of the osteogenic influence of salicylate is seen in teeth. Berry and Nickols (1979) showed that salicylates impair developmental patterns, although the actual effect on odontoblasts is not clear.

A commonly described and often contentious skeletal abnormality in experimental and clinical teratology is cleft palate formation (Burdi, 1977). Cleft palate is a serious medical problem in clinical management and patient care, but equally disturbing is its association with a high incidence of other medical problems involving soft tissues—neurological abnormalities, congenital heart disease, miscellaneous hernias and delayed maturation (Shah and Halperin, 1982). Iron-deficiency anaemias were reported in 10% of 304 patients with cleft palate; haemoglobin levels of $<11.4\,\mathrm{g\,dl^{-1}}$ were possibly attributable to poor dietary habits. Cleft palate occurs with a high incidence in certain strains of mice, and has been described in numerous experimental studies in which animals have been dosed *in utero* with high doses of vitamin A, aminopterin, thalidomide, diazepam (Valium), the environmental defoliant 2,4,5-trichlorophenylacetic acid (2,4,5-T) and cortisone (Fogh-Andersen, 1971; Safra and Oakley, 1976; Nanda and Romeo, 1978). Underlying mechanisms suggested for cleft palate formation include defects in chondrogenesis, and inhibition in the horozontalization of lateral palatal shelves and their fusion in the midline (Asling *et al*., 1960; Loevy, 1962; Ross and Walker, 1967). Impaired mucopolysaccharide synthesis, delays in mitosis and postmitotic cell migration, induced myopathy, or impairment in lysosomal enzyme degradation of prechondrous mesenchyme may be contributory in each case (Burdi *et al*., 1972; Shah and Halperin, 1982).

Toxic and teratogenic factors influencing the development and functional maturation of cartilages and bone late in prenatal life and postnatally act mainly through impairment of essential nutrients, alterations in mineral metabolism or through inhibiting essential biosynthetic events. They may be generalized or target a particular tissue depending upon the nature of the deforming influence, the time of exposure and the developmental state of the tissue. Continued growth and maturation in cartilage and bone depend upon a regular source of nutrients (**Table 1**). Lucille Hurley (1977) emphasized the special importance of nutrition in the perinatal period and noted that malnutrition leading to low birth weight is a common cause of congenital abnormality and permanent anatomical aberration. Whereas at one time there was a commonly held belief that foetuses *in utero* were protected from malnutrition or nutritional stress by the maternal organism, early experimental observations by Hale (1937) showed that piglets born to sows deficient in vitamin A were low in birthweight and displayed a high incidence of malformation and reduced postnatal viability. Although there is extensive epidemiological evidence to demonstrate that nutritional deprivation and malnutrition as in kwashiorkor is a cause of structural abnormality, low birth weight and reduced neonatal survival, much of our present knowledge on the importance of vitamins, minerals, amino acids and proteins in prenatal and postnatal growth derives from controlled and reproducible experimental studies in animal models (Hurley, 1968; O'Dell, 1968). Although some subtle and some major interspecies differences will preclude a direct extrapolation of results in animal models to humans, it can be safely assumed that the biochemical mechanisms involved in tissue morphogenesis in bone, cartilage and soft tissues will be similar in all mammals, and that studies conducted in rodents, rabbits, pigs and so on, will be of reliable predictive value for humans.

6 ACCUMULATION OF METALS IN BONE: A PROTECTIVE MECHANISM?

The principle mineral components of normal mammalian bone include calcium hydroxyapatite and various bone salts, including magnesium, phosphate, citrate, fluoride, hydroxyl and chloride (McLean and Urist, 1969; Urist *et al*., 1968). These mineral salts vary in concentration but confer hardness and rigidity to the bone. They are mostly soluble in mineral acids and assayed by atomic absorption spectrometry following prolonged immersion in dilute solutions. Calcium hydroxyapatite crystals are of central importance in the uptake and release of anions and cations. Thus, citrate ions and carbonates are probably arranged on the surface of the crystals, but carbonates may substitute for phosphate ions within the crystal structure. Even in histologically normal trabeculate or dense bone, the calcium hydroxyapatite crystal structure is not stable and is subject to variations, with fluoride substituting for hydroxyl groups

and bone-seeking cations replacing calcium (Samachson, 1968).

The ability of hydroxyapatite and mucosubstances in bone to concentrate and bind metal ions has several implications in physiological and toxicological terms, notably in regulating the uptake and mobilization of ions with nutrient value, like calcium and magnesium (Herring, 1969). The greatest proportion of the body calcium load is bound in bone, partly as a structural component and partly as a labile moiety. This labile calcium is available as a multifunctional ion, as enzyme cofactor, tissue modulator or physiological factor in many tissues in the body. It is mobilized in cases of nutritional or other forms of deficiency by hormonal modulation (Lansdown, 2002a). Profound bone-seeking metals like cadmium deplete labile calcium, and calcium in the structural matrix, leading to osteoporosis, particularly in patients subject to postmenopausal changes (Åkesson *et al*., 2006). Sodium also is a normal constituent of bone, but as Biltz and Pellegrino (1969) found, concentrations found in mammalian bone show no constant correlation with the total mineral content. Bone is a major source of labile zinc but its role in providing a reservoir for zinc in cases of deficiency is less clear (Lansdown *et al*., 2007). Regulation of zinc concentration in body fluids is controversial but serum concentrations seem to relate to circulating levels of carrier proteins and hormones (e.g. parathyroid hormone); dietary factors may be involved. Of greater toxicological significance is the capacity of bone, dentine and cartilage to concentrate and bind metal ions with questionable or no acknowledged physiological or nutritional role in the body (e.g. lead, cadmium, silver, aluminium), and which are recognized toxins in key soft tissues like liver and kidney. Analysis of the mineral content of bone through iliac crest biopsies provides an indication of exposure to such metals and the concentrating ability of hydroxyapatite or other constituent of cartilage or bone (Lindh *et al*., 1980). The assay of bones from workers in Sweden using atomic absorption spectrometry, neutron activation analysis and X-ray emission analysis in a proton microprobe showed that workers exposed to lead had about five-fold greater levels of bone-bound lead. Elsewhere, bone samples of prehistoric North American Indians analysed for lead and cadmium showed appreciably lower concentrations of the metals than seen in modern day populations in Europe and the USA (Ericson *et al*., 1991). Thus, ratios of lead to calcium ($8.4 \pm 4.4 \times 10^{-7}\,\mu g\,g^{-1}$ dry weight) were many times lower than seen in modern populations ($210–350\,\mu g\,g^{-1}$). Analytical studies provide information on the mineral content of tissues and offer the opportunity to calculate ionic balances as an index of toxicity.

Increasing use of xenobiotic metals in medical devices and concerns over environmental pollution have resulted in an increasing availability of techniques to monitor low levels of metal in tissue. We now have the ability to monitor xenobiotic metals concentrated in human bone and appreciate imbalances in physiological concentrations of key metals like calcium, zinc and magnesium leading to pathological conditions, notably osteoporosis; the stability of xenobiotic metal hydroxyapatite complexes; release of xenobiotic metals from bone; and their metabolism via carrier proteins to vulnerable soft tissue.

Information compiled so far in relation to such metals as aluminium, silver, cadmium and lead provides an incomplete profile of the inherent risks associated with environmental contamination and indicates the need for further biochemical and pathological investigation. Aluminium is used extensively in industrial processes but its value in renal dialysis is controversial. Berlyne *et al*. (1972) assessed the toxicity of several aluminium compounds including aluminium hydroxide in rats dosed orally and parenterally, and identified increased aluminium deposits in bone. They did not report histological changes but noted that tissue and plasma aluminium concentrations were increased two-fold in uraemic animals, consistent with their unpublished human studies. D. J. Sherard (unpublished observations, 1972) disclaimed these experimental studies and maintained that they were a misrepresentation of normal routes of human exposure to aluminium in diuresis, and that the observations were at variance with his own clinical experience. He reported no evidence of bone disease in patients exposed to aluminium through renal dialysis for up to six years. Elsewhere, aluminium-related osteomalacia dystrophy was observed in two long-term studies of dialysis patients; aluminium possibly displaced calcium in hydroxyapatite (Ward *et al*., 1978; Parkinson *et al*., 1979). The authors reported that the aluminium content of bone correlated well with levels of osteoclast activity in iliac crest biopsies, and that bone volume correlated with aluminium content (Cournot-Witmer *et al*., 1979). X-radiography revealed phalangeal erosions, subperiosteal resorption in long bones, and severe osteomalacia. Clinicians have questioned also whether high aluminium levels in bone may be correlated with phosphate or fluoride concentrations (Parsons *et al*., 1971). In teeth, a stable chemical balance seems to exist between the aluminium content and the fluoride. More recent work suggests that the risks identified in experimental studies are insufficient to justify replacing aluminium hydroxide in uraemic therapy (Thurston *et al*., 1972; Verberckmoes, 1972).

Silver is a less contentious metal and so far has not been associated with clinical evidence of toxicity in bone or other tissues (Lansdown, 2002c; 2006; Lansdown and Williams, 2004). Silver has enjoyed widespread use as a broad-spectrum antimicrobial substance in medical devices including orthopaedic prostheses, bone cements, surgical pins and dental materials. The silver compounds used in medical devices ionize in the presence of

body fluids to release biologically active Ag^+, which readily binds receptors on cell surfaces, and induces and binds the zinc and copper carrier proteins, metallothioneins I and II (Lansdown, 2002b). Earlier biochemical evidence that Ag^+ evokes release of Ca^{2+} from the sarcoplasmic reticulum vesicles isolated from rat muscle homogenates through activation of calcium channels or calcium ion pump mechanisms involving magnesium (Tupling and Green, 2002; Prabhu and Salama, 1990), suggests that silver ion absorbed by bone may trigger release of labile calcium and lead to pathological changes. However, no evidence has been seen to establish that Ag^+ displaces Ca^{2+} or activates Mg^{2+} in bone leading to osteoporotic or physiological changes. Human osteoblasts exposed *in vitro* to a novel nanosilver bone cement exhibited normal behaviour and formed cellular processes indicating good biocompatibility (Alt *et al*., 2004). In another study, morphological alterations were reported in rat osteosarcoma-derived (osteoblast-like) cells exposed to silver, gold, palladium, copper or nickel–titanium alloy wire as used in dental materials (Cortizo *et al*., 2004). Silver and copper wires with an exposed area of $0.157\,cm^2$ were cytotoxic to cultured osteoblasts, whilst other elements appeared to be biocompatible. Cells exposed to silver were smaller than in controls but some mitoses and apoptotic bodies were observed. Copper wire evoked more profound cytopathic changes, ranging from total loss of viability to abnormal cytoplasmic inclusion, impaired growth and loss of cellular integrity. Spadaro *et al*. (1979) evaluated silver-containing polymethyl methacrylate as used in bone cements, by implanting samples intramuscularly in rabbits. Tissues surrounding implant sites were morphologically normal and exhibited only a mild foreign-body reaction, indicative of good biocompatibility of the material *in vivo*.

The toxicology of lead in bone and cartilage is complex and still imperfectly understood, but substantial evidence exists to show that lead interacts with and may displace key mineral elements in bone, notably calcium, zinc, copper, iron and magnesium, which contribute to bone structure and exhibit central roles in cell metabolism, proliferation and homeostasis (Moore, 1979). Settle and Patterson (1980) emphasized the strong affinity of lead for calcium receptors and claimed that biochemical systems regulating calcium metabolism 'operate passively' on some other elements including lead and barium, and reflect small differences in their chemical properties. Whilst experimental evidence suggests that lead inhibits uptake of calcium and displaces it from bone (Gruden *et al*., 1974), dietary calcium, in the rat at least, can modulate lead concentrations in bone and its mobilization to soft tissues (Vega *et al*., 2002). Experimental studies suggest that lead efflux from bone is related to bone resorption during lactation. It seems that a homeostatic balance is achieved between calcium and lead, and that this is regulated by calciotropic and pregnancy-related hormones (Silbergeld, 1991). Lead uptake and metabolism is sensitive to vitamin D and parathyroid hormone, and is influenced by dietary concentrations of sodium citrate, vitamins C and D, certain amino acids, proteins, fats and sugars, and mineral salts including Ca^{2+}, Mg^{2+} and phosphate (Moore, 1979; Smith *et al*., 1978). Lead is a cumulative poison, and uptake from the intestine and through respiration occurs independently of the body and tissue levels and against concentration gradients. No recognized feedback mechanism seems to exist to limit lead absorption as occurs with calcium and most trace metals. As with other metals, lead is metabolized in the form of a carrier-protein complex. A proportion of this lead will be excreted via the skin, hair, nail, urine and faeces, but as much as 90% may be deposited in bone (Moore, 1979). In one clinical study, 68 men exposed occupationally to lead showed increased serum concentrations of 1,25-dihydroxyvitamin D (Mason *et al*., 1990). Hypervitaminosis correlated well with blood lead and lead concentrations in tibial biopsies.

Somervaille *et al*. (1988) discussed the value of X-ray fluorescence assessment of tibial lead concentrations as a guide to occupational exposures. Differing views are expressed as to the true toxicological significance of lead bound in bony tissues (Rabinowitz *et al*., 1977; Rosen and Markowitz, 1980; Rosen, 1983). Pounds and Rosen (1986) considered that bone was not only a place of storage for lead, but a target tissue for lead toxicity, but this has to be ratified clinically. Lead is readily taken up by osteocytes, and concentrates in hydroxyapatite matrix from which it is released to evoke potentially toxic and irreversible damage in many soft tissues, notably the brain and kidney (Emmerson and Thiele, 1960; Rosen, 1985; Silbergeld, 1991). Lead locates in osteoblast and osteoclast mitochondria which are vulnerable to lead-induced swelling and depressed respiratory activity (Goyer and Krall, 1969). Further studies are required to investigate other intracellular pathways of lead metabolism and toxicity in bone cells and how these are influenced by hormones, drugs and nutrients (zinc, magnesium iron, etc.). Some authors believe that much of the lead bound in bone is bio-inert and unavailable for metabolism to vulnerable tissues (De Mechele, 1984). This argument is fuelled by the observation that only part of this lead is available for chelation by EDTA (ethylenediaminetetraacetic acid) or other cytoprotective agents (Pounds and Rosen, 1986). In sites of toxic action, lead exhibits a strong affinity for sulfhydryl (–SH) groups, lysine residues, and hydroxyl (–OH) groups, and it binds to and inhibits a variety of proteins including enzymes.

Lead pollution from traffic fumes and water systems is a potential cause of tooth decay. Researchers in Spain have suggested that lead absorbed from fumes interacts with the minerals of tooth enamel and that exposed children and individuals with tooth

decay displayed more than three times the level of blood lead than those with normal healthy teeth (Pearce, 1997). The concentration of lead in bone has been shown to correlate with levels of nephropathy, lead in teeth and neurophysiological development in children (Emmerson, 1963; Needleman *et al*., 1979).

Cadmium is a profound bone-seeking element, and high exposure is a known cause of bone damage and osteoporosis (Åkesson *et al*., 2006). A study of women's health in the Lund area of Sweden revealed that menopause, smoking, body-weight status and hormone replacement therapy affect blood and bone cadmium levels. Patients of 53–64 years of age exposed to low-levels of cadmium exhibited a significant interaction between cadmium and menopause; increased cadmium excretion was associated with negative effects on bone mineral density. Experimental studies in rat emphasize the strong interactions between cadmium and calcium; cadmium administered orally in diet or by parenteral injection impaired calcium absorption and metabolism leading to osteoporotic and osteomalacic changes in bone (Itokawa *et al*., 1974). In part, this may be attributable to cadmium-induced renal damage and impairment of phosphate and calcium metabolism (Friberg, 1984; Kawamura *et al*., 1978). Histological analysis of femurs of cadmium-fed hypocalcaemic rats revealed reduced cortical osseous tissue, whereas in calcium-sufficient cadmium-treated animals, the metaphyseal plate was thinned and zones of mineralization disturbed, and trabecular bone formation was abnormal (Itokawa *et al*., 1974). Osteoclast activity was also prominent in femurs of rats fed low levels of calcium and 100 ppm cadmium in diet.

7 CARCINOGENICITY

The toxicology of cartilage and bone rarely extends to a consideration of the potential carcinogenic or mutagenic effects of environmental contaminants and industrial chemicals in skeletal tissue. Spontaneous bone tumours are rare in rodents and are seldom an issue in toxicological studies (Luz and Gössner, 1994). In an evaluation of 368 chemicals, the International Agency for Research on Cancer (IARC) identified 26 chemicals for which carcinogenicity in humans was unequivocal, and a further 221 for which evidence of carcinogenicity in animals provided some evidence for putative carcinogenicity in man (Tomatis *et al*., 1978; International Agency for Research on Cancer (IARC), 1980; US DHHS, 2005). Importantly, many of the reports scrutinized fail to recognize that bone or cartilage in any part of the body is a target for putative carcinogens or that either tissue is a potential site for metastases (Haseman and Lockhart, 1993). However, the IARC has discussed the hazards associated with radioactive metals for which unequivocal risk of carcinogenicity is indicated in experimental studies in rodents (Litvinov and Soloviev, 1990).

External local or whole-body radiation with α-, β- or γ-emitters is a potential cause of osteogenic or osteoblastic sarcoma in rats (Litvinov, 1964; Litvinov and Soloviev, 1990). Osteogenic tumours were reported in rats exposed orally, parenterally or by intraosseous route to bone-seeking radionuclides including phosphorus (^{32}P), calcium (^{45}Ca), strontium (^{89,90}Sr), barium (^{149}Ba), radium (^{226}Ra) and uranium (^{238}U), which by their systemic nature appear to evoke pathogenic and potentially neoplastic changes in all bones of the skeletal system (Litvinov and Soloviev, 1990). Radiation-induced tumours commonly occur in the regions of active endochondrial ossification at the interface between the metaphysis and diaphyseal regions of immature long bones. Changes tend to be more prevalent in spongy bone where the metabolically active tissues of the endosteum, periosteum and around Haversian canals are particularly vulnerable to β-emissions. A typical example is seen in a study where young Wistar rats were exposed to 3.7 MBq strontium (^{90}Sr) and developed pathological changes in areas of medullary osteogenic sarcoma within 8–10 months of intramuscular injection (Graf *et al*., 1970). In early carcinogenesis, normal osteogenic profiles were markedly disturbed and retarded, but bone formation predominated over resorption. Progressive degenerative and dysplastic changes preceded frank neoplasia, manifest by abnormal bone trabeculae and osteoid, with deposits of dystrophic collagen and amorphous protein.

Induction and severity of carcinogenic change is directly related to the radioactivity emitted by the element administered, exposure time, and the age and physiological activity of the bone area exposed. At high doses, β-emitting isotopes are potentially fatal to animals before tumours develop. Luz and Gössner (1994) noted that the majority of α-particle induced osteosarcomas in mice are of vertebral origin, but unusually in the case of β-emitter ^{90}Sr exposure, tumours tend to be spinal following high doses of radiation, and predominantly in diaphyseal regions of long bones at low levels (Nilsson, 1962; Nilsson, 1970). Occasionally, these murine osteosarcomas induced by ^{90}Sr incorporate a chondroblastic element which is rarely the case with α-emitters. The mechanism is unclear.

Bone tumours have been observed less frequently following parenteral or oral administration of nonradioactive carcinogens, including 7,12-dimethylbenzo[b]phenanthrene (DMBA), 1-(2-hydroxyethy)-1-nitrosourea, vinyl chloride and 3,3-dichlorobenzene (Mirvish *et al*., 1987; Viola *et al*., 1971; Pliss, 1965). Waalkes *et al*. (1991) have extensively reviewed the carcinogenicity of cadmium in experimental and human studies. They reported bone tumours (mainly osteogenic sarcomas) in young Fischer F344 rats following single subcutaneous injections (30–70 mM) of cadmium chloride). In other

experiments, they reported osteogenic sarcomas induced in the ear cartilages of 14 of 168 Wistar rats which had nickel and copper ear tags inserted (Waalkes *et al*., 1987). Nickel is an acknowledged soft-tissue carcinogen, whereas copper is an essential trace metal with a role in cell proliferation and collagenesis (US DHHS, 2005). Although the work has not been repeated, it suggests that carcinogenesis in this case is in a two-stage form, where nickel is the inducer and copper is the promoter. In other respects, bone tumour promotion in rats at least is achieved by local external irradiation and/or by administration of growth hormone or thyroxine (Litvinov and Soloviev, 1990).

Beryllium is a nonmetallic element known to induce tumours in experimental animals and following occupational exposures in humans (Berlin *et al*., 1994). In the latter situation, lung tumours are a particular hazard (Smith and Suzuki, 1980), but osteosarcomas are reported in rabbits following intravenous or intramedullary administration of metallic beryllium, or beryllium oxide, carbonate, phosphate or silicate, and zinc beryllium silicate (Fodor, 1977). Beryllium oxide injected intravenously (1%) in rabbits was shown to concentrate in bone marrow throughout the skeletal system and cause local haematopoietic damage. Irregular osteogenesis with fibrosis was reported prior to appearance of pleomorphic medullary tumour formation in metaphyseal regions of long bones (Fodor, 1977). There was little evidence of osteoclastic activity, and bone breakdown was minimal. No human cases of beryllium-induced bone tumours have been seen.

The possible mechanism for osteosarcoma induction in rats by separating metaphyseal growth plate regions from periosteal tissues by cellophane film is unclear (Korobko, 1966; Studitski, 1966); it is unclear whether the osteosarcomas were induced by the cellophane film *per se,* or by the mere physical act of disturbing tissue 'balances'. The carcinogenicity and mutagenicity of substances leaching from the cellophane film remains to be ratified.

More direct evidence for the carcinogenicity of xenobiotic materials in bone or cartilage is provided by experimental studies where test materials have been instilled or injected into the medullary cavity of long bones or into articular cartilages of rats. Thus, the multifocal carcinogens DMBA and benzo[a]pyrene induced high yields of osteogenic sarcomas when injected into the medullary cavity of femurs (Litvinov and Soloviev, 1990; Moritani, 1977). Further, this tumour incidence was promoted by feeding animals rachitogenic (low vitamin D) diets. Other experiments demonstrate that intraosseous administration of the carcinogenic metals chromium and nickel can be a cause of osteosarcoma (Guelstein, 1965). A copper-chelated *N*-hydroxy-2-acetyl aminofluorine administered in a similar manner into rat femur was shown to evoke osteosarcoma, chondrosarcoma and haemangiosarcoma (Stanton, 1967).

In an attempt to identify the carcinogenic properties of metal alloys used in prosthetic devices, Lewis *et al*. (1995) and Sunderman (1989) administered metal powders by intra-articular route in Fischer F344 rats. Whereas no neoplastic activity was identified in animals treated with cobalt–chromium–molybdenum (CoCrMo) or titanium–aluminium–vanadium (TiAlV) complexes, either at injection sites or at distant locations, poorly developed primary pleomorphic sarcomas were seen in animals injected with nickel subsulfide. (Nickel subsulfide is listed as a material for which sufficient evidence exists for carcinogenicity (respiratory tract) to humans through industrial exposure (US DHHS, 2005)). Sunderman (1989) considered that sarcomas at implantation sites were a potential, albeit rare, problem with implantation of prostheses, and that surgeons should select prostheses on the basis that they are not subject to corrosion or mechanical failure and are safe in the presence of human tissue.

Whereas there is still no conclusive evidence for the carcinogenicity of cadmium in human bone or cartilage, Friberg *et al*. (1974) reported that over 20% of women aged over 50 years in the Jintzu River region of Japan developed leg pains and bone tenderness following exposure to high cadmium levels in soil. Their bones were deformed and susceptible to fracture, possibly due to serious malnutrition, but cadmium toxicity is probably implicated. Cadmium is a cause of chondrodystrophy and abnormal bone in embryonic and neonatal skeletal structures (Mulvihill *et al*., 1970; Holmberg and Ferm, 1969). More recent studies of cadmium poisoning in the Shipham (UK) area have failed to demonstrate the carcinogenicity of cadmium in bone/cartilage at greatly increased body cadmium levels (Philipp, 1985).

8 DISCUSSION

Cartilage and bone are vulnerable to toxic damage and structural deformation at any stage from early prenatal life through to adulthood. Toxic agents targeting skeletal tissue may exert their influence by a direct action on vulnerable cells at periods of high proliferative activity or differentiation, or they may influence their local environment by impairing nutrients or regulatory mechanisms modulated by hormones, cytokines and growth factors. The damage or structural changes seen in each case reflect the nature and severity of the toxic insult, its target tissue(s) and biosynthetic pathways, and the age and developmental state of the individual. Commonly, toxic changes or structural defects arising prenatally in periods of maximal differentiation can be expected to be reflected in subsequent phases of development and the definitive structure and function of the musculoskeletal system in the adult. Deformities in long bone, vertebral and skull development induced at later stages will

more frequently involve transitory or progressive alterations in mineral metabolism and the functional capacity of the tissues. Carcinogenic changes in bone and cartilage are not widely discussed, but are a recurrent problem in people exposed occupationally and environmentally to certain bone-seeking radioisotopes and toxic metals like beryllium. These substances are mutogenic and bind strongly to the hydroxyapatite moiety of the bone matrix.

My long-standing interests in mineral metabolism and in the action and interaction of metals in biological systems lead me to conclude that many toxic agents, potentially toxic to bone and possibly cartilage at some stage, act through blocking the availability and metabolism of key minerals such as calcium, zinc and magnesium. Bivalent metals, in particular, interact and compete for cellular receptors at sites of gastrointestinal absorption, carrier proteins in the circulation, and on cell membranes. Imbalances in trace metal ions, attributable to impairment in absorption, blockage of metabolic channels by ionic interaction or inactivation of enzyme systems, are potential causes of developmental abnormality, functional and pathological change. Investigative studies in intact and *in vitro* cell systems show that cartilage and matrix vesicles play a central role in mineralization, and that agents like salicylates and cadmium which impair mucopolysaccharide synthesis and chondrocyte maturation are causes of defective mineralization (Fleisch *et al*., 1975).

The ability of bone to concentrate toxic metals like lead without exhibiting obvious pathological changes, except following chronic exposure, has several clinical complications. Bone provides a reservoir from which toxic agents are released to invoke injury in vulnerable soft tissues, even though mechanisms of metal binding are frequently unclear and the circumstances and modulation of ion release into the systemic circulation are equivocal. Lead, for example, has been extensively studied as an environmental contaminant and as a cumulative neurotoxin. It shows a strong tendency to accumulate in bone and is released progressively with potential risks of neurodegeneration with impaired intellectual development (Moore, 1979; Carson *et al*., 1974). Further studies are required to evaluate the metabolic and toxic consequences of chronic exposure to aluminium, strontium and other environmental metals on long-term bone damage using newer and more sensitive analytical techniques.

The implications of silicon in collagenesis and bone formation are unclear. Although silicon is regarded by some regulatory authorities as an essential trace element, published views on its biochemical role in the body are based on research conducted 50 years ago (Carlisle, 1982; 1988; Lansdown and Williams, 2007). Presently, although nutritionists list silicon as a trace metal, accurate daily requirements are not known. A second contentious nutrient is strontium. Daily requirements for human health are not documented and its role in bone metabolism is equivocal. Interestingly, a strontium salt (strontium ranelate) (Protelos®, Servier Laboratories Ltd.) is listed as a therapeutic means of reducing bone resorption in patients with postmenopausal osteoporosis and to reduce the risk of vertebral injury and hip fracture (BNF, 2007).

Review of the literature suggests that the full extent of toxic injury to bone and cartilage is not fully appreciated and that information is widely scattered and incomplete. Whilst it is common practice to analyse skeletal growth and development in teratological studies by alizarin-staining techniques, structural and functional damage in bone and cartilage in medium to long-term toxicological studies is rarely analysed. Histological examination in representative long bones will show up evidence of osteoid resorption or rarefaction in cartilage and bone matrix, as characterized by parathyroid disease or hypovitaminosis D, but more subtle changes in mineral content are not appreciated other than through bone ashing and analytical studies using atomic absorption spectrometry. This suggests that guidelines in routine toxicological investigation might be revised as and when biochemical evidence suggests that an environmental substance is likely to target bone or bone mineral metabolism.

Clinical studies of cartilage and bone largely concentrate on age-related and genetically induced deformities and implications of hormonal changes leading to osteoporosis. Development of thyrocalcitonin-like drugs to alleviate reduction in bone mass in conditions like Paget's disease is ongoing, and therapies including salcatonin (a synthetic or recombinant salmon calcitonin) have been introduced to lower plasma calcium levels in patients with hypercalcaemia or postmenopausal osteoporosis (BNF, 2007). Other drugs available include teriparatide (a recombinant form of parathyroid hormone) and cinacalcet (Mimpara®, Amgen Ltd.). A further category of therapies aimed at reducing bone mass include the bisulfonates, which are adsorbed to the hydroxyapatite matrix and act to stabilize the rate of bone growth and inhibit mineral turnover in osteoporotic states.

Studies of clinical bone disease and mechanisms of toxicology affecting skeletal tissue will continue to be of interest to palaeontologists studying the prevalence of diseases in ancient civilizations. Not only have the observations of ancient bones retrieved from the Qumran region near the Dead Sea revealed the dietary habits of people living in the area at the possible time of writing of the Dead Sea Scrolls, but they have helped to identify environmental conditions and prevalence of disease affecting bone at the time, as much as modern day orthopaedic clinicians and laboratory scientists (Steckoll *et al*., 1971). The red dye from the madder plant (Ca^{2+} *Rubia tinctorum*) is recorded as being one of the most important natural dyestuffs in the ancient Mediterranean region (Löw, 1924). Other analyses of ancient bones have illustrated patterns of exposure to toxic materials like lead and cadmium in early times. It is interesting to see from

Toxicology of the Endocrine System

Robert W. Kapp Jr. and John A. Thomas

CONTENTS

1 INTRODUCTION

Information flow which permits physiological responses between cells, tissues and organs is critical to survival and homeostasis of living organisms. The primary pathways for these physiological data are the nervous and endocrine systems. These pathways operate independently and cooperatively in many complex ways in order to optimize the organism's ability to function. The nervous system is usually directly connected to the affected organ and sends electrical impulses directly to the affected organ in much the same way a hard-wired landline telephone would send signals. The nervous system controls actions that need immediate attention and are rapid in nature, such as heartbeat, skeletal movements and breathing. The endocrine system is generally not directly connected to the affected organ and sends chemical messages over a distance as a mobile telephone would send and receive signals over a distance. The hormone gland produces a discreet chemical message that can be read by a specific chemical receptor in the regulated organ at some distance away, which switches a particular activity on or off. The endocrine system controls actions that are usually slower and are critical,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072

but do not need immediate attention, such as cellular growth and development and metabolism.

The concept of the distinction between endocrine and nervous system controls has become less rigid in recent years as we have gained knowledge about multicellular organism physiology. Over the years it has been shown that the chemical and nervous system control of bodily functions works in concert with the immune system to maintain a delicately balanced 'milieu intérior' or homeostasis (Kapp and Thomas, 2008). There are many areas of crossover, where both systems have some influence. For instance, important controlling endocrine glands, such as the hypothalamus, are derived from neural tissue. The hypothalamus produces antidiuretic hormone (ADH) and oxytocin and various hypothalamic releasing hormones—which are considered to be neural hormones, since the hypothalamus is derived from neural tissue. Also, the adrenal medulla is neurological in origin and its chromaffin cells produce norepinephrine (noradrenaline), which is chemically identical to the norepinephrine produced by nervous system transmitters. Catecholamine receptors located throughout the body in various tissues react the same to norepinephrine no matter where it originated. Further distinctions can be noted in the simple definition of a hormone as a substance produced by a ductless gland, secreted into the blood to be carried to some distant target to produce an effect. This is true for a vast majority of hormones, however, it is now known that some hormones act within the very tissue that they regulate and circumvent the need to move through the blood stream. Hormones that act upon the same secretory cells are termed autocrines while those that act upon adjacent cells are termed paracrines.

Hormones are very specific in nature binding to a specific receptor in much the same way a key fits into a lock. At any place and time there may be a multitude of hormones or 'keys' present at the location of the 'locks', but only one specific hormone fits and activates a hormone receptor. Therefore, even though hormones reach all parts of the body, only target cells with compatible receptors are equipped to respond. Once a receptor and a hormone bind, the receptor carries out the hormone's instructions, generally by altering the cell's existing proteins, building new proteins or turning off production of new proteins. These actions create hormonally mediated chemical reactions throughout the body and maintain internal stability for survival. The endocrine system regulates virtually all critical biological processes from conception through to old age, including, but not limited to, metabolism, development of the brain, nervous system, bone structure, reproductive glands, reproductive function, blood sugar levels, water and electrolyte balance, red blood cell production and control of functions such as circulation, digestion and adsorption.

Over 50 hormones have been specifically identified in mammals to date and there are probably others that have not yet been identified (US EPA, 2006). There are several categories of hormones, including bioamine-derived, polypeptides, proteins, steroids and fatty acids (Kapp and Thomas, 2008). These hormone classes differ in their general molecular structures, which changes their chemical properties in such a way as to affect whether or not the hormone can enter a target cell and how they can modulate the various activities of that cell. Steroid and fatty-acid molecules enter the target cell's cytoplasm or the nucleus by virtue of their compatible chemical properties. The subsequent hormone–receptor complex binds with the appropriate nuclear DNA and results in the regulation of specific hormone responsive genes. Bioamine-derived hormones are similar to some of the basic proteins and can enter the target cell, where they can interact with specific receptor proteins located at specific sites within the nuclear DNA. Polypeptide and protein hormones are chains of amino acids of varying length, which cannot enter the cell as previously described, but regulate the cellular activity by interacting with specific cell-surface receptors (Hiller-Strumhöfel and Bartke, 1998). Signal transduction by cell-membrane-bound receptors occurs either via intracellular second messengers (e.g. cyclic adenosine monophosphate (cAMP), calcium or phosphatidylinositol metabolites), or through mechanisms such as phosphorylation of serine, threonine or tyrosine residues of intracellular kinases and other enzymes (Leung and Steele, 1992).

2 CONTROL OF HORMONAL ACTIVITY

In order to maintain homeostasis, the mechanisms that control the production and secretion of hormones must be closely managed within a very tight range. To achieve this, many hormones are produced that not only regulate various metabolic functions, but regulate each other in complex negative feedback systems. Transport of hormones to target tissues can involve carrier plasma proteins such as sex-hormone-binding protein (SHBP) that specifically, and with high affinity, bind the hormone while it is transported through the circulatory system. These carrier proteins can be a limiting factor in that they often possess low capacities (Grishkovskaya *et al.*, 2000). Albumin, on the other hand, has a high capacity to bind hormones for transport, but has low specificity, hence limiting the transport of some biogenic amines, steroids, thyroid and some polypeptide hormones.

Once a hormone has been transported to the target by the carrier proteins, it must interact with the receptor at the target site to have a biologic effect. In order to have a biologic effect, the hormone must become unbound from the carrier protein. A bound hormone is not able to exert an effect at the receptor site, membrane surface or present in the cytoplasm. In order to permit exposure of the needed amount of hormone, there exists a delicate

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

equilibrium among the bound hormone (B), the plasma protein (P) and unbound or free hormone (F) which is expressed in the following equation (Porterfield, 2001):

$$F \times P = [B] = [F] \times [P] \div [B] \quad (1)$$

The free hormone is the critical moiety for activation, as well as for deactivation in feedback control. Although there is some evidence to suggest that hormonal receptor internalization may play a role in some processes, most polypeptide hormones interact with cell-membrane-surface receptors. In contrast, steroid and thyroid hormones interact with intracellular receptors. Transport into the cell may be aided by cell membrane transporters (e.g. megalin), and once inside the cell, the steroid or thyroid hormone receptor complexes are transported to the nucleus, where they may modulate gene expression by binding to certain DNA regulatory sequences.

Overall, the endocrine system utilizes two primary control systems to respond to physiological changes: (i) internal controls from the various concentrations of the hormones themselves and (ii) nervous system override of the self-regulating chemical system. The primary function of the nervous control override is to respond to external stimuli (e.g. fight-or-flight-type situations), which results in a hormonal readjustment. The continuous self-regulation is a complex physiologic hierarchy of chemically mediated controls which modulates the homeostasis of the endocrine system through a series of negative feedback loops, where the output of a hormone controls the input in a simple inverse relationship. As the concentration of the hormone increases in the system, the hormone itself decreases the call for the hormone, in much the same way as a thermostat regulates room temperature. As the temperature increases, the thermostat turns off the heating unit until the temperature drops to a predetermined point, whereupon the signal is once again sent to the heating unit to increase heat. In its simplest form, hormonal regulation is the involvement of a single endocrine gland, which is activated and deactivated as in this thermostat example. On the other hand, complex hormonal regulation is another level of control which includes the 'master endocrine gland' or anterior pituitary (adenohypophysis), as well as the target receptors. The anterior pituitary is frequently referred to as the 'master endocrine gland' because it controls a number of other glands and target cells throughout the body. For example, the anterior pituitary produces a number of hormones, including trophic hormones that regulate the activity of other endocrine glands such as thyroid-stimulating hormone (TSH), which regulates the thyroid gland, and adrenocorticotrophic hormone (ACTH), which regulates the adrenal cortex. Also included as trophic hormones are luteinizing hormone (LH) and follicle-stimulating hormone (FSH) which regulate the release of steroid hormone in the ovaries and testes and stimulate the maturation of eggs and sperm, respectively. The secretory releases of these endocrine glands feed back to decrease the hormonal releases of the previously noted hormones, thereby regulating the system to within a narrow range needed for normal homeostasis. A negative feedback loop inhibits an endocrine pathway whereas a positive feedback loop enhances or augments an endocrine response. Hence, the constant feedback from the target organ glands to the hypothalamus and pituitary ensures that the level of hormone governing hormonal activity remains within the boundaries necessary for homeostasis. Interestingly, these negative feedback boundaries can change at different physiological stages in life, thus creating varying sensitivities to hormone levels to permit—for instance—sexual maturation. On the other hand, positive feedback boundaries and sensitivities are altered in female menstrual cycles where increasing oestrogen levels temporarily stimulate, rather than inhibit, LH release from the pituitary and hypothalamus, resulting in enhanced oestrogen levels leading to ovulation, the formation of the corpus luteum and progesterone release. The general relationships within the adenohypophyseal-hypothalmic axis are depicted schematically in **Figure 1**.

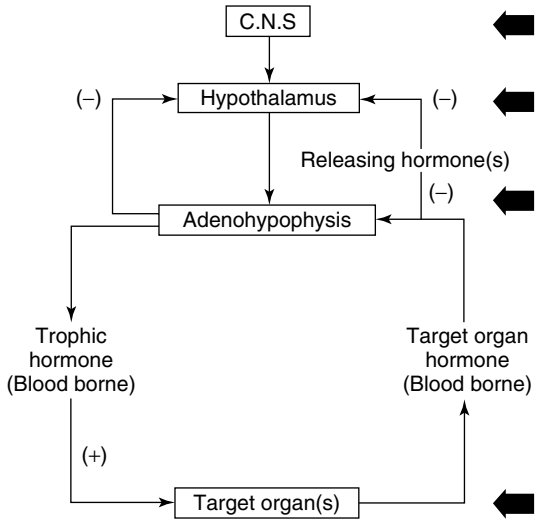

Figure 1 Hormonal feedback system between the adenohypophysis and endocrine target organs: (+) sign denotes hormonal stimulation, (–) sign denotes an inhibitory action and (←) arrows denote common sites of potential interference by toxic agents.

That the concentration of a hormone can be determined by three critical factors: (i) rate of production, (ii) rate of delivery and (iii) rate of elimination. The rate of hormone production is affected by many factors, and is controlled by feedback loops. Feedback loops can further be modulated by other endocrine systems that are pulsatile, cyclical or are stimulated through other mechanisms. The integration of various feedback loops gives rise to a complex cascade of endocrine

responses to particular stimuli. The rate of hormone delivery is affected by the rate of blood flow to the target receptor. Lastly, the rate of elimination is affected by two factors: (i) the body's ability to metabolize and excrete the hormone from the bloodstream and through renal elimination and (ii) the inherent physiological rate of degradation of the hormone. Some hormones have short biological half-lives while others have long biological half-lives. Protein binding can affect a hormone residence time in the blood. The constant feedback from the target organ glands to the hypothalamus and pituitary gland creates a steady state where the given hormone remains within appropriate boundaries. Therefore, the negative feedback system generally operates, whereby hormones that are released by the target organ glands reach a predetermined level, they essentially affect a cessation of hormone release by the hypothalamus or pituitary.

It has been shown that the physiological state of the organism can change the level of the hormone trigger or the sensitivity of the negative feedback system. For instance, sexual maturation occurs with the successive reduction in sensitivity of both the hypothalamus and the pituitary to the natural gonadal steroid hormones resulting in enhanced gonadal hormone release.

3 ENDOCRINE DISRUPTION

Some drugs and chemicals have been shown to affect the endocrine system in ways that can lead to metabolic disruptions, developmental anomalies and reproductive dysfunction (see **Endocrine Disruption in Toxic Responses**; Gornall *et al*., 1986; Thomas, 1996). An endocrine disruptor is defined as 'an exogenous agent that interferes with the production, release, transport, metabolism, binding, action or elimination of natural hormones in the body responsible for the maintenance of homeostasis and the regulation of developmental processes' (Kavlock, 1999; US EPA, 2008). With this recognition of the effects of oestrogen-like environmental chemicals in the environment, the potential for detrimental changes to the endocrine system in intact animals could be of considerable concern. These exposures could result in perturbations to the finely tuned endocrine system that could bring about changes in maturation, development and regulation of various critical bodily functions that would put the organism at risk for survival. It is believed that there are four categories of adverse effects that could be mediated by endocrine disruptors, including cancer, immunological effects, neurological effects, and reproductive and developmental effects (US EPA, 1996).

There appears to be ample evidence that endocrine disruptors have affected changes in laboratory animals, as well as selected animals in the wild such as birds, alligators and so on (Aulerich *et al*., 1973; Broley, 1958; Gilbertson *et al*., 1991; Guillette *et al*., 1995; Mason *et al*., 1986). The effects in humans have not been as clearly elucidated and are scientifically controversial (Kavlock, 1999). In a recent publication, the US Environmental Protection Agency (EPA) stated: 'The seriousness of the endocrine disruptor hypothesis and the many scientific uncertainties associated with the issue are sufficient to warrant a coordinated federal research effort' (US EPA, 2006). It is anticipated that future developments in endocrine disruption detection will include additional hormone assays that may be added to standard hormonal assays.

4 ENDOCRINE MODULATION

Specific target organs of the endocrine system in addition to the foetus and the neonate can by affected by external chemicals and drugs (Thomas, 1989). Many of these target organs are modulated by secretions from the anterior pituitary, which can also be perturbed by external chemicals. Various chemicals have been shown to be toxic to the female reproductive system and male accessory sex organs. Organs such as the thyroid gland, the adrenal gland, the testes, the ovaries and the pancreas can also be affected by certain external chemicals and drugs. Drugs and synthetic steroids have been shown to alter glandular internal secretions directly or by modifications in the level of trophic hormone secretion from the adenohypophysis. Unanticipated effects of drugs on an endocrine organ can interfere with the assessment of a diagnostic test. Approximately 90% of endocrine toxicities appear to occur in the adrenal gland, the gonads and the thyroid gland (Ribelin, 1984; Colby, 1988; Thomas and Thomas, 2000). Some endocrine target organs have specific localized cell populations that appear to be more susceptible to toxins than others and may lead to multiple changes in hormonal balance. Chemically induced modifications in pituitary function can affect target end-organs. Similarly, chemically induced changes in hepatic microsomal enzyme systems can alter the secretions of sex steroids (Thomas and Thomas, 2000).

Toxic effects on gonads and teratogenesis are important aspects of endocrine aberrations brought about by external chemicals and drugs (Thomas and Thomas, 2000). It has been shown that reproductive toxicity (see **Developmental Neurotoxicity**) and developmental toxicity (see **Developmental Toxicology**) often involve the endocrine system. It should be noted however, that there are other nonreproductive endocrine target organs that can be affected by external chemicals and drugs. Chemicals and drugs can adversely alter the thyroid, adrenals, testes, ovaries and pancreas internal secretions either directly with their internal secretions or by interfering with trophic hormone secretion by the adenohypophysis.

Table 1 Hormone assay and endocrine functions for the trophic hormones of the anterior pituitary gland and their respective hypothalamic releasing hormones

Adenohypophyseal trophic hormones		Hypothalamic releasing hor mones	
Abbreviation	Full identification	Abbreviation	Full identification
ACTH	Adrenocorticotrophic hormone	CRH	Corticotrophic-releasing hormone
		VP	Vasopressin
TSH	Thyroid-stimulating hormone	TRH	Thyrotrophin-releasing hormone
FSH	Follicle-stimulating hormone	FHR	Follicle-stimulating hormone-releasing hormone
LH	Luteinising hormone	LRH	Luteinizing hormone-releasing hormone
GH	Growth hormone	SRH,GRH	Somatotrophin-releasing hormone
		SRIF[a], GIH	Somatotrophin-release inhibiting factors
Prl	Prolactin	PIH	Prolactin-inhibiting hormone
		PRH	Prolactin-releasing hormone
MSH	Melanocyte-stimulating hormone	MRH	Melanocyte-stimulating hormone-releasing hormone
		MRIH	Melanocyte release-inhibiting hormone

[a]Somatostatin.
Source: Thomas and Thomas (2000).

Because of the fact that many chemicals can change the adenohypophyseal hormone releases, it is important to take that into account when assessing pituitary function. Drug-induced changes in pituitary function tests can lead to misinterpretations and therapeutic mistakes (Thomas and Thomas, 2000).

Chemically induced changes in sex steroids can affect pancreatic secretions of insulin. Stress results in an increased secretion of glucocorticoids and can also affect changes in insulin secretions and can affect a decrease in ACTH levels. The pituitary gonadotrophins FSH and LH can be altered by agents that act directly on the testes and the ovaries.

Some drug-induced changes in the endocrine system balance can be therapeutic, such as use of synthetic progestational steroids to suppress pituitary gonadotrophins, which affords millions of women with a chemical means of birth control. Similarly, the suppression of excessive endogenous hormone secretion can be exploited therapeutically, as in the case of synthetic adrenocorticoids reducing ACTH levels.

Insight into pituitary target organ feedback systems is of value when attempting to predict the effects of potentially toxic agents on specific endocrine target organs (Thomas and Keenan, 1986). Generally, chemically induced changes that affect pituitary/target organ relationships are seldom manifest after a single exposure to a toxic agent. Rather, compounds that can exert deleterious effects upon the endocrine system generally require longer exposure scenarios, usually coupled with repeated administrations. For instance, agents that cause hepatic microsomal enzyme induction usually require seven or more days of exposure before affecting a measurable change in the endocrine system.

Hormones of the adenohypophysis and their hypothalamic releasing hormones are shown in **Table 1**. The trophic hormones being released from the adenohypophysis are relatively high-molecular-weight substances that are frequently proteins or glycoproteins. These glycoprotein hormones are often involved in the modulation of metabolism and reproduction.

Other specific endocrine cell types found in the adenohypophysis are responsible for the synthesis of the trophic hormones such as corticotrophs (ACTH), gonadotrophs (FSH and LH), thyrotrophs (TSH), somatotrophs (growth hormone (GH)) and lactotrophs (prolactin (Prl)). It has been shown that there are a number of environmental factors which can affect hypothalamus activity, such as light, darkness, temperature variations and stress. These factors can produce either increases or decreases in trophic hormone secretions from the adenohypophysis, which include both long-loop hormonal feedback systems (i.e. individual target organ secretions) and short-loop feedback systems (i.e. the trophic hormone itself affects its own secretion by modulating hypothalamic or inhibiting factors (see **Figure 1**).

Chemicals, including certain classes of therapeutic drugs, can interfere with the release of trophic hormones

or can perturb their synthesis (Thomas and Thomas, 2000). Other agents exert inhibiting effects at various sites within the adenohypophyseal target-organ system, resulting in the inhibition of the biosynthesis of target-organ hormone secretions. The sensitivity of the each site of action varies depending upon the concentration and toxic moiety in play. For example, environmental stress can and does affect the secretory activity of certain hypothalamic releasing hormones, which subsequently alter pituitary–target-organ relationships. Rapidly dividing meiotic cells in the gonads are frequently more vulnerable to chemical changes than slower dividing somatic cells. Indirectly, some toxic agents are known to bind to circulating blood proteins, which results in alterations in the critical ratios of bound and unbound levels of target organ hormones, subsequently modifying the sensitive pituitary–target-organ relationship.

The physiological hierarchy that exists within the endocrine system is a series of complicated and interwoven feedback loops that constantly regulate each other. The feedback is the modulation of output by an end-product, such as a hormone or a metabolite. Other hormonal loops can be modulated leading to pulsatile, cyclic waves, such as hormonal diurnal rhythms. The integration of all these sundry feedback loops give rise to a complex cascade of endocrine responses which can be difficult to separate, but act in concert with one another to maintain homeostasis.

One of the complex feedback systems within the body is the hypothalamic-pituitary-adrenal (HTPA) axis. The HTPA axis is a complex set of direct influences and feedback interactions between the hypothalamus, the pituitary gland and the adrenal or suprarenal gland that controls reactions to stress and regulates an assortment of body processes, including digestion, the immune system, sexuality and behaviour. The paraventricular nucleus of the hypothalamus produces ADH (which is also known as vasopressin) and corticotrophin-releasing hormone (CRH). ADH is a water-conservation hormone and acts as an antidiuretic. It is released when the body is dehydrated and has significant water-conserving effects on the kidneys. It is also a potent vasoconstrictor. The release of CRH is affected by stress, the concentration of cortisol and also by the diurnal cycle. The level of cortisol rises quickly upon wakening. The concentration of cortisol peaks within an hour and then slowly drops over the course of the day until it stabilizes at its lowest concentration during the middle of the sleep cycle. Aberrations in the diurnal cortisol cycles have been associated with insomnia (Backhaus *et al*., 2004) and chronic fatigue syndrome (MacHale *et al*., 1998). Cortisol appears to act within the brain at mineralocorticoid and glycocorticoid receptors, as well as the hippocampus, which is an important controlling factor in the HTPA axis. CRH and ADH act synergistically to regulate the anterior pituitary by stimulating the secretion of ACTH from the corticotrope cells. ACTH in turn stimulates the secretion of glucocorticoids (primarily cortisol biosynthesis from cholesterol). The cortisol inhibits, via a negative feedback mechanism, both the hypothalamus and the pituitary gland, subsequently reducing the production of CRH and ADH. Interestingly, the local effects of cortisol include up-regulation of enzymes which are precursors to the synthesis of epinephrine (adrenaline) and norepinephrine, resulting in a positive feedback to the pituitary increasing the breakdown of proopiomelanocortins (POMCs) into ACTH.

Another feedback system is the hypothalamic-pituitary-thyroid (HPT) axis, which regulates metabolism via feedback loops between the hypothalamus, the pituitary and the thyroid gland. The hypothalamus senses low circulating levels of thyroid hormone and responds by releasing thyrotrophin-releasing hormone (TRH), stimulating the pituitary to synthesize TSH, which ultimately stimulates the thyroid to produce thyroid hormone. The thyroid hormone itself then turns off the production system at levels that are within the range sensed as normal by the hypothalamus.

The hypothalamic-pituitary-gonadal (HPG) axis is yet another feedback system that combines the effects of the hypothalamus, the pituitary gland and the gonads and is a critical part in the development and regulation of various organs, such as the reproductive and immune systems. The HPG axis is regulated normally through negative feedback by hydrophobic and hydrophilic hormones. Gonadotrophin-releasing hormone (GnRH) is secreted from the parvicellular neurons which ultimately reaches the anterior pituitary triggering the gonadotrophs to release LH and FSH. FSH and LH in turn act directly upon the gonads producing sex hormones. Hence, this hormonal release within the HPG axis is also a negative feedback mechanism between the hypothalamus, the pituitary and the gonads.

The classic concept of the endocrine system is that endocrine cells release a hormone that is transported to a receptor site in a target tissue, where the hormone binds to the receptor site and exerts a biological effect. Endocrine systems in general encompass those tissues that release a hormone that is transported through the bloodstream to a receptor cell in a target tissue. However, the advent of new techniques in tissue cell cultures and molecular biology has permitted the identification of several intercellular signalling pathways that do not transport hormones via the general circulatory system to the target tissue. Examples of paracrine systems are various growth factors and inflammatory mediators such as arachidonic acid metabolites, complement factors, cytokines, clotting factors and somatostatin. Examples of autocrine systems include cytokine interleukin-1 found in monocytes and peripheral membrane protein in T cells.

Many classification schemes have been devised for describing hormones. Some classify hormones by their

Table 2 Categories of hormones

Category	Example(s)
Biogenic amines	Epinephrine
Polypeptides	Thyroid-releasing hormone
Proteins	Insulin, growth hormone
Steroids	Oestrogens, androgens
Thyroid hormones	Thyroxine
Fatty acids	Prostaglandins

chemical source or according to their solubility characteristics, and others define hormones according to chemical composition (Baxter *et al*., 2004; Porterfield, 2001). One classification system that is recognized in the literature divides hormones into six general chemical categories, including biogenic amine hormones, polypeptide hormones, protein hormones, steroid/sterol hormones and fatty-acid hormones (see **Table 2**).

Bioamine-derived hormones include catecholamines such as epinephrine, norepinephrine, serotonin (indoleamine) and histamine (imidazoleamine). They are hydrophilic in nature and are similar to compounds found in the nervous system that can exert local effects in tissues. Biogenic amines are small, biologically active, modified single amino acids. They act primarily as neurotransmitters and are capable of affecting mental functioning.

Polypeptide hormones are short amino-acid chains, while protein hormones are composed of many amino acids and polypeptides together in a single molecule and are generally hydrophilic in nature. These types of hormones can range in length from three amino acids (e.g. TRH) to lengths of just under 200 amino acids (e.g. GH). They can be composed of two or more subunits (e.g. gonadotrophins) or may be linked by disulfide bonds (e.g. insulin). These hormones are synthesized in the endoplasmic reticulum.

Steroid/sterol hormones are derived from cholesterol, contain a skeleton with a cyclopentanoperhydrophenanthrene ring (four connected rings) structure and are hydrophobic in nature. Steroid hormones are generally synthesized in the adrenal cortex, the placenta and the gonads. Because they are fat soluble, these hormones can readily cross cell membranes and have intracellular receptors, which assist in the transport across the membrane. Once into the cytoplasm, steroid hormones bind to specific metalloprotein receptors forming a steroid–receptor ligand complex, which permits further migration into the nucleus. Upon penetration into the nucleus, the ligand complex binds to specific DNA sequences and induces transcription of its target genes. Examples of steroid hormones include the sex steroid hormones, corticosteroids, mineralocorticoids, vitamin D and retinoic acid. Recent evidence suggests that megalin, a member of the low-density-lipoprotein receptor superfamily of endocytic proteins, is a critical facilitator of steroid entry into cells (Birn *et al*., 2005).

Thyroid hormones are intermediate molecular-sized group of hormones that fall in between biogenic amine hormones, and short polypeptide hormones. Thyroxine (T_4) and triiodothyronine (T_3), are tyrosine-based hormones produced by the thyroid gland. Thyroxine contains four iodine atoms and is produced by attaching iodine atoms to the ring structures of tyrosine molecules. Thyroxine is converted to the active T_3 (three to four times more potent than T_4) within cells by deiodinases (5′-iodinase). The major form of thyroid hormone in the blood is thyroxine (T_4). The ratio of T_4 to T_3 released in the blood is roughly 20 to 1. The thyroid hormones are further processed by decarboxylation and deiodination to produce iodothyronamine (T_1a) and thyronamine (T_0a).

Fatty-acid hormones or eicosanoids are generally derived from polyunsaturated fatty acids such as linoleic acid and phospholipids, with the most prominent of these being arachadonic acid. Eicosanoids are made by oxygenation of 20-carbon essential fatty acids (EFAs)—either omega-3 ($\omega - 3$) or omega-6 ($\omega - 6$). They exert complex control over many bodily systems, mainly in inflammation or immunity. Other groups of hormones in the fatty-acid class include prostaglandins, prostacyclin, leukotrienes and thromboxanes, lipoxins, isoprostanoids and hydroxylated fatty acids (Soberman and Christmas, 2003). They are synthesized throughout the body and their primary effects are paracrine and autocrine in nature through both surface and nuclear receptors (Porterfield, 2001). These hormones are rapidly inactivated by being metabolized, and are typically active for only a few seconds.

5 BIOCHEMICAL ASSESSMENT

Assessing endocrine function is an important aspect of determining the mechanisms involved with endocrine toxicity. Measurement of hormonal metabolite levels in blood can reveal important information regarding the site of endocrine toxicity. Potential sites of toxicity include the site of hormone synthesis and release, the receptor site, the intracellular signalling pathway sites, the entire pathway of transport from the endocrine gland to the target cell, including the hormone carrier proteins and other factors which could alter the bound status of the hormone during transport and/or release.

Endocrine system evaluation may reveal much about the pathophysiology of endocrine toxicology, yet biochemical assessment methods have limitations when examining toxicological mechanisms. For example, perturbation of some factors within the specific endocrine mechanism being examined may not be detected by

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

simply measuring the level of circulating hormone. One can only get a macroscopic view of the toxic mechanisms in play due to the complex interplay of regulatory and counter-regulatory feedback loops, as well as a host of other variables, such as diurnal cycles, stress, changes in binding coefficients at carrier protein sites and changes in the physiology of intracellular signalling pathways (Gardner and Nissenson, 2004).

Until the 1960s, the measurement of hormones was limited to *in vivo* bioassays. An *in vivo* bioassay determines the biological activity of a hormone by noting its effect on a live animal or isolated organ preparation. Historically, bioassays have used hypoglycaemia to measure insulin, bone growth to measure GH and ovarian weight change to measure gonadotrophins. The primary drawbackof *in vivo* endocrine bioassays is that they are often difficult to quantify The discovery of monoclonal antibody techniques greatly enhanced the accuracy and methodology of measuring hormones. Subsequently, antibody-based competitive protein-binding assays such as radioimmunoassay (RIA) were developed with the availability of radioactive, or tracer hormones.

In vitro bioassays employ endocrine-responsive tissue-cell-culture lines that can assess the amount of biologically active hormone in sera. The hormonal activity of the sera can be determined by measuring a cellular response to a particular hormone. Hormonally induced changes in adenylate cyclase activity have been used, but more recently, changes in intracellular calcium levels, phosphoinositol metabolites and protein phosphorylation have been used to assess hormonal activity. Other *in vitro* bioassays can examine changes more distal to the receptor/signal-transduction mechanisms, and note changes in enzymatic activity or steroidogenesis. Finally, some *in vitro* bioassays can assess the mitogenic responses to a given hormone.

A problem with *in vitro* bioassays is that there may be coexisting stimulatory/inhibitory substances in the sera which can confound the observed response. For this reason, it is difficult to design a valid bioassay without using fractionated serum, which requires full characterization of an endocrine-responsive cell line.

5.1 Radioimmunoassay

With the development of the RIA, Yalow and Berson (1959) were able to measure nanomolar concentrations of hormones. Immunoassays are based upon the fact that specific proteins can distinguish three-dimensional structures at the molecular level by tightly binding to those specific molecules produced by a biological organism in a highly complex mixture, providing a means to measure these proteins in a controlled situation. The process involves mixing known quantities of radioactive antigen (frequently labelled with gamma-radioactive isotopes of iodine attached to tyrosine) with antibody to that antigen, then adding unlabelled antigen and measuring the amount of labelled antigen displaced. Initially, the radioactive antigen is bound to the antibodies. When unlabelled antigen is added, the two compete for antibody binding sites. The higher concentrations of unlabelled antigen bind to the antibody, displacing the radioactive variant. The bound antigens are subsequently separated from the unbound ones.

An RIA uses radioactive isotopes to identify these specific proteins. RIAs allow measurement of biological materials not previously detectable by chromatographic or spectrophotometric techniques (Krumm, 1994). They are also used for hormones that are unable to fix complement when bound to antibodies or they can be used to identify crossreacting antigens that compete and bind with antibodies.

Generally, RIAs are divided into two categories: competitive inhibition and noncompetitive inhibition. The competitive assays use a single specific antibody which is fixed to a surface and a corresponding analogue of the protein to carry the label. The protein in the sample competes with the labelled analogue for binding positions on the antibody. Once the unbound analogue is separated, the amount of label remaining is inversely related to the amount of bound protein. Competitive inhibition of radiolabelled hormone–antibody binding by unlabelled hormone (either as a standard or an unknown mixture) is the principle of most RIAs. A standard curve for measuring antigen (hormone) binding to antibody is constructed by placing known amounts of radiolabelled antigen and the antibody into a set of test tubes. Varying amounts of unlabelled antigen are added to the test tubes. Antigen–antibody complexes are separated from the antigen and the amount of radioactivity from each sample is measured to detect how much unlabelled antigen is bound to the antibody. Smaller amounts of radiolabelled antigen–antibody complexes are present in the fractions containing higher amounts of unlabelled antigen. Usually a standard curve is constructed that measures the percentage of radiolabelled antigen bound with the concentration of unlabelled antigen present. Competitive assays are compatible with a wide variety of proteins and are used for the majority of low-molecular-weight proteins.

Noncompetitive inhibition assays utilize two specific antibodies to 'capture' the protein being examined. One antibody (termed the *capture protein*) is immobilized to a surface and a second (termed the *label protein*) carries the label. In this assay, the protein being examined is bound simultaneously by both the capture and label proteins. At completion of the assay, the unbound label protein is separated and measured and the remaining label is measured and is directly proportional to protein concentration in the sample. Noncompetitive assays are generally limited to those proteins of sufficient size to

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be able to bind two materials simultaneously, typically proteins and microorganisms.

Although several methods exist for the separation of antigen–antibody complexes, two methods are most commonly employed in RIAs. These are the following: (i) The double-antibody technique, which precipitates the antigen–antibody complexes out of solution by utilizing a second antibody binding to the first antibody. Although other means of antigen–antibody precipitation exist, they can sometimes chemically alter antigen–antibody binding properties. The drawback to the double-antibody technique is expense, which makes this technique uneconomical for RIA screening procedures. (ii) The dextran-coated activated charcoal technique involves the addition of dextran-coated activated charcoal to the sample followed by immediate centrifugation that absorbs free antigen and leaves antigen–antibody complexes in the supernatant. This technique works best when the molecular weight of the antigen is 30 kDa or less. Also, sufficient carrier protein must be present to prevent adsorption of unbound antibody.

The RIA technique permits the determination of hormone concentration in a sample of protein or urine. Various factors, such as ionic strength and pH can affect the antigen binding and subsequent accuracy of the test, therefore controlled conditions are necessary when assessing the standard and the test sample. Other drawbacks to the RIA include the fact that some RIAs lack specificity, which is generally due to nonspecific crossreactivity of the antibody. Since the assays utilize radioactive materials, any laboratory performing RIAs must be regulated by the Nuclear Regulatory Commission (NRC). Notwithstanding the complexities associated with the RIA and monoclonal antibody methodologies, these are the techniques of choice in the examination of trophic hormones. RIAs are sensitive, requiring minute sample amounts compared to bioassays.

5.2 Enzyme-Linked Immunosorbent Assay (ELISA)

Because the radioactivity associated with RIA posed a health threat, a safer alternative was sought. A suitable alternative to RIA would substitute a nonradioactive signal in place of the radioactive signal. It was found that when certain enzymes (such as peroxidase) react with appropriate substrates (such as 3,3′,5,5′-tetramethylbenzidine), they can result in changes in colour, which can be used as a signal; however, the signal has to be associated with the presence of an antibody or antigen. Hence the enzyme has to be linked to an appropriate antibody. This linking process was independently developed by Stratis Avrameas and G.B. Pierce (Lequin, 2005). This development resulted in the enzyme-linked immunosorbent assay (ELISA), which produces an end-product that is nonradioactive and can be assessed with a spectrophotometer. This change eliminated the complex handling and disposal issues involved with radioisotopes, as mandated by the NRC for safety and control measures. ELISA is comparable to the immunoradiometric assay (IRMA), except that an enzyme tag is attached to the antibody instead of a radioactive label. The hormone is bound to the enzyme-labelled antibody, and the excess antibody is removed for IRMAs. Since it is necessary to remove any unbound antibody or antigen by washing, the antibody or antigen has to be fixed to the surface of the container, that is, an *immunosorbent* has to be prepared (Wide and Porath, 1966). After excess antibody has been removed, or the second antibody containing the enzyme has been added (two-site assay), the substrate and cofactors necessary are added in order to visualize and record enzyme activity. The level of hormone present is directly related to the level of enzymatic activity. The sensitivity of ELISAs can be enhanced by increasing the incubation time for producing substrate. Occasionally, the substrate formed may yield a colour change, so that detection of the hormone being measured can be determined visually.

5.3 Immunoradiometric Assays (IRMA)

IRMAs are similar to RIAs in that both use a radiolabelled substance in an antibody–antigen reaction. The radioactive label in the IRMA assay, however, is attached to the antibody instead of the hormone. This assay is based upon the reversible and noncovalent binding of an antigen by a specific antibody labelled with a radioisotope, and excess of antibody, rather than a limited quantity, is present in the assay. All the unknown antigen becomes bound in IRMA rather than just a portion, as in RIA; IRMA assays are more sensitive. There are basically two types of IRMA assays: (i) In the one-site assay, the excess antibody that is not bound to the sample is removed by addition of a precipitating binder. (ii) In the two-site assay, a hormone with at least two antibody-binding sites is adsorbed onto a solid phase, to which one of the antibodies is firmly attached (either the walls of the assay tube itself or to beads that are added to the biological sample in assay buffer). After binding to the antibody is completed, a second antibody labelled with ^{125}I is added to the assay. This ^{125}I antibody reacts with the second antibody-binding site composed of antibody-hormone-labelled antibody. In contrast to RIA and similar competitive protein-binding assays, the amount of hormone present is directly proportional to the amount of radioactivity measured in the assay (Bennett and Cells, 1992; Dumon *et al.*, 1996).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

5.4 Enzyme-Multiplied Immunoassay Technique (EMIT)

The enzyme-multiplied immunoassay technique (EMIT) is a type of immunoassay in which the ligand is labelled with an enzyme replacing the radiolabels, and the enzyme–ligand–antibody complex is enzymatically inactive, allowing quantitation of unlabelled ligand. The antibody binding alters the enzyme characteristics, allowing for measurement of hormone without separating the bound and free components (i.e. homogeneous assay). EMIT assays are used in drug monitoring of urine, but because of lack of sensitivity have not been used to assess hormones. No extraction is required and the assay can be completed within a few minutes (Foltz *et al*., 1980). The enzyme is attached to the hormone/drug being tested. This enzyme-labelled antigen is incubated with the sample and with antibody to the hormone/drug. Binding of the antibody to the enzyme-linked hormone either physically blocks the active site of the enzyme or changes the protein conformation so that the enzyme is no longer active. Once antibody binding occurs, the enzyme substrate and cofactor are added and enzyme activity can be measured. If the sample contains hormone or drug, it will compete with enzyme-linked hormones for antibody binding, the enzyme will not be blocked by antibody, and more enzyme activity will be measurable (Johnson, 1988).

5.5 Monoclonal Antibodies (mAb)

Monoclonal antibodies (mAb or moAb) are antibodies that are identical because they are produced by one type of immune cell that are all clones of a single parent cell. Given most any substance, it is possible to produce antisera containing a variety of polyclonal antibodies to create monoclonal antibodies that specifically bind to that substance. These monoclonal antibodies can then serve to detect or purify that substance. This has become an important tool in biochemistry, molecular biology and medicine. Many hormones can now be assessed using monoclonal antibody techniques. Antibodies against hormones have been used in many types of RIAs and radioreceptor assays; but polyclonal antisera can create some nonspecificity problems, such as cross-reactivity and variation in binding affinity. Therefore, it is desirable to produce a group of antibodies that selectively bind to a specific region of the hormone (i.e. antigenic determinant). In the past, investigators produced antisera to antigenic determinants of the hormone by cleaving the hormone and immunizing an animal with the fragment of the hormone containing the antigenic determinant of interest (e.g. ACTH immunization with the 24 amino-acid N-terminal of the hormone). This approach solved some problems with crossreactivity of antisera with other similar antigenic determinants, but problems were still associated with the heterogeneous collection of antibodies found in polyclonal antisera.

A process of producing monoclonal antibodies involving human–mouse hybrid cells was first described by Schwaber and Cohen (1973) and the process was further developed by Georges Köhler and César Milstein (Köhler and Milstein, 1975). The concept was to use a line of myeloma cells that had lost their ability to secrete antibodies, fuse these cells with healthy antibody-producing B-cells and select for the successfully fused cells. Because propagation of a single antibody-producing cell *in vitro* does not occur, Köhler and Milstein used spleen cells from an immunized mouse and fused them with myeloma cells (malignant lymphocytes) in the presence of a reagent that causes the cells to fuse (e.g. Sendai virus of polythylene glycol). The fused cells or hybridomas share characteristics of their antibody-producing cells from the spleen by continuously synthesizing identical antibodies and could be infinitely propagated *in vitro* using tissue-culture techniques. The production of monoclonal antibodies offered investigators a homogeneous collection of antibodies that could selectively bind to a specific antigenic determinant with the same affinity.

Further complications arise because unfused spleen cells do not survive in tissue culture media. To separate unfused myeloma cells from hybridomas, the cells are placed in hypoxanthine, aminopterin and thymidine (HAT) medium. Myeloma cells used in the production of monoclonal antibodies lack the enzyme hypoxanthine-guanine-phosphoribosyltransferase (HGPRT), whereas hybridomas contain the enzyme (contributed by fused spleen cells). Because the main pathway of DNA synthesis is blocked by aminopterin, only cells containing HGPRT can utilize hypoxanthine and synthesize DNA in order to propagate. Thus, unfused myeloma cells are eliminated in HAT medium because they lack HGPRT. Once the hybridomas have been isolated from unfused cells, they are separated into individual colonies and the type of antibody they produce is characterized. Identification of a hybridoma clone that is producing a specific antibody to the antigen of interest allows for harvesting large quantities of the monoclonal antibody. While monoclonal antibodies offer a highly sensitive, specific method for detecting antigen, sometimes increasing monoclonal-antibody specificity compromises affinity of the antibody for the antigen. Monoclonal antibody techniques provide a means of producing a specific antibody for binding antigen. This technique is useful for studying protein structure relations and has been used for devising specific RIAs.

5.6 Gene Expression

Gene expression is the process in which the inheritable information in the DNA sequence in a gene is made into a gene product, for example, protein or RNA. Several steps in the gene expression process may be modulated, including the transcription step and the post-translational modification of a protein. The effect of an endocrine modulator or disruptor can influence gene expression via transcriptional control. By increasing or decreasing the rate of gene transcription it is possible to modify gene expression and by quantitating the amount of messenger ribonucleic acid (mRNA) for a given gene, it is possible to measure the effect on transcriptional gene expression (Shupnik, 1995). Since mRNA represents a relatively small fraction of RNAs in the cell, methods have been developed which are sensitive and specific for detecting changes in mRNA levels and can distinguish between transfer ribonucleic acid (tRNA) and ribosomal ribonucleic acid (rRNA).

Suppression (or suppressive) subtractive hybridization (SSH) is a technique that uses the polymerase chain reaction (PCR) to quickly compare the expression of mRNA from different samples, which can show the relative difference in the concentration of these molecules and can be used to identify mRNAs that are differentially expressed between tissue or cell types under different hormonal or environmental conditions (Sambrook *et al*., 1989; Munir *et al*., 2004). SSH is a method which allows for the rapid isolation of differentially distributed nucleic acids, where the substrates in the process are nucleic acids (tester component) which contain specifically expressed sequences that are to be extracted (target component) and nucleic acids that are utilized for comparison of the target molecules (driver component). The tester is subsequently combined with the driver to form a 'tester–driver' hybrid which is the nontarget component. 'Tester–tester' hybrids and single-stranded tester molecules are also formed, which represent the fractions amplifying the target molecules. After completion of hybridization, the target and nontarget fractions are separated and quantified.

5.7 Polymerase Chain Reaction

The PCR is another molecular biology technique for enzymatically replicating specific regions of DNA or complementary DNA (cDNA) template without using a living organism. PCR is thought to have been conceived by Mullis in 1983. The technique allows a small amount of the DNA molecule to be amplified many times by using a pair of oligonucleotide primers (usually ranging from 10 to 40 kb in length, flanking a DNA sequence of interest—approximately 100–500 kp in length), a thermostable DNA polymerase (an enzyme that catalyses the elongation of DNA from a template) and deoxynucleotide triphosphates (dNTPs, reaction buffer and magnesium (Innis *et al*., 1990). Oligonucleotide primers are first designed to be complementary to the ends of the sequence to be amplified, and then are mixed in molar excess with the DNA template and deoxyribonucleotides in a buffer. Following heating to denature the original strands and cooling to promote primer annealing, the oligonucleotides each bind to a different strand of the target fragment. The primers are positioned so that when each is extended by the action of a DNA polymerase, the newly synthesized strands will overlap the binding site of the opposite oligonucleotide. The cycles of PCR are performed in a machine called a *DNA thermal cycler*, which can be adjusted to optimize the amplification of DNA, depending on a number of variables (e.g. the length and nature of the DNA sequence, the source and quality of the DNA template, and the application of the procedure by heating and cooling the internal reaction tubes within a precise temperature range for each reaction step). DNA templates can be derived from genomic DNA (e.g. human, animal, bacterial or viral), or RNA that has been converted to a DNA template using reverse transcriptase (reverse transcriptase polymerase chain reaction (RT-PCR)). PCR can be employed to detect mRNA for hormones, growth factors, polypeptides, receptors and other proteins involved with the endocrine system.

5.8 *In Situ* Hybridization and Immunochemistry

In situ hybridization (ISH) is a type of hybridization that uses a labelled complementary DNA or RNA strand or probe (a fragment of DNA of variable length usually 100–1000 bases long, used to detect the presence of nucleotide sequences in DNA or RNA samples that are complementary to the sequence in the probe) to localize a specific DNA or RNA sequence in a portion or section of *in situ* tissue. Tissue samples are treated to increase permeability, permitting the desired probe to enter the cell. The samples are fixed, embedded and thinly sectioned prior to hybridization. Hybridization is permitted at elevated temperatures and then the excess probe is removed. A complementary probe is labelled, thus permitting the precise location and quantification of the probe remaining in the tissue. Other methods of signal detection include fluorescence (e.g. fluorescent *in situ* hybridization (FISH)). FISH is a cytogenetic technique used to detect and localize specific DNA sequences on chromosomes. Fluorescence microscopy is utilized to localize specific DNA sequences on chromosomes. For instance, a probe is constructed and is tagged with fluorophores with specific targets. The preparation is embedded and subsequently examined under the fluorescence microscope. Low abundance mRNAs can

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be detected by *in situ* PCR, which amplifies the amount of nucleic acid target in the tissue. This technique is useful for detecting hormone or receptor subtypes that are biologically unique, by combining immunogenic features with related biological molecules.

Immunochemistry is a process of detecting and localizing synthesized proteins in cells of a tissue section utilizing antibodies (Watkins, 1998; Ramos-Vara, 2005). The antibody is tagged with a colour-producing tag. Primary monoclonal or polyclonal antibodies are then visualized with a secondary marker, such as fluorochrome-conjugated secondary antibody or streptavidin-biotin labels. Selection of a fluorochrome depends on microscopy wavelength and filters, the stability of the signal, the type of the tissue being examined and whether there is a need for double-labelling. This technique is widely used in basic research to help characterize the distribution and localization of biomarkers in different parts of a tissue. Immunohistochemical detection of tissue antigens often lacks a degree of sensitivity.

The *indirect method*, on the other hand, involves an unlabelled primary antibody (first layer) which reacts with tissue antigen, and a labelled secondary antibody (second layer) which reacts with the primary antibody. This method is more sensitive due to signal amplification through several secondary antibody reactions with different antigenic sites on the primary antibody. The second layer antibody can be labelled with a fluorescent dye or an enzyme.

Some markers are known for specific cancers such as CEA (carcinoembryonic antigen) (Hammarstrom, 1999), which is used for identification of adenocarcinomas. CD15 has been identified as a marker for Hodgkin's disease (Xue *et al*., 2000). Another useful marker is CD117 which is also called KIT or the C-kit receptor. CD117 is a marker for gastrointestinal stromal tumours (GISTs) (Edling and Hallberg, 2007).

Immunohistochemistry can be a powerful complement to ISH, but it has limitations, such as a lack of antibody specificity, denaturation of the antigen during fixation and cell membrane permeability.

5.9 Signal Transduction

Signal transduction refers to any process by which a cell converts one kind of signal or stimulus into another type of signal. Most processes of signal transduction involve an ordered sequence of biochemical reactions inside the cell, which are carried out by enzymes which are activated by second messengers and result in a signal-transduction pathway. These processes can last only a few milliseconds, as in the case of ion flux, or for hours or even days relative to gene expression. The number of proteins and other molecules that are involved in the signal transduction increases as the process emanates from the initial stimulus, resulting in a signal cascade which begins with a relatively small stimulus that elicits a large response. This is referred to as amplification of the signal. Besides affecting hormone receptor activation, some compounds can inhibit inactivation of signal-transduction pathways, such as phosphodiesterase inhibitors like caffeine and theophylline. Sildenafil and tadalafil are selective inhibitors of Type V phosphodiesterase, which degrades the cyclic guanosine monophosphate (cGMP) in the corpus cavernosum leading to vascular engorgement in erectile dysfunction (Francis and Corbin, 1999).

Most signal transduction involves the binding of extracellular signalling molecules (or ligands) to cell-surface receptors that face outward from the plasma membrane and trigger events inside the cell. It has also been shown that intracellular signalling cascades can be triggered through cell-substratum interactions, as in the case of integrins, which bind ligands that occur in the extracellular matrix. Steroids are another example of extracellular signalling molecules that may cross the plasma membrane due to their lipophilic or hydrophobic nature (Beato *et al*., 1996). After binding to their receptors, some of the hormones can act to promote steroid-responsive genes (Hammes, 2003). Within multicellular organisms, there are many small molecules and polypeptides that coordinate a cell's individual biology as it relates to the maintenance and survival of the organism as a whole. These molecules can be classified as follows: hormones Sugden *et al.* (2004), growth factors (Carpenter and Cohen, 1990), extracellular matrix components (Rensing, 1972), cytokines (Schroder *et al*., 2004), chemokines (Chung *et al*., 1995), neurotransmitters (Kistler *et al*., 1982) and neurotrophins (Wiesmann and de Vos, 2001). Hormones are a generic class of molecules able to initiate signal transduction, these include insulin (a polypeptide), (Adams *et al*., 2000), testosterone (a steroid) (Roy and Chatterjee, 1995) and epinephrine (an amino acid derivative; in essence, a small organic molecule) (Small *et al*., 2003). Common endocrine signal-transduction mechanisms include activation of cyclic AMP, activation of cGMP, activation of serine, tyrosine and threonine kinases, activation of phosphoinositides, release of intracellular calcium and control of receptor-operated ion channels.

In multicellular organisms, many different signal-transduction processes are required for coordinating the behaviour of individual cells to support the function of the organism as a whole. Sensing of both the external and internal environments at the cellular level relies on signal transduction. Many disease processes, such as diabetes, heart disease, autoimmunity and cancer, arise from defects in signal-transduction pathways. Environmental stimuli may be molecular in nature, as described above or more physical, such as light striking cells in the retina of the eye (Burns and Arshavsky, 2005), odorants

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

binding to odorant receptors in the nasal epithelium, (Ronnett and Moon, 2002) or bitter and sweet tastes stimulating taste receptors in the taste buds (Wong *et al*., 1996), further highlighting the critical importance of signal transduction to homeostasis in the multicellular organism. Cellular responses to extracellular stimulation that require signal transduction include activation of genes, (Lalli and Sassone-Corsi, 1994), alterations in metabolism and the stimulation or suppression of locomotion (Bornfeldt *et al*., 1995).

Receptors can be roughly divided into two major classes: (i) intracellular receptors which must cross the cell membrane to initiate signal transduction and (ii) cell-surface receptors which span the plasma membrane of the cell, with one part of the receptor on the outside of the cell (the *extracellular domain*), and the other on the inside of the cell (the *intracellular domain*). In this case the signal transduction occurs as a result of stimulatory molecule or the binding of a ligand to its extracellular domain; the ligand itself does not pass through the plasma membrane.

6 ENDOCRINE RECEPTORS

Many receptors for endocrine target organs are ligand-dependent transcriptional regulators that fall into the superfamily of proteins that include oestrogens, androgens retinoic acid, thyroid hormone and vitamin D. These hormones have a molecular weight between 300 and 400 Da and can permeate the cell's plasma membrane. Once inside the cell, these hormones bind to specific proteins in the cytoplasm or nucleus which are known as receptors. These intracellular proteins are specific for each protein and are concentrated at the appropriate endocrine target organ. Thus, male sex accessory organs, such as the prostate gland possess a high density of androgen receptors (ARs) while the female reproductive organs contain a high density of oestrogen receptors (ERs). The binding of the hormone to plasma receptor initiates a cascade of responses that will ultimately alter the activity of the target endocrine organ. This mechanism is termed the second-messenger hypothesis. In this hypothesis the hormone is the first messenger which contains certain information for the target organ receptor. The binding of the hormone subsequently interacts with other cellular components either to activate or suppress transcription of a target organ gene in a promoter and the cell-specific event. Sunderland discovered cAMP and showed that it had an intermediate role in many hormonal functions (Kresge *et al*., 2005). It appears that there are several types of receptors found in hormone regulation, including G-protein (guanine nucleotide-binding protein) receptors, ion channel receptors, receptors containing tyrosine kinase, receptors associated with tyrosine kinase, steroid receptors, ERs, ARs and thyroid receptors (TRs).

6.1 G-protein-coupled Receptors (GPCRs)

G-protein-coupled receptors (GPCRs), also known as seven transmembrane receptors (because they usually span the membrane seven times) or G-protein-linked receptors (GPLRs), comprise the largest protein family of transmembrane receptors that sense molecules outside the cell, and activate internal signal-transduction pathways and, ultimately, cellular responses. G-proteins were discovered by Alfred G. Gilman and Martin Rodbell in 1994 (Lodish *et al*., 2000). G-protein-coupled receptors function as chemical switches, alternating between an inactive guanosine diphosphate (GDP)- and active guanosine triphosphate (GTP)-bound state, ultimately regulating downstream cell processes. They are activated by an external signal in the form of a ligand or other signal mediator, which causes a conformational change in the receptor, causing activation of a G-protein to release GDP. This, in turn, causes the uptake of GTP, resulting in activation or deactivation of adenylyl cyclase, forming cAMP. The G-protein hydrolyses the GTP almost immediately, which then decreases the G-protein's affinity for the catalytic subunit and ends the cycle. Receptor-activated G-proteins are bound to the inside surface of the cell membrane. They consist of G_α and tightly associated $G_{\beta\gamma}$ subunits. There are four main families for G_α subunits: $G_{\alpha s}$, $G_{\alpha i}$, $G_{\alpha q/11}$ and $G_{\alpha 12/13}$. These groups differ primarily in effector recognition, but share a similar mechanism of activation.

$G_{\alpha s}$ stimulates the production of cAMP from adenosine triphosphate (ATP). The direct stimulation of the membrane-associated enzyme adenylate cyclase causes the cAMP to act as a second messenger that interacts with and activates protein kinase A (PKA). PKA can then phosphorylate downstream targets. $G_{\alpha i}$ inhibits the production of cAMP from ATP. $G_{\alpha q/11}$ stimulates membrane-bound phospholipase Cβ, which then cleaves phosphatidylinositol biphosphate (Pip2) into two second messengers, inositol triphosphate (ip3) and diacylglycerol (DAG). $G_{\alpha 12/13}$ are involved in Rho family GTPase signalling and control cell-cytoskeleton remodelling, therefore regulating cell migration. $G_{\beta\gamma}$ sometimes also have active functions, for example, coupling to L-type calcium channels (a type of voltage-dependent calcium channel) (Filmore, 2004).

6.2 Ion-Channel Receptors

Ion-channel receptors are regulated by ligands and are usually very selective to one or more ions, like Na^+, K^+, Ca^{2+} or Cl^-. Such receptors located at synapses convert the chemical signal of a hormone directly and very quickly into the receptors that regulate the flow

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of ions through specific channels in the membrane. The most common are calcium channels, for example the calcium-calmodulin system. Calcium/calmodulin directly activates calcium/calmodulin-dependent protein kinase I by binding to the enzyme and indirectly promotes the phosphorylation and synergistic activation of the enzyme by calcium/calmodulin-dependent protein kinase I kinase. In this system a hormone binding to the ion channel receptor opens the calcium channels permitting the calcium concentration to rise. Frequently calcium binds to calmodulin as it transits the membrane (Chin and Means, 2000).

6.3 Receptors Containing and Associated with Tyrosine Kinase

Receptors containing tyrosine kinase usually consist of ligand-binding domains containing a transmembrane receptor with a tyrosine kinase domain protruding into the cytoplasm. This receptor contains tyrosine kinase as an integral part of the receptor. When the activating hormone binds to the receptor, the tyrosine kinase is activated, resulting in two effects: autophosphorylation that can potentiate the signal and phosphorylation of the tyrosine residues on adjacent proteins, thereby regulating their activity.

Receptors associated with tyrosine kinase recruit to a receptor following hormone binding and are involved in a number of signalling cascades, principally those involved in cytokine signalling (Manning *et al*., 2002).

6.4 Steroid Receptors

Steroid hormone receptors are intracellular receptors (usually cytoplasmic) that create signal transduction for steroid hormones. Steroid hormone receptors are part of the nuclear receptor family that include a group of homologous structured receptors that bind to nonsteroid ligands such as thyroid hormones and vitamin A, as well as to vitamin D, and orphan receptors. Steroid hormones, such as the oestrogens, bind to receptors in the cell cytoplasm and are translocated to the nucleus, where they can activate a series of complex biochemical events. In most cases the uptake into the nucleus is covered up by heat shock proteins (HSPs) which bind the receptor until the hormone is present. Most inactive steroid receptors are sequestered in a complex with HSP90 (Smith and Toft, 1993). Steroid receptors are composed of six domains based upon amino acid similarity and mutational analysis (Ekena *et al*., 1996). The AB domain contains a hormone-independent transcriptional activating function, while the conserved C domain is the site of DNA binding. The D domain is a hypervariable region while the E and F domains are conserved ligand-binding domains of the steroid receptor.

6.5 Oestrogen Receptors (ERs)

The ER is a member of the nuclear hormone family of intracellular receptors which is activated by the hormone 17β-oestradiol (Dahlman-Wright *et al*., 2006). The main function of the ER is as a DNA-binding transcription factor which regulates gene expression. There are two different forms of the ER, usually referred to as α and β, each encoded by a separate gene. Oestrogen receptor α (ER-α), also known as NR3A1 (nuclear receptor subfamily 3, group A, member 1), is a nuclear receptor which is activated by oestrogen (Tanaka *et al*., 2003). The ER is a ligand-activated transcription factor composed of several domains important for hormone binding, DNA binding and activation of transcription. Oestrogen receptor β (ER-β), also known as NR3A2 (nuclear receptor subfamily 3, group A, member 2), is a nuclear receptor which is also activated by the sex hormone oestrogen (Koehler *et al*., 2005).

While the biological importance of the α and β ERs remains elusive, there do appear to be differences in their anatomical distribution. ER-α is expressed in the uterus, pituitary, gonads and selected other organs. ER-β is found in the lungs, bladder, brain, gonads and prostate. Both receptors have a high binding affinity for oestradiol and diethylstilboesterol. Both receptors will also bind to several weak oestrogens and other xenobiotics (Thomas, 1998). An E-screen assay (for oestrogenic activity) has been proposed using the MCF-7 human breast cell line (Soto *et al*., 2006). While the assay is fairly sensitive, it is not specific. Oestrogen structure–binding-affinity relationships and affinity-labelling and site-directed mutagenesis studies on ER α and β have provided more insight into the interaction between the receptor and the ligand (Anstead *et al*., 1997). The ultimate action of the ligand–receptor complex is endocrine modulation of the transcription of specific target organ genes.

6.6 Androgen Receptors (ARs)

The AR, also known as NR3 C4 (nuclear receptor subfamily 3, group C, member 4), is a type of nuclear receptor which is activated by binding of either of the androgenic hormones testosterone or dihydrotestosterone (Roy *et al*., 1999). The AR primary function is as a DNA-binding transcription factor which regulates gene expression (Matsumoto *et al*., 2007). However, the AR also has additional functions independent of DNA binding (Heinlein and Chang, 2002; Fix *et al*., 2004). Androgens mediate androgen-induced male sexual development and function (Zhou *et al*., 1994), and directly

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

regulate many biological processes, which are mediated by a nuclear receptor that exhibits four major activities, including steroid binding, DNA binding, transactivation and nuclear localization (Lindzey *et al*., 1994). The primary mechanism of action for ARs is direct regulation of gene transcription. When androgen binds to the AR, it affects a conformational change in the receptor causing dissociation of HSPs, dimerization and transport from the cytoplasm to the cell nucleus, where the AR dimer binds to a specific sequence of DNA known as a hormone response element. ARs interact with other proteins in the nucleus, resulting in increased or decreased regulation of specific gene transcription. Increased transcription produces more messenger RNA, ultimately increasing the production of the specific protein being regulated. ARs interact with certain signal-transduction proteins in the cytoplasm and can cause rapid changes in cell function independent of changes in gene transcription, such as changes in ion transport. Regulation of the signal-transduction pathways by these cytoplasmic ARs can indirectly lead to changes in gene transcription.

The AR can be studied using a three-dimensional quantitative structure–activity model that might be important for the identification of environmental contaminants with potential endocrine-disrupting properties (Waller *et al*., 1996). Thus, chemicals that have avidity for the AR can be identified for their toxicological potential upon the endocrine system.

6.7 Thyroid Receptors (TR)

The TR is a type of nuclear receptor that is activated by the binding hormone (Flamant *et al*., 2006). The TR plays critical roles in regulation of metabolism, heart rate and organism development (Yen, 2001; Harvey and Williams, 2002). TRs are transcription factors that regulate gene transcription either positively or negatively after binding thyroid hormones (e.g. thyroxine). TR interacts with transcriptional corepressors. There are three forms of the TR that are known to bind to the thyroid hormone, $\alpha 1$, $\beta 1$ and $\beta 2$:

1. TR-$\alpha 1$ (high expression in cardiac and skeletal muscles)
2. TR-$\beta 1$ (expressed in brain, liver and kidney)
3. TR-$\beta 2$ (expression limited to the hypothalamus and pituitary).

Certain mutations in the thyroid hormone receptor are associated with thyroid hormone resistance (Olateju and Vanderpump, 2006), which is a rare syndrome where the thyroid hormone levels are elevated, but the TSH level is not suppressed, or not completely suppressed, as would be expected. The most common cause is mutations of the β form of the thyroid hormone receptor, of which over 100 different mutations have been documented (Refetoff and Dumitrescu, 2007; Refetoff, 2008).

7 ENDOCRINE TARGET ORGAN TOXICITY

Perturbation of a target organ by a drug or chemical can be mediated through the central nervous system (CNS) by interfering with trophic hormone secretion or by a chemical or drug acting directly upon the particular target organ. Thus, there are both indirect (e.g. via the adenohypophysis) and direct-acting sites of action. In addition, hepatic microsomal enzyme systems responsible for endogenous steroid metabolism can also be affected by xenobiotics.

7.1 Adrenal Glands

The adrenal glands are located in the thoracic abdomen situated on their anterosuperior aspect of the kidneys. In humans, these glands are found at the level of the 12th thoracic vertebra and receive their blood supply from the adrenal arteries. They are responsible for regulating the stress response via the synthesis of corticosteroids and catecholamines. The adrenal glands are each separated into two distinct structures—the adrenal medulla and the adrenal cortex. The adrenal cortex and the adrenal medulla are a functional unit and together manifest a capacity to manage changes in both internal and external environmental conditions.

The adrenal medulla is the central core of the adrenal gland, surrounded by the adrenal cortex. The medulla consists of neurons that are part of the sympathetic branch of the autonomic nervous system and is chiefly populated with chromaffin cells, which are the source of the catecholamines, epinephrine and norepinephrine, fast-acting hormones that signal an immediate physiological change and are derived from the amino acid tyrosine. The medulla releases these neurotransmitters into the blood instead of at a synapse. Therefore, although it is part of the nervous system, the medulla functions as an endocrine gland. These chemicals are part of the fight-or-flight response initiated by the sympathetic nervous system. The adrenal medulla is also the main source of dopamine, which is a catecholamine closely related to epinephrine and norepinephrine that functions in the brain, including important roles in behaviour and cognition, motor activity, motivation and reward, inhibition of milk production, sleep, mood, attention and learning.

The adrenal cortex is located along the perimeter of the adrenal gland and manages stress responses at a slower pace through the production of mineralocorticoids and glucocorticoids, such as aldosterone and cortisol,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

as well as androgens from cholesterol (Pikuleva, 2006). The adrenal cortex is composed of three tissue layers. The external layer is termed the zona glomerulosa which secretes mineralocorticoids such as aldosterone as part of the renin-angiotensin system regulating the blood pressure. The intermediate layer is termed the zona fasciculata, and produces cortisol, which is involved in the response to stress, increases blood pressure, hyperglycemia and suppression of the immune system. The production of steroid hormones by the adrenal cortex is triggered by the secretion of ACTH by the anterior pituitary gland. These hormones act at the level of gene expression to affect fundamental biochemical processes. Mineralcorticoids affect the body content of sodium and potassium by acting on the kidney to promote the reabsorption of sodium ions (Na^+) into the blood. Water follows the salt and this helps maintain normal blood pressure. Glucocorticoids affect body fuel metabolism by stimulating gluconeogenesis in the liver: the conversion of fat and protein into intermediate metabolites that are ultimately converted into glucose. Cortisol and the other glucocorticoids also have an anti-inflammatory effect on the body by depressing the immune response—especially cell-mediated immune responses—hence they function to help the body respond to injuries.

The principal mineralocorticoid in humans is aldosterone although deoxycortisosterone exhibits mineralocorticoid activity. Cortisol, the major glucocorticoid produced in humans, has some mineralocorticoid activity. Aldosterone modulates body electrolytes and promotes the renal absorption of sodium in the ascending portion of the loop of Henle in the distal tubule and in the collecting tubule. Aldosterone facilitates the urinary excretion of potassium and hydrogen ions. Mineralocorticoid deficiencies produce a rise in extracellular fluid potassium concentration and reductions in sodium and chloride content, which can lead to diminished cardiac output and death.

Cortisol or hydrocortisone, corticosterone and cortisone display varying degrees of glucocorticoid activity. Cortisol is probably the most important human glucocorticoid. It is essential for life, and regulates or supports a variety of important cardiovascular, metabolic, immunologic and homeostatic functions. The glucocorticoids stimulate gluconeogenesis and decrease glucose utilization. Cortisol stimulates several processes that collectively serve to increase and maintain normal concentrations of glucose in blood. These effects include stimulation of gluconeogenesis in the liver, resulting in the synthesis of glucose from nonhexose substrates such as amino acids, and glycerol from triglyceride breakdown. It further mobilizes amino acids from extrahepatic tissues—which serve as substrates for gluconeogenesis (Freeman, 2004). Glucocorticoids appear to interfere with the transport of amino acids into extrahepatic cells and combined with continuing protein catabolism in these cells, results in an increase in plasma amino acids. This increase in plasma amino acids levels and their subsequent transport into the liver may promote gluconeogenesis. Cortisol also conserves glucose by inhibiting the uptake of glucose in muscle and adipose tissue. It also stimulates the fat breakdown of adipose tissue. The fatty acids released by lipolysis are used to produce energy in muscle, while the released glycerol provides additional substrate for gluconeogenesis. In many steroidogenic cells, these responses often arise from the stimulation by an appropriate trophic hormone acting through the cyclic AMP second-messenger signalling pathway. The focus for this acutely regulated step in steroidogenesis appears to be determined by the transfer of the substrate cholesterol to the inner mitochondrial membranes. Cholesterol needs to be transferred from the outer mitochondrial membrane to the inner membrane where cytochrome P450scc enzyme is located, to split off the cholesterol side chain, which is the first enzymatic step in steroid synthesis. The aqueous phase between these two membranes cannot be crossed by the lipophilic cholesterol, unless certain proteins assist in this process, which is primarily mediated by the action of a steroidogenic acute regulatory protein (StAR) on the peripheral benzodiazepine receptor (PBR), causing the movement of Cl^- out of the mitochondria, bringing the outer and inner mitochondrial membranes together. The StAR is a transport protein that regulates cholesterol transfer within the mitochondria, which is the rate-limiting step in the production of steroid hormones (Alpy and Tomasetto, 2006; Stocco *et al.*, 2005).

7.1.1 Toxicological Effects

The adrenal cortex is vulnerable to chemical lesions because the adrenal cortical cells contain a high concentration of lipid cells which are used as substrate in the production of steroid hormones. The lipophilic toxic compounds tend to accumulate in these lipid-rich cells of the adrenal cortex. Additionally, the adrenal cortical cells contain many enzymes (e.g. cytochrome P450 family) which can metabolize these xenobiotic compounds. These compounds result in direct toxic effects by covalent interactions with macromolecules or via oxygen activation generating free radicals (Capin, 2008). Many substances can cause lesions in the adrenal gland (See **Table 3**). Such lesions may be localized and in specific areas of the gland. Chemically induced changes can cause specific biochemical changes. Carbon tetrachloride causes adrenocortical necrosis, but its site of toxicity is in the zona reticularis which is the innermost layer of the adrenal cortex. Spironolactone, a mineralocorticoid antagonist, causes functional lesions in the zona fasciculata which is directly on top of the zona reticularis. Dichlorodiphenyltrichloroethane (DDT) metabolites (e.g. 3-methylsulfonyl-1,1-dichloro-2,2-bis (*p*-chlorophenyl) ethylene (3-methylsulfonyl-DDE))

Table 3 Agents known to cause lesions to the adrenal gland

Adrenal cortex	Adrenal medulla
Adriamycin	Acrylonitrile
Aminoglutethimide	ACTH
4-Aminopyrazolo (3,4-d)pyrimidine	Alloxan
Cadmium	Blocadren
Carbon tetrachloride	Chlordecone
Chloramphenicol	*o*-Chlorobenzylidine
Chlordane	Cysteamine
Chloroform	Dichloromethane
Chlorphentermine	7,12-Dimethyl-benzanthracene
Chlorpromazine	Oestrogens
Copper	Growth hormone
Cyclosporin	Interleukin-2
Cyproterone	Lactitol
o,*p*′-DDD	Lactose
Danazol	Malathion
Dichlorvos	Mannitol
7,12-Dimethyl-benzanthracene	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyrine (MPTP)
Etomidate	Neuroleptics
5-Fluorouracil	Nicotine
Kepone	Pyrazole
Ketoconazole	Reserpine
Nicotine	Retinol acetate
Phenobarbital	Sorbitol
Polychlorinated biphenyls	Thiouracil
Spironolactone	TSH
Tamoxifen	Thyroid hormones
TCDD	1,1,2-Trichloroethane
Tetrahydrocannabinol	Xylitol
Toxaphene	

Source: Kapp and Thomas (2008); Colby and Longhurst (1992) and Thomas and Keenan (1986).

exert their adrenotoxic effects by specifically binding to a nonextractable residue in the zona (Colby and Longhurst, 1992; Colby *et al*., 1996; Lindhe *et al*., 2002). Hexadimethrine bromide causes toxic damage to the zona glomerulosa, which is the most superficial layer of the adrenal cortex, lying directly beneath the adrenal gland's capsule, and ischaemic necrosis of the zona fasciculata and reticularis.

Acrylonitrile produces adrenal necrosis in experimental animals (Szabo and Sandor, 1997). The acute adrenocorticolytic effect of a single exposure to acrylonitrile rapidly causes adrenal haemorrhage and necrosis. Interestingly, cysteamine and pyrazole produce quantitatively similar lesions to those produced by acrylonitrile. Repeated injection of 7,12-dimethylbenz[a]anthracene (DMBA) produces mammary tumours in experimental animals and results in slow progressive adrenal necrosis (Fu *et al*., 2005). In contrast to the single dose administration of other adenocorticolytic agents (e.g. acrylonitrile and cysteamine), multiple injections of thioguanine are necessary to produce haemorrhagic necrosis of the adrenal cortex.

Chemicals may directly or indirectly affect adrenal cortical secretions. It has been shown that the response of the adrenal gland to ACTH may be compromised by chemically induced changes in membrane receptors, cyclic nucleotide levels, protein synthesis and other biochemical processes involved in stimulating steroidogenesis. Changes in biochemical processes in adrenal cortical secretions produced by chemicals can be mediated by several different mechanisms. The adrenal cortex is highly vascularized, and has a high concentration of cytochrome P450 and lipids providing a milieu conducive to assimilating and sequestering fat-soluble toxins. Xenobiotics can undergo detoxification during metabolism, resulting in potentially more toxic intermediates and may contribute to the overall toxicological actions of a compound. Differences in adrenal metabolism of xenobiotics among species may account for some differential toxicity noted among various chemicals. Hence, the adrenal xenobiotic-metabolizing P450 isoenzymes may also contribute to the overall toxicological actions of a compound. Triaryl phosphates (e.g. tricresyl phosphate (TCP) and butylated triphenyl posphate (BTP)) cause inhibition of cholesterol ester hydrolase. Cholesterol acyltransferase inhibitors are also adrenotoxic. Agents that inhibit acyl-CoA:cholesterol acyltransferase, an enzyme that catalyses the esterfication of cholesterol have cytotoxic action on the adrenal gland (Chang *et al*., 2006).

7.2 Gonads

The gonads include the ovaries and testes and provide two major functions: (i) each produces germ cells or gametes (e.g. spermatozoa in the testes and ova in the ovaries; (ii) the gonads synthesize steroid sex hormones which are critical for the development and functioning of the reproductive organs. In addition these hormones produce secondary sex characteristics such as facial hair in males and breast development in females. There are three basic types of sex hormones: (i) oestrogens (e.g. oestradiol) which produce feminizing effects; (ii) progestogens (e.g. progesterone) that prepare and maintain the uterus for pregnancy and (iii) androgens (e.g. testosterone) which

produce masculinizing effects. In addition to these basic reproductive functions, these sex hormones are active in other critical bodily functions, such as carbohydrate and lipid metabolism, bone growth and the cardiovascular system.

7.2.1 Ovaries

In females, the ovaries are located internally on the posterior wall of the pelvis lateral to the position of the uterus. They are structurally supported by three ligaments—the suspensory ligament, the broad ligament and the ovarian ligament. The ovaries are in close proximity to the fallopian tubes, which participate in the reproductive process by transporting the ovum from the ovary to the uterus. Hormonal modulation of the female reproductive system is quite complex and involves many neuroendocrine factors and hormones that act in concert to produce mature gametes. Hormone modulation incorporates a series of cyclic events and is influenced by the adenohypophysial-hypothalamic-gonadal axis. Successful reproduction in the female depends upon highly coordinated actions of numerous biochemical processes, including gametogenesis, sperm–ovum interactions and the processes of implantation, embryo development and parturition. The ovaries, not only produce eggs for reproduction, but also secrete female sex hormones. Ovarian function is dependent upon the stimulatory effects of the FSH and LH. These two hormones are secreted from cells in the anterior pituitary called gonadotrophs. Most gonadotrophs secrete only LH or FSH, but some appear to secrete both hormones. FSH regulates the development, growth, pubertal maturation and reproductive processes of the human body. FSH initiates follicular growth which affects the granulosa cells. There is a concomitant rise in inhibin B, and FSH levels then decline in the late follicular phase. At the end of the luteal phase, there is a slight rise in FSH that seems to be of importance to start the next ovulatory cycle. Ovulation of mature follicles on the ovary is induced by a large burst of LH secretion known as the preovulatory LH surge. Residual cells within ovulated follicles proliferate to form corpora lutea, which secrete the steroid hormones progesterone and oestradiol. Progesterone is necessary for maintenance of pregnancy, and, in most mammals, LH is required for continued development and function of corpora lutea. The main role of the oestrogens is to coordinate the normal development of the female genitalia and breasts. As females move through adolescence, oestrogens promote the growth of the uterus, vagina and breasts. In addition oestrogens determine the pattern of fat deposition throughout the body, which results in the typical female shape. In the adult female, the primary functions of oestrogens include regulation of the menstrual cycle and control of libido. During pregnancy oestrogens also contribute to the regulation of lactation.

Progestogens are also produced by the ovaries during various phases of the menstrual cycle as well as during pregnancy. In preparation for pregnancy, progestogens cause changes in the uterine lining and promote development of the mammary glands in preparation for lactation.

7.2.1.1 Toxicological Effects

The ovaries are a target organ for chemical injury (Mattison *et al*., 1990). Granulosa cells, which form a single layer around the oocyte, produce steroids and many growth factors, which interact with the oocyte during development. FSH stimulates these cells to convert thecal cell androgens to oestradiol with aromatase. In addition, post ovulation, the granulosa cell produces progesterone which assists in pregnancy maintenance. These granulosa cells also possess many sites of vulnerability to chemical or heavy metal insults. Agents that are gonadotrophin antagonists can injure gonadotrophin receptors or can interfere with receptor activity. The thecal cells may also be targets for chemical or heavy metal injury (Chrysikopoulos, 2000). Agents that impair cell proliferation, migration and communication may affect thecal cell function; however, there is a paucity of data about thecal cell vulnerability to chemical insults. Oocytes are similarly vulnerable to chemical injury, especially by lead, cadmium and mercury (Mattison *et al*., 1990). In general, heavy metals have been shown to affect ovarian function (Thomas and Thomas, 2000).

During menopause, oestrogen production from the ovaries is eventually terminated, which can result in various symptoms, such as hot flushes, heart palpitations, anxiety, depression and osteoporosis. Hormone replacement therapy (HRT) involves the medical management for treatment for surgically menopausal, perimenopausal and postmenopausal women, which is based upon the assumption that this therapy may prevent discomfort and health problems caused by diminished circulating oestrogen and progesterone hormones. The treatment generally involves a series of drugs designed to artificially boost hormone levels to help prevent some of these symptoms. The main types of hormones involved are oestrogens, progesterone and sometimes testosterone. Menopausal hormone therapy once seemed the answer for many of the conditions women face as they age. It was thought that hormone therapy could prevent heart disease, osteoporosis and cancer, while improving women's quality of life. In 2002 however, findings emerged from clinical trials that showed this was not the case. The oestrogen-plus-progestin therapy increased women's risk for heart attacks, stroke, blood clots and breast cancer. It also doubled the risk of dementia and did not protect women against memory loss. However, the therapy had some benefits: it reduced the risk for colorectal cancer and bone fractures. The findings come from the Women's Health Initiative (WHI), launched in 1991 by the National Institutes of Health to test

ways to prevent a number of medical disorders in postmenopausal women (WHI, 2008). The objective of this women's health research initiative was to conduct medical research into some of the major health problems of older women. In particular, clinical trials were designed and funded that address cardiovascular disease, cancer and osteoporosis. It consisted of a set of clinical studies on hormone therapy, diet modification and calcium and vitamin D supplements; an observational study and a community prevention study. A recent review of the WHI data indicates that there was a greater risk of fatal and nonfatal malignancies occurred after intervention with HRT, while the risk index was 12% higher in women randomly assigned to HRT compared with placebo (Heiss *et al*., 2008). There are other publications which minimize the findings of the WHI (Goldman, 2004).

An increasing number of studies have shown that certain risks are associated with combinations of progestins and equine oestrogens (Smith *et al*., 2004). According to a report citing early findings and reported at a recent American Academy of Neurology meeting, hormone therapy may help protect against dementia, even though it raises the risk of mental decline in women who do not take the drugs until they are older. Because these have been used most commonly and for the longest time, there are many more studies of these forms of hormones than of some of the newer forms with newer delivery systems, and therefore the most is known about these kinds (Knopman *et al*., 2007). Whether or not such risks exist with other forms of oestrogens and progestins, and other delivery systems, remains to be seen.

7.2.2 Testes

Male mammals have two testicles, which are located below the penis and are generally contained within an extension of the abdomen called the scrotum. The collecting tubules inside the testicle join together to form a tube called the epididymis which transports spermatozoa. The epididymis becomes the spermatic cord which continues to form a short tube called the ejaculatory duct. It is this duct that opens into the urethra (the tube from the bladder to the end of the penis), just above the prostate gland. Hormonal modulation of the male reproductive system is much less complex than that of the female. The testicles are homologous to the ovaries in that they produce gametes (but in this case spermatozoa) and they secrete a sex hormones (e.g. testosterone). It is possible to perturb the male reproductive system indirectly at the hypothalamic-adenohypophysis axis or directly at the level of the testes. As in the female, the functions of the testicles are stimulated by the gonadotrophin hormones produced by the anterior pituitary—LH (also referred to as the interstitial cell stimulating hormone (ISCH) in males) and FSH. These gonadotropic hormones modulate selected cellular processes with the testes, with FSH stimulating spermatogenesis and LH (ICSH) stimulating the production of testosterone in the Leydig cells. The principal androgenic steroid produced by the testes is testosterone, whose main function is to stimulate the development and growth of the male genital tract. Additionally, testosterone promotes protein generation (anabolic activity) which leads to enhanced muscle mass. In the foetus, testosterone ensures the development of the male genitalia. During puberty testosterone enhances the growth of the male sex organs and promotes other male characteristics such as deepening of the voice, growth of facial, pubic and body hair, enhanced muscle size and strength, enhances bone growth and strength, promotes sperm production and maintains the male libido. Testosterone binds to sex-hormone-binding-globulin (SHBG) and appears to work in conjunction with other carrier proteins to control the equilibrium between the free and bound androgens (Kapp and Thomas, 2008). While the gonadotrophins play an important physiological role in maintaining the integrity of the male reproductive system, there are a number of important local testicular factors including Sertoli cells, Leydig cells and germ cells. There are also peritubular cells and endothelial cells, which are located in the vascular system of the testes. These subpopulations of cells found throughout the mammalian testes are subject to some degree of local regulation by factors such as peptide growth factors, cytokines, preopiomelanocortin derivatives, neuropeptides and steroids (Foote and Berndtson, 1992; Foster, 1992; Ewing, 1992; Spiteri-Grech and Neischlag, 1993; Weinbauer *et al*., 2001).

7.2.2.1 Toxicological Effects

Xenobiotics, certain drugs and heavy metals can injure different gonadal cell populations and/or biochemical processes and they may act directly or indirectly through the CNS or possibly a combination of the two. The typical general characteristics of chemicals that are gonadotoxicants include: increase in lipophilicity, affinity for the AR, molecular weight <400 and the ability to cross the blood–testes barrier. Nutrition can play a significant role in maintaining the metabolic integrity of the testes and the male accessory sex organs and hence can affect the toxicity of a material in the testes. Heavy metals appear to affect different sites within the testes including the germ cell, Leydig cell and the Sertoli cell (see **Table 4**). Heavy metals—with the exception of lead—act directly upon the testes to cause damage to the germ cell (Thomas and Thomas, 2000). Cadmium, on the other hand, acts at several sites, but most frequently injures the endothelial cells of the vascular supply of the testes. **Table 5** shows many drugs/chemicals and relevant biological activities that can affect the secretion of the Leydig (interstitial) cell androgens (e.g. testosterone and dihydrotestosterone)

Table 5 Chemicals and drugs producing Leydig cell hyperplasia and neoplasia

Agent	Agent class or biological activity
Cadmium	Heavy metal
Carbamazepine	Anticonvulsant/analgesic
Cimetidine	Histamine receptor blocker
Chlomiphene	Treatment of infertility
Cyclophosphamide	Antineoplastic
Diethylstilboestrol	Synthetic hormone
Dimethylformamide	Industrial use (tannery, leather goods, metal dyes)
Diltiazem, verapamil, nefedipine, telodipine	Calcium channel blockers
Diuron	Herbicide
Finasteride	5-α Reductase
Flutamide	Antiandrogen
Guanadrel	Adrenergic blocker
Gemfibrozil	Hypelipidaemic
Hydrazine reserpine	Antihypertensive
Mesulergine	Dopamine (D2) agonist/antagonist
Methoxychlor	Pesticide with oestrogen properties
Metronidazole	Antiprotozoal
Methylcholanthrene	Experimental carcinogen
Nafarelin	Luteinizing hormone-releasing hormone analogue
Nitrosamine	Industrial and food uses
Oestrogen	Hormone
Oxolinic acid	Antimicrobial
Perfluorooctanoate	Industrial ingredient (plasticizers, lubricant/ wetting agents)
Procymidone	Systemic fungicide
Spironolactone	Diuretic
Vidarabine	Antiviral

(Thomas and Thomas, 2000). The mechanism of toxicity is generally competitive antagonism in the case of those substances that possess some inherent hormonal activity (e.g. oestrogen, diethylstilbestrol, spironolactone). In some instances the metabolite and not the xenobiotic itself is the testicular toxin. **Table 6** summarizes some of the indirect testicular toxins. In general, these gonadotoxins interfere with spermatogenesis and, depending upon the dose and exposure, can produce varying degrees of sterility. Both diethylhexyl phthalate (DEHP) and its metabolite monoethylhexyl phthalate (MEHP) are injurious to germ cells. It is also believed that these phthalates may interfere with Sertoli cell function.

Table 6 Metabolites which are toxic to the testes

Parent compound	Metabolite
Acrylamide (industrial chemical)	*N*-Methylacrylamide, *N*-isopropylacrylamide
Amiodarone (antiarrhythmic drug)	Desethylamiodarone
Benomyl (antifungal)	Carbenolazim
Cephalosporin analogues (antimicrobial drug)	*N*-Methyltetrazolethiol
Dibromochloropropane (nematocide)	Dichloropropene derivatives
Diethylhexyl phthalate (fungicide)	Monethylhexyl phthalate, 2-ethylhexanol
Ethylene glycol monethyl ether (solvent)	2-Methoxyacetaldehyde
n-Hexane (solvent)	Hexane-2,5-dione
Vinclozolin (fungicide)	Butenoic acid derivative and an enanilide metabolite

7.3 Thyroid Gland

The thyroid gland is located on the anterior spinal chord between vertebrae C-5 and T-1. Thyroid hormones regulate the metabolism of almost every organ in the body. Normal thyroid function is a prerequisite for normal growth and development, the development of the nervous system and the normal functioning of the nervous, cardiovascular and gastrointestinal systems. Thyroid hormone serves to increase the metabolism of most body tissues. For instance, thyroid hormone stimulates the production of those proteins involved in heat generation. This is critical for maintaining body temperature in mammals. Thyroid hormone also enhances metabolic processes of carbohydrates, lipids and proteins that help generate energy necessary for bodily functions. Thyroid hormone is also necessary for the normal development of teeth, skin and hair follicles.

The thyroid produces two structurally related hormones—triiodothyronine (T_3) and thyroxine (T_4). Both of these hormones are iodinated derivatives of tyrosine and both are referred to as 'thyroid hormone'. In addition, the thyroid follicles which produce these hormones contain a protein termed thyroglobulin. Parafollicular cells or C cells which secrete calcitonin are found throughout the thyroid gland. Calcitonin is critical in the regulation of vitamin D, bone mineralization and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the decrease in the calcium absorption process. While T_4 represents about 90% of the hormone produced by the thyroid gland, T_3 is the more active of the two. Interestingly, much of the T_4 is converted to T_3 in target organs such as the liver and kidneys.

The secretory process of the thyroid gland is under the influence of the adenohypophyseal-hypothalamic system and is mediated by TSH. TSH production is controlled by a TRH, which is produced in the hypothalamus and transported to the anterior pituitary gland, where it increases TSH production and release. When the thyroid is functioning normally it is termed euthyroidism. Hypersecretion of the thyroid gland leads to the condition termed thyrotoxicosis which can cause increased height growth and increased speed of all the body's organs and intestines. Undersecretion of the thyroid gland or hypothyroidism can lead to a severe skin and tissue disorder termed myxoedema. Congenital hypothyroidism results in cretinism and is characterized by mental retardation. Thyroid hyperplasia is also known as a goitre and may be caused by autoimmunity or a nutritional deficiency of iodine.

Thyroid cell growth and function are regulated by hormones and growth factors that bind to cell surface receptors that are coupled via the G-proteins, Gs and Gq, to the adenyl cyclase and phospholipase C signal-transduction systems (Wettschureck and Offermanns, 2005). G-proteins function as 'molecular switches', alternating between an inactive GDP- and active GTP- bound state, ultimately going on to regulate downstream cell processes. G-proteins were discovered by Gilman and Rodbell (Roche, 1996). They found that when a hormone like adrenaline was bound to a receptor, the receptor did not stimulate enzymes like adenylate cyclase directly. Instead, the receptor stimulated the production of a G-protein, which then stimulated the adenylate cyclase to produce a second messenger, cyclic AMP. The binding of TSH to its receptor results in activation via the G-proteins of the andenylyl cyclases and phospholipase C signalling pathways (Popov *et al*., 1997).

7.3.1 Toxicological Effects

Knowledge of thyroid gland biochemistry is important to understanding endocrine toxicity. **Table 7** shows the drugs and chemicals that interfere with the secretion of thyroid hormones. T_3 and T_4 are synthesized in several steps as shown and toxic agents can inhibit synthesis at several sites (Thomas and Thomas, 2000; Kester *et al*., 2004; Atterwill and Flack, 1992). These agents can be categorized by their mechanisms of toxic action. **Table 8** shows that drugs such as salicylates, anticoagulants and phenyltoin can change thyroid function by affecting T_4 uptake, ^{131}I uptake and thyroid-binding globulin (TBG) concentrations. Propylthiouracil (PTU), a drug used in the treatment of hyperthyroidism, decreases both T_3 and T_4.

Table 7 Drugs and hormones that interfere with the secretion of thyroid hormones

Blockage of iodide trapping	Blockage of iodide oxidation	Mechanism not established
Chlorate	Amphenone	Acetazolamide
Hypochlorite	Carbimazole	Chlorpromazine
Iodate	Cobalt	Chlortrimeton
Nitrate	Methimazole	Thiopental
Perchlorate	*p*-Aminosalicylate	Tolbutamide
Thiocyanate	Phenylbutazone	
	Phenylindanedione	
	Propylthiouracil	
	Resorcinol	

Source: Kapp and Thomas (2008).

Phenoxyisobutyrate derivatives such as clofibrate produce histological changes in the thyroid gland. Occupational cyanide exposure can impair thyroid function and is a known goitrogen (ATSDR, 2006).

Lithium has been shown to cause hypothyroidism by several proposed mechanisms. It may act directly by inhibiting the iodine-concentrating capacity and by interfering with the biosynthesis of iodotyrosine and iodothyronines. It could also inhibit the secretion of thyroid hormones by stabilizing follicular cell microtubular systems (Henry, 2002; Greller, 2007). Chlorine dioxide used for the bleaching of wood pulp, bleaching of flour and for the disinfection of some municipal drinking-water systems may decrease T_4 levels (IRIS, 2000) Amiodarone, an antiarrhythmic drug used to treat various forms of tachyarrhythmias, has been shown to cause both hyperthyroidism and hypothyroidism, since iodine constitutes 37.3% of its molecular weight (Meek and Smallridge, 2001). Amiodarone is also structurally similar to thyroxine which contributes to the effects of amiodarone on thyroid function. Amiodarone has specific inhibitory effects on agonist-stimulated functions in thyroid cells, which may interfere with TSH receptor interactions. (Batcher *et al*., 2007).

Many agents can affect the binding, distribution and metabolism of thyroid hormones, but infrequently cause permanent alterations in thyroid function, as evidenced by **Tables 7** and **8**. Prolonged thyroid hormone alterations caused by xenobiotics may lead to follicular cell carcinogenesis (Atterwill and Cockburn, 1997; NCI, 2008). Xenobiotic-induced thyroid tumours may be due to increased circulating levels of TSH, which may be the result of increased metabolism of T_4 via heparin enzymatic conjugation with uridine diphosphate glucuronosyl transferase (UGT) which is a family of enzymes that catalyse the addition of sugars to lipids and other apolar xenobiotics (Bock and Köhle, 2005). Increases in

UGT activity might be a useful biomarker for tumorigenic changes in thyroid hormone levels subsequent to exposure to TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) (Matsuura *et al*., 2001). The thyroid hormone-decreasing effects of TCDD are primarily extrathyroidal and mediated by a marked reduction of hepatic T_4 UGT activity (Schuur *et al*., 1997; ten Tusscher and Koppe, 2004).

Several plant toxins are considered natural goitrogens. Vegetables such as mustard, radish, horseradish, cress, cabbage, Brussels sprouts, kohlrabi, kale, cauliflower, broccoli, turnip, swede and rapeseed contain glucosinolates which are a class of organic compounds that contain sulphur, nitrogen and a group derived from glucose. They occur as secondary metabolites of many plants of the order *Brassicales* and also the genus *Dryetes* (Bones and Rossiter, 1996). Glucosinolates can be metabolized into thiocyanates and isothiocyanates, which are potent natural goitrogens. Further, garlic, onions and chives contain 5-substituted cysteine sulfoxides, which are also natural goitrogens.

Certain herbicides such as chlorinated phenylureas, biscarbamates, substituted uracils, pyridazinones and the biphenyl ethers can produce changes in thyroid gland activity. Nitrofen, a diphenyl ether herbicide, has been associated with congenital diaphragmatic hernia (CDH), and may interfere with thyroid hormone secretion (Kling *et al*., 2005). Apparently, nitrofen reduces follicular size and colloidal density in the thyroid (Christian and Trenton, 2003). Triazines are also herbicides that suppress the thyroid. Amitrole is chemically related to the triazines and also can promote an antithyroid action. This mechanism appears to be through the inhibition of thyroid peroxidase (TPO), which produces a decrease in thyroid hormone levels which, in turn, causes hyperplasia of the thyroid. As with other antithyroid compounds, amitrole can induce thyroid tumours (Durham, 2002). Aminothiazole is a heterocyclic amine that has a direct action upon the thyroid and acts by inhibiting T_4 synthesis and acceleration its deiodination. 2-Aminothiazole can be used as a thyroid inhibitor in the treatment of hyperthyroidism and it has antibacterial activity (Uchikawa *et al*., 1996). The herbicide 2,4-D can decrease serum protein-bound iodine. Fungicides such as nabam, zineb and ziram can also inhibit iodine uptake by the thyroid. Dithiocarbamate pesticides are toxic to the thyroid and appear to act upon TPO (Marinovich *et al*., 1997; WHO, 1970). The fluorinated herbicide thiazopyr causes an increase in thyroid follicular cell tumours in rats by increasing the amount of circulating TSH. This increase in TSH appears to stimulate the thyroid follicular cells resulting in follicular cell hypertrophy, hyperplasia and ultimately neoplasia (Holz *et al*., 1997).

Polychorinated biphenyls (PCBs) and polybrominated biphenyls (PBBs) also affect thyroid gland metabolism causing goitres and hypothyroidism. This mechanism may be related to the ability of PCBs to cause developmental neurotoxicity (Miyazaki *et al*., 2004). Several polyhydroxyphenols, including resorcinol, catechol, hydroquinone, phloroglucinol and orcinol have been shown to inhibit TPO (Linsay and Gaitan, 1989).

Some chemicals, such as thioamine drugs, act directly upon the thyroid gland. In addition to these direct-acting antithyroidal agents, some drugs affect liver thyroid hormone-conjugating enzymes. Drugs that induce

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

hepatic microsomal P450, for example, phenobarbital and β-naphthoflavone can cause hepatocellular and thyroid follicular cell hypertrophy (Johnson *et al*., 1993). Some drugs alter thyroid function indirectly through the CNS or the adenohypophysis (Philip *et al*., 1999). Glucocorticoids also impair basal and TRH-stimulated TSH levels (Pekary *et al*., 2006). Phenytoin sodium is a commonly used antiepileptic drug which decreases the TSH response to TRH by enhancing the cellular uptake and metabolism of T_4 (Nader, 2004). Acetylsalicylic acid and L-DOPA (3,4-dihydroxy-L-phenylalanine) can also suppress TSH responsiveness by displacement of thyroid hormones from TBG (Daminet, *et al*., 2003).

7.4 Pancreas

The pancreas is located in the posterior to the stomach in close proximity to the duodenum. The pancreas has two distinct functions: (i) It acts as an exocrine organ by producing digestive enzymes and an alkaline fluid, and secretes them into the small intestine through a system of exocrine ducts. The digestive enzymes include trypsin, chymotrypsin, pancreatic lipase and pancreatic amylase, and are produced and secreted by acinar cells of the exocrine pancreas. (ii) It acts as an endocrine organ which made up of a million cell clusters called islets of Langerhans (Hellman *et al*., 2007). There are four main cell types in the islets which can be classified by their secretion, including α cells, which secrete glucagon, β cells, which secrete insulin, δ cells, which secrete somatotrophin and F cells (PP cells), which secrete pancreatic polypeptides (PP). In addition ε cells of the pancreas have also been identified as releasing ghrelin, an appitite-promoting peptide (Prado *et al*., 2004).

The exocrine pancreas constitutes the majority of the pancreas and is regulated by both neural and endocrine controls. During periods between digestion, little secretion takes place, but as food enters the stomach and, as chyme flows into the small intestine, pancreatic secretion is strongly stimulated. Trypsin and chymotrypsin are proteases which are synthesized by the pancreas. Interestingly, they are packaged as inactive precursors and the secretory vesicles also contain a trypsin inhibitor to keep them inactive until they are safely out of the pancreas and the ducts. The proteases are converted to their active forms by enterokinase, which is located in the intestinal mucosa.

The endocrine pancreas produces hormones in the islets of Langerhans which are directly secreted into the blood stream. The types of cells and their secretions are shown in **Table 9**. The two primary hormones released for the pancreas are insulin and glucagon. Insulin is the primary regulator for carbohydrate homeostasis by controlling the blood glucose levels. Insulin also regulates the uptake of amino acids and electrolytes, muscle tone and the release of triglycerides. Glucagon complements glucose regulations through glucogenolysis (the release of glycogen stores) and gluconeogenesis (the biosynthesis of additional glucose).

A primary concern in testing for toxicity of an experimental drug is the potential for the compound to interfere with the normal functioning of the pancreatic α cells. Often pancreatic toxicity is heralded by hyperglycaemia. The relationship between insulin and carbohydrate, fat and protein metabolism is evident in diabetes mellitus. Insulin is an anabolic hormone that promotes sequestration of carbohydrate, fat and protein storage depots throughout the body. Its actions are exerted primarily on skeletal muscle, liver and adipose tissue. On the other hand, the actions of glucagon are counter-regulatory to insulin by producing gluconeogenesis and glucogenolysis in the liver. The interplay between these two hormones contributes to homeostasis in glucose concentrations and thus to the availability of

Table 9 Cells of the islets of Langerhans and their hormones

Cell type	Location	% of total cells	Hormone	Function
α-cell	Periphery of islets	10–15%	Glucagon	Carbohydrate metabolism—stimulates glycogen to glucose
β cell	Throughout islets	70–80%	Insulin and amalin	Insulin—manages removal and use glucose from the blood
				Amalin—contributes to glycaemic control
δ cell	Periphery of islets	3–5%	Somatotrophin	Hormone which inhibits various releases from the anterior pituitary and the GI tract
F (PP) cell	Head of pancreas	<1%	Pancreatic polypeptide	Regulates the pancreas secretion activities (endocrine and exocrine); also affects hepatic glycogen levels and gastrointestinal secretions
ε Cell	Throughout islets	<2%	Ghrelin	Stimulates growth hormone secretion; regulates energy balance via hunger

Table 10 Class I drugs commonly associated with acute pancreatitis (>20 cases reported and one + rechallenge)

Drug	Function
Asparaginase	Chemotherapeutic
Azathioprine	Immunosuppressant
Furosemide	Diuretic
6-Mercaptopurine	Immunosuppressive
Mesalamine	Anti-inflammatory
Oestrogens	Hormone replacement
Opioids	Analgesic
Pentamidine	Antimicrobial
Steroids	Immunosuppressant
Sulfamethoxazole	Bacteriostatic drug
Sulindac	Nonsteroidal anti-inflammatory drug (NSAID)
Sulfasalazine	Sulfa anti-inflammatory
Tetracycline	Broad-spectrum polyketide antibiotic
Valproic acid	Anticonvulsant and mood-stabilizer

metabolic energy to all cells. Glucagon acts in concert with other fuel-mobilizing hormones to balance the metabolic effects of insulin.

7.4.1 Toxicological Effects

Acute pancreatitis typically is an inflammation of the pancreas that involves the surrounding tissue. Generally, gallstones account for about 30–60% of the cases, while excessive use of alcohol accounts for about 15–30% of the cases. Less common causes include hypertriglyceridemia, hyperparathyroidism, trauma, pancreatic tumours, endoscopic retrograde cholangiopancreatography (ERCP) and postabdominal and nonabdominal surgical procedures (Eltookhy and Pearson, 2006). Drug-induced pancreatitis (DIP) is less common, but it still accounts for up to 5% of the cases found in the general population (Greenberger and Toskes, 2008). There is no clear evidence that drugs that cause acute pancreatitis also cause chronic pancreatitis (Trivedi and Pitchumoni, 2005). Acute pancreatitis is frequently accompanied by increased level of pancreatic enzymes—notably amylase. The mechanism of cellular inflammation in pancreatitis is not understood, but several factors may contribute. Factors that stimulate primary sensory neurons include hydrogen ions, heat, leukotrienes, arachidonic acid metabolites, bradykinin and proteases such as trypsin, all of which may participate in the generation of acute pancreatitis (Liddle and Nathan, 2004). The cellular and molecular mechanisms involved in sensory nerve activation within the pancreas are complex; however, a key factor to the development of the damage to the pancreas often occurs as the result of digestive enzymes leaking into the pancreas and starting to digest the organ itself. This sets up inflammation, and when the inflammation settles, the scarring process distorts the pancreas, making further attacks of inflammation likely. Thus a vicious cycle develops. As previously noted, drug-related episodes of pancreatitis account for about 5% of the pancreatitis case reports found in the literature. Most of the evidence for drug-induced pancreatitis is anecdotal, thus making definitive classifications difficult at best. There are numerous complicating factors that add to the complexity of making the determination, so, many authors have classified drug association with pancreatitis based upon the number of cases reported in the literature. Based upon that assumption, Trivedi and Pitchumoni (2005) proposed a classification which categorizes drugs into Class I, II or III. Class I drugs are associated with pancreatitis and have at least 20 reported cases of acute pancreatitis with at least one case with a positive rechallenge (see **Table 10**). Class II drugs are associated with pancreatitis and have >10 but <20 reported cases of acute pancreatitis with or without positive rechallenge (see **Table 11**). Class III drugs are all medications implicated in pancreatitis, for example, Class

Table 11 Class II drugs commonly associated with acute pancreatitis (>10 but <20 cases reported)

Drug	Function
Acetaminophen (paracetamol)	Analgesic and antipyretic
Carbamazepine	Anticonvulsant and mood stabilizer
Cisplatin	Chemotherapeutic
Cytarabine	Chemotherapeutic
Cyclopenthiazide	Chemotherapeutic
Enalapril	Angiotensin converting enzyme (ACE) inhibitor
Erythromycin	Macrolide antibiotic
Hydrochlorothiazide	Diuretic
Interferon-α	Chemotherapeutic
Lamivudine	Nucleoside analog reverse transcriptase inhibitor (nRTI).
Octreotide	Synthetic somatostatin
Oral contraceptives	Birth control
Phenformin	Antidiabetic
Rifampicin (rifampin)	Bactericidal antibiotic

Table 12 Class III drugs commonly associated with acute pancreatitis (all drugs implicated)

General functional category	Drug
Antimicrobial agents	Abacavir, alatrofloxacin, amoxicillin, ampicillin, atovaquone, azithromycin, ceftriaxone, cidofovir, ciprofloxacin, clarithromycin, dapsone, demeclocycline, didanosine, delavirdine, doxycycline, efavirenz, enfurvirtide, ertapenem, fluconazole, foscarnet, ganciclovir, indinavir, isoniazid, lamivudine, levofloxacin, metronidazole, minocycline, monocycline, nelfinavir, nitrofurantoin, norfloxacin, quinolones, quinpristin/dalfopristin, penicillin, ribavirin, rifapentine, ritonavir, saquinavir, stravudine, trovafloxacin, trimethoprim/sulfamethoxazole, voriconazole, zalcitabine, zidovudine
Anti-inflammatory agents	Celecoxib, codeine, colchicine, diclofenac, hydrocodone, ibuprofen, ketoprofen, ketorolac, meloxicam, sulinac, mefenamic acid, morphine, nabumetone, naproxen, oxycodone, piroxicam, rofecoxib
Antineoplastic agents	Alemtuzumab, asparaginase, capecitabine, cyclophosphamide, doxorubicin, estramustine, gefitinib, ifosfamide, imatinib, levamidole, methotrexate, oxaliplatin, paclitaxel, pegasparaginase, tamoxifen, thalidomide, trastuzumab, vinblastine, vinorelbine
Cardiovascular agents	Amiodarone, amlodipine, ateriolol, benazepril, bendroflumethiazide, candesartan, captopril, chlorothiazide, chlorthalidone, enalapril, ethracrynic acid, fosinopril, furosemide, hydrochlorothiazide, irbesartan, lisinopril, losartan, methyldopa, metolazone, mexilitine, moexipril, perindopril, prazosin, polythiazide, quinapril, ramipril, thiazide, trandolapril
Gastrointestinal agents	Azathioprine, balsalazide, cimetidine, diphenoxylate, famotidine, granisetron, mercaptopurine, mesalamine, olsalazine, omeprazole, ondansetron, pantoprazole, phenolphthalein, rabeprazole, ranitidine, sulfasalazine
Synthetic hormones	Cortisone, danasol, dexamethasone, fludrocortisone, methylprednisolone, octreotide, prednisolone, prednisone, somatrophin, conjugated oestrogens, ethinyl oestradiol, oestradiol
Hyperlipidaemia agents	Artorvaststin, bezafibrate, fenofibrate, fluvastatin, gemfibrozil, lovastatin, pravastatin, simvastatin
Immunomodulating agents	Cyclosporine, glatiramer, interferon β-1b, interferon γ-1b, mycophenolate, sirolimus, tacrolimus, thalidomide, peginterferon α-2B
Neuropsychiatric agents	Aripiprazole, bupropione, carbamazepine, citalopram, clozapine, divalproex sodium, escitalopram, felbamate, fluoxetine, gabapentin, lamotrigine, mertazapine, olanzapine, paroxetine, quetiapine, risperidone, rivastigmine, sertraline, sumatriptan, tacrine, topiramate, valproic acid, venlaflaxine, zolmitriptan
Thrombolytic agents	Aspirin, alteplase, anagrelide, dipyridamole, reteplase, streptokinase
Miscellaneous agents	Acitretin, alendronate, calcitrol, clomiphene, contrast media, doxercalciferol, etanercept, finasteride, glimepiride, glyburide, gold, granulocyte colony stimulating factor (G-CSF), infliximab, isotretinoin, metformin, MMR vaccine live, montelukast, penicillamine, pergolide, pilocarpine, propofol, propylthiouracil isotretinoin, repaglinide, riluzole, rivastigmine, ropirinole, tacrine, tretinoin

I, Class II and all others with $\leq$10 reported cases (see **Table 12**).

Pancreatitis appears to be induced by a number of different mechanisms and the effects can be direct or indirect. In general, direct effects include toxicity- and hypersensitivity-type reactions. Indirect effects include, but are not limited to, ischaemia, thrombosis and increased viscosity of pancreatic juices (Frazee, 2004). The correlation between antibiotics and pancreatitis is poorly understood and has been speculated to be due to immune-mediated reactions, toxic metabolites and increased pressure of the sphincter of Oddi by gallbladder contractions (Blomgren *et al*., 2002). DIP is reported to be 40% higher in antibiotic treatment of opportunistic infections associated with human immunodeficiency virus (HIV) (Trivedi and Pitchumoni, 2005). Management of these infections is complicated by the fact that there are a plethora of drugs that have been reported to cause acute pancreatitis and are yet necessary for the patient.

Table 13 Diabetogenic agents

Agent	Function	Susceptible species
Alloxan	Experimental diabetes induction	Several
Cyproheptadine	Antihistamine; antiseroton-ergic	Rodents
Hexamethyl-melamine	Antineoplastic	Rat
Pyriminil (Vacor)	Rodenticide	Human
Streptozocin	Experimental diabetes induction; antineoplastic	Several
Verapamil	Calcium-channel blocker	Human

Source: Thomas and Thomas (2000).

Alloxan destroys pancreatic β cells and leads to experimental diabetes mellitus in rodents. Alloxan has avidity for rodent pancreatic β cells and concentrates in this organ. It is rapidly metabolized to dialuric acid, a product that undergoes autoxidation to yield peroxide, superoxide anion and free radicals. Streptozocin is also a β-cell toxin whose toxic properties reside in its *N*-methylnitrosourea moiety. Streptozocin is also an alkylating agent. Nitroso agents such as streptozocin and cycasin induce long-lasting damage to both the β cells and the neurons (Eizirik *et al*., 1996). Both alloxan and streptozocin can damage pancreatic DNA. Streptozocin also impairs reproductive function by causing a reduction in LH secretions by the pituitary (Bestetti *et al*., 1997).

Agents effective in producing hyperglycaemia are referred to as diabetogenic substances. The common diabetogenic substances are listed in **Table 13**. The list covers a broad biological spectrum of chemicals that are able to cause destruction of the β cells of the pancreas. Although alloxan was one of the first agents used to produce β cell necrosis, it has largely been replaced by streptozocin to produce experimental insulin-dependent diabetes. Cyproheptadine (CHP), pentamidine and hexamethylmelamine are capable of suppressing the function and altering the morphology of insulin-secreting cells. CHP is an antihistaminic and antiserotonergic agent which acts as a 5-HT_2 receptor antagonist. 5-HT_2 receptors are receptors for the neurotransmitter and peripheral signal mediator serotonin, also known as 5-hydroxytryptamine or 5-HT. CHP also blocks calcium channels. CHP and its analogues appear to suggest that the inhibition of insulin synthesis known to be elicited by CHP treatment of RINm5F cells (insulin-producing clonal cells) and intact animals involves alterations of initiation-factor phosphorylation leading to a decrease in insulin synthesis and of stored insulin in insulin-producing cells (Fischer, 1996; Hawkins and Fischer, 2004). Pentamidine is an antimicrobial used for prevention and treatment of pneumocystic pneumonia, a severe pneumonia often seen in patients with HIV. The exact mechanism of its antiprotozoal action is unknown (though it may involve reactions with ubiquitin), despite the fact that it is a basic therapeutic modality (in concurrence with multiple antifungal medications) when treating *Acanthamoeba* infections in immunocompromised patients (Nguewa *et al*., 2005). Hexamethylmelamine is used to treat refractory ovarian cancer. Although hexamethylmelamine structurally resembles an alkylating agent, it has not been found to have alkylating activity *in vitro*. The mechanism by which exerts its anticancer effect is unknown, but there is some evidence that it may inhibit DNA and RNA synthesis (Hansen and Hughes, 1991). Diphenylhydantoin (DPH) is a commonly used antiepileptic which exerts inhibitory effects upon insulin secretion. The mechanism of action of DPH is also not well characterized, however extensive research strongly suggests that its main mechanism is to block frequency-, use- and voltage-dependent neuronal sodium channels, therefore limiting repetitive firing of action potentials (Ebert *et al*., 1997). Diazoxide is an antihypertensive which also has an inhibitory effect upon insulin secretion. Diazoxide acts as a potassium-channel activator causing local relaxation in smooth muscle by increasing membrane permeability to potassium ions, thus switching off the voltage-gated calcium ion channels, which inhibits that action potential (Korotkov *et al*., 2006).

Thiazolidinediones (TZDs)—also referred to as glitazones—and related compounds are a group of active ingredients that augment the action of insulin in insulin-resistant states. TZDs act by binding to peroxisome proliferator-activated receptors (PPAR)s, a group of receptor molecules inside the cell nucleus, specifically *PPAR*γ (gamma). The normal ligands for these receptors are free fatty acids (FFAs) and eicosanoids or oxygenated EFA signalling molecules. When activated, the receptor migrates to the DNA, activating transcription of a number of specific genes. This class of oral antidiabetic agents decrease hyperglycaemia and hyperinsulinaemia by increasing insulin-sensitivity in target tissues.

Oral hypoglycaemia drugs such as sulfonylureas act by increasing insulin release from the β cells. They are used therapeutically for diabetes mellitus Type II (formerly termed noninsulin-dependent diabetes mellitus (NIDDM, or adult onset diabetes). Cyclosporine is an immunosuppressant drug widely used in postallergenic organ transplant to reduce the activity of the patient's immune system and subsequently the risk of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat072

organ rejection. Cyclosporine is thought to bind to the cytosolic protein cyclophilin (immunophilin) of immunocompetent lymphocytes, specifically the T-lymphocytes. This complex of cyclosporine and cyclophylin inhibits calcineurin, which under normal circumstances is responsible for activating the transcription of interleukin-2. It also inhibits lymphokine production and interleukin release and therefore leads to a reduced function of effector T-cells. It does not affect cytostatic activity (Pritchard, 2005). Cyclosporine also has an effect on mitochondria by preventing the mitochondrial permeability transition (PT) pore from opening, thus inhibiting cytochrome c release, which is a potent apoptotic stimulation factor (Borel, 2002).

Cholecystokinin (CCK), a peptide hormone of the gastrointestinal system responsible for stimulating the digestion of fat and protein and enhancing insulin secretion, can be antagonized by loxiglumide, a CCK A receptor antagonist. This may, in turn reduce the level of metabolic stress on the acinar cells and has been shown to mitigate the severity of acute pancreatitis. CCK receptors can be found in the gall bladder and pancreatic membranes.

Vanadate has been demonstrated to interact chemically with the hydrogen peroxide formed by amine oxidases resulting in the generation of peroxovanadium. This material can mimic virtually all the biological effects of insulin (Nolte *et al*., 2003).

Benzylamine, a substrate of semicarbazide-sensitive amine oxidase, has been shown to stimulate glucose uptake and inhibit lipolysis in human fat cells (Iglesias-Osma *et al*., 2004). Galparan is a chimeric peptide that can powerfully stimulate reversible insulin secretion acting at a distal site in the stimulus-secretion coupling of the β cell (Östenson *et al*., 1997). Chemicals such as cobalt can selectively destroy pancreatic α cells. There are species differences with regard to α-cell destruction. The injection of cobalt chloride has been shown to produce degranulation and vacuolization of the α cells in rabbits, dogs and guinea pigs (Mobasheri *et al*., 2006).

Some drugs, such as alloxan and streptozocin produce destruction of β cells leading to diabetogenic states, while others cause pancreatitis. Hence, both endocrine and exocrine functions are vulnerable to inflammation and chemically induced necrosis. The possible mechanisms of some DIP are listed in **Table 14**. Diuretic-induced changes in electrolytes appear to be correlated with acute pancreatitis—especially in association with hyperglycaemia—the state produced by a higher than normal level of glucose in the blood. Tetracyclines may exert direct pancreatotoxicity: azathioprine—an immunosuppressant which acts to inhibit purine synthesis necessary for the proliferation of cells—suppresses the immune system, yet also has a direct cytotoxic action (Konstantopoulou *et al*., 2005). Valproic acid is an anticonvulsant and mood-stabilizing drug, primarily in the treatment of epilepsy and bipolar disorder which exerts direct cytotoxic effects (Admirant *et al*., 2006). L-Asparaginase, an enzyme that catalyses the hydrolysis of asparagine to aspartic acid and is used to treat acute lymphoblastic leukemia, has been shown to be directly correlated to acute pancreatitis (Appell *et al*., 2007).

Table 14 Possible mechanisms of drug-induced pancreatitis

Mechanism	Drugs implicated
Pancreatic duct construction	Indomethacin, salicylates (via prostaglandin inhibition), opiates
Immune suppression	Steroids, azathioprine
Cytotoxic effect	Azathioprine, colaspase (L-asparaginase)
Arteriolar thrombosis	Oestrogens
Osmotic effects	Contrast media
Pressure effects	Contrast media
Metabolic effects (ionic changes)	Thiazides
Direct cellular toxicity	Sulfonamides, furosemide (frusemide), chlorothiazide
Possible hepatic mechanism (via free radicals)	Paracetamol (acetaminophen), tetracyclines

Source: Thomas and Thomas (2000).

Although some drugs can cause acute pancreatitis, their mechanisms of toxicity are poorly understood. In others some underlying aspects of the pathobiology of experimental acute pancreatitis are known. Animal models of pancreatic carcinoma have been induced by chemical carcinogens and by transgenic methods. Hence drugs or chemicals not only exert short-term inflammatory responses in the pancreas, but also their chronic effects may lead to tumourigenesis. Pancreatic tumourigenesis may be caused by several mechanisms (Obourn *et al*., 1997; Esposito *et al*., 2007; Maitra and Hruban, 2008). These suggested mechanisms are CCK receptor agonism, typsin inhibition, alteration in gut fat content, cholestasis and altered bile flow/composition, many based upon a genetic predisposition germ-cell and somatic-cell gene mutations. Drugs that produce peroxisome proliferation also produce pancreatic acinar cell hyperplasia/adenocarcinomas (Obourn *et al*., 1997; Vitale *et al*., 2007; Pogue-Geile *et al*., 2006).

Numerous agents and proposed mechanisms induce disorders of glucose metabolism. The most important are those that produce hypoglycaemia (**Table 15**) and those that produce hyperglycaemia (**Table 16**). The effects of a

drug on glucose metabolism may be due to a combination of factors involving the secretion and action of insulin, as well as counter-regulatory hormones and responses. **Table 15** delineates some possible hypoglycaemic mechanisms. The most important therapeutic agents causing hypoglycaemia include insulin, the biguanides, the thiazolidinediones and the sulfonylurea drugs. Mechanisms that can produce hyperglycaemia are shown in **Table 16**. The adverse metabolic effects of a drug and its underlying mechanisms may provide important insights into the control of glucose regulation.

Immunotoxicology

Robert W. Luebke, Celine A. Beamer, Christal Bowman, Jamie DeWitt, Kymberly Gowdy, Victor J. Johnson, David M. Shepherd and Dori M. Germolec

CONTENTS

1 OVERVIEW

For the purposes of risk assessment, immunotoxicity is defined as unintended modulation of immune function. Depending on dose, duration of exposure, mode of action and biopersistence, immune system effects may be detectable at the molecular or cellular level (altered markers of exposure) and/or at the organism level (altered function, adverse health effects). As depicted in **Figure 1**, suppression of immune function is associated with increased rates of infection and some types of cancer, whereas inappropriate modulation of the immune system may result in allergic and autoimmune responses.

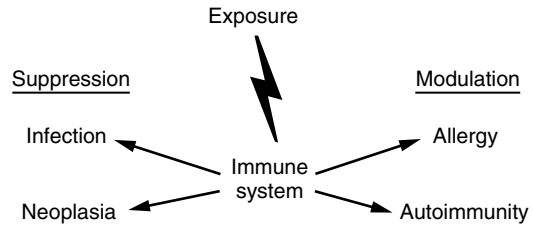

Figure 1 Xenobiotic exposure and immunocompetence.

1.1 Function of the Immune System

The immune system is a complex set of cellular and soluble mediators that protects the body against infectious agents and certain types of tumour cells via adaptive and innate responses. Adaptive responses require recognition of foreign antigens via the complex interaction of cell-surface molecules, production of growth factors, lymphocyte proliferation (clonal expansion) and implementation of effector mechanisms that ultimately mediate destruction of the foreign threat. The response is very specific, but is rather slow (4–10 days to the peak response). In contrast, innate responses do not require antigen recognition or clonal expansion and thus provide a rapid response (<24 hours) to infection.

Although most immune responses are beneficial, hypersensitivity reactions and autoimmune diseases are examples of inappropriate responses that cause morbidity and may be fatal. The diseases are believed to require genetic susceptibility and an environmental trigger. Hypersensitivity responses include four distinct types of immune responses. Allergy (Type I or immediate hypersensitivity) is characterized by the production of antibodies (typically IgE, immunoglobulin E) against normally innocuous molecules, including pollen, components of food, drugs and insect venoms. These antibodies attach to receptors on mast cells and eosinophils and trigger the release of potent proinflammatory and vasoactive compounds that cause smooth muscle contraction, swelling and inflammation. The most extreme manifestation of Type I responses is anaphylaxis, in which bronchoconstriction, airway oedema and cardiovascular effects may cause death. Type II and Type III responses are often associated with autoimmune disease; antibodies bind to host cells or tissues (Type II) or form complexes with antigens and accumulate in tissues (Type III), triggering inflammation and, in some cases, cytotoxic responses that destroy host tissues. Type IV responses are mediated by thymus-derived lymphocytes (Section 1.2) that respond to modified host proteins (e.g. allergic contact dermatitis to metals) or to exogenous proteins that are recognized as foreign (e.g. poison ivy). Autoimmunity is characterized by an immune response directed against host tissues that, for a variety of reasons, are not recognized as 'self'. This may be the result of a failure to remove self-reactive cells (Section 1.2), or failure to develop regulatory cells that limit immune system activity. Although some degree of autoreactivity is not uncommon, a robust response to self invariably leads to tissue damage and, in extreme cases, death. Although autoimmune diseases have been extensively studied, the initiating events are poorly understood. Hypersensitivity and autoimmunity are discussed in greater detail later in this chapter.

1.2 Cells and Tissues of the Immune System

Immune cells are located throughout the body, either in discrete organs, such as the bone marrow, spleen, thymus and lymph nodes or in diffuse accumulations of lymphoid and myeloid cells, as are found in association with the skin, lung and gastrointestinal tract, strategic locations for detection of entering pathogens and exogenous proteins (**Figure 2**). Nonspecific effector cells include macrophages (production of proinflammatory mediators, phagocytosis of pathogens and dead cells), natural killer (NK) cells (contact-dependent killing of certain tumour cells and pathogens) and polymorphonuclear (PMN) leukocytes (phagocytosis of bacteria). Lymphocytes are the prime cellular effectors of adaptive responses and are classified by their tissue of origin and subdivided based on function or maturity. Bone marrow-derived lymphocyte progenitor cells that migrate to and mature in the thymus are referred to as T lymphocytes or T cells; B lymphocytes or B cells are also derived from the common lymphocyte progenitor population and take their name from the Bursa of Fabricius, the site of B cell maturation present only in avians. In all other vertebrates, B cells migrate to and mature in bursal equivalents, including the spleen and lymph nodes. T cells that assist in and amplify other immune responses are known as T helper (Th) cells or CD4+ T cells, because they express CD4 antigen (CD - cluster of differentiation) on the cell

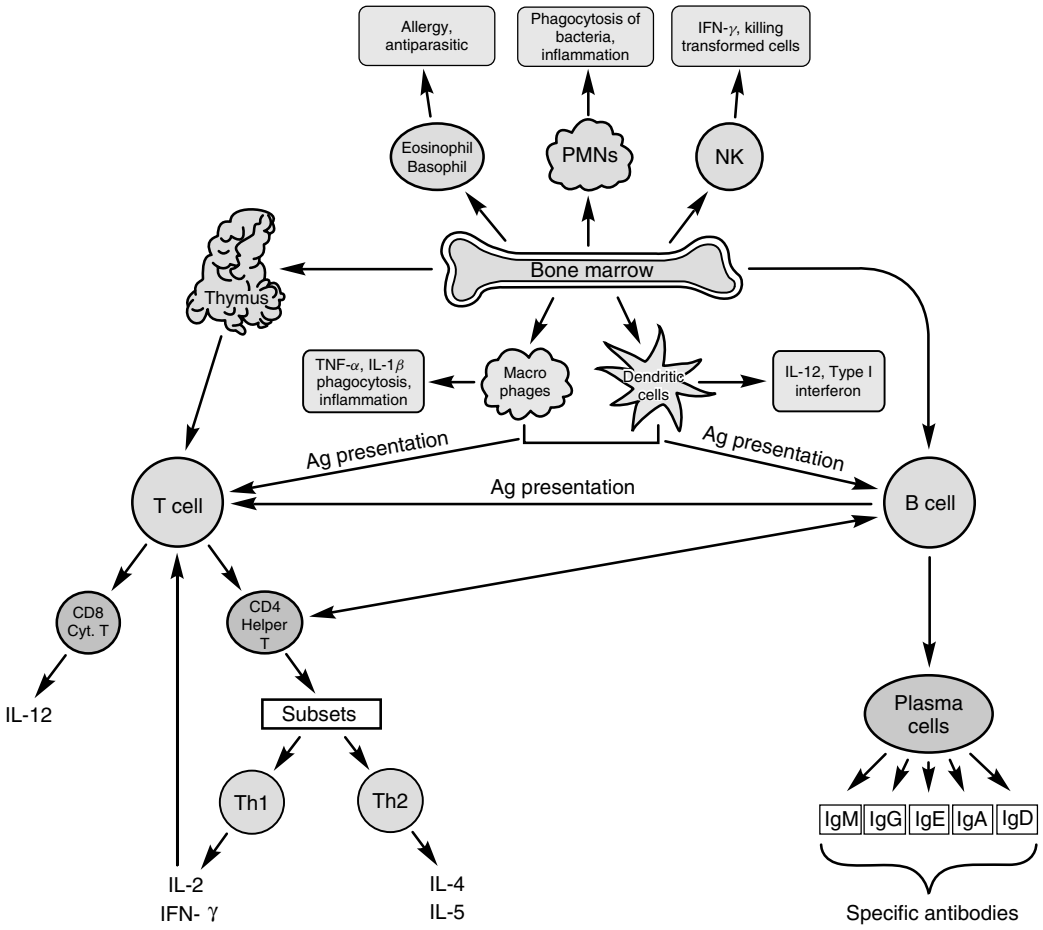

Figure 2 Cells and mediators of the immune system.

surface. Subpopulations expressing surface CD8 antigen down-regulate other immune responses (T suppressor cells; Ts) or act as effectors to destroy infected or neoplastic cells (T cytotoxic cells; Tc).

The bone marrow is the major haematopoietic organ in adult mammals. It is located within the central cavity of the major long bones, as well as in the core of the spongy bones of the sternum, skull and vertebrae. The marrow contains a complex mixture of stem cell progenitors that differentiate into cells of the erythroid, myeloid, platelet and lymphoid lineages. Compounds that target the bone marrow cells, certain malignancies and other processes that compromise marrow function are associated with profound alterations in immune function.

The thymus is the site of T cell maturation and selection. Selection is critical to establishing and maintaining tolerance to constitutively expressed 'self' proteins (antigens) present on somatic cells. Most (>95%) immature T cells that migrate to the thymus are eliminated, because of either inefficient or overzealous recognition of host antigens. Failure to remove these autoreactive clones is a contributing factor in autoimmune disease. Compounds that target the thymus may cause significant suppression of cellular and humoral immune function by disrupting maturation of T cell progenitors.

The spleen contains periarteriolar lymphoid sheaths (T cell areas), adjacent follicles (B cell areas), the marginal zone within the white pulp and large numbers of NK cells in the red pulp, which serves as a high-volume filter for the circulatory system. Follicle cellularity and germinal centre development have been reported to be the most sensitive histopathological predictors of immunotoxicity (Germolec *et al.*, 2004), because these compartments consist of highly active structures, formed as a direct result of immune activation that stimulates extensive lymphocyte proliferation and differentiation.

Lymph nodes consist of the cortex, composed of follicles and germinal centres (the B cell zone) and the paracortex (the T cell zone). Lymph nodes act as filters for the lymphatic and circulatory systems, trapping infected or damaged host cells, and can serve as a local source of activated immune cells in response to infection or inflammation. As discussed above for the spleen, germinal centres are distinct, highly active structures, formed as a direct result of immune activation, and thus would be susceptible targets for chemical-induced insult. Specialized lymphoid tissues

associated with the skin and mucosal surfaces are discussed in Section 2.

1.3 The Innate Immune Response

Cells of the innate immune system are 'early responders' and arrive at the site of infection within hours. Pathogen-associated molecular patterns (PAMPs), structural and genetic components of infectious agents, are expressed by microbes and recognized by innate immune system cells via pattern recognition receptors (PRRs), including membrane-bound toll-like receptors and cytosolic NOD (nonobese diabetic)-like receptors. Ligation of PRRs activates phagocytic cells to engulf bacteria and to release proinflammatory molecules that activate other cells and attract new cells to the site of infection. PRRs on the surface of dendritic cells (DCs) play a key role in stimulating antigen processing and presentation to lymphocytes, thus driving the development of the adaptive response. In addition to phagocytic myeloid cells, specialized lymphocytes known as NK (natural killer) cells recognize and bind to some types of tumour cells and destroy the targeted cell by release of granules containing lytic enzymes. A variety of soluble mediators contribute to innate responses as well, including the complement cascade (lysis of cells and augmented phagocytosis of bacteria) and cytokines (modulation of the inflammatory response). Innate responses are well conserved phylogenetically; the same or very similar responses that mediate resistance to infection in invertebrates act as a first line of defence in mammals to destroy similar classifications of pathogens.

1.4 Induction of the Adaptive Immune Response

1.4.1 Antigen Recognition, Processing and Presentation

When substances from infectious agents or altered host cells are recognized as foreign, a complex series of events is initiated that culminates in an immune response. Protein antigens are captured, processed to peptide fragments, and presented to lymphocytes bearing antigen-specific surface receptors by professional antigen presenting cells (APCs) (macrophages, B cells and dendritic cells), triggering cytokine production, gene rearrangement, cell proliferation, differentiation and maturation into cells responsible for effector function and immunological memory. Triggering of this process depends on concurrent binding of processed peptide to antigen receptors and host-specific proteins of the major histocompatibility complex (MHC) to receptors on the responding lymphocytes. Polymorphisms in MHC proteins can alter antigen presentation and recognition, leading to specific nonresponsiveness ('tolerance') to an antigen, or enhanced responsiveness to foreign or self-antigens, resulting in allergy or autoimmune disease. A lack of surface MHC antigens, as occurs on certain neoplastic cells, acts as a trigger to initiate cell lysis by NK cells of the innate immune system.

1.4.2 Cell-Mediated Responses

Recognition of antigens and co-stimulatory molecules on APCs by cell-surface receptors on naive T cells initiates a highly regulated signalling cascade that culminates in clonal expansion of effector and memory cells. The circumstances of antigen processing and antigen presentation ultimately control whether the resulting clones are helper (Th) or effector T cells (Tc or regulatory T cells; Treg). Th cells produce cytokines that regulate immune function and can be further subdivided into subpopulations which assist other cells (Th1) or which stimulate and perpetuate antibody responses (Th2). Th2 cytokine production predominates in newborns and is also associated with increased allergy and asthma. Soon after birth there is a switch to the Th1-dominated adult phenotype, important in eliminating certain bacteria and viruses.

1.4.3 Antibody Synthesis

Circulating naive B cells encounter antigen in lymph nodes or tissue-associated lymphoid tissues and become activated. B cells recognize antigen via membrane-bound antibody/immunoglobulin (Ig) molecules that act as antigen receptors. Crosslinking of Ig molecules on the cell surface initiates a signal transduction cascade that, with the appropriate stimulus from cytokines, leads to activation, proliferation and differentiation into antibody-secreting plasma cells. Considerable heterogeneity in the composition and arrangement of amino acids in the Ig binding site makes recognition of a large number of widely diverse antigens possible. Five classes of antibodies—IgM, IgG, IgE, IgA and IgD—have been described based on the characteristics of their heavy chain polypeptides, and each of these antibody classes has distinct expression patterns and functional properties. IgM, the first antibody to be produced, is generally of low affinity; however, its pentameric conformation allows it to bind effectively to multivalent antigens such as bacterial cell-wall polysaccharides, and it plays a significant role in the activation of the complement system. IgG is the most abundant isotype in serum and is important in the neutralization of bacterial toxins, opsonization of pathogens for phagocytosis and complement-mediated cell lysis. IgA is important in immunity at the mucosal surfaces of the body and protects via binding and crosslinking of pathogens. IgE binds with high affinity to mast cells, leading to the release of inflammatory mediators involved in the clearance of parasites and allergic

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

hypersensitivity responses. Although IgD is present on the surface of all naive B cells, it is generally lost during maturation and its function is not well defined.

1.5 Resistance to Infection

Infectious organisms fall into two categories: those that only survive or multiply inside host cells (viruses and facultative intracellular organisms) and bacteria that multiply outside host cells (e.g. *Streptococcus, Staphylococcus, Haemophilus*). In the earliest stages of infection, all bacterial pathogens may be controlled by nonspecific defences. However, organisms may replicate quickly and cause an overwhelming infection if not rapidly controlled. If innate immunity is compromised by chemical exposure, bacteria may proliferate too rapidly for innate immunity to be effective. Individuals at the extremes of age are more susceptible to these organisms because innate and adaptive immune functions are compromised in these populations (Burns-Guydish *et al*., 2005; Roberts *et al*., 2005). Likewise, a majority of heritable or acquired conditions that alter antigen presentation, T helper cell activity or antibody responses also predispose to infection (Buckley, 2003).

Extracellular pathogens are eliminated by phagocytic cells of the innate immune system after being coated by antibody. Antibodies also bind to and neutralize bacterial products (e.g. diphtheria toxin, *botulinum* toxins). Human exposure to certain environmental chemicals prior to immune system maturation has been associated with increased susceptibility to infection with extracellular bacteria (Section 3). The primary protective response to intracellular bacteria is mediated by products of Tc cells that in turn activate phagocytic cells to kill internal bacteria, or, in the case of viral infection, are directed against the infected host cell, leading to lysis of the infected cell. Infection with obligate intracellular pathogens are more commonly observed in individuals with defects in cellular immunity.

2 LOCAL IMMUNE RESPONSES

2.1 Mucosal-Associated Lymphoid Tissue (MALT)

Lymphoid tissues are classified as either primary or secondary organs based on their functional differences. Primary lymphoid organs include bone marrow and thymus, where haematopoietic stem cells and undifferentiated lymphocytes acquire their basal phenotype, and secondary lymphoid organs include the spleen, lymph nodes and mucosal-associated lymphoid tissue (MALT). MALT is a diffuse network of lymphoid tissues found on the surface of organs that encounter exogenous challenges such as microbes and soluble antigens, interconnected via the lymphatic system. Mucosal surfaces are prominent in the gastrointestinal, respiratory and urogenital tracts; the presence of MALT on these susceptible areas allows a localized response to a foreign antigen that results in immunological memory or tolerance. Although not part of the MALT system, the skin also has unique localized immune function (Section 2.1.4).

MALT is organized in multiple functional compartments including lymphoid follicles and the overlying follicle-associated epithelium, which contains microfold/membranous (M) cells, epithelial cells that allow the transport of micro organisms and soluble molecules across the epithelium, giving lymphoid tissues access to luminal antigens. Collections of MALT are covered by a mucous layer that provides a physical and chemical barrier against pathogens, as well as local concentrations of antibodies and other host defence molecules including lysozymes, complement, collectins and defensins.

Toll-like receptors (TLRs) are found on a number of cell types in the MALT, including macrophages, DCs and epithelial cells, and provide a link for signalling APCs to respond to an invading pathogen. In addition, signalling via TLRs in MALT can modulate potentially damaging proinflammatory responses, down-regulate immune responses and establish antigenic tolerance (Abreu *et al*., 2001).

MALT contains large numbers of intraepithelial lymphocytes (IELs) that are situated in the mucosal epithelium and, together with the epithelial cells, form an immunological barrier. The majority of IELs are CD3+ T cells expressing either $\alpha\beta$ or $\gamma\delta$ T cell receptor (TCR), approximately 80% belonging to the CD8 subset. Cells bearing the $\gamma\delta$ TCR are essential for the induction and regulation of antigen-specific IgA (Fujihashi *et al*., 1996), the dominant antibody isotype of the mucosal immune system. IgA and IgM are synthesized by plasma cells and transported to and released from the mucosal surface by immature epithelial cells that express polymeric immunoglobulin receptors on their basolateral surfaces.

2.1.1 Gut-Associated Lymphoid Tissue (GALT)

Multiple lymphocyte-rich areas are present in the intestine, including Peyer's patches, isolated lymphoid follicles, and lymphoglandular complexes which make up the gut-associated lymphoid tissue (GALT). These structures are randomly distributed throughout the intestinal tract with the greatest density in the jejunum. However, the size, number, distribution and composition of the Peyer's patches can vary among species and strain (Bruder *et al*., 1999). Ingested antigens can move through the intestinal lumen via M cells in the Peyer's patches without inducing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

an immune response, a mechanism called oral tolerance. The maintenance of immunologic tolerance, one of the unique features of the GALT, inhibits inflammatory responses to commensal organisms and ingested antigens, thereby preventing autoimmunity and food allergy.

2.1.2 Nasal-Associated Lymphoid Tissue (NALT)

In humans, the lymphoid structures termed Waldeyer's ring and the adenoids comprise the nasal-associated lymphoid tissue (NALT), whereas in rodents NALT is composed of paired lymphoid aggregates in the caudoventral portion of the left and right nasal passages at the entrance to the nasopharyngeal duct. APCs such as macrophages and dendritic cells are scattered throughout NALT but are less numerous than in other mucosal immune tissues such as the Peyer's patches.

2.1.3 Bronchial-Associated Lymphoid Tissue (BALT)

There is a great diversity of bronchial-associated lymphoid tissue (BALT) among species, and BALT is normally not found in dogs, cats and hamsters, whereas the largest BALT is found in rabbits (Pabst and Gehrke, 1990). Regardless, BALT can be induced in mice by pathogen exposure and has some characteristics similar to other species (Moyron-Quiroz *et al*., 2004). T and B lymphocytes located in the BALT generate cytotoxic and antibody-mediated reactions that rid the lung of pathogens while maintaining the delicate tissues for oxygen exchange.

2.1.4 Skin

Although the skin is not typical MALT, it does provide a barrier from environmental factors and is the site of local immune responses. Specialized APCs, termed Langerhans' cells (LCs), are situated in the epidermis and dermis. When antigen is encountered, the cells migrate to draining lymph nodes, and present the processed antigens to T cells, resulting in differentiation and activation. LCs play a pivotal role in regulating the balance between immunity and peripheral tolerance.

2.2 Toxicant Insult to MALT

The mucosal surfaces and skin are the first sites of contact with foreign antigens and chemicals. Toxicant exposures can cause the breakdown of mucosal immunity by either altering immune responses or decreasing tolerance, and may result in local or systemic effects. For example in the gut 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) has been reported to target the GALT, resulting in a marked decrease in IgA secretion and impaired oral tolerance to ovalbumin (OVA) (Kinoshita *et al*., 2006). Cyclophosphamide given orally has been shown to suppress antibody production in the GALT but also in the spleen (Kuper *et al*., 2003).

Chronic inhalation of ozone has been reported to damage the respiratory tract-associated lymphoid tissues. Ozone induces lesions in the nasopharyngeal epithelium and increases mucus production, suggesting NALT damage and possible dampening of the mucosal immune response (Harkema *et al*., 1997), whereas in the BALT it has been shown to suppress lymphocyte function (Jakab, 1993). These decrements have also been associated with increased susceptibility to respiratory infections with pathogens such as *Listeria monocytogenes*, which requires T cell-mediated immune responses in order to clear the organism (Steerenberg *et al*., 2004). NALT and BALT are also known as important sites for the induction of mucosal tolerance, and chemical exposures have been shown to alter this process. For example, exposure to diesel exhaust particles has been shown to elicit profound adjuvant effects in humans and animal models of respiratory allergy, and may play a role in overcoming tolerance to normally innocuous proteins.

Exposure to a number of toxicants and naturally occurring substances can damage the protective properties of the skin. Suppression or inappropriate modulation of the skin's immune response can alter its barrier function, making it a potential route of entry for pathogens. For example, multiple doses of UV increase susceptibility to microbial, fungal and viral pathogens and alter LCs migration and function (Kripke *et al*., 1990). Chemical exposure may also activate the skin immune system, resulting in hypersensitivity responses in the skin (Section 6).

3 IMMUNOSUPPRESSION AND RESISTANCE TO DISEASE

3.1 Introduction

Defects in immune function may be primary (inherited) or follow accidental or deliberate exposure to industrial chemicals, drugs, radiation, stress or infectious agents (acquired). Suppression may range from mild and transient to profound and long lasting, depending on the nature of the defect, and, in the case of drugs and xenobiotics, the duration of exposure and rate of clearance, and the stage of immune system maturity during exposure. Mild suppression may only be detected by laboratory tests, whereas moderate suppression may be expressed as an increased incidence or severity of common, community-acquired infections. Severe suppression, as observed in AIDS and certain primary immunodeficiency diseases, is typically associated with opportunistic

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

infections that do not usually pose a threat to the general population, and is an unlikely consequence of exposure to xenobiotics in the environment (Luebke *et al*., 2004). However, the range of 'normal' function is broad in humans, and is influenced by gender, age, genotype, nutritional status and the use of therapeutic and recreational drugs, factors that account for most of the variability reported in mean immune values. The consequences of exposure to potential immunotoxicants are thus the product of host immunocompetence at the time of exposure, immunotoxicant potency and the dose and virulence of infectious agents encountered following exposure. As such, exposures that do not cause biologically significant changes in immune function in some individuals may be sufficient to render others more susceptible to infection.

3.2 Mechanisms of Immunosuppression

Acquired immunodeficiency may be the result of reduced cell numbers, reduced or inappropriate cell activity or a combination of effects. Mechanisms of suppression include developmental arrest, metabolic pathways blockade, abnormalities in cytokine synthesis or secretion, disrupted signalling pathways, impaired DNA synthesis and lymphocyte proliferation and/or failure of normal apoptotic mechanisms. Complete suppression of immune function or haematopoiesis is unlikely to occur following exposure to chemicals not specifically designed to target the immune system, because the immune system is self-renewing and there is functional overlap in most host-protective responses. However, if an immune defect occurs in cells that cannot be replaced, (e.g. certain bone marrow cells), persistent suppression effects typically follow.

Examples of immunosuppression secondary to reduced cell numbers include the effects of xenobiotics on bone marrow function, and the effects of corticosteroids on immature cells. Polycyclic aromatic and aryl hydrocarbons decrease production of stromal cell-derived growth and differentiation factors critical for pluripotent immune cell progenitors, thus reducing the supply of B cell and T cell precursors (Jensen *et al*., 2003). Increased hypothalamic–pituitary–adrenal axis activity in response to chemical or physical stressors, or the therapeutic use of corticosteroids, results in apoptosis of immature lymphocytes, reducing the pool of available naive cells. Corticosteroids also reduce the production of many cytokines, including those associated with both inflammation and antibody synthesis, by interfering with gene expression or reducing the stability of cytokine mRNA (messenger RNA), thus suppressing immune-cell function. Other immunotoxicants (e.g. the benzene metabolite benzoquinone, TCDD, lead) reduce cell function by inhibiting critical transcription factors, reducing or preventing normal activity, but not necessarily leading to cell death.

3.3 Increased Human Susceptibility to Disease with Mild to Moderate Immunosuppression

Both infectious and neoplastic diseases are associated with immunodeficiency, although infectious diseases are more likely to be identified in short-term epidemiological studies and may appear to be more common due to differences in latency. Infections are common at the population level but occur relatively infrequently in individuals, with one to two episodes reported per year. Therefore, detecting xenobiotic-related increased rates of infection in epidemiological studies is difficult, thus limiting the number of reports that demonstrate an increased susceptibility in exposed humans. Immunodeficiency is also associated with an increased incidence of certain virally induced tumours, such as non-Hodgkin's lymphomas and tumours of the skin (Penn, 2000). Suppression of cell-mediated immunity has been associated with higher incidences of skin cancers, leukaemias and lymphoproliferative disorders in transplant patients. Severe immunosuppression, as seen in patients with AIDS, has been associated with Kaposi's sarcoma and Epstein–Barr virus-associated B cell lymphomas.

3.3.1 Adult Exposure to Environmental Chemicals

Increased rates of infections have been reported in children and adults following accidental or occupational chemical exposure. Pesticide exposure has been associated with increased incidence of infection and autoimmune disease, although the power of many studies is limited by small numbers of self-selected subjects. Living near a dump site containing organochlorine pesticides, volatile organic compounds and metals, was associated with a higher incidence of *herpes zoster* (reactivated herpes infection causing shingles), but not other infectious diseases (Arndt *et al*., 1999). Occupational exposure to lead has been associated with an increased incidence of influenza infections in a group of lead-refinery workers (Horiguchi *et al*., 1992) and similarly, welding fumes with respiratory bacterial infections (Antonini *et al*., 2003).

3.3.2 Chronic Stress

It is well established that chronic stress associated with divorce, bereavement or caregiving for Alzheimer's patients results in low-to-moderate degrees of immunosuppression and increased infectious disease incidences

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Kiecolt-Glaser *et al*., 2002). For example, the rate of respiratory infections and clinical colds in healthy subjects administered nasal droplets containing respiratory syncytial virus or coronavirus increased in a dose-responsive manner with increasing degrees of psychological stress (Cohen *et al*., 1991). Furthermore, rates of seroconversion following immunizations with hepatitis B vaccine were negatively correlated with the level of stress in students under academic pressure. Even more striking were the effects on pneumococcal vaccine responses in Alzheimer's caregivers, where a significant decrease in antibody titre occurred in current caregivers compared to controls over the six-month period following immunization (Glaser *et al*., 2000). Immune testing in chronically stressed individuals indicates that increased rates of infection correlate with altered lymphocyte populations, even though values are within normally reported ranges.

3.3.3 Correlation of Infections with Immune System End Points

Prospective studies in patients receiving haematopoietic stem cell transplantation (HSCT) provide an excellent model to identify quantitative relationships between immune end points and disease. In these individuals, immunodeficiency can persist for well over a year due to pregrafting radiation treatment, and is manifested as decreases in primary antibody responses and delayed hypersensitivity responses (Ochs *et al*., 1995). The incidence of infections exceeds 80% during the first two years postengraftment, with 50% of the patients having three or more infections, and opportunistic infections predominate (Ochs *et al*., 1995). Infections that occur in the first month following transplant are most likely due to deficiencies in granulocytes, and later infections appear to be due to deficiencies in CD4+ T cells and B cells. HSCT patients also manifest deficiencies in humoral immunity, presumably due to insufficient T cell help, rather than direct B cell deficits. Studies in organ transplant patients have also provided insights into the long-term consequences of moderate immunosuppression. Infection rates range between 65 and 70% during the first six months post-transplantation (Sia and Paya, 1998). With the advent of long-term monitoring, an increased incidence in cancer has also been noted in this population.

4 DEVELOPMENTAL IMMUNOTOXICITY (DIT)

4.1 Ontogeny of the Immune System

Immune development begins with haematopoiesis; the resultant pluripotent progenitor cells develop into myeloid or lymphoid lines after colonization of the liver, bone marrow, spleen and thymus. Initial lineage-restriction begins within sites of lymphopoiesis in the foetal liver; further differentiation and maturation into specific lymphocyte subpopulations occurs in the thymus (T cells) or bone marrow (B cells). Most types of T and B cell are functionally immature at birth and do not attain full maturity for several weeks, months or years into postnatal life, depending on the species.

Organogenesis of the lymphoid system is independent of initial lymphopoiesis in the liver and bone marrow. Thymus-derived lymphocyte development, including positive and negative T cell selection, is not completed until after the thymic medulla forms. Once in the thymus, thymocytes mature into CD4+ or CD8+ thymocytes that migrate to the periphery as functional Th and Tc lymphocytes, respectively (Holladay and Smialowicz, 2000). B lymphocyte development involves immunoglobulin gene rearrangement, which diversifies the assortment of antigen receptors, and selection by self-antigens; immature B cells that are stimulated by self-antigens are removed or inactivated. T and B cell maturity is achieved, in part, after antigens are encountered, and a pool of memory T and B cells in secondary lymphoid tissues is formed (Holsapple *et al*., 2003). Cells of both the innate (granulocytes, macrophages, eosinophils and NK cells) and adaptive (T and B cells) immune system are also functionally immature at birth.

The foetus is essentially an allograft that the mother's immune system must tolerate or risk rejection. Therefore, during pregnancy, the maternal immune system is biased towards the Th2 pattern of cytokine expression to ensure an adequate maternal antimicrobial humoral response, and reduced proinflammatory Th1-type reactions that may lead to foetal rejection. The predominant foetal phenotype is also Th2-biased, which is likely from *in utero* exposure to antigens that cross the placenta and prime foetal T cells (Kay, 2001). As exposure to microbes increases after birth, the cytokine profile shifts to Th1-mediated responses. Exposure to environmental chemicals that skew the Th1/Th2 balance, particularly air pollutants, has been suggested as a contributing factor in the increased incidence of allergic disease.

4.2 Sensitive Windows in Immune System Development

The requisite programmed events of immune-system development increase susceptibility to agents that may disrupt one or more critical steps. According to Landreth (2002), five windows of sensitivity exist in the developing rodent immune system. In the prenatal period, the immune system is especially vulnerable to insult during stem cell formation, liver development

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(as a haematopoietic organ), and colonization and establishment of the bone marrow and thymus. In the postnatal period, sensitivity to insult is increased during maturation to immunocompetence, and during the establishment of immune memory.

4.2.1 Chemical Modulation of the Developing Immune System

Several environmental agents have been implicated as developmental immunotoxicants. These include chlorinated compounds such as TCDD and PCBs (polychlorinated biphenyls), lead, mercury, organotins, pesticides (e.g. chlordane, heptachlor and hexachlorobenzene) and therapeutics (e.g. diazepam, diethylstilbestrol and dexamethasone). Although developmental exposure to these agents produces a myriad of effects, animal data indicate that timing of exposure determines the immunotoxicological outcome (**Table 1**). For example, if lead exposure occurs throughout gestation, delayed-type hypersensitivity (a functional measure of cell-mediated immunity) is decreased; if exposure is during the first half of gestation, it is unaffected (Dietert *et al*., 2002).

Evidence that developmental immunotoxicity (DIT) is a concern in the human population is provided by the well-documented association between PCB exposures and infections in children from China, Japan, the Netherlands and Canada. Studies of accidentally exposed populations in Japan (Yusho) and China (Yu-Cheng) suggested an association of PCBs, their thermal breakdown products (quaterphenyls) and polychlorinated dibenzofurans with immune abnormalities and increased infections. Developmental PCB exposure was associated with recurrent respiratory infections in the Yusho and Yu-Cheng study populations, as were recurrent episodes of otitis media in the Yu-Cheng population and in infants in arctic Quebec, Canada with high levels of organochlorine exposure. In Dutch preschool children, PCB levels in breast milk (non-ortho and coplanar PCBs) were also associated with increased recurrent otitis media and other symptoms of respiratory infection. In these children, the body burden of PCBs at age 42 months was associated with a higher prevalence of recurrent otitis media and chicken pox. The impact, if any, of background levels of these chemicals on disease burden has not been determined.

Table 1 Selected examples of efficacy of testing in adult rodents to detect immunotoxicity following exposure during immune system development[a]

Exposure	Reported effects	NOAEL/LOAEL	Adult vs. developmental testing
		Diethylstilbestrol	
PND 1–5	↓Antibody, NK activity	One dose level (2.2 mg kg^{-1})	Adequately detect LOAEL, but not lifetime persistence
Adult, 5 day	↓Antibody, DTH	0.2/2.0 mg kg^{-1} day^{-1}	
		Diazepam	
GD 14–20	↓Resistance to infection	One dose level (1.25 mg kg^{-1})	Adequately detect LOAEL, but not persistence
Adult, 3 day	↓Antibody, DTH	2.0/4.0 mg kg^{-1} day^{-1}	
		Lead	
GD 14–21	↓DTH, ↑IgE	None/250 ppm DTH, 100 ppm IgE	Adequately detect LOAEL, but not effects on IgE
Adult, 3 wk	↓DTH	128 ppm/512 ppm	
		2,3,7,8-Tetrachlorodibenzo-*p*-dioxin	
GD 14	Thymic atrophy, ↓DTH	1.0/3.0 μg kg^{-1}	Adult testing did not detect suppression that occurred in offspring
Adult, once	↑Antibody synthesis	1.0/3.0 μg kg^{-1}	
		Tributyltin oxide	
Preweanling	↓NK cell activity	None/5.0 mg kg^{-1} day^{-1}	Adult testing did not detect suppression that occurred in offspring
Adult, 10 day	↑Antibody synthesis	1.25/2.5 mg kg^{-1} day^{-1}	

[a]See (Luebke *et al*., 2006) for additional information. GD–gestation day, PND–postnatal day, DTH–delayed type hypersensitivity, LOAEL–lowest observed adverse effect level, NOAEL–no observed adverse effect level.

4.3 Evaluation of Developmental Immunotoxicity

Rodents are commonly used to assess the potential effects of toxicants on immune system development, although the timing of particular developmental landmarks during gestation and immediately postpartum differs significantly from that in humans. Because rats and mice have relatively immature immune systems at birth, significant developmental events occur after birth (Holladay and Smialowicz, 2000). Thus, timing of exposure relative to birth is an important element of experimental design, and must be taken into account when extrapolating rodent data to potential windows of increased sensitivity in humans.

Data generated in a number of laboratories have demonstrated that the effects of chemicals on the developing immune system may last longer and/or occur at lower doses than effects on adults. It has therefore been suggested that assessment of immunotoxicity in adult animals may not adequately reflect the severity or the persistence of the effects of developmental exposure. A DIT study must consider when a toxicant is administered and for how long, as well as the end point being evaluated. Rodents are considered appropriate models for humans in DIT testing, as long as immune system ontogeny is considered when interpreting the resulting data (Holsapple *et al*., 2003). In general, DIT studies utilize the same end points as those evaluated in adult immunotoxicity studies (Holsapple *et al*., 2003). However, as most traditional immune end points are difficult to assess in rodents less than three weeks of age, DIT studies are usually conducted after weaning.

5 AUTOIMMUNITY

5.1 Autoimmune Diseases

Autoimmune diseases result from a breakdown of immunological tolerance, leading to immune responses against self-molecules. The mechanisms for this self-reactivity are the same as those associated with responses to foreign antigens, including activation of the innate and adaptive immune systems, excessive production of inflammatory mediators, activation of T lymphocytes or the generation of antibodies with specificity for self-antigens. In many instances the events that initiate the immune response to self are unknown; however, intrinsic factors (e.g. specific gene polymorphisms, gender-related hormones and age) and extrinsic factors (e.g. lifestyle, exposures to certain drugs, chemicals and infectious agents) have been shown to be associated with the induction, development or exacerbation of autoimmunity. Autoimmune disorders can affect virtually any site in the body, and present as a spectrum of diseases ranging from organ-specific, in which antibodies and T cells react to self-antigens localized in a specific tissue, to systemic, characterized by reactivity against a specific antigen or antigens present in various tissues. Recent estimates suggest that 3–5% of the general population suffer from autoimmune diseases, and there is epidemiological evidence that the prevalence of certain autoimmune diseases is increasing in industrialized countries (reviewed in World Health Organization, 2006). In addition, there is evidence that a number of common health problems, such as atherosclerosis, schizophrenia, inflammatory bowel disease, autism and aspects of male and female infertility may have an autoimmune component. Women have a significantly higher risk of developing an autoimmune disease than men. A female predominance is observed in the most common autoimmune diseases (thyroiditis, scleroderma, systemic lupus erythematosus (SLE), multiple sclerosis (MS), rheumatoid arthritis (RA)). However, there appears to be a higher risk among men for some autoimmune diseases, such as ankylosing spondylitis and adult-onset diabetes.

5.2 Mechanisms of Autoimmunity

Lymphocytes that recognize self-antigens with high affinity undergo negative selection in the bone marrow (B cells) and thymus (T cells) and are eliminated via apoptosis. However, autoreactive B and T cells constitute a normal part of the immune cell pool and natural autoantibodies are observed in sera from normal, healthy individuals. The presence of these cells presents a low-grade risk for autoimmune disease in most individuals because recognition of self-antigens occurs with low affinity and can be controlled by peripheral tolerance, a post-thymic control mechanism that limits antigen-specific activity via the regulatory interactions of a variety of cell types and soluble mediators. A good example of one such regulatory check is the requirement for two signals from APCs, one antigen-specific and a second nonspecific signal, for lymphocyte proliferation. In the absence of a co-stimulatory signal, self-reactive cells are rendered unresponsive (anergic). However, in some instances, these autoreactive cells can recognize self-antigens in situations that overcome anergy and make the antigens appear immunogenic. One such example is cytokine-mediated polyclonal activation following infection or chemical-induced inflammation. In these cases, the inflammatory stimulus or a microbial protein may serve as an adjuvant and tolerance can be broken.

Following activation, regulation of beneficial immune responses is mediated by a number of inhibitory pathways that balance the positive and negative aspects of immune

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

system activation. Intrinsic defects or chemical agents that modify these regulatory pathways may lead to failure in restoring normal immune homeostasis and contribute to the pathogenesis of autoimmune disease. Changes in apoptotic pathways, leading to inappropriate cell death or survival, or disturbances in the clearance of apoptotic cells, have been suggested as the underlying mechanisms for several autoimmune diseases including RA, SLE and Hashimoto's thyroiditis. Dysfunction of regulatory NK T cell or T cell activity due to altered cytokine production, and/or deletion or mutation of cell-surface molecules, has been described for several autoimmune diseases. Organ-specific autoimmune diseases are typically characterized by cell-mediated responses directly affected by autoreactive CD8+ Tc cells or indirectly via release of proinflammatory cytokines and other soluble mediators by activated CD4+ T cells and macrophages. In contrast, systemic autoimmune diseases are frequently characterized by specific autoantibodies, which can cause injury via activation of complement, blocking or stimulating cell-surface receptors or by aggregation into immune complexes that activate nonspecific inflammatory responses.

5.2.1 Genetic Predisposition

Familial aggregation and laboratory animal studies suggest a clear association between genetics and essentially all autoimmune diseases. Concordance rates between identical twins range from approximately 9 to 40%, depending on the disease. Limited concordance may be explained by nonidentity in immune repertoires due to T cell receptor and Ig gene recombination, variations in receptor assembly, and somatic mutation. Additional evidence indicates that environmental factors also contribute to disease aetiology (Section 5.2.2). Any gene coding for products that are involved in the induction and maintenance of self-tolerance and in regulating immune effector functions as well as organ-specific functions may be involved in defining individual susceptibility. The most clearly established genetic association is with specific alleles within the MHC gene complex (Rose and Mackay, 2006). Polymorphisms in regulatory regions of genes coding for immunoinhibitory receptors, such as CTLA-4 (cytotoxic T lymphocyte antigen 4), which down-regulate T-cell activation, have also been shown to be important in disease susceptibility. Gene polymorphisms that affect the function or the level of expression of regulatory or effector molecules of inflammation, fibrosis or other pathologic processes involved in autoimmune disease development have also been observed. Examples of these include systemic sclerosis (TGFβ1, TGFβ2, TGFβ3), juvenile idiopathic arthritis (IL-1α), RA (IL-4, TNF-α), SLE (IL-10, TNF-α), Sjögren's syndrome (IL-10), juvenile idiopathic inflammatory myopathies (IL-1 Rα) and Wegener's granulomatosis (IL-10). Finally, polymorphisms in genes associated with nonimmune parameters, such as drug-metabolizing enzymes, may result in differential susceptibilities to drug or chemical-induced autoimmunity. This is likely the result of changes in the generation of protein adducts and covalently modified antigens through the use of alternative metabolic pathways. In the majority of autoimmune diseases, a multigenic process with multiple susceptibility loci working in concert has been suggested.

5.2.2 The Role of Environmental Factors in Autoimmune Diseases

Environmental factors have been shown to be important triggers for expression of autoimmunity and have been suggested to both induce onset and modulate disease severity (**Table 2**). Lifestyle factors such as diet, smoking, therapeutic and recreational drug use, infection with certain bacteria and viruses and exposure to UV radiation and environmental chemicals have all been implicated in the pathogenesis of autoimmune diseases (Heindel *et al*., 1999).

For some diseases, the causal link between infection and autoimmunity is well established. Many peptide fragments of microbial agents are homologous with host proteins, and the induction of an immune response to these antigens results in cross-reactivity with self-antigens and the induction of autoimmunity. The best example of this 'molecular mimicry' is a membrane protein on the β-haemolytic streptococcus bacterium, which has a high degree of homology with cardiac myosin. Antibodies that target the bacterium also cross-react with cardiac muscle and induce rheumatic fever. Antibodies to *Yersinia enterocolitica*, a bacterium normally associated with food poisoning outbreaks, cross-react with a variety of thyroid antigens, and increased levels of antibodies to *Yersinia* have been demonstrated in patients with Graves' disease or autoimmune thyroiditis. Microbial pathogens can also serve as adjuvants by nonspecifically stimulating innate immunity, inducing the production of soluble mediators and co-stimulatory molecules important in the perpetuation of the immune response.

For other environmental factors, the associations with autoimmunity have been suggested from epidemiologic studies and/or animal models or *in vitro* studies. Many of the chemical and therapeutic agents that have been linked to autoimmunity act through a chemical-induced alteration of self-peptides (Heindel *et al*., 1999). Metals such as mercury induce autoimmune disease via the creation of new high-affinity binding sites for MHC molecules. Drugs such as penicillin and halothane induce reactions in which antigen-specific T cells provide help

Table 2 Chemicals and drugs associated with autoimmunity[a]

Autoimmune syndrome	Compound
Haemolytic anaemia	α-Methyldopa Penicillins Sulfa drugs
Hepatitis	Halothane Interferon-α Ethanol Halothane
Scleroderma/systemic sclerosis	Vinyl chloride Trichloroethylene Spanish toxic oil Tryptophan Silicone Interleukin-2 Diphenylhydantoin
SLE or lupus-like syndrome	Aromatic amines Chlorpromazine Formaldehyde Hydralazine Interferon-γ Isoniazid Procainamide Silica Trichloroethylene
Thyroiditis	Iodine Lithium PCBs, PBBs
Thrombocytopaenia	Interferon-α Rifampicin Quinidine Iodine
Vasculitis	Allopurinol Silica Tetracyclines

[a]Adapted from Rose and Mackay (2006). This is not meant to be a comprehensive review, but is meant to provide illustrative examples of the types of compounds associated with autoimmunity. PBB—polybrominated biphenyl.

to antibody-producing B cells that recognize chemically modified proteins but not the native form of the self-protein.

5.3 Animal Models of Autoimmune Diseases

Animal models of autoimmunity have been used to explore both molecular mechanisms and therapeutic interventions for a variety of autoimmune diseases (Germolec, 2005). With the advent of transgenic and knockout mice, the number of genetically predisposed, autoimmune models has significantly increased (Boyton and Altmann, 2002). In the genetically predisposed models, mild to severe syndromes spontaneously develop, and are frequently due to alterations in genes encoding for MHC molecules, immune receptors or cytokines. The lupus-prone MRL mouse and the NOD model for insulin-dependent diabetes are two excellent examples of models where point mutations have been used to elucidate the role of specific genetic loci in the disease process.

In models where autoimmunity is induced by exposure to chemical or biological agents, foreign substances are used to initiate the autoimmune disease state. These may include biological substances such as bacterial or viral antigens, environmental chemicals or therapeutic drugs. One of the more commonly employed models used in toxicology studies is the Brown Norway (BN) rat model, in which the animals are injected with low doses of $HgCl_2$. Although the chemical exposure produces no overt signs of toxicity, the rats develop an immunologically mediated disease characterized by T cell-dependent polyclonal B cell activation, autoantibodies to specific components of the glomerular basement membrane and proteinuria similar to that observed in humans with autoimmune glomerulonephritis.

Immunization with purified self-antigens can elicit autoimmune responses, particularly when adjuvants are administered in conjunction with self-proteins. A frequently used model of this type, experimental autoimmune encephalomyelitis, is induced in laboratory rodents by injection of myelin basic protein in the presence of Freund's complete adjuvant. The resulting pathology is a T cell-mediated autoimmune disease characterized by lymphocytic infiltration in the central nervous system and destruction of the myelin nerve sheath with resultant paralysis, similar to that observed in patients with MS.

In each type of model the development and severity of symptoms has multiple components, in that the presence of the disease and its progression can be influenced by age, hormonal and/or environmental factors. In addition, there is a tendency for more than one autoimmune disorder to occur in several of the individual models. Nevertheless, a number of syndromes similar to those clinically observed in humans can be mimicked in animal models.

6 HYPERSENSITIVITY REACTIONS

6.1 Introduction

Hypersensitivity reactions represent abnormal adaptive immune responses to normally innocuous exogenous agents and/or altered host proteins commonly referred to as allergens. These reactions often involve a lag period between the initial encounter with the offending

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

agent and the hypersensitivity response. Once sensitized, the host immune system mounts one or more of the four distinct hypersensitivity responses (Section 1.1). Secondary exposure to the agent elicits an aggressive immune response resulting in tissue inflammation and destruction that may be life threatening, as in the case of systemic anaphylaxis.

6.2 Respiratory Hypersensitivity

6.2.1 Clinical Condition and Pathogenesis

The respiratory system serves the vital function of supplying oxygen and removing waste carbon dioxide from tissues with the upper airways filtering and conditioning the air for the lungs where gas exchange occurs. Respiratory hypersensitivity affects many aspects of airway function, ranging from a bothersome runny/itchy nose to disconcerting wheeze and shortness of breath and even fatal airway constriction. Allergen exposure manifests as an early phase, a late phase or dual responses, which are the result of isolated or combined Type I and Type IV hypersensitivity reactions. The early-phase response is primarily driven by allergen-specific IgE antibody, produced following sensitization, which is bound to surface receptors of mast cells and basophils residing in circulation and respiratory tissue (D'Amato, 2006). Inhalation of allergen results in crosslinking of IgE and activation/degranulation of mast cells, leading to the release of preformed mediators such as histamine and leukotrienes. These molecules, among others, elicit the effector responses of rhinitis in the upper airways (sneezing, itching, rhinorrhoea and severe nasal obstruction) or asthma in the lower airways (dyspnoea, wheeze, coughing and chest tightness).

Hypersensitivity reactions in the airways often involve an extended late-phase cell-mediated response that occurs several hours after inhalation of allergen. Mediators released during the early-phase response as well as activated lymphocytes producing cytokines and chemokines orchestrate the recruitment of effector inflammatory cells to the airways. Eosinophils, basophils, mast cells, neutrophils, lymphocytes, plasma cells and macrophages infiltrate the airway tissue and lumen to varying degrees, depending upon the nature of the allergen and the site of allergen exposure. These cells become activated in the tissue and liberate mediators aimed at destruction and elimination of the 'foreign' allergen. Unfortunately, these same mediators cause damage to host tissues resulting in the pathology and symptomatology of asthma and rhinitis.

The early- and late-phase reactions culminate in the pathological changes characteristic of respiratory hypersensitivity diseases. Cellular inflammation of the upper airways results in mucosal thickening, vasodilation and oedema, all culminating in nasal obstruction. Inflammation can also lead to epithelial changes such as goblet metaplasia and excessive mucus production, also contributing to obstruction. In severe and chronic cases, denudation, extensive metaplasia, hyperplasia and/or atrophy of the epithelium may occur, dramatically affecting the respiratory, olfactory and air conditioning/filtering functions of the upper airway. When the hypersensitivity reaction occurs in the lower airways, similar pathological changes in the airway epithelium and cellular inflammation ensue, which contributes to bronchoconstriction and congestion of the lung airspaces. In addition, chronic hypersensitivity responses in the lung, as observed in asthma, can lead to thickening and fibrosis of the basement membrane as well as hypertrophy of the smooth muscle layer. Together, these remodelling events contribute significantly to reduction in effective gas exchange and airway hyper-responsiveness or 'twitchy airways' that characterize asthma (Lloyd and Robinson, 2007).

6.2.2 Environmental/Occupational Exposures Contributing to Airway Hypersensitivity

Many of the compounds that we encounter on a daily basis, either through the indoor and outdoor environments or occupational atmospheres, can lead to sensitization and subsequent hypersensitivity responses in the upper and lower airways (**Table 3**). Common environmental causes include pollen from trees and grasses, fungal spores, house dust mites, cockroaches as well as pet dander and saliva. Environmental triggers of hypersensitivity reactions tend to be high-molecular-weight (HMW) agents capable of eliciting an immune response following antigen processing. Airway hypersensitivity reactions elicited by workplace exposures can be directed towards HMW and low-molecular-weight (LMW) agents. Prominent examples of HMW agents include flour proteins and enzymes responsible for Baker's rhinitis/asthma, latex proteins encountered by healthcare workers, proteins from dander and urine causing airway hypersensitivity in animal care workers, and enzymes used in a variety of industries including dry-cleaning. Airway sensitization and disease could also occur following occupational exposure to LMW chemicals, although these compounds tend to be too small to elicit an immune response directly and instead will haptenize host proteins, producing neo-epitopes capable of eliciting an immune response. Common examples include diisocyanates (e.g. toluene diisocyanate) and acid anhydrides (e.g. trimellitic anhydride) in the paint and plastics industry, metals (e.g. platinum salts and beryllium), and LMW compounds encountered in the wood working/manufacturing industry (plicatic acid) (Johnson and Luster, 2006). This discussion has listed many of the well-established mediators

Table 3 Agents that contribute to hypersensitivity responses

Hypersensitivity response	Molecular weight	Environmental agents	Occupational agents
Respiratory	HMW	Pollen from trees and grasses, fungal spores, house dust mites, cockroaches, pet dander and saliva	Wheat and other grain proteins, enzymes for baking, laundry and dry-cleaning enzymes, latex proteins, proteins from dander and urine, fish and shellfish allergens, vegetable gums
	LMW	Fragrance chemicals	Diisocyanates, acid anhydrides, platinum salts, beryllium, nickel, cobalt, aluminium, plicatic acid and other chemical sensitizers in wood dust, amines, aldehydes, resin acids, hair dressing chemicals
Skin	HMW	Penicillin, polymyxin, bacitracin	Latex proteins, animal-associated proteins
	LMW	Nickel, gold, mercury, fragrance chemicals, lanolin, terpenes, acrylates, thimerosal, urushiol	Nickel, chromium salts, diisocyanates, acid anhydrides, dyes, resin acids, acrylates and methacrylates, aldehydes, thiuram
Food allergy	HMW	Proteins from milk, eggs, fish, shellfish, tree nuts, peanuts, wheat, and soya beans	Egg, milk and wheat from food processing, latex proteins
	LMW	Natural food colourings, synthetic food colourings	Carmine, epigallocatechin gallate from processing of green tea

of airway hypersensitivity; however, it is important to note that many more have been recognized, and additional environmental and occupational airway sensitizers are being identified.

6.3 Hypersensitivity Responses in the Skin

6.3.1 Clinical Condition and Pathogenesis

The skin serves as an important barrier between body tissues/fluids and the external environment. Hypersensitivity reactions involving the skin can compromise this barrier, increasing host susceptibility to infectious agents and toxic compounds. Such reactions are usually directed towards LMW compounds that are capable of penetrating the complex stratification of the skin and result in delayed (24–48 hours) cell-mediated responses (Type IV hypersensitivity). However, immediate hypersensitivity reactions in the skin, commonly referred to as immunologic urticaria and atopic dermatitis, can also occur following sensitization and subsequent skin exposure to HMW proteins capable of eliciting specific IgE production, as in the case of contact allergy to natural rubber latex (Toraason *et al*., 2000). Clinical symptoms observed following secondary exposure to the skin allergens include pruritus and stinging sensations that are accompanied by vesicular and bullous lesions and/or pigment alterations at the site of allergen contact. Inflammatory pustules and secondary bacterial infections may accompany these rashes, which can be progressive and destructive if further allergen exposure is not prevented.

LMW contact allergens penetrate the skin and bind to host proteins that are subsequently phagocytized and processed by LCs residing in the epidermis (**Figure 3**). These cells migrate to draining lymph nodes and present the allergens to T cells, leading to differentiation and clonal expansion (Cavani *et al*., 2007). Proteins capable of inducing immunologic urticaria undergo a similar process of inducing host sensitization, although initial exposure to these allergens can occur through routes other than skin, such as in the diet. In the case of immunologic urticaria, secondary skin contact with the allergen leads to crosslinking of allergen-specific IgE on mast cells, which causes degranulation and release of cytotoxic granule proteins and histamine that mediate a local immediate-type hypersensitivity reaction (Type I). In contrast, re-exposure to contact allergens eliciting a delayed-type response (Type IV) results in the recruitment and activation of specific T cells that liberate proinflammatory cytokines and chemokines that, in turn, attract additional inflammatory cells to the skin, thus contributing to the growing erythema and induration. These events begin shortly after allergen exposure but the symptoms only become evident around 12–48 hours following contact. Down-regulatory mechanisms then take over, including the production of IL-10 by Treg (Cavani *et al*., 2007), leading to the

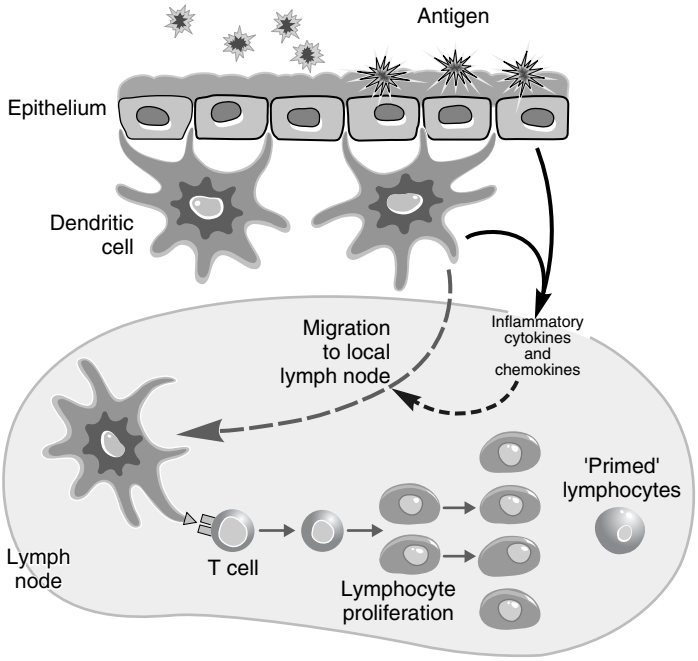

Figure 3 Antigen processing and presentation.

resolution of the cellular infiltrates, with the exception of memory T cells that will respond to subsequent exposure.

6.3.2 Environmental/Occupational Exposures Contributing to Hypersensitivity Responses in the Skin

Contact allergens of environmental origin include compounds found in clothing (dyes and resins), cosmetic/hygiene products (lanolin, fragrance terpenes, acrylates in fingernail coatings), antibiotics (polymyxin, bacitracin), preservatives (formaldehyde, thimerosal), and plant products, including urushiol, the chemical responsible for the response to 'poison ivy'. Metals commonly used in the manufacture of jewellery and keys and also in the dental industry, such nickel, gold and mercury, can cause hypersensitivity responses in the skin. The majority of agents responsible for immunologic urticaria are common food products including dairy, numerous fruits (e.g. apricot, apple, peach, olive) and nuts (e.g. peanuts, sesame seeds), meats (e.g. beef, chicken, turkey), seafood (e.g. codfish, clams, shrimp), and vegetables (e.g. beans, cabbage). In addition to skin reactions, these food products can also induce respiratory effects, gastrointestinal effects and anaphylaxis depending on the degree of sensitization. Allergic reactions in the skin are often related to LMW chemical exposure in the workplace. Examples include hypersensitivity responses in cement workers (chromate), autobody painters (diisocyanates, epoxy resins, hardeners), woodworkers (abietic acid), plastics manufacturers (acid anhydrides, acrylates) and healthcare workers (latex, thiuram, methacrylates).

6.4 Hypersensitivity Reactions towards Foodstuffs (Food Allergy)

6.4.1 Clinical Condition and Pathogenesis

Food allergy is a relatively new topic of interest to toxicologists. Advances in biotechnology, particularly the genetic modification of food crop plants, have raised concerns regarding dietary exposure to novel antigens of unknown allergenicity. Food allergy results from undesirable immune responses directed towards dietary proteins. Under normal circumstances, oral exposure to novel proteins leads to a state of immune tolerance. However, for reasons that remain largely unknown, some immunogenic dietary proteins are recognized aggressively by the immune system and act as allergens. Therefore, basic research to understand mechanisms of immune tolerance may also provide valuable insight into the complex aetiology of food allergy. Subsequent exposure to the protein allergen elicits an allergic response resulting in a range of digestive problems such as nausea, vomiting, diarrhoea and abdominal pain. The allergic response is not restricted to the digestive system and can manifest as respiratory problems (allergic rhinitis and asthma), skin problems (hives, atopic dermatitis, immunologic urticaria) and systemic anaphylaxis. The underlying immunopathogenesis of food allergy usually

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

involves IgE-mediated Type I hypersensitivity responses that are mechanistically similar to those addressed above for respiratory and skin immediate hypersensitivity responses. However, some dietary proteins can cause cell-mediated (Type IV) immune responses to food that are frequently delayed or chronic, and include food protein-induced enterocolitis, proctitis and enteropathy, as well as coeliac disease.

6.4.2 Environmental/Occupational Exposures Contributing to Food Allergy

According to the US Food Allergen Labelling and Consumer Protection Act of 2004, there are eight major food groups that account for more than 90% of food allergies: milk, eggs, fish, shellfish, tree nuts, peanuts, wheat and soya beans, although over 160 other foodstuffs have been shown to contain allergenic proteins. The incidence of allergy to specific foods tends to vary geographically due to dietary exposure levels and is increasing due to altered food preparation habits and introduction of non-native foods to regional diets. Food allergy is more prevalent in children, with allergies to milk, eggs, soya and wheat frequently being outgrown whereas sensitivities to peanuts, tree nuts, fish and shellfish often persist into adulthood.

It is generally assumed that allergies to food proteins are initiated and provoked via the oral route. However, there is evidence for allergic sensitization by other routes of exposure, such as the respiratory tract and skin (James and Crespo, 2007; Strid *et al*., 2005). Inhalation and cutaneous exposure to food antigens most frequently causes sensitization in occupational settings where food processing generates dust or airborne food particles (e.g. wheat allergy following inhalation in bakers; seafood allergy following skin exposure in processors). Importantly, these alternate routes of exposure may circumvent the natural development of oral tolerance to food proteins. Another concern is cross-reactivity between respiratory/skin allergens and food proteins. The best known example of this is the association between birch pollen allergy and allergy to certain fruits such as apples or peaches. Latex allergy in healthcare workers, which may be acquired by sensitization through the skin or respiratory tract (Toraason *et al*., 2000), is associated with reactions to papayas, bananas, avocados and other fruits and vegetables.

6.5 Genetics and Hypersensitivity

Genetic variation plays a critical role in determining interindividual differences in susceptibility to hypersensitivity diseases. Hypersensitivity responses tend to be more frequent in individuals with atopy, the genetic predisposition to produce high levels of IgE. In addition, genetic polymorphisms, especially those within immune response and MHC genes, have been shown to influence the development of allergic diseases caused by environmental and occupational allergens (Yucesoy *et al*., 2007).

6.6 Assessment of Hypersensitivity Reactions

6.6.1 Assessing Respiratory Hypersensitivity

Assessment of respiratory hypersensitivity reactions in humans involves comprehensive pulmonary function testing, airway hyper-reactivity to cholinergic stimuli and/or histamine, serum antibody responses, and skin prick testing with common aeroallergens. These diagnostic procedures can help confirm disease and also provide insight into the cause, although they often do not definitively identify the allergen responsible, especially in the case of occupational exposures. Specific inhalation challenge testing with the suspect agent can be used to link clinical outcomes to the exposure agent. Although no validated experimental testing methods have been established, numerous animal models have been developed to identify and study the mechanisms of respiratory hypersensitivity, including models of asthma and rhinitis (Johnson and Luster, 2006; Johnson *et al*., 2007).

6.6.2 Assessing Hypersensitivity Responses in the Skin

Allergic responses in the skin are diagnosed in patients through clinical examination and detailed exposure history and timeline. It is often difficult to distinguish between irritant and allergic manifestations of dermatitis, and skin biopsies are rarely performed in a diagnostic setting. A powerful tool for identification of the offending allergen is skin patch testing (Mowad, 2006). Several animal models have been proposed for the detection of skin sensitizers/allergens. The local lymph node assay (LLNA), guinea pig maximization test (GPMT) and the mouse ear swelling test (MEST) have all been validated for the detection of skin allergens (Section 8.5).

6.6.3 Assessing Allergenicity of Novel Food Proteins

Transgenic food crops as well as alterations to native diets pose new challenges for risk assessment. Genetic engineering changes the expression of proteins in the crop, which may alter the dose and/or exposure milieu for new or normally tolerated proteins. A major obstacle to overcome is the lack of definitive characteristics for

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

allergen, including food allergen, identification. However, allergenic proteins tend to be heat stable, glycosylated, 10–70 kDa in size, and resistant to degradation by acid and digestive enzymes. Though many allergens resist degradation, the association is not absolute; some allergens are highly labile, whereas nonallergenic proteins may be stable. Therefore, allergenicity assessment is currently a weight-of-evidence approach including *in silico* analysis of structural and amino acid sequence homology (recommended eight contiguous amino acids) with known protein allergens, assessment of heat stability, and determination of resistance to digestion in simulated gastric fluid (Kimber *et al*., 2007). Due to limitations of these methods, current research efforts are focussing on development and validation of new tools including structural databases, serum screening techniques and animal models.

Rodent models of food allergy have capitalized on the fact that the majority of food allergens induce IgE-mediated responses. Therefore, the BN rat, BALB/c mouse and C3H/HeJ mouse have been used for the majority of testing due to their inherent skew towards a Th2 allergic phenotype and high IgE production (McClain and Bannon, 2006). These models have focussed mainly on peanut, OVA and milk proteins, and have demonstrated high levels of IgE production indicative of sensitization. However, lack of standardization due to variable use of adjuvant, varying routes of exposure and even uncontrolled prior life-stage exposure to the target protein make screening for novel protein allergens very difficult (de Jonge *et al*., 2007). Rodent models tend to replicate the IgE response to food allergens seen in humans but often fail to present similar clinical symptoms. Other models using dogs and pigs are available that consistently demonstrate many clinical characteristics of human food allergy including respiratory involvement, digestive problems and even anaphylaxis (McClain and Bannon, 2006).

7 MOLECULAR MECHANISMS OF IMMUNOTOXICITY

7.1 Linking Immunotoxicants and Cellular Responses

In light of the fundamental role that the immune system plays in the maintenance of the health of the individual, the interaction of xenobiotics and regulatory mechanisms within the immune system has become an area of intense interest. Recent technologies allowing genome- and proteome-wide analysis of immune responses upon exposure to xenobiotics do not provide a complete picture of immunotoxicity since there may not be a direct correlation between gene and protein expression and biological function. Because of the potentially profound effects resulting from disruption of the immune system's balance, there exists a need to understand how xenobiotics can alter the genetic, cellular, biochemical and molecular mechanisms underlying immune function.

7.2 Signal Transduction

Activation of the immune response following antigen–receptor binding is mediated by signalling pathways critical to regulation of cellular function and immune system-associated genes. Cell-associated enzyme families, including tyrosine protein kinases, protein kinase C (PKC) and mitogen-activated protein kinases (MAPKs), phosphorylate transcription factors that up-regulate gene expression or proteins that alter cellular function without affecting gene expression. Other signalling pathways that are activated by oxidative damage and other types of cellular stress result in protein phosphatase activity that ultimately controls apoptotic pathways, cell activation and cellular differentiation.

The family of MAPKs, including c-Jun N-terminal kinase (JNK), p38 and extracellular signal-related kinases (ERKs), are all involved in stress signalling in immune cells following acute cell injury. The brominated flame retardant, tetrabisphenol A, stimulates the immune function of mussel haemocytes *in vitro* through kinase-mediated cell signalling (e.g. MAPKs and PKCs) thereby altering microbicidal activity towards *E. coli*, such as lysosomal enzyme release, phagocytic activity and extracellular superoxide (O_2^-) production (Canesi *et al*., 2005). Cadmium, a well-known carcinogenic and immunotoxic metal, also induces a calcium–ROS–JNK–caspase-3 signalling pathway (ROS—reactive oxygen species), leading to apoptosis of murine macrophages. Moreover, cadmium-induced alterations in calcium signalling regulate phosphorylation/dephosphorylation of JNK and p38, as well as the modulation of signal transduction pathways for proliferation, mitochondrial activity and necrosis (Kim and Sharma, 2004).

Cellular stress in immune cells also activates signal transduction pathways that are associated with survival pathways such as ERK and protein kinase B (PKB, also known as Akt). For example, 2-cyano-3-hydroxy-*N*-(4-trifluoromethylphenyl)-butenamide, which is an active metabolite of leflunomide (a clinical treatment for RA), decreases the number of viable human primary mast cells through apoptosis. Its mechanism of action includes inhibition of Akt via a concentration-dependent inhibition of PDK1 (pyruvate dehydrogenase kinase, isozyme 1) phosphorylation,

which controls Akt activation and the downstream molecules caspase-3 and caspase-9 (Sawamukai *et al*., 2007).

Heat shock proteins (hsps) also play a critical role in the adaptive response of immune cells to stress. Upon entering the draining mediastinal lymph nodes, *Bacillus anthracis* (anthrax) endospores germinate and bacteria quickly multiply, causing overwhelming and lethal bacteraemia. Studies by During *et al*. (2007) in both human neutrophils and HeLa cells suggest that anthrax lethal toxin blocks both p38 MAP kinase and hsp27 phosphorylation, resulting in inhibition of actin-based motility and reduced neutrophil chemotaxis.

7.3 Transcription Factors—Gene Expression

Xenobiotics may cause dysregulation of gene expression via direct effects on transcription, modulation of intracellular signalling cascades, or by altering the storage, synthesis or release of extracellular signalling molecules. Some toxic chemicals may directly regulate transcription of specific target genes by the activation of receptors that function as ligand-activated transcription factors. Perhaps the best-studied ligand-activated transcription factor in the immune system is the glucocorticoid receptor. When activated with glucocorticoids (or dexamethasone) this receptor transitions into the nucleus, binds to glucocorticoid response elements and inhibits the transcriptional activation of numerous genes, including proinflammatory and anti-inflammatory cytokines. Another well-characterized ligand-activated transcription factor is the aryl hydrocarbon receptor (AhR). Following binding to high-affinity ligands such as polyhalogenated aromatic hydrocarbons (i.e. TCDD and PCBs), the AhR translocates to the nucleus and heterodimerizes with aryl hydrocarbon receptor nuclear translocator (ARNT). Binding of this activated complex to dioxin response elements on target genes (e.g. IL-2) leads to transcriptional regulation of the immune response. It remains to be determined how other ligand-activated transcription factors such as the pregnane X-receptors and constitutive androstane receptors, which are xenosensors of endocrine disruptors (i.e. environmental oestrogens) may affect the immune system.

Alternatively, gene transcription may be affected by crosstalk of intracellular receptors with signal transduction networks. For example, activation of the AhR leads to disruption of the NF-κB (nuclear factor κB) and AP-1 (activator protein 1) signalling pathways in immune cells (Tian *et al*., 2002; Nebert *et al*., 1993). NF-κB is a ubiquitous transcription factor that regulates the expression of many immune-related genes and inflammatory cytokines. Although primarily considered to be proinflammatory in nature, activation of NF-κBs also results in anti-apoptotic (prosurvival) signalling—and the delicate balance between the two functions must be tightly regulated.

7.4 Cytokines

The immune system is regulated by a variety of soluble polypeptide mediators termed cytokines, which are produced by cells of the immune system, as well as other nonimmune cells within the local microenvironment. Cytokines that regulate and maintain normal immune homeostasis, and play a vital role in the development of an immune response may be altered by exposure to toxicants such as organophosphate pesticides, heavy metals and endocrine disruptors (Li, 2007; Hemdan *et al*., 2007; Chalubinski and Kowalski, 2006). During innate immune responses, cytokines are primarily secreted by phagocytic cells and NK cells, but in adaptive immune responses they are mainly produced by APCs and lymphocytes. Although often described separately, crosstalk between the innate and adaptive immune systems is frequent, and cytokines represent a major means of communication between the two.

Cytokines exhibit a number of general biological effects that are important to understand when considering their roles in immunotoxicology. A single cytokine may be pleiotropic in action, for example affecting a number of different cell types or targets (**Table 4**). Similarly, cytokines may act back upon the cell source that secreted them in an autocrine manner and/or on neighbouring cells in a paracrine manner. Cytokines also exhibit multiple effects on different cell types, often with synergistic or opposing results. This frequently means that cytokines act as molecular messengers to coordinate the interplay between, and control of, different component cell types in the immune response—an action that is of great importance in the amplification of the immune response.

In normal immune responses, cytokines are released by, and act upon, cells which are in close proximity to one another such that detrimental bystander effects are limited. In contrast, during acute and/or chronic inflammatory conditions, cytokines may be released in sufficient quantity such that systemic effects are observed. The balance between production of a satisfactory immune response or tissue damage also depends on homeostatic mechanisms. Continuous cell stimulation may result in sustained production of soluble mediators that induces a chain of responses, which if left unchecked may be damaging. The short half-life of cytokines provides evidence that under normal conditions most soluble mediators are rapidly eliminated by a variety of different

Table 4 Selected proinflammatory and anti-inflammatory cytokines of interest to immunotoxicology

Cytokine	Source	Function
	Proinflammatory	
Interleukin 1 (IL-1)	Macrophages, dendritic cells, B cells	Inflammatory mediator Increases production of other cytokines
Interleukin 2 (IL-2)	Activated T cells	Growth and activation of T and B cells Growth and activation of NK cells
Interleukin 6 (IL-6)	Macrophages, dendritic cells, B cells, activated T cells	Multiple effects on T cells Myeloid cell development Regulation of acute phase proteins
Interleukin 12 (IL-12)	Macrophages, dendritic cells, B cells	Differentiation of Th cells Stimulates production of IFN-γ
Interferon gamma (IFN $-\gamma$)	T cells, NK cells, epithelial cells, fibroblasts	Increases MHC expression Enhances CTLs, NK and macrophage activity Stimulates production of IL-1 and TNF-α
Tumour necrosis factor alpha (TNF-α)	Macrophages, dendritic cells, lymphocytes, mast cells	Increases MHC expression Activates macrophages Enhances tumour cell killing
	Anti-inflammatory	
Interleukin 4 (IL-4)	Mast cells, T cells, stromal cells, basophils	Growth and differentiation of B cells Inhibition of Th1 cells
Interleukin 10 (IL-10)	Macrophages, dendritic cells, T cells, B cells	Regulation of macrophage and Th cells Stimulates B cell proliferation
Interleukin 13 (IL-13)	Macrophages, T cells	Stimulates B cell differentiation and IgE production
Transforming growth factor beta (TGFβ)	Macrophages, megakaryocytes, chondrocytes	Inhibits cytokine production and activity Inhibits B cell proliferation Stimulates wound healing

processes, thereby ensuring their limited bioactivity. However, toxic agents that act on either the mediators themselves or the cells that produce them may cause damaging immune responses such as hypersensitivity, chronic immunodeficiency or autoimmune conditions.

8 HAZARD IDENTIFICATION AND RISK ASSESSMENT OF IMMUNE SYSTEM TOXICITY

8.1 Hazard Identification

Guidelines for evaluating the potential for chemicals and drugs to induce immunosuppression or hypersensitivity have been published by a number of agencies, including the US Food and Drug Administration, the US Environmental Protection Agency, the Organisation for Economic Cooperation and Development and the World Health Organization, and are available on the agencies' web sites. There currently are no regulatory testing guidelines for autoimmunity.

8.2 Approaches for Detecting Immunosuppression

Immunotoxicologists have applied tiered panels of assays to identify suppressive immunomodulatory agents in laboratory animals or via focussed epidemiological studies. The configurations of testing panels vary, but typically include assessment of one or more of the following: (i) lymphoid organ weights and histopathology; (ii) quantitative assessment of lymphoid tissue cellularity and peripheral blood haematology; (iii) immune cell function at the effector or regulatory level; and/or (iv) host resistance studies involving infectious or neoplastic challenge. The first tier is usually a screen for immunotoxicity, while subsequent tiers consist of more specific or confirmatory studies, host-resistance studies or in-depth mechanistic studies. At present, most information regarding these models comes from the US National Institute of Environmental Health Sciences,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat073
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

National Toxicology Program (NIEHS/NTP) (Luster *et al*., 1988) and the Netherlands National Institute of Public Health and the Environment (RIVM) (van Loveren and Vos, 1992). Recently, a database consisting of over 50 compounds, including environmental, industrial and pharmacologic agents evaluated in one or more tiers of the NIEHS/NTP panel was analysed in an attempt to improve the accuracy and efficiency of screening for immunosuppression. Although some datasets had limitations, a number of important conclusions were drawn from these data (Luster *et al*., 1988; 1992).

- The T-dependent antibody response (TDAR) has good predictive value, while assessment of as few as two or three other immune parameters may successfully predict immunotoxicants in mice. However, commonly employed gross measures, such as lymphoid organ weights were somewhat insensitive as measures of immunotoxicity.
- A good correlation existed between changes in functional tests and altered host resistance. However, immune changes were often observed in the absence of detectable changes in host resistance, suggesting that immune tests are, in general, more sensitive than host-resistance assays.
- No single immune test was identified which could be considered highly predictive for altered host resistance in mice. However, combining several immune tests increased the ability to predict host-resistance deficits, in some cases to 100%.
- Most immune-function—host-resistance relation ships followed a linear rather than threshold model, suggesting that even small changes in immune function may theoretically translate into a deficit in host resistance. However, because of the variability in the responses, it was not possible to establish linear or threshold models for most of the chemicals.

8.3 Species and Dose Considerations

Although the pharmacokinetics of chemicals may differ between experimental animals and humans, rodents have proven to be useful models for examining the immunotoxicity of non-species-specific compounds. The exposure route should parallel the most probable route of human exposure, at dose levels likely to establish a distinct dose–response curve as well as a no-observable-adverse-effect-level (NOAEL). Immune system changes observed at overtly toxic dose levels should be interpreted cautiously since stress and malnutrition are known to impair immune responsiveness. Inclusion of a positive control group, exposed to a well-characterized immunosuppressant, is also important to validate the robustness of the assay.

8.4 Evaluation of Immune Function

A detailed list of tests and methods used to screen compounds, evaluate resistance to infection or neoplastic challenge or determine mode/mechanism of action is beyond the scope of this chapter. Reference works (Burleson *et al*., 1995) are an excellent source of detailed protocols and discussions of assay merits and shortcomings. The response evaluated by the TDAR is usually considered to be the best single indicator of immune function, probably because it requires intact macrophage (antigen processing), Th cell (source of stimulatory cytokines) and B cell (differentiation into antibody-producing plasma cells) function. Human antibody studies have generally been limited to measuring titres to common vaccine antigens. Studies of primary immune responses in newborns and young children in conjunction with established vaccination programs (such as against measles, diphtheria, tetanus and poliomyelitis) may offer a significant opportunity to assess chemical-induced alterations in immune status in populations with identified chemical exposure.

Cellular immunity is traditionally thought of as reactions mediated by T cells, exclusive of the Th component of antibody responses. Cytokines released by antigen-specific T cells amplify inflammatory responses, down-regulate normal immune responses to prevent tissue damage, affect contact-dependent killing of altered host cells and regulate the activity of self-reactive cells. Because clonal expansion of antigen-specific cells is critical to immune function, the proliferative capacity of T cells has been used as an *ex vivo* correlate of clonal expansion, although the predictive value of the assay is limited (van Loveren and Vos, 1992). The mixed lymphocyte response, an *in vitro* proliferative response to foreign antigens, rather than a polyclonal activator, is now preferred as a functional correlate of T cell expansion. Cytotoxic T lymphocytes (CTLs) play a central role in destroying chemically or virally modified host cells and neoplastic cells bearing tumour antigens. CTL function is typically assessed by culturing antigen-primed T cells, generated either *in vivo* or *in vitro*, with labelled tumour cells or foreign lymphocytes, and measuring label release.

Innate immune function may or may not be included in tiered testing panels, although the functional status of macrophages may be assessed as phagocytic activity, release of soluble mediators, and bactericidal or tumouricidal activity. Lysis of labelled tumour cells is the most common measure of NK cell function, and a variety of methods are available to assess the function of neutrophils, including chemotaxis, phagocytosis and the respiratory burst.

8.5 Evaluation of Allergic Contact Dermatitis

Guinea pigs were traditionally used to test the sensitizing potential of chemicals, but animal costs, sensitivity issues and subjectivity of the assay end point led to the development of other assays (Burleson *et al*., 1995). The MEST is similar to the guinea pig assay in that both immune sensitization and elicitation of an immune response phases are required. In this assay, a compound is applied to the ear pina and evaluated by measuring changes in ear thickness following challenge. An alternative test is the LLNA in which the test material or appropriate control is applied topically in three successive daily applications to both ears of the test species, usually the mouse. Cell proliferation is subsequently measured in the lymph nodes draining the ears. At least one concentration of the test chemical must produce a three-fold increase or greater in lymphocyte proliferation in the draining lymph nodes of test animals compared with vehicle-treated control mice to be considered a positive.

8.6 Immunotoxicity Risk Assessment

As of 2008, formal guidance for immunotoxicity risk assessment has not been published, although efforts are underway in the US and Europe to develop guidelines. However, the basic risk paradigm of hazard identification, dose–response assessment, exposure assessment and risk characterization is applicable for immunotoxicity risk assessment. Confidence that the data reflects immunotoxicity can be judged with criteria similar to those described for end points such as cancer, as follows:

- Clear evidence of immunotoxicity: Dose-related changes in function (e.g. antibody synthesis or resistance to disease) or effects in multiple end points that suggest biological plausibility (i.e. alterations in NK cytotoxicity and NK cell numbers).
- Some evidence of immunotoxicity: No change in functional parameters but statistically significant, dose-related adverse changes in lymphoid tissue, histopathology or peripheral blood leukocyte counts.
- Equivocal evidence of immunotoxicity: Marginal deficits in immune parameters that may be chemically related (e.g. statistically significant changes in one or more parameters at middle or low doses, but not at high doses, in the absence of other supportive data).

Regardless of the end point being measured, data generated to assess immunotoxicity must be considered *in toto*, including dose responsiveness, general indications of toxicity, appropriateness of the test methods and the historical predictive value of the data.

ACKNOWLEDGEMENTS

The authors wish to thank Dr. Marsha Ward and Dr. Helen Cunny for their insightful suggestions and comments on this work.

Mutagenesis

Anthony Lynch

CONTENTS

1 INTRODUCTION

'Mutagenesis' is defined by the Collins English Dictionary as the origin and development of mutation, and a 'mutagen' is a substance or agent that can induce genetic mutation. In a recent edition of the BBC Radio 4 series 'In our Time', the broadcaster Melvyn Bragg introduced a programme on Genetic Mutation (BBC archive at *www.bbc.co.uk/radio4/history/inourtime*) by referring to the lines written by the British geneticist J. B. S. Haldane, which he penned while lying mortally ill with cancer:

Cancer's a funny thing:
I wish I had the voice of Homer
to sing of rectal carcinoma,
which kills a lot more chaps, in fact,
than were bumped off when Troy was sacked…

Bragg went on to say that 'Haldane knew better than most that many cancers and many other diseases are caused by genetic mutation. Indeed, to understand mutation fully may explain the ravages of illness and even unlock the secrets of ageing. But mutation, so often a destroyer of life, is also its creator. Without it, the variety of living things on earth simply wouldn't exist. It is, in the Darwinian view of life, the raw material of evolution'. The aims of this chapter are to provide an overview of the organization of the genetic material, DNA, and describe the mechanisms by which mutations arise in DNA (mutagenicity) and the links between mutation and the role they play in heredity diseases and cancer; and also other multifactorial diseases and ageing. The chapter goes on to describe the discipline of genetic toxicology, its history and the development of assays for the measurement of mutations in model organisms. It culminates in a description of the standard regulatory battery of *in vitro* and *in vivo* tests used to assess the potential genotoxic liability of a novel test agent, plus additional supplementary tests that can be used to investigate further the underlying biological mechanisms resulting in genotoxicity, and thereby improve hazard characterization and/or risk assessment. The chapter continues with a discussion on data interpretation and current concepts of risk assessment in genetic toxicology and concludes with an outline of the challenges faced by genetic toxicology in the new Millennium, and describes developments within the discipline

to meet these challenges. Other chapters of this volume are inextricably linked to this subject, including those on metabolism (see: Cytogenetics (**Cytogenetics**), Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation (**Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**), Carcinogenicity and Carcinogens that are also Genotoxic Carcinogens (**Carcinogenesis and Carcinogens that are also Genotoxic**), Reproductive Toxicology and Developmental Toxicology (**Reproductive Toxicology** and **Developmental Toxicology**) and Regulations (Part 10)).

2 GENETICS, DNA STRUCTURE AND FUNCTION

Genetics is the study of inheritance, and the phrase genome, coined by Professor Hans Winkler in the 1920s, is the term used to describe the entirety of the hereditary information for a specific organism which is encoded by the genetic material, deoxyribonucleic acid (DNA). Consisting of gene sequences, regulatory sequences and structural sequences, the DNA contains all the basic information necessary to construct and control cell function and thus may be thought of as the Lego® of life.

The DNA is located in the nucleus of the cell and contains four different nucleotides: the larger purine bases, adenine (A) and guanine (G), consisting of two aromatic rings, and the smaller pyrimidine bases, cytosine (C) and thymine (T), consisting of a single aromatic ring (**Figure 1**). The bases are paired together in a precise fashion by hydrogen bonds: adenine with thymine (A:T) and cytosine with guanine (C:G); thus they connect the sugar phosphate backbone of the molecule, like the runs of a ladder, resulting in the characteristic double-helix structure of DNA (**Figure 1**), first proposed by the Nobel Prize laureates, Watson and Crick (1953). One consequence of the conserved base pairing in the double-helix structure is that each strand is the exact reverse of the other. The original 'coding strand' is called the sense strand, whilst the opposite strand is known as the antisense strand.

In prokaryotic organisms, such as bacteria, DNA is organized into a single molecule, normally a closed circle, which is not complexed with protein. In eukaryotic

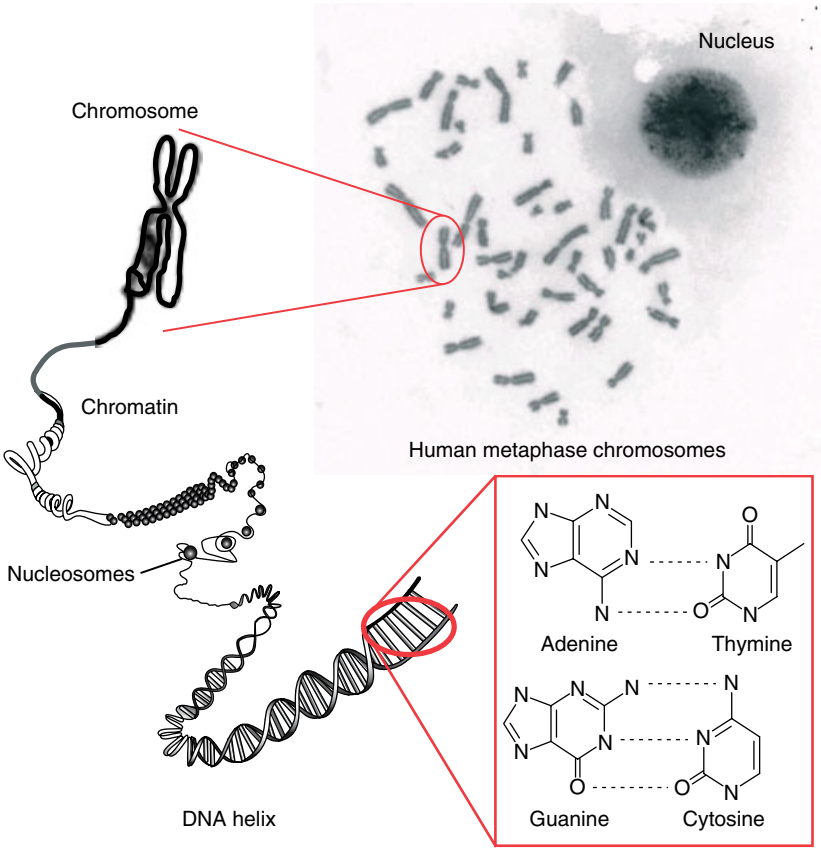

Figure 1 DNA structure and organization within the cell. The complement of 46 metaphase chromosomes (human karyotype) is shown lying next to an intact nucleus. One chromosome is blown up to reveal the degree of chromatin condensation and associated nucleosome structures involved in the organization of eukaryotic DNA. The red box shows the molecular structure of the nucleoside bases which form the 'struts' of the DNA helix, and the bonds between the pyrimidine and purine bases (dashed lines).

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

organisms, however, DNA is organized into higher-order structures called chromosomes, which are comprised of DNA complexed with proteins called histones to form chromatin. Human chromatin consists of approximately 2 m of DNA coiled around a series of nucleosomes, with each nucleosome consisting of histones H2A, H2B, H3 and H4 as heterodimers that form a core unit. The histone tails carry a positive charge and are capable of interacting with the polyanionic back bone of DNA, contributing to nucleosome stability (Yap and Zhou, 2006). The nucleosomes are themselves tightly packaged with other proteins, to produce chromosomes which are parcelled into the nucleus (**Figure 1**). Surprisingly, even in this form chromatin retains a large degree of functionality (Richmond, 2006). The cells of each species contain a distinct number of chromosomes in their genomes; for humans this number is 46, arranged as 23 pairs (**Figure 1**), whilst for Chinese hamsters this is 22, arranged as 11 pairs. Thus each species has a characteristic compliment of chromosomes, known as a karyotype. Contained within the length of each chromosome are the genes. Each gene codes for, and controls the production of, a specific polypeptide or protein.

2.1 Genetic Code, Genes and Gene Regulation

The individual bases in DNA represent the fundamental units of genetic language in all living organisms (akin to the alphabet of human languages), whereas the linear sequence of bases within the entire genome represents the complete instruction manual. To be of any use, however, the information contained in the genome must be deciphered by living cells via the genetic code. This is the set of rules by which information encoded in genetic material is translated into polypeptides and proteins (amino acid sequences). Specifically, the code defines a mapping between trinucleotide sequences or triplets in the DNA, called codons, and amino acids, via an RNA intermediate, and is regulated by the processes of transcription and translation (see below). Each triplet codon specifies a single amino acid within the genetic code.

A structural gene may be defined as a linear sequence of codons which codes for a functional polypeptide or protein; that is, a linear sequence of amino acids. Individual polypeptides/proteins may have structural, enzymatic or regulatory roles within the cell or organism. In prokaryotic organisms, genes are made up of simple nucleic acid sequences which are transcribed directly into messenger RNA (mRNA) and then translated into proteins. In contrast, genes in eukaryotic organisms are organized into 'intragenic regions' or introns and 'extragenic regions' or exons. Discovered by the 1993 Nobel Prize laureates, Roberts and Sharp, and coined by the biochemist Walter Gilbert, the term exons refers to nucleic acid sequences that are transcribed into mRNA and eventually code for amino acids in polypeptides and proteins, whereas introns are DNA sequences which are found between exons, but are not transcribed (Gilbert, 1978). Genes which contain introns are known as interrupted genes. Simple eukaryotic organisms such as yeasts have very few interrupted genes, whereas in higher-order species, like mammals, almost every gene has an intron. The number and DNA sequence length of individual exons that code for different proteins vary. Some proteins are derived from genes with only three or four exons, but others may have many more. Introns sometimes allow for alternative splicing of a gene, so that several different proteins which share some sequences in common can be translated from a single gene. For example, Nogo proteins are a group of polypeptides belonging to the reticulon family (Oertle and Schwab, 2003). Cloning of the *Nogo* gene showed three major transcripts, referred to as Nogo-A, -B, and -C, originated by alternative splicing (Nogo-A vs. Nogo-B) or differential promoter usage (Nogo-C vs. Nogo-A/B). The control of mRNA splicing is performed by a wide variety of signalling molecules.

The expression of structural genes is regulated by a special set of codons, organized as 'promoter' sequences. The promoter sequence is a regulatory region of DNA, generally located upstream to a gene that provides the initial binding site for RNA polymerase, the enzyme that synthesizes the RNA from the coding region of the gene, and promotes transcription of the gene (see below). Different promoter sequences have different affinities for RNA polymerase, due to specific DNA sequences called response elements, which are recognized by proteins known as transcription factors. These factors bind to the promoter sequences, recruiting RNA polymerase. In eukaryotic organisms, some sets of structural genes with linked functions have a single promoter, and their coordinate expression is controlled by another regulatory gene called an operator. A group of such genes is called an operon. The activity of the operator is further controlled by a protein called a repressor, since it stops the expression of the whole operon by binding to the operator sequence, preventing RNA polymerase from binding to the promoter. Repressors can be removed by relevant chemical signals or in a time-related fashion.

In eukaryotic organisms, promoters are extremely complex and diverse and can be difficult to characterize, particularly in higher species. Indeed, the expression of a particular gene may be regulated by the concerted action of both *cis*- and *trans*-acting elements. The promoter sequence may be considered as the principal *cis*-acting regulatory element which promotes transcription of, and is physically adjacent to, the coding sequences of the gene, although some *cis*-acting regulatory elements that moderate gene expression may be located up to several kilobases upstream from the transcriptional start codon ATG; for example, the haemoxygenase-1 (*hmox-1*) gene promoter contains regulatory sequences ~5 kb

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074

upstream of the site for the start of transcription (Elbirt and Bonkovsky, 1999). *Trans*-acting factors affect the expression of genes that may be physically located very far away, sometimes 3′-prime from the gene promoter, as with the *GADD45* (growth arrest and DNA damage) gene (Zheng *et al*., 2000), and, on occasion, even on different chromosomes. Promoters may be classified according to the type of gene expression control they provide and may be considered tissue and/or development specific, constitutive (where gene expression is seen in virtually every tissue irrespective of cell type and/or developmental stage and/or environmental factors) or inducible (where expression may be modulated by environmental and/or temporal factors, including chemical exposures). Examples of the last of these are the aryl hydrocarbon inducible promoters of the cytochrome P450 gene family.

2.1.1 Transcription and Translation

The DNA of each protein-coding gene is transcribed into a template molecule of the related polymer RNA, known as messenger RNA(mRNA), by RNA polymerase. Although similar to DNA, mRNAs are single stranded, and possess the base uracil instead of thymine, and the sugar ribose rather than deoxyribose. These molecules act as short-lived copies of the genes being expressed. The mRNA in turn is translated on the ribosome into an amino acid chain or polypeptide. The process of translation requires transfer RNAs (tRNAs) specific for individual amino acids with the amino acids covalently attached to them, guanosine triphosphate as an energy source, and a number of translation factors. tRNAs have anticodons complementary to the codons in mRNA, and can be 'charged' covalently with amino acids at their 3′ terminal CCA ends. Individual tRNAs are charged with specific amino acids by enzymes known as aminoacyl tRNA synthetases, which have high specificity for both their cognate amino acids and tRNAs. The high specificity of these enzymes is a major reason why the fidelity of protein translation is maintained.

The standard genetic code is shown in **Table 1** and shows each amino acid specified by each of the 64 codons. For example, the codon AAA represents the amino acid lysine, and ACA and ACU represent threonine (standard three-letter designations, Lys and Thr, respectively). There are $4^3 = 64$ different codon combinations possible with a triplet codon of three nucleotides. In reality, all 64 codons of the standard genetic code are assigned for either amino acids or stop signals during translation. If, for example, an RNA sequence, AUGCCCUUU is considered and the reading-frame starts with the first A (by convention, 5′ to 3′), there are three codons, namely, AUG, CCC and UUU, each of which specifies one amino acid

Table 1 The standard genetic code

mRNA codon	Amino acid	mRNA codon	Amino acid	mRNA codon	Amino acid	mRNA codon	Amino acid
AAA	Lysine (Lys)[a]	ACA	Threonine (Thr)	AGA	Arginine (Arg)	AUA	Isoleucine (Ile)
AAC	Asparagine (Asn)	ACC	Threonine (Thr)	AGC	Serine (Ser)	AUC	Isoleucine (Ile)
AAG	Lysine (Lys)	ACG	Threonine (Thr)	AGG	Arginine (Arg)	AUG[b]	Methionine (Met)
AAU	Asparagine (Asn)	ACU	Threonine (Thr)	AGU	Serine (Ser)	AUU	Isoleucine (Ile)
CAA	Glutamine (Gln)	CCA	Proline (Pro)	CGA	Arginine (Arg)	CUA	Leucine (Leu)
CAC	Histidine (His)	CCC	Proline (Pro)	CGC	Arginine (Arg)	CUC	Leucine (Leu)
CAG	Glutamine (Gln)	CCG	Proline (Pro)	CGG	Arginine (Arg)	CUG	Leucine (Leu)
CAU	Histidine (His)	CCU	Proline (Pro)	CGU	Arginine (Arg)	CUU	Leucine (Leu)
GAA	Glutamic acid (Glu)	GCA	Alanine (Ala)	GGA	Glycine (Gly)	GUA	Valine (Val)
GAC	Asparagine (Asp)	GCC	Alanine (Ala)	GGC	Glycine (Gly)	GUC	Valine (Val)
GAG	Glutamic acid (Glu)	GCG	Alanine (Ala)	GGG	Glycine (Gly)	GUG	Valine (Val)
GAU	Asparagine (Asp)	GCU	Alanine (Ala)	GGU	Glycine (Gly)	GUU	Valine (Val)
UAA[c]	Stop	UCA	Serine (Ser)	UGA	Stop	UUA	Leucine (Leu)
UAC	Tyrosine (Tyr)	UCC	Serine (Ser)	UGC	Cysteine (Cys)	UUC	Phenylalanine (Phe)
UAG[d]	Stop	UCG	Serine (Ser)	UGG	Tryptophan (Trp)	UUG	Leucine (Leu)
UAU	Tyrosine (Tyr)	UCU	Serine (Ser)	UGU	Cysteine (Cys)	UUU	Phenylalanine (Phe)

[a] Standard three-letter designations are shown in parenthesis.
[b] Also known as the start of translation codon.
[c] Also known as the ochre codon.
[d] Also known as the amber codon.

(i.e. methionine, proline and phenylalanine). This RNA sequence will be translated into an amino acid sequence, three amino acids long. From **Table 1** it can be seen that the genetic code has redundancy but no ambiguity. For example, although codons AAA and AAG both specify lysine (redundancy), neither of them specifies any other amino acid (no ambiguity). The codons encoding one amino acid may differ in any of their three positions. For example the amino acid glutamic acid is specified by GAA and GAG codons (difference in the third position); the amino acid leucine is specified by UUA, UUG, CUU, CUC, CUA, CUG codons (difference in the first or third position); while the amino acid serine is specified by UCA, UCG, UCC, UCU, AGU, AGC (difference in the first, second or third position).

A position of a codon is said to be a four-fold degenerate site if any nucleotide at this position specifies the same amino acid. For example, the third position of the threonine codons (ACU, ACC, ACA and ACG) is a four-fold degenerate site, because all nucleotide substitutions at this site are synonymous, that is, they do not change the amino acid. Only the third positions of some codons may be four-fold degenerate. A position of a codon is said to be a two-fold degenerate site if only two of four possible nucleotides at this position specify the same amino acid. For example, the third position of the glutamic acid codons (GAA, GAG) is a two-fold degenerate site, so is the first position of the leucine codons (UCA, UCC, CCU, CCC, CCA, CCG). In two-fold degenerate sites, the equivalent nucleotides are always either two purines (A/G) or two pyrimidines (C/U), so only transversional substitutions (i.e. purine to pyrimidine or pyrimidine to purine, see below) in two-fold degenerate sites are nonsynonymous. A position of a codon is said to be a nondegenerate site if any mutation at this position results in amino acid substitution. There is only one possible three-fold degenerate site where changing three of the four nucleotides has no effect on the amino acid, while changing the fourth possible nucleotide results in an amino acid substitution. This is the third position of an isoleucine codon: AUU, AUC or AUA all encode isoleucine, but AUG encodes methionine. There are three amino acids encoded by six different codons: serine, leucine and arginine. Only two amino acids are specified by a single codon; one of these is the amino acid methionine, specified by the codon AUG, which also specifies the start of translation; the other is tryptophan, specified by the codon UGG. The degeneracy of the genetic code is what accounts for the existence of silent mutations (see below).

These properties of the genetic code make it more fault-tolerant for point mutations. For example, in theory, four-fold degenerate codons can tolerate any point mutation at the third position, although codon usage bias restricts this in practice in many organisms; two-fold degenerate codons can tolerate one out of the three possible point mutations at the third position. Since transition mutations (i.e. purine to purine or pyrimidine to pyrimidine) are more likely than transversion mutations (i.e. purine to pyrimidine or vice versa), the equivalence of purines or that of pyrimidines at two-fold degenerate sites adds a further fault tolerance.

2.1.2 The Cell Cycle

The majority of somatic (nonreproductive) cells in the body undergo cycles of cell growth and cell division resulting in the formation of daughter cells. The totality of events leading to, and including cell division, is known as the cell cycle (**Figure 2**), and consists of four recognized stages:

- **G1 (gap 1):** the cell enlarges and prepares to replicate the DNA
- **S-phase (DNA synthesis):** the complement of chromosomes is duplicated
- **G2 (gap 2):** there is little cellular activity during this phase; the cell synthesizes RNA and proteins required for mitosis
- **M-phase (mitosis):** the complement of chromosomes separates to produce two new, identical daughter cells.

The new daughter cells may either enter G1 immediately, or alternatively, may undergo a rest period (termed G0) until presented with a stimulus to replicate. Cells at the G1 phase may re-enter the G0 rest period up to a point where the cell becomes committed to undergoing division, called the restriction point. Cells may undergo up to 30–45 divisions during a lifetime (depending on cell type), after which the cells age (a process termed senescence), enter a period of crisis and then die.

2.1.2.1 DNA Replication (S-phase)

Double-stranded DNA has a unique property in that it is able to make identical copies of itself when supplied with precursors, relevant enzymes and cofactors. The first step in DNA replication requires that the two strands of DNA are uncoiled, in an unzipping process, as the hydrogen bonds are broken. This results in single-stranded DNA and exposure of free base pairs, to which new complementary deoxyribonucleotide triphosphates bind under the control of a DNA polymerase enzyme, forming new base pairs and hence a new strand of DNA. Once again, because base pairing is always the same, the new strand is a reverse copy of, or complementary to, the original, producing two exact copies of the original double helix. The period of the cell cycle where DNA replication occurs is referred to as S-phase (or DNA synthesis).

2.1.2.2 Cell Division (M-phase)

Mitosis and cytokinesis together define the mitotic (M)-phase of the cell cycle, the division of a cell into

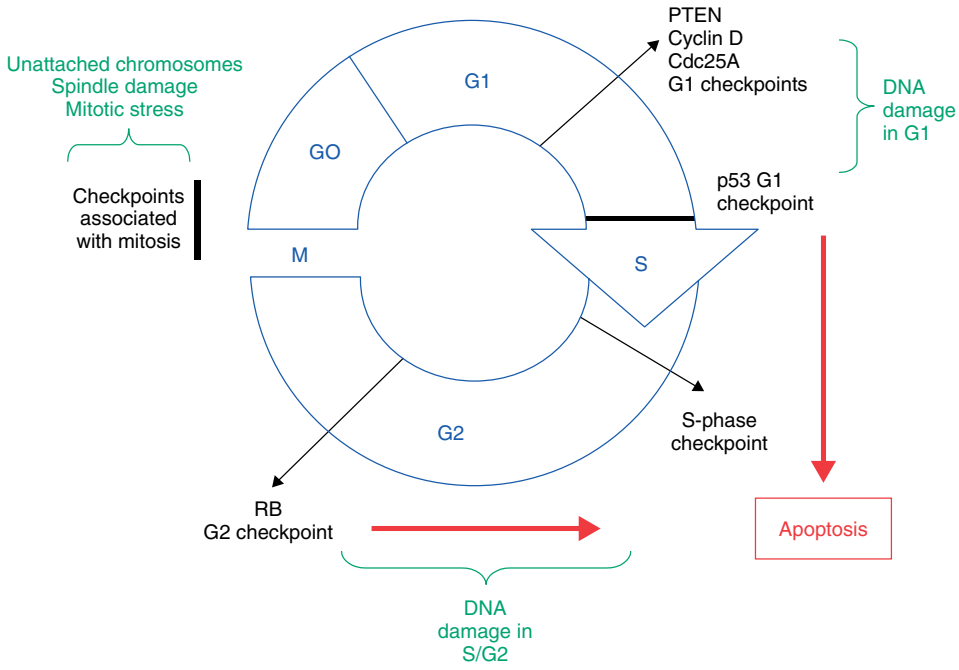

Figure 2 The cell cycle. The cell cycle is divided into G1 (cell growth 1), S (DNA synthesis), G2 (cell growth 2) and M (mitosis). DNA or genomic damage results in cell cycle delay through the activation of cell cycle checkpoints. If the damage is repaired then the cycle resumes. If there is too much damage then the cell may undergo apoptosis (programmed cell death). The cyclins, for example Cdc25A and cyclin D, plus the tumour suppressor proteins p53, RB and PTEN contribute to cell cycle control in mammalian cells. Loss or mutation of genes encoding these proteins encourages cell proliferation and the deregulation of cell cycle blocks in response to genetic damage.

two daughter cells, each with the genetic equivalent of the parent cell. Mitosis is the process by which the chromosomes in the cell nucleus are divided in order to generate two, haploid, daughter nuclei. The process of mitosis in mammalian cells is complex and highly regulated. The sequence of events is divided into phases, termed prophase, metaphase, anaphase and telophase. During prophase, nuclear chromatin material condenses to form chromosomes, the nuclear envelope disassembles and the centrosomes migrate to opposite poles of the cell. The mitotic spindle apparatus is then assembled under the control of centrosomes, which function as microtubule organizing centres at opposite poles of the spindle. The microtubule fibres from opposing poles of the mitotic spindle attach to one another or to the chromosomes via kinetochores, complex protein structures located at the centromeres of chromosomes. During metaphase, the chromosomes become aligned at the metaphase plate, an imaginary line that is equidistant from the two spindle poles. This even alignment is due to the counterbalance of the pulling powers generated by opposing kinetochores and centrosomes. At anaphase, the proteins that bind sister chromatids together are cleaved, allowing them to separate, and the spindle apparatus pulls the sister chromatids to opposite poles of the spindle. Mitosis is concluded with telophase, when sister chromatids arrive at the opposite poles of the spindle, decondense and become enveloped by new nuclear membranes to form the daughter nuclei. Mitosis is generally followed immediately by cytokinesis, where the two daughter nuclei, cytoplasm, organelles (including the centrosomes) and cell membrane are divided equally between the two daughter cells. An interactive animation showing the various stages of animal cell mitosis may be viewed at *www.cellsalive.com/mitosis.htm*.

2.1.2.3 *Cell Cycle Regulation*

Regulation of the cell cycle involves steps crucial to the cell, including detecting and repairing genetic damage, and provision of various checks to prevent uncontrolled cell division. The 2001 Noble Prize for Physiology was shared by Hartwell, Hunt, and Nurse for the discovery of the key molecular events that control the cell cycle (for an illuminating account of this work see Nurse, 2002). There are two main classes of regulatory molecules, cyclins and cyclin-dependent kinases (CDKs), which control progress through the cell cycle (reviewed by Nurse, 1997; also see Malumbres and Barbacid, 2005; Besson *et al*., 2008). Many of the genes encoding cyclins and CDKs are conserved among eukaryotic organisms, but in common with other biological systems, the organization of cell-cycle control systems is more elaborate in higher-order species (Sánchez and Dynlacht, 2005). The two main checkpoints are the G1/S checkpoint and the G2/M checkpoint. G1/S transition is a rate-limiting step

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in the cell cycle and is also known as the restriction point, as the cell cannot proceed to the next phase until checkpoint requirements have been met. Cell-cycle checkpoints are used by the cell to monitor and regulate the progress of the cell cycle, thereby ensuring that various phases are completed before progress can continue and/or to repair DNA damage and prevent damaged or incomplete DNA from being passed on to daughter cells.

The proteins encoded by the tumour suppressor genes *TP53* and retinoblastoma (*Rb*) play an important role in triggering both the G1/S and G2/M checkpoints (**Figure 2**). The p53 protein, voted molecule of the year in 1993 by the journal *Science*, is a transcription factor that becomes activated when the cell is subject to various types of DNA damage and/or other cellular stresses; for example membrane damage, oxidative stress, osmotic shock, heat shock, nucleotide depletion and deregulated oncogene expression. Once activated, p53 plays a pivotal role in inducing cell cycle arrest and activating DNA repair enzymes. The cell cycle arrest provides time for the repair of DNA damage before the cell replicates its DNA (G1/S) or prior to mitosis (G2/M), where unrepaired damage can be lethal to the cell or lead to the formation of deleterious mutations. Checkpoint-arrested cells resume cell cycle progression once damage has been repaired, whereas cells with unrepairable DNA lesions undergo permanent cell cycle arrest or programmed cell death (apoptosis), which may also be initiated by p53. The signalling pathways associated with p53 and DNA damage surveillance, cell cycle arrest and apoptosis are highly elaborate and beyond the scope of this chapter; therefore the reader is referred to the following reviews: Meek (2004); Helton and Chen (2007); Chumakov (2007); Schmitt *et al*. (2007); Branzei and Foiani (2008).

Surprisingly, the centrosome is increasingly being recognized as a key player in regulating cell cycle events, such as orchestrating entry into mitosis, anaphase onset, cytokinesis, G1/S transition, and monitoring DNA damage. Recently, the centrosome has also been described as a hub where regulatory complexes, such as kinases, phosphatases and other cell cycle regulators accumulate to coordinate multiple cell-cycle-specific functions. Dysfunctional centrosomes are associated with various diseases including cancer, Alström's syndrome (Online Mendelian Inheritance in Man™ (OMIM™) database reference #203800; see **Box (1)**), various neurological disorders, and several types of infertility (reviewed by Schatten, 2008). In addition, there are a number of other key structural and protein components which are pivotal for mitotic fidelity; for example, the spindle checkpoint and G(1) postmitotic checkpoints which monitor for gross cell division aberrations and thereby prevent the likelihood of aneugenicity and/or polyploidy (reviewed by Decordier *et al*., 2008).

Box 1 Mendelian Inheritance in Man™ database

Founded in the 1960s by the eminent human geneticist, Dr. Victor McKusick (John Hopkins University), who remains the current curator, the Mendelian Inheritance in Man™ (MIM™) database catalogues all known human genes and genetic disorders and focusses on the relationship between phenotype and genotype. The online version, OMIM™ (at *www.ncbi.nlm.nih.gov*) was set up in 1985 and contains full-text and referenced overviews of all known Mendelian disorders and over 12 000 genes. OMIM™ is updated daily, and the entries contain many links to other genetics resources. For an illuminating account of his life-works and origins of medical genetics as a discipline, the reader is referred to an autobiographical review by McKusick (2006).

Therefore, the control of the cell cycle, DNA replication and mitosis are highly complex process which are critical to the maintenance of the fidelity of DNA and genomic stability. Disregulation of the cell cycle (McDonald and El-Deiry, 2000) or DNA synthesis (McCulloch and Kunkel, 2008) or mitosis (Schatten, 2008), for example via mutation in p53, cyclins or DNA polymerases and/or disruption to centrosome function and so on, may result in genomic instability, and is associated with increased cancer susceptibilities. For example, mutations in p53 are common in many human cancers and thus p53 is considered to be a key 'gatekeeper' in multicellular organisms, protecting genomic stability, and thereby suppressing cancer (Helton and Chen, 2007). As such, p53 is often described as 'the guardian of the genome' (see below).

2.2 Gene Mutation, Mutagenesis and Mutagenicity

The concept of gene mutation (from the Latin word *mutare*, to change) was originally developed by one of the first geneticists, Hugo Marie de Vries, following his rediscovery of Gregor Mendel's laws on heredity in the 1890s, and based on his observations on the evening primrose, *Oenothera* (de Vries, 1900). However, it was later discovered that much of what de Vries was describing in terms of his evidence had nothing to do with what is now known as genetic mutation. To the modern geneticist/genetic toxicologist, the term '*gene mutation*' is used to mean a detectable permanent (heritable) change within a single gene or its regulatory sequences, and 'mutagenesis' is the term used to describe the process by which this occurs. The term 'gene mutation' is therefore usually applied to point mutations; that is,

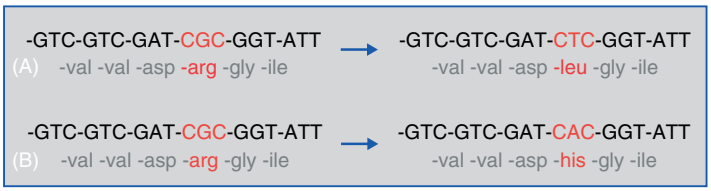

Figure 3 Single base substitution mutations. (A) Single base substitution (guanine replaced by thymidine) in the fourth codon, resulting in a transversion mutation (a mutation in which a purine/pyrimidine is exchanged for a pyrimidine/purine base pair or vice versa); (B) single base substitution (guanine replaced by adenine) in the fourth codon, resulting in a transition mutation (in which a purine is exchanged for another purine nucleotide or a pyrimidine by another pyrimidine nucleotide).

qualitative changes within a single gene involving one or a few nucleotide bases in the DNA sequence (see below). However, it is also common to find the term 'gene mutation' applied more loosely, referring to larger changes involving deletion of chromosomal fragments and/or whole chromosomes (also known as aneuploidy) and even to changes in whole chromosome sets (polyploidy).

Mutagenicity is the capacity to induce permanent changes within genes or their regulatory sequences. The changes may be single base substitutions, insertions, deletions and so on (see below). Sometimes, the term is used more loosely to describe *genetic toxicity (or genotoxicity)*; that is, a broader term that refers to any deleterious change in the genetic material regardless of the mechanism or fate of the induced change. Thus genotoxicity may also encompass nonpermanent and/or premutagenic lesions in the DNA, such as DNA adducts (see below), or may reflect cellular responses, such as the induction of DNA repair systems or cell cycle delay (see above), that are used to infer the presence of DNA damage either directly (DNA adducts) or indirectly (induction of DNA repair or cell cycle delay). However, since DNA damage *per se* may or may not result in permanent genetic changes, it is recommended that specific terminology is used where appropriate, depending on context.

Gene mutations may be characterized in various ways, depending on their molecular make-up or genetic consequences.

2.2.1 Single Base Substitutions (Point Mutations)

Gene mutations can occur when one base is substituted for another, leading to a single base substitution (also known as a point mutation). There are basically two types of base substitution; the first is where one purine base or one pyrimidine base is substituted for another; this type of base substitution is called a transition mutation. In comparison, the substitution of a purine base for a pyrimidine base or vice versa is called a transversion mutation. Viewed in another way, the orientation of purine and pyrimidine bases remains the same in a transition mutation but is reversed in a transversion mutation (**Figure 3**). Both types of base substitution are observed within mutated genes.

Because of the redundancy in the genetic code (see above), about a quarter of all possible base substitutions produce silent (or synonymous) mutations that do not result in amino acid replacements. Single base substitutions, however, may lead to codon changes within the coding sequence of a gene that result in a nonsynonymous mutation, which can occur in one of three main ways:

- **Missense mutations** result from single base substitutions that lead to the insertion of an 'inappropriate' amino acid into the polypeptide during translation. Most single base substitutions will often have no functional effect and are termed conservative substitutions. Nonconservative substitutions, however, have a dramatic effect on protein function depending on the context of the amino acid change within the polypeptide sequence. For example, if the changed amino acid involves the active centre of an enzyme this can lead to a gross reduction in, or indeed, complete loss of, enzyme function. Alternatively, if the amino acid change affects protein folding and its three-dimensional tertiary structure, then the formation of a mutant protein may result, with a similar outcome in loss of biological activity. Many of the abnormal haemoglobins associated with human sickle cell disease and thalassaemias are the result of missense mutations.
- **Nonsense mutations** are single base substitutions which result in the formation of a new inappropriate terminator (or nonsense) codon (see **Table 1**) within the 'reading frame' of the gene. This can lead to the premature termination of gene transcription. The polypeptide formed from such mutated genes will be truncated, that is, shorter than normal, and usually inactive, although on rare occasions the truncated protein may acquire a new and/or novel function (i.e. 'gain-of-function' mutation).
- **Frameshift mutations** arise from the deletion or insertion of nucleotide bases in the DNA that result in a change in the 'reading frame' of a gene (**Figure 4**). A deletion involves the loss of one or

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

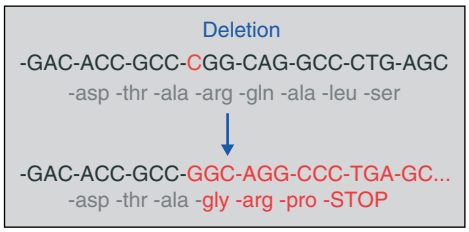

Figure 4 Frameshift mutation. Single base deletion at cytosine in the fourth codon results in a change of the downstream reading frame and introduction of a premature stop codon to produce a nonsense mutation.

more nucleotides, and if a deletion occurs within a coding sequence that involves one, two, or a larger number of bases which is not a multiple of 3, the deletion will result in a change in the 'reading frame' of the gene. Larger deletions may result in partial or whole gene deletions, and may arise through unequal crossover between repeat DNA sequences; for example, as seen in the human genetic disease hereditary and sensory neuropathy Type 1, or chromosomal damage. An insertion, in contrast, involves the addition of one or more nucleotides into the DNA sequence. Again, if the insertion occurs in a coding sequence and involves one, two, or a larger number of bases that is not a multiple of 3, the deletion will result in a change in the 'reading frame' of the gene. Frameshift mutations tend to have a dramatic effect on the translation of the affected gene, as most amino acids after the point of the insertion or deletion of bases will differ from the wild-type in the resulting mutant polypeptide. Very often a new terminator codon is introduced into the reading frame downstream from the point of the insertion or deletion, so, again, a truncated polypeptide will result. As with nonsense mutations, frameshift mutations usually result in polypeptides that are inactive, although, again on rare occasions, they may be 'gain-of-function' mutations.

Single base substitutions, deletions and insertions may also occur in key promoter elements, and these may impact on the transcriptional regulation of a gene, sometimes resulting in reduced and/or total loss of gene expression. Occasionally, mutations result in 'gain-of-function', either as a result of increased levels of gene expression or the development of a new capacity. All types of mutation that result in an altered polypeptide or gene expression, no matter how they arise, can, in turn, have a marked effect on the phenotype of the affected cell (most often due to the loss of enzyme/protein function and the resulting biological sequelae). Much use of phenotypic changes is made in mutagenicity tests. Sequence variants with no obvious effect upon phenotype may be termed polymorphisms.

The vast majority of base substitutions, frameshift mutations, deletions and insertions occur spontaneously, through errors in DNA replication, repair or mitotic division, although they can be induced by exposure to environmental mutagens such as ultraviolet light, ionizing radiation (IR) (i.e. cosmic rays and/or nuclear radiation) and/or genotoxic chemicals. Although the molecular mechanisms resulting in mutation induction maybe specific to a particular environmental genotoxin, the potential hazards associated with environmental exposure to genotoxins capable of inducing different types of genetic mutation are equivalent. Somatic mutations may cause adult-onset disease, such as cancer, but these mutations cannot be transmitted to offspring. A mutation in the germline can be transmitted to future generations, unless it affects fertility or survival into adulthood. It is estimated that each individual carries up to six recessive mutant alleles that in a homozygous state would have serious biological consequences, that is, result in lethality or severe genetic disease (see below).

2.2.2 Chromosome Abnormalities

These may be divided into structural and numerical abnormalities. Structural chromosomal rearrangements result from chromosome breakage (also known as clastogenicity) and, on occasion, subsequent reunion of the chromosomes in a different configuration. Structural chromosomal rearrangements can be balanced or unbalanced. In balanced rearrangements the chromosome compliment is complete, with no loss or gain of genetic material, for example the reciprocal translocation of genetic information from one chromosome to another. They are generally harmless, with the exception of rare cases where one of the breakpoints may adversely impact the expression of important regulatory genes; for example, Philadelphia chromosome, a diagnostic marker of chronic myeloid leukaemia, is associated with a translocation in the *BCR-ABL* oncogene which transforms cells (Sessions, 2007). An unbalanced rearrangement, as the name suggests, usually results in a net loss of genetic material (and rarely gain) and is associated with more adverse genetic consequences. Numerical chromosomal abnormalities involve the gain or loss of one or more whole chromosomes, which is known as aneuploidy, or the addition of one or more haploid complements of chromosomes, which is known as polyploidy. The types of chromosome abnormalities and mechanisms by which they arise are described in more detail in **Cytogenetics**.

2.2.3 DNA Adducts

The reaction of a chemical genotoxic carcinogen with DNA, either directly or after metabolic activation, typically involves covalent binding of an electrophilic carcinogen with a nucleophilic site in DNA, to form

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

a DNA adduct. Guanine is by far the most prevalent target in DNA, and adducts have been described at several sites within the guanine molecule (e.g. N7, C8, O6 and exocyclic N2 positions), although adducts have been reported for all of the bases present in DNA. Such adducts can be small, such as the simple addition of ethyl and methyl groups associated with DNA alkylation or oxidized DNA bases such as O6-MeG, or they can be bulky, owing to reaction with large polycyclic organic molecules such as the metabolites of benzo(a)pyrene or aflatoxin B_1 (e.g. aflatoxin B_1 and the 8,9-dihydro-8-(*N*′7-guanyl)-9-hydroxy-aflatoxin B_1 adduct), or a combination of small and bulky adducts such as those associated with reactive oxygen species (Phillips, 1997). Fundamental to the advances made in the last two decades has been a vast effort to elucidate the chemical structures of DNA adducts. Adduct species formed via chemical reactions with naked DNA *in vitro,* as well as in experimental biological model systems, have been characterized using various sensitive analytical techniques mass, fluorescence and nuclear magnetic resonance spectrometry, high-pressure liquid chromatography, thin-layer chromatography (TLC), and so on (reviewed by Sharma and Farmer, 2004). Further information, on a molecular level, has been obtained by subjecting purified adducts to nuclear magnetic resonance and other methods to determine stereospecificity and three-dimensional structure. For a review of the field over the past two decades see Delaney and Essigmann (2008).

Adducts can form chemical links between adjacent nucleotide bases on the same DNA strand (intrastrand crosslinks) and can form interstrand crosslinks between each strand of double-stranded DNA. If a DNA adduct involves the nitrogen or oxygen atoms involved in base pairing, and the adducted DNA is not repaired, base substitution can result. Some unrepaired alkylated bases are lethal, owing to interference with DNA replication, while others, such as O6-methylguanine (O6-MeG) lead to mutation if unrepaired. These differences indicate that not all DNA adducts are equivalent. In fact, some adducts appear not to interfere with normal DNA functions or are rapidly repaired, others are mutagenic and yet others are lethal. DNA adduct levels, measured at any single point in time, reflect tissue-specific rates of adduct formation and removal, which depend upon genotoxic carcinogen exposure and activation, DNA repair, adduct instability and tissue turnover (Poirier *et al*., 2000). As such, DNA adduct levels have been used as biomarkers of exposure to potential genotoxic carcinogens in a wide variety of human occupational and environmental exposure studies. The correlations of DNA adducts, however, with cytogenetic biomarkers of genetic damage (such as chromosome aberrations or micronuclei (MN)) or indeed target organ tumourigenicity, are invariably complex, with examples of both positive correlation and no correlation whatsoever (reviewed by Gyorffy *et al*., 2008).

Some compounds that have a flat, planar structure, such as the anthracyclins, can intercalate between the DNA strands of the DNA helix and bind reversibly but noncovalently to DNA. The most extensively studied DNA intercalating agents are acridine and its derivatives. The intercalated molecules may interfere with DNA replication or the activity of repair enzymes and cause additions and deletions of base pairs, and are therefore frameshift mutagens, especially in bacteria and bacteriophage, but do not otherwise show a wide range of mutagenic properties. Recent advances in technology for detecting intercalation (Snyder, 2007) suggest this may be a property of a wider range of chemicals than previously recognized. For example, quite a number of flavonoids appear to intercalate into DNA. However, their mutagenic properties may be dominated by the fact that many of them are also able to inhibit topoisomerase II enzymes, and are therefore likely to be clastogenic (Ferguson and Denny, 2007).

Protein adduct formation is considered to be a valuable surrogate for DNA adduct formation since many chemical carcinogens bind to both DNA and protein in blood with similar dose–response kinetics. Haemoglobin and serum albumin are the proteins of choice because they are readily accessible, more abundant than DNA, and have known rates of turnover. Since protein adducts are not removed by active repair processes, chemically stable adducts of haemoglobin or serum albumin provide a more precise measure of dose integrated over the lifespan of the proteins in question (reviewed by Farmer and Shuker, 1999). Thus protein adducts have been used as biomarkers of exposure to potential genotoxic carcinogens in a variety of human occupational and environmental exposure studies, for example with heterocyclic amines, dietary genotoxic carcinogens present in cooked red meat (Lynch *et al*., 1991; 1993).

2.3 DNA Repair

The integrity of the genome is crucial for its function. However, DNA in living cells is inherently unstable and it is constantly attacked by damaging agents that threaten its integrity. These agents can arise from cellular metabolic processes or can be induced by environmental factors. Insults such as hydrolysis, oxidation, alkylation, and mismatch of DNA bases, are endogenous sources of DNA damage; IR, ultraviolet radiation (UVR), and many kinds of chemical agents are common sources for exogenous DNA damage.

DNA damage can lead to severely impaired cellular functioning, which might cause cell death, or can induce permanent changes in the DNA sequence, contributing to oncogenesis, premature ageing and severe genetic disorders (Hoeijmakers, 2001; van Gent *et al*., 2001). Cells have developed complex signal transduction,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

cell-cycle-checkpoint and repair pathways to respond to DNA damage and promote genomic stability. About 150 genes associated with DNA repair have been identified in humans to date (Wood *et al*., 2005). This is not surprising, considering that DNA molecules can be damaged in many ways and repair systems must be able to recognize and deal with each type of damage.

Exposure of mammalian cells to genotoxic agents activates an intricate network of mechanisms collectively known as the DNA-damage response. This response includes DNA repair and DNA-damage signalling pathways that alert the cell to the presence of DNA damage and coordinate the appropriate response (Iliakis *et al*., 2003; O'Driscoll and Jeggo, 2006). The DNA-damage response leads to slowing or arrest of cell-cycle progression at defined checkpoints, and DNA repair, but also to marked alterations in numerous physiological processes, such as an increase in cellular levels of deoxyribonucleotides, changes in chromatin structure at the site of DNA damage, changes in gene-expression profiles, and probably also in protein synthesis, degradation and trafficking (Jackson, 2002; Rouse and Jackson, 2002; Shiloh, 2003).

Different DNA-repair pathways exist that are essential for cells to efficiently respond to DNA damage. These pathways include: (i) the direct reversal pathway, (ii) the mismatch repair (MMR) pathway, (iii) the nucleotide excision repair (NER) pathway, (iv) the base excision repair (BER) pathway, (v) the homologous recombination (HR) pathway, and (vi) the nonhomologous end-joining (NHEJ) pathway. In 1994, the journal *Science* voted the 'DNA repair enzyme' molecule of the year!

2.3.1 Direct Reversal of DNA Damage

Direct reversal of the DNA damage is in most cases not possible due to thermodynamic or kinetic reasons. In some cases, however, the DNA damage can be reversed directly. These repair reactions are direct one- or two-step processes, and do not require multiple proteins like the repair pathways.

2.3.1.1 Photoreactivation of Pyrimidine Dimers

UV light induces the formation of covalently linked dimers of cytosine and thymine bases which are adjacent to each other on the same strand of DNA. Two common UV products are the cyclobutane pyrimidine dimer (CPD) and, at one-third the frequency of that, the 6,4 photoproduct (6,4 pyrimidine-pyrimidone).

The enzyme photolyase binds to complementary DNA strands and is able to split the pyrimidine dimer (Sancar, 2003). This reverse reaction can occur when the enzyme is activated by energy absorption from blue or UV light (300–500 nm). Photolyases are flavoproteins, and consist of two light-harvesting factors, FADH2 (in all photolyases) and, as a second cofactor, depending on the class, either a pterin in folate photolyases or a deazaflavin in deazaflavin photolyases. The pyrimidine dimer is cleaved by an electron transfer of the reduced FADH2 (Sancar, 2003). Photolyases are found in prokaryotes and lower eukaryotes, but not in placental mammals.

2.3.1.2 Direct Reversal of O6-alkylguanine

Alkylating agents can transfer methyl or ethyl groups to various O or N sites in guanine, thereby modifying the base and interfering with its pairing with cytosine during DNA replication. The O6 site in the guanine has the highest mutagenic potential and is, besides the N2 position, highly selectively alkylated by substances that react via an SN1 mechanism (Margison *et al*., 2002). The most abundant environmental alkylating substance is dimethylnitrosamine, which is formed during food preparation. Besides environmental substances, there are also alkylating substances, which are used as chemotherapeutics for cancer treatment (e.g. procarbazine, carmustin).

The methyl group at the O6 site of guanine is removed by the DNA repair enzyme O6-methylguanine-DNA methyltransferase (MGMT) via a one-step methyl transfer reaction. During this reaction the methyl group is transferred from the alkylated base onto an internal cysteine residue within the active centre of the alkyl-transferase. This results in the restoration of the guanine within the genomic DNA. The alkyl group transfer leads to irreversible inactivation of the transferase and targets it for ubiquitylation and proteasome-mediated degradation. This so-called 'suicide reaction' implies that the cells' capacity for repairing O6-guanine lesions depends on the pre-existing MGMT levels in the cell, or the rate at which cells can resynthesize MGMT.

DNA alkyltransferases are ubiquitously found in prokaryotic and eukaryotic organisms (Wood *et al*., 2005). The human MGMT acts in a similar way to the Ogt protein of *E. coli*, which is constitutively expressed in this micro-organism. O6-MeG lesions, which are not repaired by MGMT, may mispair with thymine during the DNA replication. In the following DNA replication cycle, thymine will pair with adenine. By this mechanism the O6-MeG lesions cause distinctive G–C to A–T point mutations, which are believed to be the driving force of the carcinogenic effects of alkylating agents. In the event of failure of direct reversal repair, these mispair lesions can potentially be repaired by the MMR pathway.

2.3.1.3 Repair of Single-Strand Nicks

In this case the damage is the presence of single-strand nicks having free 5′-phosphates and 3′-hydroxyls. Nicks with other configurations or nicks accompanied by additional backbone or base damage require more complex processing prior to repair.

DNA ligase repairs single-strand nicks by catalysing phosphodiester bond formation using adenosine

triphosphate (ATP) or nicotinamide adenine dinucleotide (NAD^+) as energy donor.

2.3.2 Mismatch Repair (MMR)

Mismatch of bases (e.g. G–T or A–C) is a common DNA lesion due to a failure in proofreading during DNA replication. Another common lesion is the incorporation of uracil (normally found in RNA) instead of thymine.

DNA MMR is a highly conserved process from prokaryotes to eukaryotes. In *E. coli* a number of genes have been discovered, which when mutated lead to hypermutation. Thus the gene products of these genes are called MutS, MutL and MutH. These proteins interact with each other as homodimers or heterodimers/trimers and are the key players in the detection of a DNA mismatch and its preparation for repair. They determine the exact position of the mismatch on the daughter strand, induce the strand separation and the recruiting of an exonuclease, which excises the mismatched base after the separated daughter strand has been nicked. There are human homologues of MutS (Msh2, Msh3 and Msh6) and MutL (Mlh1 and Pms1), but not MutH. The endonuclease function of MutH in prokaryotes leads to the above-mentioned DNA nicking prior to strand separation. In humans this function is accomplished by MutL homologues (Kunkel and Erie, 2005).

MMR factors also seem to be involved in the physiological function of immunoglobulin (Ig) diversification, an essential process for immunity. The Ig diversification is achieved by somatic hypermutation (SMH), as well as recombination in the heavy chain variable (VDJ) region and class-switch recombination (CSR), two processes mediated by NHEJ. Studies with MMR mutants in mice have suggested an implication of the MMR pathway in SMH and also CSR, since Msh2, Msh6 and ExoI mutants display reduced levels of MMR in CSR and SMH (Kunkel and Erie, 2005).

2.3.3 Nucleotide Excision Repair (NER)

The NER pathway plays an important role in the repair of different kinds of DNA damage caused by UVR and mutagenic chemicals, and its impairment in humans is associated with growth defects, excessive UV sensitivity, and, in certain cases, increased skin cancer. Discovered in 1964, the NER apparatus represents the sole enzyme system responsible for the removal of bulky DNA adducts and is universally found in all free-living organisms, including mycoplasmas. In addition to bulky adducts, the enzyme system repairs many other lesions that do not distort the helix, including O6-MeG and other methylated bases.

In NER, an enzyme system hydrolyses two phosphodiester bonds, one on either side of the lesion, to generate an oligonucleotide carrying the damage. The excised oligonucleotide is released from the duplex, and the resulting gap is then filled in and ligated to complete the repair reaction. This nuclease activity, unique to DNA repair, is called excision nuclease (exinuclease). The enzyme activity of exinuclease results from sequential and partly overlapping activities of several polypeptides that bind to DNA and utilize the energy released by ATP hydrolysis to deform (kink and unwind) the DNA and eventually excise the lesion by dual incisions.

A side effect of this wide substrate range is that exinuclease even 'excises' mismatched nucleotides; however, in contrast to the MMR process, the exinuclease will excise a mismatched base from either strand and can actually cause mutation fixation rather than mutation avoidance. Fortunately, this activity is rather inefficient so that mutations caused by this side reaction do not significantly contribute to the mutation load of cells.

Only three proteins (UvrA, UvrB and UvrC) are required in NER in the prokaryotes, whilst more than 30 proteins are involved in the mammalian NER (Truglio *et al*., 2006). Although prokaryote and eukaryote exinucleases perform the same function and share remarkably similar excision mechanisms, the subunits comprising the exinuclease activity share very little homology.

Two NER subpathways have been identified: the global genome NER (GG-NER) that repairs DNA damages throughout the genome, and the transcription -coupled NER (TC-NER) that is specific for detecting and removing damages within actively transcribed genes.

During the multistep process of the NER pathway, the DNA lesion is recognized and the oligonucleotide containing the lesion is removed. The gap is then filled with the ligation of a new oligonucleotide which is complementary to the opposite DNA strand. It has been discovered that a factor essential for transcription (TFIIH) is recruited to the damage site and involved in NER. This fact has created considerable interest, particularly with regard to the finding that there is preferential repair of the transcribed strand in expressed genes. In fact, early work on gene-specific repair showed that essential or active genes were preferentially repaired compared with inactive genomic regions or the bulk of the genome (i.e. 99% noncoding); for example, mouse and human fibroblasts have identical survival curves to UV irradiation *in vitro*, however, most of the pyrimidine dimers are removed from human cells after 24 h, whereas only 20% are removed from mouse cells. This suggests mouse cells preferentially repair those dimers essential to survival. Therefore, preferential repair reflects the cell's ability to survive DNA damage.

NER is involved in three human genetic syndromes: xeroderma pigmentosum (XP, OMIM reference *611153), Cockayne syndrome (CS, OMIM #216400) and trichothiodystrophy (TTD, OMIM #601675). These syndromes are characterized by neurodegeneration, increased cancer frequency and ageing (Thoms *et al*., 2007). XP patients are sensitive to short sun exposures

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and have a greater than 1000-fold increased skin cancer risk that usually develops at an average age of 10 years old. XP individuals may also develop neurological abnormalities. Mutations in different genes coding for proteins involved in the NER pathway are responsible for causing XP: these mutations are located within the genes *XPA, XPB, XPC, XPD, XPE, XPF* and *XPG*. The mutations in *XPC* or *XPE* impact only the GG-NER pathway, whereas mutations in the remaining genes affect both GG-NER and TC-NER (Thoms *et al*., 2007).

CS is an autosomal recessive genetic disease and it is very rare in humans (Thoms *et al*., 2007). CS patients are also sensitive to sunlight but they do not have predisposition for skin cancer. The disease is characterized by growth retardation, cognitive impairment and ophthalmologic disorders. CS individuals have a very short lifespan and usually die in the first or second decade of life. The causes of CS are mutations within two proteins that are essential for DNA damage recognition in NER. TTD is also rare and inherited as an autosomal recessive disorder. The clinical features of TTD are brittle hair and nails, dwarfism and ataxia (Thoms *et al*., 2007). Many mouse models for NER mutations have been studied. Mice that carry a homozygous mutation for XP genes are viable, except the *XPD* mutants that show embryonic lethality (Nakane *et al*., 1995; Harada *et al*., 1999; Itoh *et al*., 2004; Yoon *et al*., 2005). Most of these mutants are UV sensitive and have an increased predisposition to UV-induced skin cancer.

2.3.4 Base Excision Repair (BER)

Base damages, the most common insult to cellular DNA, are repaired by the BER pathway (Wilson and Bohr, 2007). BER includes a short-patch BER subpathway that replaces a single nucleotide, and a long-patch subpathway during which 2–13 nucleotides are incorporated.

Initially the damaged base is removed by glycosylases such as Ogg1 and Mutyh. The glycosylases catalyse the hydrolysis of the *N*-glycosylic bonds linking the bases to the deoxyribose-phosphate backbone of DNA, leaving an abasic sugar in the DNA called an apurinic or apyrimidinic site (AP site), depending on the nature of the base removed. Then the endonuclease APE1 digests the DNA strand at the apurinic or apyrimidinic site. DNA polymerase β (Pol β), in the case of the short-patch BER subpathway, or Pol β and/or Pol ε or δ, in the case of the long-patch BER subpathway, fills the gap by incorporating nucleotides in the DNA strand. Then the complex XRCC1/ligase III carries out the strand ligation during the short-patch subpathway. Other proteins are involved in the long-patch subpathway for the DNA synthesis step, and ligase I carries out the strand ligation. Examples of BER include removal of uracil, hypoxanthine and methyladenine from DNA; however BER has a limited substrate range because the DNA glycosylases that initiate the repair process are in intimate contact with the lesion during catalysis.

In the past there was only a small amount of evidence to support the involvement of BER in human disorders or in cancer. However, a human genetic disorder linked to defective BER has recently been identified. This autosomal recessive disorder, called MUTYH-associated polyposis (MAP, OMIM reference #608456), is characterized by a biallelic germline mutation of the *MUTY* gene (OMIM reference 604933), and causes multiple colorectal adenomas and carcinomas (Cheadle and Sampson, 2007). The main function of the glycosylase MUTYH in the BER is the excision of adenines misincorporated opposite 8-oxoG when oxidative DNA damage occurs. When this damage is not repaired properly, G:C $\rightarrow$ T:A mutations are induced. These mutations are typically found in the adenomatous polyposis coli (*APC*) gene in MAP tumours.

In recent years also, mouse models have been generated and have shown that knockouts of individual glycosylases are viable, which is explained by partial redundancy between different glycosylases. Ogg1$^{-/-}$ mice were normal (Klungland *et al*., 1999; Ocampo *et al*., 2002). Mutyh$^{-/-}$ mice developed intestinal tumours after a long latency (Sakamoto *et al*., 2007). The double knockout Ogg1$^{-/-}$ Mutyh$^{-/-}$ mice show a stronger phenotype: they have elevated cancer susceptibility and shorter lifespan with 50% of double mutants developing lung tumours, lymphomas and sarcomas by 15 months of age (Xie *et al*., 2004).

On the other hand, inactivation of BER proteins which function downstream of the glycosylases induce embryonic or postnatal lethality, highlighting the vital importance of the process as a whole. Murine homozygous mutants for LigI, Lig III and Xrcc1 die before birth (Petrini *et al*., 1995; Puebla-Osorio *et al*., 2006; Tebbs *et al*., 1999), whilst homozygous mutants for Pol β die immediately after birth (Gu *et al*., 1994; Sugo *et al*., 2000).

2.3.5 Homologous Recombination and Nonhomologous End Joining

DNA double-strand breaks (DSBs) are considered to be the most dangerous form of DNA damage (Hoeijmakers, 2001; Khanna and Jackson, 2001; Rich *et al*., 2000; van Gent *et al*., 2001). They are generated when the two complementary strands of the DNA double helix are broken simultaneously at sites that are sufficiently close to one another that base pairing and chromatin structure are insufficient to keep the two ends juxtaposed (Jackson, 2002). Thus, with DSBs, DNA loses physical integrity and information content on both strands, making repair more difficult to perform than for other types of DNA damage in which the complementary strand is used as a template. Moreover, the biochemical configuration and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the structure of broken DNA ends can be very diverse and they may require processing prior to ligation.

DSBs can be generated following exposure of cells to exogenous agents or can arise during endogenous processes. IR, such as X- and γ-rays, is probably the most significant exogenous agent inducing DSBs. Other exogenous agents that can induce DSBs are radiomimetic or chemotherapeutic drugs, such as bleomycin, neocarzinostatin, etoposide and other topoisomerase inhibitors (Povirk, 1996). DSBs are generated also by endogenous agents such as reactive oxygen species (ROS) produced during cellular metabolism (Lieber *et al*., 2003). Metabolically generated ROS species are unlikely to give rise to the clustered damage observed with IR; nevertheless, they produce DSBs that are likely associated with damaged bases and sugars (Pouget and Mather, 2001). Furthermore, DSBs are produced during programmed chromosomal rearrangements, such as meiosis to initiate recombination between homologous chromosomes, VDJ and immunoglobulin isotype CSR (Khanna and Jackson, 2001). Physiological DSBs can be also generated when the replication machinery meets nicks or other types of lesions, from mechanical stress on the chromosome, or at the termini of chromosomes due to defective metabolism of telomeres (d'Adda di Fagagna *et al*., 2004; Mathieu *et al*., 2004).

There is experimental evidence supporting a causal relationship between DSBs, genomic instability and carcinogenesis. Indeed, incorrect repair of DSBs may cause loss or amplification of chromosomal material or translocations. These events can lead to tumourigenesis if, for example, they are associated with the inactivation of tumour suppressors or activation or deregulation of proto-oncogenes (Jackson, 2002; Khanna and Jackson, 2001). Many cancers of lymphoid origin exhibit chromosomal rearrangements that have arisen as a consequence of the defective DSB repair of V(D)J recombination intermediates (Vanasse *et al*., 1999). Besides, mutations in factors involved in DSB signalling and repair lead to chromosomal instability (CIN) and to increased cancer predisposition in humans and in animal models (Ferguson and Alt, 2001; O'Driscoll and Jeggo, 2006).

The two main pathways to repair DSBs are HR and NHEJ (Jackson, 2002; Lieber *et al*., 2003; Valerie and Povirk, 2003). A third pathway, single-strand annealing (SSA), can be considered as a variant of HR. HR and NHEJ are largely distinct from one another and function in complementary ways. Their fundamental differences are the requirement for a homologous template DNA and the fidelity of DSB repair. A review of the early events in the mammalian response to DNA DSBs has recently been published by Riches *et al*. (2008).

HR relies on extensive sequence homology and involves copying the missing information from an undamaged homologous chromosome. In principle, this is error free and occurs without the loss of genetic information. Conversely, NHEJ does not require an undamaged DNA molecule and joins the broken DNA ends using little or no sequence homology. In most cases, this pathway results in the loss of a few nucleotides at the broken DNA ends. Hence, NHEJ is typically error prone and is an imperfect process from the standpoint of preserving genomic information. SSA is similar to HR and is dependent upon homologous sequences flanking the break site. Also this process leads to loss of genetic material since the nonhomologous sequences are removed and, after annealing of the homologous sequences, ligation completes the reaction.

HR and NHEJ pathways are highly conserved throughout eukaryotic evolution, but their relative importance differs from one organism to another. Simple eukaryotes such as yeasts rely mainly on HR to repair DSBs, while in higher eukaryotes NHEJ is the predominant DSB repair pathway (Jackson, 2002). This difference could be related to their genome organization. The genomes of multicellular eukaryotes have a substantial fraction of repetitive DNA (about 40% of the human genome). Therefore, the search for a homologous template DNA during HR is insurmountable when the break occurs in the portion of the genome that is repetitive, and homology partners might be chosen inappropriately, except during late S, G2 and M phases, when a sister chromatid is optimally positioned physically (Lieber *et al*., 2003). Indeed, the relative contribution of HR and NHEJ in mammalian cells differs depending on the stage of the cell cycle. Cells defective for HR, such as *RAD54* mutants, show a relatively flat IR-sensitivity pattern during the cell cycle, and they are more IR sensitive only during the late S to G2 phases (Sonoda *et al*., 2006). Instead, cells defective for NHEJ are extremely sensitive in the G1 and early S-phases (Sonoda *et al*., 2006). This indicates that NHEJ functions throughout the cell cycle and is the predominant mechanism for DSB repair during G0, G1 and early S-phases, whereas HR is most efficient during the late S and G2 phases of the cell cycle. However, these pathways are not mutually exclusive, and repair events that involve both HR and NHEJ have been detected. Moreover, they are not necessarily independent, and the coordinated action of both pathways is necessary in order to repair a DSB with minimal error. In addition to its crucial role during G0, G1 and early S-phases, the NHEJ pathway is essential to repair DSBs that occur during V(D)J recombination and Ig CSR in developing lymphocytes.

2.4 Human Genetics and the Consequences of Mutation

The human gene pool is known to carry many deleterious genes acquired from preceding generations, and over

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

11 000 traits or monogenic (single gene) genetic disorders have been described that follow recognized patterns of Mendelian inheritance. It is clear that these arise as a result of DNA changes affecting particular chromosomes or genes. They can be grouped as follows:

1. Autosomal dominant inheritance, in which a change in only one of a pair of alleles is sufficient for the condition to be expressed.
2. Autosomal recessive inheritance in which both alleles must be mutated for the trait to become manifest.
3. Sex-linked inheritance, which may also be recessive or dominant, where the mutant gene is on a sex chromosome and will be expressed at high frequency in males (XY), and at a much lower frequency in females (XX), if the gene is X-linked and acts in a recessive manner.
4. Genomic imprinting.
5. Polygenic and multifactorial inheritance, in which the condition results from the interaction of several genes and may include an environmental component.

Each type of inherited defect is discussed in more detail below, with examples describing the impact each has on the human population; more detailed discussions can be found in reputable human genetics textbooks, such as Emery's *Elements of Medical Genetics* (Turnpenny and Ellard, 2005). Another source of information is the OMIM™ database (**Box 1**). At a molecular level, the germline alterations identified in Mendelian diseases include a broad variety of DNA changes, from 'microlesions' to 'gross lesions'. The microlesions constitute the largest category of DNA sequence alterations (52 027 out of 59 613, or 92.3%). These include single base-pair missense/nonsense and splicing mutations or small deletions among 2229 genes listed in the Human Gene Mutation Database (HGMD; *www.hgmd.org*) as of August 2008. The remainder (4586 or 7.7%) are 'gross lesions', including gross deletions (3452), repeat variations (149), gross insertions/duplications (545) and complex rearrangements (440).

2.4.1 Autosomal Dominant Inheritance

Genetic conditions resulting from autosomal dominant inheritance usually only manifest in individuals carrying both a normal allele and abnormal or mutant allele, that is, in the heterozygous state (an allele is an alternative form of a gene found at the same locus on homologous chromosomes). It is often possible to follow dominantly inherited disorders through many generations of a family. The most common example of a monogenic autosomal dominant disorder is familial hypercholesterolaemia (FH, OMIM reference #143890), which can result from mutations in either the low density lipoprotein receptor gene (*LDLR*, OMIM *606945), or the apolipoprotein B-100 gene (*APOB*, OMIM #144010), or the recently identified proprotein convertase subtilisin/kexin type 9 gene (*PCSK9*, OMIM *607786) (Austin *et al*., 2004). These patients have abnormally high serum cholesterol levels, which increases the risk of coronary heart disease. Homozygotes (who have two copies of the mutant allele) usually die from cardiac infarction in the third decade of their lives, while about 50% of heterozygotes die of ischaemic heart disease before the age of 60.

2.4.2 Autosomal Recessive Inheritance

Genetic conditions resulting from autosomal recessive inheritance are usually only manifested in individuals with two copies of the mutant allele, that is, they are homozygous recessive, whereas individuals heterozygous for the mutant allele are healthy *carriers* of the trait but show no features of the disorder. In most cases, affected individuals are likely to be 'compound heterozygotes'; that is, they will have inherited one mutant allele from one parent and another, different mutant allele, from the other parent. In other words, they will carry two mutations at the same locus, unless their parents are related, when they are likely to be homozygous for the same mutation by decent, inherited from a common ancestor. Thus genetic disorders due to recessive genes are normally rare as the prevalence of the condition depends on the frequency of carriers in any one population.

One of the most common examples of an autosomal recessive genetic disorder is cystic fibrosis (CF, OMIM reference #219700), which is caused by mutations of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene (Riordan *et al*., 1989). More than 1400 mutations associated with CF have been described (Flume and Stenbit, 2008), with some mutations resulting in milder forms of the disease (see Turnpenny and Ellard, 2005, for a more in-depth account). The disease has a high prevalence in Western European Caucasian populations, with an incidence of 1 in 2000 live births, and accounts for 1–2% of admissions to children's hospitals. The prevalence, however, is lower in American Africans (1 in 15 000) and American Asians (1 in 31 000). The clinical features of CF are characterized by a generalized disorder of the mucus-secreting glands of the lungs, pancreas, mouth and gastrointestinal tract, as well as the sweat glands, as a result of disregulation of the CFTR protein which plays a principal role as a chloride channel transporter in epithelial cell membranes. As a result, mucus production is more viscous than normal and this leads to an increased susceptibility for infection by pathogenic micro-organisms. Chronic lung disease caused by recurrent infection eventually leads to fibrotic changes in the lungs, with secondary cardiac failure, a condition known as *cor pulmonale*. Although antibiotics and physiotherapy have been very effective in increasing the average life expectancy of affected children, from less than 5 years in 1955 to around 30

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

years at present, CF remains a significant clinical burden (Flume and Stenbit, 2008).

2.4.3 Sex-Linked Inheritance

Sex-linked inheritance refers to patterns of inheritance shown by genes located on the sex chromosomes. Genes located on the X chromosome are X-linked, whilst those on the Y chromosome are Y-linked. This leads to special patterns of inheritance, particularly with recessive genes. Genetic disorders associated with X-linked recessive inheritance are usually only manifest in males, as the affected individual will be hemizygous for the mutant allele present on his single X chromosome. Such genetic diseases are transmitted to affected males by heterozygote healthy carrier females, as well as by affected males, to their obligate carrier daughters, with a consequent risk to male grandchildren through these daughters (Turnpenny and Ellard, 2005). In other words, a female with a recessive allele on the X will not show the syndrome, as is the case for normal recessive alleles. An affected male, however, with such a gene on his X chromosome will not be able to mask it with the normal copy, as this is not present on his Y chromosome.

One of the most common examples of an X-linked recessive disorder is Duchenne muscular dystrophy (DMD, OMIM reference #310200), the most common form of muscular dystrophy with a prevalence of 1 per 3500 live male births, which is due to mutation in the dystrophin gene (Koh *et al*., 1987). The clinical features are characterized by progressive weakness and wasting of certain muscles which usually manifest as an awkward gait, inability to run quickly and propensity to fall. The muscle fibres undergo necrosis, to be replaced by fatty and fibrous tissue. Most boys are wheelchair bound by the age of 10, and the majority die by 20 years of age, usually due to heart failure (for further information see Turnpenny and Ellard, 2005).

Genetic disorders resulting from X-linked dominant inheritance are manifest both in females and in males, and although uncommon, they superficially resemble autosomal dominant traits because affected females have a one in two chance of transmitting the condition to their daughters and sons. There is, however, an important difference because an affected male will transmit the trait to all of his daughters but none of his sons (as sons inherit their single X chromosome from their mothers). An example of an X-linked dominant disorder is Charcot-Marie-Tooth disease Type 1X (CMT1X, OMIM reference #302800), a clinically and genetically heterogeneous group of hereditary motor and sensory peripheral neuropathies, caused by mutations in the gap junction beta 1 (*GJB1*) gene, located on the X chromosome. The gene encodes the gap junction protein connexin 32, although the natural history of CMT1X is poorly understood (Shy *et al*., 2007).

Genetic disorders resulting from Y-linked dominant inheritance, which affect males only, are rarer still. Examples include mutations in the 'deleted in azoospermia' family of genes (*DAZ* genes, OMIM reference 400003), which encode highly conserved RNA-binding proteins that are essential for gametogenesis and male fertility (Reynolds and Cooke, 2005), and the 'sex determining region-Y' gene (Su and Lau, 1993), which encodes a transcription factor that is a member of the high mobility group (HMG)-box family of DNA-binding proteins (Harley and Goodfellow, 1994). Mutations in the 'sex determining region-Y' gene (*SRY*, OMIM 480000) give rise to XY females with gonadal dysgenesis (Swyer syndrome, OMIM 306100) and translocation of part of the Y chromosome containing this gene to the X chromosome in XX males (OMIM 278850).

2.4.4 Genomic Imprinting

Generally, individuals inherit two allelic copies of every gene, a maternal copy and a paternal copy, and both alleles are expressed equally at most loci. The genomic imprinting of genes represents an exception to this rule and refers to maternally and/or paternally inherited genes which contain specific epigenetic modifications, for example via DNA methylation at cytosine bases and/or chromatin remodelling via histone acetylation, which result in heritable changes in gene expression that are not coded in the DNA sequence itself. Such epigenetic modifications result in differential gene expression patterns in the offspring. Thus, individual germline marks can control allelic-specific silencing or activation of imprinted genes, and sometimes neighbouring genes also, which can lead to clusters of imprinted transcripts. In the simplest scenario, only one of the two alleles at an imprinted gene locus is expressed. In other cases, an imprinted locus can include a variety of maternally expressed, paternally expressed and bi-allelically expressed transcripts (reviewed by Ubeda and Wilkins, 2008). Imprinted genes have been associated with a wide range of diseases; evidence for epigenetic abnormalities at imprinted loci have been observed in cloned mammals (Jaenisch *et al*., 2005), and their disruption has been reported in several human genetic disorders, such as imprinted in Prader-Willi syndrome (IPW, OMIM *601491) and Angelman syndrome (AS, OMIM #105830) and also in various cancers (see below).

2.4.5 Polygenic and Multifactorial Inheritance

Simple monogenic modes of inheritance represent the tip of the iceberg of disease where gene mutations play a part, and many disorders demonstrate familial clustering that does not follow Mendelian patterns of inheritance. Examples include common congenital malformations such as cleft lip, anencephaly, spina bifida and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

also common diseases of both childhood and adulthood, for example asthma, diabetes mellitus, hypertension and ischaemic heart disease, various degenerative neurological disorders, and so on. Although all show some genetic determination, other factors, including environmental ones, are implicated in their aetiology, and therefore these disorders are said to show multifactorial inheritance. In addition, many gene loci can be involved in the aetiology of common diseases; that is, they are polygenic. Each individual gene may have only a small effect and act with varying dominance—that is, some genes have low penetrance and are only expressed in some individuals, and therefore the genetic contribution is not always straight forward. In other words, some genes play a more important part than others (see Turnpenny and Ellard, 2005, for further discussion).

An example of multifactorial inheritance is Type 1 (insulin-dependent) diabetes mellitus (IDDM, OMIM 222100), a disorder of glucose homeostasis which results from the destruction of the insulin-producing β cells of the pancreas due to an autoimmune response. Family studies have indicated that predisposition to the condition is polygenic. The principal genes leading to susceptibility are within the major histocompatibility complex (MHC) HLA class II loci and a promoter polymorphism of the insulin gene. It is clear, however, that even a sufficient complement of susceptibility polymorphisms at disease-associated genes, both inside and outside the MHC, does not always lead to the development of disease at a clinical level, as genetically identical twins are often much less than 100% concordant (reviewed by Todd, 1999). Nongenetic factors are also associated with the disease—in particular, infection with specific viruses. There is an increased prevalence of Type I diabetes in congenital rubella patients, and there is an increased frequency of Coxsackie B viral antibodies in newly diagnosed diabetics compared with controls (Field *et al*., 1987). It is possible that viral infection is a stress that catalyses the pathological process which leads to Type I diabetes, without being a direct component.

The previous discussion illustrates the bewildering complexity surrounding the nature of just one multifactorial disease. The genetic mechanisms underlying most multifactorial diseases are poorly understood. Molecular epidemiology research is beginning to unravel some of the mysteries (reviewed by Dekker and van Duijn, 2003), particularly with the establishment of large population-based biobanks, such as UK Biobank (*www.ukbiobank.ac.uk*). Nevertheless, there remains much to elucidate.

2.4.6 Reproductive Effects

Approximately 15% of all conceptions result in spontaneous miscarriages, and chromosome abnormalities are present in 40–50% of all first trimester pregnancy losses (although this figure is likely to be higher if miscarriages in unrecognized pregnancies were to be taken into account). In newborn infants, congenital abnormalities are present in 2–3% of births, of which 50% may be exclusively attributed to genetic factors. In developed countries, genetic disorders and congenital malformations together account for 30% of all childhood hospital admissions and 40–50% of all childhood deaths. Genetic conditions are also responsible for the impairment of male and female fertility (Turnpenny and Ellard, 2005). The contribution of environmental exposures to this human genetic burden is unknown.

What is clear is that if a potent genotoxin is able to cross the placental barrier, it is very likely to interfere with differentiation of the developing embryo and thus possess teratogenic potential. Of the 40 or so recognized human teratogens, about a quarter have sufficient information to establish that they are clearly genotoxic, 5 of which are anticancer drugs: busulfan, ciclophosphamide (cyclophosphamide), cytarabine, mercaptopurine (6-mercaptopurine) and daunorubicin/doxorubicin (Bishop *et al*., 1997). These compounds display a wide variety of genotoxic mechanisms and it is very likely that a particular human teratogen will produce its effects by several different mechanisms. However, mutagens form only one class of teratogens, and a large proportion of 1000+ teratogenic agents identified in animal models are not mutagenic. Alternative mechanisms of teratogenesis include cell death, retarded differentiation, vascular insufficiency and inhibited cell migration (see **Developmental Toxicology**).

2.4.7 Ageing

Genetic instability is widely thought to be involved in the process of ageing, and a large body of evidence has been gathered in recent years which shows that nuclear DNA damage, gene mutations and cytogenetic damage, such as translocations, insertions, dicentrics and acentric fragments, accumulate with age in mammalian cells (Vijg, 2000; Karanjawala and Lieber, 2004). In humans, there are several genetic disorders associated with phenotypes characterized by shortened lifespan and/or premature ageing, for example, ataxia telangiectasia (AT, OMIM #208900), Bloom's syndrome (BLM, OMIM #210900), Cockayne syndrome Type A (CSA, OMIM #216400), Hutchinson-Gilford Progeria Syndrome (HGPS, OMIM #176670), TTD (OMIM #601675), Werner's syndrome (WRN, OMIM #277700), and so on. Disorders caused by these mutations are termed segmental progeroid syndromes, because they accelerate some, but not all, signs of normal ageing. Many of the heritable mutations giving rise to the symptoms of accelerated ageing in these patients partially or wholly inactivate proteins that sense or repair DNA damage (see above). This finding suggests

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

that failure to maintain genomic integrity underlies at least some ageing phenotypes.

For example, WRN patients probably represent the best model for premature ageing in adult humans, and the disease is characterized by premature greying, cataracts, loss of subcutaneous fat, skin atrophy, osteoporosis, diabetes, atherosclerosis and malignancies (Goto, 1997). The defective gene in WRN, the *RECQL2* gene, encodes a helicase which possesses a DNA exonuclease domain and is believed to play a role in the maintenance of overall genomic stability. The RecQ family of DNA helicases is of particular interest since several human RecQ helicases are defective in diseases associated with premature ageing and cancer, and are believed to play a role in the maintenance of genomic stability through their catalytic activities and protein interactions in various pathways of cellular nucleic acid metabolism, with an emphasis on DNA replication and repair (reviewed by Brosh and Bohr, 2007).

HGPS, in contrast, is a rare childhood progeria syndrome characterized by a striking precocious senility. Death from coronary artery disease is frequent and may occur before 10 years of age. HGPS is caused by mutations in the lamin A (*LMNA*) gene, the product of which, lamin A, is an essential nuclear matrix protein underlying the inner nuclear membrane required for nuclear organization and shape, DNA replication and repair (Eriksson *et al*., 2003). Mutations in the gene are believed to have a devastating effect on nuclear architecture and function that is responsible for the premature ageing seen in HGPS. Interestingly, certain severe forms of WRN are reported to be associated with mutations in the *LMNA* gene also.

Mouse mutants defective in genome maintenance, like their human counterparts, often display segmental progeria and exhibit the characteristics of early onset of ageing. For example, mouse models with mutations in DNA excision repair that affect both NER and transcription coupled repair (TCR) show symptoms of accelerated ageing; for example, CSA and CSB null mice, and mice with a defect in the NHEJ gene, *Ku80* (*Ku86*), *AT* and *ReqQ* helicase genes. However, $wrn^{-/-}$ mice have no obvious ageing phenotype, except on a p53 null background (Lombard *et al*., 2000), possibly because the role and regulation of the *WRN* gene differs between mouse and human (reviewed by Hasty *et al*., 2003).

Cellular senescence, a phenotype characterized by cell cycle arrest, is often used as an *in vitro* model of cellular ageing (Ben-Porath and Weinberg, 2004; 2005). In many primary human cells, replicative cell senescence is related to progressive telomere shortening associated with cell passage (Harley *et al*., 1990). Telomeres are the repetitive sequences of 5–15 kb in length, consisting of 5′-TTAGGG-3′ tandem repeats and specialized proteins, which cap the ends of linear eukaryotic chromosomes, protecting them from degradation, fusion and recombination. The 3′ overhang of the repeat is arranged in a T-loop structure that protects the individual chromosome ends from end to end chromosome fusion and prevents the single strand being recognized as a double-strand break, triggering the cell DNA repair system (Griffith *et al*., 1999). Under normal cell division and chromosome replication, the telomere region shortens because DNA polymerase uses RNA primers that are degraded after elongation (Moyzis *et al*., 1988). Once a telomere has shortened beyond a critical threshold, after about 25–40 cell passages (depending on cell type), the DNA ends become structurally unstable. This leads to *TP53*/*Rb* activation, resulting in either replicative senescence or cell crisis, leading to cell cycle arrest (**Figure 2**). Interestingly, HGPS-affected individuals have abnormally short telomeres, and mutations in DNA repair genes which are associated with premature ageing also confer premature senescence, for example, WRN cells senesce prematurely in culture.

Among the various sources of somatic DNA damage (see above), ROS, such as superoxide anion, hydroxyl radical, hydrogen peroxide, nitric oxide, and so on, which are the natural by-products of oxidative energy metabolism in the cell, are thought to be one of the prime causes of ageing. ROS can cause lipid peroxidation, protein damage, and several types of DNA lesions, including single- and double-strand DNA breaks, DNA-adducts and DNA strand crosslinks. Longer-lived animal species generally show higher resistance to oxidative stress compared to shorter-lived species (Kirkwood and Holliday, 1979), and lifespan extension has been observed in various genetically modified animal models with increased resistance to ROS, such as $p66^{SHC}$ mice and insulin-like growth factor Type 1 receptor (IGF-1 R) knockout mice (reviewed by Hasty *et al*., 2003). Indeed, caloric restriction, an intervention that extends lifespan in many organisms, is also believed to decrease ROS production (Barja, 2004). In addition, levels of DNA adduct 8-oxoguanine (oxo8dG), a major product of oxidative damage to DNA, accumulate with age (Hamilton *et al*., 2001). The ROS theory of ageing is reviewed in detail by Balaban *et al*. (2005).

In conclusion, the accelerated ageing symptoms in humans and mice with genetic defects in genome maintenance strongly suggest that genome instability, driven by oxidative damage, is a primary cause of normal ageing. Moreover, the contention that nuclear DNA is an important target of age-related change is supported by evidence that nuclear DNA damage and mutations accumulate with age. While ROS are likely to be one important source of this damage, there are numerous other cellular and environmental sources of damage, and the impact of such lesions may be enhanced by age-related defects in DNA repair capacity. Accumulation of mutations in critical genes may be one general mechanism by which compromised DNA repair could contribute to ageing. In addition, p53–Rb mediated senescence and apoptosis are also likely contributors to ageing, since both

of these respond to DNA damage and protect against cancer by eliminating severely damaged/senescent terminally differentiated cells that no longer function. Thus the sum of these effects, particularly in adult stem cells, may lead to accelerated degenerative changes and provide links to the physiology of ageing (Kenyon and Gerson, 2007).

2.5 Cancer and Carcinogenesis

Cancer (or neoplasia) represents a vast medical problem and as a cause of death is second only to cardiovascular disease. According to Cancer Research UK there were 153 491 deaths from cancer in the United Kingdom in 2005. More than 1 in 3 people will be expected to develop some form of cancer during their lifetime and ~285 000 new cases of cancer are diagnosed every year (*http://info.cancerresearchuk.org*). In terms of human prevalence, the most common cancers are those of the lung, bowel, breast and prostate; these account for more than half of all new cases and nearly half of all cancer mortalities. Evidence for the existence of cancer can be dated back as far as prehistoric times, having been found in the skeletons of ancient peoples, such as Egyptian mummies.

The term 'cancer' derives from the Latin for crab—due to the resemblance of the swollen veins around a tumour to a crab's limbs. Cancer is not a single disease; there are over 200 pathologically distinct neoplastic entities (each depending on the cell/tissue-type of origin). Nevertheless, all cancers are generally characterized by uncontrolled abnormal cell growth, which eventually forms a cell mass, or tumour. Tumour development, or tumourigenesis, generally occurs over a period of years, and cancer incidence is more prevalent in aged populations. Sooner or later, the tumour will generally invade and destroy surrounding normal tissues, and cells from the tumour can spread (metastasize) through the bloodstream or lymphatic system to start new tumours in other parts of the body.

The process of carcinogenesis, that is, the change in cells from normal, controlled cell division and differentiation to cells that are transformed, dividing without check, and are undifferentiated or abnormally differentiated, does not appear to occur as a single step. In other words, transformation is a multistage process and involves a sequence of events from tumour cell initiation, to promotion, malignant conversion and progression. Evidence for this comes from *in vitro* studies (e.g. cell transformation studies), animal models and clinical/epidemiological observations and, in particular, the long latency period between cell initiation and the appearance of a tumour in the target tissue and the progression to metastatic disease (see **Carcinogenesis and Carcinogens that are also Genotoxic**).

2.5.1 Cancer Genetics

All cancers are genetic in origin and involve an accumulation of inherited and somatic cell mutations in specific cancer genes such as oncogenes, tumour suppressor genes, DNA repair genes and other cancer susceptibility genes (see below) and/or epigenetic changes affecting cancer gene regulation. The disease, at the genetic level, is often characterized by progressive genomic instability, somewhat reminiscent of ageing in some respects, and the acquisition of particular cancer cell phenotypes, such as cell growth deregulation and immortalization, de-differentiation, angiogenesis and metastasis. For example, the majority of metastatic tumours show abnormal karyotypes and genomic alterations involving chromosome copy number gains and/or losses; these impact differential gene expression and cellular development. Many altered regions are thought to be the location of novel candidate tumour suppressor genes and/or oncogenes. A small proportion of cancers are predisposed by inherited germline mutations in specific cancer susceptibility genes, such as Li-Fraumeni syndrome (OMIM reference #151623), which is associated with mutations in the *TP53* tumour suppressor gene, (OMIM *191170), retinoblastoma (mutations in the *RB1* gene, OMIM +180200) and familial adenomatous polyposis (FAP) of the colon (OMIM #175100), which is associated with mutations in the *APC* gene, (OMIM *611731).

2.5.2 Oncogenes

An oncogene is a protein encoding gene, which, when deregulated, participates in the onset and development of cancer. Genetic mutations resulting in the activation of oncogenes increase the chance that a normal cell will develop into a tumour cell. A proto-oncogene is a normal gene that can become an oncogene due to mutations or increased expression. Proto-oncogenes code for proteins that help to regulate cell growth and differentiation, and are often involved in signal transduction of mitogenic signals and transcriptional regulation of downstream genes in the nucleus. Upon *activation*, which generally involves mutation at a single allele because they are gain-of-function mutations, a proto-oncogene (or its product) becomes a tumour inducing agent, that is, an oncogene (see **Table 2**).

2.5.3 Activation of Oncogenes

A proto-oncogene can become activated to an oncogene by a relatively small modification of its original function. There are three basic activation types:

- A mutation within a proto-oncogene can cause a change in the protein structure, causing
  - an increase in protein (enzyme) activity and/or
  - loss of gene regulation.

Table 2 Genomic fidelity and cancer susceptibility genes

Category	Pathways affected	Examples
Oncogens	Growth factors and mitogens, signal transduction kinases, nuclear transcription factors . . .	*EGFR, VEGFR, RAS, RAF, SRC, WNT, FOS, JUN, MYC, ERK . . .*
Tumour suppressor genes	Cell cycle regulation coupled with DNA damage surveillance	*TP53, RB, PTEN, APC, BRCA1 . . .*
Cell cycle control	Cyclin-dependent kinase inhibitors	*WAF1, Kip1* and *Kip2 . . .*
DNA repair genes	Various DNA repair pathways: BER, NER, MMR . . .	*Ogg1, Mutyh, MSH, PMS, XPA . . .*
Apoptosis genes	Balance between pro- and anti-apoptotic pathways	*BCL2, DAPK . . .*

- An increase in protein activity, caused by
  - an increase in gene expression
  - an increase of protein stability, prolonging its existence and thus its activity in the cell
  - a gene duplication resulting in an increased amount of protein in the cell.
- A chromosomal translocation causing
  - inappropriate or constitutive gene expression, that is, in the wrong cell type or at the wrong time; for example, *c-Abl* in chronic myaloid leukaemia.

Over-expression of growth factor receptors is a frequent occurrence in cancer and has been observed in many tumour types, including colorectal cancer (CRC) and adult astrocytoma. In the latter, both PDGFRα and EGFR dimerise once activated by ligand binding. This initiates autophosphorylation of cytoplasmic domains stimulating the Ras/Raf/Map pathway and activating PI3-kinase. PI3-kinase then phosphorylates phosphatidylinositol-4,5-diphosphate (Pip2) to phosphatidylinositol-3,4,5-triphosphate (Pip3). The cellular levels of Pip3 are regulated by phosphatase and tensin homologue (PTEN). Pip3 is bound to the intracellular cytoplasmic membrane, where it recruits proteins with pleckstring homology domains, including Akt, a well-known anti-apoptotic and survival factor (reviewed by Kohn, 1999; Mirza *et al*., 2003).

2.5.4 Tumour Suppressor Genes

Tumour suppressor genes encode for proteins which generally inhibit tumorigenesis, and their existence was originally inferred from experiments where tumour cells were fused with normal cells in culture that resulted in nontumourigenic hybrids. Subsequent loss of specific individual chromosomes or specific regions of a chromosome in the hybrid, and derived from the normal parental cell, resulted in the re-emergence of the tumorigenic phenotype. Numerous tumour suppressor genes have since been identified, and the functions of the associated proteins fall into several categories:

1. The activities of the cyclin-dependent kinase (CDK) family are in turn regulated by cyclin-dependent kinase inhibitors (CDIs), which are essential for continuing the cell cycle. If these genes are not expressed the cell cycle will arrest, effectively inhibiting cell division (Fero *et al*., 1998).
2. Cell cycle regulation and DNA damage surveillance: the cell cycle can be arrested by tumour suppressor genes of the p53 and Rb pathways that are activated by aberrant proliferative stimuli or DNA damage (reviewed by Kohn, 1999; Mirza *et al*., 2003). After cell cycle arrest, there is an opportunity to rectify DNA damage where necessary. The role of some members of the p53 and Rb pathways is to maintain low levels of inactive *TP53* in the absence of genomic damage allowing normal cell cycle function.
3. If the DNA damage is irreparable, the cell enters senescence or undergoes apoptosis (programmed cell death), preventing replication of the damaged genome (Malumbres and Barbacid, 2001). Apoptosis in multicellular organisms involves a series of biochemical events leading to a characteristic cell morphology and death, characterized by a variety of morphological changes, including blebbing, changes to the cell membrane such as loss of membrane asymmetry and attachment, cell shrinkage, nuclear fragmentation, chromatin condensation and chromosomal DNA fragmentation (see **Cytogenetics**). Mutations in genes regulating apoptosis can shift the balance between pro- and anti-apoptotic influences, and may contribute to genomic instability, if cells carrying DNA damage are permitted to survive. Such cells which survive past their 'use-by-date' are capable of replication and they and their progeny are subject to increased genomic instability, increasing the likelihood of the cell becoming cancerous or diseased (Schmitt *et al*., 2007).
4. Some tumour suppressor genes encode for proteins involved in cell adhesion which prevent tumour cells from dispersing, block loss of contact inhibition, and inhibit metastasis. These proteins are known as metastasis suppressors.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The majority of tumours have mutations in multiple tumour suppressor genes, causing major disruptions to the p53 and Rb pathways (Hahn and Weinberg, 2002) and/or apoptosis pathways or both (**Table 2**). Tumour suppressor genes generally require mutations in both alleles before a particular gene can contribute to tumourigenesis. In other words, both maternal and paternal copies of the gene must be inactivated for the tumour to develop, and in many spontaneously arising tumours, individual chromosomes or specific regions of a chromosome are lost or deleted which contain putative tumour suppressor genes; that is, these tumours demonstrate loss of heterozygosity (LOH). As such, mutant tumour suppressor alleles are usually recessive, whereas mutant oncogene alleles are typically dominant. The first tumour suppressor protein discovered was the Retinoblastoma protein (pRb) in human retinoblastoma (Fung *et al*., 1987). This provided evidence for the classical 'two-hit' hypothesis first proposed by A.G. Knudson, following his observation that the age of onset of retinoblastoma followed second-order kinetics, implying that two independent genetic events were necessary (Knudson, 1971). He recognized that this was consistent with a recessive mutation involving a single gene, but requiring biallelic mutation.

Another important tumour suppressor is the p53 tumour suppressor protein encoded by the *TP53* gene. Homozygous loss of p53 is found in 70% of colon cancers, 30–50% of breast cancers and 50% of lung cancers. Mutated p53 is also involved in the pathophysiology of leukaemias, lymphomas, sarcomas, neurological tumours and many others. Interestingly, certain p53 mutations can function as a 'dominant negative', meaning that a mutated p53 protein can prevent the function of the normal protein copy from the unmutated allele (Baker *et al*., 1990), and represents a notable exception to the 'two-hit' rule for tumour suppressors. Other tumour suppressor genes which are exceptions to the 'two-hit' rule are those which exhibit haploinsufficiency (i.e. when a single functional copy does not produce enough of a gene product to bring about the normal 'wild-type' condition, leading to an abnormal or diseased state). An example of this is the p27Kip1 cell cycle inhibitor, in which mutation of a single allele causes increased carcinogen susceptibility (Fero *et al*., 1998).

The activation of *TP53* transactivates many genes with varied functions, including those involved in apoptosis and inhibitors of the pRb pathway preventing cell proliferation (**Figure 5**). The transcription of $p21^{WAF-1}$ is activated by *TP53* and inhibits the pRb pathway. *MDM2* transcription is also initiated by *TP53*, which itself acts as a negative regulator of *TP53*. Cell cycle progression is also regulated through the release of E2F transcription factors by pRb phosphorylation, which initiates $p14^{ARF}$ transcription. This protein inhibits MDM2, preventing p53 degradation, consequently increasing p53 cellular concentration and inducing cell cycle arrest or apoptosis (Mirza *et al*., 2003). The pRb pathway controls cell cycle progression from G1 to S-phase. The release of E2F transcription factors through pRb phosphorylation initiates the transcription of S-phase genes. Mitogenic stimuli up-regulate CCND1, CCND2 and CCND3, which bind CDK4 or CDK6. This complex phosphorylates the pRb protein, causing the release of E2F transcription factors. Phosphorylated pRb also modulates chromatin structure (Zhang and Dean, 2001). CDK inhibitors, $p15^{INK4b}$ and $p16^{INK4A}$, compete with the cyclins to bind CDK4 or CDK6, blocking complex formation and the pRb pathway (Hahn and Weinberg, 2002).

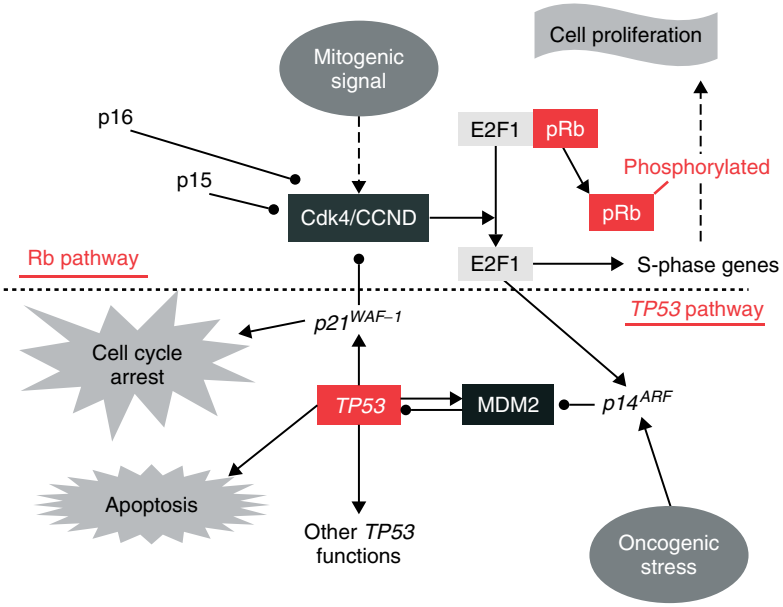

Figure 5 *TP53* and Rb pathways.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

PTEN encodes a tumour suppressor lipid phosphatase, which negatively regulates the oncogenic, proliferative and anti-apoptotic promoting characteristics of Akt (Li *et al*., 1997). The *PTEN* gene, the second most frequently deleted tumour suppressor gene (after *TP53*), encodes a protein pivotal to DNA-damage-induced apoptosis and cell cycle arrest, with a role in cyclin D down-regulation and subsequent inhibition of G1–S-phase transition (**Figure 2**). Thus PTEN acts by opposing the action of PI3K, which is essential for anti-apoptotic, pro-tumorigenic Akt activation (Yin and Shen, 2008). Other examples of tumour suppressor genes include *APC* in colorectal cancer (see below) and *BRCA1* in breast cancer.

2.5.5 Genomic Instability

It has long been suggested that multistage carcinogenesis requires a mutator phenotype (Loeb, 1991). This idea is now supported by examples wherein defects in several pathways that determine the fidelity of DNA, including replication, mitotic division and cell cycle progression result in increased genomic instability and increased susceptibility to cancer (see **Table 2**). For example, microsatellite instability (MSI) is a feature in approximately 15% of human colorectal cancers and is also found in gastric and endometrial tumours. MSI is caused by defective DNA MMR, which leads to profuse insertions and deletions in microsatellites and is associated with increased mutation prevalence (Røyrvik *et al*., 2007). While cancer is the most cited example, a number of other diseases are also associated with defects in DNA fidelity maintenance and genomic stability. These include Alzheimer's disease, CS, Parkinson's disease, Friedreich's ataxia, Huntington's disease, TTD, a number of progressive neuropathies and multiple mitochondrial wasting diseases and ageing (see Schmitt *et al*., 2007; McCulloch and Kunkel, 2008 and references therein).

Chromosomal instability is also a feature of most human cancers. Mutations in CIN genes increase the rate at which whole chromosomes or large parts of chromosomes are lost or gained during cell division. CIN causes an imbalance in chromosome number (aneuploidy) and an enhanced rate of LOH, which is an important mechanism of inactivating tumour suppressor genes. A critical question in cancer biology is whether CIN is an early event in carcinogenesis and thus a driving force of tumourigenesis or whether it is a later event associated with metastasis (Michor *et al*., 2005).

2.5.6 Cell Immortalization

Cell immortalization is a further event that contributes to malignant growth of neoplastic cells. In most cases, this is thought to be achieved through the maintenance of chromosome telomeres. As described above, telomere shortening is associated with replicative cellular senescence. Deletion of *TP53* significantly attenuates cellular effects of telomere dysfunction, but only during the earliest stages of genetic crisis (Chin *et al*., 1999). Tumour cells evade replicative senescence through the activation of telomerase, a riboprotein complex that adds TTAGGG repeats to the telomeres, preventing shortening (Bocchetta and Carbone, 2004). It has been suggested that over 85% of human cancers have measurable levels of telomerase activity, allowing indefinite proliferation (Shay and Bacchetti, 1997). Tumours without telomerase activity are thought to maintain telomere length through a process known as alternative lengthening of telomeres (ALT). This involves nonreciprocal recombination between telomeres of different chromosomes (Bryan *et al*., 1997).

2.5.7 Angiogenesis

Angiogenesis is the formation of new blood vessels from those that already exist and is controlled through a balance of proangiogenic and antiangiogenic factors. A high level of angiogenesis occurs during embryonic development but is limited in adults to the menstrual cycle and tissue repair/remodelling. This complex physiological process is now recognized as an essential component of tumour development and progression (Folkman, 1990). During tumorigenesis the angiogenic signal balance is pushed towards new vessel growth to create a vascular network that facilitates nutrient and waste product exchange and thus allow tumour growth to exceed 1–2 mm^3 (Folkman, 1990). Furthermore, the extent of tumour vascularity correlates with increasing tumour malignancy. Indeed, tumour cells that are more than 10 cell layers from a blood vessel are hypoxic and it is this lack of oxygen that inhibits tumour growth (Evans *et al*., 2001); such tumours also show areas of necrosis linked to extensive tissue hypoxia.

A plethora of growth factors, cytokines and respective receptors are involved in angiogenesis causing basement membrane degradation, endothelial cell migration, proliferation and tubular formation (reviewed by Folkman, 2002). The most prominent factor is VEGFα, an endothelial cell mitogen that binds to the tyrosine kinase receptors VEGFR-1 and VEGFR-2 and initiates endothelial cell proliferation, migration and development of new blood vessels (Kanno *et al*., 2000). Significantly, the expression of this factor is mediated by hypoxia-inducible factor 1 (Hif1), a factor stabilized under hypoxic conditions (Forsythe *et al*., 1996).

2.5.8 Epigenetics

In normal cells, epigenetics can be defined as the mechanisms that preserve inheritable gene expression patterns and functions without altering the genome sequence. The epigenetic network is complex but can be summarized into four tiers of regulation via: DNA methylation, chromatin remodelling, histone modification, and noncoding

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

RNAs (ncRNAs). It has become increasingly evident that major disruptions to the epigenetic network are common in the vast majority of tumours, and promoter hypermethylation is recognized as the most common epigenetic alteration in tumours causing loss or down-regulation of tumour suppressor gene expression (Esteller, 2006).

The methylation of cytosine residues located within dinucleotide CpG repeats does not occur randomly within the genome, but clusters in CpG-rich regions known as CpG islands that are primarily located at the 5′ end of genes. These islands often span the promoter, untranslated region and exon 1, indicating the beginning of a gene sequence. In the DNA of normal cells, 5-methylcytosine (5mC) constitutes 0.75–1% of all nucleic acid bases and 3–4% of methylated cytosines (Paz *et al*., 2002). Furthermore, in normal cells, methylation controls the gene expression of imprinted genes, X-chromosome genes in the female, germline specific genes and tissue-specific genes (Feinberg *et al*., 2002). In comparison, CpG dinucleotides are often unmethylated in normal cells and hypermethylated in tumour cells, silencing gene expression (Esteller, 2005).

Hypomethylation has also been documented in tumour cells and has been attributed to tumorigenesis. In such cases, tumour cells have been found to have 20–60% less genomic 5mC than normal cells, occurring mainly at coding regions and introns, compared to hypermethylation, that is usually found at promoter regions. Reduced levels of 5mC are thought to invoke chromosome instability, reactivation of transposable elements and loss of imprinting, promoting mitotic recombination and LOH (Esteller, 2005). It has also been suggested that hypomethylation increases with tumour malignancy (Fraga *et al*., 2004).

Genes that control global genome methylation have been investigated in many tumours and cancer. A family of genes with DNA methyltransferase activity including *DNMT1, DNMT2, DNMT3a, DNMT3b* and *DNMT3L*, are thought to play a role in the maintenance of promoter region methylation. Differential expression of only *DNMT1* in colon cancer cells was shown to have little effect on global methylation. However, when both *DNMT1* and *DNMT3a* were down-regulated, methyltransferase activity was lost and methylation was reduced to less than 5% of the original level (Rhee *et al*., 2002).

Tumour suppressor genes are frequently hypermethylated in tumours, with significant consequences that provide cells with a selective advantage (**Table 3**). The cell cycle inhibitor $p21^{WAF-1}$ is hypermethylated in a variety of cancers, allowing cells to proliferate and escape senescence (Merlo *et al*., 1995). Other genes involved in tumour cell cycle control found to be hypermethylated include the *Rb* gene and $p15^{INK4b}$. Regulation of *Rb* gene methylation status has also been linked to chromatin conformation at the promoter region, suggesting that several epigenetic mechanisms are simultaneously involved (De La Rosa-Velazquez *et al*., 2007). Several genes in the *TP53* network, including $p16^{INK4A}$ and *TP73,* have been found to be hypermethylated. Methylation, and consequent silencing of $p16^{INK4A}$, allows uninhibited MDM2 to induce *TP53* degradation (Esteller *et al*., 2001). Furthermore, genes of the APC/β-catenin, E-cadherin and Wnt signalling pathways are often methylated in tumours, including *APC, E-cadherin, H-cadherin, FAT* and *SFRP1* (Esteller *et al*., 2001; 2000; Graff *et al*., 1995; Paz *et al*., 2003; Toyooka *et al*., 2001).

Alterations in methylation patterns also affect DNA repair mechanisms in tumours. Silencing of the mismatch DNA repair gene, *hMLH1* , has been found in colorectal, endometrial and gastric tumours in conjunction with

Table 3 Examples of genes hypermethylated in colorectal cancer, and their molecular consequences

Gene	Function	Location	Tumour profile	Consequences
$p16^{INK4a}$	Cyclin-dependent kinase inhibitor	9q21	Multiple types	Entrance in cell cycle
$p14^{ARF}$	MDM2 inhibitor	9q21	Colon, stomach, kidney	Degradation of p53
hMLH1	DNA mismatch repair	3p21.3	Colon, endometrial, stomach, glioblastoma	Frameshift mutations
MGMT	DNA repair of 06-alkylguanine	10q26	Multiple types	Mutations, chemosensitivity
LKB1/STK11	Serine/threonine kinase	19p13.3	Colon, breast, lung	Unknown
RARβ2	Retinoic acid receptor	3p24	Colon, lung, head and neck	Vitamin sensitivity
FAT	Cadherin, tumour suppressor	4q34–35	Colon	Dissemination
APC	Inhibitor of β-catenin	5q21	Colon	Activation of β-catenin route
SFRP1	Secreted frizzled-related protein-1	8p12–p11	Colon	Activation of Wnt signalling
COX-2	Cyclooxygenase-2	1p25	Colon, stomach	Anti-inflammatory resistance
GATA-4	Transcription factor	8p23–p22	Colon, stomach	Silencing of target genes
GATA-5	Transcription factor	20q13	Colon, stomach	Silencing of target genes
DAPK	Pro-apoptotic	9q34.1	Lymphoma, lung, colon, glioblastoma	Resistance to apoptosis

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

microsatellite instability (Fleisher *et al*., 1999). Furthermore, the methylation status is a good predictive marker of response to chemotherapy with alkylating agents (Fukushima *et al*., 2005; Soejima *et al*., 2005).

The role of chromatin remodelling and histone modification as mechanisms involved in tumour and cancer development is only just emerging. The regulation of chromatin structure and transcription is often influenced by post-translational modification of histone tail residues, affecting the accessibility of transcription factors to DNA. This includes methylation, acetylation, phosphorylation and ADP-ribosylation (Vitolo *et al*., 2000). A specific group of transcription factors are involved in chromatin structure remodelling allowing other transcription factors access to DNA regions (Thomas and Chiang, 2006). Alterations in chromatin structure can also occur through ATP-dependent nucleosome remodelling (Johnson *et al*., 2005). Histone acetyltransferases (HATs), histone methyltransferases (HMTs) and histone deacetylases (HDACs) are all involved in a proposed aberrant histone modification signature for cancer (Fraga and Esteller, 2005). A large study by Ozdag *et al*. illustrated that six different cancer types had a unique pattern of histone modifier gene expression compared to that of the corresponding normal tissue or other cancers (Ozdag *et al*., 2006).

The extent of ncRNA involvement in epigenetics is largely unknown. Small regulatory ncRNAs include microRNAs (miRNAs) and small interfering RNAs (siRNAs), which are approximately 22 nucleotides in length and suppress translation in two ways. miRNAs undergo nonperfect pairing with target mRNA preventing translation, and siRNAs pair perfectly with target mRNA causing degradation by the RNA-induced silencing complex. siRNAs are also involved in the silencing of chromatin and chromosome dynamics (Mattick and Makunin, 2006).

Recent discoveries suggest that the role of ncRNAs in disease is broader than initially understood, involving the control of gene expression through chromatin architecture and transcription (Mattick and Makunin, 2006). miRNA expression profiles have been used to classify human cancers (Lu *et al*., 2005), and disrupted miRNA target genes have been characterized in pituitary adenomas (Bottoni *et al*., 2007). Furthermore, miRNAs have been found to be disrupted in adult primary glioblastoma (GBM) through microarray analysis. In the primary GBM investigated, nine miRNAs were significantly up-regulated and four were significantly down-regulated. When the tumours were clustered according to the expression profile similarity of the miRNAs, a clear distinction could be seen between normal controls and GBM samples, suggesting a role for miRNAs in GBM development (Ciafre *et al*., 2005).

The role of somatic cell mutations and epigenetic changes in cancer may be exemplified by CRC or cancer of the bowel. The third most common form of cancer in the UK, with an incidence of approximately 44 persons per 100 000 population (see *http://info.cancerresearchuk.org*), the majority of sporadic CRCs are believed to develop from 'benign' adenomas. The adenomas are thought to arise from aberrant crypt foci (ACF) in colorectal mucosa, the earliest known morphological precursors to CRC. ACF can be subclassified as dysplastic, heteroplastic (nondysplastic) and mixed types. The progression of an ACF through to small adenoma and on to malignant carcinoma (**Figure 6**) is thought to take between 5 and 10+ years, but only a fraction of ACF and small proportion of adenomas proceed to malignant disease (reviewed by Suehiro and Hinoda, 2008). The genetic changes associated with the adenoma–carcinoma sequence in CRC were first described by Vogelstein *et al*. (1988). The Vogelstein model of CRC (**Figure 6**) describes the acquisition of somatic mutations in various cancer genes (tumour suppressor genes, oncogenes, DNA repair genes and other cancer susceptibility genes) in a predictable linear sequence from initiated stem cells through to benign tumour and frank metastatic disease. Thus the Vogelstein model has been used to provide a genetics-based working hypothesis of the carcinogenic process involving gene mutations associated with initiation and progression of neoplastic cells in the adenoma–carcinoma sequence (reviewed by Cho and Vogelstein, 1992). Over the past two decades, the general principals of the Vogelstein model have been extended to various other cancer types, for example, neurological cancers (Karakoula *et al*., 2008) and chronic myelogenous and acute lymphoblastic leukaemias (Karakosta *et al*., 2005).

In part, the Vogelstein model was based on the genetic analysis of tumours from patients with FAP (OMIM #175100), a rare genetic disorder where individuals have a predisposition for early onset CRC as a result of inherited mutations in the tumour suppressor gene, *APC* (adenomatous polyposis coli). Patients with FAP typically develop hundreds to thousands of colorectal adenomas, which begin to appear in adolescence (Petersen *et al*., 1991), and by the age of 35 years 95% of individuals have polyps (Evans *et al*., 1993). A mouse model of FAP, called Min (multiple intestinal neoplasia) has also been described and was originally identified in a pedigree established from mating a C57BL/6 J (B6) male treated with ethylnitrosourea with an AKR/J (AKR) female (Moser *et al*., 1990). Heterozygous B6-Min mice typically develop ~30 intestinal tumours (mostly adenomas) and usually die within four months of birth; *Min* homozygotes die *in utero* (Moser *et al*., 1990). As such, both FAP and Min are considered to have a common aetiology, that is, analogous genetic predisposition and similar morphology of adenomatous polyps, and Min is therefore regarded by many researchers as a model of human FAP and CRC.

However, there is extensive heterogeneity within the mutational spectrum of families with FAP, with over 826

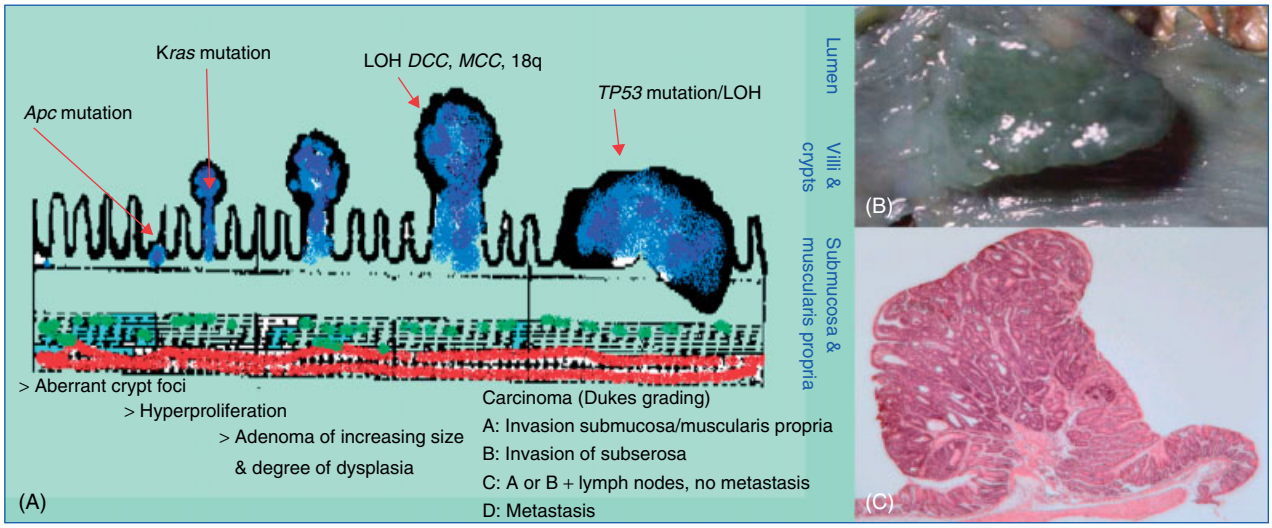

Figure 6 The adenoma–carcinoma sequence model in colorectal cancer. (A) Schematic of adenoma formation and associated genetic changes over time. Mutation in *Apc* is considered an initiating mutation in this model, and progression is characterized by the acquisition of additional mutations in key cancer-susceptibility genes, such as the oncogene *ras*, and loss of heterozygosity in tumour suppressor genes such as deleted in colorectal cancer (*DCC*) and mutated in colorectal cancer (*MCC*) genes and often *TP53* at the carcinoma stage; (B) adenoma in colon of Apc^{Min} mouse; (C) histopathological section of colon adenoma from Apc^{Min} mouse.

different germline mutations identified (Beroud *et al*., 2000), and significant genotype–phenotype correlation exists between the locations of *APC* germline mutations and polyposis severity (Soravia *et al*., 1998; van der Luijt *et al*., 1996). In contrast, mice heterozygous for *Min* inherit a single specific mutation in *Apc*, the murine orthologue of the human tumour suppressor gene *APC*. The nonsense mutation results from a T → A transversion in nucleotide 2549 of *Apc*, converting codon 850 from leucine (TTG) to a stop (TAG) codon (Su *et al*., 1992). Mahmoud *et al*. (1997) concluded that the resulting truncated Apc protein exerts a dominant-negative effect which is associated with changes in the growth characteristics of preneoplastic tissue, including decreased apoptosis and proliferation and decreased enterocyte migration. As such, the codon 850 mutation present in Min is more likely to be representative of the 'severe end' of the mutational spectrum seen in FAP, a conclusion consistent with experimental evidence for a dominant-negative effect of APC gene products associated with severe polyposis in humans (Dihlmann *et al*., 1999).

In addition, the B6-Min mouse strain carries additional genetic susceptibility factors which strongly influence the severity of the phenotype. For example, *Mom1* ('modifier of *Min*-1') accounts for ~50% of the genetic variation in tumour frequency across different mouse strains (Dietrich *et al*., 1993). The secretory phospholipase (*Pla2g2a*) gene is considered a good candidate for *Mom1,* which is a semidominant modifier of both polyp number and size (MacPhee *et al*., 1995; Cormier *et al*., 1997). Another modifier of *Min* (*Mom2*) has also been reported and acts in a dominant fashion, significantly reducing the incidence of colorectal adenomas (Silverman *et al*., 2002). Background strain can also affect colorectal adenoma frequency. For example, B6-Apc^{Min} mice crossed with the CAST inbred strain exhibit a total absence of colorectal adenomas; an observation independent of *Mom1* status (Koratkar *et al*., 2002). Thus it is clear that strain-specific genes influence susceptibility to intestinal adenomas. Transgenic mouse models of FAP, such as $Apc^{\Delta 716}$ (Oshima *et al*., 1995) and Apc^{1638N} (Fodde *et al*., 1994) also demonstrate varying cancer susceptibilities. For example, $Apc^{\Delta 716}$ mice develop hundreds (250–650) of small intestinal adenomas, whereas Apc^{1638N} develop only five to six tumours per mouse, predominantly small intestinal adenomas and carcinomas (Yang *et al*., 1997).

In mammals, the loss of *APC* tumour suppressor gatekeeper function is associated with the initiation of intestinal tumorigenesis (Nakamura *et al*., 1991). Functional loss of *APC* has been shown or proposed to arise from several different mechanisms: mutation in *APC*, nondisjunction, homologous somatic recombination, and epigenetic silencing. In FAP, somatic mutations resulting in LOH at *APC* are determined by the site of the germline mutation. For example, FAP patients with germline *APC* mutations within codons 1194–1392 show mainly allelic loss in their colorectal adenomas, whereas LOH in other FAP patients tends to occur by truncating mutations in the 'mutation cluster region' located at codons 1286–1513 in exon 15 (Lamlum *et al*., 1999). These results suggest that different *APC* mutations provide cells with different selective advantages, with mutations close to codon 1300 providing the greatest advantage.

Genetic analysis of adenomas in Min mice also shows 100% LOH of the wild-type *Apc* allele on mouse chromosome 18. In contrast to FAP, however, research clearly shows that homologous somatic recombination rather than chromosome loss is the primary cause of adenoma formation in the Min mouse model (Haigis and Dove, 2003). Thus neoplastic growth in the Min mouse can be initiated in the absence of genomic instability, and polyp development is likely to occur independently of environmental factors known to influence disease progression in humans with FAP (Tischfield and Shao, 2003). Somatic mutations in the *Apc* gene in Apc^{1638N} mice are also associated with the entire loss of mouse chromosome 18. Interestingly, the mouse orthologues of *MCC* (mutated in colorectal cancer) and *DCC* (deleted in colorectal cancer), two putative tumour suppressor genes implicated in human CRC, also map to mouse chromosome 18. In contrast to FAP patients, however, mutations in the *K*-, *N*- and *H-ras* genes or exons 7 and 8 of the *TP53* gene are uncommon in these mouse models. These studies suggest that genetic inactivation of *Apc* is an initiating event in murine as well as human intestinal tumorigenesis, but thereafter, tumour growth and progression follow different mutational pathways in these two species (Smits *et al*., 1997). As such, there are distinct differences, in terms of genetics, molecular carcinogenesis and tumour pathogenesis, between mouse models of CRC and the human inherited condition, FAP. Moreover, until comparatively recently, there was a failure to recognize that sporadic CRC is in fact a multipathway disease, comprising disparate subgroups with particular clinical, pathological and molecular features, with underlying genetic/genomic instability. Thus the oversimplification of the evolutionary pathway characterized by the Vogelstein model may have, in part, confounded the identification of risk factors associated with sporadic CRC, whether genetic, constitutional or lifestyle related (reviewed by Jass, 2007).

2.6 Environmental Exposures, Mutagenesis, Cancer and Heritable Genetic Effects

A small proportion of cancers are predisposed by inherited germline mutations in specific cancer susceptibility genes, such as Li-Fraumeni syndrome (*TP53*) and FAP (*APC*). Such mutations may occur spontaneously, owing to rare errors in DNA replication and cell division. Environmental factors, however, contribute significantly to the majority of cancer aetiologies, and exposure to many different environmental agents is associated with increased cancer risk; for example, exposure to viruses (e.g. acute transforming retroviruses), ionizing and nonionizing radiations absorbed by DNA (e.g. X-rays, ultraviolet light in sunlight) or particular chemical species capable of covalently interacting with DNA or the fidelity of the cell division apparatus. For example, human epidemiological studies demonstrate significant associations between ultraviolet exposure from sunlight and skin cancer, cigarette smoke exposure and lung cancer, and aflatoxin B_1 contamination in food and liver cancer. These associations are also true for many cancers linked to industrial exposures, for example vinyl chloride exposure and liver cancer in the plastics industry. In the majority of human cancers, however, the differentiation between genetic and environmental factors is not always obvious and it is not clear which genetic changes or environmental exposures are causative.

There is also good evidence to show that inherited mutational changes in humans, although individually rare, collectively are responsible for a significant proportion of genetically determined diseases and heritable (congenital) malformations. However, to date, no adverse heritable genetic effects have been documented in humans following exposure to mutagens, including children born to people exposed to very large doses of radiation and/or mutagenic drugs, and so on (Sankaranarayanan, 1990). For example, epidemiological and other investigations have failed to find convincing associations between exposure, germline mutagenicity and heritable malformations in the offspring of survivors exposed to IR at Hiroshima and Nagasaki (Otake *et al*., 1990), Chernobyl fallout (Little, 1993) or mutagenic cancer therapies in general (Boice *et al*., 2003), although for female childhood cancer patients the transgenerational effects of treatment may include restricted foetal growth and early births among their offspring (Signorello *et al*., 2006). These contrast markedly with the identification of human mutagenic carcinogens.

With regard to the induction of *de novo* (new) mutations into the gene pool there are many reasons why environmental causes of heritable mutation, as evidenced by human genetic disease, are difficult to discern. According to Elespuru and Sankaranarayanan (2007), among them are: (i) Very large sample sizes are required to detect small increases in individual, rare, Mendelian disorders. As such, there has been a lack of statistical power in historical epidemiological studies which have set out to investigate associations between exposure to individual mutagens and increases in specific human genetic traits (deleterious or otherwise). (ii) The fact that most well-monitored disease-causing germ cell mutations are not of *de novo* origin but are inherited (i.e. low 'signal-to-noise' ratio). (iii) An inability, at least in early studies, to distinguish newly arising mutations from inherited ones. (iv) A tradition of monitoring congenital anomalies as surrogates, when germ-cell mutations attributable to disease, inherited or *de novo*, are but a tiny fraction of visible birth defects (again, low 'signal-to-noise' ratio). (v) Lack of practical ways to associate the time of origin of mutations with environmental exposures. (vi) Lack of appropriate, large-scale

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

studies of the relationship between common genetic damaging agents, such as tobacco smoke or certain medicines, and adverse nonsomatic genetic outcomes.

Advances in current knowledge about the genetic basis of human genetic diseases, mutagenic mechanisms and the actions of environmental mutagens, however, suggest that the assessment of the human health impact of germ cell mutations may now be feasible (Elespuru and Sankaranarayanan, 2007). For example, *molecular epidemiology* is beginning to characterize the types of mutations found in specific genetic diseases, using the knowledge gained from the human genome project and data on the relationships between exposure to environmental agents and the particular DNA sequence alterations they cause. In addition, the development of more practical assays for germline mutagenesis, for example transgenic gene mutation assays (see below), and the use of mouse minisatellite mutations (Dubrova *et al*., 1993) and repetitive DNA sequences as mutational targets (Bouffler *et al*., 2006), plus insights gained from population-based genetic screening in personalized medicine, mean that where once it was considered to be almost impossible to trace back germline mutations to specific causative agents in the past, this may now become feasible in the future.

3 GENETIC TOXICOLOGY

3.1 History of the Discipline

As eluded to by Bragg, it has been known for several hundred years that exposure to particular chemicals or complex mixtures can lead to cancer in later life (Doll, 1998). It has also been recognized that chemicals can also induce heritable changes in man, and these may potentially lead to diseases in the next generation.

There had been accumulating evidence throughout the twentieth century that such changes can arise as a consequence of damage to DNA and the resulting mutations. Prior to the Second World War, the only mutagen known was radiation. For example, Muller (1927) showed that X-rays could induce mutations in the germ cells of the fruit fly *Drosophila melanogaster,* and for a short period it was thought that the mutation process required the high activation energy that could only be provided by radiation (Crow, 1989). The first published report of a chemical mutagen was for allyl-isothiocyanate from mustard oil (Auerbach and Robson, 1944). The discovery that mustard gas was also a potent mutagen (Auerbach and Robson, 1946) was based on the observation that the skin blistering observed in people exposed to mustard gas was similar to the skin lesions caused by radiation exposure. The discovery of other chemical mutagens soon followed, for example urethane, ethylene oxide, epichlorohydrin, and so on.

The realization that the integrity of human DNA is essential for the future of the species and the health of its individuals and that exposure to particular human-made chemicals and exposure to radiation, particularly following the use of the atom bombs at Hiroshima and Nagasaki, could result in increases in heritable defects in human children, led to calls for controls of known hazards and the identification and control of new hazards. Another factor was the impact of drugs, particularly antibiotics, in reducing infant mortality and disease. Thus, the relative contribution made by heritable diseases has increased dramatically in the latter half of the twentieth century.

Novel chemicals were recognized as representing an additional potential source of damage to DNA (directly or indirectly via effects on DNA replication and repair, mitosis, etc.). This concept slowly emerged in the 1950s and 1960s with the growing number of studies showing that a variety of human-made chemicals were mutagenic in various test systems, along with improved understanding of the basis of genetics. Several seminal conferences were held around this time with a focus on chemical mutagens and their potential risk to future generations. For example, in 1963 Muller stated that humans were being exposed to a great number of new chemicals, such as food additives, drugs and pesticides, not encountered by previous generations, and that humans were not specifically adapted to such chemicals by natural selection (reviewed by Wassom, 1989).

Genetic Toxicology became recognized as a formal discipline in May 1969 when the Environmental Mutagen Society (EMS) was founded in the USA under the chairmanship of Professor Alexander Hollaender (Oak Ridge National Laboratory) and a group of interested geneticists (as recounted by Wassom, 1989). In the following year the European Environmental Mutagen Society (EEMS) was formed under the Presidency of Professor Fritz H. Sobels (University of Leiden, the Netherlands). The primary thrust of these societies was towards estimating risks to germ cells. However, this was broadened in the 1970s when evidence began to accumulate that carcinogenicity and mutagenicity were linked. Indeed, early analyses of rodent carcinogens and noncarcinogens suggested that almost all carcinogens were also mutagens (Ames *et al*., 1973). From 1973 onwards various national expert committees were formed to advise governments on what approach could be taken to screen new chemicals for potential heritable or carcinogenic risks, and thus appropriate testing was recommended to minimize the risk of genotoxicity. From 1976 onwards, key methods papers were written for what were to become mainline tests in the various national guidelines. The EMS monographs edited by Alexander Hollaender *(Chemical Mutagens, Principles and Methods for Their Detection)* were very influential in this regard. Various other countries also began to issue national guidelines for mutagenicity testing, including Italy (Comma, 1977), the USA (US

EPA, 1982) and the UK (DHSS, 1981). In 1984 the European Economic Community issued 'recommendations' for all new drugs at the Product Licence Application stage (EEC, 1984). Practical handbooks on mutagenicity testing procedures were published, in the UK, firstly by Parry and Venitt (1984) and subsequently in the 1990s by the UK Environmental Mutagen Society. The series of books entitled 'Basic Mutagenicity Tests', 'Supplementary Mutagenicity Tests' and 'Statistical Evaluation of Mutagenicity Test Data', edited by David Kirkland and published by Cambridge University Press, were very influential at the time (Kirkland, 1989; 1990; Kirkland and Fox, 1993). Nowadays, these recommended procedures have been augmented by a series of publications from the International Workshop on Genotoxicity Testing Procedures (IWGTP).

The first IWGTP Workshop was held in Melbourne in 1993 (as a two-day satellite meeting of the Sixth International Conference on Environmental Mutagenesis). Organized by David Kirkland (UK), Mike Selby (USA) and Toshio Sofuni (Japan), the focus of the meeting was towards standardizing recommendations on genotoxicity test procedures around the world. At the time, there was a growing realization that many countries and regions of the world had introduced detailed recommendations or requirements on test methodology, but independently of any other guidelines, thereby leading to a diverse range of recommendations. For industry this often meant tests had to be performed more than once to modified protocols in order to provide data acceptable to different countries, leading to wasted resources and time. For regulatory agencies it meant often trying to evaluate data from protocols with which they were unfamiliar and by methods with which they did not necessarily agree (Kirkland, 1994). Follow up workshops have been held on a regular basis since the inaugural meeting and the various recommendations have been published in peer-reviewed journals (see **Table 4**).

In the 1990s, the harmonisation of genotoxicity testing requirements for pharmaceuticals was also underway as a result of the International Conference on Harmonisation (ICH) program (Müller *et al*., 1999). This process brought together regulatory authorities from Europe, Japan and the USA, and experts from the pharmaceutical industry in these three regions. Areas of disharmony were identified and differences in regulation with respect to genotoxicity in the three regions were discussed. The guidelines that emerged were an evolution of pre-existing guidelines in Japan and the European Union. At the same time as the ICH process was occurring, the OECD (Organisation for Economic Co-Operation and Development) also updated a number of its genotoxicity guidelines. Both processes influenced each other, resulting in similar recommendations.

Today it is not possible to register a new drug, food additive, and so on, or transport a new industrial chemical within the major industrialized nations, without providing basic mutagenicity information, and, therefore, it has become necessary to determine whether widely used chemicals or potentially useful new chemicals possess the ability to damage DNA. The discipline of genetic toxicology exists to achieve this aim. In industry, such information may be used to discard a new chemical if a safer alternative can be found, to control or eliminate human exposure for a mutagenic industrial compound, or for a drug, to proceed with development if benefits clearly outweigh risks. Data concerning the mutagenicity of a chemical have become part of the basic toxicological information package. They are needed for decision making and to reduce risks that might otherwise be unforeseen.

The current paradigm for regulatory genetic toxicology involves a tiered strategy towards testing, and this has been largely adopted throughout all sectors of industry. The minimum genotoxicity package generally consists of (i) an *in vitro* bacterial assay for gene mutation, (ii) an *in vitro* mammalian cell assay for gene mutation and/or cytogenetic damage, and (iii) an *in vivo* mammalian assay for cytogenetic damage (**Figure 7**). In the pharmaceutical industry, the ICH guidelines for genotoxicity (ICH Topic S2A *Guidance on Specific Aspects of Regulatory*

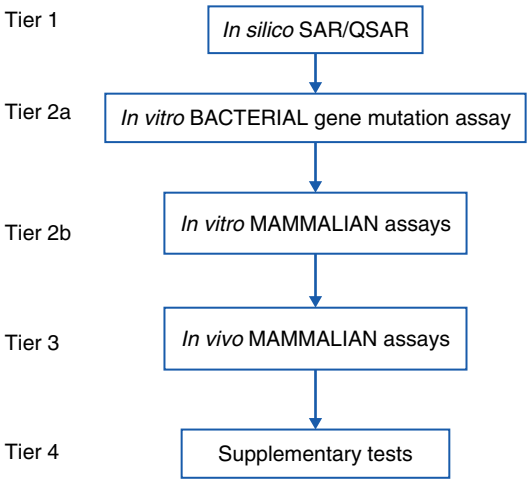

Figure 7 Tiered approach to genotoxicity testing. The tiered approach involves an initial evaluation of potential drug candidates without any biological experimentation whatsoever (Tier 1). Selected compounds are then evaluated for genotoxicity using a simple *in vitro* bacterial system (Tier 2a), usually the Ames test. This is followed by further testing using an *in vitro* mammalian cell system (Tier 2b); for example, a chromosome aberration assay or mouse lymphoma assay. The use of these assays permits highly genotoxic compounds to be filtered, and thereby reduces potential toxicity issues in later development (Tier 3). The tiered approach promotes the 'clean development' of new compounds or drug candidates, which reduces the need for additional *in vivo* investigative studies using supplementary tests (Tier 4).

Genotoxicity Tests for Pharmaceuticals; and S2B *A Standard Battery of Genotoxicity Testing of Pharmaceuticals*) describe both the philosophy and types of assays that comprise the testing regimen recommended by regulatory agencies for the assessment of new drugs. The ICH guidelines recommend that *in vitro* studies should be completed before commencing Phase I clinical trials in humans, and the complete battery of tests should be complete by the time Phase II clinical studies begin (Lynch and Connelly, 2003).

A comprehensive description of the individual test systems used for screening new compounds for genotoxic activity is described in the subsequent sections of this chapter. The strategies, study designs and terms described below largely reflect the custom and practice in those laboratories of which the author has experience. However, similar approaches are used throughout the pharmaceutical, consumer product, chemical and contract research industries for genetic toxicology. By default, development of a drug intended for oral administration in the clinic is assumed, as this is by far the predominant route in clinical practice. Evaluation of the genotoxicity of a test agent given by non-oral routes requires some adaptations, but the principles of testing remain the same.

3.2 The Standard Test Battery

3.2.1 *In Silico Assessment of Genotoxicity and Carcinogenicity*

Recent advances in combinatorial chemistry and high-throughput screening technologies have led to a massive explosion in the numbers of potential drug candidates being produced at the earliest stages of drug discovery. Consequently there is a greater need to acquire alternative methods for the prediction of toxicity in order to be able to cut these numbers rationally to manageable proportions. Computer-based or *in silico* 'expert systems' for predicting genotoxicity have been developed in order to screen new active substances for potential chemical activity prior to any biological testing (Greene, 2002). These systems fit broadly into two categories, although there is an overlap between them. The first comprises mathematical models, in which correlations are sought between chemical structure and biological activity, and the second includes predictive models, which rely on existing knowledge in the form of rules describing historical data (Dearden, 2003). The application of computational tools for reducing the attrition rate of compounds during drug discovery by predicting adverse drug reactions in preclinical development has recently been reviewed by Muster *et al.* (2008).

3.2.1.1 *Quantitative Structure–Activity Relationships (QSAR)*

The assumption supporting the use of quantitative structure–activity relationships (QSARs) for the prediction of toxicity is that 'biological activity may be described as a function of chemical constitution'. This was first proposed by Crum-Brown and Frazer (1868), and latterly has been driven by the work of Corwin Hansch (for a historical review see Rekker, 1992). In the main, one of the most successful applications of QSAR has been genotoxicity, primarily for well-defined congeneric series of chemical structures.

Rules-based expert systems rely on existing knowledge about chemical structures and their associated toxicological potential, rather than forming empirical relationships. It is fair to state that no system routinely outperforms another. Localized QSAR models for highly conserved congeneric series provide the optimum concordance values, although rules-based systems are applicable to a wider range of chemical entities. The most commonly used systems are summarized below.

- DEREK (Deductive Estimation of Risk from Existing Knowledge; LHASA UK Ltd.) (*www.lhasalimited.org*) is a knowledge-based system for the qualitative prediction of a range of toxic end points (principally mutagenicity, carcinogenicity and skin sensitization). The system has a rules base consisting of molecular substructures (toxophores)

which have been associated with a toxic outcome. A novel structure is presented to the system, and any toxophores are returned with corresponding descriptive text for the user to review. An example of a DEREK genotoxic alert is shown in **Figure 8**.

- COMPACT (Computer-Optimized Molecular Parametric Analysis of Chemical Toxicity) (*http://ukpmc.ac.uk/articlerender.cgi?artid=633320*) may be used to predict the capability of a compound to act as a substrate for cytochrome P450. Structural characteristics are used to determine the ability of a molecule to fit into the enzyme binding site, and electronic characteristics are used to determine the likelihood of oxidative metabolism. Expert knowledge is then required in order to assess the toxicological significance of such metabolism, for example, activation of a test article to electrophilic metabolites capable of reacting with DNA.
- OncoLogic (LogiChem Inc.) (*www.epa.gov/nrmrl/std/mtb/pdone/tfs11.pdf*) is a PC-based program for the prediction of carcinogenicity based on human expert knowledge. Predictions are made using a hierarchical decision tree, with four subsystems available for the prediction of fibres, metals or metal-containing compounds, polymers and organic chemicals. The organics module is the most extensive, with in excess of 40 000 discrete rules derived from over 10 000 compounds. The system requires the user to specify the chemical class of the query molecule. It then follows a series of predefined rules to produce a mechanism-based evaluation of carcinogenic potential.
- M-CASE ('Multiple Computer Automated Structure Evaluation'; MultiCASE Inc.) (*www.multicase.com/index.html*) analyses the structural fragments of the compounds in a 'training' database to identify biophores, that is, those fragments responsible for the toxicological end point (such as carcinogenicity and mutagenicity) for which data are contained in the database. It compiles a dictionary containing the contribution of each biophore to the particular toxicological outcome. The bioactivity

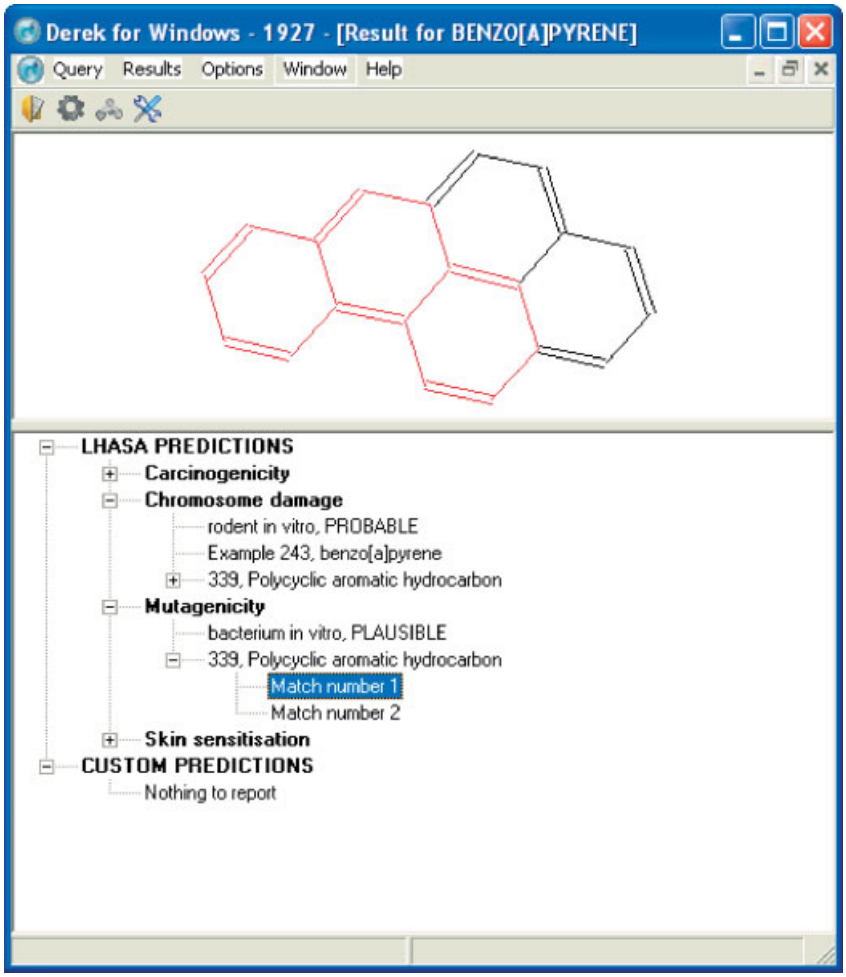

Figure 8 *In silico* predictions of genotoxicity. Computer software, such as DEREK (Deductive Estimation of Risk from Existing Knowledge; LHASA UK Ltd., Leeds, UK) may be used to predict genetic toxicity via chemical structure; in this case benzo(a)pyrene (B(a)P).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of any compound not in the training database is predicted from the sum of the contributions of the biophores that it contains.

Recently, Mayer *et al*. (2008) evaluated 650 compounds from the Carcinogenic Potency Database (CPDB) to assess the predictivity of OncoLogic (Version 4.1) and MCASE (Version 3.1) with respect to Ashby–Tennant structural alerts (Ashby and Tennant, 1994) and genetic toxicity testing, individually and in combination. The sensitivity of the methods for predicting carcinogens and the specificity for predicting noncarcinogens was examined. Potent carcinogens, defined as those with TD_{50} values (i.e. the dose resulting in 50% of animals with tumours) of less than $6.25\,mg\,kg^{-1}$ body weight day^{-1}, were then examined separately. The study concluded that SAR analysis programs and structural alerts perform well for compounds with low human exposure levels and have the potential to supplement the results of routinely requested genetic toxicity tests in a weight-of-evidence approach in predicting carcinogenicity.

All of these systems, however, have their own strengths and weaknesses; for example, in rules-based systems the most important attributes are the quality and quantity of the knowledge databases supporting the predictive algorithms. Unfortunately, these are frequently biased towards certain chemical classes and to compounds with positive toxicological outcomes, such that nontoxic compounds are often under-represented. Attempts have been made to form noncongeneric models, but the multiplicity, and often uncertainty, of biological end points makes this approach far more complex (Benigni and Richard, 1996). Therefore, when new chemical structures with unknown toxicological potential are analysed the systems are liable to provide inaccurate predictions.

However, the predictive accuracy of these databases has improved in recent years as they have become more comprehensively populated with different chemical classes and as the rules influencing the knowledge-based systems have been refined. In the author's laboratory, QSAR assessments are routinely performed on all development compounds prior to any 'wet testing'. *In silico* assessments are also used to prioritize the testing of drug intermediates, impurities and degradents with genotoxic alerts (see below). This has helped to reduce drug development costs by reducing late phase attrition. As the prediction has been exhaustively optimized for early safety-relevant end points such as genotoxicity, future activities are likely be focussed on more idiosyncratic toxicities in patients, by making these tools more relevant to human disease.

3.2.2 In Vitro Assays

Genetic toxicology is one area in which the strength of *in vitro* testing is particularly apparent. Many genotoxins require metabolic activation, and *in vitro* assays facilitate control over the provision of a bioactivating system, usually a microsomal enzyme-containing preparation from the liver of rats treated with a wide spectrum cytochrome P450 inducer (see below for a more comprehensive overview). Microbial or cellular systems often also permit concentrations to be used that could not be achieved in the plasma of animals or humans. This is important in evaluating a compound's *potential* for genotoxicity, which is relevant to particularly susceptible individuals, or to tissues in which the compound accumulates to very high local concentrations. *In vitro* studies are also useful in investigating mechanisms of genotoxic action that would be extremely difficult to pursue in animals. Compounds shown to be potent genotoxins in *in vitro* assays can be—and generally are—eliminated from further development at that point. Those that are negative, or in which a risk–benefit estimate remains favourable, still require *in vivo* assessment, which is mandatory for drug and chemical registration.

In the *in vitro* assays, cells (bacterial and mammalian) are treated with test agents in the presence and absence of exogenous mammalian oxidative metabolizing system (S9-mix), to mimic mammalian metabolism (Garner *et al*., 1972). A phenobarbital/5,6-benzoflavone or aroclor 1254-induced rat liver postmitochondrial fraction (S9) may be used as an exogenous oxidative metabolizing system (McGregor *et al*., 1988). The S9 fraction may be obtained commercially, for example, MolTox™ (Molecular Toxicology Inc., USA) or generated 'in house'. Every batch of rat liver S9 fraction should be checked for sterility, protein content, ability to convert known promutagens to bacterial mutagens and cytochrome P450 enzyme (e.g. alkoxyresorufin-O-dealkylase) activity. Batches of S9 may be stored as frozen aliquots at $-80\,^{\circ}C$ prior to use and should be thawed and mixed with appropriate cofactors to produce S9-mix when required.

3.2.2.1 Bacterial Mutation Tests

The study of mutation in bacteria and bacterial viruses has had a fundamental role in genetics, particularly in relation to the understanding of biochemical pathways, identifying DNA as the hereditary material, and providing insights into gene structure, regulation, and the basis for mutagenesis, and so on. Early studies on the biosynthesis of amino acids in the bacteria *Escherichia coli* (Yanofsky, 1971) and *Salmonella typhimurium* (Ames, 1971), using mutant strains unable to grow in the absence of specific amino acids, were the very basis of the bacterial 'reverse' mutation assay. For an illuminating insight into the early development of these assays the reader is referred to reviews by MacPhee (1989) and Mortlemans and Zeiger (2000).

This pioneering work eventually resulted in what is commonly known as the Ames *Salmonella*/microsome mutagenicity assay (or simply *Salmonella* test; Ames

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

test); a short-term bacterial 'reverse' mutation assay specifically designed to detect a wide range of chemical substances that can produce genetic damage that leads to gene mutations (Ames *et al*., 1975; Green, 1978; Maron and Ames, 1983). The test employs several histidine-dependent (auxotrophic) *Salmonella* strains, each carrying different mutations in various genes in the histidine operon. These mutations act as hot spots for mutagens that cause DNA damage via different mechanisms. When the *Salmonella* tester strains are grown on a minimal media agar plate containing a trace of histidine, only those bacteria that revert to histidine independence (his+), by acquiring a second mutation that directly reverses or suppresses the original mutation in the histidine operon, are able to form colonies. In other words, the second mutation restores prototrophy, that is, the ability for the affected cell to grow in the absence of the relevant amino acid, histidine. The absence of the essential amino acid in the culture medium provides the selective pressure which enables a small number of mutant colonies to grow from a few individual bacteria within a population of millions of unmutated cells (that are unable to grow). This simple concept underlines the great strength of the bacterial 'reverse' mutation assay, since the number of spontaneously induced revertant colonies per plate is relatively constant, whereas when a mutagen is added, the number of revertant colonies per plate is increased, usually in a concentration-dependent manner.

The *Escherichia coli* WP2 tryptophan reverse mutation assay detects trp(−) to trp(+) reversion in comparison. All WP strains carry the same AT base-pair mutation at a critical site within the *trpE* gene which blocks the biosynthesis of tryptophan prior to the formation of anthranilic acid (Bridges *et al*., 1967). The assay is currently used by many laboratories in conjunction with the Ames *Salmonella* assay for screening chemicals for mutagenic activity. In general, the *E. coli* WP2 assay procedures are the same as those for the Ames *Salmonella* assay (detailed below), with the exception that limited tryptophan instead of limited histidine is used. The WP2 strains are used as a substitute for, or as an addition to *Salmonella* strain TA102 which also carries an AT base pair at the mutation site (reviewed by Mortlemans and Riccio, 2000).

The relative simplicity and speed of the Ames *Salmonella* and *E. coli* WP2 assays, in addition to the qualitative relationship (relatively high specificity and sensitivity) between mutation in bacteria and rodent carcinogenicity, for most classes of DNA-reactive compounds, has promoted their worldwide adoption as an initial screen to determine the mutagenic potential of new chemicals and drugs. Over the years, many validation studies have been performed to determine the reproducibility of test results on an intralaboratory and interlaboratory level, and also the sensitivity and correlation of the Ames test with animal carcinogenicity studies. It has indeed been established that there is a high predictivity of a positive mutagenic response in the Ames test for rodent carcinogenicity (Zeiger, 1985; 1987). The test therefore is in many instances used as a first screen to determine the mutagenic potential of new chemicals and drugs. The Ames *Salmonella*/*E. coli* WP2 test is also used for submission of data to regulatory agencies for registration or acceptance of many chemicals, including drugs and biocides. National (COM, 2000) and international (OECD, 1997a) guidelines have been established for performing these mutagenicity assays and to ensure uniformity of testing procedures (reviewed by Gatehouse *et al*., 1990; Mortlemans and Zeiger, 2000; Mortlemans and Riccio, 2000).

An alternative approach is to use bacteria to detect 'forward mutations' such as the acquisition of resistance to a toxic chemical (e.g. an amino acid analogue) or an antibiotic (such as streptomycin). Although genetic systems which detect forward mutations have an apparent advantage, in that a wide variety of genetic changes (e.g. point mutation, deletions, insertions) may lead to a forward mutation, the spontaneous mutation rates tend to be relatively high (Gatehouse *et al*., 1990). Therefore, if a particular mutagen causes rare specific changes, these changes may be lost against the background of more common events. Forward mutation systems in bacteria, however, are no longer commonly used in regulatory genetic toxicology.

3.2.2.1.1 Tester Strains

The most widely used strains are those developed by Professor Bruce Ames and colleagues, which are mutant derivatives of the organism *Salmonella typhimurium*. Each strain carries one of a number of mutations in the operon coding for histidine biosynthesis. In each case the mutation can be reverted either by base-change or by frameshift mutations. The genotypes of the commonly used strains are listed in **Table 5** along with the DNA sequence at the site of the original mutation in the relevant histidine gene. With the exception of the TA102 strain, all the other strains contain G–C base pairs at the site of the histidine mutation, and this has some effect on the selectivity of the mutagens detected, that is, those that act preferentially on these bases.

Many carcinogens (or their metabolites) are large molecules that are unable to cross the outer cell wall of wild-type *Salmonella*, therefore Ames introduced *rfaE* mutations (deep rough) into the *Salmonella* tester strains, which results in defective lipopolysaccharide, and increases the permeability of the cell wall to bulky hydrophobic chemicals (Ames *et al*., 1973). In addition, bacteria possess several major error-free DNA repair pathways which can repair DNA damage without generating mutations. By removing the UV endonuclease component B (*uvrB*) gene, Ames was able to increase the sensitivity of the tester strains to mutagens by several

TA1537	*hisC3076 rfa* Δ *gal chlD bio uvrB*	ICR364-OH induced +1 C frameshift mutation	Imidazoleacetol phosphate transaminase	Frameshift mutagens; for example ICR-191, 9-aminoacridine, and epoxides of PAHs	Isono and Yourno (1974)
TA1538	*hisD3052 rfa* Δ *gal chlD bio uvrB*				

[a]*rfa*—deep rough; *gal E*—UDP galactose 4-epimerase; *chlD*—nitrate reductase (resistance to chlorate); *bio*–biotin; *uvrB*—UV endonuclease component B; Δ—deletion of genes following this symbol; PAHs—polycyclic aromatic hydrocarbons; pAQ1—a plasmid carrying the *hisG428* gene; pKM101–a plasmid carrying the *mucA8* genes that enhance error.

orders of magnitude (note the deletion through *uvrB* also includes the nitrate reductase (*chl*) and biotin (*bio*) genes, hence the genotypes described in **Table 5**).

DNA interstrand crosslinking agents (e.g. mitomycin C, psoralens, UVR), however, require an intact excision repair pathway to generate mutations (see Kondo *et al*., 1970). Thus, it is useful to include a strain with an intact excision repair pathway in the test battery. *Salmonella typhimurium* TA102 is such a strain. The relative loss in sensitivity to other types of mutagen due to the *uvrB*+ background is offset by the presence of multicopies of the *hisG428* mutation on plasmid pAQ1 in this strain.

The *E. coli* WP2 trp E series possess a terminating ochre mutation in the *trp E* gene, which codes for anthranilate synthetase, an enzyme late in the biosynthetic pathway for tryptophan. The ochre mutation involves an A–T base pair (Bridges *et al*., 1967). Reverse mutation can take place at the original site of mutation or in the relevant tRNA loci, and thus all types of transition and transversion can be detected. Although error-prone repair is present, strains possessing *ruvrA* mutations and mutator plasmids (pKM101 or R46) have advantages, including the detection of some frameshift mutagens. In addition to being effective general strains for mutagen detection, studies by Wilcox *et al*. (1990) have shown that a combination of *E. coli* WP2 lip E (pKM101), which has a functioning excision repair system for the detection of cross-linking agents, and *E. coli* WP2 ir-p E urrA (pKM 101) can be used as alternatives to *Salmonella* TA102 for the detection of oxidative mutagens. The *E. coli* strains have the advantage of lower spontaneous mutation rate and are somewhat less difficult to use and maintain.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

During the 1990s, an improved understanding of the molecular process of mutagenesis and advances in biotechnology led to the development of engineered bacterial strains for specific areas of genotoxicity research. In particular, the introduction of genes for the enzymes involved in mutagen activation and the processing of DNA damage resulted in a number of new tester strains. For example, bacterial strains expressing specific bacterial enzymes (e.g. *N*-acetyltransferases and nitroreductases) were constructed for the metabolism/detection of nitroaromatic compounds (nitropyrenes) in complex mixtures (Watanabe *et al*., 1990). Also, modifications to DNA repair capacity were introduced, for example *S. typhimurium* TA1535 with inactivated MGMT. Consequently, this strain is extremely sensitive to the mutagenic action of direct acting alkylating agents (Yamada *et al*., 1995). Recently, eukaryotic P450s have also been expressed in bacteria, as reviewed by Guengerich *et al*. (1996). The expression of human P450 enzymes in bacterial cells has made possible the development of mutagenicity assays where metabolic activation takes place within the internal milieu of the target cell (reviewed by Josephy, 2002). At present, these systems do not appear in general use.

Many chemical mutagens and carcinogens generate DNA lesions which block replication, often because of their bulky character, and result in the induction of the SOS response. This response, in turn, increases mutagenesis and survival by allowing replicative bypass of the DNA lesions. As the induction of the SOS response strongly correlates with DNA damage, spectrophotometric assays based on the expression of reporter genes (β-galactosidase (*lacZ*) or luciferase (*LUC*)) transcribed from an SOS promoter have been developed. The SOS chromotest (Quillardet and Hoffnung, 1993) and the Umu test (Oda *et al*., 1992) are such examples. The Ames II test (Gee *et al*., 1994) developed in the Bruce Ames laboratory at the University of California, Berkeley, is based on the same principle as the traditional test, and is a liquid microplate version which offers several advantages over the original, including a higher-speed format, new strains, colorimetry, easy handling and the possibility of automated plating and plate reading. The assay requires lower amounts of test chemical and shows good correlation with the traditional assay (Gee *et al*., 1998). The assay is based on the use of strains TA7001–TA7006 and TA98. Like the traditional strains, the genetic backgrounds of the TA700X strain series have been modified to improve the sensitivity of their reversion. Individually, these strains are designed to revert by only one specific base-pair substitution out of all possible changes. Thus, when mixed, all base-pair substitution mutations can be represented in one culture. The TA98 strain is used for the detection of frameshift mutations. The Ames II test is available commercially from Xenometrix (see *www.aniara.com*).

3.2.2.1.2 Bacterial Reversion Tests: Practical Aspects

The protocol most widely used is the plate incorporation assay (described briefly below). Treat and plate tests and fluctuation tests have also been used (reviewed by Tweats and Gatehouse, 1999). A comprehensive description of the Ames/*Salmonella* test is provided by Mortlemans and Zeiger (2000) and the *Escherichia coli* WP2 tryptophan reverse mutation assay by Mortlemans and Riccio (2000).

In the current OECD, ICH and Committee on Mutagenicity (COM) Guidelines, the following base set of bacterial tester strains is recommended:

- *S. typhimurium* TA98, TA100, TA1535
- *S. typhimurium* TA1537 or TA97 or TA97a
- *S. typhimurium* TA102 or *E. coli* WP2 uvrA or *E. coli* WP2 uvrA (pKM101).

As mentioned earlier, strains TA102 or *E. coli* WP2 uvrA are included to detect point mutations at AT sites. To detect crosslinking agents specifically, it is suggested that the repair-proficient *E. coli* strain WP2 (pKM101) might be selected. Whichever strain is selected, the genetic compositions of the tester strains are fundamental to the operation of these tests and therefore should be assured.

3.2.2.1.3 Storage and Checking of Tester Strains

It is paramount that tester strains are regularly checked to ensure their characteristic genetic features are maintained, particularly if there is cause for concern, for example, extreme fluctuations of the spontaneous mutation values between experiments. These checks should include:

- Amino acid requirement (i.e. histidine for *S. typhimurium* strains; tryptophan for *E. coli* WP2 strains).
- Sensitivity to diagnostic mutagens using pairs of strains designed to give either a strong or weak response.
- Resistance to ampicillin for strains carrying pKM101 and tetracycline for strains carrying pAQ1.
- Regular monitoring of background mutation rates and induced mutation rates with reference mutagens (i.e. 'positive controls').

The importance of these checks together with careful storage and cell culture maintenance and response to reference mutagens can not be over-emphasized: failure to apply them can result in much wasted effort.

3.2.2.1.4 Ames *Salmonella*/Plate Incorporation Method

Plate incorporation tests are carried out essentially as described by Maron and Ames (Maron and Ames, 1983), and should be conducted with and without external

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

metabolic activation. In short, the test involves preparation of the appropriate amount of bacterial culture, test article and S9-liver fraction (or S9-buffer as appropriate) in sterile glass tubes (maintained at 37 °C) to which is added molten top agar (maintained at ~45 °C) supplemented with limiting amounts of biotin and the required amino acids (histidine or tryptophan). The final mixture is quickly poured over Vögel Bonner plates and allowed to set. The plates are then inverted and incubated for approximately 48–72 hours at ~37 °C in the dark before scoring for revertant colonies.

Before carrying out the main test, it is necessary to conduct a preliminary toxicity test, performed to the same basic protocol as the mutation test, except that instead of scoring the number of mutants on, for example, minimal media plates with limiting amounts of the required amino acid, the number of survivors is scored on fully supplemented minimal media. This preliminary toxicity test will also demonstrate excess growth, which may indicate the presence of histidine or tryptophan or their precursors in the test material, which could make testing for mutagenicity impracticable by this method. Sterility check plates should also be prepared and run in parallel with both toxicity and main tests.

In the main test, the upper treatment level should be 5 mg plate^{-1} for freely soluble, nontoxic compounds. Where toxicity is observed at lower concentrations, the highest concentration tested should show evidence of significant toxicity; this may be detected by a reduction in the number of revertants or a diminution of the background lawn (see below). For compounds that are relatively insoluble in the test system, the lowest precipitating concentration (determined by eye at the end of the incubation period) should be used as the maximum test concentration, up to 5 mg plate^{-1}. It is recommended that a minimum of three plates per dose be used and at least five analysable concentrations be selected for scoring, although the concentrations obtained may be strain specific in the event of variable strain toxicity. Vehicle and positive control compounds (**Table 6**) should be tested in parallel, and, generally, two standard plate incorporation tests are performed to support a submission of data to regulatory authorities for the registration of chemicals, drugs and biocides, although a single, well-conducted test may be appropriate (ICH S2B: A Standard Battery for Genotoxicity Testing of Pharmaceuticals, 1997 and revision expected in 2009).

3.2.2.1.5 Scoring of Plates

Before scoring the treatment plates it is important to review the vehicle control and sterility-check plates in order to confirm that the assay has been performed correctly. It is important to monitor the number of mutant colonies present on untreated or vehicle controls. Acceptable ranges are shown in **Table 7**. Deviations in background reversion frequencies should be viewed with suspicion and investigated, as it is possible that strain cross-contamination has occurred or media quality has been compromised, and so on (see above on checking of tester strains). In addition, the toxicity of the various treatment plates should be determined in order to select the appropriate plates for scoring; this requires the evaluation of bacterial lawns on the agar plates after the incubation period, rather than a quantitative assessment of cell survival.

The addition of limiting amounts of the required amino acid to the top agar allows the bacteria to undergo approximately six to eight cell divisions. In many cases, this limited growth is essential for mutagenesis to occur by allowing fixation of the mutational lesions. The bacterial revertants (pre-existing and induced) will continue to grow in the absence of the essential amino acid and will give rise to visible colonies. These are easily scored against a slightly hazy-looking background lawn which is made up of microcolonies of auxotrophic bacteria, that is, those that are dependent on the required amino acid. Examination of the background lawn in the absence of toxicity will reveal the presence of densely packed

Table 6 Positive control compounds used in the standard plate incorporation Ames test

Strain	Positive control, concentration in μg plate^{-1}	Vehicle
Without S9

[a]Mortlemans and Zeiger (2000).
[b]Wilcox *et al*. (1990).
[c]Mortlemans and Riccio (2000).

microcolonies which form a uniform layer. However, when a chemical is toxic there may be 'thinning' or complete absence of the background lawn compared to the vehicle control for that strain. A reduction in the number of revertant colonies to levels below the spontaneous reversion level may also be seen on occasion and this may reflect toxicity too, but could also indicate antimutagenic properties of the test article. A complete absence of the background lawn indicates a high level of toxicity with the inability of the bacteria to grow and form a lawn. Such toxic concentrations should not be used, as colonies may appear which are not true revertants, but are instead surviving auxotrophic cells. These colonies will be visible to the naked eye. If necessary the phenotype of any questionable colonies (pseudo-revertants) should be checked by plating the bacteria onto histidine- or tryptophan-free medium, as appropriate.

The presence of the background bacterial lawn may be recorded using the following general assessments:

- **Very slight toxicity:** very slight thinning (up to 10% loss) of the background bacterial lawn and increase in the size of the lawn microcolonies compared to vehicle control.
- **Slight toxicity:** slight thinning (up to 30% loss) of the background bacterial lawn and increase in the size of the lawn microcolonies compared to vehicle control.
- **Clear toxicity:** marked thinning (30–70% loss) of the background bacterial lawn and increase in the size of the lawn microcolonies compared to vehicle control.
- **Severe toxicity:** lack of background bacterial lawn on over 80% of the plate, lawn colonies visible to the naked eye.
- **Toxic:** complete killing of all the test bacteria.

Plates are also evaluated (by eye) for the presence of test compound precipitation at the end of the incubation period. The number of bacterial colonies per plate is scored, usually with the aid of an automatic colony counter; however, where necessary the plates may be scored manually, for example, plates with large amounts of colonies or heavy precipitate. Bacterial mutation plates may be stored at 2–8 °C for up to one week prior to scoring.

3.2.2.1.6 Expression and Interpretation of Results

The number of colonies per plate is recorded and mean values calculated for each concentration of test compound used. Mean values may also be expressed as a ratio of the mean concurrent vehicle control value (i.e. fold increase). The values for vehicle control of number of revertants for each strain must be within or close to appropriate ranges determined from the laboratory historical control data, and positive control cultures should show clear, unequivocal, positive responses. There should be an absence of confounding technical problems such as contamination, outliers, excessive toxicity or unacceptable numbers of lost plates. Tests that do not fulfil these criteria should be rejected and not reported.

If the data for any test agent treatment concentration shows a response greater than or equal to two times the concurrent vehicle control value (strains TA98, TA100, TA102, WP2 uvrA (pKM101) and WP2 (pKM101)), or greater than or equal to three times the concurrent vehicle control value (TA1535 and TA1537), in conjunction with a concentration-dependent response, the result is considered positive. Where the data for any strain shows a concentration-dependent response, approaching the two- or three-fold threshold as detailed above, but does not exceed it, or the two/three-fold increase in an appropriate strain is obtained only at the highest concentration tested, or there is an isolated increase with evidence of toxicity to the bacterial strain at the next highest test dose, then the result may be equivocal and further testing may be required for clarification, as follows:

- The test may be repeated using the strain(s) and a narrowed-down concentration range with which the initial positive result was observed in order to assess/confirm reproducibility.
- A second preincubation-type test (Yahagi *et al*., 1975) may be conducted (see below) or alternatively a different metabolic activation system may be used, for example using a higher concentration of S9-liver mix, or S9-liver fraction from an alternative species (if appropriate).
- Testing in additional bacterial strains (e.g. WP2 (pKM101) or TA102) can also be considered.

A number of statistical programs have been developed for analysing *Salmonella* mutagenicity data, and all have their strengths and weaknesses (see review by Mahon

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

et al., 1989). It should be recognized that variation within experiments does occasionally produce weak positive results that are not obtained in repeat assays. In addition, experimental variability of unknown origin may occur from time to time, yielding a stronger positive result that, similarly, is not confirmed in repeat experiments. In such cases the components of the test system should be thoroughly checked. If no further positive result is obtained the test compound should be regarded as nongenotoxic.

3.2.2.1.7 Modification of the Plate Incorporation Method

The liquid preincubation assay (also known as the Yahagi test) is a modification of the standard plate incorporation assay and involves exposing the tester strains for a short period of time in a small volume containing the test agent with buffer or external metabolic activation prior to plating on minimal agar medium (Yahagi *et al*., 1975). It is believed that the modification renders the test more sensitive than the standard assay for the detection of some classes of genotoxic carcinogens, for example nitrosamines and azo dyes. This is because short-lived mutagenic metabolites have a better chance of reacting with the tester strains in the small volume of the preincubation mixture compared to when the incubation mixture is plated immediately on minimal defined agar plates. In addition, the smaller preincubation volume results in a higher effective concentration of S9-liver fraction and cofactors in the external metabolic activation mix. All procedures are exactly as described in the standard plate incorporation test with the following modifications: sterile glass tubes are prepared and maintained at 37 °C before adding the appropriate amount of the required test compound, vehicle or positive controls and S9-liver fraction metabolic activation mix for a fixed period of time (usually 20–60 minutes). The top agar is added and the final mixture is poured over Vögel Bonner plates. The plates are then inverted and incubated for approximately 72 hours at ∼37 °C in the dark before scoring for revertant colonies. All positive control final concentrations are the same as described in the standard plate incorporation test with the exception of WP2 uvrA (pKM101), for which the concentration of 4NQO is reduced to 1 μg plate^{-1}.

3.2.2.1.8 Fluctuation Tests

The fluctuation test, originally devised by Luria and Delbruck (1943) was further developed as a genotoxicity assay in the 1970s (reviewed by Hubbard *et al*., 1984) and more recently by Flückiger-Isler and Kamber (2007). In the fluctuation test the number of mutants in a series of small independent replicate cultures is determined. Amino acid-requiring bacteria are treated in a suitable medium either with or without a metabolizing system, with the chemical to be tested and with a trace of the required amino acid. As for the Ames test, this trace allows a few generations of growth, which allows mutation expression following the initial DNA damage. This mixture is then divided into a large number of aliquots, for example into 50 test tubes or the 96 wells of a microtitre tray. When the trace of amino acid is consumed, only cells that have reverted at the target gene, thus restoring biosynthesis of the relevant amino acid, can grow. Test tubes or wells containing such a revertant become turbid and the medium in the well or tube becomes acid, as a result of acid release during growth. A pH indicator such as bromocresol purple or bromothymol blue can highlight such changes. The pH of the medium will drop into the range 5.2–6.8 in such cultures, causing a change of the indicator to yellow. A statistically significant, reproducible increase in the number of positive wells or tubes indicates a mutagenic response. The preferred methods of statistical analysis have been reviewed in Robinson *et al*. (1989).

For a description of other types of bacterial reversion assays or more exotic modifications of the Ames test, for example the desiccator assay for volatile liquids and gases, and so on, the reader is referred to Tweats and Gatehouse (1999) and the review of the Ames/*Salmonella* assay by Mortlemans and Zeiger (2000), respectively.

3.2.2.2 Mammalian Cell Mutation Assays

3.2.2.2.1 Mouse Lymphoma Assay

The mouse lymphoma assay (MLA) using the thymidine kinase (*tk*) gene is the most widely used of the various *in vitro* mammalian cell gene mutation assays. There are currently two equally acceptable methods for performing the assay, one using soft agar medium for cloning and enumeration of mutants and the other using liquid medium and 96-well microwell plates (Cole and Arlett, 1984).

The MLA detects gene mutations and chromosomal damage in proliferating mammalian L5178Y mouse lymphoma cells *in vitro*. The assay selects for mutations at the *tk* locus, an autosomal gene of moderate size (11–13 kb), located on chromosome 11 in the mouse genome, which encodes for a pyrimidine salvage enzyme involved in a biochemical pathway for nucleic acid breakdown products. The mouse lymphoma L5178Y cell line is heterozygous for thymidine kinase, that is, $tk^{+/-}$. When L5178Y ($tk^{+/-}$) cells are grown in culture medium containing the toxic base analogue, 5-trifluorothymidine (TFT), only mutant ($tk^{-/-}$) cells are able to survive. Thus the assay selects for forward mutation at the *tk*-locus (**Figure 9**).

TFT-resistant, L5178Y ($tk^{-/-}$) mutant colonies may be characterized as large colonies or small (slow-growing) colonies (**Figure 9**). Molecular analysis has indicated that large colonies generally arise from cells subject to genotoxic events which occur within the *tk* gene locus (i.e. intragenic lesions such as base-pair substitutions, frameshift mutations and/or small deletions, etc.). These

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

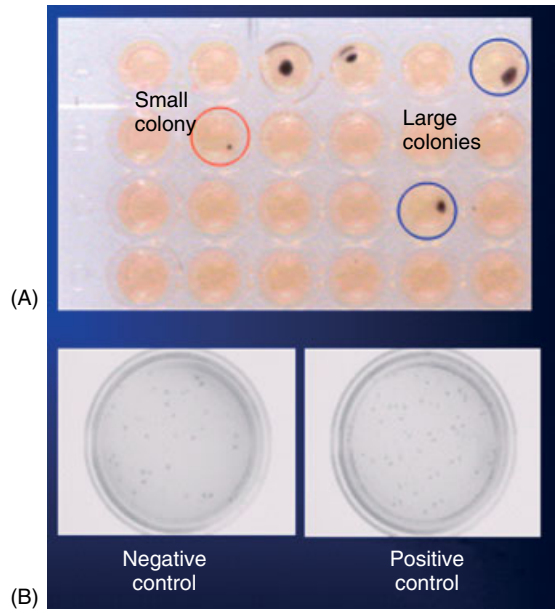

Figure 9 Mouse lymphoma assay. (A) Microwell-plate version; (B) agar plate version (note 'pin-prick' colonies).

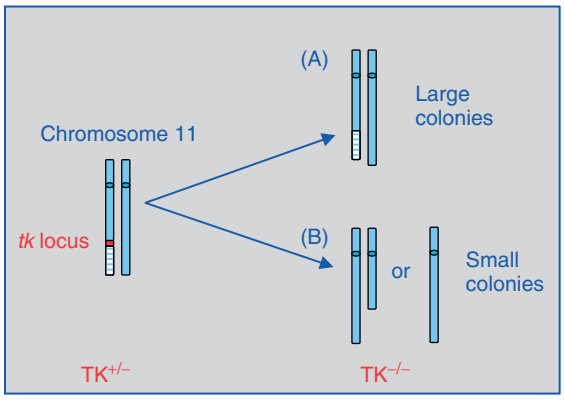

Figure 10 Colony sizing in the mouse lymphoma assay. The thymidine kinase locus is proximal to a number of genes essential to cell growth (located at the end of the q-arm of chromosome 11). (A) Intragenic mutation at the *tk* locus (i.e. point mutations or small deletions) result in large colony formation; (B) large deletions or chromosome loss (extragenic mutations) result in small colony formation (due to the loss of the essential growth genes).

affect only the *tk* gene and result in significant reduction or total loss of gene expression and/or thymidine kinase enzyme function. In contrast, small colony $tk^{-/-}$ mutants are derived from cells with much larger aberrations on chromosome 11b, the chromosome homologue that carries the wild type (active) *tk* gene, which may arise from chromosomal recombination, chromosomal deletion (clastogenic) or chromosomal loss (aneugenic) events (Applegate *et al*., 1990; Moore *et al*., 1985). Thus, in cell lines heterozygous for the *tk* allele, both mutations in the *tk* gene, and chromosomal events involving the gene, may be detected by selecting *tk* mutants in culture medium containing TFT (**Figure 10**). Therefore, mutant ($tk^{-/-}$) colony sizing in the MLA may provide information regarding genotoxic mechanism (gene mutation, clastogenicity and/or aneuploidy).

The MLA, like the majority of mammalian gene mutation systems, requires colony formation to detect mutants; this has the benefit of allowing further analysis of selected clones to verify the mutational origins of the LOH events leading to TFT resistance, for example by DNA sequencing or the use of molecular probes.

3.2.2.2.2 The Test System

In the MLA, a preliminary cytotoxicity test is generally followed by three independent mutation assays: two in which cells are treated for 3–4 hours in the presence and absence of exogenous mammalian oxidative metabolizing system (S9-mix), to mimic mammalian metabolism (Amacher and Turner, 1982; McGregor *et al*., 1988), and a third in which cells are treated for 24 hours in the absence of S9-mix. The purpose of the 24 hours exposure arm is to account for compounds that induce cell cycle delay or cell division aberrations. Such compounds often induce aneuploidy and these are not always detected using a short 3–4 hour exposure period (Moore *et al*., 2002).

The test methodology is based on established procedures (Clive *et al*., 1979; 1995; Cole *et al*., 1990; Moore *et al*., 1985) and the assay should be conducted in accordance with the general principles of current regulatory guidelines (OECD, 1997e; ICH S2B: A Standard Battery for Genotoxicity Testing of Pharmaceuticals, 1997). In addition, the recommendations of the MLA workgroup of the IWGTP should also be employed to ensure consistency in results and data interpretation. The MLA workgroup, chaired by Dr. Martha Moore (National Health and Environmental Effects Research Laboratory, US Environmental Protection Agency) since its inception at the IWGTP meeting in Washington DC in the spring of 1999, consists of experts from Japan, Europe and the USA. The MLA workgroup has been responsible for the production of several documents relating to the conduct of the MLA, which specifically address the following: (i) recommendations for an appropriate cytotoxicity measure, (ii) issues related to the use of a 24-hour treatment time (including the ability of the assay to detect aneugens), and (iii) criteria for data acceptance and appropriate approaches to data evaluation (Moore *et al*., 2000; 2002; 2003; 2006; 2007).

The description of the assay below is based on the microwell method protocol that is used in the author's laboratory and is based on the recommendations of the MLA workgroup. Other protocols may include minor deviations to the protocol described below. Any major deviations in the agar method are included, were appropriate, for completeness.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.2.2.2.3 Cell Line and Culture

L5178Y ($tk^{+/-}$) mouse lymphoma cells were originally isolated by Dr. Donald Clive (Burroughs Wellcome Co., USA). Cultures may be obtained from established cell banks (e.g. The European Collection of Cell Cultures: see *www.hpacultures.org.uk*). Cells should be karyotyped on receipt and stocks should be prepared and stored frozen in liquid nitrogen. Each batch of frozen cells should be purged of L5178Y ($tk^{-/-}$) mutants, checked for spontaneous mutant frequency (MF) and genetic stability and also be *Mycoplasma* free. Cell media and culture conditions have been described by Moore and Howard (1982). Culture media should be supplemented with heat-inactivated horse serum in order to eliminate a factor present in other sources of animal sera which degrades TFT (Moore and Howard, 1982).

3.2.2.2.4 Rationale for Dose Selection

The maximum concentrations tested in the MLA are defined by current guidelines (see above) and are restricted to 5000 $\mu g\,ml^{-1}$ or 10 mM for freely soluble compounds, or the limit of solubility or toxicity, whichever is lowest. If compound solubility is a limiting factor, the maximum concentration tested is generally set as the lowest level at which compound precipitate is observed by eye at the end of treatment. Vehicle controls, diluted to the same extent as the test-compound solutions, and a positive control should be used. In the author's laboratory, methylmethane sulfonate (20 $\mu g\,ml^{-1}$ for 3 hour, and 5 $\mu g\,ml^{-1}$ for 24 hour treatments) and benzo(a)pyrene (3 $\mu g\,ml^{-1}$) are generally used as positive controls in the absence and presence of S9 activation, respectively.

3.2.2.2.5 Mammalian Oxidative Metabolizing System (S9-mix)

A phenobarbital/5,6-benzoflavone (Elliot *et al.*, 1992) or aroclor 1254 (Amacher and Turner, 1982) induced rat liver postmitochondrial fraction (S9) may be used as an exogenous oxidative metabolizing system in the short (3–4 hour) treatment arm of the MLA, but not the 24-hour treatment arm. Cole *et al.* (1990) noted that S9 itself (or culture medium in which S9 has been preincubated) maybe mutagenic in the MLA when used for prolonged periods (18–24 hours) or at high concentrations (50 μl S9 ml^{-1}), and therefore S9 is not included in the 24-hour treatment arm of the MLA.

3.2.2.2.6 Preliminary Cytotoxicity Test and Main Test

A preliminary cytotoxicity test is generally conducted with the test agent using a standard range of concentrations to define toxicity limits (unless solubility or existing toxicity data indicate otherwise), in the presence (3-hour treatment) and absence (3-hour and 24-hour treatments) of metabolic activation (S9-mix). Single cultures are generally acceptable. The relative suspension growth (RSG) values are calculated as described below and these are used to determine the main test concentrations to be used. Based on the results of the preliminary cytotoxicity test, a minimum of five test concentrations are generally selected for testing in the MLA, both in the presence and absence of S9-mix. A range of concentrations, from nontoxic to appropriate dose-limiting levels should be selected, and the concentration range may be specific for each treatment arm of the study (i.e. 3 or 24 hours duration of exposure and presence/absence of S9-mix). As fluctuations in osmolality of more than 50 mOsm kg^{-1} (Scott *et al.*, 1991) or extremes of culture-medium pH (Brusick, 1986) are associated with increased mutant frequencies, these parameters may be measured, on a case-by-case basis (e.g. if the final concentration in the medium is anticipated to be ~10 mM or the molecular weight of the test compound is unknown), and subsequently used to define the limit concentration. In the author's laboratory, testing is routinely limited to those compounds with a molecular weight of less than 200, based on previous experience.

3.2.2.2.7 Expression Period

Following treatment with the test agent, L5178Y cell cultures should be maintained in an incubator at 37 °C for a period of two days to allow time for any residual thymidine kinase enzyme and wild-type RNA to degrade in $tk^{-/-}$ null mutants. This ensures sufficient time has passed so that the mutant phenotype (i.e. TFT resistance) may be expressed. During this time, cell densities ($<1 \times 10^6$ cells ml^{-1}) are maintained by subculturing. From observations of cell growth and recovery during the expression period, four to five test concentrations plus vehicle and positive controls are selected for plating to assess viability (cloning efficiency (CE)) and TFT resistance (mutant assessment).

3.2.2.2.8 Plating for Viability

At the end of the expression period, cell densities should be determined using a Coulter counter or haemocytometer, and selected cultures should be adjusted to contain 10 000 cells ml^{-1} (except for the preliminary cytotoxicity test, where this adjustment is not made). Cultures are then adjusted to 8 cells ml^{-1} and aliquots transferred to two 96-well microtitre plates (0.2 ml $well^{-1}$, averaging 1.6 cells per well). The plates are placed in a humidified incubator and maintained for a minimum of three days (viability test) or one to two weeks (mutation assays) at 37 °C with 5% (v/v) CO_2 in air. Wells containing viable clones (i.e. ≥50 cells per clone) may be identified under a microscope or by eye, and counted.

3.2.2.2.9 Plating for Determination of Mutant Frequency (MF)

At the end of the expression period, cell densities are determined using a Coulter counter or haemocytometer,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and selected cultures adjusted to 1×10^4 ml^{-1} with culture media containing TFT (3 μg ml^{-1}), and transferred to four 96-well microtitre plates (0.2 ml well^{-1} at 2×10^3 cells per well). The plates are then placed in a humidified incubator and maintained for one to two weeks at $37 \pm 1\,^{\circ}$C, with $5 \pm 0.5\%$ (v/v) CO_2 in air. Wells containing mutant clones may be identified, either under a microscope or by eye, and counted. Only colonies of >50 cells should be scored. Where toxicity is a limiting factor, the lowest concentration that provides a relative total growth (RTG) value in the range 10–20% will normally be selected as the maximum treatment concentration for the scoring of mutant frequency. Where this is not possible then the highest treatment concentration selected for scoring MF should result in a RTG value as close to this range as possible. In these circumstances, the validity of the data should be assessed in accordance with the principles discussed by Moore *et al*. (2002). In addition, where one or more treatment concentrations provide the same or similar toxicity levels, only one of these treatment concentrations will normally be scored for MF, provided that at least four treatment concentrations are scored overall.

3.2.2.2.10 Colony Counting and Sizing

If increases in MF compared with the vehicle control are observed, the distribution of large and small colonies may be determined for the vehicle and positive controls and for those concentrations of test compound showing increases in mutant colony frequency. The criterion for sizing colonies is based on morphology and is generally <1/4 well diameter for small colonies and >1/4 well diameter for large colonies (Moore *et al*., 1985; 2000).

'Suspension growth' (SG) is a measure of the growth in suspension during treatment and the expression period. SG is calculated as follows:

$$\text{Suspension growth} = a \times b \times c \qquad (1)$$

where

$$a = \left(\frac{D_0 \text{ post-treatment cell count}}{\text{Pretreatment cell density}}\right)$$

$$b = \left(\frac{D_1 \text{ cell count}}{\text{Cell count set up on } D_0 \text{ post-treatment}}\right)$$

$$c = \left(\frac{D_2 \text{ cell count}}{\text{Cell count set up on } D_1}\right)$$

NB for three-hour treatments assume that $a = 1$.

Usually the denominators for b and c are 2×10^5 cells ml^{-1}. However, if cytotoxicity causes the cell count to be lower than 2×10^5 cells ml^{-1} following treatment and/or if the cells do not grow during part of the expression period, it can be lower. In these cases, the respective cell count values have to be entered into the calculation above.

RSG is a measure of the cell growth in suspension during treatment and the expression period, relative to the mean vehicle control suspension growth.

RSG is calculated as follows:

$$RSG\,(\%) = \left(\frac{\text{Individual SG value}}{\text{Mean control SG value}}\right) \times 100 \qquad (2)$$

Viability is the measure of the cells' ability to clone; that is, *cloning efficiency* (CE).

CE is calculated as follows: for microtitre plate tests, calculations are based on $P(0)$, the proportion of wells in which a colony has not grown:

$$P(0) = \left(\frac{\text{Number of wells with no colony}}{\text{Total number of wells}}\right) \qquad (3)$$

The CE for each culture is calculated according to the following:

$$CE = \left(\frac{-\ln P(0)}{\text{Number of cells per well*}}\right) \times 100 \qquad (4)$$

*Number of cells per well is 1.6, on average, on all viability plates.

Relative total growth (RTG) is the measure of cytotoxicity relative to the vehicle control and takes into account all cell growth and cell loss during the treatment period and the two-day expression period (RSG), and the cells' ability to clone two days after treatment (viability).

$$RTG = RSG \times \left[\frac{\text{Individual viability value}}{\text{Mean control viability value}}\right] \qquad (5)$$

Mutant frequency (MF) is calculated as follows:

$$MF = \frac{-\ln P(0) \text{ for mutant plates}}{\text{Number of cells per well*} \times \left(\frac{\text{viability}}{100}\right)} \qquad (6)$$

*Number of cells per well is 2000, on average, on all mutant plates.

Mutant frequencies for each treatment concentration of test compound will be expressed as a ratio of the concurrent mean vehicle control mutant frequency (i.e. fold increase). Small and large colony mutant frequencies will be calculated in an identical manner, using the relevant number of empty wells for small and large colonies.

3.2.2.2.11 Acceptance Criteria and Data Evaluation

The acceptance criteria for the negative/vehicle control parameters for the soft agar and microwell methods of performing the MLA using 3–4 and 24-hour treatments as recommended my the MLA workgroup are shown in **Table 8**.

The background MF for the MLA shows a broad range of values (**Table 8**), which on occasion may produce a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 8 Assay acceptance criteria for the MLA

Measure	Agar method	Microwell method
MF	$35–140 \times 10^{-6}$	$50–170 \times 10^{-6}$
CE (%)	65–120	65–120
SG[a]	8–32	8–32
SG[b]	32–180	32–180
GEF	90	126

[a] 3 h treatments.
[b] 24 h treatments.

'statistically' positive dose–response within the normal range of the background MF for some experiments. Therefore, a biologically relevant approach to MLA data evaluation has been recommended. This requires that the induced MF exceeds a value based on the global background MF, which is unique for each MLA method (agar or microwell). This value is known as the global evaluation factor (GEF). The basic rationale for this approach can be found in Moore *et al*. (2003). In addition, statistical analysis should be applied to determine whether there is a dose-related increase in MF. The adoption of this procedure disregards small increases in induced MF, judged by experts in the assay to be of little or no toxicological significance, but includes statistical analysis to evaluate the presence of a positive dose-related trend. In numerical terms, the GEF has been defined as the mean of the negative/solvent MF distribution plus one standard deviation, and GEF values for the agar and microwell versions of the assay are described in **Table 8**.

To meet the GEF criterion for a positive result then a test culture must have an MF of at least $50 + 126$ (microwell GEF) $= 176 \times 10^6$, or $35 + 90$ (agar GEF) $= 125 \times 10^6$ in the microwell and agar versions of the assay, respectively. In addition, an appropriate statistical trend test should be applied to determine whether there was a positive dose-related increase in MF. This approach should be applied in all experiments, that is, those that use single or replicate cultures for each data point. A test-agent response in an experiment is positive if both the induced MF for any treatment meets or exceeds the GEF and a positive trend test is obtained. A test-agent response is clearly negative if both the trend analysis and the GEF are negative. Occasionally, either (but not both) the GEF or the statistical analysis may indicate a positive response and these situations should be evaluated on a case-by-case basis. It is generally advisable to conduct one or more additional experiments to better define the assay response (particularly in the 30–10% RTG cytotoxicity range).

In approaching the evaluation of MLA experiments the following points should be borne in mind:

1. **Does the experiment meet all assay acceptance (quality control) criteria?** If it does not, the experiment should be declared invalid and repeated. This is particularly important if the data appears to be negative. 'Negative' experiments that do not meet the assay acceptance criteria should not be included in the overall evaluation of a chemical test article.
2. **Has the cytotoxicity range of the test article been adequately covered?** Generally this requires the testing of test-agent concentrations that cover the range between 100 and 10% RTG. A more detailed set of recommendations is reported in Moore *et al*. (2002).
3. **Is the observed response positive, negative, or equivocal?** Lastly, determine whether the data from a single experiment is definitive or whether additional experiments are required to confirm the result. It is generally necessary to adjust the dose selection for any confirmatory experiment(s), particularly when the result is equivocal (see Moore *et al*., 2002).

As ever, biological relevance should be a major factor in data evaluation and it is recommended that all studies be considered in their entirety before reaching a final evaluation of a test agent.

3.2.2.2.12 Chromosome Aberration Assay

Chromosome aberrations and related events are associated with many human genetic diseases and there is substantial evidence that chromosomal damage is also associated with the process of carcinogenesis, both in humans and experimental animal models (see above). The chromosome aberration (CA) assay detects structural chromosome aberrations in cultured mammalian cells (Preston *et al*., 1981), generally using traditional cytogenetic methods and light microscopy. The test is used to screen for possible mammalian mutagens and carcinogens and may be used as an alternative to the MLA in the standard genotoxicity test battery (**Figure 7**). Briefly, the test involves exposing cell cultures to a test article both with and without metabolic activation. At predetermined intervals that are specific for each cell type (representing ~1.5 cell cycles), the cell cultures are treated with a metaphase-arresting substance (e.g. Colcemid® or colchicine), harvested, stained, and metaphase cells are analysed microscopically for the presence of chromosome aberrations. The methodology describing the conduct of the test can be found in OECD (1997b), and is explained in detail in **Cytogenetics**.

An agent that produces structural changes in chromosomes is known as a clastogen, and the term clastogenicity refers to the capacity to induce structural chromosomal aberrations. Structural aberrations may be of two types, chromosome or chromatid, and many compounds that are positive in this test are mammalian carcinogens; however, there is not a perfect correlation between this test and carcinogenicity (see Section 4 below). The mechanisms by which the different types of structural aberrations arise are described in more detail in **Cytogenetics**. Studies may be conducted in established cell lines or primary cell cultures. For example, the CHL (Chinese hamster lung) (Ishidate and Sofuni,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1985) and CHO (Chinese hamster ovary) (Galloway *et al*., 1987) rodent cell lines are routinely used. The cells are selected on the basis of growth ability in culture, stability of the karyotype, chromosome number, chromosome diversity and spontaneous frequency of chromosome aberrations. The use of human peripheral blood lymphocytes is also recommended because these cells maintain a stable karyotype as short-term (primary) cultures (Evans, 1976), and there is increasing evidence to suggest that the use of human cell lines reduces the frequency of irrelevant positive results (Kirkland *et al*., 2007). Increases in numerical chromosome aberrations, particularly polyploidy, can be detected but the assay is not specifically designed to evaluate aneuploidy or polyploidy. Indeed, it has been considered that an increase in polyploidy may indicate that a chemical has the potential to induce numerical aberrations, as the majority of definitive aneugens evaluated as part of a European Centre for Ecotoxicology and Toxicology of Chemicals (ECETOC) research programme induced polyploidy *in vitro* (Aardema *et al*., 1998). However, particularly *in vitro*, polyploidy is induced by many types of insult and the end point does not necessarily reflect a potential for aneuploidy (Mitchell *et al*., 1995; Galloway, 2000). Therefore, positive results for *in vitro* polyploidy have to be interpreted with much caution (Müller *et al*., 1999). Indeed, in a recent study by Muehlbauer *et al*. (2008), the polyploidy end point was shown not to be a reliable indicator for aneugenic potential in structural CA assays in lymphocytes, as it clearly over-predicts the frequency of truly aneugenic compounds.

3.2.2.2.13 Micronucleus Test

The *in vitro* micronucleus test is a genotoxicity assay for the detection of micronuclei (MN) in the cytoplasm of interphase cells grown in cell culture, first described by Countryman and Heddle (1976). MN present in interphase cells can result from acentric chromosome fragments (i.e. those lacking a centromere) or whole chromosomes that are unable to migrate to the poles during mitosis, but only in cells that have undergone cell division during or after exposure to a test article. The predominant induction of either type of micronucleus can be used to classify chemical activity according to the underlying mechanism of action (MOA), that is, aneugenicity (chromosome loss) or clastogenicity (structural chromosome aberrations). The convincing demonstration of the presence of whole chromosomes in MN has been made possible through the availability and application of suitable molecular cytogenetic technologies. For example, the combination of centromeric and telomeric probes using fluorescence *in situ* hybridization (FISH) (Doherty *et al*., 1996) or kinetochore probes using immunocytochemical labelling of kinetochore proteins (Lynch and Parry, 1993) for the detection and quantification of chromosome loss, and chromosome-specific centromere probes for the detection and quantification of nondisjunction has now been successfully used to analyse the aneugenic activity of an extensive range of chemicals. Thus, the *in vitro* MN test can also provide information on the mechanisms of chromosome damage and micronucleus formation, and many compounds that are positive in this test are mammalian carcinogens (for reviews see: Parry and Sorrs, 1993; Kirsch-Volders, 1997; Parry and Parry, 2006; Fenech, 2007). However, like the chromosome aberration test there is not a perfect correlation between the *in vitro* MN test and carcinogenicity (Kirkland *et al*., 2005; 2006; Matthews *et al*., 2006a; 2006b).

Briefly, the test involves exposing cell cultures to a test article both with and without metabolic activation. At predetermined intervals that are specific for each cell type, the cell cultures are harvested, stained, and interphase cells are analysed for the presence of MN using microscopy. MN represent damage that has been transmitted to daughter cells, whereas chromosome aberrations scored in metaphase cells may not be transmitted. Because MN in interphase cells can be assessed relatively objectively, laboratory personnel need only determine whether or not the cells have undergone division and how many cells contain an MN. As a result, the preparations can be scored relatively quickly and analysis can be automated by flow cytometry (Bryce *et al*., 2008; Collins *et al*., 2008a) and/or image analysis (Diaz *et al*., 2007). This makes it practical to score thousands instead of hundreds of cells per treatment as in the *in vitro* chromosome aberration test, increasing the statistical power of the assay. The *in vitro* MN test has been used in a variety of established rodent cell lines (CHO, V79, CHL, and L5178Y) and in primary human lymphocytes. Protocols have been described with and without the use of the actin polymerization inhibitor cytochalasin B, which inhibits cytokinesis, resulting in the formation of binucleated cells (Fenech and Morley, 1986). The addition of the cytochalasin B prior to the targeted mitosis allows for the identification and selective analysis of MN frequency only in those cells that have completed one mitosis, because such cells are binucleate (reviewed by Fenech, 2007). The *in vitro* MN test has been used in academia and industry for hazard identification as an alternative/replacement of the *in vitro* structural chromosome aberration test, or as a back-up test to elucidate MOA (aneugenicity vs. clastogenicity) for risk assessment purposes (see Section 4 below). The test has already gained widespread international interest, as it offers significant advantages over the assessment of chromosome aberrations, since slide reading is more objective and quicker, resulting in a much higher throughput. Metaphase analysis, by contrast, is very tedious, time consuming and has a low throughput. A limitation of the test is that the assay does not provide information about the types of structural chromosome aberrations and/or polyploidy.

In the past decade, several studies have been performed to support the validity of the *in vitro* MN test for incorporation into the standard regulatory genotoxicity test

battery as an alternative to the *in vitro* structural chromosome aberration test. These include, in particular, the international validation studies coordinated by the Société Française de Toxicologie Génétique (SFTG) (Aardema *et al*., 2006; Clare *et al*., 2006; Lorge *et al*., 2006; Oliver *et al*., 2006; Wakata *et al*., 2006) and the reports of the International Workshop on Genotoxicity Testing (IWGT) (Kirsch-Volders *et al*., 2000b; 2003a). A high correlation (>85%) between the *in vitro* structural chromosome aberration test and the *in vitro* MN test has also been observed (Miller *et al*., 1997; 1998). More recently, a formal validation for the test has been carried out by the European Centre for the Validation of Alternative Methods (ECVAM). This consisted of a retrospective validation of the existing data (reviewed by Corvi *et al*., 2008), which concluded that the *in vitro* MN test is reliable and a relevant genotoxicity assay that can be used as an alternative to the *in vitro* structural chromosome aberration test. Indeed, recent revisions of international regulatory guidances, such as the new European Chemicals Regulation, REACH (registration, evaluation, authorization of chemicals) and ICH2 for pharmaceuticals (see below) have recommended the adoption of the *in vitro* MN test as an alternative to the structural chromosome aberration assay and/or MLA. A draft OECD guideline for the conduct of *in vitro* MN test (TG 487) for regulatory purposes is currently under review and is likely to be adopted in 2009. It remains to be seen, however, how quickly the test is accepted by regulatory authorities as an alternative system in the standard test battery.

The methodology describing the conduct of the *in vitro* MN test and the mechanisms by which MN arise are described in more detail in **Cytogenetics**.

3.2.3 In Vivo Assays

3.2.3.1 The Rodent Micronucleus Assay

The micronucleus assay (Matter and Schmid, 1971; Heddle, 1973; Schmid, 1975) is an *in vivo* test that detects structural (clastogenicity) or numerical (aneuploidy) chromosomal damage that arises from acentric chromosomal fragments or lagging whole chromosome(s) that fail to incorporate into daughter nuclei after nuclear division in proliferating somatic cells. MN are well-characterized biomarkers of genetic damage that are commonly evaluated in lymphocytes and erythrocytes due to the ease of obtaining blood samples. The target cell in the bone-marrow micronucleus test is the developing erythroblast. During the formation of enucleated erythrocytes, at the final cell division of the erythroblast, the nuclear contents fragment in a process termed karyorrhexis, in a process similar to apoptosis (Hristoskova, 2004). The fragments are collectively expelled from the cell, contained in a plasma membrane. This is an efficient process, but occasionally some material is left behind in the immature erythrocyte. In haematology, these fragments are termed Howell-Jolly bodies, and constitute at least a part of the background frequency of MN seen in cells from untreated animals (the other component arising from spontaneous structural and numerical chromosomal aberrations).

The rodent *in vivo* micronucleus assay, using either bone marrow or peripheral blood, is often the default assay for regulatory genetic toxicology assessment *in vivo*. The test methodology, which is described in detail in **Cytogenetics** and **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**, should be conducted in accordance with the general principles of current national and international regulatory guidelines (OECD, 1997c; ICH S2A: Specific Aspects of Regulatory Genotoxicity Tests for Pharmaceuticals, 1996; ICH S2B: A Standard Battery for Genotoxicity Testing of Pharmaceuticals, 1997; Richold *et al*., 1990).

Experience has shown that the assay has proved useful for the detection of agents that induce chromosomal damage as:

- the end point is easy to score,
- it provides good statistical power as many cells can be scored for the presence of MN, and
- there is evidence that chromosomal breakage always leads to micronucleus formation; thus, if the micronucleus test is negative (and the compound and/or its metabolites can be shown to reach the bone marrow), chromosomal aberrations in this tissue can be ruled out.

The converse, however, is not always true, since indirect physiological mechanisms, for example the stimulation of haematopoiesis or decreases in core body temperature, can also result in small increases in micronucleus frequency in the bone marrow, above control values, and these may sometimes account for a positive micronucleus assay. Thus it is important to exclude the possibility of nonrelevant mechanisms which do not indicate genotoxic hazard when considering whether or not a test agent has induced chromosomal breakage, or indeed whether or not the micronucleus assay is the most appropriate end point for assessment (Tweats *et al*., 2007).

Nevertheless, the rodent bone marrow micronucleus test is perceived as having relatively high specificity for the detection of genotoxic carcinogens; that is, false positives are apparently rare, although the sensitivity is only considered moderate, in that not all genotoxic agents or genotoxic metabolites necessarily reach the bone marrow in sufficient quantities to produce a detectable genotoxic response. Thus, with the regulatory genotoxicity test batteries currently in use, the results of *in vivo* genotoxicity tests play a vital role in risk and hazard assessments. Increases in micronucleated bone-marrow cells are given great regulatory weight, indicating that the test compound is likely to be a genotoxic carcinogen.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.2.3.2 *Unscheduled DNA Synthesis Assay*

The unscheduled DNA synthesis (UDS) assay, using primary rat hepatocytes, was first developed by Professor G. Williams (1976; 1977), and the method provides a means of assessing test-agent-induced nuclear DNA excision repair, as determined by the amount of radiolabelled (usually tritium) thymidine incorporated into the nuclei of cells that are not in S-phase (Rasmussen and Painter, 1966). Thus, the UDS assay provides indirect evidence of the DNA-damaging ability of a test agent, as it is assumed that the induction of DNA repair would have been preceded by DNA damage. The UDS assay can be performed either *in vitro* or *in vivo/in vitro*; however, the UDS assay does not, in itself, indicate if a test agent is mutagenic, because it provides no information regarding the fidelity of DNA repair, nor does it identify DNA lesions repaired by mechanisms other than DNA excision repair (see Section 2.3 on DNA repair).

In July 1997, the OECD guideline for the *in vivo* UDS assay was ratified (OECD, 1997d). The UDS assay is usually conducted using rats, although other species may be used if justified. OECD methodology recommends that two dose levels are selected on the basis of preliminary toxicity testing, with the highest dose defined as the maximum tolerated dose (MTD). At least three animals per group (typically males only) are administered the test agent (generally once, by gavage), and each assay generally consists of three test-article doses, one vehicle control and one positive control. According to the OECD guideline, two sampling times should be used. For the early (2–4 hours) sampling time only one positive control (*N*-nitrosodimethylamine, (NDMA)) is recommended. The second group of animals is sacrificed 12–16 hours after treatment. The liver is generally used for analysis because, under normal circumstances, there is a low proportion of hepatocytes in S-phase, although theoretically, any tissue with a low proportion of replicating cells may be used. The liver is also the site of first-pass metabolism for chemicals administered orally or by intraperitoneal injection, although the latter is not a recommended route of exposure in the UDS assay because it could potentially expose the liver directly to the chemical.

Cultures of hepatocytes are prepared and incubated in medium containing tritiated thymidine (for ~18 hours) and slides are prepared and processed for autoradiography using standard techniques (Butterworth *et al*., 1987; Kennelly *et al*., 1993). At least 100 cells per animal are examined, and both nuclear and cytoplasmic grains should be counted to determine the net nuclear grain count (i.e. cytoplasmic grains subtracted from nuclear grains). Chemicals inducing a significant increase in mean net nuclear grain count for at least one treatment group are considered to have induced UDS and are therefore deemed positive (**Figure 11**). Additional recommendations for the performance of UDS assay *in vitro* and *in vivo* are reviewed by Madle *et al*. (1994). Although the *in vivo* UDS assay protocol takes into account the pharmacokinetic and pharmacodynamic properties of a test agent when assessing its genotoxicity, contemporary regulatory experience suggests that the UDS assay is relatively insensitive to all but the most potent genotoxins (Kirkland and Speit, 2008). As such, the rat-liver UDS assay has all but fallen from favour in recent times and is no longer considered the default second *in vivo* assay in the context of most modern regulatory genotoxicity testing regimens. Nevertheless, the UDS assay may still be useful as a follow-up assay to investigate putative genotoxic agents that require metabolic activation as the liver is the target organ.

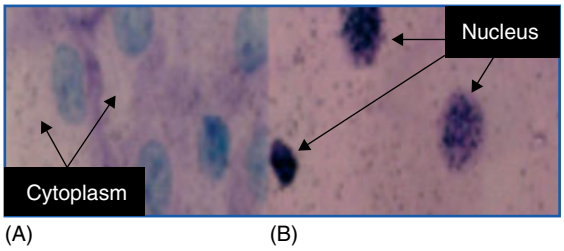

Figure 11 Unscheduled DNA synthesis assay. (A) Control liver; (B) treated liver (note significant net grain counts present in nucleus).

3.2.3.3 *Comet Assay*

The Comet assay (also known as the single cell gel electrophoresis assay) is a simple, rapid and sensitive technique for measuring and analysing DNA strand breakage within individual mammalian cells. The methodology, originally developed by Ostling and Johanson (1984) and modified by Singh *et al*. (1998), combines the simplicity of biochemical techniques for detecting DNA single-strand breaks (strand breaks and incomplete excision repair sites), alkali-labile sites and DNA crosslinks, with the single-cell approach typical of cytogenetic assays, and can be applied to both *in vitro* and *in vivo* systems (recently reviewed by Collins, 2004; Collins *et al*., 2008b).

The Comet assay is based on the ability of negatively charged loops/fragments of DNA to be drawn through an agarose gel in response to an electric field. The degree of DNA migration can be correlated to the extent of DNA damage induced within the cells (Olive *et al*., 1990). The profile of the cells and the degree of DNA migration may be scored on a photomicrograph or captured and examined using an image analysis system. The resulting images look like a 'comet', with a distinct head, comprised of intact DNA, and a tail, consisting of damaged or broken pieces of DNA; hence the name Comet assay (**Figure 12**). The use of alkaline conditions of pH >13 enables alkaline-labile sites as

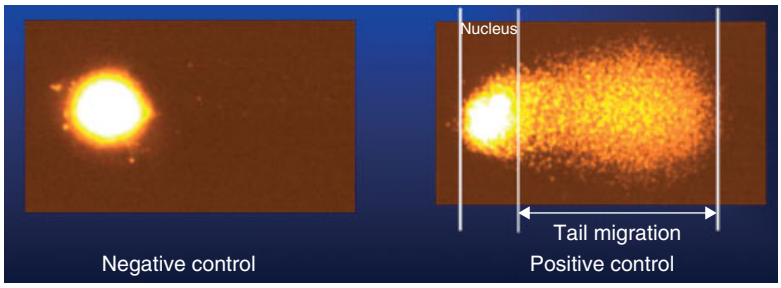

Figure 12 Comet assay. (A) Cell from control liver showing intact nucleus; (B) treated liver (note migration of DNA fragments to form comet tail).

well as single-strand and double-strand DNA breaks to be expressed during electrophoresis, thus increasing the sensitivity of the assay (Singh *et al*., 1998).

The main advantages of the Comet assay include: (i) the collection of data at the level of the individual cell, allowing more robust statistical analyses; (ii) the need for only a small number of cells per sample; (iii) sensitivity for detecting DNA damage; and (iv) use of any eukaryote single cell population both *in vitro* and *in vivo*, including cells obtained from exposed human populations and aquatic organisms for ecogenotoxicological studies and environmental monitoring (Collins *et al*., 2001; Dixon *et al*., 2002; Jha, 2004). In combination with the fluorescence *in situ* hybridization techniques (Comet-FISH), the application of this assay has also been extended to determine sequence- or gene-specific damage and repair (McKenna *et al*., 2003), as well as being of possible diagnostic use (Kumaravel and Bristow, 2005). In addition, the assay is being used in translational research to assess whether tumour radio-sensitivity (Fisher *et al*., 2007) and chemo-sensitivity (Smith *et al*., 2007) can be determined. This would allow clinicians to tailor the management of individual patients, adjusting cancer therapy to those for whom it will be of most benefit and reducing the likelihood of patients receiving toxic, and as such, ineffective therapy (McKenna *et al*., 2008).

The Comet assay has demonstrated potential as a powerful tool for assessing chemically induced DNA strand breaks in a wide range of tissues (Sasaki *et al*., 2000). In this capacity, the method has distinct advantages over conventional *in vivo* mutagenicity tests, such as the rodent bone marrow micronucleus test or the liver UDS test. For example, the Comet assay is recommended by the UK COM as an appropriate test for assessing the genotoxic potential of short-lived reactive mutagens at their site of contact or as a supplementary *in vivo* test for investigation of genotoxicity in tissues other than the bone marrow (COM, 2000). In these circumstances, the bone marrow or liver may not be the first tissue exposed to the test article or may not be the target for a particular test agent. As such, the Comet assay provides an important alternative for the identification of site-of-contact clastogens and/or for those compounds that act in organs other than the bone marrow or liver. Moreover, in a recent review of appropriate follow-up testing *in vivo*, Kirkland and Speit (2008) reported that the Comet assay detected almost 90% of bone marrow micronucleus test-negative or equivocal carcinogens and concluded that the Comet assay should play a more prominent role in regulatory testing strategies than the UDS test.

At present there are no OECD guidelines available for the Comet assay and the use of the *in vivo* Comet assay for evaluation of genetic toxicity within a regulatory framework is still under evaluation, although an international interlaboratory ring trial is underway to develop a validated assay for OECD ratification under the auspices of JaCVAM (Japanese Center for the validation of alternative methods). Moreover, recent revisions of international regulatory guidances such as ICH2 for pharmaceuticals (see below) have recommended the Comet assay as alternative to the UDS assay as a follow up second *in vivo* assay to the rodent bone marrow micronucleus test. Protocols that have been designed in accordance with the recommendations of the IWGTP *in vivo* Comet assay workgroup should be adopted (Tice *et al*., 2000; Burlinson *et al*., 2007) and detailed protocols may be found in the literature (Fielder *et al*., 1993; Lovell *et al*., 1999; Hartmann *et al*., 2003; 2004) or on the Comet assay web site (*www.cometassay.com*).

3.2.3.3.1 The Comet Assay: Practical Aspects

In the *in vivo* Comet assay, a minimum of three animals per group (typically males only) are administered the test agent, generally once, by gavage, although multiple-dosing regimens, usually 24 hours apart, can be used if justified. In the author's laboratory, the *in vivo* Comet assay is usually conducted in rats, although other species, such as mouse, have been used on occasion. The degree of DNA damage within specific tissues or cells may be investigated in any tissue or organ from which single-cell suspensions can be prepared. Typically these are the liver, stomach, bone marrow and peripheral blood lymphocytes. The tissues are usually sampled 2–6 and 16–26 hours after the last dose, but when the protocol involves multiple dosing only the 2–6 hour sample

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is required. Briefly, cell suspensions are embedded in agarose gel on glass microscope slides and treated with a combination of detergent and high-salt solution to rupture the cell membranes and cause cell lyses, extract the nuclear proteins and leave the supercoiled DNA in a nucleus-type structure, called the nucleoid. Subsequently, the supercoiled DNA is left to relax and 'unwind' in a strongly alkaline buffer. As DNA carries a net negative charge, the nonsupercoiled loops and single-strand fragments migrate towards the anode on electrophoresis whilst DNA strand breaks result in further migration into the gel. A discussion on electrophoresis conditions may be found in the review by Collins *et al*. (2008b). Following electrophoresis, the DNA is neutralized and stained using a nucleic acid-specific dye, such as propidium iodide. In the author's laboratory, the cells are visualized and quantitated using fluorescence microscopy linked to an image analysis system.

The extent of DNA migration maybe scored in three ways (manually or using customized imaging software):

- **Tail length:** defined as a measurement from the point of greatest intensity within the comet head, to the end of the fluorescing tail.
- **Tail % intensity (% tail DNA):** defined as the percentage of the total DNA present within in the comet tail.
- **Tail moment:** defined as the product of the tail length and the fraction of total DNA present within the comet tail (i.e. % tail DNA).

According to Collins *et al*. (2008b), % tail DNA covers the widest range of damage and is linearly related to break frequency across most of the range (based on calibration experiments with X-ray or gamma irradiation where ~0.2–10 Gy equivalents roughly produce 0.06–3 breaks per 10^9 daltons (i.e. one hundred to several thousand breaks per human cell). Therefore, tail intensity is recommended as the parameter of choice.

3.2.3.3.2 Cytotoxicity Assessment

It has been well recognized that comet images resulting from excessively damaged cells, that is those that are necrotic or apoptotic, are characterized by small or nonexistent heads and large diffuse tails; these are sometimes referred to as 'ghost' comets (Fairbairn *et al*., 1995). Cell death is associated with increased levels of DNA strand breaks, and therefore high levels of cytotoxicity can confound the interpretation of the Comet assay. In the author's laboratory, therefore, sections of tissue are reserved for the histopathological examination of necrosis and apoptosis. These are analysed only when a test article is considered positive in the Comet assay in order to exclude any potentially confounding cytotoxic doses that may affect interpretation of the data. Further information regarding viability is discussed by Collins *et al*. (2008b).

3.2.3.4 Transgenic Mutation Assays

Several transgenic rodent (TGR) (mouse and rat) mutation assays have been developed during the past two decades to study mutagenesis *in vivo*. A comprehensive review of transgenic rodent gene mutation (Tg-GM) assays and their potential use in a regulatory context has recently been published by Lambert *et al*. (2005). Notes on guidance for routine testing have also been defined by the IWGTP and are described by Thybaud *et al*. (2003). The performance of Tg-GM assays with respect to predicting rodent carcinogens has recently been reviewed (Kirkland and Speit, 2008) and these authors concluded that Tg-GM assays should play a more prominent role in regulatory testing strategies as appropriate follow-up testing *in vivo*.

3.2.3.4.1 The Development of Transgenic Rodent Gene Mutation (Tg-GM) Assays

Compared to existing regulatory assays for measuring *in vivo* genotoxicity, which are generally limited to bone marrow, peripheral blood and liver, Tg-GM assays provide a significant advance in our ability to rapidly assess spontaneous and test-agent-induced mutations *in vivo* in virtually any tissue or organ, and they allow comparative studies between them. Tg-GM assays close the 'gene mutation–chromosome aberration' paradigm *in vivo*, and furthermore, these assays provide a relatively simple means to analyse mutations at the molecular level. This can supply mechanistic information about mutagens; for example, in cases where a chemical agent causes only a marginal increase in mutation frequency, a unique mutation spectrum may determine whether the agent is positive or negative. Investigations using repeat doses may provide data with immediate relevance to carcinogenicity bioassays, and, moreover, they may also provide a novel opportunity for studying the effects of nongenotoxic carcinogens on endogenous mutation induction in target tumour tissues. Finally, they may improve on current methods for the assessment of heritable damage in germ cells (historically determined by the specific-locus and dominant lethal (DL) tests) and, therefore, they have the potential for reducing animal usage.

All of the available Tg-GM animal models have been genetically engineered on the common principle of using specific prokaryotic 'reporter' genes stably inserted into the host animal genome. These transgenes can be easily recovered from target tissues, using various shuttle vector technologies or gene capture, and analysed for mutations in suitable bacterial assays. The prokaryotic transgenes are not transcribed and are nonpathogenic to the host animal. A general outline of the steps involved in mutation analysis in Tg-GM assays is shown in **Figure 13**.

3.2.3.4.2 Mouse Models and Reporter Transgenes

The following section describes the animal strains, the reporter transgenes and basis for mutation detection used in the various TGR models developed for gene mutation

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

analysis *in vivo* to date. Two Tg-GM animal models (Muta™Mouse and BigBlue®) are sold commercially, however, only Muta™Mouse is currently available in the UK. As with any other rapidly changing scientific endeavour, it is likely that new 'second generation' Tg-GM models will be proposed and developed in the future, for example through crossing separate transgenic strains to yield 'double transgenic' animals.

3.2.3.4.3 Muta™ Mouse

Originally described by Gossen *et al.* (1989), this was the first transgenic strain developed for the analysis of gene mutations *in vivo*. This system features genomic integration of a bacteriophage λ shuttle vector containing the bacterial *lacZ* gene. The λgt10-*lacZ* shuttle vector is approximately 47 kb in length and is flanked by *cos* sites. Within the Muta™Mouse genome, the λgt10-*lacZ* shuttle vector resides as a concatamer of approximately 40 copies (Blakey *et al.*, 1995), which is located on chromosome 3 (Swiger *et al.*, 1994). After isolation of genomic DNA from the transgenic organs/tissue of interest, the λ genomes are excised by, and packaged with, a bacteriophage λ packaging extract. The resulting phage particles are then used to transfect a lacZ $^{(del)}$ *E. coli* strain in the presence of X-gal. This produces blue plaques on a bacterial lawn for phage with wild-type *lacZ* and clear plaques for mutant *lacZ* following overnight incubation. In addition, the exact sequence alteration in the *lacZ* transgene can be determined by DNA sequencing.

This system has been improved significantly by using a selection assay in lieu of colour screening. This makes it possible to assay large numbers of phage particles, whereby only mutant particles form plaques (Dean and Myhr, 1994). This is based on the ability of LacZ to metabolize phenyl-β,D-galactoside (P-gal) into galactose. In *gal E* host cells (carrying a plasmid containing the *gal T* and *gal K* genes), this accumulates as UDP-galactose, which is toxic to the cells. However, phage particles with mutant *lacZ* are able to transfect the bacterial host cells and form plaques.

The genotoxic carcinogen, B(a)P has been shown to induce gene mutations in various organs (forestomach, spleen, colon and glandular stomach) in Muta™Mouse when given orally at doses of 75 and 125 mg kg^{-1} body weight day^{-1} for five consecutive days (Hakura *et al.*, 2000). These B(a)P doses were also shown to be carcinogenic in Muta™Mouse (Hakura *et al.*, 1998).

3.2.3.4.4 BigBlue®

First described by Kohler *et al.* (1991), this model utilizes the bacterial *lacI* gene integrated into a bacteriophage λ shuttle vector, as a target reporter gene. The construct is present in approximately 40 copies per cell genome, integrated at a single locus in a head-to-tail arrangement. The B6 C3F1 mouse strain was the first to be engineered, that is, the same genetic background as used in the National Toxicology Program. In addition, a transgenic BigBlue® rat and rat cell line have been constructed (Dycaico *et al.*, 1994).

After isolation of genomic DNA from a tissue, the λ genomes are excised by, and packaged with, a bacteriophage λ packaging extract. When used to transfect *E. coli lacZ* bacteria grown on X-gal LB-plates, phage particles with a wild-type *lacI* gene will produce a clear bacteriophage plaque, while those that have sustained a mutation in the *lacI* gene will produce a blue plaque. The ratio of blue plaques to clear plaques determines the MF. In addition to the determination of mutant frequencies, the exact sequence alteration can be determined by DNA sequencing.

A BigBlue® hemizygous p53$^{+/-}$ double transgenic mouse strain is available (Taconic, Germantown, NY) which permits the analysis of gene mutations in a short-term cancer model.

3.2.3.4.5 Gpt-Δ

First described by Nohmi *et al.* (1996), this assay is useful for the simultaneous detection of point mutations and deletion mutations. This system uses a bacteriophage λ EG10 construct with integrated plasmid pYG144. The plasmid has the *E. coli gpt* gene flanked by two loxP sequences. When the rescued phages are transfected into *E. coli* YG6020 expressing Cre recombinase, the phage DNA is converted into plasmid pYG142 carrying the chloramphenicol resistance gene and the *gpt* gene, which is sensitive to point mutations. The *gpt* mutants can be positively detected as colonies when grown on plates containing chloramphenicol and 6-thioguanine (6-TG). The EG10 DNA carries a Chi site along with *red* and *gam* genes, so that wild-type phages display Spi+ (sensitive to P2 interference) phenotype. Mutant phages lacking both the *red* and *gam* genes (i.e. Spi−), can be positively selected as plaques that grow in P2 lysogens of *E. coli*, such as XL1 Blue MRA (P2) cells.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.2.3.4.6 SupF

A transgenic model carrying the *supF* amber suppressor tyrosine tRNA gene as a reporter was developed by Leach *et al*. (1996). The *supF* gene was selected because the tRNA gene offers a target sensitive to mutations at almost every base pair, it has a short coding sequence (85 bases) which makes it highly amenable to DNA sequencing, and there is an extensive *supF* mutagenesis database. To control for locus-specific effects, three independently derived transgenic strains were created, each containing approximately 80–100 copies of the *supF* gene per cell genome integrated in a head-to-tail arrangement at different loci.

After isolation of genomic DNA from a tissue, the λ supF genomes are excised and packaged into phage. These are used to infect *E. coli* C1a lacZ125 (am) cells grown on X-gal plates. Phage particles with a wild-type *supF* gene produce blue plaques, while those with a mutation in the *supF* gene will produce clear plaques. Mutation frequency is determined by the ratio of clear plaques to blue plaques. Detection is possible because mutants in the *supF* gene do not suppress amber mutations in the *lacZ* gene in the host cell. Again, the exact DNA sequence alteration can be determined by DNA sequencing.

3.2.3.4.7 λ cII

The use of the bacteriophage lambda cII gene as a mutational target in transgenic animals was first described by Jakubczak *et al*. (1996). This system uses the *cII* gene in a forward, positive-selection system and can be used with all transgenic systems based on the integration of bacteriophage λ, for example BigBlue® (Papp-Szabó *et al*., 2003) and Muta™Mouse (Smith *et al*., 1999).

The cII protein induces the expression of the *cI* and the integrase genes. The products of these genes are required for integration of the λ DNA into the bacterial genome, and this results in lysogeny. A mutation in the *cII* gene results in growth of λ particles and lysis of the cell. The cII gene is only 294 base pairs long and provides a convenient target for analysis of mutations by DNA sequencing.

3.2.3.4.8 LacZ Plasmid Assay

The development of a lacZ plasmid-based transgenic mouse model, which uses gene capture to rescue the reporter transgene, has been reported by Boerrigter *et al*. (1995).

Isolated genomic DNA from transgenic tissue is digested with *Hin*dIII restriction enzyme to release the pUR288 plasmid. The vector is purified and enriched by gene capture using LacI repressor magnetic beads, and the plasmids are circularized by T4-ligation. Competent $lacZ^{(del)}$ bacteria are transformed by electroporation, and lacZ mutants are grown using a positive-selection assay similar to that used in the Muta™Mouse assay. Mutant clones can be picked to make plasmid preparations and further characterized by Southern analysis following electrophoresis, or by sequencing the *lacZ* gene. Analysis of spontaneous and X-ray (5×0.5 Gy)-induced mutant *lacZ* genes showed that 40–50% of all mutations were caused by large deletions. The possibility of detecting a broad spectrum of mutations in the lacZ plasmid-based transgenic mouse is an obvious advantage for studying *in vivo* mutagenesis.

3.2.3.5 Performance of Tg-GM Assays and Regulatory Use

Bacteriophage-based Tg-GM assays such as Muta™ Mouse and BigBlue® have been shown to yield very low responses to clastogenic (chromosome-breaking) agents such as methyl methane sulfonate (MMS) and mitomycin-C, which predominantly induce large deletions in DNA, and there is concern that Tg-GM assays may be insensitive to the detection of such mutations (Suzuki *et al*., 1993; 1997; Lynch *et al*., 2008a). This is most likely due to the fact that phage particles are unable to package vectors less than 40 kb or greater than 52 kb in size (Gossen *et al*., 1995) and therefore vectors containing DNA deletions of 5–10 kb or more cannot be rescued from genomic DNA. Thus, if the majority of DNA lesions induced by a test article are a result of large DNA deletions (i.e. >10 kb), then it is unlikely that they would be detected in any Tg-GM assay.

3.2.3.6 Other In Vivo Mutation Tests

Insect tests, such as those in the fruit fly *Drosophila melanogaster*, for example the sex-linked recessive lethal test and the somatic mutation and recombination test (SMART) assays which include (i) the wing mosaic system and (ii) white eye/white-coral eye mosaic system (reviewed by Wurgler *et al*., 1984; de Mitchell and Combes, 1984) are no longer widely used in commercial genotoxicity testing. The same is true for the majority of *in vivo* mammalian tests developed in the 1950s and 1960s such as the mouse somatic spot test (Russell and Major, 1957; Russell, 1984) and the mouse specific locus (SL) test (Russell, 1951; Carter *et al*., 1956; Russell *et al*., 1989), although the dominant lethal (DL) test (Bateman, 1966; Holmstrom *et al*., 1993) is still an option cited in some regulatory guidelines, for example ICH. The DL test has been recommended for use in a strategic sense, to determine whether a test agent which is genotoxic in somatic cells is also genotoxic in germ cells.

The rodent assays enjoyed popularity in the 1960–1980s and were included as part of the GENETOX program (see **Box 2**) of reports (*http://toxnet.nlm.nih.gov*), but they have fallen from favour in more recent times. This is mostly due to the large numbers of animals required and also the perceived lack of sensitivity of the end points measured. Although still of interest to the academic geneticist, they are no longer considered relevant to modern standard regulatory genotoxicity testing regimens and are not commercially

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

available. However, it is conceivable that a DL test could still be requested by a regulatory agency if there was sufficient concern regarding the potential for germ cell mutagenesis.

Box 2 The GENETOX program

The US Environmental Protection Agency's GENETOX program is a multiphased effort to review and evaluate the existing literature in assay systems available in the field of genetic toxicology. The first phase of the GENETOX program selected assay systems for evaluation, generated expert panel reviews of the data from the scientific literature and recommended testing protocols for the systems. Phase II established and evaluated the database of chemical genetic toxicity data for its relevance to identifying human health hazards. The ongoing phase III continues reviewing and updating chemical data in selected assay systems. Currently, data exist on over 4000 chemicals in 27 assay systems. The review data are published in GENETOX, a toxicology data file of the National Library of Medicine's (NLM) Toxicology Data Network (TOXNET®). The review and analysis components of GENETOX comprise 45 published papers, and several others are in preparation.

3.2.3.7 Rodent Dominant Lethal Assay

A DL mutation is one occurring in a germ cell which does not cause dysfunction of the gamete, but which is lethal to the fertilized egg or developing embryo. Thus the DL effects cause embryonic or foetal death, and induction of a DL event after exposure to a test agent indicates that the substance has affected germinal tissue of the test species. DLs are generally accepted to be the result of chromosomal damage (structural and numerical anomalies) but gene mutations and toxic effects cannot be excluded.

Generally, rats or mice are used as the test species. Strains with low background dominant lethality, high pregnancy frequency and high implant numbers are recommended. Male animals are exposed to the test substance and mated to untreated virgin females. In a typical experiment, the number of males in each group is usually sufficient to provide between 30 and 50 pregnant females per mating interval. Concurrent positive (e.g. cyclophosphamide or ethyl methane sulfonate (EMS)) and negative (vehicle) control groups should be included. The various germ-cell stages can be tested separately by the use of sequential mating intervals. The females are sacrificed after an appropriate period of time and the contents of the uteri are examined to determine the numbers of implants and live and dead embryos.

The calculation of the DL effect is based on comparison of the live implants per female in the treated group to the live implants per female in the control group. The increase of dead implants per female in the treated group over the dead implants per female in the control group reflects the postimplantation loss. The postimplantation loss is calculated by determining the ratio of dead to total implants from the treated group compared to the ratio of dead to total implants from the control group. Preimplantation loss can be estimated on the basis of corpora lutea counts or by comparing the total implants per female in treated and control groups.

Several treatment schedules are available. The most widely used requires single administration of the test substance. Other treatment schedules, such as treatment on five consecutive days, may be used on a case-by-case basis if justified. Normally, three dose levels are used with the highest dose producing signs of toxicity (e.g. slightly reduced fertility and slightly reduced body weight) or limit dose ($2\,g\,kg^{-1}$) or limit of solubility.

Test performance: Individual males are mated sequentially at appropriate predetermined intervals to one or two virgin females. Females should be left with the males for at least the duration of one oestrus cycle or alternatively until mating has occurred as determined by the presence of sperm in the vagina or by the presence of a vaginal plug. The number of matings following treatment should be governed by the treatment schedule and should ensure that germ-cell maturation is adequately covered. Females should be sacrificed in the second half of pregnancy and uterine contents examined to determine the number of implants plus live and dead embryos. The ovaries may be examined to determine the number of corpora lutea.

Data reporting and analysis: Data should be tabulated to show the number of males, the number of pregnant females and the number of nonpregnant females. The results of each mating, including the identity of each male and female, should also be reported individually. For each female, the dose level and week of mating and the frequencies of live implants and of dead implants should be enumerated, with clear recording of early and late deaths. If preimplantation loss is estimated, it should be reported. Preimplantation loss can be calculated as the difference between the number of corpora lutea and the number of implants or as a reduction in the average number of implants per female in comparison with control matings.

Interpretation of results: There are several criteria for determining a positive result, one of which is a statistically significant dose-related increase in the number of DLs. Another criterion may be based upon detection of a reproducible and statistically significant positive response for at least one of the test points. A test substance which does not produce either a statistically significant

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

dose-related increase in the number of DLs or a statistically significant and reproducible positive response at any one of the test points is considered nonmutagenic in this system. Both biological and statistical significance should be considered together in the evaluation.

A positive DL assay suggests that under the test conditions the test substance may be genotoxic in the germ cells of the treated sex of the test species. A negative result suggests that under the conditions of the test the test substance may not be genotoxic in the germ cells of the treated sex of the test species.

Several other rodent assays are capable of monitoring germline mutation. These include traditional assays such as the morphological SL test and the heritable translocation (HT) assay, and more modern assays such as the expanded simple tandem repeat (ESTR) and TGR mutation assays have been developed. The performance of these assays has recently been reviewed by Singer *et al*. (2006).

3.2.4 Supplementary Tests

3.2.4.1 Gene Reporter Assays

The 'traditional' regulatory genetic toxicology assays described above have one particular attribute in common; they detect the end product of a genotoxic event (for example, a gene mutation, DNA fragmentation, chromosome aberrations, etc.). The advent of mature molecular biology technologies in the 1990s coupled with an increased understanding of DNA damage and repair has led to the development of assays which allows genetic toxicologists to detect the cells' molecular response to genotoxic stress, which may be applied as a surrogate biomarker for the traditional end points.

The importance of the cellular response to genotoxic stress is exemplified by the discovery of a number of proteins encoded by key oncogenes and tumour suppressor genes that are central to the mammalian response to DNA damage (see above). Some of these proteins, such as p53, BRCA1, c-MYC and AP-1, are transcription factors with well-established roles in the response to genotoxins and in human carcinogenesis. Monitoring the activity of these pivotal genes, via gene and/or protein expression or through the expression of the downstream genes they transactivate or repress has the potential to identify genotoxic carcinogens, and possibly even nongenotoxic carcinogens. By coupling promoter sequences from these pivotal genes to reporter gene technology such as chloramphenicol acetyltransferase (CAT), LacZ, LUC and Green Fluorescent protein (GFP) it is possible to monitor the cellular response to various genotoxic stresses (Bullock and Gorman, 2000; Gorman *et al*., 1982; An *et al*., 1982; Alam and Cook, 1990; Prasher *et al*., 1992; de Wet *et al*., 1987). The standard regulatory genotoxicity tests are designed to detect and quantify rare genetic events, whereas gene reporter assays monitor the response of the entire population of cells exposed to a genotoxic stress. Reporter gene assays are not expected to take the place of the current regulatory assays; rather they complement them, allowing the genetic toxicologist to better understand the data they obtain from the regulatory assays (Todd *et al*., 1995; Walmsley, 2005; Hastwell *et al*., 2006). A key advantage of the reporter gene assays is the opportunity for these tests to be deployed early in new chemical entity development where the amount of compound is limited, and/or a large number of compounds are to be screened. (For a more detailed review of reporter genes the reader is directed to Alam and Cook, 2003).

3.2.4.1.1 Xenometrix CAT-Tox (L) assay

The CAT-Tox (L) assay consists of 14 recombinant cell lines derived from the human hepatoma cell line, HepG2, each stably transfected with a unique stress response gene promoter or synthesized consensus response element (**Table 9**) fused to the *CAT* reporter gene (Todd *et al*., 1995). Each of the 14 lines has been derived from genes that respond to a variety of cellular injuries whereas the parental cell line, HepG2, is included for the measurement of cytotoxicity. The CAT-Tox (L) assay provides a molecular profile of cellular stress and toxicity by measuring the activity of the 14 stress gene promoter–*CAT* fusions, and uses a 2×96-well microplate format which requires only milligram quantities of test compound; generally five concentrations are tested and results are available within 24–48 hours. Using the CAT ELISA system the fold induction of each of the *CAT* fusions maybe described as a three-dimensional histogram, a 'XenoMatrix'. Todd *et al*. (1995) have shown that the CAT-Tox (L) assay is able to detect subtle differences in mechanisms of action among closely related compounds.

3.2.4.1.2 The Yeast GreenScreen® GC (Genotoxicity-Cytotoxicity) Biosensor

Central to the GreenScreen® GC biosensor assay (Gentronix Ltd., Manchester, UK) is a RAD54-yEGFP DNA damage response reporter. This reporter utilizes the promoter of the yeast *S. cerevisiae* DNA-damage inducible gene *RAD54* to drive the production of the yEGFP (yeast enhanced GFP) reporter (Walmsley *et al*., 1997). The response to DNA damage and the induction of the *RAD54* promoter in yeast is well characterized (Tan *et al*., 1999). *RAD54* encodes a structural element of the HR repair pathway and is transcriptionally up-regulated in response to a broad spectrum of genotoxins. This assay has been designed as a high-throughput assay based on a 96-well plate format which requires only milligram amounts of compound, and results are available within ~16–20 hours (Cahill *et al*., 2004). Extensive validation studies demonstrate that the GreenScreen® GC assay exhibits high specificity (i.e. compounds with positive results are

Table 9 Stress gene promoter–*CAT* fusion constructs used in the CAT-Tox (L) assay

Promoter–fusion constructs	Endogenous gene product	Function
CYP1A1	Cytochrome P450 IA1	Phase I biotransformation enzyme
GST Ya	Glutathione *S*-transferase *Ya* subunit	Phase II biotransformation enzyme
HMTIIA	Metallothionein IIA	Sequestration of heavy metals
FOS	*c-fos*	Member of *AP-1* transcription factor complex
XHF	Collagenase	Inflammatory mediator
HSP70	70 kDa heat shock protein	Helps to refold or sequester damaged proteins (protein chaperone)
GADD153	153 kDa growth arrest and DNA damage protein	Involved in cell cycle regulation and response to genotoxic agents
GADD45	45 kDa growth arrest and DNA damage protein	Involved in cell cycle regulation and response to genotoxic agents
GRP78	78 kDa glucose-regulated protein	Endoplasmic reticulum protein chaperone and also responds to DNA damage and calcium ionophores
Response element–fusion construct	**Name**	**Function**
XRE	Xenobiotic response element	Binding site for Ah receptor–planar aromatic hydrocarbon complexes
NF-κB-RE	NF-κB response element	Binding site for NF-κB transcription factor (oxidative stress)
CRE	cAMP response element	Binding site for CREB protein
p53RE	53 kDa protein tumour suppressor response element	Binding site for p53 transcription factor (DNA damaging agents)
RA-RE	Retinoic acid response element	Binding site for retinoic acid–retinoic acid receptor complexes

Adapted from Todd *et al*. (1995).

very likely to be genotoxic carcinogens), but relatively low sensitivity (Cahill *et al*., 2004; Van Gompel *et al*., 2005; Knight *et al*., 2007). This most likely reflects the differences between yeast and mammalian cells with regard to the cellular responses to genotoxic stress, and where in yeast the HR repair pathway is not induced in response to certain genotoxic events, such as aneuploidy. However, the GreenScreen® GC assay does cover a number of eukaryotic targets not present in bacterial cells (chromatin and DNA-metabolizing enzymes acting on chromatin, etc.), and therefore identifies some compounds missed by the Ames test. Knight *et al*. (2007) suggest that as part of early screening, a test battery of the Ames test ± S9 metabolic activation and a GreenScreen® GC assay would provide a firm basis to prioritize compounds

Table 10 Results of the standard genotoxicity assays for eight known rodent carcinogens that cause protein and DNA adducts

Compound	Adduct	Ames	*In vitro* mammalian tests		*In vivo* mammalian assay	
			Mouse lymphoma	Chromosome aberrations	Micronucleus	Chromosome aberrations
Butadiene	Hb/DNA	+	−	+	+	+
Vinyl chloride	DNA	+		+	+	
Aflatoxin	Hb/DNA	+	+	+		+
Benzo[a]pyrene	Hb/Alb/DNA	+	+	+	+	+
4-Aminobiphenyl	Hb/Alb/DNA	+		+	+	
Ethylene oxide	Hb/DNA	+				
NNK	Hb	+		+	+	

Hb—haemoglobin; Alb—albumin; NNK—*N*′-nitrosonornicotine and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone.

for development, reducing the number of hazardous compounds proceeding to regulatory genotoxicity assays, including animal tests, while not producing misleading positive results which can lead to the rejection of valuable compounds.

3.2.4.1.3 The Mammalian GreenScreen® HC (Human Cell) Biosensor

In the GreenScreen® HC assay (Gentronix, Manchester, UK), like the GreenScreen® GC assay, a DNA damage response promoter is used to drive the transcription of a reporter gene. Due to the more complex gene expression regulation in higher eukaryotes, however, a number of cis-acting regulatory elements have also been utilized in the construction of the biosensor (Hastwell *et al*., 2006). The GreenScreen® HC assay uses the transcriptional response of the of the human *GADD45a* gene in the human lymphoblastoid cell line TK6. *GADD45a*, the first gene to be identified as a target of p53 (Kastan *et al*., 1992), plays a fundamental role in maintaining genomic stability following genotoxic stress, with roles in cell cycle regulation and DNA repair, and emerging roles in apoptosis (Gao and Richardson, 2001; Zhan, 2005). Exposure of the modified TK6 cells to a genotoxin induces the *GADD45* promoter and expression of *GFP* reporter; thus cells fluoresce green when subjected to genotoxic stress. The GreenScreen® HC assay is also based on a 96-well plate format and requires milligram amounts of compound; data are available within 48 hours. Validation studies have shown that the GreenScreen® HC assay has both high sensitivity and specificity for genotoxic carcinogens, and unlike other *in vitro* mammalian genotoxicity assays, is not prone to false-positive prediction of *in vivo* genotoxicity/genotoxic carcinogenicity (see below). The assay has been transferred to several laboratories, and has been shown to be robust and reproducible (Billinton *et al*., 2008). An adaptation to the GreenScreen® HC assay that uses flow cytometry and allows for the inclusion of S9-mix has recently been described (Jagger *et al*., 2009).

3.2.4.2 DNA and Protein Adducts

Various analytical methods have been used to investigate the mechanism of carcinogen activation and monitor human exposure to environmental carcinogens, since carcinogen-adduct measurement provides a integrated biomarker of carcinogen intake, metabolic activation and delivery to the target macromolecule in target tissues. Protein adducts are not repaired and are considered primarily as exposure monitors, but DNA adducts may give further information about the mutagenic significance of the exposure. Indeed, such DNA damage is recognized as an early event in the carcinogenic process. As such these techniques have been used for measuring environmental, occupational and dietary exposures to a variety of genotoxic compounds in human populations (reviewed by Wild and Pisani, 1998; Sharma and Farmer, 2004; Farmer *et al*., 2005). Occasionally, these assays are used as supplementary tests to the standard genotoxicity battery to help elucidate whether a test agent is a DNA-reactive genotoxin or not. **Table 10** lists several compounds that require metabolism to various reactive intermediates and are positive in the standard battery of genetic toxicology assays, which covalently bind to proteins and/or DNA to form adducts.

3.2.4.2.1 ^{32}P-postlabelling Assay

The ^{32}P-postlabelling assay is one of the most common methods used for the detection of DNA adducts. Nuclear DNA from cells treated in culture *in vitro* or from target organs and tissues from exposed animals or individuals may be analysed. The procedure involves the enzymic digestion of DNA to 3′-mononucleotides and labelling with T4 polynucleotide kinase using (γ-^{32}P)ATP followed by chromatographic separation of the labelled adducts, usually by two-dimensional TLC (**Figure 14**) but the use of high-pressure liquid chromatography and mass spectroscopy have also been reported (reviewed by Sharma and Farmer, 2004). The limits of sensitivity of the standard ^{32}P-postlabelling assay range from 1 adduct in 10^8 to 1 in 10^9 nucleotides (i.e. 2–3 orders of magnitude higher than reported background mutation frequencies). The sensitivity of the assay may be increased to 1 adduct in 10^{10} or 10^{11} nucleotides by adduct enrichment techniques, which

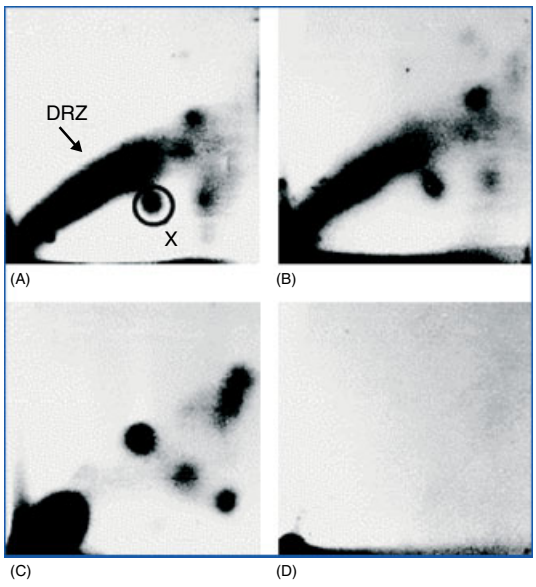

Figure 14 ^{32}P-postlabelling assay. Autoradiograms of ^{32}P-postlabelled human DNA isolated from the placenta of individuals environmentally exposed to benzo(a)pyrene (B(a)P): (A) human placenta with diagonal radioactive zone (DRZ), that is, where DNA adducts are not completely resolved by thin-layer chromatography. X signifies a major adduct; (B) human placenta; (C) B(a)P rat liver standard; (D) rat liver negative control.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074

remove normal nucleotides from the digest before ^{32}P-labelling (Phillips and Castegnaro, 1993). Enrichment is normally achieved using 1-butanol extraction or nuclease P1 digestion (which dephosphorylates normal nucleotides and prevents them from being substrates for T4 polynucleotide kinase and ^{32}P-phosphorylation). The choice of enrichment techniques, however, needs scientific justification and some prior knowledge of the type of adduct likely to be produced.

3.2.4.2.2 Interpretation of ^{32}P-postlabelling Assay Results

The reaction of chemical carcinogens with DNA, either directly or after metabolic activation, typically involves covalent binding of an electrophilic carcinogen with a nucleophilic site in DNA. Guanine is by far the most prevalent target, although adducts have been reported for all bases (Farmer and Shuker, 1999). Thus the demonstration of DNA adducts in the ^{32}P-postlabelling assay suggests a direct (DNA-reactive) genotoxic mechanism. However, the DNA adduct levels in a particular cell type and/or tissue, measured at any point in time, will reflect specific rates of adduct formation and removal, which depend upon carcinogen activation, DNA repair, adduct instability and tissue turnover (Poirier *et al*., 2000).

The disadvantage of the ^{32}P-postlabelling assay is that the chemical identity of a particular adduct is not easily determined without the use of standards, which after post-labelling, can be compared with unknown lesions to help interpretation. In the absence of a chemical standard the interpretation of assay results may be complex, for example, with the investigation of a new chemical entity. This is because, without further characterization of the DNA adduct itself, one cannot be sure of the origin of the DNA adduct. Additional studies, for example the removal of the DNA adduct from TLC plate and mass spectroscopy analysis, or the use of a radioisotope-labelled standard, may be required to demonstrate that the adduct complex contains the chemical in question.

In contrast, the absence of DNA adducts in a ^{32}P-postlabelling assay may imply that the chemical in question is non-DNA reactive or simply not amenable to detection under the conditions of the assay. Many factors may impact the performance the assay, such as chemical instability, resistance to enzymic digestion or phosphorylation, poor recovery using standard enrichment techniques or inappropriate chromatography procedures. These, in turn, may influence assay sensitivity and reliability. All of these factors should be considered when the ^{32}P-postlabelling assay is used as a supplementary test for regulatory purposes.

3.2.4.2.3 Protein Adducts

Protein adduct formation is considered to be a valuable surrogate for DNA adduct formation, as many chemical carcinogens bind to both DNA and protein in blood with similar dose–response kinetics, and the levels of adduct formation are determined by external dose. Although there is no evidence to suggest that the formation of protein–carcinogen adducts is in any way associated with carcinogenesis, the presence of such adducts nevertheless demonstrates both exposure and activation. Indeed, the use of blood proteins as molecular dosimeters has distinct advantages over the use of DNA. Blood proteins (haemoglobin and albumin) are readily obtainable and relatively long lived. Haemoglobin has a lifetime of 120 days in humans whereas albumin has a biological half-life of ~45 days. Their metabolic activity is also very limited and they lack repair mechanisms to remove covalently bound adducts. Since protein adducts are not removed by active repair processes, chemically stable adducts of haemoglobin or serum albumin provide a more precise measure of dose integrated over the lifespan of the proteins in question (reviewed by Farmer *et al*., 2005). Furthermore, chronic exposure to carcinogens leads to accumulation of protein–carcinogen adducts, which in the case of 4-aminobiphenyl increase to plateau values 30-fold those seen after an acute dose. Adducts of other genotoxic carcinogens also reach steady state levels during chronic exposure, and these properties facilitate the detection of protein–carcinogen adducts following chronic exposure to low levels of carcinogen. These advantages have been exploited by several groups to evaluate human exposure to a variety of carcinogenic alkylating and arylating agents (Neumann, 1988). The application of mass spectrometry analysis for the detection of acid-labile (sulfinamide) protein adducts produced by carcinogenic aromatic amines has also been reported (Lynch *et al*., 1991; 1993). Using such analytical techniques, the lowest limits of sensitivity of protein adduct measurements can be below 1 pmol adduct per g protein.

3.2.4.2.4 Covalent Binding to DNA or Protein

Another method of measuring DNA and/or protein adducts is to use radioisotope-labelled compounds and measure covalent binding by liquid scintillation counting (Davies *et al*., 1995; Lynch *et al*., 1991). This is a well-established technique, but requires the specific chemical synthesis of radiolabelled molecules, usually with tritium or stable isotopes (such as ^{14}C or ^{17}N). The significance of low-level binding observed in these assays is often difficult to interpret since some low-level activity measured may not be due to covalent binding to DNA.

3.2.4.3 Alternatives to the Rodent Bioassay

3.2.4.3.1 SHE Cell Transformation Assay

The Syrian Hamster Embryo (SHE) cell transformation assay (SHE assay) is a short-term *in vitro* test that measures morphological cell transformation, a biological end point which is considered to model carcinogenicity in the two-year rodent bioassay (LeBoeuf *et al*., 1990; 1996). Uniquely, the SHE assay is capable of detecting both genotoxic and nongenotoxic rodent carcinogens (LeBoeuf *et al*., 1996) and has an impressive empirical

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

correlation (>80%) with predicting the outcome of the rodent bioassay (Myhr and Zhang, 2000; Mauthe *et al*., 2001). In recent years, this empirical correlation alone has promoted some regulatory agencies to request short-term carcinogenicity tests, and specifically *in vitro* cell transformation tests like the SHE assay, to aid in the risk assessment of *in vitro* genotoxicants (Bigger, 2003).

On closer inspection, however, the impressive empirical correlation figures appear to be based on data biased in terms of the ratio of rodent carcinogens to noncarcinogens tested in the SHE assay. Therefore many more noncarcinogens require testing to provide a more accurate assessment of performance of the SHE assay. In addition, and aside from the fact that evaluation of morphological cell transformation *in vitro* remains subjective, the intrinsic variability seen in the SHE assay and lack of repeat testing in the existing data set is also a cause for concern. Moreover, the effect of pharmacologically active agents, particularly at high *in vitro* test concentrations, in the complex mixture of embryological cells is unknown. Similarly, although the mechanism of tumour formation in an *in vivo* rodent assay can in some cases be understood with respect to the pharmacological activity of the compound, no similar mechanistic understanding exists for the SHE assay. On the contrary, it is not understood how chemicals that induce species/sex/tissue-specific tumours through well-studied mechanisms (such as peroxisome proliferation in liver tumours, or compounds that induce thyroid tumours through the proliferative effects resulting from increased thyroxine clearance) should be positive in the SHE transformation assay (Ashby, 1997). Thus, without a better understanding of the differences in the mechanisms of morphological transformation and rodent tumours, many consider it premature to use empirical correlation alone for making regulatory decisions (Farmer, 2002).

For these reasons the SHE assay is rarely used in the pharmaceutical industry as a regulatory tool for the assessment of carcinogenic potential. Nevertheless, the SHE cell assay has been positioned as a predictive tool for genotoxic and nongenotoxic rodent carcinogenicity, and is more typically employed by industries outside of the pharmaceutical industry, like environmental and consumer products, where testing in animals and/or the development of products that induce rodent tumours is unacceptable. For example, the SHE assay may be used to discriminate between rodent carcinogens and rodent noncarcinogens for certain classes of chemicals like aromatic amines where the SHE assay has been more predictive than the bacterial reverse mutation test (Kerckaert *et al*., 1998). Moreover the impact of REACH legislation in the EU and the imminent drafting of an OECD guideline for the SHE assay may lead to the resurgence of the SHE assay outside of the pharmaceutical industry. Further research, however, will be required to establish the relevance and reliability of the SHE assay and elucidate the mechanisms underpinning SHE cell morphological transformation if it is to be anything other than a 'black box' predictor of carcinogenicity (Harvey *et al*., 2005).

At present the SHE assay does not remove the need for either a traditional rodent carcinogenicity study or assessment in an alternative carcinogenicity model. The future of the SHE assay will be dependant on a number of factors, not least a formal validation study to establish its reliability to predict carcinogenicity. The establishment of official guidelines for the conduct of the assay would be a prerequisite prior to any industry validation. Ideally in the future cell transformation assays should attempt to use human cells rather than primary rodent tissue, to enable a more representative model of human carcinogenesis.

3.2.4.3.2 Short-Term Carcinogenicity Assays

The substantial cost (financial and high number of animals required) and duration (approximately 3.5 years to final report) of lifetime carcinogenicity studies, using the two-year rodent bioassay, has been the subject of extensive debate and concern, along with doubts about the assay's reliability (as results are frequently considered to be of questionable relevance for human safety). This led the scientific community to search for suitable, shorter term alternatives to the standard rodent bioassay in the 1990s. The aim was to develop assays in animal models which allowed more rapid investigations of potential carcinogenicity by reducing the latency period of tumour development, reducing animal numbers, cost, time and improving the interpretation of rodent cancer bioassay data.

Several mouse models were developed bearing genetic manipulations to reduce tumour latency for the assessment of carcinogenesis (**Table 11**). These included tumour suppressor gene knockout mouse models, for example $p53^{+/-}$ hemizygous (Harvey *et al*., 1993) and XPA null mice (de Vries *et al*., 1997), and mouse models transgenic for additional copies of specific (proto)oncogenes such as TgHras2 (Yamamoto *et al*., 1997), Tg.AC (*ras*) (Hansen *et al*., 1995) and OncoMouse® (*myc, ras* and *neu*) (Stewart *et al*., 1984). Four of the genetically modified models ($p53^{+/-}$, XPA null, TgHras2 and Tg.AC) were the subject of extensive multilaboratory validation studies which were conducted under the auspices of the International Life Sciences Institute (ILSI) (reviewed in detail in a special issue of *Toxicological Pathology* **30**, 2002). In contrast, OncoMouse® was the subject of extensive worldwide legal wrangling over patent rights in the 1990s (now resolved), which held up the scientific development of the model. In addition, the neonatal mouse model (ICH guideline) was also investigated as a potential alternative model in the ILSI trials along with the SHE assay.

Generally, these models reduce the duration of testing to approximately 26 weeks. Although the issues of biological significance and predictiveness are far from resolved, the performances of the four models used in the

Table 11 Mouse strains used in short term carcinogenicity bioassays

Mouse model	Genotype and phenotype	Reference
The $p53^{+/-}$ hemizygous mouse	C57BLK/N6 × FVB mouse background with one copy of the tumour suppressor gene *p53* 'knocked out'; an increased incidence of cancer	Harvey *et al*. (1993)
Tg.AC mouse	FVB/N mouse strain with four copies of an activated Harvey *ras* oncogene coupled to a zeta-globin promoter and an SV40 viral polyadenylation sequence with an increased incidence of skin cancer	Hansen *et al*. (1995)
Tg.Hras2 mouse	Hemizygous for multiple copies of the human *c-Ha-ras* gene with enhancer/promoter. Activated *ras* (following chemical insult) initiates expression of genes controlling cell proliferation	Yamamoto *et al*. (1997)
The $XPA^{-/-}$ (null) mouse	Deletion of both copies of the Xeroderma pigmentosum gene, a DNA repair defect with an increased incidence of skin cancer	de Vries *et al*. (1997)
OncoMouse®	Transgenic mouse carrying an activated *myc* oncogene under the control of the mouse mammary tumour virus promoter	Stewart *et al*. (1984)

ILSI trial have been reviewed by Pritchard *et al*. (2003). The $p53^{+/-}$, TgHras2 and Tg.AC models all showed good concordance with the rodent bioassay but all missed some human carcinogens when the models were used to examine 99 chemicals/drugs. When an alternative model was used in combination with the rat bioassay, no human carcinogens were missed.

Nowadays, regulatory authorities may suggest the use of one or more of these transgenic models when a positive *in vitro* genotoxicity assay is obtained. For example, in the pharmaceutical industry such an *in vitro* positive finding may result in an 'on hold' status of a drug's clinical development and may prevent repeat-dose clinical studies in man until it is resolved. A negative result in an alternative carcinogenicity test may be used to allay concerns and permit continued clinical development. The regulatory acceptance for these models, however, still varies somewhat between Europe and the USA. For example, European regulators do not support the use of alternative models by default but feel more science is required and that genotoxic compounds can be detected by many standard tests. The FDA on the other hand has suggested the use of different transgenic models depending on the nature of the initial positive result. For nongenotoxins Tg.AC or TgHras2 is suggested, for genotoxins the $p53^{+/-}$ mouse or mouse neonatal assay or a SHE assay is recommended. The alternative models are not without their limitations; for example, the TgHras2 model has a high background incidence of lung tumours, as well as a myopathy, which may limit its use in some cases. Standard rodent carcinogen bioassays (in the rat) are still required as there are more historical data on carcinogenic mechanism in rats and more compounds are positive in 'rat only' than in 'mouse only' studies. Because of this, the development of new murine models raises additional concerns, and limited experience with transgenic mice increases the risk of results of debatable human relevance, but which nonetheless imperil or delay regulatory approval. Nevertheless, regulatory pressure to use such models is increasing, and results are beginning to influence interpretative thinking.

3.2.4.4 *Photogenotoxicity Testing*

It is well known that solar UVR induces DNA damage (Cleaver and Crowley, 2002) and that UVR exposure is the major aetiological cause of skin cancer in humans (Melnikova and Ananthaswamy, 2005). It has also been known for many years that some molecules can absorb light that is either visible or UV and become photoactivated. This can lead to a number of biologically relevant toxicities, including allergy, irritation, genotoxicity and carcinogenicity, when applied to the skin directly or systemically (Gocke, 2001). For example, certain drug classes such as fluoroquinolone antibiotics and psoralens are known to enhance photocarcinogenesis in animal models (Gocke *et al*., 1998; Dunnick *et al*., 1991), and there is now good evidence that patients treated with PUVA (Psoralen plus UVA) have a small, but real increased risk of squamous cell carcinoma (Lim and Stern, 2005). In addition, some molecules may greatly enhance the carcinogenic effects of UVR. As such, photosafety testing has become a regulatory requirement for pharmaceutical or cosmetic (dermatological and sunscreen) products that absorb light or UVR between the wavelengths of 290 and 700 nm in the electromagnetic spectrum and are applied either topically, or locally, and/or reach the skin or eyes via systemic exposure.

In Europe, the conditions for the photosafety evaluation of pharmaceuticals and cosmetics are described by

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The European Medicines Agency (formerly the European Agency for the Evaluation of Medicinal products (EMEA)) Committee for Proprietary Medicinal Products (CPMP) 'Notes for Guidance on Photosafety Testing' or the 'Notes of Guidance of the EU Scientific Committee on Cosmetics and Non-Food Products (SCCNFP)', respectively. In the USA, the Federal Drug Administration (FDA) Centre for Drug Evaluation and research (CDER) guidances serve the same purpose (and cover both drugs and consumer products such as sun-screens). These guidance documents describe the strategy for evaluating the photosafety of products prior to review by regulatory authorities. In Europe, testing may include an assessment of acute phototoxicity (photoirritation) (Lasarow *et al*., 1992; Holzhutter, 1997), photoallergy, photogenotoxicity and photocarcinogenicity (for a review see Maurer, 1987).

In terms of photogenotoxicity testing, the main objective has been to make an assessment of the potential of a compound to turn into a photochemical carcinogen upon activation with UV or visible (solar-simulated) radiation. Several *in vitro* photogenotoxicity assays, such as the photo-Ames, photo-chromosome aberration and photo-Comet assays have been described in the literature and are based on standard 'dark' versions of *in vitro* regulatory assays used for genotoxicity assessment (for reviews see Meunier *et al*., 2002; Brendler-Schwaab *et al*., 2004, Kersten *et al*., 1999). In contrast, in its Guidance for Industry and subsequent paper by Jacobs *et al*. (2004), the FDA clearly state that they have no requirement for a separate photogenotoxicity test, and focus much more on results of the phototoxicity test using the 3 T3-NRU (Neutral Red uptake) assay. If the latter is positive, they recommend labelling to indicate that the test agent may cause photoirritation in humans and for individuals to avoid exposure to the sun.

In recent years, experience of industry suggests that the *in vitro* photosafety (phototoxicity/photogenotoxicity) assays are over-sensitive and that the photogenotoxicity assay in particular may also lack specificity. This is based on the lack of biological plausibility for the response of certain chemicals in the photogenotoxicity assays (Lynch *et al*., 2008b), reports of reproducibility issues (Kasper *et al*., 2005) and identification of a new phenomenon, termed pseudophotoclastogenicity (Dufour *et al*., 2006). As a consequence, the EMEA safety working group have proposed a revision of the CPMP guidance on Photosafety Testing in 2008 to address these concerns.

The points for consideration will focus on the following:

1. A refinement of the criteria for deciding whether photosafety testing is required, as these are considered rather unspecific and apparently result in testing of too many new pharmaceuticals. Therefore, a better prediction of possible photobiological properties or lack thereof is required.
2. Currently the guideline stipulates a parallel approach to photosafety testing; that is, phototoxicity, photoallergy and photogenotoxicity. A tiered approach, where photoallergy and photogenotoxicity testing would usually not be required if the compound in question is clearly negative in an initial *in vitro* phototoxicity study would provide a more suitable and efficient testing strategy.
3. Oversensitivity and the occurrence of 'pseudo-effects' with *in vitro* models recommended by the current guideline, and in particular photogenotoxicity. The use of some test models for regulatory purposes can no longer be justified and these need to be replaced by more appropriate approaches.
4. The question of timing of photosafety evaluation during drug development.

4 INTERPRETATION OF GENETIC TOXICOLOGY DATA

The assessment of the potential genotoxicity (and carcinogenicity) of a new chemical entity is an essential part of product development in the pharmaceutical, chemical and consumer product industries. Compound-related genotoxicity and carcinogenicity findings are assessed and are considered as part of the risk–benefit continuum based on intended use (including clinical indication for drugs) and anticipated human exposure, and are regulated accordingly (**Figure 15**).

As mentioned above, the minimum regulatory genotoxicity package generally consists of (i) an *in vitro* bacterial assay for gene mutation, (ii) an *in vitro* mammalian cell assay for gene mutation and/or cytogenetic damage, and (iii) an *in vivo* mammalian assay for cytogenetic damage. The aim is to assess the potential of a compound to induce genetic damage, directly or indirectly, by various mechanisms. A negative result in all three assays is usually sufficient to provide evidence for a lack of genotoxic potential, although additional testing may be required for substances with structural chemical alerts, or when there is evidence of the carcinogenicity of structurally similar compounds. Assays producing equivocal results should be repeated. More testing is also needed if one or more of the assays produces a positive result, but the nature of the findings is insufficient to drive immediate termination of development. A risk assessment is made using the results of the complete package, taking into account the significance and limitations of each test. Thus a single positive result may reveal a theoretical hazard, but cannot automatically be interpreted as an unacceptable genotoxic risk, especially if *in vivo* studies are negative. Indeed, it is increasingly accepted that a positive result should not be considered in isolation, and that a weight-of-evidence approach considering

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

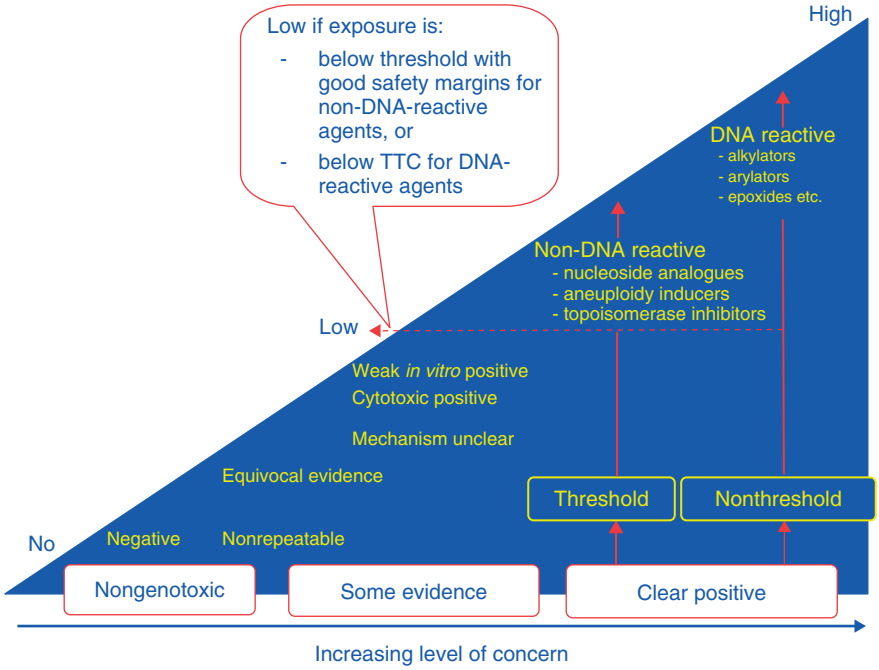

Figure 15 Risk–benefit continuum for genotoxicity. TTC: threshold of toxicological concern (see main text). (Figure adapted from Tweats and Gatehouse (1999).)

all pertinent data should be preferred. As part of this weight-of-evidence approach, information on the mode of action, kinetics, and the extent of human exposure is useful for risk assessment (US Environmental Protection Agency (EPA), 2005a; Dearfield and Moore, 2005; Jacobson-Kram and Jacobs, 2005; Thybaud *et al*., 2007a; 2007b). This may include further investigations using one or more of the supplementary tests described above to provide a mechanism-based risk assessment. In addition, the option to test whether the compound induces tumours in animal models may also be considered. Any decision should be made on a case-by-case basis, with scientific justification. For example, threshold-based arguments may be used for non-DNA reactive compounds, such as aneugens, that is, compounds that induce chromosome loss (aneuploidy), and therefore risk assessments may be based on safe margins of exposure in the patient population.

4.1 Threshold Mechanisms in Genetic Toxicology

The ECETOC has defined an 'absolute' threshold as a 'concentration below which a cell would not "notice" the presence of the chemical'; that is, a threshold assumes that a biological effect only occurs at concentrations above a certain threshold concentration of a chemical. In other words, 'the chemical is present but does not affect the cellular target'. However, the precise characterization of such a threshold is difficult to prove experimentally (Schneiderman *et al*., 1979). In contrast, a 'pragmatic' threshold can be considered as a concentration below which any effect is considered biologically unimportant (Lutz, 1998), and may be defined, in part, with the help of statistical tests (Lovell, 2000). For example by determining the concentrations where increases do not exceed the range of responses seen in the negative control in a well-conducted series of experiments. Although a threshold may be defined by statistical modelling, the existence of such a threshold must be justified from biological arguments and not just from statistical ones. Biological mechanisms and effects have to exist which change abruptly or cause a 'break' of the process when the 'effective' concentration is surpassed (Edler and Kopp-Schneider, 1998).

Genotoxic chemicals which interact directly with DNA have historically been thought to abide by 'the single hit, single target' hypothesis, first proposed by Knudson (1971), whereby a cancer-causing mutation may result from a single interaction causing a nucleotide base change (reviewed by Kirsch-Volders *et al*., 2003b). It is therefore postulated that such chemicals do not exhibit a threshold for genotoxicity. From a regulatory perspective, this has been interpreted such that it can be assumed there is no safe level of DNA damage, however low this is within the DNA. In contrast, for chemicals that do not interact directly with DNA but cause inactivation or modification of redundant or multiple cellular targets, the converse is held to be the case; that is, these chemicals have a threshold dose above which a toxic response

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is produced. Examples of non-DNA-damaging genotoxic substances include those that target the mechanical components required for chromosome segregation (e.g. microtubules, kinetochores, centrioles), DNA metabolism and/or synthesis (e.g. topoisomerases, DNA polymerases, imbalanced nucleotide pool) or DNA repair (e.g. polymerases, endonucleases, ligases). The demonstration and acceptance (by the scientific and regulatory community) of the concept of a threshold of genotoxic activity can have important economic implications for the use of individual chemicals and drugs. The unambiguous demonstration of a threshold of genotoxic activity indicates that a compound will not produce mutations (or chromosomal effects) below a critical exposure level, thus reducing the potential for the induction of cancer or congenital abnormalities at these exposures.

For example, spindle poisons, which disrupt the mitotic machinery, are widely accepted as having no observed effect levels (NOELs) for the induction of aneuploidy (COM, 2000), since multiple targets need disabling before an effect is seen (Elhajouji *et al*., 1995; 1997). Potential thresholds have been established for several aneugens including colchicine, mebendazole, nocodazole, nitrobenzene, benzonitrile, benomyl and its major active metabolite carbendazim, all of which are spindle inhibitors (Elhajouji *et al*., 1995; Grawé *et al*., 1998; Bentley *et al*., 2000; Decordier *et al*., 2002; Bonacker *et al*., 2004). Another example is topoisomerase inhibitors. In mammalian cells, the interaction of topoisomerase II poisons with DNA through the formation of a topoisomerase/DNA/drug cleavage complex results in the biological lesion that is ultimately believed to be responsible for the induction of clastogenicity and/or cytotoxicity (Fortune and Osheroff, 2000). It is this indirect mechanism of DNA damage, therefore, that is generally held for the genotoxicity of topoisomerase II poisons and provides the biological mechanism which underpins the threshold concept for this class of compound. Potential thresholds have been established for several topoisomerase inhibitors using the *in vitro* micronucleus assay and statistical modelling, including etoposide, doxorubicin, genistein and ciprofloxacin (Lynch *et al*., 2003).

More recently, the concept of threshold mechanisms for direct DNA damaging agents, including some alkylating agents, has been postulated (Jenkins *et al*., 2005). The premise is based on the fact that mammalian cells have a number of cellular defences that provide protection to the cell and may limit permanent DNA damage (e.g. DNA repair, chemical detoxification, physical barriers such as cellular and nuclear membranes and redundant targets, etc.). These homeostatic mechanisms and cytoprotective processes are particularly important in the low-dose exposure range, and may prevent and/or limit induced damage from becoming permanent so long as the cellular defences do not become saturated. This can result in a NOEL; that is, the experimental concentration below which no statistically significant increase in mutations is detected. For example, Doak *et al*. (2007) have shown that MNU (methylnitrosourea) and ENU (ethylnitrosourea) display linear dose-responses for chromosomal damage and point mutations (determined by the micronucleus and hypoxanthine-guanine phosphoribosyltransferase (*HPRT*) gene forward mutation assays, respectively), whereas MMS and EMS have nonlinear dose-responses containing a range of nonmutagenic low doses. More recently, Muller *et al*. (2008) showed that EMS demonstrated a threshold for genotoxicity in animal studies *in vivo*. Based on these data, threshold arguments were successfully used by the pharmaceutical company, Roche, to support a risk assessment made to the regulatory authorities for an absence of risk to patients exposed to EMS present as an impurity in a batch of the HIV drug, Viracept (nelfinavir).

The nonlinearity in the dose-response for certain alkylating agents such as EMS is thought to be due to homeostatic maintenance by DNA repair, which is efficient at low doses of compounds that primarily alkylate N^7-G and rarely attack oxygen atoms. Indeed, all organisms exist in environments which lead to low levels of DNA damage being induced, and they have evolved to cope with this. Thus, for many people, the concept that thresholds (or NOELs) exist and that organisms can tolerate low levels of DNA damage is self-evident, and therefore, the logical extension of these arguments is the existence of pragmatic thresholds for certain DNA-reactive genotoxins with regard to carcinogenicity. These ideas, however, still remain controversial, but nevertheless, this work, and other arguments (see Bolt and Degen, 2004) has led to the possible distinction of four groups of carcinogens:

- nonthreshold genotoxic carcinogens (for low-dose risk assessment, a linear nonthreshold (LNT) model appears appropriate);
- genotoxic carcinogens, for which the existence of a threshold cannot be sufficiently supported (in these cases the LNT model is used as a default assumption, based on scientific uncertainty and the precautionary principle);
- genotoxic carcinogens for which a practical threshold is supported; and
- nongenotoxic carcinogens and non-DNA-reactive carcinogens (e.g. spindle poisons and topoisomerase inhibitors). For these compounds an absolute threshold is associated with a clearly founded no-observed-adverse-effect level.

The current regulatory viewpoint remains that thresholds have to be proven on a 'case-by-case' basis. This point of view may well change as more data become available from chemicals with similar modes of action. It is again important to point out that DNA-damaging agents and non-DNA-damaging agents are mechanistically distinct and are likely to be treated differently in regulatory terms.

4.2 Threshold of Toxicological Concern (TTC)

Genotoxic or carcinogenic impurities in drugs are considered to represent a risk to patients, with no associated benefit. The regulation of the levels of genotoxic and carcinogenic impurities in drugs to ensure they impart no risk or have an acceptable level of risk can be challenging as it is widely accepted that complete avoidance of such impurities in drugs is unrealistic (McGovern and Jacobson-Kram, 2006).

The importance of controlling impurities in drug substance and drug products is well established. The thresholds for identification, reporting and qualification of impurities are described in the ICH Q3A/B/C Guidance. While the scope of this regulatory guidance is restricted to new drug products, it also offers a framework for the assessment of drug-related impurities in later clinical development. The ICH Q3 guidance describes the process for assessing the general, genetic and special toxicity of impurities in drug substance. For example, ICH Q3A recommends that for a drug substance where the clinical dose is less than 2 g day, impurities that are at a level of 0.05% must be reported, impurities that are at a level of 0.1%, or represent a total dose of 1 mg (whichever is lower) must be identified, and finally impurities that are at a level of 0.15%, or represent a total dose of 1 mg (whichever is lower) must be qualified.

Typically, qualification requires general toxicology studies (from 14 to 90 days) and genetic toxicology studies (including an assessment of the potential to induce point mutations and chromosome aberrations) on either the impurity or with parent drug substance containing appropriate levels of the impurity. The guidance for residual solvents is more specific, in that it describes a toxicology-based risk assessment approach that defines acceptable limits, known as a permissible daily exposure (PDE), for individual solvents. This PDE approach considers the NOEL from the most relevant toxicity studies alongside various risk factors to account for extrapolation between species, variability between individuals, and so on. Importantly, while these PDEs for individual solvents appear precise, the standard errors around them in terms of mg day^{-1} are likely to be large.

A recognized shortcoming of the ICH Q3 regulatory guidance is that the genetic toxicology qualification of drug substance impurities is highly insensitive. For example, impurities that are potent mutagens (e.g. with similar potency to MMS) may go undetected in a standard genetic toxicology study if present in drug substance at the 0.15% qualification threshold. Likewise, the calculation of a PDE for genotoxic agents is considered to be problematic, as current dogma assumes that DNA-reactive genotoxic agents represent some degree of risk even at very low levels of exposure (i.e. there is no safe dose). In response to this issue, the European Medicines Agency's Committee for medicinal products for human use (CHMP) issued a new guidance in January 2007, to address the Toxicological assessment of genotoxic impurities and the determination of acceptable limits for such impurities in active substances (European Medicines Evaluation Agency, 2006).

The CHMP guidance applies to all new active drug substances in development and, in certain cases, existing drug substances if there is a cause for concern. The main focus of the guidance is on the assessment of direct-acting DNA-reactive substances (as the default assumption for such substances is that they are likely to be genotoxic carcinogens). Although indirect-acting genotoxic substances that can be demonstrated to act via a biologically meaningful threshold were also considered. The CHMP proposed that for the latter class of compound, if sufficient experimental data was available, a PDE approach could be adopted to determine acceptable levels of an impurity in a drug. However, it was recognized that demonstration of such thresholds can often be problematic, and in most cases the default assumption for a genotoxic impurity would be that it was a nonthresholded genotoxic carcinogen.

In considering the control of direct-acting DNA-reactive impurities, the CHMP stated that ideally such substances should be controlled to levels 'as low as reasonably practicable (ALARP)' but also accepted that in many cases this was not technically possible; it is estimated that ~20–25% of all pharmaceutical synthetic routes contain DNA-reactive substances (Delaney, 2007). In such cases, the CHMP argued that the acceptable levels of such direct-acting DNA-reactive impurities in a drug would require justification from a toxicological perspective (i.e. calculation of an acceptable daily intake using rodent carcinogenicity data). However, the CHMP also recognized that in the majority of cases this type of comprehensive toxicology data would not be available for potentially DNA-reactive drug-related impurities. Therefore, the CHMP proposed a pragmatic, risk-based approach to address this situation, that involved limiting DNA-reactive impurities in a drug substance/product to a level known as the threshold of toxicological concern (TTC).

The regulatory paradigm known as the TTC was originally developed by the FDA as the threshold of regulatory concern and was defined as a level of any unstudied chemical that would not pose a risk of significant carcinogenicity or other toxic effects (Threshold of Regulation for Substances Used in Food-Contact Articles (Final Rule), 1995). The TTC figure was derived following a series of linear extrapolations involving the doses of known rodent carcinogens that induced tumours in half of the test animals (i.e. TD_{50} mg $kg^{-1}day^{-1}$) to doses of 0.15 μg day^{-1} that would be equivalent to less than a one in a million (1×10^{-6}) upper bound lifetime risk of cancer; also known as a 'virtually safe dose' (Rulis, 1989;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Munro, 1990; Kroes and Kozianowski, 2002). Some adjustments around this original TTC level based on structural class, recognition of the conservative nature of the linear extrapolation model and its application to pharmaceutical development resulted in the CHMP defining a new TTC figure for genotoxic impurities in drugs of $\sim 1.5\,\mu g\,day^{-1}$ that was associated with a one in one hundred thousand (1×10^{-5}) upper bound lifetime risk of cancer. It is important to recognize that the risks associated with such low levels of genotoxic impurities are vanishingly small. For example they are much lower than the annual risk of death by natural causes (above the age of 40), by road accident, playing soccer or homicide in the UK (Calman, 1996).

The CHMP accepted that in certain cases that application of the TTC for genotoxic impurities will not always be appropriate and that higher levels may be acceptable depending on the seriousness of the clinical indication (e.g. for life-threatening conditions), or if human exposure to the genotoxin will be greater from other sources (Delaney, 2007) or if the duration of exposure to the impurity is limited. The last of these considerations (i.e. duration of exposure) has been the subject of much debate and it is now recognized that a 'staged TTC' approach, in which acute exposure to a genotoxic substance at levels greater than the TTC is considered to be of comparable risk to chronic exposure to the levels equal to the TTC (Müller *et al*., 2006). The concept clearly has wider implications given that short-term exposures to high concentrations of an environmental genotoxin are a regular cause of concern in areas outside the pharmaceutical industry (Bos *et al*., 2004).

In summary, risk–benefit considerations made for parent drugs cannot be extended to genotoxic impurities in drug substance/product. Recent CHMP guidance, which is aimed at the control of genotoxic impurities in drug substance/product, are based on the concept of TTC. The assumptions used in the TTC are extremely conservative and the TTC may significantly over-estimate the risk associated with low levels of genotoxic substances. Nevertheless, and perhaps more interestingly, the CHMP guidance has reintroduced the concept that for DNA-reactive carcinogens, there will be acute and chronic exposure levels that could be considered to be associated with an acceptable carcinogenic risk. This is an important paradigm shift from the prevailing dogma of the 'no safe dose' which resulted from 'the single hit, single target' hypothesis (Knudson, 1971), given the risks associated with exogenous exposure to agents that can induce carcinogenicity are a source of great personal and social relevance (European Medicines Evaluation Agency, 2007).

4.3 Cytotoxicity

Regulatory guidelines stipulate the maximum test concentration required in the *in vitro* mammalian genotoxicity assays as the lowest of $5\,mg\,ml^{-1}$, 10 mM, the limit of solubility, or the threshold of cytotoxicity. The methods for cytotoxicity used in genotoxicity assays and defined by OECD and ICH guidelines a decade or more ago, are now undergoing rigorous scientific scrutiny in concert with the development of more accurate technologies. One of the main reasons for this new scrutiny is the high frequency of positive *in vitro* findings in the genotoxicity test batteries with agents found to be noncarcinogenic in rodents and thought not to pose a carcinogenic health hazard to humans. For example, Kirkland *et al*. (2005; 2006) recently reported that 75–95% of known noncarcinogens were positive in one or more of the standard *in vitro* genotoxicity assays. In this analysis, the false-positive rate was highest in mammalian cell tests such as the chromosome aberration assay in Chinese hamster cells (the analysis was based on over 700 chemicals with rodent carcinogenicity data). These data, subsequently confirmed by Matthews *et al*. (2006a; 2006b) using FDA and EPA databases, demonstrate that positive results from *in vitro* mammalian genotoxicity assays do not accurately predict rodent carcinogenicity or human carcinogenic risk.

The need to reconsider the evaluation of positive findings in mammalian genotoxicity assays *in vitro* and their impact on risk assessment has been highlighted by regulatory authorities (US Environmental Protection Agency (EPA), 2005a; 2005b; Dearfield and Moore, 2005; Jacobson-Kram and Jacobs, 2005; FDA (Food and Drug Administration) CDER (Center for Drug Evaluation and Research), 2006) and organizations such as the IWGT (Thybaud *et al*., 2007a), ECVAM (Kirkland *et al*., 2007) and the Health and Environmental Sciences Institute (HESI), which is the global branch of ILSI (Thybaud *et al*., 2007b). One of the re-occurring themes is the rationale for the selection of the highest *in vitro* concentration, including the required levels of cytotoxicity currently prescribed by various regulatory guidelines for *in vitro* tests. It follows that accurate cytotoxicity assessments are critical to improve the scientific rigour of these *in vitro* assays to ensure accurate human risk assessment. In addition, recent evidence suggests that rodent cell lines, and in particular Chinese hamster cells, produce more positive results in the *in vitro* structural chromosome aberrations assay compared with human cell lines (Hilliard *et al*., 2007) and therefore the choice of cell type may lead to positive results not relevant to humans (Kirkland *et al*., 2007).

Rodent cell lines are exceptionally sensitive to cytotoxicity-related chromosomal damage (compared with human cells) because of relaxed cell cycle regulation. For example, CHO cells uniquely continue

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat074
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to undergo cellular growth during DNA synthesis inhibition and the degree of aberrant growth is directly related to the degree of subsequent cytotoxicity and cell death (Kung *et al*., 1990a; 1990b), implying that the mechanisms for clastogenicity and cytotoxicity are intrinsically linked in these cells. The sensitivity of CHO cells therefore makes them more susceptible to artefactual increases in chromosomal damage. This may also account for the increased sensitivity of rodent cells in cytogenetic assays compared with human cells.

Cytotoxicity in cultured mammalian cells is a function of the methods used to estimate it (Fellows and O'Donovan, 2007). The use of traditional end points such as mitotic inhibition and/or final cell counts as a percentage of control to assess toxicity often underestimates toxicity (Armstrong *et al*., 1992; 2000; Kirkland, 1992; Galloway, 2000; Greenwood *et al*., 2004; Fellows and O'Donovan, 2007). Cell counts can be misleading; for example, in cultures seeded at 0.5×10^6 cells per culture, if controls double to 1×10^6 during the experiment, a treated culture in which cell division is totally shut down, that is, complete failure to grow during the expression period, will have a cell count 50% of control at the end of the experiment. This underestimation is exacerbated with increasing toxicity and is a particularly confounding issue for compounds shown to produce cell cycle arrest *in vitro*. For example, it is well known that chromosome aberrations are often associated with cytotoxicity and DNA synthesis inhibition (Galloway *et al*., 1998; Hilliard *et al*., 1998) which can be induced *in vitro* by compounds that do not directly damage DNA. It is also recognized that chromosome aberrations may occur under conditions that would not be relevant *in vivo* (Kirkland and Muller, 2000).

Measures of cytotoxicity such as relative population doubling (RPG) and relative increase in cell counts (RICC), that evaluate population growth during the treatment period, may provide more suitable end points for use, as they are sensitive to all cytotoxic compounds regardless of MOA, and are equally sensitive in human and rodent cell lines (Galloway *et al*., 2000; Fellows *et al*., 2008; Bromfield, 2009). Greenwood *et al*. (2004) have shown that several non-DNA-reactive chemicals and metabolic poisons would not have given positive chromosome aberration results if the 50% cytotoxic concentration had been chosen based on a reduction in population doubling rather than a reduction in cell count, and that, using this measure, no important DNA-reactive genotoxicants would be missed. Similarly, data presented at a recent ECVAM workshop (Kirkland *et al*., 2007) by Kirchner demonstrated that relative cell count, mitotic index and reduction in population doublings produce quite different concentrations for 50% toxicity. These observations confirm that accurate assessment of cytotoxicity is critical for assay validity (Fellows *et al*., 2008) and therefore this is likely to be an area of ongoing refinement in the coming years.

5 THE FUTURE

Following a 30-year period of regulatory guideline convergence and a decade or so of stability, the current genetic toxicology paradigm is now undergoing a period of revision, with the possibility of divergence in regulatory guidelines, as different industrial sectors respond to varying regulatory and/or societal/political demands specific for each business. For example, in Europe the Seventh Amendment to the Cosmetics Directive (2003/15/EC) will prohibit the use of animals for safety testing of cosmetics ingredients from 2009/2013, which is driving the rapid development of *in vitro* human tissue genotoxicity assays, such as the skin micronucleus assay. The new European Union chemical legislation (EC 1907/2006) concerning the REACH will require genotoxicity testing of ~30 000 existing chemicals and is responsible, in part, for driving refinements in *in silico* testing and the robustness of *in vitro* assays. These diverse imperatives are likely to have a significant impact, particularly in regulatory genotoxicity testing, and drive future changes in the discipline.

For example, in the pharmaceutical industry, the revision of the ICH guidelines is currently underway and these are likely to be implemented in 2009. The revised draft guidance makes use of experience accumulated over more than 10 years with the existing S2A and S2B guidance. There is clear recognition worldwide among regulatory agencies of an urgent need to update the guidance

1. with strategies to address the high frequency of positive results in the mammalian cell genotoxicity assays *in vitro* (for the reasons described above), and
2. to include options for newer assays now that substantial experience has been gained, such as the *in vitro* micronucleus assay and the Comet assay for DNA strand breaks.

The revised ICH S2 guidelines therefore reinforce the upper toxicity limits for CA of 50% toxicity, and for MLA of 80% reduction in RTG. They also support the reduction in the top concentration for *in vitro* mammalian cell assays from 10 to 1 mM, based on several lines of reasoning:

1. The 1 mM limit maintains a component of hazard identification, being above known blood plasma and tissue levels for pharmaceuticals.
2. Most physiological processes and K_m values for enzymes, and so on, are well below 100 μM.
3. Review of the data compiled by the ICPEMC (International Commission for Protection against Environmental Mutagens and Carcinogens) to support the original 10 mM limit confirms that *in vivo* clastogens are detectable at 1 mM or less *in vitro*, and that compounds of concern for potential human genotoxicity are detectable at 1 mM or below.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4. Experience in pharmaceutical companies confirms that compounds that may be considered 'relevant' positives based on knowledge of mechanism, DNA damage detected in other assays, or *in vivo* positive results, are positive at 1 mM or less.
5. Finally, the 1 mM limit is supported by data reviews when the whole battery is taken into account; for example, a mutagen such as EMS, which induces chromosome aberrations in the mM range, is recognizable by its structure and is clearly positive in the Ames test, so EMS would not be 'missed' by omitting the *in vitro* mammalian cell assay or limiting it to 1 mM.

The revised ICH S2 guidelines also extend the standard battery to include an option that comprises an Ames test and two *in vivo* tests, the *in vivo* micronucleus assay and *in vivo* Comet assay for DNA damage, which is the strategy that is currently in use by the US National Toxicology Program (**Box 2**). Existing ICH guidance (S2A and S2B) and the FDA's guidance (FDA (Food and Drug Administration) CDER (Center for Drug Evaluation and Research), support the concept that two *in vivo* genotoxicity assays, in appropriate tissues and with documented exposure, outweigh the positive results in mammalian cell assays *in vitro*, such as CA and MLA. Based on this concept, it follows that an effective test battery comprising an Ames test and two *in vivo* end points should be equally acceptable. Furthermore, the revisions promote the integration of *in vivo* genetic toxicity studies into existing toxicology studies where possible, thus saving animals and taking advantage of the exposure and other toxicological information generated in the toxicity study. The guidance contains stringent criteria for establishing that the dose level is high enough to maximize sensitivity *in vivo*. At present, there is sufficient information to support this integrated approach for the micronucleus assay but there is limited experience with the Comet assay, and therefore the guidance notes that protocol adaptations may be needed to allow integration. If repeat-dose toxicology studies are not appropriate for genotoxicity assays then the option to revert to the standard battery may be followed. Additional reductions in animal use are enabled by eliminating the requirement for concurrent positive controls in every *in vivo* assay, provided the laboratory has demonstrated appropriate competence with the assay and reproducible results with positive controls. Also, a reduction in nonrelevant positive results in the *in vitro* assays is expected to reduce animal use in follow-up testing. It will be interesting to see the impact these revisions will have on reducing the high frequency of nonrelevant positive results in the new genetic toxicology test battery.

5.1 Translational Medicine and Biomarkers of Genetic Damage

Different cytogenetic end points have been employed to assess the burden of genetic damage, particularly for human populations. However, these methods have traditionally suffered from the limited number of countable cells and potential individual differences in analysing cells (both in terms of investigator bias and interindividual variability). They are also influenced by confounders such as age, gender, overall health status, immune status, smoking habits and other environmental exposures, and so on, and therefore have not provided reliable translational biomarkers of individual genetic damage.

One of the most promising new developments for a translational biomarker of individual genetic damage has been the automated measurement of MN in reticulocytes, that is, immature, RNA-containing erythrocytes. Since the spleen eliminates micronucleus-containing reticulocytes in humans, previous data concerning this end point were limited to splenectomized individuals (Schlegel and MacGregor, 1984; Tucker *et al*., 1993; Zuniga *et al*., 1996; MacGregor *et al*., 1997; Smith *et al*., 1990). Now, methods have been found to enrich very young reticulocytes from peripheral blood samples before they are trapped by the spleen (Abramsson-Zetterberg *et al*., 2000; Dertinger *et al*., 2003; 2004). The assay relies on the identification, selection and evaluation of the youngest fraction of reticulocytes, that is, those less than 48 hours old, representing ~10% of circulating reticulocytes. These cells are identified by the expression of a specific cell surface marker, the transferrin (CD71) receptor, which is active for only a few hours after the young reticulocyte enters the peripheral circulation. The assessment of micronucleated reticulocytes in the youngest fraction of reticulocytes mitigates against the effects of active splenic removal of micronucleated cells in various species, including rat (Schlegel and MacGregor, 1984; MacGregor *et al*., 2006; Hayashi *et al*., 2007), dog (Harper *et al*., 2007) and human (Dertinger *et al*., 2003; 2004; 2007), although this means that the 'memory' of the biomarker is relatively short with respect to acute exposures. *Plasmodium berghei*-containing erythrocytes may be used as a calibration standard (Dertinger *et al*., 2000), and the method has been validated to GLP standards as an alternative cytogenetic end point in the mouse (Torous *et al*., 2005), rat (Torous *et al*., 2000; 2003; MacGregor *et al*., 2006; Hayashi *et al*., 2007) and dog (Harper *et al*., 2007). In all three species, the analysis of micronucleated reticulocytes correlates with microscopic scoring of MN from bone marrow samples or peripheral blood. Moreover, automation using flow cytometry greatly reduces the labour of scoring, permits the evaluation of far more cells (20 000 compared with 2000 is

Table 12 Frequency of micronucleated reticulocytes in normal human adult, juvenile and paediatric patients and following various therapeutic interventions

Patients	%MN-reticulocytes	References and comments
Healthy Cancer	0.12 (0.01–0.36) Significant increase on days 1–4	Abramsson-Zetterberg *et al*. (2000)
Healthy Cancer	0.09 ± 0.06 (0.01–0.20) Significant increase on days 2–4	Dertinger *et al*. (2003)
Healthy	0.11 ± 0.06	Dertinger *et al*. (2004)
Healthy Cancer	0.12 ± 0.06 Significant increase on days 2–4	Dertinger *et al*. (2007)
HIV mothers and Infants	Off treatment Mother: 0.12 ± 0.02 Infant: 0.17 ± 0.02 On HIV treatment >10-fold increase	Witt *et al*. (2007)
Children with sickle cell disease	Off treatment 0.22 ± 0.13 On hydroxyurea treatment 3-fold increase	Harrod *et al*. (2007)
Thyroid cancer patients treated with Radioiodine therapy (100–700 mSv)	Pretreatment 0.13 ± 0.05 Post-treatment (121 mGy) 0.56 ± 0.16	Stopper *et al*. (2005), Grawé *et al*. (2005)

standard), and this in turn provides greater reproducibility than microscopy.

Importantly, micronucleated reticulocytes have been used as a biomarker of cytogenetic damage in various human clinical studies. A summary of the human data (**Table 12**) shows that there is high consistency in the mean spontaneous frequency of micronucleated reticulocytes in normal human adult, juvenile and paediatric populations and that the baseline frequencies are similar to those previously reported for rodents and dogs (Harper *et al*., 2007). Despite interindividual variation in human populations, the intra-individual variation is low (Abrahamsson Zetterberg *et al*., 2000). Indeed, not only is the variation over time in the same individual generally substantially lower than the interindividual variation, but also that obtained for different types of chromosome aberrations determined in the same individual over time (Abramsson-Zetterberg *et al*., 2000; Andersson, 1993). Human exposure to genotoxic agents has been demonstrated to produce significant increases in mean micronucleated reticulocyte frequencies in blood samples obtained from various treatment groups. For example, cancer patients receiving various chemotherapy treatments (Abramsson-Zetterberg *et al*., 2000; Grawé *et al*., 2005; Stopper *et al*., 2005; Dertinger *et al*., 2007); HIV infected mothers and their infants receiving antiretroviral therapy to prevent vertical transmission of the HIV virus (Witt *et al*., 2007); and children with sickle cell disease receiving hydroxyurea treatment (Harrod *et al*., 2007). Furthermore, micronucleated reticulocyte frequencies are negatively correlated with folate status (Abramsson-Zetterberg *et al*., 2006) and positively correlated with smoking (Offer *et al*., 2005). Thus, the assessment of micronucleated reticulocytes in peripheral blood provides an opportunity for a translational biomarker of acute genetic damage, from preclinical species into the clinic and/or for human biomonitoring studies. Whether or not this will lead to an increase in the assessment of genetic damage in human remains to be seen. A debate as to the impact of low levels of acute genetic damage with respect to long-term risk in humans will be required beforehand.

6 CONCLUSION

The assessment of the potential genotoxicity (and carcinogenicity) of a new chemical entity is an essential part of product development in the pharmaceutical, chemical and consumer-product industries. Genetic toxicology is a complex science because there are many different types of genetic damage, caused by a variety of different genotoxic agents and chemicals. The challenge for genetic toxicology is to provide tests which are accurate. For safety assessment there has to be a high degree of certainty that mutagenic carcinogens will be detected and human exposure limited. For hazard assessment there has to be a high degree of certainty that noncarcinogens are not misclassified, as this can lead to

scare stories, needless concern about chemicals that are safe and rejection of potentially valuable compounds. During the process of development, compound-related genotoxicity and carcinogenicity findings are assessed and are considered as part of the risk–benefit continuum based on intended use (including clinical indication for drugs) and anticipated human exposure, and are regulated accordingly.

ACKNOWLEDGEMENTS

I would like to thank my colleagues Drs. Robert Rees, James Harvey, Caterina Marchetti, Paul Hastwell, Tracy Warr and Nicky Potter for their insightful discussions and review of this chapter.

Cytogenetics

Diana Anderson, Adolf Baumgartner and Eduardo Cemeli

CONTENTS

1 INTRODUCTION

There are various types of cytogenetic change which can be detected in chromosomes; in particular, structural chromosome aberrations (CAs), sister chromatid exchanges (SCEs), and numerical changes which could result in aneuploidy, polyploidy or micronuclei (MN). CA assays are used to detect the induction of chromosome breakage (clastogenesis) in somatic and germinal cells by direct observation of chromosomal damage during metaphase analysis, or by indirect observation of MN. CAs detected with these assays are mostly lethal to the cell during the cell cycle following the induction of the damage. The presence of CAs, however, indicates a potential to induce more subtle and therefore transmissible chromosomal damage, which survives cell division to produce heritable cytogenetic changes. Cytogenetic damage is usually accompanied by other genotoxic damage, such as gene mutation.

1.1 Cytogenetic Damage and its Consequences

Structural and numerical chromosomal aberrations in somatic cells are involved in the aetiology of neoplasia (Beckmann *et al*., 1997); while in germ cells they can lead to perinatal mortality, dominant lethality or congenital malformations in the offspring (Chandley, 1981; Anderson *et al*., 1999; Marchetti and Wyrobek, 2005) and some congenital tumours (Anderson *et al*., 1999; Nomura *et al*., 2004). Over 80% of all structural chromosomal aberrations in humans occur *de novo* and are of paternal origin (Thomas *et al*., 2006). Chromosome defects arise at the level of the individual chromosome or at the level of the chromosomal set, so affecting number of chromosomes.

1.2 Individual Chromosome Damage

Damage to individual chromosomes consists of breakage of chromatids, which must result from a discontinuity of both strands of the DNA in a chromatid. How mutagens produce chromosome breakage is complex and not fully understood, but DNA lesions which are not in themselves discontinuities will produce breakage of a chromosome as a consequence of their interference with the normal process of DNA replication. Important in making the initial DNA lesion are reactive oxygen and nitrogen species, which can produce DNA damage either directly or indirectly via lipid peroxidation and formation of etheno-DNA adducts (Martinez *et al*., 2003). In haploid micro-organisms and prokaryotes chromosome breaks are usually lethal, but in diploid eukaryotes this is not so. In these organisms chromosome breaks may reconstitute in the same order as a result of nonhomologous end joining or homology-directed repair of DNA double-strand breaks, resulting in no apparent cytogenetic damage (van Gent and van der Burg, 2007). However, unrepaired or misrepaired breaks could result in CAs (Iliakis *et al*., 2004) and thus most of these aberrations may contribute to mutagenesis and carcinogenesis (Hanawalt *et al*., 2003). DNA damage may even result in cell death (apoptosis) at the next or following mitoses—if, for example, unrepaired chromosomal fragments are introduced into the zygote via an affected germ cell, the embryo may die at a very early stage from a dominant lethal mutation (Fukamachi *et al*., 2001). It has been shown that oocytes can tolerate via their repair capacity only $<8\%$ sperm DNA damage (Ahmadi and Ng, 1999). Open DNA ends upon chromosome breaks are exposed to nucleolytic attacks (Fisher and Zakian, 2005) and prone to loss of genetic material, hence the necessity to efficiently repair at any cost. When chromosome breaks are then rejoined in a different order from the original one, chromosomal rearrangements are the consequence (Bryant, 2004). Hence, chromosome-type and chromatid-type aberrations but not SCEs can predict cancer risk (Norppa *et al*., 2006). There are various types of chromosomal rearrangements (ISCN, 2005):

Chromosomal exchanges are a result of the rearrangement of segments between two chromosomes due to one or more breaks in each of these chromosomes and, depending on the position of the centromeres in the rearranged chromosomes, different configurations will result (see **Figure 1** for the most common aberrations).

1. Asymmetrical exchanges arise when one of the rearranged chromosomes carries both centromeres while the other carries none. These chromosomal rearrangements are known as a *dicentric* (*dic*) and an *acentric* (*ace*) fragment. The somatic or germ cell carrying this anomaly usually dies, death being caused by segregation difficulties of the dicentric fragment or the loss of the acentric fragment at cell division. Such a chromosomal rearrangement contributes to dominant lethality. However, cells carrying a dicentric fragment could in $\leq 50\%$ of the cases progress past mitosis, causing various other disruptions via bridge–breakage–fusion events (Gisselsson *et al*., 2000; Krishnaja and Sharma, 2004).
2. *Reciprocal translocations* (*t*), which are symmetrical exchanges, occur when each rearranged chromosome carries just one centromere. This allows the zygote to develop normally, but when such heterozygotes form germ cells at meiosis, about half of their gametes will be genetically unbalanced, since they have deficiencies and duplications of chromosomal material (Benet *et al*., 2005). The unbalanced gametes which survive produce unbalanced zygotes, which results in death shortly before and after birth, or congenital malformations (Munne, 2002).

Robertsonian translocations (rob) originate through centric fusion of two acrocentric chromosomes (chromosomes 13, 14, 15, 21 or 22) to produce a single metacentric or submetacentric chromosome by deleting the short arms. These rearrangements are very common in humans (Bandyopadhyay *et al*., 2002). When Robertsonian translocations are produced in a germ cell through a breakage and fusion in the short arms, as a consequence of loss of the derived acentric fragments a genetic deficiency can result. Some Robertsonian translocations are able to survive but others pose a risk. In heterozygotes, the two arms of the derivative chromosome may pair with the two separate homologous chromosomes at meiosis but segregate in a disorderly manner. Some of the resulting germ cells lack copies (nullisomy) or carry two copies (disomy) of one or the other of the two chromosomes involved, which results in monosomic or trisomic embryos. Monosomic embryos die early but trisomic embryos, which carry three copies of a chromosome, can survive to birth or beyond. If chromosome 21 is involved in the translocation, it can form a translocation trisomy

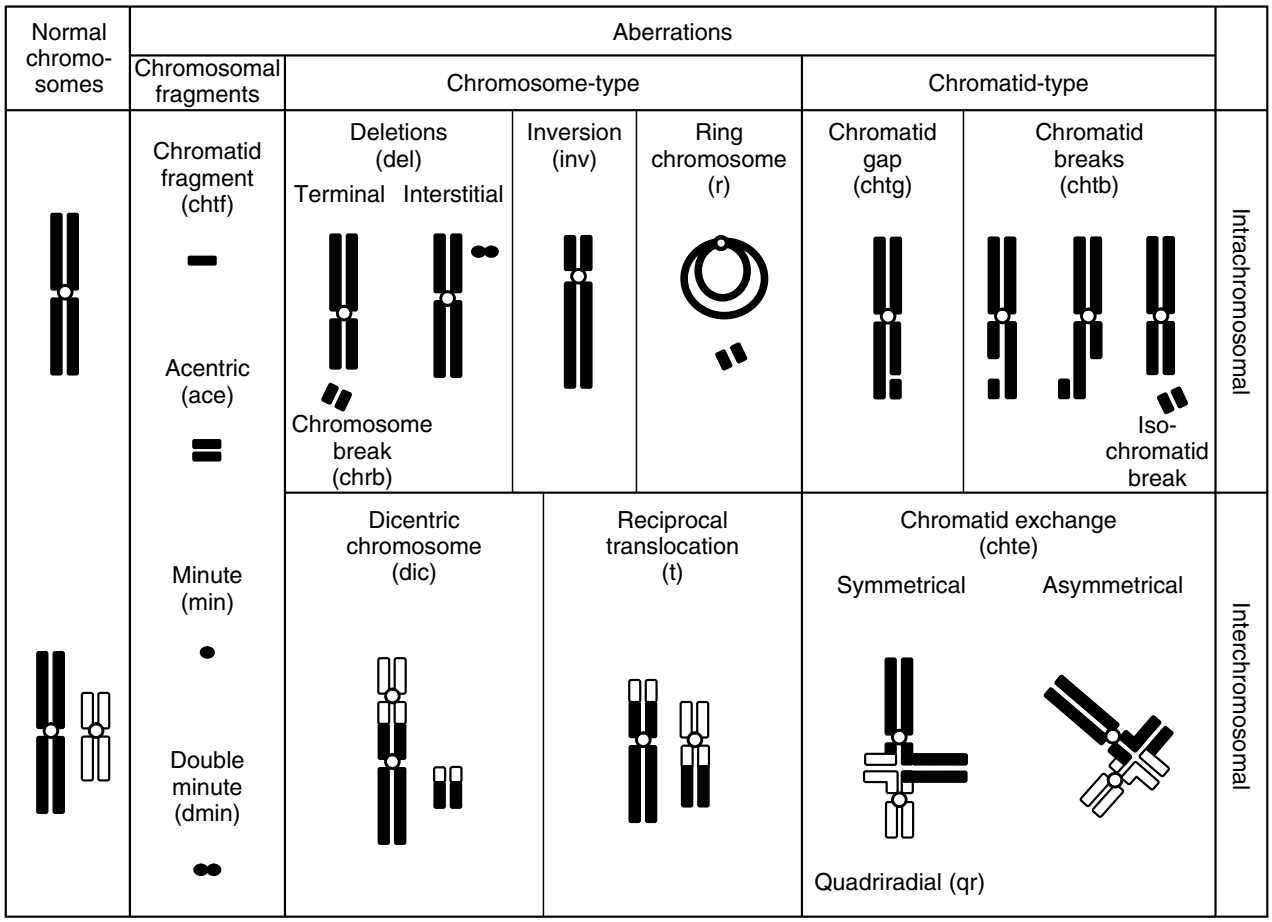

Figure 1 Overview of frequent chromosome-type and chromatid-type aberrations after a clastogenic or chemical insult. These aberrations can occur within a single chromosome (intrachromosomal) or between two or even more chromosomes (interchromosomal). The chart also shows the designations for chromosomal fragments being mostly generated after chromosomal damage. Note that even if the aberrations for a terminal deletion and an isochromatid break seen under the microscope are the same, the mechanisms to form such aberrations (chromosome break vs. chromatid break) are different. A more detailed description of various other aberrations and their abbreviations can be found in An International System for Human Cytogenetic Nomenclature (ISCN, 2005).

and produce inherited Down's syndrome (this differs from nondisjunctional Down's syndrome trisomy).

Ring chromosomes (r) can either derive from one or from more than one chromosome. For the latter possibility, the ring chromosome can even carry several centromeres. However, a ring chromosome does not necessarily need to have a centromere. For instance, a ring chromosome with one centromere normally originates from two subtelomeric breaks on either arm within the affected chromosome deleting the terminal chromosomal material as an acentric fragment. Bridge–breakage–fusion events of ring chromosomes as well as dicentrics, during the cell cycle may even further contribute to structural aberrations and genetic heterogeneity (Gisselsson *et al.*, 2000), especially in the germ line.

Inversions (inv) arise when two breaks occur in the same chromosome. For *paracentric inversions* these breaks are located on the same arm; for *pericentric inversions* the breaks occur on either side of the centromere. The portion between the two breaks is detached and becomes reinserted in the opposite way to its original position, that is, the gene order is reversed. This need not cause a genetic problem in somatic cells, but imbalanced gametes could result in congenital malformation or foetal death.

Deletions (del) and deficiencies (loss of chromosomal material) are produced interstitially when two breaks arise close together in the same chromosome. The two ends of the chromosome join when the fragment between the breaks becomes detached. Terminal deletions on the other hand can cause the loss of a chromosome end. At the next cell division the unattached piece of chromosomal material is likely to be lost. Large deletions may contribute to dominant lethality. Small cryptic deletions are difficult to distinguish from point mutations. Deletions may uncover pre-existing recessive genes. If one gene that is essential for survival is uncovered, it can act as a lethal in a homozygote and as a partial dominant in a heterozygote.

Various types of cytogenetic events can lead to neoplasia in humans, such as reciprocal translocations or nonreciprocal rearrangements with chromatin loss, deletions or duplication of whole chromosomes or chromosome segments (Gilbert, 1983; Solomon *et al*., 1991; Albertson, 2006). Cytogenetic aberrations have been found in over 45 000 human neoplasms and tumours linked to specific structural balanced rearrangements (Croce, 1987; Mitelman *et al*., 2004). Such changes can cause the elimination of tumour suppressor genes, resulting in malignancy, or activation of proto-oncogenes (Suhardja *et al*., 2001; Yang *et al*., 2007). The mechanisms by which proto-oncogenes become activated to their oncogenic forms in tumour cells include, as well as single-point mutations, deletions, inversions and translocations of gene material between chromosomes creating for instance fusion genes, as well as gene amplification (O'Connell, 2003; Mitelman *et al*., 2004; Peter *et al*., 2005; Albertson, 2006). The consequence of this genetic change may be the altered production of an otherwise normal gene product (Cox and Goding, 1991). This can occur either by increasing the expression rate of the gene (transcriptional activation) or by post-transcriptional stabilization of the messenger RNA (mRNA) or the final protein product. Both mechanisms have been seen in Burkitt's lymphoma cells and in mouse plasmacytomas induced by pristane (CAS 1921-70-6) treatment. In these tumours the normal cellular MYC (c-Myc) gene, which is involved in the control of cell proliferation, is translocated to the immunoglobulin locus (Hecht and Aster, 2000; Boxer and Dang, 2001; Janz, 2006). This initiates a dysregulated expression of the MYC proto-oncogene at 8q24.21 (Rui and Goodnow, 2006) and causes elevated levels of the MYC protein or inability to switch off the gene at the appropriate time, and finally uncontrolled cell proliferation (Gartel and Shchors, 2003). Thus, chromosome rearrangements may induce neoplasia by activating a potential oncogene that is a proto-oncogene (Bos, 1992).

Another mechanism operates in the case of human chronic myeloid leukaemia (CML). A proportion of cases of this disease carry the 'Philadelphia chromosome'. This term depicts the derivative chromosome 22 resulting from a reciprocal t(9;22)(q34;q11) translocation (ISCN, 2005; Jorgensen and Holyoake, 2007). As a consequence the ABL1 (c-ABL) proto-oncogene on chromosome 9 (9q34.1) becomes joined with the BCR region on chromosome 22 (22q11.23) resulting in the expression of a fusion protein encoded by both DNA sequences (Shtivelman *et al*., 1985; Jorgensen and Holyoake, 2007). The exact mechanism of this fusion protein causing cell transformation was poorly understood (Maru, 2001); however, in recent years the molecular underlying mechanism became clear and led to the development of specific BCR-ABL tyrosine kinase inhibitors like imatinib mesilate (Gleevec™) or dasatinib (Sprycel®), which allow a targeted approach in treating CML (Melo *et al*., 2003; Panigrahi and Naithani, 2006; Steinberg, 2007).

The tumour state can also be inherited. Most hereditary predispositions affect only one particular cell type, however; the genes with the relevant germ-line mutation are not cell-type specific and thus increase the risk to unrelated cell types (Bignold, 2004). Retinoblastomas and osteosarcomas, for instance, develop in children who inherit a defective chromosome 13 from one parent. The defect has been shown to involve a deletion or mutation in the RB1 gene at the 13q14.2 locus (Issing *et al*., 1993; Houdayer *et al*., 2004). Tumours arise when the normal copy of the same gene on the other chromosome is lost or mutated in early childhood. This demonstrates that the gene when present in a functional state has suppressive effects on the development of tumours. Genes on chromosome 11 (e.g. WT1 at 11p13 or H19 at 11p15.5) are also frequently lost or epigenetically modified and thus silenced in tumours or in children with the Tay–Sachs familial variant of Wilms' tumour (Koufos *et al*., 1985; Fukuzawa *et al*., 1999). The predisposition *per se* is due to the inheritance of a defective allele of a tumour suppressor (Rohde *et al*., 1997).

1.3 Chromosome Set Damage

Accuracy of chromosome replication and segregation of chromosomes to daughter cells require accurate maintenance of the chromosome complement of an eukaryotic cell (Ghosh *et al*., 2006). Chromosome segregation in meiosis and mitosis is dependent upon the synthesis and functioning of the proteins of the spindle apparatus and upon the attachment and movement of chromosomes on the spindle. The kinetochores attach the chromosomes to the spindle and the centrioles are responsible for the polar orientation of the division apparatus (Taylor *et al*., 2004; Bloom, 2005). Sometimes such segregation events proceed incorrectly and homologous chromosomes separate, with deviations from the normal number (aneuploidy) into daughter cells or as a multiple of the complete karyotype (polyploidy). When both copies of a particular chromosome move into a daughter cell and the other cell receives none, the event is known as nondisjunction (Duesberg *et al*., 1999; Hassold *et al*., 2007).

Aneuploidy in live births and abortions arises from aneuploid gametes during germ cell meiosis. Trisomy or monosomy of large chromosomes leads to early embryonic death. Trisomy of the smaller chromosomes allows survival but is detrimental to the health of an affected person (Nagaishi *et al*., 2004); for example Down's syndrome (trisomy 21), Patau syndrome (trisomy 13) and Edward syndrome (trisomy 18) (Altug-Teber *et al*., 2007). Sex chromosome trisomies (Klinefelter's syndrome and XXX syndromes) and the sex chromosome monosomy (XO), known as the Turner syndrome, are also compatible with survival.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Aneuploidy in somatic cells is involved in the formation of human tumours (Duesberg and Rasnick, 2000; Bignold, 2007). The 'Mitelman Database of Chromosome Aberrations in Cancer' gives a detailed overview of how chromosomal aberrations relate to tumour characteristics (Schaefer *et al*., 2001; CGAP, 2008). An abnormal number of chromosomes seems to be the primary cause of the genomic instability in neoplasms, due to destabilization of the karyotype and the genes (Atkin, 2003; Duesberg *et al*., 2004). Up to 10% of tumours are monosomic or trisomic for a specific chromosome as the single observable cytogenetic change. Most common among such tumours are trisomies 8, 9, 12 and 21 and monosomy for chromosomes 7, 22 and Y (Dey, 2004).

Thus, chromosome changes can have severe consequences in cells and whole organisms, and this present chapter will be concerned with cytogenetic assays which measure gross chromosome changes in human somatic and germ cells *in vitro* and *in vivo*. Various regulatory guidelines have been developed to measure cytogenetic damage at the national level; for example by the US Environmental Protection Agency (EPA), the UK Environmental Mutagen Society (UKEMS), at the European level in the Official Journal of the European Community (OJEC), but most importantly at the international level of the Organisation for Economic Cooperation and Development (OECD). The OECD currently has 30 member states and the membership includes many of the world's major industrial nations. However, it is important to note that a number of significant states are not members, including the BRIC countries (Brazil, Russia, India and China): of course, this does not prevent contract houses in India and Brazil being able to perform studies to OECD guidelines. The pharmaceutical industry has agreed a harmonized approach through the acceptance and implementation of the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) and the ICH issues guidelines for pharmaceuticals in three major economic regions: Europe, Japan and the USA. The veterinary equivalent to the ICH is the International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH) and the objective of the VICH is the issuance of guidelines for veterinary pharmaceuticals. The OECD, ICH and VICH guidelines constitute the three major sets of internationally harmonized genotoxicity guidelines in regulatory use.

2 *IN VITRO* CYTOGENETICS ASSAYS

2.1 Introduction

The *in vitro* cytogenetic assay is a short-term mutagenicity test for detecting chromosomal damage in cultured mammalian cells, for example human lymphocytes. For cultured cells, techniques most frequently used for cytogenetic evaluation are the micronucleus assay (MNA), the chromosome aberrations test (CAT) and the sister chromatid exchange test (SCET). MNA provides information on DNA damage, cytostasis and cytotoxicity, while CAT also covers DNA damage, but additionally it might reveal the precise chromosomal rearrangement which has occurred. However, metaphase spreads are required for the evaluation of these rearrangements using transmissive light microscopy. These classical techniques can be combined with modern fluorescence *in situ* hybridization (FISH) methods like spectral karyotyping (SKY) in order to provide a more detailed assessment. For instance, if CAT is combined with FISH, specific regions of a chromosome can be pinpointed and the rearrangements can be tracked. In MNA, two types of micronuclei are generated: those originating (i) from acentric chromosomal fragments and/or (ii) from nondisjunction of whole chromosomes. The use of FISH on MNA preparations discerns whether the genetic material within the micronucleus is due to clastogenesis (acentric fragments) or aneugenesis (mis-segregated chromosomes bearing a centromere). Matsuoka and colleagues proposed a simple way to distinguish aneugens from clastogens, based on the capability of aneugens to induce a larger number of polynuclear and mitotic cells than clastogens (Matsuoka *et al*., 1999). MNA is a system originally developed for the detection of genetic material in interphase cells that does not migrate to the corresponding poles. It also measures other events such as nucleoplasmic bridges (NPBs), nuclear buds (NBUDs), cell death (necrosis or apoptosis) and the nuclear division index (NDI). In recent years, MNA has evolved into a 'cytome' assay (see **Figure 2**) for comprehensively measuring a chromosomal instability phenotype and altered cellular viability caused by genetic defects and/or nutritional deficiencies and/or exogenous genotoxins (Fenech, 2006). As stated in the OECD guidelines 473 and 487 (OECD, 1997a; 2007) for testing chemical compounds, MN represent damage that has been transmitted to daughter cells whereas CA scored in metaphases may not be transmitted. Because MN in interphase cells can be assessed relatively objectively, laboratory personnel need only to determine whether or not the cells have undergone division and how many cells contain MN. As a result, the preparations can be scored relatively quickly and analysis can be automated. This makes it practical to score thousands instead of hundreds of cells per treatment, increasing the statistical power of the assay. Finally, there is the potential to detect aneuploidy-inducing agents that are more difficult to study with CAT, although MNA does not allow identification of polyploidy (OECD, 2007). Current effort is being addressed to validate a fully automated system for scoring MN. It is worth taking into account

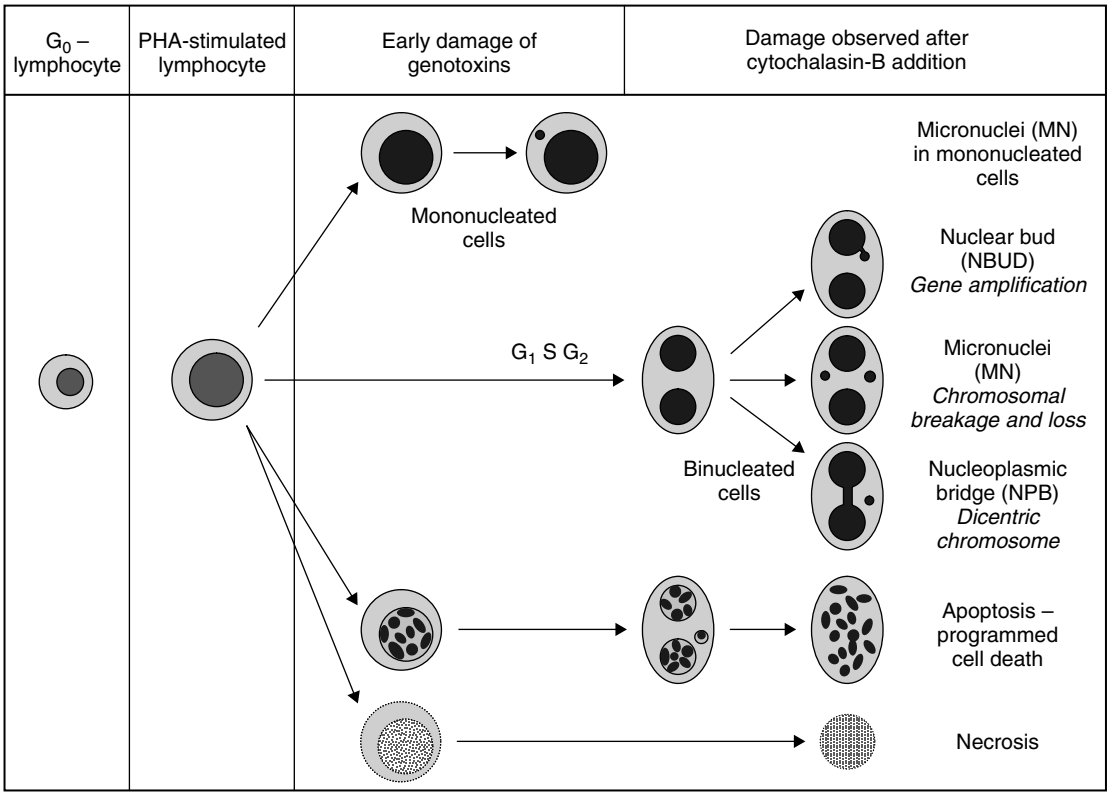

Figure 2 Based on the cytome assay (Fenech, 2006) this outline shows possible chromosomal damage after a genotoxic treatment. As cytochalasin-B does not allow cytokinesis but only the generation of daughter nuclei, the damage seen in binucleated cells is MN resulting from chromosomal breakage and loss, nucleoplasmic bridges due to dicentric chromosomes, and nuclear buds as a consequence of gene amplification. Additionally, MN in mononucleated cells can be observed as well as apoptotic and necrotic events.

that these assays can be used as complementary and/or as a substitute for each other.

Since MNA and CAT are complementary, it has been considered whether it is necessary to use both simultaneously for testing purposes. Kirkland *et al*. (2005) state that there is evidence that the majority, if not all, clastogens are detected by the induction of MN, or are positive in the Ames test, or are inducing mutations in the mouse lymphoma assay. All suspected aneugens, however, induce MN *in vitro* when tested according to current rigorous recommendations. Thus, there is no reliable scientific basis to include both CAT and MNA in addition to the Ames test and mouse lymphoma assay. Since MNA detects both aneugens and clastogens, it alone could complement the Ames test and mouse lymphoma assay (Kirkland *et al*., 2005).

Despite the high correlation observed *in vitro* between CAT and MNA there is no formal validation for the MNA *in vitro*. Thus, the European Centre for the Validation of Alternative Methods (ECVAM) has recently performed a retrospective evaluation (Corvi *et al*., 2008). Two publications fulfilled the criteria established to evaluate the reliability of the test and these were (i) the German ring trial (von der Hude *et al*., 2000) and (ii) the *in vitro* MNA with Chinese hamster V79 cells: results of a collaborative study with 26 chemicals (Lorge *et al*., 2006). It was concluded that the MNA is reliable and relevant and can be used as an alternative method for CAT. Consequently, there are concerns over whether this conclusion can be extrapolated *in vivo*. Hence, the situation *in vivo* is rather unclear and as yet no one has provided a definitive answer.

The cytogenetic techniques mentioned herewith, namely, MNA, CAT and SCET are employed for assessment of biomarkers of exposure. For years, the outcomes of cytogenetic monitoring studies have been assessed to ascertain whether there could be a positive relationship between higher frequencies of CAs or MNs and prediction of cancer. A great variety of results have been observed, and some studies displayed a positive relationship with cancer (Rossner *et al*., 2005; Norppa *et al*., 2006; Boffetta *et al*., 2007; Bonassi *et al*., 2007; 2008). However, this was strongly dependent on the end point, because one end point provided a positive outcome while the other was negative (Hagmar *et al*., 1998a; 1998b; Norppa *et al*., 2006). Occasionally, negative correlations were due to a lack of statistical

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

power or lack of follow-up studies. Another issue is the presence of confounding factors. Gender, age, smoking habits, diet, occupational exposure and in-house levels of radon, among other factors, certainly influenced these results. Thus, an extensive questionnaire is necessary when monitoring (Carrano and Natarajan, 1988). Some of these confounding factors such as age and gender are known to increase the frequency of MN and CA (Surralles *et al*., 1996; 1999; Fenech, 1998). However, other factors such as smoking still provide contradictory data (Fenech *et al*., 2003; Mateuca *et al*., 2006). Mostly lymphocytes are employed as a reporter/surrogate tissue for monitoring, although current effort is being addressed in exfoliated cells (Fenech *et al*., 2007; HUMN, 2008) and reports are already available using buccal cells for monitoring (Pastor *et al*., 2002; Martinez *et al*., 2005; Thomas *et al*., 2007; 2008).

2.2 Cell Types

Established cell lines, cell strains or primary cell cultures may be used for cytogenetic evaluation of chromosomal damage, for example Chinese hamster cells, Syrian hamster embryos, mouse lymphoma L5178Y cells, human or other mammalian peripheral blood lymphocytes. The particular cell system must be validated and consistently sensitive to known clastogens. The United States EPA indicates that the cells employed for *in vitro* CAT must be selected on the basis of stability of the karyotype, chromosome number, chromosome diversity and spontaneous frequency of CAs (EPA, 1998a). Likewise, the background frequency of MN will influence the sensitivity of the assay, as it is recommended that cell types with a low, stable background frequency of micronucleus formation should be used (OECD, 2007).

When human peripheral lymphocytes are used for MNA they should be obtained from young, healthy, nonsmoking individuals with no known recent exposures to genotoxic chemicals or radiation. If cells from more than one donor are pooled for use, the number of donors should be specified (OECD, 2007). It has to be borne in mind that the MN frequency increases with age and this trend is more prominent in females than in males (Norppa *et al*., 2006). On the other hand, Chinese hamster cell lines have a small number of large chromosomes (11 pairs). Chinese hamster ovary (CHO) cells in which there has been an extensive rearrangement of chromosome material, and the chromosome number may not be constant from cell to cell, are frequently used (Doppalapudi *et al*., 2007; Tayama *et al*., 2008). Polyploidy, endoreduplication and high spontaneous CA frequencies can sometimes be found in these established cell lines, but careful cell culture techniques should minimize such effects. Therefore, cells should be treated in their exponential growth phase when cells are in all stages of the cell cycle.

2.3 Solvents, Positive and Negative Controls

When the solvent of a test compound differs from the culture medium or water, the solvent by itself, a mixture of solvent and S9 mix as well as an untreated control without this particular solvent have to be used as negative controls. Since cultured cells are normally treated in their usual growth medium, the solubility of the test material in the medium should be ascertained before testing. Various organic solvents are used, such as dimethyl sulfoxide (DMSO), dimethylformamide, ethanol or acetone. However, where possible, water should be used with the consideration that water greater than 10% (v/v) can be toxic because of nutrient dilution and osmolality change. The solvent/vehicle should (i) not react with the test substance, (ii) be incompatible with the survival of the cells and (iii) should not interfere with S9 activity at the concentration used (OECD, 2007). Extremes of pH can be clastogenic. It has been shown that low pH (pH 6.6) leads to CA and SCE in CHO cells and that these effects are S-phase dependent (Morita, 1995). Osmolality conditions must be maintained (Kirkland, 1992).

A known clastogen should always be included as a positive control. When metabolic activation via S9 mix is used, a positive control chemical known to require metabolic activation should also be used to ensure that the system is functioning properly. Without metabolic activation, a direct-acting positive control chemical should be used (**Table 1**).

2.4 Treatment of Cells

Cultured cells *per se* might not be able to activate various potential clastogens. For this reason, the effects of metabolic activation might be determined by supplementing the treatment regime with S9 mix or by using genetically engineered cells which express biotransformation enzymes (Parry *et al*., 1995). In the latter case, the choice of the cell line used should be scientifically justified (Doherty *et al*., 1996). The phase of the cell cycle during which they are treated poses variations regarding the sensitivity towards clastogens, and thus, the number of MN, CA and SCE induced varies. For this reason, continuous treatment is preferable. This, however, is not a problem when treating in the absence of S9 mix, but treatment over extended periods of time is not advisable in the presence of S9 because it becomes cytotoxic (O'Hare and Atterwill, 1995). Treatments of about three hours are usually carried out. However, cells may be treated with chemicals either continuously up to harvest time or for a short time followed by washing and addition of fresh medium to allow cell cycle progression. When metabolic activation is used, S9 mix should not exceed 1–10% (v/v) within the culture

Table 1 Recommended reference chemicals for MNA and CAT (OECD, 2007)

Category	Chemical	CAS number
1. Direct acting clastogens	Cytosine arabidinose	147-94-4
	Mitomycin C	50-07-7
2. Clastogens requiring metabolic activation	Benzo(a)pyrene Cyclophosphamide	50-32-850-18-0
3. Aneugens	Colchicine	64-86-8
	Vinblastine	143-67-9
4. Negative substances	Di(2-ethylhexyl)phthalate	117-81-7
	Nalidixic acid	389-08-2
	Pyrene	129-00-0
	Sodium chloride	7647-14-5

medium (EPA, 1998a). It has been shown that the S9 mix is clastogenic in CHO cells and mouse lymphoma cells (Cifone *et al*., 1987; Kirkland *et al*., 1989) but not in human lymphocytes, where blood components, for example catalase, can inactivate active oxygen species which could cause chromosome damage. When S9 mix from animals treated with other enzyme-inducing agents, such as phenobarbital/beta-naphthoflavone, is used, clastogenesis may be minimized (Kirkland *et al*., 1989).

Prior to testing, it is necessary to determine the cytotoxicity of the test material, in order to select a suitable dose range for the *in vitro* cytogenetic assay both with and without metabolic activation. The range most commonly used determines the effect of the agent on the mitotic index (MI) in CAT and the NDI, replication index (RI) or cytochalasin-B proliferation index (CBPI) in MNA. For CAT, the highest dose should inhibit mitotic activity by approximately 50% (EPA, 1998a; ECCD, 2000), 75% (Scott *et al*., 1990) or exhibit some other indication of cytotoxicity. If the reduction in MI is too great, insufficient amounts of cells can be found for chromosome analysis. At least 1000 cells per culture are required for the preliminary study in order to determine the MI. For MNA, the CBPI, RI or NDI should be determined from at least 500 cells per culture following the method of Eastmond and Tucker (1989). If treatments are performed without cytochalasin-B, then it is necessary to provide evidence that the cells being scored have proliferated in the culture (EPA, 1998a). Large numbers of publications provide this value as CBPI (Decordier *et al*., 2007; Paiva *et al*., 2008; Yuzbasioglu *et al*., 2008) or NDI (Colognato *et al*., 2007; Yavuz-Kocaman *et al*., 2008). The formula to calculate the NDI is provided by Fenech's protocol in the cytokinesis-block micronucleus cytome assay (Fenech, 2007). The lowest value possible is 1.0, which is only obtainable if all cells fail to divide; however, if all viable cells complete one cell division, then the value is 2.0. The value can only be greater than 2.0 if a substantial proportion of the cells have completed more than one nuclear division (Fenech, 2007). Fenech also describes a more accurate assessment of nuclear division status and provides a modified formula (Fenech, 2000). The inclusion of necrotic and apoptotic cells in the total number of cells scored at higher toxic doses of chemicals provides more accuracy since it can be expected that a proportion of the cells become nonviable. It is therefore important to note that both the binucleated (BN) cell ratio and the NDI are overestimated if necrotic and apoptotic cells are not included when scoring cells (Fenech, 2000).

According to the OECD guidelines, the highest concentration should aim to produce $50 \pm 5\%$ cytotoxicity (OECD, 2007). It is stated in all guidelines that if no cytotoxicity or precipitate is observed, the highest test concentration should correspond to 0.01 M, 5 mg ml^{-1} or 5 µl ml^{-1}, whichever is the lowest and, moreover, the chemical must be tested up to the maximum solubility in the treatment medium and not just the maximum solubility in stock solutions (Scott *et al*., 1990; EPA, 1998a; OECD, 2007).

A minimum of three doses of the test material should be used—the highest chosen as described above, the lowest on the borderline of toxicity and an intermediate one. Up to six doses can be managed satisfactorily, and this ensures the detection of any dose response and that a toxic range is covered. Cells from only three doses need to be analysed.

2.5 Treatment Schedule

Duplicate cultures should be applied to all concentrations investigated, also being strongly recommended for negative/solvent cultures. Single cultures might be acceptable if minimal variations are found when compared to historical data.

For MNA, Fenech (2007) provides a protocol described in a stepwise fashion and it also incorporates the material and equipment required for its performance.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

For complementary information, the OECD guideline 487 is recommended (OECD, 2007). The performance of CAT must be in compliance with the EC Commission Directive 2000/32/EC–B.10 (ECCD, 2000), the OECD guidelines (OECD, 1997a) or the EPA recommendations (EPA, 1998a), which also supplies detailed protocols. Despite the comprehensive information provided in the above-mentioned publications and guidelines, some remarks are necessary. Firstly, the treatment schedule for cell lines and primary cells might differ somewhat from that of lymphocytes which require mitogenic stimulation to begin the cell cycle (Fenech *et al*., 2003). Secondly, it has to be borne in mind that most aneugens and clastogens exert their effects in a short time (3–6 hours) in the presence and absence of S9 (Lorge *et al*., 2006), followed by removal of the test substance and a growth period of 1.5–2 cell cycles. Cells are sampled at a time equivalent to 1.5–2.0 times the cell cycle; however, the sampling time might be extended if it is known or suspected that the test substance might disrupt the cell cycle. If treatment is extended, the presence of S9 mix could be reduced unless compensated for. In the case of MNA, options are offered to allow treatment of the cells with the test chemical in the absence or presence of cytochalasin-B (OECD, 2007). For CAT, a repeated test should include an additional sample at approximately 24 hours if a first experiment produced negative results (OJEC, 1984).

Taking into account the differential sensitivity of the cell towards the chemical depending on the phase of the cell cycle, and therefore variation in the outcome, the most efficient approach for MNA is to test lymphocytes 44–48 hours after phytohaemagglutinin (PHA) stimulation (Fenech, 2007). This is also the case for CAT. This is because cell cycle synchronization has dissipated.

2.6 Scoring Procedures

Prior to scoring, slides should be coded, randomized and then scored 'blind'. Scoring should only be carried out by an experienced observer who knows the criteria. Matching more than one scorer is also advisable. A detailed description of the criteria for scoring with the cytokinesis-block MNA using isolated human lymphocyte cultures was published in 2003 by Fenech and colleagues participating in the Human MicroNucleus (HUMN) project (Fenech *et al*., 2003; HUMN, 2008). However, the most updated criteria for MN scoring have been presented by Fenech (2007), which indicates several parameters to be considered: (i) number of viable mononucleated, binucleated, multinucleated cells per 500 cells scored; (ii) number of apoptotic cells per 500 cells; (iii) Number of necrotic cells per 500 cells; (iv) number of MN in at least 1000 BN cells; (v) frequency of BN cells containing MN in at least 1000 BN cells; (vi) frequency of BN cells containing NPBs in at least 1000 BN cells; and (vii) frequency of cells containing NBUDs in at least 1000 BN cells.

For CA, the classification and nomenclature is based on that established by the International System for Human Cytogenetic Nomenclature (ISCN, 2005). Metaphase cells should be sought under low-power magnification and those with well-spread, that is, nonoverlapping, clearly defined nonfuzzy chromosomes, should be examined under a high-power microscope with oil immersion. It is acceptable to analyse cells with total chromosome numbers or that have lost one or two chromosomes during processing. In human lymphocytes ($2n = 46$) 44 or more centromeres and in CHO cells ($2n = 22$; range 21–24) 20 or more centromeres can be scored. Chromosome numbers can be recorded for each cell, to give an indication of aneuploidy. Only cells with increased chromosome numbers (above 46 in human lymphocytes and 24 in CHO cells) should be considered in this category, since decreases can occur as artefacts through processing steps. Two hundred cells (100 from each of two replicates) should be scored per treatment group. This number can be reduced when high numbers of aberrations are observed. When ambiguous results are obtained, there may be further 'blind' reading of these samples. Although the purpose of the test is to detect structural CAs, it is important to record polyploidy and endoreduplication (EPA, 1998a).

2.7 Data Recording

For MNA, the following information should be included on a score sheet (Fenech, 2007): (i) name of the person scoring the slides; (ii) code number of each slide; (iii) number of BN cells scored; (iv) frequency of MN in 1000 BN cells; (v) frequency of BN cells containing MN in 1000 BN cells; (vi) frequency of BN cells with NPBs in 1000 BN cells; (vii) frequency of BN cells with NBUDs in 1000 BN cells; (viii) frequencies of viable mono-, bi-, tri- and tetranucleated cells, necrotic and apoptotic cells in a total of 500 cells; and (ix) NDI.

Optional additions to the score sheet include (a) the distribution of BN cells with 0, 1, 2, 3 or more MN in 1000 BN cells and (b) the coefficient of variation for duplicate estimates of the above parameters.

Likewise, the information required for CAT must contain the slide code, scorer's name, date, cell number, number of chromosomes and aberration types. These should include chromatid and chromosome gaps, deletions, exchanges and others. From the score sheets, the frequencies of various aberrations should be calculated and each aberration should be counted only once. A space for the Vernier reading, comments and a diagram of the aberration should be available. Recording microscope coordinates of cells is necessary and allows verification of abnormal cells. For cells with aberrations, a photographic record is also useful.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2.8 Presentation and Interpretation of Results

The guidelines clearly state the information that should be included in a test report (OECD, 1997a; 2007; EPA, 1998a; ECCD, 2000). Similarly, Fenech's review (2007) provides the information that a manuscript based on the MNA must contain.

In cytogenetic assays the absence of a clear positive dose-response relationship at a particular time frequently arises. This is because a single common sampling time may be used for all doses of a test compound. CA yields can vary markedly with post-treatment sampling time of an asynchronous population, and increasing doses of clastogens can induce increasing degrees of mitotic delay (Scott *et al*., 1990). Additional fixation times should clarify the relationship between dose and aberration yield. In the case of Chinese hamster fibroblasts, for instance, a number of chemicals which gave negative responses with a fixation time of 24 hours became positive at 48 hours (Ishidate, 1988).

When it comes to the determination of a positive result, the biological relevance of the results should be considered first. Considerations such as obtained values falling within historical records or published literature can provide guidance. Adequate statistical methods must be applied, but must not be the only determinant of a positive response (OECD, 2007). In some instances, it might be worth considering an increase of the statistical power, by performing further testing. Where CA yields are on the borderline of statistical significance above control values, the inclusion of gaps could be useful (Anderson and Richardson, 1981). Further details on this approach may be found in the UKEMS guidelines (Scott *et al*., 1990).

3 *IN VIVO* CYTOGENETICS ASSAYS

Damage induced in whole animals can be detected in *in vivo* chromosome assays in either somatic or germinal cells by examination of metaphases or the formation of micronuclei. The micronucleus test in erythroblasts can also detect whole chromosome loss or aneuploidy in the absence of clastogenic activity and is considered comparable in sensitivity to chromosome analysis (Tsuchimoto and Matter, 1979; OECD, 1997b; EPA, 1998b). Rats and mice are generally used for *in vivo* studies, with the mouse being employed for bone marrow micronucleus analysis and the rat for metaphase analysis, but both can be used for either. Mice are cheaper and easier to handle than rats, and only a qualitative difference in response has been found between the species (Albanese *et al*., 1988). Chinese hamsters are also widely used for metaphase analysis because of their low diploid chromosome number of 22. However, there are few other historical toxicological data for this species.

3.1 Somatic Cell Assays

3.1.1 Metaphase Analysis

Metaphase analysis can be performed in any tissue with actively dividing cells, but bone marrow is the tissue most often examined. Cells are treated with a test compound and are arrested in metaphase by the administration of colcemid or colchicine at various sampling times after treatment. Preparations are examined for structural chromosome damage. Because the bone marrow has a good blood supply, the cells should be exposed to the test compound or its metabolites in the peripheral blood supply, and the cells are sensitive to S-dependent and S-independent mutagens (Topham *et al*., 1983; OECD, 1997c; EPA, 1998c).

Peripheral blood cells can be stimulated to divide even though the target cell is relatively insensitive (Newton and Lilly, 1986). It is necessary to stimulate them with a mitogen since the number of lymphocytes which are dividing at any one time is very low. Cells are in G_0 when exposure is taking place, so they may not be sensitive to cell-cycle-stage-specific mutagens and any damage might be repaired before sampling.

3.1.2 Micronuclei

The assessment of micronuclei is considered simpler than the assessment of metaphase analysis. This assay is most often carried out in bone marrow cells, where polychromatic erythrocytes (PCEs) are examined; damage is induced in the immature erythroblast and results in a micronucleus outside the main nucleus, which is easily detected after staining as a chromatid-containing body (OECD, 1997b). When the erythroblast matures, the micronucleus, the formation of which results from chromosome loss during cell division or from chromosome breakage forming centric and acentric fragments, is not extruded with the nucleus. Micronuclei can also be detected in peripheral blood cells (MacGregor *et al*., 1980). In addition, they can be detected in liver (Tates *et al*., 1980; Braithwaite and Ashby, 1988) after partial hepatectomy or stimulation with 4-acetylaminofluorene, or they can be detected in any proliferating cells.

3.1.3 Germ Cell Assays

The study of chromosome damage is highly relevant to the assessment of heritable cytogenetic damage. Many compounds which cause somatic cell damage have not produced germ cell damage (Holden, 1982) and, so far, all germ mutagens have also produced somatic damage. As tests for germ cell cytogenetics are not prominent in regulatory guidelines, Kirkland contacted 12 regulatory agencies in 1987, sending detailed questionnaires, and 7 responded (Kirkland, 1987). The germ cell tests are rarely requested as a matter of course. When they are

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

indicated, a dominant lethal test (most often) or heritable translocation test (sometimes) would be seen as most useful, not the mouse specific locus assay, due to large animal numbers. As most widely used germ cell cytogenetic assays do not detect inherited mutations or effects on meiotic processes, they were not readily accepted as alternatives. Preston (1994) considered the future of germ cell cytogenetics. It is possible to assess numerical and structural alterations in the male in differentiating spermatogonia, spermatocytes and postmeiotic cells (at the first cleavage division), and for the female in oocytes and the zygote. He predicted that advances would be made in the identification of specific alterations through FISH of interphase spermatozoa in humans (Baumgartner *et al*., 1999). The Comet assay has also allowed the study of effects in human sperm (Anderson *et al*., 2003; Schmid *et al*., 2007).

With the reduction in use of animal studies in recent years, much of the basic research in germ cell systems was carried out two or three decades ago. Germ cell data, however, are still needed for genetic risk estimation, and testing can be performed in male or female germ cells. The former are most often used, owing to systemic effects in females. Testing in the male is performed in mitotically proliferating premeiotic spermatogonia, but chromosomal errors in such cells can result in cell death or prevent the cell from passing through meiosis. Damage produced in postmeiotic cells, the spermatids or sperm are more likely to be transmitted to the F_1 progeny (Albanese, 1987). In females it is during early foetal development of the ovary that oogonial divisions and prophase stages of meiosis up to arrested diplotene stage occur. Therefore, testing necessitates the use of pregnant mothers at suitable gestation stages. The arrested dictyate oocyte stage is the most commonly tested stage in the adult female. To test other stages during the first or second meiotic divisions demands the use of oocytes undergoing ovulation, which occur naturally or are hormone stimulated. It is thus more difficult technically to test female germ cells.

3.2 Heritable Chromosome Assays

Damage may be analysed in the heritable translocation test, which involves the examination in male F_1 animals of diakinesis metaphase I spermatocytes for multivalent association (Leonard, 1973; 1975; Cattanach, 1982). Fertilized ova can also be analysed by cytogenetic analysis (Albanese, 1987), or early embryos can be examined by metaphase analysis (Hansmann, 1973). Such techniques are demanding technically, and the heritable translocation assay requires large numbers of animals to attain appropriate sample sizes. Chromosome damage in fertilized ova or early embryos may not be compatible with survival after birth, so it is only the heritable translocation assay which provides absolute evidence of induced heritable effects. In foetal mice which have been exposed transplacentally after exposure of the mother, tissues can be assessed for micronuclei or metaphase analysis. Cole and colleagues scored MN in polychromatic erythrocytes in the liver or peripheral blood of foetal mice (Cole *et al*., 1981). Such methods have been reviewed and are used to investigate factors which might affect embryos (Henderson, 1986).

3.3 Experimental Design—General Features of *In Vivo* Assays

3.3.1 Treatment of Animals

A control group dosed with a vehicle used routinely or an untreated control will be needed in addition to vehicle controls. Water soluble materials can be administered in distilled water or isotonic saline, and the pH may require adjustment if there is a marked deviation from physiological pH. Various substances other than water can be used as controls. Although DMSO is used within *in vitro* studies, it is not wise to use it in animal studies. It is locally irritant and toxic, and increases the penetration through cell membranes, so altering absorption and distribution patterns. Methyl cellulose or carboxymethyl cellulose (0.5% up to 2%, w/v) can be used as a water-based vehicle for homogeneous suspensions obtained after milling. For those substances that are not miscible with water, corn (maize) oil can be used, but this could affect absorption rates. Tween 80 may also aid in the suspension of non-wettable materials. Routes of administration, such as gavage, intraperitoneal (ip), intradermal or intravenous (iv), can be used with these agents, but for inhalation routes an experienced inhalation toxicologist is required to advise on the most appropriate action.

It is usually necessary to determine the toxicity of the test substance unless this is available from the scientific literature. The test substance is required for regulatory purposes to be tested at the maximum tolerated dose—that is, a dose which produces some signs of toxicity such as hypoactivity, piloerection, ataxia, ptosis or a change in the body weight. Toxicity of the animals is usually observed over a 14 day observation period. In the case of the MNA, to determine toxicity to the cells, the ratio between polychromatic and normochromatic erythrocytes (normocytes or NCEs) can be measured and, in the case of metaphase analysis, MIs. These values are measured over a period up to 72 hours.

The highest dose, when toxicity is not evident, ranges from 2 to 5 g kg^{-1}, according to different regulatory guidelines (Richold *et al*., 1990). A single dose level is considered adequate for screening purposes, but for more extensive evaluation, several dose levels are required. Dose values should not normally exceed 10 ml kg^{-1} by the ip and iv route or 20 ml kg^{-1} by the oral route. There

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is often a 10-fold separation between the upper and lowest dose, and there is also an intermediate dose. Sometimes the lowest dose is selected as the most appropriate for man. Less than 2-fold separation factor for doses should not be considered.

In terms of the route of exposure, there is a need to maximize the chance of absorption or to mimic human exposure. In a collaborative study, the oral and ip routes were compared and found to be equally sensitive when toxicity is accounted for (Hayashi *et al*., 1989), and it was argued that the ip route and the route relevant to human exposure could be used sequentially in the evaluation of a compound (Shelby, 1986). However, Ashby (1985) argued against the ip route as being suitable. In general, the oral route is preferable, and dermal or subcutaneous routes are not used unless it is clear that the compound is absorbed or used by these routes (Ashby, 1985).

A concurrent vehicle control group should be included in each experiment at each sampling time in order to compare the treated groups. Untreated controls can be induced when a nonstandard vehicle is used. A positive control group should be included to confirm the sensitivity of the assay and check on the scoring. A sufficient dosage of the positive control substance is required to check on any reduced assay sensitivity.

Assays are usually performed only once, but if equivocal results are obtained, another study design or alternative dosage route may be considered for sensitivity optimization.

There are various requirements for animal husbandry and welfare, and, in the UK, project and personal licences are mandatory for animal experimentation. Various safety precautions are necessary to protect personnel from exposure to suspect mutagens and carcinogens (Ehrenburg and Wachtmeister, 1977; Waters, 1980), and special waste disposal procedures should be observed.

3.3.2 Rodent Micronucleus Test

The rodent micronucleus test can be used as a sensitive screen to assess hazard or for more extensive/qualitative hazard determinations to aid in risk assessment. Rats and mice can be used and methods are available to avoid contaminating mast cell granules in rats, which stain in a similar way to micronuclei. Fluorescent stains can be used (Hayashi *et al*., 1983; MacGregor *et al*., 1983) as well as haematoxylin and eosin (Pascoe and Gatehouse, 1986). For good-quality preparations, the use of cellulose columns is recommended (Romagna and Staniforth, 1989). Romanowsky-type stains, such as May-Grunwald/Giemsa (Schmid, 1976) or Wright's stain (Albanese and Middleton, 1987) are routinely employed for mouse micronuclei.

It is suggested in various international guidelines (OECD, 1997b; 2007; 1997c) that five males and five females be used per group, although only a few quantitative differences in clastogenic responses have been shown to exist between sexes (Henry *et al*., 1980; CSGMNT, 1986). The use of two sexes has been debated. The EEC, OECD and EPA recommend the use of both sexes but the UKEMS (Richold *et al*., 1990) and Japanese Guidelines (JMHW, 1984) suggest the use of males only. This obviously reduces animal numbers, and Lovell and colleagues state that with a group size of seven, there is not a significant loss in test sensitivity if 2000 PCEs are read (Lovell *et al*., 1989).

Since no qualitative differences exist in response to clastogens, even though different strains of rats and mice have different spontaneous frequencies of micronucleated polychromatic erythrocytes (MPEs) (CSGMNT, 1988), there is no preferred strain. It is appropriate, however, that the spontaneous incidence should not exceed 0.4% (i.e. 4 per 1000 PCEs) (Topham *et al*., 1983). Young animals of 6–8 weeks for mice and 8–10 weeks for rats should be used, to avoid fat deposition in the marrow, since fat in older animals interferes with the clarity of staining.

The experimental unit is the animal and not the cell, but if less than 500 cells are examined clusters of cells might be formed (Albanese and Middleton, 1987; Mirkova and Ashby, 1987). Regulatory guidelines generally require 1000 PCEs scored per animal. Mirkova and Ashby (1987) favoured the reading of 2000 PCEs. However, the minimum number of PCEs to score per animal depends upon the spontaneous frequency of micronuclei; the lower the frequency the greater the number of PCEs per animal requiring analysis to detect a specified level of increase in MPEs. Two thousand PCEs should be scored if the control incidence is less than 0.2%. Confirmation of equivocal results could be achieved by extending numbers of PCEs read before a repeat study. For positive controls, the group size can be smaller (no fewer than three animals), using an optimal sampling time with a dose to monitor sensitivity. To determine toxicity, the PCE : NCE ratio is examined, and alterations in the ratio result from the inhibition of division or maturation of nucleated erythropoietic cells or replenishment of marrow with peripheral blood. A total of 1000 erythrocytes (PCEs and NCEs) should be examined.

For the micronucleus test, either a single-dose study with two harvest times at 24 and 48 hours after treatment or a multiple-dose study with two or three doses 24 hours apart, followed by a single harvest time 24 hours after the last dosing, is considered acceptable (Richold *et al*., 1990). A 72 hour sampling time was initially required, based on the results with 7,12-dimethylbenzanthracene (Salamone and Heddle, 1983), but responses can be shown at earlier times (Ashby and Mirkova, 1987). Most regulatory authorities, however, require three sampling times, and 24 hours is suitable to detect most chemicals which induce micronuclei. It was not necessary to sample the marrow of treated animals earlier than 19–24 hours after dosing (MacGregor *et al*., 1987), since the lifespan of an immature or RNA positive erythrocyte is between

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

10 and 20 hours in both rat and mouse (Salamone and Heddle, 1983).

Usually both femurs are removed and cleared of extraneous muscle. From the proximal end the shafts are aspirated with a needle and the marrow flushed out with serum to obtain a homogeneous cell suspension. The cells are concentrated by centrifugation at 800–1000 rpm for 5 min. A small drop of suspension is spread on the smear-free slide and pulled with a cover glass (Schmid, 1976). Another method is to push the marrow onto the slide with a pin inserted in the epiphysial (distal) end. The marrow is mixed with serum to disperse the cells, using the edge of a second slide (Salamone and Heddle, 1983). Alternatively, a fine sable paint brush in physiological saline is inserted into the distal end of the femur and drawn across the slide for up to four strokes with fewer cells at the end of strokes (Albanese and Middleton, 1987).

The scored elements are the micronucleated cells and not the number of micronuclei. The majority of MN are circular but some are oval or ring shaped; doubtful shapes should not be scored. Cells which are orange/red after staining should be classed as mature (NCEs); those which are bluish as immature (PCEs). The frequency of micronuclei in NCEs should be 0–1 per 1000. For each animal the number of PCEs, NCEs, micronucleated PCEs and micronucleated NCEs as well as PCE : NCE ratio should be recorded. It is not necessary to record Vernier readings for micronucleated cells. The micronuclei arise from anaphase lag of chromosome fragments, bridged translocations or detached whole chromosomes. Detailed recommendations on the type of statistical analysis to be carried out on data generated in this assay have been proposed (Lovell *et al*., 1989). The positive and negative control values should fall within the historical control range for the laboratory. If the test material has been administered at the highest dose and there is a negative response, the test material should be classified as negative under the test conditions. No-effect levels could be used in risk evaluation.

3.3.3 Rodent Bone Marrow Metaphase Analysis

Most bone marrow metaphase assays have been carried out in the rat, although mouse and Chinese hamster are also used. The assay is conducted at doses up to the maximum tolerated dose (MTD) or for nontoxic substances 2 or 5 g kg^{-1}, depending on the regulatory authorities. A dose that causes a 50% reduction in the MI or some other index of cellular toxicity in a preliminary toxicity assay is also used. A single dose may be used for screening purposes but for hazard assessment at least three doses should be used. A dose relevant to man is sometimes included and an intermediate between it and the MTD. Other protocols, including a 10-fold and one-third of the MTD have been used (Anderson and Richardson, 1981) but the UKEMS (Richold *et al*., 1990) recommended that dose levels should be separated by approximately 2-fold intervals. The OECD guideline 475 (OECD, 1997c) recommends five males and five females but the UKEMS (Richold *et al*., 1990) recommends seven males per test group only. The OECD (OECD, 1997c) recommends that 50 cells per animal be scored (500 per test group) and the UKEMS (Richold *et al*., 1990) also recommends that this number is scored.

It was recommended that cells be sampled at 6, 24 and 48 hours after a single dose administration. Cells were also sampled at 6 and 24 hours after a multiple administration. The UKEMS debated the use of a 48 hour sampling and suggested that it should only be used when there was evidence of mitotic delay. This can be determined during the preliminary toxicity assay. OECD guideline 475 (OECD, 1997c) now recommends only two samplings at 24 and 48 hours and after multiple dosing, sampling between 18 and 24 hours and between 36 and 48 hours.

A mitotic arresting agent such as colchicine or colcemid is dosed to the animals at 2–4 hours prior to sampling. Methods for satisfactory stained metaphase spreads have been described (Adler, 1984). All slides should be coded and randomized. Various readings should be taken of aberrations and recorded for future reference and Good Laboratory Practice audits. The classification criteria of Scott *et al*. (1990) can be used and all aberrations should be described fully in the raw data. For each animal, the number of cells scored, the number of cells with each aberration type, the frequency of aberrations including and excluding gaps should be determined. Recommendations on the statistical analysis of this assay have been made by Lovell *et al*. (1989). The positive and negative control values should fall within the acceptable range for the laboratory for a substance to be considered positive or negative under the conditions of the study.

3.3.4 Germ Cell Cytogenetic Assays

Either mouse or rat can be used but the mouse is generally the preferred species. Normally such assays are not conducted for routine screening purposes.

Spermatogonial metaphases can be prepared by Evans' air-drying technique (Evans *et al*., 1964) for the first and second meiotic metaphase (MI and MII) in the male mouse. This method is not so suitable for rat and hamster. The numbers of spermatogonial metaphases can be boosted if, prior to hypotonic treatment, the testicular tubules are dispersed in trypsin solution (0.25%). At least one month between treatment and sample should be allowed to pass in the mouse to allow treated cells to reach meiosis. It was established that 11 days and 4 hours was required for spermatogonial cells to reach preleptotene and 8 days and 10 hours to reach zygotene (Brook and Chandley, 1986). It takes 4 hours for cells to move from MI to MII but test compounds

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

can alter this rate. A search for multivalent formation can be made at MI for the structural rearrangements induced in spermatogonia. Using electron microscopy, it became possible to examine the synaptonemal complex at pachytene (Cawood and Breckon, 1983). Errors of segregation should be searched for at the first meiotic division in the male mouse, MII cells showing 19 (hypoploid) and 21 (hyperploid) chromosomes (Brook and Chandley, 1986). Various groups describe assays in the female mouse and procedures used for inducing ovulation by hormones and treatment of specific stages of meiosis (Hansmann and El-Nahass, 1979; Brook, 1982; Brook and Chandley, 1985).

There are still some differences between ICH and OECD guidelines that must be addressed (Kirkland, 1998; 2002). Examples are: When are differences and toxicity metabolism between males and females sufficient that both sexes need to be used in *in vivo* testing? What is considered sufficient exposure of target tissue for a valid *in vivo* test? When is absorption considered sufficiently low that *in vivo* testing would be considered appropriate? What efforts need to be taken to ensure a compound does not possess a structural alert?

4 SISTER CHROMATID EXCHANGE ASSAYS

SCEs occur between both sister chromatids of replicating chromosomes. They result in a change in morphology of the chromosome at homologous loci, which involves breakage and reunion.

4.1 Historical View

The first visualization of SCEs happened in the late 1950s in plant cells, using radioactive tritium and autoradiography (Taylor, 1958). Then, with the addition of the DNA base analogue 5′-bromodeoxyuridine (BrdU), in combination with Hoechst dye 33258 staining, it was possible to clearly discern the sister chromatids (see **Figure 3**), and to reveal SCEs (Latt, 1973). Later, the Giemsa staining was reported to detect SCEs (Korenberg and Freedlender, 1974). However, the standard method for the visualization of SCEs became the combination of fluorescence plus Giemsa (FPG) (Perry and Wolff, 1974). The FPG procedure is recommended in view of the fact that stained slides can be stored, and microscope analysis is simpler. Alternatives to this method have appeared over the years, for example: utilization of an antibody binding to BrdU-substituted DNA following denaturation (Pinkel *et al*., 1985), such as biotin-16-2′-deoxyuridine-5′-triphosphate (biotin-dUTP) (Wojcik *et al*., 2004), use of DAPI (2-(4-amidinophenyl)-1H -indole-6-carboxamidine) (Lin and Alfi, 1976; Lin *et al*., 1976) or propidium iodide (Tucker *et al*., 1986) in combination with low doses of BrdU. SCE scoring is a time-consuming technique, and the necessary precautions have to be taken to work with BrdU. However, the concentrations of BrdU added to

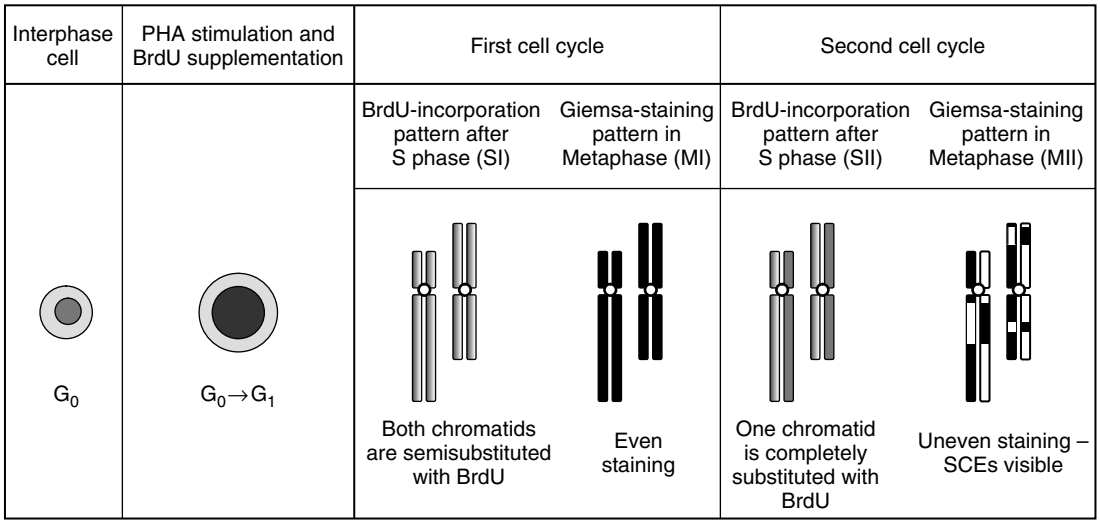

Figure 3 SCEs can be visualized in the second mitotic metaphase as the assay is based on the incorporation of BrdU in the newly synthesized DNA strands during S Phase (semiconservative replication). After PHA stimulation, lymphocytes progress into the first cell cycle. In the first mitotic metaphase the DNA strands of both chromatids are semisubstituted with BrdU leading to an even staining of the chromosomes. In the second mitotic metaphase one chromatid remains semisubstituted with BrdU while the other is fully substituted. This leads to an uneven staining where one chromatid becomes darker than the other. SCEs become visible only then after interchromatid exchanges of similar regions on each chromosome producing 'harlequin' chromosomes.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the culture medium have to be very low not to induce mutagenic effects. Thus, assays which need very low concentrations of BrdU are advantageous.

In general, the methodology developed to reveal the presence of SCEs is based on the semiconservative replication hypothesis (Meselson and Stahl, 1958). Therefore, the requirement to observe SCEs at metaphase is that cells must past through S phase (Wolff *et al*., 1974).

4.2 Mechanism(s) of SCE Generation

Based on the fact that genotoxins linearly induced SCEs and single-gene mutations, it was possible to affirm that SCEs are related to mutational events (Carrano *et al*., 1978). Also research used repair-deficient mutants which, after treatment with genotoxins, yielded an increase in SCEs (Thompson *et al*., 1981). This explains the inability of the cell to repair efficiently replication-blocking lesions, which result in fork collapse and initiation of homologous recombination to repair the broken DNA replication fork upon encountering a nick or a gap in the parental strand (Wilson and Thompson, 2007). In recent years, the underlying molecular mechanisms generating SCEs have become clearer. SCEs seem to result from a mechanism involving the RAD51 dependent double-strand repair (Gonzalez-Barrera *et al*., 2003). Other investigators, however, also claim a nonhomologous end joining (NHEJ) mechanism of repair as an SCEs mediator (Painter, 1980; Bryant and Helleday, 2006). Interestingly, SCEs provide a different and alternative end point when compared to CAs and MNs, since the mechanisms underlying them are dissimilar.

BrdU, a base analogue, by itself contributes to the generation of SCEs (Stoilov *et al*., 2002). This might be due to the highly reactive bromine atom which interacts with agents like ionizing and UV radiation, so enhancing the frequency of SCEs (Wojcik *et al*., 2004). This is likely to be due to the formation of single-strand breaks (SSBs) or alkali-labile sites (ALSs) (Dillehay *et al*., 1984). In addition to compounds generating SSBs and ALSs, other SCE inducers are alkylating agents, base analogues, S phase dependent compounds and inhibitors of fork progression such as mitomycin C. Furthermore, conditions which increase the burden of SSBs, like XRCC1 deficiency (Thompson *et al*., 1982), inhibition of poly(ADP-ribose) polymerase 1 (PARP-1) (de Murcia *et al*., 1997), or inhibition of DNA synthesis (Degrassi *et al*., 1989), contribute to the generation of SCEs.

The baseline SCE frequencies in human and mouse peripheral lymphocytes are 3.6 and 2.4 SCEs per cell per generation (Tucker *et al*., 1986), being invariant at the lowest BrdU levels in humans. Taken together, it is evident that SCEs are an integral part of DNA replication, even in the absence of agents known to induce SCEs. Further, SCEs occur at the replication points (Latt and Loveday, 1978). This is due to a maximal SCE generation at the beginning of the replication which decreases as replication progresses.

4.3 Experimental Design

The SCET is based on the breakage within the sister chromatids and the subsequent exchange of regions within these chromatids. This process is conservative and 'virtually' an error-free process because there is generally no alteration of genetic information during the reciprocal exchange via homologous recombination (Wilson and Thompson, 2007). Visualization, however, requires one chromatid being bifiliarly substituted with BrdU, while the other sister chromatid is monofiliarly substituted. This test has been correlated with recombinational repair, promotion of point mutations, gene amplification, cytotoxicity and estimation of cell division.

Established cell lines, primary cell cultures or rodents may be used. Detailed information on the performance of SCE *in vitro* and *in vivo* assays may be obtained in reviews on SCET (Latt *et al*., 1981; Perry *et al*., 1984; Perry and Thompson, 1984). Guidelines are also available for *in vitro* (OECD, 1986; EPA, 1996a) and *in vivo* (EPA, 1996b) SCE assays. The *in vitro* methods will be briefly explored here.

Either monolayer or suspension cultures can be employed, as well as human lymphocytes. Human fibroblasts are less suitable because of their long cell-cycle duration. When using monolayer cultures, the cultures are set up the day before BrdU treatment so that the cells will be in exponential growth before the addition of BrdU or the test compound. A number of experimental designs can be carried out with SCET (Wojcik *et al*., 2004). SCEs can be visualized by growing cells for either two rounds of replication in the presence of BrdU or for one round with BrdU and the next without. If BrdU is added after cells were treated with a DNA-damaging agent, the effect on SCEs can only be analysed in the second post-treatment mitosis. Analysis of the first post-treatment mitosis requires cells, monofiliarly labelled with BrdU, being treated. Whichever the procedure, the cells are allowed to undergo the equivalent of two cell cycles before cell harvest. A spindle inhibitor such as colchicine or colcemid is introduced for the final 1–2 hours of culture to arrest cells in metaphase, after which the cells are harvested and chromosome preparations are made by routine cytogenetic techniques. Peripheral blood cultures are established in medium containing BrdU and PHA. Colcemid is added 1–2 hours before harvest and the cells are harvested between 60 and 70 hours post PHA

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

stimulation. Cell harvest and slide preparations are conducted according to routine cytogenetic methods.

In the absence of metabolic activation, BrdU and the test agent can be added simultaneously and left for the duration of BrdU labelling. Shorter treatments should be used in the presence of metabolic activation or to avoid synergistic effects with BrdU; then, cells can be pulse treated, for example for 1 hour before BrdU addition (Edwards *et al*., 1993). If metabolic activation is not required, treatment is best conducted during the final 24 hours of culture, or if metabolic activation is required, a pulse exposure may be employed to treat cultures at the first S phase at around 24–30 hours, or at 48 hours for an asynchronous population.

The number of concentrations and cultures, use of duplicates, extended cultures when negatives are found, positives recommended, use of negatives and so on follow the same principles as for MNA and CAT, and these have been detailed previously. However, there are some differences: (i) The concentration of organic solvents for the test compound should not exceed 0.8% (v/v), as higher concentrations could lead to slight elevations in the SCE level (Perry *et al*., 1984). (ii) Exposure of cells to fluorescent light during the culture period leads to photolysis of BrdU-containing DNA and a concomitant increase in SCE frequency (Wolff and Perry, 1974). Consequently, SCE cultures should be kept in the dark and manipulated under subdued light conditions such as yellow safe light. Furthermore, media used in SCE assays should be stored in the dark, since certain media components produce reactive SCE-inducing intermediates on exposure to fluorescent light (Monticone and Schneider, 1979). (iii) Even for an apparently unambiguous positive response with a greater than two-fold increase in SCEs over the background level at the highest dose, and with at least two consecutive dose levels with an increased SCE response, a repeat study is necessary to show a consistent response (Perry *et al*., 1984).

Regarding scoring, slides should be read coded and randomized. The quality of differential staining will determine the ease and accuracy of SCE scoring, and, to eliminate variation, results from different observers should occasionally be compared. Furthermore, to avoid observer bias, matched scorers should have slides from different treatment groups equally distributed among them, as with all cytogenetic studies.

5 HUMAN MONITORING

People exposed to environmental mutagens can be examined for chromosome damage in peripheral blood lymphocytes. Briefly, a sample of blood is taken per individual (about 10 ml), and chromosome preparations are made in the usual way (Evans and O'Riordan, 1975) from the lymphocytes, which have been stimulated into division by a mitogen such as PHA. This is because lymphocytes are normally resting in G_0 stage. A detailed questionnaire is also taken from the individual at the time of blood sampling, relating to lifestyle habits. These could act as confounding factors in study interpretation when increases in chromosome damage are found. Such exogenous lifestyle factors include smoking, drinking alcohol and caffeine, therapeutic drug usage, X-ray examinations, recent viral infections and so on. Endogenous factors (age, gender, etc.) are also taken into account. Such human monitoring questionnaires and appropriate study designs have been described by the International Commission for Protection Against Environmental Mutagens and Carcinogens (ICPEMC) (Carrano and Natarajan, 1988), and many human monitoring studies have been described in a special issue of Mutation Research (Anderson, 1988). International Programme on Chemical Safety (IPCS) guidelines for the monitoring of the genotoxic effects of carcinogens in humans have also been described in a special issue of Mutation Research (Albertini *et al*., 2000).

6 THE HUMAN GENOME

One of the most exciting developments in cytogenetics was the launching of the Human Genome project in 1986 by the Department of the Environment in the USA. The ultimate goal of the project was to analyse the structure of human DNA, to determine the location of all human genes on chromosomes. In April 2003 the draft sequencing of the complete human genome finally finished after one and a half decades (NCBI, 2008a); however, the exact number of genes remains still unknown.

6.1 Mapping and Sequencing the Human Genome

The human genome (build 35) consists of up to 20 000–25 000 genes located on the 23 pairs of chromosomes covering 99% of the euchromatic genome, that is 2.85 billion nucleotides interrupted by only 341 gaps (IHGSC, 2004). By 2006, the completion of the DNA sequence was announced for the last of the different 24 human chromosomes (Muzny *et al*., 2006; Scherer *et al*., 2006). The resulting sequence is a generic sequence representative of humans in general.

The homologue chromosomes from each pair derived either paternally or maternally consist of a DNA–protein complex, which essentially encodes the genes, among other functional elements. The basic DNA structure is represented by a double-stranded helix composed of a linear array of nucleotides carrying four different bases

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(adenine, A, thymine, T, cytosine, C and guanine, G). These bases are precisely paired, opposite to each other (A-T and G-C), and the consecutive order of these bases along the DNA strand determines the information content of a particular gene or piece of DNA. The length of the genes varies, ranging from about 2000 to 2×10^6 bp. Sequencing determines the order of the nucleotides or base pairs in a DNA molecule, while mapping is the process which determines the spacing and position of genes, or other genetic landmarks on chromosomes, relative to one another. There are two types of maps, genetic and physical, which differ in the methods used to construct them and in the measurements used to determine the distance between genes.

Up to 25 000 human genes embedded within 3 billion base pairs have been mapped so far. The National Center for Biotechnology Information (NCBI) database holds today the information on 39 954 genes, including hypothetical genes and open reading frames (ORFs) (NCBI, 2008b). It is presumed that functionally important DNA is conserved among humans. Also, DNA regions, such as genes involved in genetic disease, are still of particular interest. Now that the human genome has been fully sequenced many scientific questions might soon be answered in detail concerning gene regulation, gene function, chromosomal organization, noncoding DNA types, gene sequence variations in diseases, multigene diseases, genomics as well as tanscriptomics.

6.2 Genetic Maps

Genetic maps can be used for the identification of genes associated with genetic disease and other biological properties, and are also used to guide in the construction of physical maps. Genetic maps are constructed by determining the frequency with which two marker genes are inherited together. Those that lie close together are inherited together more frequently than those genes that are further apart. Genetic studies of families determine how frequently two genes are inherited together. The distance between genes is measured in centimorgans (cM). Two markers are 1 cM apart when during transmission from parents to children they are separated 1% of the time. The average distance for a centimorgan is about 106 bp in physical length.

6.3 Physical Maps

The numbers of nucleotide pairs constitute the units of physical length of the distance between sites on physical maps. These can be constructed in different ways derived from recombinant DNA techniques, which allow the isolation and cloning of DNA fragments and the identification of specific sequence markers on DNA, and determine the distance between and order of such chromosome markers.

A position or locus within the genome can be specified by a sequenced genomic clone, an mRNA or sequence-tagged site (STS) or expressed sequence tags (ESTs) marker (Lee *et al*., 2005). Databases at the NCBI (USA) or the UCSC (University of California Santa Cruz, USA) hold the information on millions of these markers. To generate a physical map, a collection of cloned pieces of DNA comprising a complete chromosomal segment or chromosome and the order of cloned pieces may be used. Constructing these overlapping clone sets, known as 'contigs', was one of the key elements in the sequencing endeavour of the Human Genome project; particularly, bacterial artificial chromosome (BAC) clones have been used (McPherson *et al*., 2001). For instance, the human (male) BAC library RPCI-11 consists of over half a million clones with known sequence/end-pair sequence and chromosomal position, covering the genome more than 32 times (Osoegawa *et al*., 2001), which makes them ideal to be used as DNA probes for modern molecular cytogenetic techniques. For large quantity sequencing, BACs have crucial advantages over earlier used clones like cosmids, plasmids, P1-derived artificial chromosomes (PACs) or yeast artificial chromosomes (YACs). They have an ideal insert length of about 200 kb, a small sized vector, they are stable bacterial clones and the BAC DNA is easy to isolate. During the last two decades sequencing became faster and cheaper due to new techniques (von Bubnoff, 2008) and therefore the construction of physical maps became more inexpensive, rapid and routine procedure.

6.4 Model Organisms

Information derived from studies of the biology of model organisms is useful in the interpretation of data obtained in studies of humans and in understanding human biology. In addition to the known human genome, other complete genomes from lower and higher organisms have been fully sequenced. Those identified as useful for comparative purposes are the bacterium *Escherichia coli*, the yeast *Saccharomyces cerevisiae*, the fruit fly *Drosophila melanogaster*, the worm *Caenorhabditis elegans*, the zebra fish *Danio rerio* and the laboratory mouse *Mus musculus*. These organisms' genomes have already been fully sequenced and their sequence can be viewed on the publicly available databases such as NCBI.

7 MOLECULAR CYTOGENETICS

Since the development in the 1970s of chromosomal staining techniques to accurately evaluate numerical abnormalities and structural aberrations, cytogenetics has

DOI: 10.1002/9780470744307.gat075
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

continuously progressed in recent years towards more precise and sophisticated techniques using the advantages gained in molecular biology as well as the knowledge assessed in the Human Genome project.

7.1 FISH and SKY

For the classical staining techniques, dyes like Giemsa have been intensively used, preferably binding to heterochromatic regions, hence resulting in a banding pattern (Bayani and Squire, 2004), which shows 300–850 bands depending on the degree of condensation and time in mitosis (Craig and Bickmore, 1993; ISCN, 2005). With the known longitudinal length of our complete genome of about 3000 Mb, each band at the highest resolution stands for approximately 3.5 Mb; thus, leaving the detection threshold for structural aberrations in typical metaphase preparations at 5–10 Mb. With modern molecular cytogenetic techniques it is now possible to target specific areas of interest using fluorescently labelled DNA probes or to extend the detection towards all chromosomes individually when looking at the whole chromosome set, by introducing differential chromosome staining.

Evaluation of chromosomal damage by FISH has been extensively carried out and improved since this technique was introduced for the classification and detection of chromosome abnormalities in the mid 1980s (Pinkel *et al*., 1986). The variety of fluorescently labelled DNA probes now ranges from whole chromosomal painting probes, chromosome arm or band probes to locus specific gene or sequence probes including repetitive probes for satellites and DNA repeats. In contrast to classical Giemsa staining techniques, more than one colour can be employed and targeted at the area of interest on a chromosome by choosing a suitable probe DNA, for example from the vast selection of BAC clones available. With the successive development of more sophisticated FISH applications by either using an interferometer or a set of optical single band-pass filters, the whole genome can now be evaluated on metaphases with one set of whole chromosome painting probes labelled with different fluorochromes using SKY (Schrock *et al*., 1996) or multiplex FISH (Speicher *et al*., 1996). Especially by targeting interphases (interphases FISH) or stretched DNA strands (fibre FISH) the resolution increased to 5 kb to 2 Mb, depending on the methodology used (Speicher and Carter, 2005). Thus, with these cytogenetic techniques at hand it is possible to evaluate for example cryptic translocations (Barbouti *et al*., 2002) which were hidden and not detectable using classical methods.

7.2 CGH and Array CGH

Comparative genomic hybridization (CGH) is another technique also based on FISH but using a different approach when detecting DNA gain and loss throughout the whole genome (Kallioniemi *et al*., 1992). In brief, isolated genomic DNA from normal tissue and from a tumour is differently labelled with fluorochromes and then hybridized onto metaphases, which are in contrast to the above FISH techniques only used as a hybridization matrix. The information about numerical abnormalities, deletions and amplifications of genetic material is entirely assessed through the ratio of the two fluorescent 'probes'. Utilizing the information the Human Genome project provided as well as microarray techniques together with CGH, a new method was developed: array CGH (Solinas-Toldo *et al*., 1997). For array CGH, the target for of the probe, namely the labelled tumour DNA, is not a metaphase spread but thousands of mapped clones that are spotted on a microscope slide (Fiegler *et al*., 2003). By selecting single-nucleotide polymorphism (SNP) array probes extending up to 100 000 SNPs per array, genotyping is possible as well as the evaluation of loss of heterozygosity (LOH) (Huang *et al*., 2004). These microarray methods either based on glass slides or silicon have the potential to rapidly and accurately screen the genome, for example for oncogenes or tumour suppressor genes in cancers, extending the information accessible from classical methods exponentially (Kashiwagi and Uchida, 2000). It has probably never been easier or cheaper to detect cryptic aberrations routinely for cytogenetic diagnostics on a large scale (Hwang *et al*., 2005; Horsley *et al*., 2006).

Modern cytogenetics has shown the power to detect cryptic aberrations and LOH on a molecular level never seen before. By combining classical cytogenetics with the outstanding variety of molecular cytogenetics, comprehensive high-resolution analysis of complex chromosomal rearrangements becomes possible (Speicher and Carter, 2005), helping to shed new light on inherited diseases and cancer.

8 EPIGENETICS

Any transgenerational phenotype would require transmission through the germ line. However, it has been demonstrated that the exposure of a pregnant rat transiently to endocrine disruptors (the antiandrogenic fungicide, vinclozolin, and the pesticide, methoxychlor) caused a spermatogenic cell defect and subfertility in the F1 generation and all subsequent generations (F1–F4). The critical exposure period was at the time of sex determination, and the transgenerational phenotype was transmitted through the male germ line (Anway *et al*., 2005). A DNA sequence mutation or chromosomal event was not involved since there was no decline of such events in subsequent generations. This suggested an epigenetic mechanism involvement due to the frequency of the phenotype, and two genes were identified in the sperm

that had altered methylation patterns associated with the phenotype; epigenetics appears to involve altered DNA methylation (Anway *et al*., 2005; 2008). Altered methylation of imprinted genes has also been shown to promote disease states (Jiang *et al*., 2004) and when the animals were one year of age additional diseases had developed such as cancer, prostate disease, kidney disease and immune cell defects. According to Skinner, epigenetics is the next layer of complexity beyond the DNA sequence and is likely in future to be a much more important factor in biology than at present realized (Skinner, 2007).

Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation

Elisabeth Lorge

CONTENTS

1 INTRODUCTION

Genotoxicity testing was initially set up to measure any toxic effects resulting in inheritable damage to DNA. For some human carcinogens, a correlation was found between carcinogenicity and genotoxicity assessed by the Ames test (Ames and McCann, 1976). Genotoxicity is a major concern in toxicity as it may cause carcinogenicity and/or genetic diseases. Therefore genotoxicity has become a part of the toxicity regulatory assessment.

Over 30 years of practice in genotoxicity, various tests have been developed, validated and refined. In the 1980s, a large variety of genotoxicity tests emerged from laboratories working on genetics, involving such experimental systems as *Drosophila* or yeasts, with protocols defined in the guidelines of the Organisation for Economic Co-operation and Development (OECD). All these tests were relevant to genotoxicity research but only a few were simple, suitable and reliable enough to justify collaborative efforts on validation and better definition of their profile of detection. Then it was time to refine and improve the protocol of the most widely used tests and monitor experimental conditions more satisfactorily. The standard minimal three-test battery issued by the International Conference on Harmonisation (ICH) for genotoxicity tests for pharmaceuticals, the S2B Guideline, was defined in 1997 for the genotoxic assessment of new pharmaceuticals (ICH, 1997). After 10 years of increasing experience with this core battery in regulatory genotoxicity testing, the time has come to think on what has been learned from this experience. More is known about the limitations of genotoxicity tests and new tools have been developed. For 30 years, different aspects of genotoxicity testing have been evaluated and debated in different groups. Now, various worldwide organizations have taken the lead in improving genotoxicity testing, relying on genotoxicity expertise; that is, the International Workshop on Genotoxicity Testing (IWGT), the European Centre for the Validation of Alternative Methods (ECVAM), the Interagency Coordinating Committee on the Validation of Alternative Methods (ICVAM), the Japanese Center for the Validation of Alternative methods (JaCVAM), the Health and Environmental Sciences Institute (HESI), the ICH and the OECD. The main concerns now are to develop relevant strategies

and adequate complementary tests to the minimal battery in the case of genotoxicity- or carcinogenicity- positive findings in preclinical studies, and to have a better understanding of the different mechanisms likely to induce a genetic change (FDA, 2006). Clear and precise guidelines for human risk assessment, relying on the entire database from all areas of Research and Development, are also being drawn up.

2 AN OVERVIEW OF GENOTOXICITY TESTS

2.1 Recent Advances in Common Genotoxicity Test Methods

The current ICH standard battery for genotoxicity testing of pharmaceuticals has been in use since 1997 (ICH, 1997). It includes a test for gene mutation in bacteria, an *in vitro* test with cytogenetic evaluation of chromosomal damage with mammalian cells, or an *in vitro* mouse lymphoma tk (thymidine kinase) assay and an *in vivo* test for chromosomal damage using rodent haematopoietic cells. This standard minimal battery of genotoxicity tests has been widely recognized as suitable for detecting genotoxic compounds since 1997 and, when negative, as sufficient for demonstrating the absence of genotoxicity. However, improvements have been made to the genotoxicity tests in recent years. New tests or new protocols have been validated. Although the standard battery is sufficient for assessing negative genotoxicity, however, the relevance of *in vitro* positive results has been addressed and it was demonstrated that this current battery is prone to give false *in vitro* positive results. Finally, in the case of positive results in this battery or in rodent carcinogenicity bioassays, additional tests should be conducted, but the appropriate tests and strategies needed for follow-up testing have to be defined more precisely. This section will give an inventory of the standard tests in the minimal battery with their improvements and possible diversifications.

2.1.1 The Bacterial Reverse Mutation Assay

The test for gene mutation in bacteria, namely the Ames test (Ames *et al*., 1973; 1975), has been used for years and is the oldest test used for genotoxicity assessment. The *Salmonella typhimurium* strains used are histidine deficient due to base substitutions or frameshift point mutations. They all come from the Bruce Ames collection of strains, originally designed to study the histidine operon, and are highly sensitive to reversion using most chemical mutagens of various types (Ames and McCann, 1976). Strains TA1535, TA1537, TA98 and TA100 will detect mutagens which are able to induce reversion of these mutations at the guanine–cytosine sites within the histidine gene. Additional strains such as *Salmonella typhimurium* TA102 or *Escherichia coli* WP2 uvrA or WP2 uvrA (pKM101), both tryptophan deficient, will be able to detect point mutations at the adenine–thymine sites (Levin *et al*., 1982). *Salmonella typhimurium* TA102 or repair-proficient WP2 *Escherichia coli* (pKM101) will be used to detect crosslinking agents (Mortelmans and Zeiger, 2000; Gatehouse *et al*., 1990; Maron and Ames, 1983).

Few changes have been made to the standard protocol over the years (OECD, 1997a). A metabolic activation, generally provided by the Aroclor 1254-induced rat liver microsomal fraction (S9) added with cofactors (S9 mix), is needed to metabolize chemicals via cytochromes P450 (see Section 3.3). In the plate incorporation method, a preparation of the tested compound is mixed with the tester strain, S9 mix, when required, and top agar, and poured on agar plates. After two or three days' incubation at 37 °C, colonies are counted. In the preincubation method, the bacteria are exposed to the compound with S9 mix in liquid medium at 37 °C. This procedure is presumed to increase the availability of reactive compounds to the bacteria (Mortelmans and Zeiger, 2000).

This test is the very first step in genotoxicity evaluation and, although it is performed on a prokaryote, it is recognized as being the most robust of the genotoxicity tests.

2.1.2 In Vitro Mammalian Cell Genotoxicity Assays

The most commonly used *in vitro* mammalian genotoxicity assays are either the L5178Y mouse lymphoma cell mutation assay or the *in vitro* chromosome aberration test, as recommended in the ICH S2B guideline (ICH 1997; OECD, 1997b; 1997c). The *in vitro* micronucleus assay is also often used as a screening or additional test to the minimal standard battery. It has recently been regarded as validated by the ECVAM (2006), and an OECD guideline is in preparation. It could be used in the future for *in vitro* genotoxicity assessment on mammalian cells as an equivalent to the mouse lymphoma cell mutation assay or the *in vitro* chromosome aberration test.

For any *in vitro* mammalian cell genotoxicity test, the recommendation is to expose cells for approximately 1.5 normal cell cycles without metabolic activation in addition to a short treatment time. Such a long treatment time is expected to allow compounds interacting with the cell cycle to be detected more efficiently (nucleotide analogues or aneuploidy inducers), or is recommended in cases where a high exposure level was impossible to achieve in short treatments. For any *in vitro* genotoxicity test, an exogenous metabolic activation system is required

for short treatments unless the cells used are proved to be metabolically competent.

2.1.2.1 The In Vitro Chromosome Aberration Test

The *in vitro* chromosome aberration test is designed to detect clastogenic activity on cultured mammalian cells. Structural chromosome aberrations are recorded after cell exposure to the tested compound. Various cell types can be used, provided cells are actively dividing at the time of treatment, are karyotypically stable and have a low spontaneous frequency of chromosome aberrations. For example, they could be mitogen-stimulated human lymphocytes in primary cultures, or Chinese hamster ovary (CHO) or Chinese hamster lung (CHL) established cell lines (Galloway *et al*., 1994).

The advantage of the *in vitro* chromosome aberration test is that it can identify the type of chromosomal aberration induced and can also be performed on normal human cells, but it is tedious, and time consuming.

Lymphocytes from whole blood or isolated lymphocytes are induced to divide in culture by a mitogen (phytohaemagglutinin). Cells are exposed to the test compound after the completion of 48 hours culture, so that each cell division stage will be represented in the cultures of asynchronous cells. For cell lines, actively growing cells are seeded at a density so that they will not reach confluence before harvest. Cells are exposed to the test compound for a short treatment period with and without metabolic activation, and sampling will take place after a recovery period of about 1.5 cell cycle length after the treatment has started. If negative results are obtained, cells will be exposed for a long, continuous period until sampling (about 1.5 normal cell cycles after the start of treatment). Longer treatment times (e.g. 48 hours until sampling) or longer recovery periods could be useful in detecting compounds which cause the cell cycle to slow down. Before harvest, cells are exposed to a metaphase-arresting substance (e.g. colchicine) so that the cultures will contain a large number of metaphase-arrested cells to allow individual chromosomes to be examined. Using this protocol, chromosomes will be examined at the post-treatment metaphases (Scott *et al*., 1990; Obe and Beek, 1982). Cells are prepared, fixed, spread on slides and stained for examination under a microscope. Analysed concentrations are selected on the basis of cytotoxicity, generally measured by the mitotic index; the highest concentrations inducing at least 50% cytotoxicity (see Section 3.2). Clastogenic activity is measured by scoring the number of abnormal metaphases and the number of breaks. Good standards for slide scoring are crucial for an accurate evaluation of clastogenicity (Savage, 1975). Chromosome and chromatid breaks, as well as chromosome or chromatid exchanges, should be recorded separately so that a specific cell stage effect can be detected if further investigations are deemed useful in elucidating a mechanism of action. Breaks are distinguished from gaps, achromatic lesions where DNA remains undamaged, by the evidence of a discontinuity in the chromosome or chromatid (Bauchinger *et al*., 1976). As gaps do not result from genetic events but reflect protein modifications along the chromatin, they are related to cytotoxicity. Therefore, they are excluded from the recording of abnormal metaphases. It can also be useful to deduce, from the type of aberration observed, the number of primary breaks theoretically needed to produce the observed structural aberration (Savage, 1975). It allows quantification of aberrations, taking their gravity into account. Generally, numerical aberrations (polyploidies or endoreduplications) are recorded concurrently with the evaluation of clastogenicity (see Section 3.4) to give an indication of possible aneugenic effects.

2.1.2.2 The L5178Y Mouse Lymphoma Cell $tk^{+}/_{-}$ Mutation Assay

The mouse lymphoma cell mutation assay is more straightforward than the chromosome aberration test, less time consuming and able to detect some aneugens, whilst the chromosome aberration test gives only indications of aneugenic effects. In the mouse lymphoma cell mutation assay, the mutation frequency at the tk locus on the L5178Y cell line is measured by the number of 5-trifluorothymidine-resistant (TFT^{R}) colonies, obtained by forward mutation from the parental type ($tk^{+}/_{-}$) to the mutant form ($tk^{-}/_{-}$). After a two-day expression period after treatment, cells are cloned in a selective medium and allowed to form mutant colonies after several days' incubation at 37 °C.

The mouse lymphoma assay was initially developed as the soft agar version (Clive *et al*., 1972; 1979). The protocol of the mouse lymphoma assay has gradually been improved over the years and is now widely used in genotoxicity assessment of pharmaceuticals. First, the microwell method based on the fluctuation test was developed (Cole *et al*., 1983; Oberly *et al*., 1997) to avoid interferences due to metabolic cooperation between mutant cells and to make the detection of mutant colonies statistically more reliable. The agar cloning method is still acceptable as there are insufficient experimental data to prefer one method over another. The colony sizing added value to the test as it was shown to be a good indicator of clastogenicity (Davies *et al*., 1995; Moore and Doerr, 1990). Indeed, the size of the mutant colonies is known to be related to the type of induced mutation, small colonies resulting mainly from large deletions or chromosome rearrangements, and large colonies resulting mainly from point mutations or small deletions. Adding a 24 hour treatment without metabolic activation to a negative 3–4 hour treatment has been shown to be useful in detecting nucleotide analogues as well as aneuploidy inducers (Honma *et al*., 1999; Moore *et al*., 2007).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Good standards for variability and statistical analysis are extensively described throughout the reports of the successive workshops including IWGT work groups (Clive *et al*., 1995; Clements, 2000; Moore *et al*., 2000; 2002; 2003; 2006; 2007). The assessment of cytotoxicity as well as acceptability and positivity criteria were also debated and agreed during these workshops. Relative total growth (RTG), based on cloning efficiency at time of mutant selection and cellular suspension growth over the two-day expression period, was definitively recommended as the appropriate measure for cytotoxicity (Moore *et al*., 2000). Positive results obtained at RTG <10% should be cautiously interpreted, as cytotoxicity-related genotoxicity effects could be induced at such a cytotoxicity (ICH, 1995). Acceptable values for suspension growth were set at 8–32 for 3–4 hour treatments and 32–180 for 24 hour treatments, and the limits for cloning efficiency at the time of mutant selection were set at 65–120%. The mutation frequency in the negative controls must be between 50 and 170 mutant colonies per 10^6 cells for the microwell version of the test and between 35 and 140 mutant colonies per 10^6 cells for the cloning agar version. In addition to the evaluation of the magnitude of an increase in mutation frequency over the negative control, the assessment of a positive response was improved by the use of the global evaluation factor (GEF). It represents the value by which the induced mutation frequency should exceed the negative control to consider a positive result as biologically relevant. Based on interlaboratory surveys, the GEF (Moore *et al*., 2003) should be 126 mutant colonies per 10^6 cells for the microwell version of the test and 90 mutant colonies per 10^6 cells for the cloning agar version.

2.1.2.3 *The In Vitro Micronucleus Test*

Micronuclei may originate either from acentric chromosome fragments resulting from chromosomal rearrangements or from breakages; that is, typically clastogenic effects produced by initial mutagenic events. They can also originate from whole chromosomes unable to migrate to the cell poles during the last stages of cell division under the action of an aneugen. Then micronuclei can be observed in the cells at the next interphase stage. When using primary cell cultures, like mitogen-stimulated human lymphocytes from whole blood or isolated lymphocytes (Elhajouji *et al*., 1994), cytochalasin B (an actin assembly inhibitor inducing a cytokinesis block) is added prior to the next interphase, so that cells which had completed one division appear as binucleated cells (cytokinesis-block method; Fenech, 1993). If cell lines are used, the use of cytochalasin B is not mandatory, provided cells are actively dividing. Cytotoxicity is evaluated by different means depending on whether cytochalasin B is used or not: cytokinesis-block proliferation index (CBPI) when cytochalasin B is used, or increased cell counts (ICCs) or population doubling (PD) when cytochalasin B is not used, based on cell counts (see Section 3.2).

The *in vitro* micronucleus test was first used in genotoxicity in the 1970s. Experience of this system was first gained in studies on human lymphocytes mostly performed for biomonitoring purposes (Fenech and Morley, 1985; Norppa *et al*., 1993a; Van Hummelen and Kirsch-Volders, 1992). Since then, due to its simplicity, it has been widely used in genotoxicity testing, especially as a screening tool for pharmaceutical research. Automated and miniaturized versions of the test have been developed for this purpose (Van Hummelen *et al*., 1995; Frieauff *et al*., 1998; Verhaegen *et al*., 1994; Nesslany and Marzin, 1999).

The use of human lymphocytes, especially for screening tests, may be limited by the availability of the cells and by the variability between human donors. Therefore, a wide variety of cells are also used to detect the induction of micronuclei in various fields of investigation, like environment or tissue-specific carcinogenesis, for example, using different cell types such as hepatocytes or keratinocytes. Suitable cell types for the *in vitro* micronucleus test also include cell lines, which are chosen for their growth capabilities and their karyotypic stability.

Data from this test have been accumulated from the literature (Garriott *et al*., 2002) and through several collaborative validation studies (Elhajouji and Lorge, 2006; Lorge *et al*., 2006; Matsushima *et al*., 1999; von der Hude *et al*., 2000). These studies have shown the accuracy of the *in vitro* micronucleus test for detecting clastogens and aneugens, and have confirmed that different cell lines are suitable for scoring micronuclei in addition to human lymphocytes (Clare *et al*., 2006): CHO cells (Aardema *et al*., 2006), CHL cells (Wakata *et al*., 2006), V79 hamster cells (Miller *et al*., 1998), and the L5178Y mouse lymphoma cell line (Oliver *et al*., 2006), allowing comparisons with the mouse lymphoma assay, and, more recently, the human TK6 lymphoblastoid cell line (Zhang *et al*., 1995; Le Fevre *et al*., 2007). A standard protocol was designed at the IWGT meetings (Kirsch-Volders *et al*., 2000; 2003a). Now the *in vitro* micronucleus assay is recognized as validated by the ECVAM (2006), and a specific OECD guideline is in preparation (OECD, 2008).

In addition to the use of the *in vitro* micronucleus assay as a standard test of the regulatory battery, the *in vitro* micronucleus test is used to discriminate aneugens from clastogens, by means of complementary techniques such as fluorescence *in situ* hybridization (FISH) with centromeric DNA sequences (Migliore *et al*., 1993) or kinetochore-specific staining (Norppa *et al*., 1993b). This is a valuable tool which is used to gain a better understanding of the mechanisms of aneuploidy (Fenech, 2007) and to determine thresholds for aneuploidy (see Section 3.6) when a compound is found positive in an *in*

vitro genotoxicity test and needs further complementary genotoxicity studies.

2.1.3 In Vivo Genotoxicity Assays

In vivo genotoxicity assays are crucial in determining the relevance for the organism of negative or positive findings obtained in *in vitro* experiments. In the whole animal, where adsorption, distribution, metabolism, detoxification and excretion are fully functional, *in vitro* positive results may not be confirmed in *in vivo* testing or, conversely, positive results could be found in the animal but not detected in *in vitro* experiments. Both situations could be due to inadequate metabolism in *in vitro* tests, irrelevant levels of exposure, differences in specificity, sensitivity or cytotoxicity between *in vitro* and *in vivo* test systems, or due to multistep indirect genotoxicity mechanisms not efficient in *in vitro* systems. Therefore, *in vitro* and *in vivo* test systems are complementary.

2.1.3.1 The Rodent In Vivo Erythrocyte Micronucleus Assay

Micronuclei arise during the anaphase step of mitosis as a result of the loss of a fragment of chromosome (clastogenicity) or the loss of a whole chromosome (aneuploidy). As micronuclei are expelled into the cytoplasm, they can easily be seen in the erythrocytes, which lack a main nucleus. The *in vivo* micronucleus assay was initially performed on bone marrow (Schmid, 1975; Heddle *et al*., 1983; Richold *et al*., 1990), which is easily exposed to the test substance or its derivatives. Bonne marrow is collected from animals receiving the test substance at different times after one or more (generally two) daily treatments. Bone marrow cells are then suspended, spread on slides and stained with May-Grünwald Giemsa to distinguish polychromatic (immature) erythrocytes from normochromatic (mature) erythrocytes. DNA-specific fluorescent stains (e.g. Acridine Orange) are also increasingly used because they make it easier to distinguish between true micronuclei and artefacts (Hayashi *et al*., 1983; Tinwell and Ashby, 1989). Erythrocytes are analysed for the presence of micronuclei (OECD, 1997d).

Due to a clastogenic or an aneugenic effect, the frequency of micronucleated polychromatic erythrocytes is increased. A clastogenic effect is revealed by an increase in micronucleated polychromatic erythrocytes starting about eight hours after bone marrow exposure to the test substance. An aneugenic effect is characterized by an increase in micronucleated polychromatic erythrocytes as early as about six hours after administration, proving that the test substance or its derivatives had interacted with the mitotic process. A clastogenic or aneugenic effect may be observed up to 48 hours after administration, depending on the pharmacokinetic properties of the test substance or on any inhibition of the cell cycle it induces (Hart and Hartley-Asp, 1983). Due to its simplicity and the possibility of scoring a high number of cells per animal (2000 polychromatic erythrocytes recommended), the micronucleus test is the most widely used *in vivo* test, compared to the *in vivo* chromosome aberration test, considered equally appropriate for *in vivo* genotoxicity assessment in the current ICH S2 guideline.

Except for specific purposes, young adult animals are used. For a long time, the *in vivo* micronucleus assay has been performed mainly on mice. However, as a species widely used in toxicology assessment, with data on toxicology, toxicokinetics and pharmacokinetics, rats are more often used for the *in vivo* micronucleus assay in pharmaceutical development (Krishna *et al*., 1991). Choosing the species used in general toxicity studies, the micronucleus test can also be integrated into repeated toxicity studies. Using the same animals for toxicity and genotoxicity purposes has the advantage of reducing the number of animals needed for toxicity studies. Additionally, in some cases, repeated treatment may increase exposure to the tested substance, and in any case will be closer to human exposure conditions. Prospective studies have already been performed for feasibility (Garriott *et al*., 1995; Hamada *et al*., 2001). Recommendations on practical aspects of a repeated integrated micronucleus assay using the same animals are under evaluation. Another major concern being evaluated is the choice of doses, because in repeated dose studies the highest tolerated dose should be, in a number of cases, lower than the maximum tolerated dose in acute treatment when the test compound exhibits toxic effects. The criteria for appropriate dose level acceptability are currently being refined.

In terms of integrating the micronucleus test into repeated toxicity studies, it might be preferable to examine polychromatic erythrocytes from peripheral blood rather than erythrocytes from bone marrow. Blood is easier to collect, and could be sampled at different times during the study without interfering with the conduct of a toxicity study. Using polychromatic erythrocytes from peripheral blood has proved satisfactory on mice where the spleen is unable to remove micronucleated erythrocytes from peripheral blood (CSGMT, 1995); therefore, steady state frequencies of micronucleated erythrocytes are similar in bone marrow and peripheral blood. In contrast to mice, rats selectively remove micronucleated erythrocytes from peripheral blood due to the spleen function (Schlegel and MacGregor, 1984), as in humans and dogs. This may theoretically have an impact on the ability to detect micronucleated erythrocytes in rat peripheral blood. This is being evaluated by the ICH revision working group, as previous studies have experimentally shown that most clastogens and aneugens are detected using rat peripheral blood erythrocytes (Hamada *et al*., 2001). The development of the micronucleus assay using peripheral blood and the use

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of fluorescent staining promoted the automated detection of micronuclei by flow cytometry (Hayashi *et al*., 2000). Another acceptable method for automated scoring of micronuclei is image analysis, provided it is appropriately validated (Romagna and Staniforth, 1989).

Many variations of the initial erythrocyte micronucleus assay are expected in the next few years, improving the predictivity of *in vivo* genotoxicity testing further (Hayashi *et al*., 2007).

2.1.3.2 The In Vivo Mammalian Bone Marrow Chromosome Aberration Test

The *in vivo* chromosome aberration test (Preston *et al*., 1987; Tice *et al*., 1994) is performed on the bone marrow of animals as in the *in vivo* micronucleus assay, but, after animals have received a metaphase-arresting agent, cells are prepared as they are in an *in vitro* chromosome aberration test (see previous sections) (OECD, 1997e). Generally, rats or Chinese hamsters are preferred to mice, whose chromosomes are small and of the same morphology. The analysis, as in the *in vitro* assay, is tedious and time-consuming and only the presence of polyploidies or endoreduplications will give an indication of a potential aneuploidy, whilst the *in vivo* micronucleus test detects aneugens. However, the *in vivo* chromosome aberration test is useful when the *in vivo* micronucleus assay is prone to give false positive results (see Section 2.2) or if, for example, the hamster is a much better model of human metabolism than rats or mice.

A variation of the test consists in collecting lymphocytes from animals receiving the test compound, inducing mitogenesis of these lymphocytes in cell culture and then obtaining metaphase spreads on slides. Such a method could be used in toxicology studies as lymphocytes are easy to collect at any time during a study (Flammang *et al*., 2007).

2.2 The Limitations of the Genotoxicity Tests

2.2.1 Bacterial Reverse Mutation Assay

Although *Salmonella typhimurium* TA102 or repair-proficient WP2 *Escherichia coli* (pKM101) will allow detection of crosslinking agents, the Ames test is poor at detecting clastogens that induce large DNA deletions because if the target sequence in the histidine or tryptophan gene of the tester bacteria is deleted, reversion to auxotrophy (histidine or tryptophan independence) cannot occur. The test is very specific, but subsequently not very sensitive. The highest tested concentrations will be limited for antibiotics and will be inefficient for specifically mammalian-cell-acting agents, such as topoisomerase inhibitors, for example. In fact, it is frequently observed that negative compounds in the Ames test could be revealed as positive in mammalian genotoxicity tests (see the Section 2.2.2).

On the other hand, attention should be paid to molecules able to free some histidine or tryptophan in the selective medium, hence artefactually increasing the number of apparent revertant colonies when using *Salmonella typhimurium* or *Escherichia coli* histidine or tryptophan mutants (Grüter *et al*., 1991).

2.2.2 In Vitro Mammalian Cell Genotoxicity Assays

The limitations of the *in vitro* mammalian test systems have been addressed for a long time (Zeiger, 1997). The difficulty in assessing the relevance of these systems compared to carcinogenicity data were often pointed out because carcinogenicity bioassays are not always the most relevant reference, and very few data exist on human carcinogenicity.

It is known that mouse lymphoma L5178Y cells might be theoretically more susceptible than other cells to genotoxic damages as they produce a dysfunctional p53 protein (Storer *et al*., 1997). In a recent compilation work, the limits of the *in vitro* mammalian cell assays were addressed (Kirkland *et al*., 2005). It was shown that the *in vitro* chromosome aberration test and the mouse lymphoma assay were lacking specificity, and that the current ICH genotoxicity battery is prone to give false *in vitro* positive results.

Of course, some of the Ames negative compounds found to be positive in at least one *in vitro* mammalian genotoxicity test are truly positive, but only detected on mammalian cells. Others may result from extreme culture conditions. Extreme pH and osmolality have been known for a long time to induce artefactual effects such as chromosome breakage (Brusick, 1986; Scott *et al*., 1991; Kirkland and Mueller, 2000; Moore and Brock, 1988). Therefore, it is recommended that pH and osmolality should be systematically checked and should not vary by more than 0.5 pH unit or 50 mOsm kg^{-1} compared to the culture medium in any of the *in vitro* mammalian cell systems ($tk^{+}/_{-}$ mouse lymphoma assay, *in vitro* chromosome aberration or *in vitro* micronucleus assay). So, cells are exposed to the compound under physiological conditions and the culture conditions will not be responsible for false positive responses.

However, extreme conditions or mammalian-specific effects do not account for all of the excess positive genotoxic responses seen in the *in vitro* mammalian cell assays. The questions addressed in the essential review of Kirkland *et al*. (2005) and the ECVAM workshop (Kirkland *et al*., 2007) are the adequacy of the current standard battery and the relevance of the high doses chosen on the basis of such a nonphysiological cytotoxicity of 90% for the mouse lymphoma assay, for example, or set at 10 mM for the noncytotoxic compounds.

2.2.3 In Vivo Micronucleus Assay

Modified erythropoiesis and changes in body temperature have been shown to interfere with micronuclei production. It is now well established that a chemically-induced decrease in body temperature, or bleeding or haemolysis, leading to accelerated erythropoiesis, may artefactually increase the spontaneous level of micronuclei.

As early as in 1985, the effects of the stimulation of erythropoiesis on the frequency of micronucleated erythrocytes were reported in peripheral blood of mice (Steinheider *et al*., 1985). The effects of erythropoietin or bleeding (Suzuki *et al*., 1989a; Hirai *et al*., 1991) on the frequency of bone marrow micronucleated erythrocytes were reported in the literature. Further studies extensively demonstrated the role of erythropoietin in the production of micronucleated erythrocytes in mice, without any concomitant genotoxic effect on the induction of chromosome aberrations in bone marrow cells (Yajima *et al*., 1993a; 1993b; 1993c; Jones and Fos, 2003), showing that it was due to a specific nongenotoxic effect on erythropoietin-receptive cells.

The mechanism of this increase in micronucleated cells is based on the acceleration of differentiation and multiplication of erythroblasts in response to bleeding, chemical-induced haemolysis or erythropoietin stimulation, making DNA repair less efficient, chromosome missegregations and disturbance of the enucleation process more frequent when cells are rapidly dividing (Suzuki *et al*., 1989b; Hamada *et al*., 2001). It has also been established in rats (Hamada *et al*., 2001; George *et al*., 1990).

These data were considered sufficiently convincing by authorities or scientists involved in the process of regulatory changes in genotoxicity testing. Indeed, in regulatory assessment, a recent example was given with 2-hydroxy-1,4-naphtoquinone, the natural dye ingredient of Henna (Marzin and Kirkland, 2004). Positive responses in mice bone marrow micronucleus assays were attributed to haematotoxicity. Therefore, this compound was regarded as safe for human use. The regulation position can also be illustrated by the issues debated at the recent IWGT (Tweats *et al*., 2007a), where erythropoiesis was clearly reported as a cause of nonrelevant *in vivo* positives, with the need to carry out another test.

Hypothermia has also been shown to induce increases in the frequency of micronucleated bone marrow erythrocytes in mice (Asanami and Shimono, 1997; 2000; Asanami *et al*., 1998; Hamada *et al*., 2001; Guzman *et al*., 2004). The mechanism is still unclear. An explanation is that hypothermia indirectly induces erythropoietin stimulation. Therefore, accelerated erythropoiesis results in enucleation anomalies as shown above. Because these micronuclei are produced from fragmentation of the interphase nucleus, hypothermia should have no effect on chromosomal aberrations. At the IWGT meeting in September 2005 (Tweats *et al*., 2007a), hypothermia was clearly reported as a cause of nonrelevant *in vivo* positives.

In conclusion, when a compound is suspected to act on erythropoiesis before the *in vivo* genotoxicity evaluation, directly or through hypothermia, it will be preferable to use the *in vivo* chromosome aberration test on bone marrow rather than the *in vivo* micronucleus test to evaluate the genetic potential of the compound, as it is less prone to produce irrelevant results in that case. Indeed, the *in vivo* chromosome aberration test can be used equally to the *in vivo* micronucleus assay without any justification, as both are considered equivalent by authorities (ICH, 1997), provided there is a test in the battery for the detection of aneuploidy.

Conversely, some compounds have been found to be positive only *in vivo*. The genotoxicity assessment of such compounds has been extensively reviewed by the working group of the IWGT (Tweats *et al*., 2007b). Differences in metabolism *in vivo* and *in vitro*, higher exposure *in vivo* in the target cells and alteration in cell lines of normal regulation pathways may account for these apparent discrepancies. Most of these cases were predictable considering the pharmacological activity, metabolism and pharmacokinetics of the tested compounds.

2.3 Additional Genotoxicity Tests and Other Tools

2.3.1 Tests for Measuring DNA Primary Lesions

Before transformation of a DNA lesion in an inheritable stable modification, an interaction between the genotoxin and DNA can be detected. Tests able to measure these primary lesions can be useful for discriminating between DNA-reactive genotoxins and indirect genotoxins. However, the results from these tests should be cautiously interpreted in relation to the possibility of thresholds, because these primary alterations are normally repaired and do not always result in permanent genetic alterations.

2.3.1.1 The UDS Test

In the standard *in vivo* unscheduled DNA synthesis (UDS) test, animals receive the test compound and the liver is collected for analysis. Liver cells are suspended and seeded onto plates for primary cultures in the presence of radiolabelled thymidine, a precursor of DNA synthesis. If DNA lesions have occurred, they are susceptible to be repaired by the excision-repair system, and a subsequent incorporation of radioactivity in the nuclei will be detected by autoradiography (Ashby *et al*., 1985; Butterworth *et al*., 1987; Kennely *et al*., 1993; OECD,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat076
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1997f). The UDS test was at first developed *in vitro* on primary cultures of treated hepatocytes. Now, the *in vivo* UDS test is widely used to detect test chemicals that would be missed in other genotoxicity tests and is recommended for additional testing by the current ICH S2 guideline (ICH, 1995). It is one of the tests recommended as follow-up for genotoxicity testing in relation to tumour findings in rodent carcinogenicity bioassays (Kasper *et al*., 2007) and is useful for testing the hypothesis of a non-DNA reacting genotoxic compound. The *in vitro* UDS on treated hepatocytes can also be used as an additional test to the standard battery (Madle *et al*., 1994). Compared to the *in vivo* UDS assay on liver, the *in vitro* UDS assay will help to assess the relevance of *in vitro* positive results.

The UDS test has the advantage of displaying Phase I and Phase II metabolic capacities, using whole animal or isolated liver cells, which are more representative of the real situation. In addition, metabolites are formed at, or very close to, the presumed site of genotoxic action, allowing the detection of various procarcinogens (Anderson *et al*., 1997; Wolterbeek *et al*., 1993).

2.3.1.2 The Comet Assay

In the Comet assay, isolated cells prepared from either cell cultures (*in vitro* Comet assay) or from any organs of treated animals (*in vivo* Comet assay) are prepared as a cell suspension, mixed with agarose and spread on slides. After an *in situ* cell lysis and DNA unwinding, slides are subjected to an electric field for electrophoresis of fragmented DNA, and stained with a DNA-specific fluorochrome. The technique has been standardized using an alkaline buffer (pH $>$ 13) for DNA unwinding and electrophoresis (Hartmann *et al*., 2003). Under the action of the electrophoretic field, DNA fragments will migrate from the nucleus according to their size, forming a DNA tail more, or less, extended (Comet tail). Slides are analysed under the microscope for the percentage of DNA in the tail, tail length and moment. An image analysis system is recommended for this analysis. The Comet assay detects single- and double-strand DNA breaks, resulting from oxidative damage, DNA–DNA, DNA–proteins crosslinks and alkali-labile sites. However, this pattern of detection of DNA lesions is not restricted to primary events resulting in clastogenicity because abasic sites, related to gene mutation, can also be detected. The Comet assay has the advantage of being applicable to any cultured cell type *in vitro* or to cell suspensions prepared from any organ. For this reason, the *in vivo* Comet assay is very useful in assessing the possibility of a compound which tested positive in the *in vitro* mammalian cell systems acting through DNA damage, and in addressing the mode of action of a compound inducing tumours in a rodent carcinogenicity bioassay when it is negative in the *in vitro* genotoxicity battery (Hartmann *et al*., 2004). Using any organ also provides a surrogate to the *in vivo* bone marrow micronucleus test in case local exposure is higher than systemic exposure. Compared to the UDS test, the Comet assay could be more sensitive in that it better detects small lesions than the UDS test and is not restricted to lesions repaired via an excision-repair process. The cytotoxicity has been a matter of concern for the Comet assay, but the confounding effects of apoptosis on genotoxicity-induced DNA breaks can be avoided now by the improvement of experimental conditions and scoring (Hartmann and Speit, 1997; Kim *et al*., 2002; Rundell *et al*., 2003). However, indirect cytotoxic mechanisms may lead to positive effects in the Comet assay (Andersson *et al*., 2003) although often associated to high cytotoxicities, so that the Comet assay could be less specific than the UDS test when evaluating the mode of action of non-DNA reacting compounds. Therefore it is necessary that a cytotoxicity assessment should be done on isolated cells in addition to histopathological examinations for the selection of the top dose used in genotoxicity assessment (Burlinson *et al*., 2007).

Many reviews have been published and a standardized protocol has been established at the IWGT of 1999 and 2005 (Tice *et al*., 1990; 2000; Brendler-Schwaab *et al*., 2005; Burlinson *et al*., 2007). Collaborative validation works have been completed or are ongoing, especially on the *in vivo* Comet assay (Sasaki *et al*., 1998; 2002).

The *in vivo* Comet assay is used at the moment for mechanistic studies and widely recognized by authorities as an additional test to the standard genotoxicity battery. It could be, in the future, increasingly used at the first steps of genotoxicity evaluation.

2.3.1.3 DNA Adducts

The formation of DNA adducts can be measured using the radiolabelled test compound and measuring its covalent binding to DNA. On the contrary, in the ^{32}P-postlabelling assay, the DNA is radiolabelled and exposed to the unlabelled tested compound. After DNA digestion, modified nucleotides are detected by two-dimensional chromatography (Randerath *et al*., 1981; Gupta, 1985). The method is highly sensitive, therefore very useful for assessing human exposure to a known compound (Randerath *et al*., 1989), even at a low exposure level. However, it is less robust for studying the possible genotoxicity of an unknown compound where modified nucleosides often need to be identified to demonstrate a real effect on DNA (Reddy, 2000). In addition, the high sensitivity of detection of primary DNA lesions makes it very sensitive to the variations of experimental conditions. Indeed, many factors, including environmental factors, are able to induce a positive signal in the highly sensitive ^{32}P-postlabelling assay (Moller and Wallin, 1998; De Bont and Van Larebeke, 2004; Li *et al*., 1995; Reddy, 2000), due to the production of reactive endogenous species, that is typically an indirect genotoxicity effect.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat076
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Therefore, the ^{32}P-postlabelling assay is less suitable than adducts measured with the radiolabelled compound to demonstrate a direct effect on DNA. It was recognized about that primary DNA alteration that 'their relationship to mutations is not precisely known' (ICH, 1995). Whilst the mechanisms involved in the UDS test and the Comet assay are better understood, the relevance of the ^{32}P-postlabelling results for mutations remains questionable.

2.3.2 Transgenic Rodent Mutation Assays

The transgenic rodent mutation assays are the only assays available for the *in vivo* detection of gene mutation in any tissue. Mutations on the transgene integrated in the genome of the treated animal are revealed after its extraction and integration in appropriate bacteria. The general principle is described in Gossen *et al*. (1989). These models are very useful for assessing the relevance of *in vitro* positive results and also for improving cancer risk assessment. Various transgenic models are available. The best known models are Muta™ mouse, Big Blue® mouse and rat, *LacZ* plasmid mouse and the *gpt* delta mouse. According to the transgene, they are able to detect punctual gene mutations or small deletions. The specifications of the protocol have been addressed in the successive IWGTs held in 1999 and in 2005 (Heddle *et al*., 2000; Thybaud *et al*., 2003). An extensive review has been published by Lambert *et al*. (2005), OECD (2009).

2.3.3 Short-Term Carcinogenicity Assessment

A number of carcinogenic compounds have a nongenotoxic mode of action. As a part of toxicity studies, but emerging with the development of genotoxicity tests, models have been developed to address the possibility of carcinogenic effects in the first steps of pharmaceutical development, long before the rodent carcinogenicity bioassays are performed. Indeed, the results of the carcinogenicity bioassays are available at the late stages of development, after the clinical studies have started, and an early assay predictive of carcinogenicity would be useful.

2.3.3.1 The In Vitro Cell Transformation Assays

For this purpose, *in vitro* cell transformation assays were developed in the 1980s (Barrett *et al*., 1979; 1984). They consist of the identification of foci of transformed cells in a culture of normal cells receiving the test compound. Either embryonic Syrian hamster embryo (SHE) cells (Barrett and Lamb, 1985) or immortalized cell lines are used, namely, BALB/c 3T3 or C3H10T1/2 cell lines (Combes *et al*., 1999; LeBoeuf *et al*., 1999).

Collaborative studies have shown a certain correlation with rodent carcinogenicity bioassays, especially with the SHE cell transformation assay, after improvements of the conditions of experiments and the scoring (Gibson *et al*., 1995; LeBoeuf *et al*., 1996; Zhang *et al*., 2004). These studies showed approximately 80% concordance between the results of the SHE cell transformation assay and carcinogenicity on a series of genotoxic and nongenotoxic compounds (see OECD, 2007 for a review). However, this good performance was contradicted by a comparative assay where only one out of five carcinogenic compounds was identified as such by the SHE cell assay (Harvey *et al*., 2005). Carcinogenicity is typically a multistep and multifunctional process, which seems difficult to model simply by the use of a short-term *in vitro* assay. Therefore, insufficient data and knowledge of the mechanisms involved in *in vitro* transformation are available at the moment to recommend using cell transformation assays as early predictors of carcinogenesis.

2.3.3.2 The In Vivo Transgenic Tumour Models

In vivo transgenic animals were developed for predicting the results of the two-year rodent carcinogenicity bioassay. These animals, excessively sensitive to carcinogens, are able to develop tumours after six months of exposure to a carcinogen instead of the two-year exposure needed in a traditional rodent bioassay. Two main models are used, the p53^{+}/$_{-}$ knockout mouse, whose tumour suppressor gene is dysregulated (Storer *et al*., 2001), and the ras-H2 mouse, whose *ras*-proto-oncogene is dysregulated (Usui *et al*., 2001).

Based on the International Life Sciences Institute (ILSI) HESI collaborative evaluation works (Robinson and MacDonald, 2001; MacDonald *et al*., 2004; Cohen, 2001) and on IWGT recommendations (Storer *et al*., 2003), these models have been extensively reviewed (for a review, see Pritchard *et al*., 2003; Jacobson-Kram *et al*., 2004; Goodman, 2001). *In vivo* transgenic tumour models are especially useful to assess the relevance of positive findings in *in vitro* genotoxicity assays or to assess the possibility of a nongenotoxic mode of action when tumours are found in the traditional two-year rodent bioassay. These models are now accepted by authorities to study the mechanism of action of nongenotoxic carcinogens.

2.3.4 High-Throughput Screening Tests

Screening tools were designed to assess genotoxic effects in pharmaceutical development as early as possible, using small amounts of chemicals, so that new potential products could be chosen more easily. With the production of large series of new chemical entities, miniaturized genotoxicity tests are needed and have been developed in pharmaceutical companies or are available on the market

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(Reifferscheid and Heil, 1996; Reifferscheid *et al*., 2005). They are reductions of the standard Ames test using smaller plates and regulatory strains (Flamand *et al*., 2001) or cultures in suspension of mixed strains representative of the regulatory strains, like the Ames II™ test (Fluckiger-Isler *et al*., 2004). These screening tests are highly predictive of the results obtained with regulatory Ames tests but, they require lower amounts of test chemicals. Therefore they can be used at the early steps of development. It is essential to add a test using mammalian cells to a screening battery, as the bacterial test will not be able to detect genotoxins acting through a mammalian cellular pathway and will miss a number of clastogens. For example, the *in vitro* micronucleus test using mouse lymphoma L5178Y cells cultured in microplates can also be used as a miniaturized version (Nesslany and Marzin, 1999). Both Ames and *in vitro* micronucleus tests often constitute a minimal screening battery but other genotoxicity tests can be used, which need lower amounts of test chemicals or have different end points (Johansson *et al*., 2004; Marple *et al*., 2004). Among the tests requiring very little compound, the GreenScreen tests, based on a gene promoter induction by DNA damage, was developed on yeast (Van Gompel *et al*., 2005) and, better, on human cells (Hastwell *et al*., 2006). Depending on the chemical class of the compound or its expected mechanism of action, all or part of these methodologies can be used. This battery of screening tests, using minimal amounts of compound, gives pharmacologists crucial information at the very early stages of development so that new nongenotoxic backups can be found and fewer compounds are dropped during their preclinical development.

2.3.5 Structure–Activity Relationships

The study of structure–activity relationships is a field of interest in genotoxicity (Ashby *et al*., 1989; Kalopissis, 1991; Rosenkranz *et al*., 1991; Benigni, 1991; Snyder and Smith, 2005). Many attempts have been made to correlate genotoxic activity with chemical structure with the hope of predicting genotoxicity and carcinogenicity from the structure. It is not an easy exercise, because the genotoxic activity of a chemical depends not only on the presence of radicals identified to be at risk, but also on other radicals present in the structure susceptible to modulate a chemical reactivity. The three-dimensional conformation of the chemical is also a major decisive characteristic. However, the structure–activity relationships of a series of chemically related compounds are fruitful to identify structures at risk in a given family of compounds and to give alerts on some chemical structures. In any case, the study of structure–activity relationships should not replace experiments in genotoxicity studies, and a presumptive reactivity will need to be confirmed in a genotoxicity experiment. The use of databases and model softwares is expanding, for identifying structures of interest in drug research or for identifying alert-structures in toxicology, especially at the early steps of genotoxicity screening (Muster *et al*., 2003). The widely used softwares are DEREK and MultiCase (Snyder *et al*., 2004), which allow an in-house elaboration of a dedicated database for the chemical classes of interest. The study of structure–activity relationships is growing in the screening set of genotoxicity tests to help to predict the genotoxicity of impurities possibly contaminating the compound (Glowienke *et al*., 2005).

3 EVALUATION OF GENOTOXICITY

3.1 Evaluation of Results

When evaluating the results, we should be able to detect a positive effect, even if it is weak, above a measurable background of spontaneous mutations, whatever the genotoxicity test used. Several criteria are used to define an assay as positive. The magnitude of the effect above a negative control value, estimated either by a statistical analysis or by an induction factor, is not predominant because it depends not only on the potency of the compound but also on the system and its interaction with the compound at high doses. Other indications such as the reproducibility for weak or equivocal positive responses will be important, together with the dose–effect relationship. Historical data of both negative and positive control values of the laboratory will be useful for monitoring the variability between experiments, with the use of limits for concurrent control values based on historical values. Some recommendations have been made specifically for several genotoxicity tests (Krishna *et al*., 2000; Gatehouse *et al*., 1994). Historical data will also be a reference for assessing the biological relevance of a genotoxicity result (Mitchell *et al*., 1990).

3.2 Evaluation of Cytotoxicity

Based on the assumption of a linear dose–effect relationship for genotoxic effects, the highest cytotoxicities are required for the top doses of genotoxicity tests. However, high cytotoxicity, required for the highest tested concentrations, may also account for some irrelevant *in vitro* positive findings. In the mouse lymphoma assay, where the surviving cell population is exposed to a majority of dying cells releasing reactive oxygen species in the medium, it is not surprising that the DNA of surviving cells is damaged. Such positive responses are regularly seen, quantitatively and qualitatively correlated with high cytotoxicity. The possibility of irrelevant positive results due to cytotoxicity has also been pointed out for the *in*

vitro chromosome aberration test (Hilliard *et al*., 1998; 2007), where the minimal level of required cytotoxicity at the top concentration was arbitrarily set at more than 50%. Therefore, the level of cytotoxicity needed in the *in vitro* genotoxicity tests is being questioned and has to be taken into account in the evaluation of results (Galloway, 2000; Kirkland and Mueller, 2000; Mueller and Kasper, 1995; Kirkland *et al*., 2005; Fellows and O'Donovan, 2007).

Given the importance of the cytotoxicity evaluation in the genotoxicity assessment, it is crucial that the measurement of cytotoxicity accurately reflects the proportion of the cell population which was unable to be hit by a mutagen, because the cell died, was dysfunctional or unable to divide. The measurements of cytotoxicity are designed to take into account these different aspects of cytotoxicity. They range from cell counts to cloning efficiency or mitotic index but none of these parameters takes into account all aspects of cytotoxicity. In the mouse lymphoma assay, the measurement of cytotoxicity has actually been improved, taking into account the short-term and the long-term cytotoxicity. For the *in vitro* chromosome aberration test, the calculation of a PD, taking into account both cell death and inhibition of cell division, has been proposed to improve the assessment of cytotoxicity (Greenwood *et al*., 2004). The use of the PD has also been shown accurate in the *in vitro* micronucleus assay in the absence of cytochalasin B (Kirsch-Volders *et al*., 2003a; Fellows *et al*., 2008; Lorge *et al*., 2008). When using cytochalasin B, the cytotoxicity relies commonly on CBPI which also takes into account cell death and inhibition of cell division (Kirsch-Volders *et al*., 2004).

3.3 Metabolic Activation

In *in vitro* test systems, an exogenous metabolic activation system is needed in cases where genotoxic metabolites could be produced by the compound. The most widely used system is the Arochlor 1254 induced rat liver microsomal fraction (S9) added with cofactors (S9 mix). A combination of beta-naphthoflavone and phenobarbital is also being used to gradually replace Arochlor (Elliott *et al*., 1992; Johnson *et al*., 1996). The S9 is presumed to contain a large panel of cytochromes. It is important that this preparation, whose composition might vary from one preparation to another, is checked for efficacy before use in genotoxicity studies. It has been shown that, provided the cofactor mix is adequate and not limiting, the amount of S9 will not be a major source of variation in metabolic efficacy (Majeska and McGregor, 1992). Rat induced liver S9 has proved to be effective in metabolizing most promutagens into mutagens (Clive *et al*., 1979). However, species differences are known between rodents, dogs, monkeys and humans. For example, some compounds such as nitrosamines are metabolized into the genotoxic active metabolite more effectively by hamsters, even when cytochromes have been induced (Amacher *et al*., 1982). Nevertheless, these differences are mostly quantitative not qualitative. It might be more realistic for pharmaceuticals to use human liver S9 instead of rodent induced liver S9, which could produce specific metabolites not relevant to human metabolism. Human S9 gave satisfactory results compared to rodent induced liver S9 (Hakura *et al*., 2005). However, human S9 could not be routinely used in genotoxicity assessment due to interindividual variations, but could be considered as a complement for risk assessment. Whatever the origin of the metabolic activation systems used in genotoxicity testing, it is an imperfect system which could produce irrelevant metabolites or, on the other hand, might be unable to produce relevant metabolites for humans. Negative and positive genotoxicity results with metabolic activation should be considered together with metabolic profiles in various species and the measurement of metabolites in plasma, in species used for toxicology assessment and in humans.

3.4 Aneuploidy

Aneuploidy is an irregular variation in the haploid chromosome number due to loss or gain of chromosomes. It represents a genotoxic and carcinogenic risk because additional or missing chromosomes will cause genomic instability or change the chromosome balance of the cell, which might be able to modify gene expression, for example reactivation of oncogenes which are normally repressed. Aneuploidy has been shown to be related to the induction of tumours (Haesen *et al*., 1993; Kolstad *et al*., 1996). Therefore, it is important that aneuploidy should be assessed for a full evaluation of the genotoxic potential of a test compound. For a long time, no standard *in vitro* genotoxicity test has been suitable for detecting aneugens, which might induce numerical chromosome aberrations. The *in vivo* and *in vitro* chromosome aberration tests, which are suitable for detecting chromosome structural aberrations, are not particularly appropriate for detecting aneuploidy. Numerical aberrations recorded in the chromosome aberration tests, that is polyploidy and endoreduplication, are not strictly indications of aneuploidy, but they may have a common origin (Mitchell *et al*., 1995). Cells arrested in metaphase by spindle poisons are able to produce both polyploidy and chromosome loss or gain, that is typically aneuploidy. However, polyploidy could also result from interference with other stages of the cell cycle, for example during telophase, inhibiting cell membrane formation at the end of mitosis, thus producing a binucleated cell (e.g. with cytochalasin B). Polyploid cells are usually produced in safe organs as a part of maturation or differentiation of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

normal cells (e.g. myoblasts) without any relationship to tumour induction. Consequently, polyploidy alone does not signal a genotoxic effect but should be verified by exploring the possibility of aneuploidy induction in a more appropriate test such as the micronucleus assay, which can also detect clastogens. Endoreduplication is a more complex phenomenon related to a disturbance in cell cycle regulation resulting in multiple copies of chromosomes, and as such, a form of polyploidy. Several S-phase cycles occur before the chromosome migrates to the poles of the dividing cell, so that metaphasic chromosomes contain multiples of two chromatids. The consequences of endoreduplication remain unclear. It is sometimes found in tumour cells but endoreduplication is also seen in normal organisms where it could be a means of increasing gene level expression. Therefore, scoring polyploidy and endoreduplication in the chromosome aberration test will not give an accurate assessment of aneuploidy and may also give signals which do not relate to a genotoxic alert.

Aneuploidy can be directly assessed by the *in vivo* and the *in vitro* micronucleus test. Aneugens will induce an increase in the number of micronucleated cells. The micronuclei induced by an aneugen will generally be larger in size than when induced by a clastogen. However, if there is a need to discriminate between aneuploidy and clastogenicity, centromere labelling can be used to discriminate accurately between micronuclei with centromeres, corresponding to a chromosome, and micronuclei lacking a centromere, corresponding to a chromosome fragment. Centromere labelling can be achieved either by immunolabelling of kinetochores with antibodies labelling specifically the kinetochore proteins (Lynch and Parry, 1993), or by FISH of DNA probes labelling specifically the DNA repetitive sequences of the centromere (Bentley *et al*., 2000; Marshall *et al*., 1996). The human antikinetochore antibody is convenient for several species as kinetochore proteins are well-preserved proteins among species. DNA centromeric probes are available for most cell types and species. These methods can be applied *in vivo* and *in vitro* and will be very useful for the evaluation of thresholds, as aneuploidy is typically a threshold mechanism (see Section 3.6).

3.5 Non-DNA-Reacting Mutagens

Over decades of genotoxicity evaluation of candidates for pharmaceutical development, the number of unique *in vitro* positive compounds has increased, without significantly changing either the way genotoxicity tests were conducted or the intended therapeutic axes. However the concepts being developed now for discovering new active pharmaceuticals involve new cellular targets. This probably results in a diversification of the possible interactions of a chemical with the different cell functions, including interactions resulting in DNA damage. In the last few years, a number of publications on the non-DNA-reactive genotoxic compounds, that is indirect mutagens, have shown that these complex interactions may account for a number of *in vitro* genotoxic positive results in mammalian cells.

Many possible targets for non-DNA-reacting mutagens have been listed (Kirkland and Mueller, 2000). To give some examples, they are: interferences with DNA repair and replication proteins, DNA precursors imbalance, lipid peroxidation, depletion in glutathione, nuclease release from lysosomes and probably many others. Any event which contributes to increasing or releasing endogenous reactive species or interferes with all the stages of cell division is susceptible to induce DNA alterations by an indirect mechanism. Aneuploidy is a special case of indirect mechanism because the ultimate target is not DNA, but it is the best known and most documented example of indirect genotoxicity (Kirsch-Volders *et al*., 2003b). There are some examples of experimentally demonstrated relationships between lysosomal breakdown or nuclease release and induction of chromosome breakage for example (Bradley *et al*., 1987). The obviously irrelevant *in vitro* genotoxic activity of sodium chloride has been shown to result from an indirect mechanism (Seidel *et al*., 2004). Another example of genotoxic effects induced through an indirect mechanism is that of carbon tetrachloride, recently shown to induce DNA adducts via oxidation and lipid-peroxidation-derived products (Eastmond, 2008). Few pharmaceuticals have been demonstrated inducing genotoxicity through an indirect mechanism (Mueller and Kasper, 1995; 2000). Spindle poisons, nucleosides and topoisomerase inhibitors have been selected for their pharmacological properties to react with a cell target likely to induce indirect genotoxicity effects. However, few pharmaceuticals have been shown to induce an unexpected and pharmacologically unrelated indirect genotoxicity. Paracetamol (acetaminophen) was shown to induce a thresholded metabolic overload (Bergman *et al*., 1996). For most pharmaceuticals showing positive findings in *in vitro* genotoxicity, the possibility of an indirect mode of action remains unknown because the compound was dropped without complementary investigations. Therefore, the number of unique *in vitro* positive compounds due to indirect mechanisms is likely to be underestimated and may partly account for the excess of positive results in *in vitro* genotoxicity testing (Kirkland *et al*., 2005).

For risk assessment in routine genotoxicity evaluation, it is essential to distinguish between thresholded effects, due to indirect mechanisms of genotoxicity, and nonthresholded effects, due to DNA-reacting mutagens. Pharmaceuticals are complex compounds having multiple cell targets. In the case of an indirect effect, the absence of a direct effect on DNA as well as a mechanism explaining the induction of mutations by an indirect effect

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat076
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

should be demonstrated. Investigating the indirect mechanisms of genotoxicity is now a part of the current thinking on the improvement of genotoxicity tests, their suitability, the possible sources of false positive results, and the appropriate complementary tests which can be added to the minimal battery so that actual genotoxic activity presenting a potential hazard for humans can be correctly assessed. These issues are examined by the IWGT, the ECVAM, the HESI, and the ICH.

3.6 Thresholds

Up to the 1990s, it was generally admitted that any amount of a compound found genotoxic, even at very high concentration in *in vitro* test systems compared to human plasma levels, was likely to present a risk when administered at a therapeutic dose. This concept relied on the irreversibility of genotoxic events. However, it has been shown at first for non-DNA-reacting compounds that thresholds account for observed nonlinear genotoxic responses. Thresholds have been measured for aneugens (Elhajouji *et al*., 1995; 1997; 1998; Morales-Ramirez *et al*., 2004), reflecting that as long as the concentration of aneugen is not sufficient to alter mitotic spindle such that the chromosome migration is disturbed, no effect will be induced by the aneugen. To generalize, indirect mechanisms of genotoxicity are thresholded mechanisms and thresholds can be measured (Kirkland and Mueller, 2000; Kirsch-Volders *et al*., 2003b). Practical thresholds have been measured for various genotoxic compounds (Asano *et al*., 2006) and the possibility of a threshold for direct-acting DNA compounds has been addressed (Jenkins *et al*., 2005). The concept of a 'threshold of toxicological concern' was introduced in the European Medicines Agency guideline on the limits of genotoxic impurities (EMEA, 2007). It derived from the Food and Drug Administration (FDA) guidance for food-contact materials (FDA, 1995) and was based on the estimated risk of inducing cancer in humans after a lifetime exposure to a carcinogen. Identifying and taking into account thresholds for genotoxic compounds will help to improve risk assessment for humans.

3.7 Strategy for Human Risk Assessment

To help to assess the relevance of *in vitro* positive results, to avoid producing irrelevant results, or to understand the mode of action of a compound, and finally evaluate the risk for humans, additional tests to the standard battery may be useful. An alternative *in vitro* chromosome aberration test or micronucleus assay on cell types other than L5178Y cells will indicate whether cell specificity is involved in an *in vitro* positive response, as well as possible aneugenic effects. *In vivo* experiments, that is, micronucleus assays after long-term exposure or in relevant target organs, that is, in most cases in liver for pharmaceuticals, in addition to toxicokinetic and pharmacokinetic data, will attest to the predictive value of *in vitro* positive results for *in vivo* situations. The *in vivo* Comet assay was also found to be very helpful in assessing *in vivo* genotoxicity in the appropriate organs detected as targets in other toxicity studies. Finally, short-term carcinogenicity tests (p53, rasH2) will increase confidence in *in vivo* negative results before the standard rodent bioassays are initiated for the assessment of carcinogenicity. Examples of decision trees have been drawn up to help in making decisions during the toxicity evaluation of a new pharmaceutical (Thybaud *et al*., 2007a; 2007b; Kasper *et al*., 2007; Kirkland *et al*., 2006; Lorge *et al*., 2007).

4 CONCLUSION

The improvements brought to the experimental genotoxicity testing as well as to the strategy of results evaluation will be useful in moving from hazard identification towards an integrated risk for cancer and genotoxicity. Over the past 30 years, genotoxicity evaluation has become a multidisciplinary science. Each compound is a specific case with an original mode of action defined on the basis of genotoxicity results, integrating the toxicity profile, the chemical and pharmaceutical properties of the compound; constantly evaluated and updated, re-assessing the risk–benefit at each step of the development.

ACKNOWLEDGEMENTS

I thank Nancy Claude, Nathalie Becourt-Lhote and Jean-Luc Delongeas for their support, and Véronique Gervais for her long-lasting friendship.
