Interestingly, the down-regulation of *Bach1* (BTB and CNC homology 1, basic leucine zipper transcription factor 1) induces accelerated ageing owing to the cancelation of the suppression of *Trp*53-dependent premature senescence possibly owing to oxidative stress. Along with this cancelation, genomic instability is also induced by *Trp*53 dysfunction (Dohi *et al*., 2008). In addition, the down-modulation of *Supt16h* (suppressor of Ty16 homologue)/*Cdc68* and *FUS* (fused sarcoma)/*TLS* (translocated in liposarcoma) induces genomic instability owing to oxidative changes in *ATM* after ionizing-radiation exposure (Gardiner *et al*., 2008; O'Donnell *et al*., 2004). Furthermore, not only genomic instability but also chromosomal instability is induced by the down-modulation of *SMC2* and *SMC4* (Losada and Hirano, 2005). *Akap9* (A kinase anchor protein 9), which is normally involved in chromosomal rearrangement in thyroid cancer cells after radiation (Ciampi *et al*., 2005), induces the radiation-dose-dependent down-modulation of gene expression also in the bone marrow and, thus, chromosomal rearrangement as well. *Baz2b* (bromodomain adjacent to zinc finger domain, 2B) generally functions in chromatin remodelling in collaboration with *Acf1* (Jones *et al*., 2000); however, the down-modulation of *Baz2b* after ionizing radiation induces chromatin instability. The down-modulation of *CTCF* (CCCTC-binding factor), in collaboration with *rad21*, results in the suppressive regulation of orchestration of the down-regulation of the chromatin loop structure in the B-cell system by an epigenetic mechanism (Degner *et al*., 2009).

Cellular Proliferation Arrest

Concerning cellular proliferation arrest, progressive epithelial maturation is down-regulated in the small intestine by the down-regulation of *Cbfa2T2* (core-binding factor, runt domain, alpha subunit 2, translocated to 2)*/MTGR1* (myeloid translocation gene-related 1) (Amann *et al*., 2005). *Zbtb7a* (zinc finger and BTB domain containing 7a), a suppressor gene belonging to the *Rb* family, also called *Pokemon*, attenuates the suppression of *ckap4/p63* (Jeon

et al., 2008), which negates the induction of cellular proliferation. On the other hand, regarding cellular differentiation arrest, the down-modulation of *CUL5* (cullin 5) suppresses cellular differentiation via the down-modulation of *E3* ubiquitination (Baxter *et al*., 2009). Furthermore, the down-regulation of *MEF2C* induces the dysregulation of differentiation of pluripotent progenitor cells as well as B cells (Gekas *et al*., 2009). However, the down-regulation of a regulator of nuclear receptor-mediated repression, *Ncor1* (nuclear receptor corepressor 1), also induces cellular differentiation arrest (Hermanson, Jepsen and Rosenfeld, 2002). The down-regulation of LIM and senescent cell antigen-like domain 1 (*lims1*) in megakaryoblast induces cellular differentiation abnormality (Chen, Hu and Shivdasani, 2007). Concerning cellular differentiation abnormality during the developmental stage, the down-regulation of *Arid5b* (AT-rich interactive domain 5B)*/Mrf2* (modulator recognition factor 2)/*desrt* induces growth retardation and failure of reproductive organ development (Lahoud *et al*., 2001). Thus, it is plausible that the down-regulation of *Arid5b* induces impairment of regeneration of the bone marrow after radiation exposure. Regarding the radiation effect on the tumour suppressor gene *NFATc3* (nuclear factor of activated T cells, cytoplasmic, calcineurin-dependent 3), the gene generally suppresses T-cell leukaemia cells as a tumour suppressor (Glud *et al*., 2005); however, the down-regulation of *NFATc3* suppresses T-helper cell type 2 (Th2)-mediated IL-13 production (Klein *et al*., 2006), thereby suppressing cellular proliferation. *MALAT1* (metastasis-associated lung adenocarcinoma transcript 1) is a *Trp*53-type suppressor gene and non-coding RNA, which is reported to be often up-regulated in malignant neoplasms (Guffanti *et al*., 2009). This up-regulation is supposed to mutate *MALAT1*. However, the down-modulation of non-mutated *MALAT1* may suppress cellular proliferation and differentiation in the bone marrow. *Bin1* (bridging integrator 1) is also a tumour suppressor, which induces proapoptotic cellular death (Cassimere, Pyndiah and Sakamuro, 2009). The down-modulation of *Bin1* cancels proapoptotic tumour suppression, which is considered to be a response to DNA damage for regeneration. *Irf8*/*ICSBP*, reported as a *Fas*-mediated apoptosis inducer (Yang *et al*., 2007) whose expression level is also reported to decrease during ageing (Stirewalt *et al*., 2009), suppresses apoptosis by radiation-induced down-modulation of itself, which may lead to leukaemogenic plausibility (Holtschke *et al*., 1996), as described above.

Tumourigenic/Leukaemogenic Plausibilities

Similarly to the down-modulation of *Irf8*, several genes show high tumourigenic/leukaemogenic plausibilities. The down-modulation of *Rasa1*, a tumour growth suppressor (Yang *et al*., 2009), results in the down-regulation of the suppressor function of *Rasa1*. *Topors* (topoisomerase I-binding protein)/*p53BP3* (p53-binding protein) is a *Trp*53-binding protein (Zhou, Wen and Ao, 1999) that stabilizes *Trp*53 by SUMOylation (Weger, Hammer and Heilbronn, 2005) and catalyses *Trp*53 by its down-regulation, resulting in an increase in tumourigenic plausibility. The down-regulation of *Gimapb* (a *GTPase*, *IMAP* family member 6) is observed in non-small cell carcinoma of the lung and is supposed to induce the dysregulation of neoplasms (Shiao *et al*., 2008). Thus, this down-regulation in the bone marrow after radiation exposure may promote leukaemogenesis. The down-regulation and dysregulation of *Jarid1-A* leads to leukaemogenic plausibility (Wang *et al*., 2009).

Haematopoiesis After Radiation Exposure

Lastly, concerning specific effect of radiation exposure on haematopoiesis, the most prominent effect is the suppression of haematopoiesis owing to the down-regulation of *Runx* via a G-protein gene, *Gna13* (guanine-nucleotide-binding protein, alpha 13), induced by the down-regulation of *Runx2* (Teplyuk *et al*., 2008). Another haematopoietic impairment is induced by the down-modulation of *Musashi homologue 2* (*MSI2*) through the attenuation of maintenance of stem cell identity (Siddall *et al*., 2006). The attenuation of maintenance of stem cell identity and also maintenance of T-cell identity in a haematopoietic microenvironment is induced by a decrease in the expression level of *Ccr9* (chemokine C-C motif receptor 9) (Chamberlain *et al*., 2008; Lai and Kondo, 2007; Wright *et al*., 2002). Similarly, the down-modulation of *c-cbl* (casitas B-lineage lymphoma) induces the instability of haematopoietic stem cell proliferation (Rathinam *et al*., 2008; Slape *et al*., 2008). *OLFM4* (olfactomedin 4) is a myeloid developmental marker (Chin *et al*., 2008). The down-modulation

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat227
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

of *OLFM4* suppresses its own haematopoietic function. Furthermore, the suppression of *chd4* (chromodomain helicase DNA-binding protein 4) induces chromatin remodelling (Srinivasan *et al*., 2006). The suppression of *Irf8*/*ICSBP*, which is induced during ageing (Stirewalt *et al*., 2009), induces chronic myeloproliferation in collaboration with *Meis1*, which promotes chronic myeloid leukaemia (CML) of bone marrow cells (Hara *et al*., 2008). The suppression of *Clec2i* (C-type lectin domain family 2, member i)/*Clr-g* in turn suppresses T-cell proliferation and IL-2 production (Tian *et al*., 2005). Lastly, when *Trpm7* is down-modulated, thymocyte development at the double-negative stage (i.e. negative for both CD4 and CD8) is disrupted during thymopoiesis, which may have significance in leukaemogenic plausibility (Jin *et al*., 2008).

3.2.3 Common Gene Profiles Overlapped With Those in the List of Ivanova et al.

Ivanova *et al*. (2002) established the stem-cell-specific gene expression profiles from the cDNA library obtained from immature haematopoietic stem-cell compartment sorted by flow cytometry. It is of interest to compare the common gene expression profile of the bone marrow after ionizing radiation with those stem-cell-specific gene expression profiles listed by Ivanova and coworkers. Eighteen probe sets (17 genes) showed overlapping. Among them, eight probe sets (seven genes) showed irradiation-dose-dependent down-regulation (dose-dependent cluster), eight probe sets were commonly up-regulated only in the 0.6-Gy-irradiated group and one probe set was commonly up-regulated only in the 3-Gy-irradiated group (dose-specific clusters). The dose-dependent genes were *Sltm* (RIKEN cDNA 5730555F13 gene), *Mef2c* (myocyte enhancer factor 2C), *Centd3* (RIKEN cDNA E030006K04 gene), *Serpinf1* [serine (or cysteine) proteinase inhibitor, clade F, member 1], *Slc12a2* (solute carrier family 12, member 2), *Rora* (retinoic acid receptor (RAR)-related orphan receptor α) and *Runx2* (runt-related transcription factor 2). The dose-specific genes in the 0.6-Gy-irradiated group were *Cox8a* (cytochrome *c* oxidase, subunit VIIIa), *Uba1* (ubiquitin-activating enzyme E1, Chr X), *Fkbp1a* (FK506-binding protein 1a), *Crebl1* (cyclic adenosine monophosphate (cAMP)-responsive element-binding protein-like 1), *Ivns1abp* (influenza virus NS1A-binding protein), *Ppap2c* (phosphatidic acid phosphatase type 2c), *Krt10* (keratin, type I cytoskeletal 10), *Terf2* (telomeric repeat binding factor 2) and *Lass4* (longevity assurance homologue 4). Only one gene, *Snrpc* (U1 small nuclear ribonucleoprotein 1C), was up-regulated in the 3-Gy-group.

3.2.4 Stochastic Gene Profiles Overlapped With Those in the List of Ivanova et al.

Each gene expression profile for the 0.6- and 3-Gy-irradiated individual mice is compared with gene expression profiles for five mice of the non-irradiated group by PCA, and union genes were collected to establish the stochastic gene profiles. Genes showing overlapping of their stochastic expression gene profiles with those in Ivanova's list were analysed. From the comparison between the 0- and 3-Gy-irradiated groups, 65 genes were selected, which included *Acadl* (acyl-coenzyme A dehydrogenase, long-chain), *Apc* (adenomatosis polyposis coli), *Ccnd1* (cyclin D1), *Ctnnd1* [catenin (cadherin-associated protein), delta 1], *Dhcr7* (7-dehydrocholesterol reductase), *Dll1* (delta-like 1), *Hspa9* (heat-shock protein 9), *Igbp1* [immunoglobulin (CD79A)-binding protein 1], *Myb* (myeloblastosis oncogene), *Mycbp2* (MYC-binding protein 2), *Tnf* (tumour necrosis factor) and *Wnt6* (wingless-related MMTV integration site 6) among others. The expressions of these genes were individually stochastic in not only 3-Gy-irradiated mice but also non-irradiated mice. Interestingly, two-thirds of these 65 genes were individually up-regulated in the non-irradiated group. From the comparison between the 0- and 0.6-Gy-irradiated groups, 36 genes were selected, which included *Baalc* (brain and acute leukaemia, cytoplasmic), *Bmp2* (bone morphogenetic protein 2), *Cdc14b* (CDC14 cell division cycle 14 homologue B), *Gja1* (gap junction protein, alpha 1/connexin 43), *Gstm1* (glutathione *S*-transferase, μ1), *Lamc1* (laminin, γ1), *Sox3* (SRY-box-containing gene 3) and *Upp1* (uridine phosphorylase 1) among others. The expressions of these genes were interestingly also individually stochastic in not only 0.6-Gy-irradiated mice but also non-irradiated mice. Furthermore, most of these 36 genes were individually up-regulated from the non-irradiated group to the 0.6-Gy-irradiated group. Whereas most of the genes, including *Runx2* and *Mef2c*, responsible for maintaining haematopoiesis were

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

down-regulated after radiation exposure specifically in the 3-Gy-irradiated mice in the case of the common gene expressions, more than one-half of genes whose functions are considered to be acceleration of the cell cycle or elimination of oxidative stresses, such as *Cyclin D1* and *Hspa9*, are, in contrast, up-regulated in the case of stochastic gene expressions.

4 HAEMATOPOIETIC NEOPLASMS

In toxicological pathology, the possible carcinogenicity/leukaemogenicity of a chemical compound is assayed by comparing neoplastic and pre-neoplastic histopathological findings between experimental group(s) treated with the test chemical and the control group treated solely with a vehicle. This is based on the conceptual principles on the development of neoplasms and pre-neoplastic histopathological findings established over the past hundred years of history of pathology since the time of Ludwig Aschoff.

When one analyses such neoplasms using a gene chip microarray technique, it should not be used to simply support findings obtained by conventional histopathological technologies and methods, not only because of unavailable databases to link such tumour-specific gene expression profiles to findings of such conventional pathological technologies and methods, but also because of further possible potentials of gene chip microarray methods. Namely, a gene chip microarray, for instance, provides not only gene expression profiles for pathological endpoints that are comparable to neoplastic endpoints related to pathological diagnosis, but also gene expression profiles for toxicological endpoints, which are linked to multiple clusters that predict epigenetic pathways before irreversible morphological fixation to pathological conditions (Table 2). In the latter case, the type of genes that would be profiled in each cluster is not fully established owing to the lack of concept and insufficient databases for toxicological predictable profiles. However, a probabilistic predictability by the latter approach may open the door to systems toxicology, which is an attractive and powerful new toxicological methodology established after the completion of the whole-genome reading project established in 2000 [*C. elegans* (*C elegans* Sequencing Consortium, 1998), *Drosophila* (Adams *et al*., 2000), mice (Waterston *et al*., 2002) and humans (Lander *et al*., 2001)].

Predictable

Gene expression profiles for neoplastic tissues and surrounding tissues both consist of profiles equivalent to those for the senescent animals, owing to the fact that such neoplastic tissues developed from equally senescent cells in the tissues. Sometimes, cancer tissues for microarray analysis are obtained by microdissection. However, gene expression profiles obtained from cancer tissues by microdissection still consist of common gene expression profiles linked to senescence as the major phenotype. Most of the gene expression profiles obtained from cancer tissues correspond to those of senescent animals. Namely, when one recalls the historical experiment conducted by Beatrice Mintz (Dewey *et al*., 1977), one can realize the fact that the major gene expression profiles from cancer tissue analysed using microarray techniques are largely those without carcinogenic phenotypes. On the other hand, one may be only able to obtain a profile for a definitive pathological endpoint for diagnosis, but fail to obtain epigenetic toxicological profiles for predicting possible tumourigenic plausibility. Microdissection excludes pre-neoplastic epigenetic changes; thus, it is unable to provide predictive cancer-specific plausible gene expression profiles from the cancer tissue, and we need another molecular strategy to replace microdissection techniques to select plausible or definitive cancer-specific gene expression profiles from most non-neoplastic gene expression profiles.

What would be an essential molecular biological strategy to replace microdissection techniques to select expression profiles related to tumourigenicity? The strategic changes in the toxicological paradigm occurring from the histological definition to the molecular biological/toxicological definition of toxicology are one of the essential topics of this section, that is to make gene expression profiles of the surrounding tissues clusterized into stochastic union genes computationally. In this section,

gene expression profiles for two types of myeloid leukaemia, one developed in the bone marrow after whole-body radiation exposure (1.5–3.0 Gy) and the other developed spontaneously in animals without radiation exposure, are chosen as the analytical models for microarray analysis. Methodologically, common gene profiles are those of genes expressed commonly among the experimental groups, excluding genes expressed in the non-treated, 21-month-old control group. Stochastic gene expression profiles, on the other hand, are those of genes expressed in individuals of the experimental group, differentiated from genes expressed in the non-treated 21-month-old control group. In the former, a number of senescent genes including housekeeping genes are appropriately removed. In the common gene profiles, genes are expressed in all members of the group but are not always expressed at a high level, whereas in the latter, gene expression profiles cannot be differentiated using a dendrogram between the experimental group and the control group. However, the profiles can be differentiated by PCA without specific supervised analysis of a signalling cascade, because radiation-induced myeloid leukaemias and spontaneous myeloid leukaemias, used as models in this section, show epigenetic and stochastic characteristics in terms of the mechanism of leukaemogenic progression. Namely, the characteristics of expression profiles are not obtained for genes commonly expressed but for genes differently and stochastically expressed.

As mentioned above, PCA and/or equivalent analytical tools define each individual gene expressed by a Euclidean vector, which has been realized owing to the remarkable progress of microarray techniques with improved repeatability. It is speculated that future progress in the field of one-cell microarray analysis may clearly elucidate epigenetic individual differences during the developmental stage and open the road to stochastic toxicology.

4.1 Radiation-Induced Myeloid Leukaemias Versus 21-Month-Old Bone Marrow Cells

In this section, radiation-induced myeloid leukaemias are focused on as an analytical model for use in gene chip microarray analysis. Radiation-induced myeloid leukaemias may develop in over 300 radiation-fragile sites with probabilistic random hitting, and they may develop as an effect of epigenetic and stochastic radiation causing deterministic DNA damage. Thus, the model is appropriate for analysing general systems toxicology from two viewpoints, that is commonality and stochasticity. The development of myeloid leukaemias in C3H/He mice clearly shows treatment-dependent specificity with a lower background incidence in the non-treated control, that is 1% spontaneous myeloid leukaemia; thus, C3H/He mice were utilized in the present study.

Myeloid leukaemias were selected from those developed from mice exposed to 1.5–3.0 Gy, where the ratio of the integral becomes comparatively higher between the radiation survival curve for haematopoietic stem/progenitor cells along the radiation exposure and the curve for the minimum number of mutated stem/progenitor cells for the development of at least one case of leukaemia as a function of radiation dose. The detailed experimental procedure is described elsewhere (Hirabayashi *et al*., 2009).

Figure 8 shows linear configurations of all the expressed genes that had been connected for over five non-treated 21-month-old bone marrow cells without developing any particular haematopoietic diseases (Nos 01 to 05 in the left panel) and six cases with radiation-induced myeloid leukaemias that developed after radiation exposures (Nos 06 to 11 in the right panel). When one focuses on one case, No. 03 for example, and categorizes genes in the order of expression level from the highest (red line) to the lowest (green line), the order of genes from the reddish line to the greenish line in each case, as observed in No. 03, is essentially comparable to that of the five individual cases in the left panel (Nos 01 to 05). Namely, the order of gene expression levels in the left panel is essentially comparable among the cases in the group (i.e. up-regulated genes in the case of No. 03 designated by greenish lines are nearly identical to those in the cases from Nos. 01 to 05). However, the order of gene expression profiles for radiation-induced leukaemia cases shown from Nos 06 to 11 is the opposite across these cases compared with those for No. 03. Namely, genes designated by reddish lines, which are highly expressed in No. 03, tend to appear in the low-expression-level zone with increased diversity and degree of individual differences in the cases of radiation-induced leukaemias from Nos 06 to 11.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat227

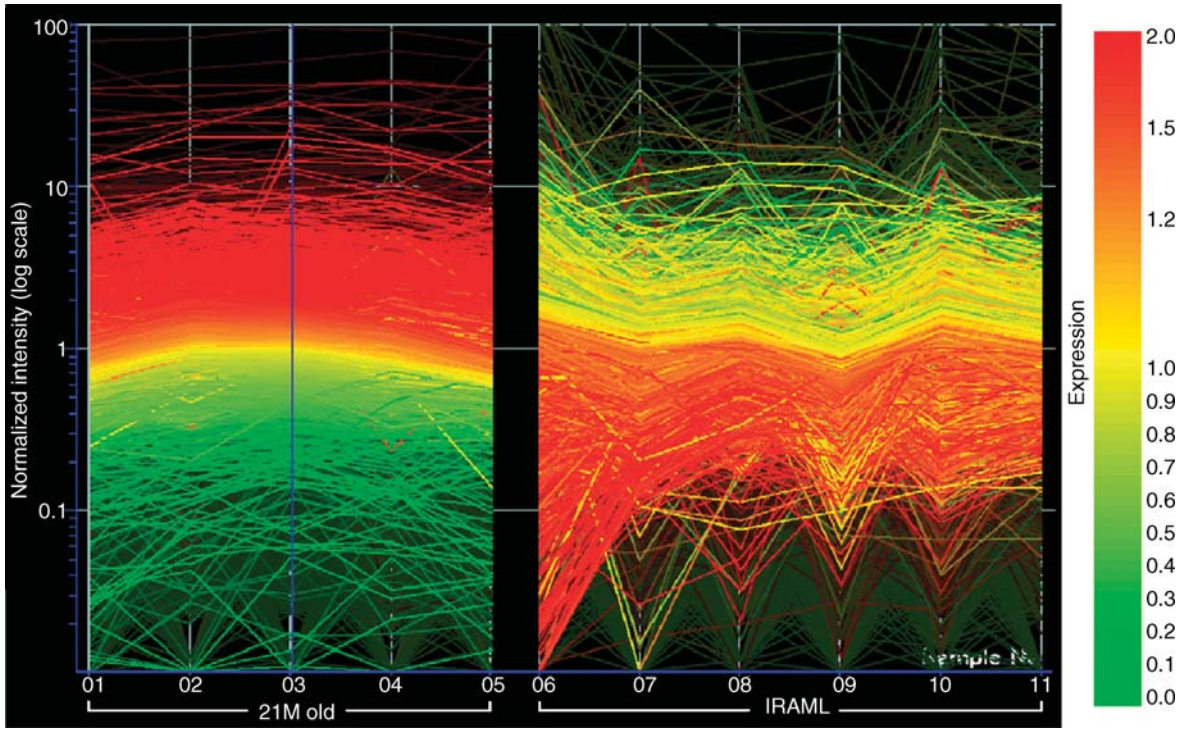

Figure 8. Linear configurations of gene expression profiles for 21-month-old bone marrow cells and radiation-induced myeloid leukaemias: microarray profiles differentiate 21-month-old bone marrow cells from radiation-induced myeloid leukaemias. The five individual data points in the left panel are for bone marrow cells from 21-month-old C3H/He mice. The other six individual data points in the right panel are for 3 Gy-radiation-induced myeloid leukaemias in C3H/He mice. Along the scale for gene expression level from the highest (red) to the lowest (green) for No. 03, the same genes of the other individuals are connected and shown by the same expression intensity colour. Accordingly, genes over-expressed in the 21-month-old mice are largely repressed in radiation-induced myeloid leukaemia cases.

Furthermore, the reddish line configurations, that is genes that are highly expressed in the 21-month-old bone marrow, are largely located below 1.0 for radiation-induced myeloid leukaemia cases. In contrast, the greenish line configurations, that is genes that are highly expressed associated with radiation-induced leukaemias, show a low expression level in 21-month-old bone marrow cells.

When one compares these gene expressions in 21-month-old bone marrow cells with those in radiation-induced myeloid leukaemias by PCA (Figure 9a), an individual gene expression in 21-month-old bone marrow cells and all gene expression profiles in radiation-induced myeloid leukaemia cases are differentiated clearly not only by component #1 but also by the eigenvector value of several components. Using components #1, #2 and #3, we can separate both groups in the three-dimensional expression diagram shown in Figure 9b. Gene expression profiles of 21-month-old bone marrow cells showed lower individual commonality than those of 2-month-old bone marrow cells (Figure 1). However, when 21-month-old bone marrow cells were compared with those of radiation-induced myeloid leukaemias, both gene expression level and commonality increased in the latter (Figure 8). These trends observed in the radiation-induced myeloid leukaemias are further extended to spontaneous myeloid leukaemia cases, as described in the next section, largely owing to the increase in the stochasticity of gene expressions.

Each gene expression profile of each individual radiation-induced myeloid leukaemia case was compared with a set of gene expression profiles of the group of 21-month-old mice by individual PCA. Union gene repertories from all PCA data with a contribution score of over 1.0 provided

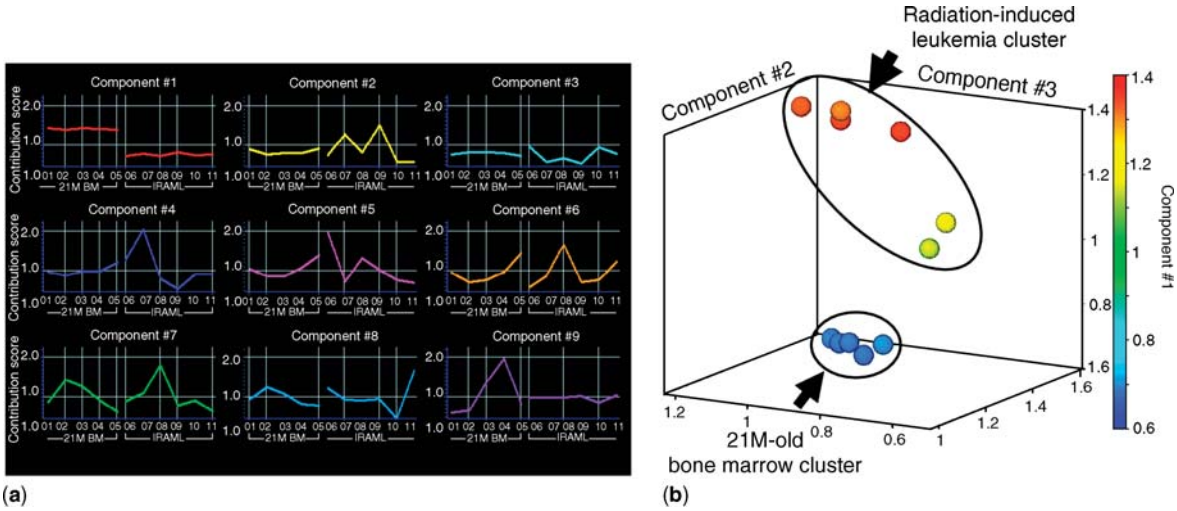

Figure 9. PCA differentiates radiation-induced leukaemias from 21-month-old bone marrow cells: three-dimensional expression clustering from results of PCA of six cases of radiation-induced myelogenous leukaemias and five cases each of 21-month-old bone marrow cells are shown in the three-dimensional contribution scores for components #1, #2 and #3, which discriminate the radiation-induced myelogenous leukaemia cluster from the 21-month-old bone marrow cell cluster. The line graph in the left panel shows actual contribution scores converted from each eigenvector value (a), which were used for the clustering of three-dimensional expressions shown in the right panel (b). Note that the contribution scores of the radiation-induced myelogenous leukaemia clusters in (a), except for components #1 and #9, comparatively diverge from those of 21-month-old bone marrow cell clusters in (a).

242 probe sets. Among them, genes with leukaemogenic/tumourigenic plausibility are tabulated in Table 3.

4.2 Spontaneous Myeloid Leukaemias Versus 21-Month-Old Bone Marrow Cells

Gene expression profiles for spontaneous myeloid leukaemias are shown by linear configurations for six mice in the right panel of Figure 10. As compared with those for 21-month-old bone marrow cells in the left panel of Figure 10, which is the same as the left panel of Figure 8, the individual expression profiles for these spontaneous myeloid leukaemia cases vary markedly from each other.

It is of interest that the expression profiles for radiation-induced myeloid leukaemias in the right panel of Figure 8 show a slightly higher commonality than the expression profiles for the spontaneous myeloid leukaemias shown in the right panel of Figure 10. Genes that are up-regulated, as shown by reddish lines in the left panels of Figures 8 and 10, are generally down-regulated in the radiation-induced myeloid leukaemia cases, as shown in the right panel of Figure 8. On the other hand, the reddish lines show different levels among cases of spontaneous myeloid leukaemias, whose detailed underlying mechanisms have been analysed and reported elsewhere (Hirabayashi *et al*., 2009).

As observed in the right panel of Figure 10, the expression profiles for spontaneous myeloid leukaemias show marked stochasticity. However, when one compares these expression profiles with those for 21-month-old bone marrow cells and extracts their characteristic common genes by PCA, these gene groups that are up- or down-regulated, and essentially are different from the common genes observed in the radiation-induced myeloid leukaemia cases, were selected, except for four genes, *MLLT7/Foxo4* (folkhead box O4)*/AFX*, *Cald1*, *Txnl2* (*Thioredoxin-like 2*)*/Glxn3* (*glutaredoxin 3*) and *ApoE* (183 probe sets were selected on the basis of the contribution score of component #1 of over 0.9 or under −0.9). First, several genes considered to function as suppressor genes are elucidated to play a role of tumourigenic/leukaemogenic promoters. Namely, myeloid/lymphoid or mixed lineage leukaemia 3 (*Mll3*) was up-regulated, thus functioning as a leukaemogenic promoter (Ruault *et al*., 2002; Tan and Chow, 2001).

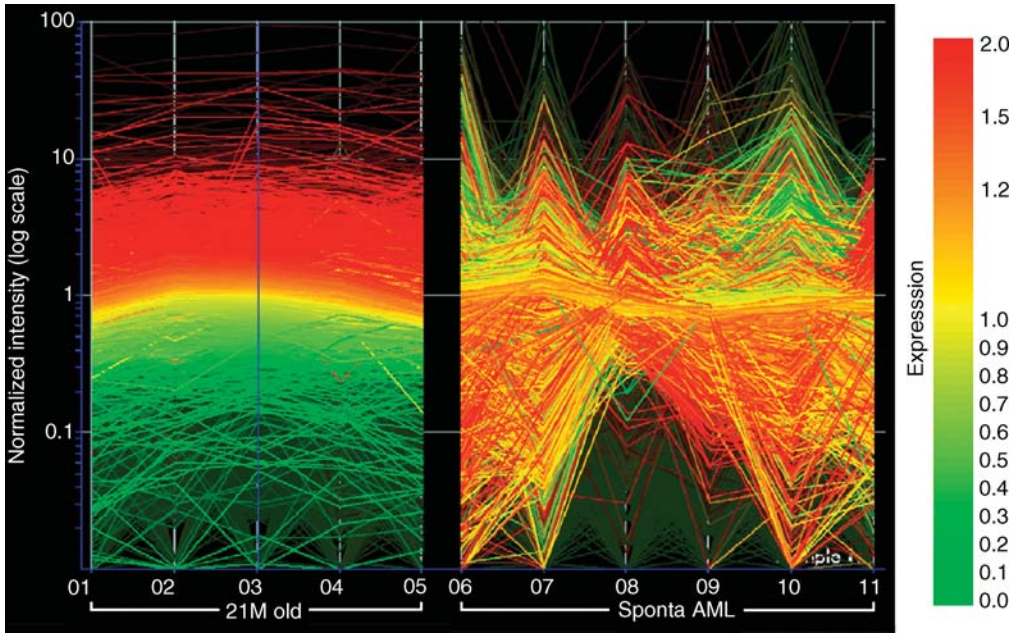

Figure 10. Linear configurations of gene expression profiles for 21-month-old bone marrow cells and spontaneous myeloid leukaemias: microarray profiles differentiate 21-month-old bone marrow cells from spontaneous myeloid leukaemias. The five individual data points in the left panel are for bone marrow cells from 21-month-old C3H/He mice. The other six individual points in the right panel are for spontaneous myeloid leukaemias in C3H/He mice. Along the scale for gene expression level from the highest (red) to the lowest (green) for No. 03, the same genes are connected and shown by the same intensity colour of gene expression. Accordingly, genes over-expressed in the 21-month-old mice are stochastically absent from one case to the other in spontaneous myeloid leukaemias.

MLLT7/Foxo4/AFX, which activate apoptosis (Tang *et al*., 2002) and are also known to be partner genes of fusion with *MLL* in acute leukaemias (Borkhardt *et al*., 1997), were down-regulated; thus, this would be functioning also as a promoter of development of leukaemias/lymphomas. Generalized down-regulation of *Pten* was observed, whose relevance to the development of HPNs has been reviewed elsewhere recently (Chalhoub and Baker, 2009). Namely, owing to the cancelation of suppression of the pathway from *PiP2* to *PiP3* by *Pten*, the accumulation of *PiP3-activated Akt* initially leads to the inhibition of $p27^{kip1}$ and consequent cell cycle progression and then inhibits apoptotic factors, such as *Bad* and *FoxO*, leading to the attenuation of stem cell quiescence/maintenance. Thus, the down-regulated *Pten* functions as a leukaemogenic promoter. Second, some genes are related to cell cycle regulation and cellular proliferation and considered to function in tumour proliferation and invasion. Namely, *caldesmon 1* (*Cald1*), known to be activated specifically during mitosis and also known as a novel *K-cyclin* (*D-like cyclin*)-*cyclin-dependent-kinase* substrate that is thought to regulate the actin cytoskeleton and consequently control cell shape, adhesion, cytokinesis and motility (Cuomo *et al*., 2005), is up-regulated. Thus, the acceleration of cell cycle by *Cald1* may contribute to oncogenicity. *Nr2C2* (nuclear receptor subfamily 2, group C, member 2), known as an orphan nuclear receptor, which is the same as *Tr4* and activates NF κ B in lymphoid follicles and the thymus (Kim *et al*., 2007), is up-regulated; thus, this may function in cellular proliferation. *Mif* (macrophage migration inhibitory factor), known to play a role in leukaemic cellular invasion and proliferation (Talos *et al*., 2005), is up-regulated. *FUS* (fusion, derived from t (12;16) malignant liposarcoma)/*Tls*, known to be a target of the signalling pathway of *ATM* (ataxia-telangiectasia mutated) (Gardiner *et al*., 2008) and also fuses with *ERG* in t(16;21) AML (Ichikawa, 1994), is up-regulated; thus, the up-regulation of *FUS* may induce a dysregulation of *Cdk1* with a *FUS*-mediated oncoprotein (Pan *et al*., 2008). Third, a few genes contribute to the induction of genomic instability and splicing abnormality, which

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat227
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

may contribute to neoplastic development. Namely, *tetra-, tri-peptidyl repeat* domain 3 (*TTC3*), which is the critical region of Down's syndrome (Tsukahara *et al*., 1998) and is involved in age-related increase in replication/transcription error (Zheng *et al*., 2008), is up-regulated, thus possibly inducing genomic instability.

The last set of genes characteristically up-regulated includes genes protecting neoplastic and leukaemic cells such as *Txnl2*/*Glxn3*, which are known to function similarly to thioredoxin in the cytoplasm (Cha and Kim, 2009), are up-regulated and thus considered to contribute to the survival of leukaemic cells. Ribosomal protein *L23* (*RPL23*) is an MDR promoter (Shi *et al*., 2004) and may thus contribute to the resistance of leukaemic cells to multidrugs. *Apolipoprotein E* (*ApoE*), which functions in the survival of chronic lymphoid leukaemia (CLL) cells (Weinberg *et al*., 2008), is up-regulated and is thus considered to be a leukaemia endpoint marker.

5 CONCLUSIONS

In response to the report of the National Research Council (NRC), "Toxicity Testing in the 21st Century: A Vision and A Strategy (Tox 21) (NRC, 2007)" investigations on new methodologies to predict xenobiotic effects of chemical compounds worldwide in the 21st century have been carried out. In Tox21 on the new dimension of toxicity testing (Schmidt, 2009), it is reported that "On the ground floor of the National Institutes of Health (NIH) Chemical Genomics Center (NCGC) in Rockville, Maryland, a ten million dollar automated laboratory spends all day and all night screening chemicals at speeds no team of human researchers could ever match. In a week, depending upon the nature of the assay, it can yield up to 2.2 million molecular data points derived from thousands of chemicals tested at 15 concentrations each." They are prioritizing chemicals by incorporating more biological aspects into the prioritization. As Robert J. Kavlock of the National Center for Computational Toxicology declared, the project may accomplish a better job selecting and prioritizing the right chemicals for only a limited number of animal testings than by other criteria such as production volume, the likelihood of human exposure or structural similarity to other chemicals with known liabilities.

Current goals of the programme are not to simply compile data on physical and chemical characteristics but rather to evaluate perturbations in toxicity signalling pathways as databases, as mentioned in the NRC report (NRC, 2007).

"Systems toxicology" is "systems biology" applied to general toxicology, which is to elucidate a universal concept of biological interactions between living organisms and xenobiotics by global assays of transcriptomics, proteomics and other various applied omics studies, on various biological phases in *in vitro* cellular responses, in developmental, pubertal and senescent stages, and at the ontological or phylogenical level.

In this chapter, the aim was to focus on systems toxicology to incorporate a new biological concept that distinguishes commonality and stochasticity from the xenobiotic responses when one incorporates data from gene chip microarray computational toxicology into systems toxicology. The multiplicity of biological reactions was better understood when common gene expression profiles and stochastic gene expression profiles are differentiated. We propose the following. First, age-related changes that are xenobiotic responses to "time" as a xenobiotic in which essential biological responses during ageing are based on a long-term relationship between living organisms and environmental xenobiotic materials with oxidative stresses and photostimulation among other. Second, we focus on xenobiotic responses, in addition to senescence, using two sample models, benzene and ionizing radiation, in which common gene expression profiles and stochastic gene expression profiles are clearly defined.

Lastly, murine myeloid leukaemias induced by radiation exposure and spontaneous leukaemias were compared with respect to their differences in gene expression profiles specifically based on individual differences in commonality and stochasticity. No sample model of strong genotoxic chemicals was introduced, which tends to provide deterministic common gene expression profiles in the present study. Stochastic biological responses are phenomenologically ordinary individual differences. However, these are based on post-transcriptomic biological diversity linked to ultimate stochastic toxicology, which is only elucidated by systems toxicology. The authors hope that their proposed concept in this chapter will help readers to recognize biological and toxicological stochastic diversities in the new era of post-genomic science.

1 INTRODUCTION

Immunotoxicity can be defined as the adverse effects of toxicants (chemicals and drugs) on the immune system. It can be divided into two types: direct immunotoxicity, which deals with direct toxic effects on cells of the immune system and results in reduced resistance to infections and increased incidence of neoplasms; and indirect immunotoxicity, in which case the xenobiotic itself is recognized as foreign, resulting in allergy and sometimes autoimmunity. Xenobiotics that are able to induce allergy are named sensitizers or allergens and can be divided into contact sensitizers and respiratory sensitizers. Exposure to contact sensitizers may result in allergic contact dermatitis, whereas exposure to respiratory sensitizers may result in occupational asthma. While validated animal models exist for the prospective identification of contact sensitizers, with the local lymph node assay currently being used most often, the prospective identification of respiratory sensitizers lacks a validated model and human data are used instead (in retrospect). The advent of non-animal testing for sensitizing capacity stimulated by legislation such as the European Cosmetics Directive and the REACH program provides major opportunities for developing assays to detect contact sensitizers and, along similar lines, respiratory sensitizers. Similar to the situation for contact sensitizers, such assays may be *in silico* quantitative structure-activity relationships (QSAR), *in chemico* (peptide reactivity), *in vitro* (cell-based assays including those relying on genomics and signal transduction), or a combination of these assays (Vandebriel and Van Loveren, 2010).

Toxicogenomics employs "omics" technologies such as genomic-scale mRNA expression (transcriptomics), cell and tissue-wide protein expression and modification (proteomics), and metabolite profiling (metabolomics), in combination with bioinformatics methods and conventional toxicology. In relation to chemical hazard and risk assessment, toxicogenomics provides tools to improve the understanding of mechanisms of toxicity, identify biomarkers of toxicity and exposure, reduce uncertainty in grouping of chemicals for assessments, (Q)SARs, inter-species extrapolation, and effects on susceptible populations. Moreover, toxicogenomics can provide alternative methods for chemical screening, hazard identification, and characterization. Because of its sensitivity, altered gene expression profiles may already be seen at doses that are relevant to human exposure, not necessarily producing adverse effects. Distinguishing adaptive from adverse effects is an issue that remains to be resolved.

Systems toxicology is defined here as the study of the interactions of all elements in a given biological

system, under stress or toxicant perturbation, to achieve a mechanistic understanding of the toxicological response. It involves integration of chemical- or stressor-affected biological systems (cells, tissues, organs, or entire organisms) at the molecular level, monitoring changes in molecular expression and conventional toxicological parameters, and iteratively integrating response data to describe the functioning organism (Waters and Fostel, 2004). In the field of systems toxicology, the analysis of complex biological responses to chemical exposure is facilitated by toxicogenomics. Because data integration results in additional knowledge of the system as a whole, systems toxicology offers the promise of developing novel reliable toxicity biomarkers and more accurate risk assessment. Software tools aiming to improve risk assessment based on gene expression data have been developed, such as Gene Ontology (GO)-Quant (Yu *et al*., 2006) and BMDExpress (Yang, Allen and Thomas, 2007). Both models describe dose–response relationships from microarray experiments within GO categories.

In this chapter, we first discuss the data that propose the oxidative stress pathway as the major one induced by contact sensitizer exposure. Second, we discuss the (less abundant) data that have led to the proposition of the PTEN pathway as the major one induced by respiratory sensitizer exposure. Third, we investigate the chemical characteristics that determine whether a sensitizer is a contact or respiratory sensitizer that have only recently begun to emerge. Fourth and finally, we hypothesize how the two different pathways may result in the *in vivo* observation of preferential Th1 and Th2 responses, respectively.

Identification of the oxidative stress response pathway as the major one induced by contact sensitizers has resulted in non-animal assays to identify them, and it is envisaged that such assays will be developed for respiratory sensitizers in the near future, thereby improving risk assessment within a systems toxicology framework.

2 OXIDATIVE STRESS RESPONSE TO CONTACT SENSITIZERS

The oxidative stress response pathway, illustrated in Figure 1, is first discussed briefly. Kelch-like ECH-associated protein 1 (Keap1) is a sensor protein that contains highly reactive Cys residues. In the absence of electrophiles (haptens), the basic leucine zipper transcription factor nuclear factor–erythroid 2-related factor 2 (Nrf2) is associated with Keap1. Keap1 anchors the Nrf2 in the cytoplasm, targeting it for ubiquitination and proteasomal degradation. Upon electrophile binding Keap1 dissociates from Nrf2, resulting in translocation of Nrf2 to the nucleus, where Nrf2 forms a heterodimer with small MAFs. This heterodimer binds to antioxidant response elements (ARE), inducing transcription of genes that contain ARE in their promoter.

Natsch (2010) recently reviewed the evidence for a major role of the oxidative stress response pathway after contact sensitizer exposure. In this section, we discuss the relevant transcriptomics data. An inventory of all genes that are dependent on the oxidative stress response is taken as a starting point. Gene profiling after *KEAP1* gene knock-down in the keratinocyte cell line HaCaT revealed upregulation of 22 genes (MacLeod *et al*., 2009).

Dendritic cells (DC) are pivotal in the immune response, uniquely able to induce the differentiation of naive T cells. DC maturation has been widely used as a model to detect contact sensitizers. Cell surface markers such as CD86 are used to measure maturation and hence sensitizing capacity. DC can be cultured from monocytes isolated from peripheral blood mononuclear cells (monocyte-derived DC or moDC) and cord blood ($CD34^+$ DC), but myeloid cell lines such as THP-1 and MUTZ-3 are also used.

Expression profiling of moDC after exposure to the contact sensitizer dinitrobenzene sulfonic acid showed upregulation of ARE-responsive genes (Ryan *et al*., 2004). From the above-mentioned list of 22 genes, aldo-keto reductase 1C2 (*AKR1C2*), malic enzyme 1 (*ME1*), phosphogluconate dehydrogenase (*PGD*), and thioredoxin reductase (*TXNRD1*) were significantly upregulated after exposure.

Three MAPK signaling pathways exist in mammals, involving extracellular signal-regulated kinases (ERKs), c-Jun N-terminal kinases (JNKs), and p38MAPK (p38). Haptens activate ERK1/2 and p38 (Becker *et al*., 2003), and activation of ERK1/2 and p38 by the contact allergen trinitrochlorobenzene could be inhibited by the thiol antioxidant *N*-acetylcysteine (NAC); this inhibitor also prevented binding of the hapten to protein (Bruchhausen *et al*., 2003).

Exposure of DC to sensitizers but not to non-sensitizers altered the redox state of the cells, as

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat228

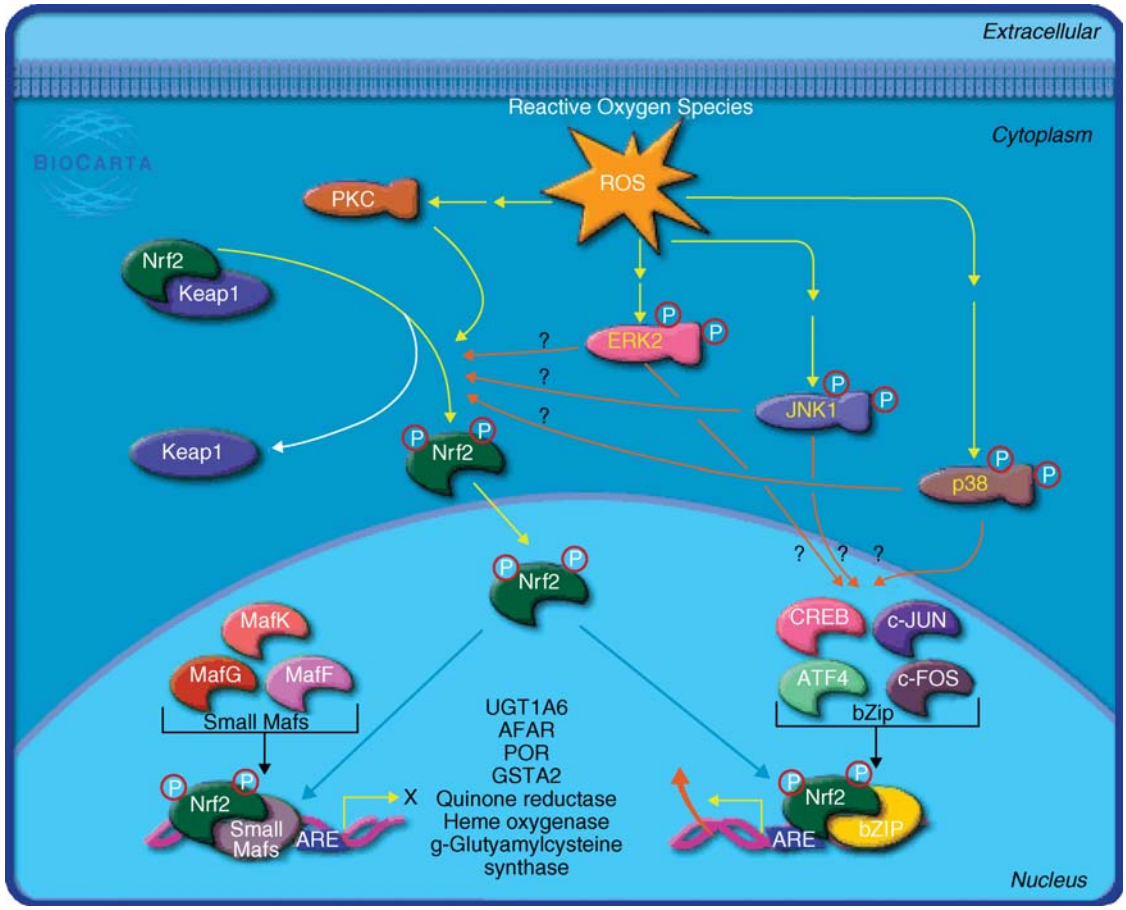

Figure 1. The oxidative stress response pathway. Upon hapten binding to Cys residues of Keap1, the Keap1/Nrf2 heterodimer dissociates and Nrf2 translocates to the nucleus. In the nucleus, Nrf2 forms a heterodimer with small MAFs, after which this heterodimer binds to ARE sites, thereby inducing transcription of ARE-dependent genes such as *HMOX1* and *NQO1*. Reproduced with permission from Biocarta (http://www.biocarta.com/pathfiles/h_arenrf2Pathway.asp) (accessed 24 November, 2009).

measured by a reduced ratio of intracellular oxidized (GSSG) versus reduced (GSH) glutathione, and this altered ratio was accompanied by p38 activation (Mizuashi *et al*., 2005). Suppressed GSSG/GSH ratio, p38 activation, and increased CD86 expression were all reduced by NAC treatment. Thus, altered oxidant/redox state is an important effect of sensitizing agents.

Exposure of $CD34^+$ DC and the THP-1 cell line to sensitizers but not irritants resulted in the increased expression of heme oxygenase-1 (*HMOX1*) and NAD(P)H:quinone oxidoreductase-1 (*NQO1*). Pre-incubation with NAC inhibited CD86 expression as well as expression of *HMOX1* and *NQO1*, showing the role of oxidative stress in this response (Ade *et al*., 2009).

From the above-mentioned list of 22 genes, aldo-keto reductase 1C1 (*AKR1C1*), ferritin heavy 1 (*FTH1*), and *NQO1* were upregulated in moDC and the MUTZ-3 cell line, after exposure to the contact sensitizer cinnamic aldehyde (Python, Goebel and Aeby, 2009).

In conclusion, each of the DC genomics studies showed affected genes that overlap with the MacLeod set of 22 genes. In order to improve comparison of the studies, complete gene profiles should be compared instead of only comparing lists of affected genes. In any case, there is significant overlap in the affected genes, suggesting robustness of the antioxidant response pathway.

A novel assay whose development was led by the identification of the oxidative stress response

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat228
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

pathway uses an ARE reporter construct (Natsch and Emter, 2008). The reporter construct contains eight ARE sequences upstream of a luciferase gene. After testing 102 chemicals, the accuracy was found to be 83% with only 4 out of 30 non-sensitizers inducing (low) luciferase activity.

In conclusion, the past few years have seen the emergence of the oxidative stress response pathway as the major pathway induced by contact sensitizers. Comparing entire sets of array data should greatly improve the comparisons between the various studies discussed in this section. An important approach that is still missing is to knock down genes involved in the oxidative stress response pathway and evaluate the effects on downstream parameters (signal transduction, DC maturation, and cytokine production) after sensitizer exposure (functional genomics). In any case, the identification of the oxidative stress response pathway provides new avenues to develop *in vitro* assays to detect contact sensitizers, including high-throughput reporter assays.

3 PTEN PATHWAY RESPONSE TO RESPIRATORY SENSITIZERS

The first successful attempt to identify respiratory sensitizers *in vitro* used the bronchial epithelial cell line BEAS-2B (Verstraelen *et al*., 2009). The phosphatase and tensin homolog deleted on chromosome 10 (PTEN) pathway, illustrated in Figure 2, was the most specific one induced. PTEN, a multifunctional phosphatase, is best known as a major tumor suppressor that dephosphorylates phosphatidylinositol-3,4,5-triphosphate (PIP3). This inositol phospholipid, which is produced by phosphatidylinositol-3-kinase (PI3K), activates the signaling kinase AKT. AKT plays an important role in anti-apoptosis, proliferation, and oncogenesis. Interestingly, PTEN activity decreased in a murine model of ovalbumin-induced airway hyperresponsiveness and bronchial inflammation, and these clinical effects, as well as VEGF levels, were reduced by administration of an adenovirus containing PTEN cDNA (Kwak *et al*., 2003; Lee *et al*., 2006). Peroxisome proliferator activated receptor γ (PPARγ) agonists as well as an adenovirus containing PPARγ cDNA had a similar effect and this effect was mediated through PTEN (Lee *et al*., 2005). Moreover, in a murine model of toluene diisocyanate (TDI)-induced asthma, adenovirus containing PTEN cDNA reduced the pathophysiological features of airway disease (Kim *et al*., 2007a). In summary, PTEN plays a pivotal role in airway inflammation and hyperresponsiveness, and TDI-induced asthma. Importantly, the clinical picture of TDI-induced asthma is exemplary for the clinical effects of respiratory sensitizers, implicating that the pathway discovered by Verstraelen *et al.* (2009) in an *in vitro* model is of clear relevance to the situation in exposed humans, giving the model additional value.

It is as yet not clear whether and to what extent the oxidative stress response is involved in the cellular response to respiratory sensitizers. The ARE reporter assay was found to be negative for respiratory sensitizers, suggesting that these compounds do not induce an oxidative stress response. A model for a role of PTEN in determining cellular susceptibility to the oxidative stress response has recently been proposed (Sakamoto *et al*., 2009). Although this model includes Nrf2-dependent induction of ARE-responsive genes such as *HMOX1* and *NQO1*, the underlying pathway is likely to be different from the oxidative stress pathway because it is unresponsive to NAC pre-treatment.

4 CONTACT AND RESPIRATORY SENSITIZERS HAVE DIFFERENT CHEMICAL CHARACTERISTICS

A recently developed *in silico* model identified two categories of respiratory sensitizers, based on a "reactivity threshold": one category with extreme electrophilicity without the capacity of cross-linking, and a second with a lower but still significant electrophilicity, combined with cross-linking capacity (Enoch, Roberts and Cronin, 2009). This report presents the first mechanism-based *in silico* prediction of respiratory sensitizers. Importantly, it is the first step in unraveling the rather enigmatic difference in chemical characteristics between contact and respiratory sensitizers. The results from Enoch, Roberts and Cronin (2009) suggest that electrophilicity is the (most important) factor in the distinction between the two types of sensitizers.

Another, less well established difference is not in the haptens themselves but in the amino acids they bind to. Theoretical considerations on respiratory sensitization provide some clues to the nature

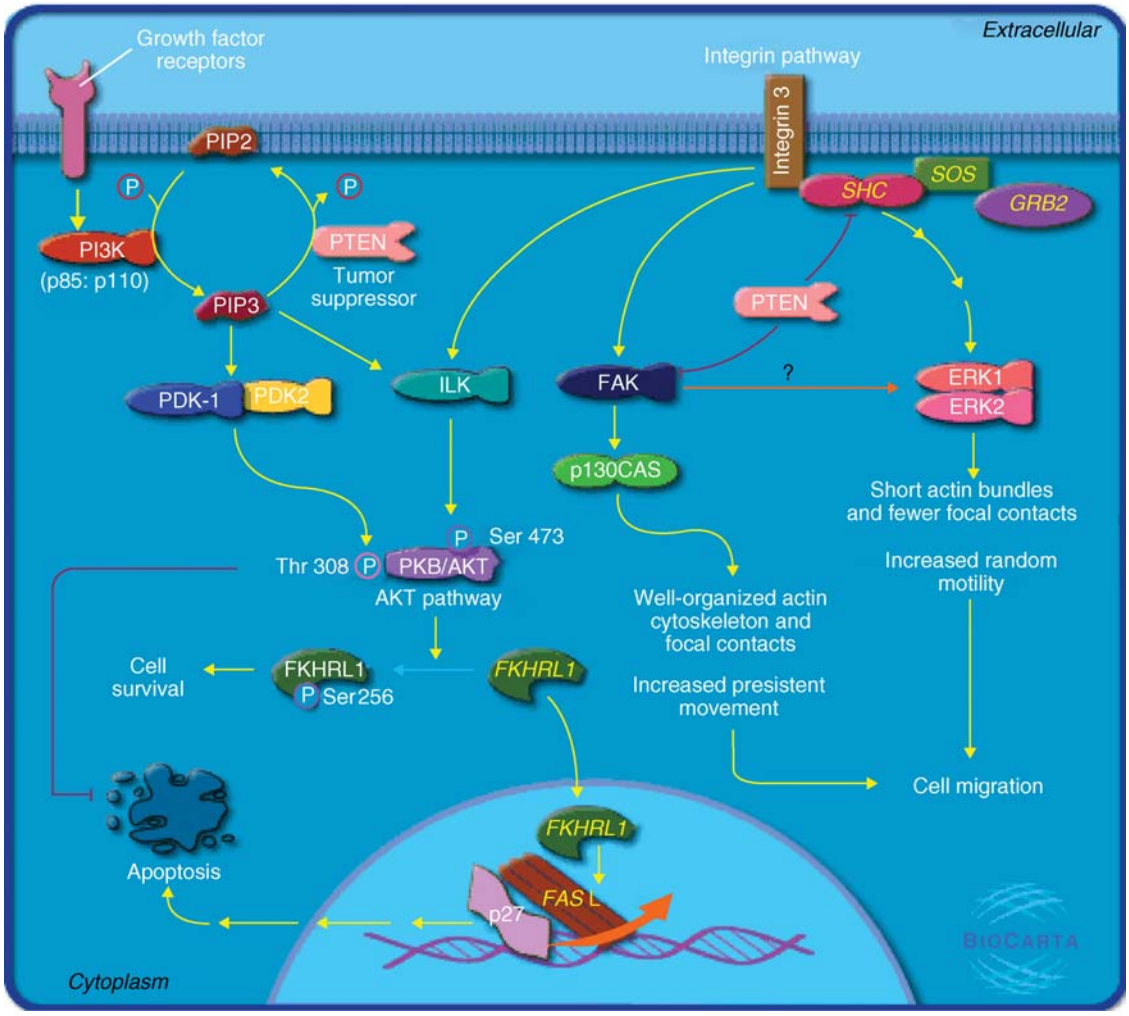

Figure 2. The PTEN pathway. PI3K activity results in PIP3 production. PIP3 activates the signaling kinase AKT. Activation of the AKT pathway inhibits apoptosis and increases cell survival. PTEN dephosphorylates PIP3, thereby inhibiting the AKT pathway. Reproduced with permission from Biocarta (http://www.biocarta.com/pathfiles/h_ptenPathway.asp) (accessed 24 November, 2009).

of respiratory sensitizers; the airways provide an oxidizing environment, so respiratory sensitizers do not bind to cysteine but to lysine instead and (even then) only 0.1% of lysine is reactive at physiological pH. This suggests that respiratory sensitizers are hyper-electrophilic. To produce enough epitopes bi- or multifunctionality is helpful (D.W. Roberts, personal communication). Clearly, the Enoch, Roberts and Cronin (2009) results are in line with these considerations.

Although it is now well established that contact sensitizers bind to Cys residues on Keap1, it is unknown which protein(s) is the target of respiratory sensitizers. As they may bind to lysine and not cysteine residues, it is unlikely that Keap1 is involved, at least not in a similar way as for contact sensitizers. If and how such mechanisms of respiratory sensitizer binding fit in the PTEN pathway is unknown.

5 DIFFERENT IMMUNE RESPONSES SKEWED IN VIVO BY CONTACT AND RESPIRATORY SENSITIZERS

We are beginning to understand the pathway(s) resulting from the response to contact sensitizers, and may thus ask the question as to how this may

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat228
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

eventually result in a Th1 response, with the knowledge that respiratory sensitizers induce a Th2, or mixed Th1/Th2, response (Dearman, Basketter and Kimber, 1995, 1996; Vandebriel *et al*., 2000, 2003; Van Och *et al*., 2002). A possible explanation may be that activation of Nrf2 by contact sensitizers results in increased glutathione levels (MacLeod *et al*., 2009). These increased glutathione levels would in turn skew Th1 responses (Peterson *et al*., 1998; Kim *et al*., 2007b). Treatment of lymph node cells from animals sensitized with the contact allergen dinitrofluorobenzene (DNFB), with antibodies to heat shock protein (HSP) 27 and HSP 70, reduced IFN-γ and IL-17 production, while increasing IL-4 and IL-10 production (Yusuf *et al*., 2009). HSPs are produced in response to, among others, oxidative stress. It may thus be suggested that oxidative stress by inducing HSP production results in Th1 skewing.

A separate line of evidence for Th1 skewing activity of the oxidative stress response is the observation that ovalbumin-sensitized and -challenged Nrf2$^{-/-}$ mice showed increased production of the Th2 cytokines IL-4 and IL-13 compared with wild-type controls (Rangasamy *et al*., 2005). Moreover, expression of the Th1 cytokine IFN-γ, but not the Th2 cytokine IL-4, decreased with aging in the ears of DNFB-sensitized and ear-challenged Nrf2$^{-/-}$ mice (Kim *et al*., 2008).

The fact that respiratory sensitizers do not, or to a lesser extent, induce the Th1 response would suggest that respiratory sensitizers do not, or to a lesser extent, induce the oxidative stress response, in line with the observation that they are negative in the ARE reporter assay (Natsch and Emter, 2008).

6 CONCLUSIONS AND FUTURE DIRECTIONS

Toxicogenomics is of great benefit to understand mechanisms of toxicity, identify biomarkers of toxicity and exposure, reduce uncertainty in grouping, and improve risk assessment. Using the oxidative stress pathway as an example, we hope to have shown that a systems toxicology approach is more advanced than one which employs toxicogenomics alone because research questions can be approached in different ways, in this case not only by genomics (*in vitro* exposure of DC) but also, *in vivo* (contact hypersensitivity), by signal transduction (role of Nrf2 and NAC) and reporter assays. With regard to respiratory sensitizers, our knowledge is still limited to an affected pathway, so different approaches should be taken here as well, but it is encouraging that the pathway involved has been shown to play a major role *in vivo* in murine models for protein- and low-molecular-weight chemical-induced asthma. In the near future, a systems toxicology approach for respiratory sensitization should result in reporter assays.

For contact sensitization, risk assessment seems to be feasible, for instance by comparing results from non-animal assays (*in vitro*, *in chemico*, and *in silico*) with EC3 values from the local lymph node assay (Vandebriel and Van Loveren, 2010). It is still remote for respiratory sensitization, partly because a validated *in vivo* model and quantitative data are lacking. To be able to identify respiratory sensitizers we propose to develop non-animal assays on the basis of human data (physiology, pathology, toxicology, genomics, etc.). This proposition also holds for risk assessment of respiratory sensitization. We anticipate that development of non-animal assays as well as risk assessment will depend on a systems toxicology framework.

1 INTRODUCTION

Maintaining food safety is becoming ever more difficult in this time of global markets, free trade and the constant development of new products that use novel methodologies. Most foodborne illnesses are caused by pathogenic micro-organisms in the food, such as bacteria, viruses, parasites, toxigenic moulds or microalgae, which produce a variety of toxins. According to the U.S. Federal Food, Drug, and Cosmetic Act (FFDCA) Sec 402(a)(1-6), food is considered adulterated if it bears or contains any poisonous or deleterious substances.

It is extremely difficult to detect specific microbes and the toxins microbes produce in contaminated food. The food industries and regulatory agencies have historically relied on conventional, well-established microbiological techniques involving pre-enrichment of pathogenic species on selective media to detect individual bacterial colonies. Biochemical or immunological methods are then used to identify the pathogens (de Boer and Beumer, 1999). Although these methods are commonly used and accepted, they are equally labour-intensive and time-consuming, and can not always distinguish whether micro-organisms are viable or non-viable. However, new systems biology techniques have enabled researchers to detect minute signals generated by microbes amid the noise of most food matrices.

Being able to detect and type pathogenic and spoilage micro-organisms at an early stage will allow us to protect our food more effectively. Traditionally, plasmid typing, pulse-field gel electrophoresis, ribotyping and random-amplified polymorphic DNA analysis were established as molecular typing methods during the genomic era (Kathariou, 2002). In recent decades, the post-genomic revolution has enabled us to track microbial toxins by exploring regulatory control of genes, proteins, and primary and secondary metabolites of microbial pathogenic circuits. The new systems biology techniques make it possible to explore the global expression of genes (genomics), proteins (proteomics) and low-molecular-weight metabolites (metabolomics) in pathogenic microbes, and study genomic-scale or cell-wide processes by combining high-throughput experimental tools. This article presents an overview of these techniques and how they can help industry and regulatory agencies to detect microbial toxins in food and feed.

Table 1. An overview of microbial toxin properties and characteristics.

Property	Exotoxin	Endotoxin
Chemical nature	Protein	Lipid A of lipopolysaccharide
Relationship to cell	Release from the cell	Integrated part of the cell wall
Gram stain	Produced by both Gram-positive and Gram-negative micro-organisms	Produced by only Gram-negative micro-organisms
Mode of action/target sites	Many types of exotoxin based on structure and function: cytotoxin, enterotoxin or neurotoxin	One type of endotoxins
Specificity	High degree: specific receptors on host target cells	Low degree: diverse range of host cells and systems affected
Symptoms	Specific/conditional effects in host	Diverse range of effects in host: fever, vomiting or diarrhoea
Toxoidable	Can be denatured to remove toxicity	Can not be denatured; chemical composition prohibits molecular modification

2 MICROBIAL TOXINS AND DETECTION

Bacteria are harmless, even helpful and actually have been proven to be beneficial to life on earth, yet there are still a few pathogenic bacteria that have the potential to cause infectious disease by producing toxins (Fischbach and Walsh, 2009; Liu and Nizet, 2009). Many foodborne diseases have been described by *Shigella*, *Escherichia coli* and *Campylobacter* as potential causative agents in raw and undercooked meat and poultry or raw milk and untreated water-borne bacteria (Wright, Danyluk and Otwell, 2009; Todd *et al*., 2008). The growth of common micro-organisms is unrestrictive and their pathogenecity depends on virulence factors, which determines the fate of bacterial toxins.

A bacterial toxin can be defined as a colloidal proteinaceous poisonous substance produced by the metabolic activities of a living organism, unstable, toxic to the tissues and capable of inducing antibody formation. There are over 220 known bacterial toxins, divided into exotoxins and endotoxins. Endotoxins (cell-associated substances) originate inside the cell, whereas exotoxins are produced outside the cell and absorbed by the host (Calandra, (2001); Driscoll, Brody and Kollef, 2007; Liu and Nizet, 2009). Endotoxins are generally enzymes produced by Gram-positive and Gram-negative bacteria. There are many more known exotoxins than endotoxins; exotoxins are known to range in toxicity, but form a class of poisons that is among the most potent, per unit weight, of all toxic substances. The properties and characteristics of endotoxins and exotoxins are compared in Table 1.

Because microbial toxins have different structures and functions, it is impossible to use a single standard technique to detect and analyse specific toxin. Conventional methods currently used for the routine detection of pathogens include enrichment techniques followed by plating methods or immunochemical and nucleic acid-based methods (Notermans and Wernars, 1991; de Boer and Beumer, 1999; Nagy *et al*., 2006). However, these techniques are time-consuming and often limited because they are designed to identify one specific toxin. Any successful toxin detection or screening system must be able to handle the challenges presented by emerging/mutated pathogens and little-known biohazards.

3 FUNCTIONAL 'OMICS' AND DETECTION OF MICROBIAL TOXINS

The high-throughput experimental approaches used in systems biology can analyse all the components of a biological system simultaneously (Ishii *et al*., 2007) and predict the systematic behaviour of cells holistically (Figure 1). This integrative approach allows researchers to study the complex metabolic and regulatory networks of pathogenesis in the microbial system, which may lead to the design of new toxin detection devices. Now that 527 bacterial and 47 archael genomes have been fully sequenced and abundant information is available about the genomics of micro-organisms such as *Escherichia coli* (http://genomeonline.org) (Liolios *et al*., 2009), the next challenges are determining the function

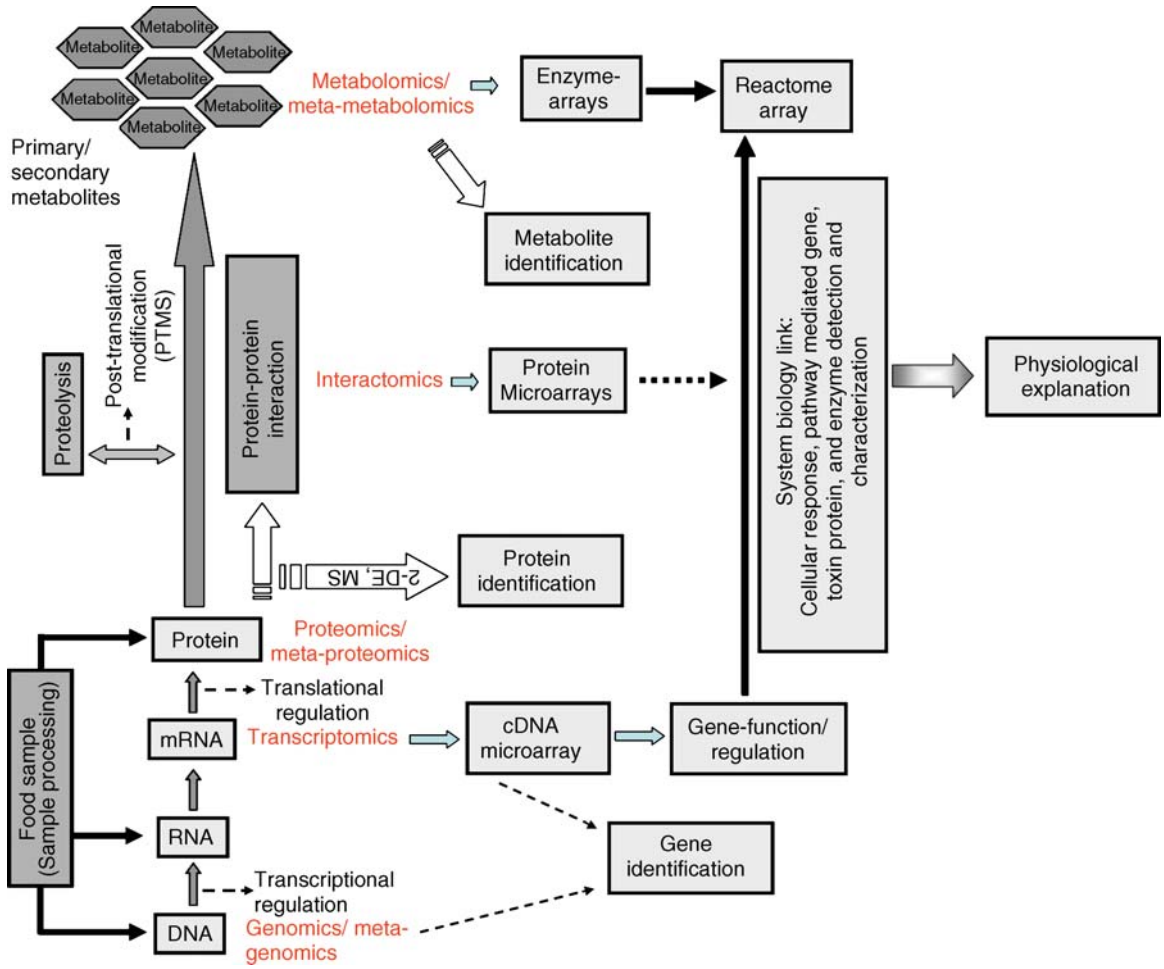

Figure 1. Integration of 'omics'-based approaches to detect microbial toxins in the post-genomics era. The enriched microbial DNA from a variety of food and related substances will end up on DNA microarrays (transcriptomics). Moving forward, extraction of whole-cell proteins and metabolites will activate systems biology route of proteomics and metabolomics, respectively, using 2DE, protein microarray and MS-based platforms. The metabolite-based enzyme arrays will further provide reactome arrays that may link to identify cellular responses, pathway-mediated genes and specific toxin proteins towards physiological explanation of specific microbe. 2DE, 2D electrophoresis; MS, mass spectrometry; PTM, post-translational modification.

of each gene and understanding the metabolic and regulatory networks within each biological system. The field of functional '-omics' consists of high-throughput global experimental approaches that make use of the information and reagents provided by structural genomics to assess gene function (Hieter and Boguski, 1997). This field has seen considerable growth in recent years, encompassing areas such as transcriptomics (global gene expression, i.e. mRNAs), proteomics (global protein expression) and metabolomics (global expression of primary and secondary metabolites) (Figure 1).

3.1 Genomics

The genome is the genetic information that flows from the DNA of an organism to the mRNA; genomics refers to analysing the expression of a large number of genes through relative or semi-quantitative amounts of RNA in biological samples. Genomics techniques and high-throughput methods can be used to facilitate the identification of potential virulence factors and their relative genes.

Traditionally, transposon mutagenesis has been used to inactivate genes in a selected bacterial

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat229
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

strain and the resulting insertion mutants have been screened for attenuation in an appropriate animal infection model in order to identify novel virulence factors. A variation on this method, signature-tagged mutagenesis (STM), incorporates unique DNA tags; this method allows mass screening of mutants in animal infection models (Hensel *et al*., 1995), but is limited to a single bacterial strain and a particular infection model. Therefore, it identifies only highly specific virulence factors, with limited extrapolation to generic virulence determinants of other pathogens. Another technique, *in vivo* expression technology (IVET), involves finding genes that are up-regulated *in vivo* (Mahan *et al*., 1993), and identifies genes other than those required for virulence. Both STM and IVET have the potential to identify genes in a pathogen that also exist in non-pathogenic strains. Whole-genome computational comparisons of related pathogenic and non-pathogenic strains can suggest genes that potentially play a role in virulence (Heermann and Fuchs, 2008; Lanie *et al*., 2007); for example, Garbom *et al*. 2004 examined hypothetical genes conserved in six human microbial pathogens in order to identify novel genes associated with virulence in *Yersinia pseudotuberculosis*.

Now that complete genome sequences for human pathogens are available, they can be used to facilitate genome organization studies, genome comparisons and functional genomics, as well as to develop microarrays (Ishii *et al*., 2007). Today's nucleotide sequencing technologies can produce complete sequences for a large number of genomes, which facilitates high-throughput gene identification (Hall, 2007; MacLean, Jones and Studholme, 2009). Determining the functions of these genes is one of the most important current challenges for molecular biology. In laboratory studies, researchers have recently estimated the minimal gene set required for bacterial cell viability (Baba *et al*., 2006; Liberati *et al*., 2006; Gallagher *et al*., 2007; French, Bell and Ward, 2008). However, such studies can identify only those bacterial genes required for viability under specific laboratory growth conditions. Both STM (Hensel *et al*., 1995) and transposon-site hybridization (TraSH) (Sassetti, Boyd and Rubin, 2001) use hybridization to identify genes that have been disrupted by transposon insertions. They have also been used to identify "niche-specific" virulence genes in pathogenic bacteria through negative selection (Andrews-Polymenis, Santiviago and McClelland, 2009). Transposon-mediated differential hybridization (TMDH) is a newer technique that has been used in one study to analyse approximately one million mutants and identify essential genes in *Staphylococcus aureus* (Chaudhuri *et al*., 2009).

The Scalar Analysis of Library Enrichments (SCALEs) is another genomics approach that uses DNA and gene-chip data to provide access to new genome-scale patterns (Struble and Gill, 2009; Warner, Patnaik and Gill, 2009). Global transcription machinery engineering (gTME) and gene-disruption methods such as transposon insertion and site-specific homologous recombination are also being used to build microbial libraries of the phenotypes by analysing their desirable traits (Warner, Patnaik and Gill, 2009).

The availability of many completed and/or in-progress genome sequences of microbes that cause foodborne diseases (listed at http://www.ncbi.nlm.nih.gov/genomes/lproks.cgi) has paved the way for functional genomics approaches including analysis of the bacterial transcriptome, proteome and metabolome (Kuipers, 1999; De Vos, 2001). Table 2 summarizes a comprehensive list of genomics databases for microbial study with respective descriptions. Based on microbial categorical identification, the genomes of Gram-negative bacteria including *Salmonella*, *Escherichia coli* and *Campylobacter* have been described, along with the use of functional genomics tools to study stress response and host–pathogen interaction (Wells and Bennik, 2003). A comprehensive literature review of genomics on microbial food safety discussing the foodborne pathogens *Listeria monocytogenes* and *Bacillus cereus* has been given previously (Abee, van Schaik and Siezen, 2004). The completed genome sequences have been utilized to develop high-throughput analytical methods such as DNA microarrays for gene expression analysis (transcriptomics).

3.2 Transcriptomics

The term "transcriptome" refers to the subset of genes that are transcribed in an organism. It dynamically links the genome, the proteome and the cellular phenotype together. Complete genome sequences can be used in comparative genomics to conduct subtractive hybridization, which can

characterize novel and unique gene sequences using DNA microarrays. The DNA microarray is a high-throughput tool with tremendous potential for detecting pathogenic microbes (Rasooly and Herold, 2008; Puttamreddy *et al*., 2008), but has certain limitations (Peplies, Glockner and Amann, 2003; Zhou, 2003). Researchers use DNA microarrays to study gene expression by identifying genes that are differentially expressed under different conditions or certain genetic perturbations (such as comparing virulent and non-virulent strains). The results are used to determine the expression patterns of genomic signature sequences, which usually represent genomic characteristics such as genes coding for rRNA, toxins, virulence factors, antibiotic resistance determinants or shared conserved indels (insertions/deletions) (Gupta and Griffiths, 2002; Gupta, 2004). One can identify micro-organisms or their important characteristics by finding these differentially expressed signature sequences.

The DNA microarray is based on a straightforward concept extrapolated from the seminal work of Edwin Southern. Southern blots (DNA–DNA hybridization) and Northern blots (RNA–DNA hybridization) use complementary gene sequences to determine the presence or absence of certain DNA or RNA with radiological, fluorogenic or chemiluminescent detectors. Traditional Northern and Southern blots identified DNA or RNA targets of interest using small numbers of specific probes, but the current convention is to refer to the known sequence as the "probe" and the unknown mixture of sequences as the "target". DNA microarrays are coated glass microscope slides with thousands of DNA samples spotted on them in a precise pattern. There are two principal types of microarrays based on the nature of the target: DNA (including cDNA, PCR products, oligonucleotides or plasmids) or RNA (Celis *et al*., 2000; Ye *et al*., 2001) based on two different spotting methods: mechanical microspotting and photolithography (Kumar *et al*., 2000). In addition, there are three major functional classes of microarrays: (a) functional gene arrays (FGAs), in which probes target genes that encode enzymes involved in key processes; (b) phylogenetic oligonucleotide arrays (POAs), which contain oligonucleotide probes that target taxonomic genes (e.g., the 16S rRNA gene); and (c) community genome arrays (CGAs), which provide the complete genomic DNA of multiple cultured strains or species (Zhou, 2003; Wu *et al*., 2006).

With the completed genome sequences of foodborne pathogens available (http://www.ncbi.nlm.nih.gov/genomes/lproks.cgi), it is now possible to analyse the expression of all genes in each genome under various pathogenic conditions using whole-genome DNA microarrays (Call, Brockman and Chandler, 2001; Shen and Higgins, 2006; Liu *et al*., 2007; Siddique, Sharma and Al-Khaldi, 2009; Weckx *et al*., 2009). Such genome-wide expression analysis provides important data for identifying regulatory circuits in these organisms. In the past, DNA microarrays have been used to evaluate microbial communities in raw milk (Giannino *et al*., 2009): oligonucleotide arrays based on a PCR method were developed for taxonomic markers and species-specific virulence genes for simultaneous identification of lactic acid bacteria and foodborne pathogenic bacteria from raw milk. Foodborne pathogens from the above studies showed a highly specific hybridization patterns with the genomic DNA from *Campylobacter jejuni*, *E. coli*, *Salmonella thyphimurium*, *Listeria monocytogenes* and *Yersinia enterocolitica* (Giannino *et al*., 2009).

Bacillus anthracis spores, which have highlighted the importance of the biodefence system in the United States, are extremely stable and able to survive under very harsh conditions. Liu and Ream 2009 determined 27 germination- and sporulation-related genes using real-time transcriptase PCR assays under different milk intervention strategies. This study revealed no overlapping in gene expression under heat treatment (ABC transporter, GTP pyrophosphokinase, germination protein gerN, stage II sporulation protein P and spore germination protein GerHC), milk pasteurization, and milk pasteurization and microfiltration strategies (stage II sporulation proteins E and A, and stage IV sporulation protein A).

Staphylococcus aureus is a major pathogen that causes staphylococcal infection and food poisoning; it produces five major classical types of staphylococcal enterotoxins (SEA, SEB, SEC, SED and SEE) as well as new SEs or SE-like superantigenes (Sags). Multiple strains of *S. aureus* harbour more than one SE gene, and identification of SEs involved in food poisoning can delay identification of the specific pathogen in a pathogenic outbreak. Lin, Chiang and Tsen 2009 developed a chromogenic microarray method that allows simultaneous detection of classical SE genes and a new SE gene (seg), which is phylogenetically highly related to SEB and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat229
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

SEC toxins. In addition, studies to detect enterotoxinogenic *S. aureus* in milk or beef homogenate containing 10–10^4 target cells per millilitre or gram of the sample revealed all six enterotoxin genes.

High-throughput genome sequencing of *Salmonella*, a prevalent foodborne pathogen, has expanded our knowledge of the evolution of epidemic isolates, allowing the creation of complete microarrays. This has improved the throughput of IVET, used to uncover promoters active during infection. In another method, STM, pools of mutants are subjected to selection. Andrews-Polymenis, Santiviago and McClelland 2009 reviewed changes in a population that was monitored on a microarray. A pathogen detection microarray was developed using various 7-mer oligonucleotides specifically targeting *Escherichia coli* O157:H7, *Salmonella enterica*, *Listeria monocytogenes* and *Campylobacter jejuni* pathogens (Suo *et al*., 2009). To achieve high-detection sensitivity and specificity, these DNA microarrays were designed by targeting specific DNA amplification instead of whole-genome random amplification. With a detection sensitivity of 1×10^{-4} ng (∼20 copies) genomic DNA, these microarrays were reported to effectively screen single or multiple pathogens in food samples, providing important genotypic information of pathogenic virulence (Suo *et al*., 2009). In another study, a rapid DNA-microarray-based detection method claimed to identify 10 different pathogenic bacteria (*Enterobacter sakazakii*, *Salmonella enterica*, *Klebsiella pneumoniae*, *Klebsiella oxytoca*, *Serratia marcescens*, *Acinetobacter baumannii*, *Bacillus cereus*, *Listeria monocytogenes*, *Staphylococcus aureus* and *Escherichia coli* O157) associated with powdered infant formula contamination, based on the 16S-23S rRNA gene internal transcribed spacer (ITS) sequences and wzy (O antigen polymerase) gene (Wang *et al*., 2009).

Besides the detection of foodborne pathogens, the success rate of DNA microarrays was tested by another event of epidemic outbreak surveillance (EOS). A custom DNA microarray was designed with the capability of detecting 20 natural (including avian flu) and bio-threat agents with strain-level resolution. The trial exercise on 10 000 samples showed the feasibility of implementing microarrays as a screening tool for EOS regardless of food or biothreat (Uttamchandani *et al*., 2008). These microarray-based platforms for pathogen detection are now on the market from Akonni Biosystems (http://www.akonni.com) and Verdus Laboratories (http://www.vereduslabs.com).

The study of functional expression of the genomic information of microbial pathogenicity using transcriptomics is powerful; however, its scope is limited by not accounting for post-transcriptional processes (Dharmadi and Gonzalez, 2004), a problem which has yet to be resolved. Other tools in '-omics' approaches such as proteomics and metabolomics, with the association of bioinformatics, offer complementary transcription studies to obtain the complete physiological descriptions of individual microbial toxins.

3.3 Proteomics

Proteomics relies heavily on protein characterization at a given time and under certain conditions in prokaryotic or eukaryotic cells. It is also dependent on the sensitivity of instruments for accurate mass determination and the availability of databases for protein identification. Because toxin proteins can mediate microbial pathogenesis, proteomics is a key part of system-level studies and it is the primary tool used to identify cellular interactions beyond the mRNA level (Graham, Graham and McMullan, 2007). Proteomics complements DNA microarray technology for monitoring gene expression and analysing global gene expression patterns at the protein level. Based on the typical workflow shown in Figure 2, discussion will focus on the most common methodologies for identifying toxins generated by food pathogens.

3.3.1 Gel-Based Detection of Microbial Toxins

In proteomics, the invention of 2-DE by O'Farrell and Klose made it possible to explore thousands of proteins at once using an extensive separation technique based on the charge in the first dimension and SDS–PAGE size fractionation in the second dimension (O'Farrell, 1975; Klose, 1975). Nowadays, Immobilized pH gradient (IPG) strips and advanced bioinformatics have remarkably improved the reproducibility and comparability of 2-DE gels. In microbes, proteins can be identified from unique cell type and quantified using 2-DE followed by software-aided quantification tools and mass spectrometry techniques (Watt *et al*., 2003;

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

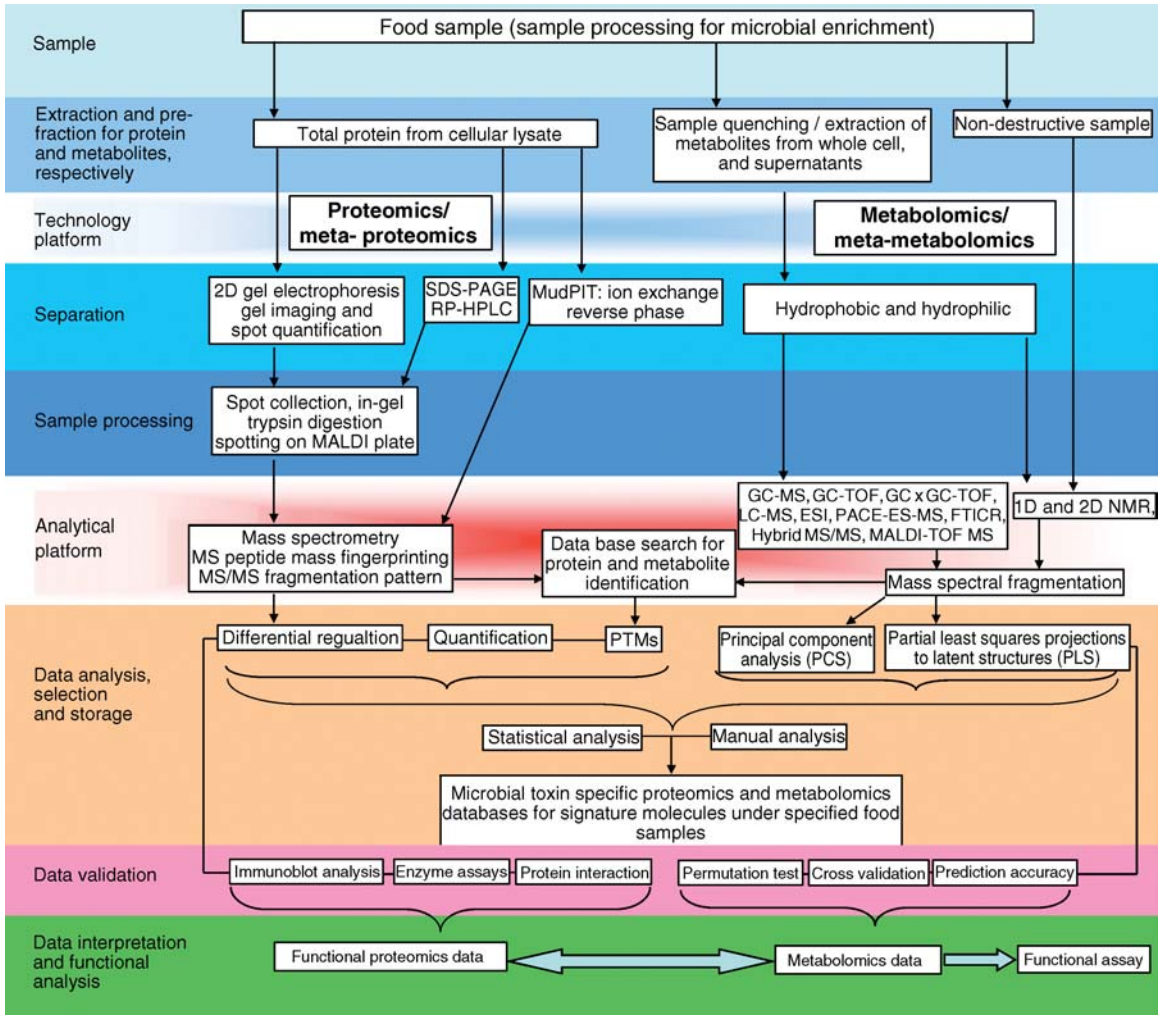

Figure 2. Typical workflow for functional 'omics' approaches, proteomics and metabolomics expression profiling experiments. A variety of methods have been established to identify and/or profile proteins and metabolites. SDS–PAGE, Sodium dodecyl sulphate–polyacrylamide gel electrophoresis; RP-HPLC, reverse phase-high pressure liquid chromatography; MALDI-TOF, matrix-assisted laser desorption ionization-time or flight; MudPIT, multidimensional protein identification technology; MS, mass spectrometry; GC-MS, gas chromatography–mass spectrometry; GC-TOF, gas chromatography–time-of-flight; NMR, nuclear magnetic resonance; LC-MS, liquid chromatography–mass spectrometry; ESI, electron spray ionization; FT ICR, Fourier transform ion cyclone resonance; PTM, post-translational modification.

Singh, 2006). Similar to transcriptomics, comparative proteomics studies assist in the identification of possible enzymatic bottlenecks in microbial pathogenesis (Oosthuizen *et al*., 2002).

The physiological state of an organism leads to a differential expression in genes and proteins. This expression induces a chain of enzymatic reactions that regulates the synthesis and secretion of many toxin proteins that are tightly controlled by regulatory elements sensitive to the environmental signals. 2-DE can explore the regulatory elements responsible for microbial pathogenesis. A dairy-associated toxigenic bacterium, *Bacillus cereus* is a well-known enterotoxin-producing food-poisoning organism and is regarded as one of the most important organisms that can contaminate pasteurized milk and milk products (Christiansson, Bertilsson and Svensson, 1999). Biofilms of this bacterium may serve as a chronic source of microbial contamination, thereby compromising food

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat229
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

quality. High-resolution 2-DE revealed 15 and seven uniquely expressed proteins between the 2- and 18-h-old biofilm proteomes of planktonic cells. Induced expression of catabolic ornithine carbamoyltransferase, lactate dehydrogenase and YhbH, a member of the sigma 54 modulation protein family, was obtained in response to environmental stresses, which indicates that this protein plays an important role in regulation of the biofilm phenotype (Oosthuizen *et al*., 2002).

An opportunistic pathogen, *Enterobacter sakazakii* has been implicated in foodborne diseases in neonates and infants. To understand the dry stress condition, *E. sakazakii* was investigated using 2-DE under two different types of osmotic stress conditions (Riedel and Lehner, 2007). A total of 80 differentially expressed protein spots were noted. Protein affiliation revealed that a number of differentially expressed proteins from desiccated and hyperosmotic-grown samples had the same functional category, but were regulated in opposite directions. The protein pattern under high salt concentration reflected that the protein modulated was involved with central metabolic pathways, whereas the adaptation of cells in a desiccated state represents an accumulation of proteins serving in a protective role for the micro-organism.

Campylobacter jejuni is a leading cause of food- and waterborne illness. Seal *et al*. 2007 studied a robust versus a poor chicken-gastrointestinal-colonizing isolate of *C. jejuni* on 2-DE, which revealed the specific expression of an outer membrane fibronectin binding protein, serine protease and a putative aminopeptidase in the soluble portion of the robust colonizer A74C. Several other proteins, including a cysteine synthase and aconitate hydratase, were detected specifically in the poor colonizer *C. jejuni* NCTC 11168-PMSRU isolate, demonstrating that proteomics is a useful tool for characterization of phenotypic variation among *Campylobacter* sp. The membrane-associated proteome of the *C. jejuni* gastrointestinal isolate (JHH1) was investigated by 2-DE and 77 proteins were identified, of which 44 were predicted to be membrane proteins. A total of 28 proteins were significantly abundant in or unique to JHH1, including eight proteins involved in chemotaxis signal transduction and flagellar motility, the amino-acid-binding surface antigens CjaA and CjaC, and four outer membrane proteins (OMPs) (Cordwell *et al*., 2008). Another proteomics analysis of pathogenesis on 2-DE identified consistent changes with modulation of essential metabolic genes, up-regulation of stress tolerance proteins and increased expression of major OMP (MOMP) and flagellar filament protein (FlaA). Among down-regulated proteins, the majority were metabolic proteins, including fructose bisphosphate aldolase (Gba), fumarate hydrotase (FumC), succinyl-CoA synthetase alpha chain (SucD) and aspartate-semialdehyde dehydrogenase (Asd) (Svensson *et al*., 2009).

Clostridium perfringens, a foodborne pathogen associated with the production of 13 different extracellular toxins, was investigated under cooked meat medium using a combination of 2-DE and MS. A total of 11 prominent proteins were over-expressed in the cells of *C. perfringens* ATCC13124 grown in cooked meat medium (Alam *et al*., 2009). In a 2-DE-based proteomic analysis, an enterohaemorrhagic *E. coli* (EHEC) O157 stress-sensitive variant of F2 (designated MP37) reflected decreased culturability, which revealed that MP37 in the viable but non-culturable (VBNC) had decreased levels of some oxidation-responsive factors (AhpCF, Ace F), but had increased levels of outer membrane protein W (OmpW) (Asakura *et al*., 2007). In pathogenesis, micro-organisms usually employ autoinducer molecules that can modulate virulence expressions, biofilm development and bioluminescence. The role of the universal autoinducer LuxS/Al-2 molecule was investigated in *E. coli* O157:H7 on 2-DE. The key finding of the study revealed that only three proteins appear to be under the direct influence of the LuxS/Al-2 system (Soni *et al*., 2007). Interestingly, these studies support identifying the protein expression in *E. coli* O157:H7 that may vary depending on the food matrix.

3.3.2 *Non-Gel-Based Detection of Microbial Toxins*

Despite its visual characterization and powerful separation of bio-molecules, 2-DE-PAGE has downsides, like other technologies. Its limitations include difficulty in resolving proteins with extremes in isoelectric point (p*I*, <4 and >8), molecular mass, stain-based resolution and inability to reveal hydrophobic proteins. Advancements implementing analytical tool MS have helped to modernize the proteomics area. MS deduces the composition of molecules by determining the particular peptide mass that results from certain combinations of

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat229
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

amino acids. To study these combinations of amino acids, proteins are routinely digested with proteases to generate peptides small enough for MS analysis, referred to as PMF. In this process, the controlled fragmentation of a peptide yields a series of overlapping fragment ions that differ by the mass of a particular amino acid, which allows the full or partial amino acid sequence of the peptide to be deduced. This phenomenon is called MS/MS or tandem MS, as it typically uses one MS analyser to select ions for fragmentation and a second to measure the fragment ions. Over the past 5 years, the gel-free techniques (Figure 2) such as liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) and protein isotope labelling have become popular in proteomics (Singh, 2006; Wolff *et al*., 2007; Gevaert *et al*., 2007).

Members of the genus *Cronobacter* are opportunistic pathogens for neonates and are often associated with contaminated milk powder formulas. Carranza *et al*. 2009 analysed surface-associated and whole-cell proteins by two complementary proteomics approaches, 1D-SDS–PAGE combined with LC-ESI-MS/MS and 2D-LC-MALDI-TOF/TOF MS, that led to the identification of 832 proteins corresponding to 19% of the theoretically expressed proteins involved in central metabolic pathways, translation, protein folding and stability. Other identified proteins were putative virulence factors, macrophage infectivity potentiator, a superoxide dismutase protecting the pathogen against reactive oxygen species and an enterobactin-receptor protein.

Campylobacter sp. was investigated under both gel- and non-gel-based proteomics approaches. The protein biomarkers were observed in the matrix-assisted laser desorption/ionization time-of-flight mass spectra (MALDI-TOF-MS) of cell lysate of five strains of *C. upsaliensis* and one strain of *C. helveticus* by "bottom-up" proteomics techniques. Fagerquist 2007 reported these protein biomarkers: periplasmic protein, 10 kD chaperonin, protein of unknown function (DUF465), D-methionine-binding lipoprotein MetQ, phnA protein, DNA-binding protein HU, thioredoxin, cytochrome *c* family protein, helix-turn-helix domain protein, asparigenase family protein and several ribosomal and conserved hypothetical proteins. Interestingly, the proteomic identification of the protein biomarkers of the non-genomically sequenced *C. upsaliensis* and *C. helveticus* identified homologous protein amino acid sequences to that of the sequenced strain. Based on MALDI TOF-TOF, Fagerquist *et al*. 2009 developed web-based software for the rapid identification of protein biomarkers of several micro-organisms.

Various fungi, oomycetes, viruses and bacteria may cause diseases in plants that can be devastating to the food supply. Padliya and Cooper 2006 reviewed MS-based proteomics for the detection of plant pathogens. *Fusarium* infections in maize are a global issue. A LC-MS/MS method was developed to detect beauvericin and the four enniatins A, A1, B and B1 in maize and maize silage (Sorensen *et al*., 2008). A form of direct sample analysis on a microchip using SELDI-TOF-MS is another promising analytical technique for specific samples (Issaq *et al*., 2002); it represents a novel approach to biomarker discovery combined with liquid chromatography. Although SELDI analysis has been useful for identifying potential biomarkers in clinical research, some have questioned its reproducibility and specificity (Jacobs and Menon, 2004; Diamandis, 2004). Another emerging technique, Fourier transform ICR (FT-ICR) MS, may allow multistage MS experiments (MS*n*) with an enhanced detection limit of 30 zmol for a 10-kDa protein (Laskin and Futrell, 2005).

Adding ESI and LC to MS has opened new analytical windows for the detection and identification of potential contaminants in the environment. A direct analysis of a peroxisomal protein pattern associated with marine contaminants in mussels *Mytilus galloprovincialis* was performed using ESI MS/MS to identify various epoxide hydrolases, peroxisomal antioxidant enzymes and SOX (Mi *et al*., 2005). Another ion source that has been developed allows the protein chips to be analysed using a hybrid triple Quadrupole/TOF MS providing additional sequencing capabilities (Seibert *et al*., 2004). With this new source, proteins can be tryptically digested directly on the arrays and the resulting fragments identified by tandem MS. An absolute quantitative mass spectrometry was developed to investigate the *Staphylococcal* enterotoxins involved in food poisoning outbreaks using QTOF-MS (Hennekinne *et al*., 2009).

3.3.3 Interactomics

In micro-organisms, many proteins take part in a multicomponent protein aggregation under

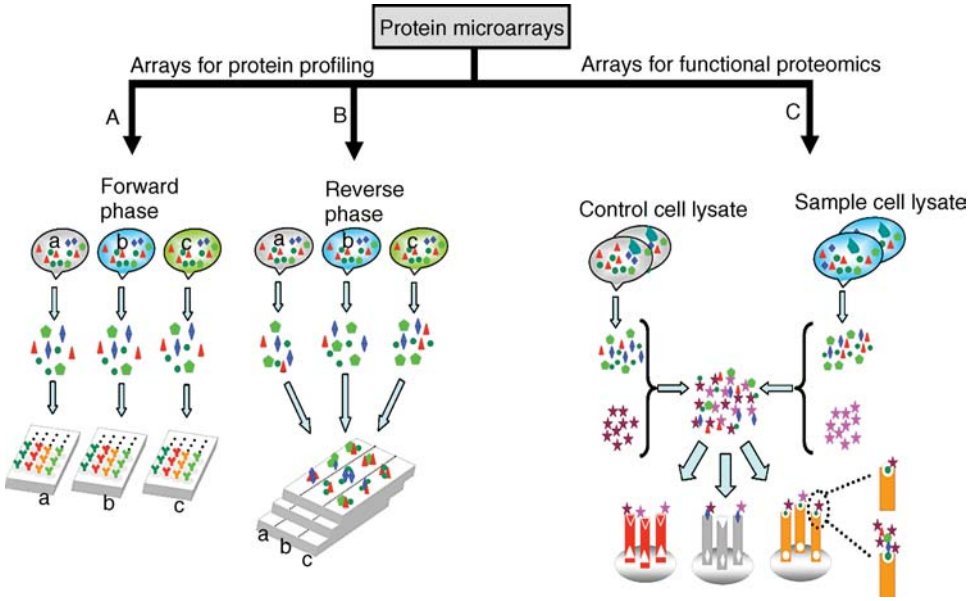

Figure 3. Different types of protein microarray platforms for microbial toxin detection. (a) In a forward-phase protein microarray platform, complex protein mixtures from different sources can be analysed on one microarray containing thousands of captured molecules. The analyte can be detected using direct fluorescent labelling or by a second specific antibody. (b) The reverse-phase protein microarray can be used to analyse whole repertoire of a protein sample that represents the physiological state of an organism. The protein sample can be immobilized onto a nitrocellulose membrane with glass backing. (c) Functional proteomics could further be achieved by designing a differential protein display platform. The control and different physiological state cellular lysate samples conjugated to distinct fluorescent molecules. Equal amounts of protein samples were mixed together and incubated simultaneously on an antibody microarray. The target molecules can be detected by their respective specific antibodies with modulated expression of proteins that may directly reflect in overlay of the colour intensities.

physiological response that affects the entire complex protein interaction network. Detection of interactive partner proteins is the prime task of second-generation proteomics, that is functional proteomics. The growing demand in genomics and proteomics for the analysis of gene and protein function is enormously enhancing the need for microarray-based assays, which are fast, accurate and sensitive. Other than the DNA microarray, as a next-generation tool, antibody-based protein microarrays are increasing in popularity (Angenendt, 2005; Kreutzberger, 2006; Kingsmore, 2006; Ehricht *et al.*, 2009) and it has been verified that this technology is capable of filling the gap between transcriptomics and proteomics (Liu and Zhu, 2005; Kerschgens, Egener-Kuhn and Mermod, 2009).

Protein arrays or biochips are in the developmental stage and can be modified for use in the field to analyse specific protein toxins in an array affixed to a platform (Figure 3). Technically, two types of protein arrays have been developed so far: focused protein profiling and arrays for functional studies. Based on the sample application, the first category can be subdivided into two groups: forward-phase protein microarrays (Figure 3A) and reverse-phase protein microarrays (Figure 3B). The forward-phase protein microarrays use sample incubation on the array so that different analytes can be detected simultaneously, as in antibody microarrays. The reverse-phase arrays, one of the latest phase microarray platforms, feature samples immobilized on a nitrocellulose membrane backing with glass (Figure 3B). Using these arrays, a large collection of probes can easily be screened within a single-step reaction (Labaer and Ramachandran, 2005). The functional protein microarray can further be designed by conjugating the cell lysate sample with the fluorescent molecules (Figure 3C). Differential expression in the target molecule can be detected by overlay of the colour intensities.

Protein Array-Based Detection of Microbial Toxins

Analytical assays are of the utmost importance to ensure food safety. In the past, many diagnostic

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat229

tests were performed based on the cell culture, plate assays, molecular technique (e.g., PCR) or immunoassay methods (e.g., ELISA – enzyme-linked immunosorbent assay) where molecules of interest could be detected in complex food samples. As the expression of most genes, proteins and biomolecules in living cells (prokaryotes or eukaryotes) is environmentally responsive, it is desirable to monitor multiple biomarkers simultaneously to predict the microbial state of action in advance.

Data obtained from protein, protein-domain and peptide microarrays can be combined to understand microbial pathogenesis and detect specific toxins. Rao *et al*. 2004 compared immobilized antibody microarrays with the Luminex flow cytometry system for detection of bacterial and viral proteins and reported lower levels of detection in the latter system, supporting the protein microarray for miniaturization. A fluorescent-labelled antibody-based array biosensor was developed to detect toxins, bacteria and viruses at low levels within 20 min in food, environmental matrixes and clinical samples. The detection limit was 25 pg ml^{-1} in a buffer of ovalbumin egg-contaminated sample and 1.3 ng ml^{-1} (13 ng g^{-1}) was obtained in non-egg pasta extract (Shriver-Lake, Taitt and Ligler, 2004). A variety of food allergen proteins from milk, eggs, hazelnuts, peanuts, shellfish and sesame were detected using biosensor immunoassays in food samples (Yman *et al*., 2006). The allergen detection limit was down to 1–12.5 μg g^{-1} in food samples.

A microarray sandwich immunoassay biosensor was tested to detect *E. coli* O157:H7. The array platform was developed using biotinylated capture antibodies on streptavidin-coated microarray slides. The capture and reporter antibodies on this array platform detected 10^6 cells ml^{-1} under optimized experimentation (Gehring *et al*., 2006). Huelseweh, Ehricht and Marschall 2006 developed a protein chip for the ArrayTube™ platform with easy and cheap handling technology, using the classical procedure of a sandwich-enzyme-linked immunosorbent assay and signal amplification by streptavidin-poly-horseradish peroxidase. With efficient detection limits, this chip was demonstrated to detect a variety of viruses (Venezuelan equine encephalitis virus, St Louis encephalitis virus, West Nile virus, yellow fever virus, Orthopox virus species), bacteria (*Francisella tularensis*, *Yersinia pestis*, *Brucella melitensis*, *Burkholderia mallei* and *Escherichia coli* EHEC O157:H7) and toxins (*Staphylococcus* enterotoxin B, ricin). It was possible to detect five of the "dirty dozen" agents on one single protein chip in parallel. Protein microarray technology is a complementary method for the study of protein *in vitro* as well. Many studies performed using protein-microarray-based platform with wide-ranging potential for biodefence were reviewed by Uttamchandani *et al*. 2008. These studies are equally important to detect foodborne pathogens and ensure the safety of the food chain. Further research on 2-DE-based, MS-based and array-based identification of proteins/enzymes may help us to evaluate the interaction of food matrices and molecules in controlling pathogen survival and virulence in foods.

Although array-based proteomics is an ambitious approach, it raises serious challenges as well. In contrast to captured molecules from DNA chips, which can easily be predicted and synthesized from complementary base pairings, captured molecules from a protein array need to be generated and screened for sensitivity and specificity. Immobilization of proteins on the array without damaging their tertiary structure is also crucial in protein microarrays because the proteins often occur in complexes. Limitations also exist in sensitivities to microarray-based protein expression, as the high background from non-specific binding could interfere with signal intensities. In addition, when the direct fluorescent-labelling approach is used, strong signals within a microspot may derive from a high concentration of a single protein molecule (Figure 3C) or from co-immunoprecipitated complex.

Because the regulatory interactions within any organism exist as a complex network on multiple levels, any individual alteration that might be detected via 2-DE or protein arrays will not necessarily change the way the microbe functions. One must conduct unbiased (metabolite) analyses when creating a gene or protein profile in order to precisely define an organism's biochemical functions. These analyses connect the gene sequence to the metabolic function (metabolome) and work together with existing genomics techniques (transcriptomics). Integration of metabolomics, proteomics and transcriptomics is still a challenge for researchers in situations where low-molecular-weight primary and secondary metabolites play an important part in the toxicity of a microbe.

3.4 Metabolomics

In the course of its life, a microbial cell will excrete hundreds of different primary and secondary metabolites that vary according to environmental factors. Metabolomics is an extension of targeted metabolite analysis to include the study of the entire metabolic content of a cell at a given time (called the metabolome). It involves three strategies: (a) metabolite fingerprinting, (b) metabolite profiling and (c) metabolome analysis.

Although DNA microarrays and proteomics can produce vast amounts of data for gene and protein expression, metabolomics has far simpler data sets, which makes data analysis and interpretation easier. A typical workflow of most common methodologies used to identify toxins has been shown in Figure 2.

Metabolites are low-molecular-weight organic compounds (<1000 Da) that are involved in general metabolic reactions or required for an organism's maintenance, growth and normal functioning. Like proteins, metabolites are expressed in a context-dependent way, and in different microbial physiological states, metabolite concentrations are directly related to protein expression (Raamsdonk *et al*., 2001); this can facilitate descriptions of those metabolic states in different growth phases. Quantifying all of the metabolites in a cellular system is the ultimate principle for any experiment in metabolomics. To achieve this, automation and miniaturization technologies have been developed that can isolate and characterize metabolites, including tools for sampling, extracting specific molecular classes, maintaining storage temperature, preparing samples and analysing those samples (Buchholz *et al*., 2002;van der Werf, Jellema and Hankemeier, 2005).

To quantify metabolites inside and outside the cell, metabolomics frequently utilizes high-throughput analyses such as nuclear magnetic resonance (NMR) and gas or liquid chromatography paired with mass spectrometry (GC-MS and LC-MS) (Buchholz *et al*., 2002; Issaq *et al*., 2009). After samples are detected using LC-MS, NMR analysis is often performed along with MS/MS experiments. Fractionation and NMR analysis are not often straightforward because the samples are usually complex and in limited quantity; profiling metabolic composition requires a combination of sensitive equipment, such as LC using MS/MS and high-resolution MS detection. One promising new system includes a hybrid MS detector such as a linear ion-trap combined with an FT; however, it is limited to identifying certain isomers (Mano and Goto, 2003; Tolstikov and Fiehn, 2002).

Metabolomics depends on the translation of information from large sets of metabolome data into genotypic and phenotypic characteristics of particular organisms. Unbiased statistical multivariate data analysis (MVDA), pattern recognition, chemometrics and biometrics tools are used to perform this. Because biological systems are multivariate and biomolecules are interdependent, scientific hypotheses can be produced by MVDA analysis through mathematically reducing parameters in data sets and visualizing their clustering behaviour (Dillon and Goldstein, 1984;Glassey, Montague and Mohan, 2000).

Various filamentous fungi and yeasts from the genera *Saccharomyces*, *Penicillium*, *Aspergillus* and *Fusarium* are well known to be involved in food spoilage by degradation or toxin contamination. There are several reviews that aim to compile extensive knowledge of metabolite production by fungi (Cole and Schweikert, 2003a, 2003b; Cole, Jarvis and Schweikert, 2003). Using metabolomics-based approaches, Smedsgaard and Nielsen 2005 described an intelligent screening strategy (ISS) for the efficient discovery of microbial products and exploitation of micro-organisms. These microbial products could be useful to determine specific bacteria from sites of toxin contamination. The micro-organisms *Campylobacter jejuni* 81-176 and *Campylobacter coli* VC167 were functionally characterized using focused and targeted metabolomics approaches, respectively (McNally *et al*., 2006; McNally *et al*., 2007). These studies were designed to demonstrate the usefulness of metabolomics for targeting compounds within the bacterial metabolome to assign functions to genes, identify metabolic intermediates and elucidate novel biosynthetic pathways. A capillary electrophoresis-TOF-MS method with integrated high-confidence analyte identification for metabolomics was developed to elucidate metabolic changes in *E. coli* (Timischl *et al*., 2008). A comprehensive global metabolic profiling of *E. coli* was examined in chemostate culture conditions in the laboratory (Winder *et al*., 2008).

To detect specific foodborne pathogens, complete profiles of their metabolomes need to be carried

out that characterize specific toxins. Specifically, enterotoxin and exotoxin activity can be profiled to characterize the neighbouring or corresponding enzymes based on qualitative and quantitative estimation. However, no report has been published so far that represents a global metabolome study to detect foodborne pathogens from given food matrices.

3.5 Bioinformatics

The tools of functional transcriptomics, proteomics and metabolomics are decisive for the description of microbial virulence, but they generate a great amount of data that may be difficult to analyse without a bioinformatics (computational tools) approach. Bioinformatics plays a key role in integrating and analysing the obtained data in DNA microarray transcriptomics. Reconstruction of metabolic potential using bioinformatics tools and databases, followed by targeted experimental verification and exploration of metabolic and regulatory network properties, are among the top challenges for those interested in improving the exploitation of food pathogens.

In microbial biotechnology, bioinformatics has been used for computation analysis of laboratory data, identification of protein coding segments and development of genomics, proteomics and metabolomics data. Bioinformaticians aimed to design computational methods to determine and predict biomolecules based on three major approaches: (a) to combine mathematical modelling and search techniques; (b) to explore, match and analyse high-level functions using mathematical modelling; and (c) to use computation search alignment techniques to compare new biomolecules within each functional '-omics' approach.

The powerful tools of systems biology (transcriptomics, proteomics and metabolomics) can be verified by *in silico* pathways based on the information biomolecules generated. The exponential growth of such verifications is summarized here in comprehensive lists of genomics (Table 2), transcriptomics (Table 3), proteomics (Table 4) and metabolomics (Table 5) databases for microbial study with respective descriptions. A comprehensive resource that can fulfil the requirements for gene-protein-based and metabolite-based detection of foodborne pathogens is still needed, however.

4 OMICS AND FUTURE IMPLICATIONS – REACTOME

After it became possible to integrate computational biology with DNA and protein microarrays, 2-DE and sophisticated analytical chemistry tools (Figure 2), biological information could be interpreted in advance. A comprehensive transcriptome, proteome and metabolome study would be especially useful in understanding microbial pathophysiology in different phases of growth and locating contamination sources in food. Thus, a new method is needed to connect functional products of genes (metabolites) with cognate enzymes/proteins and produce global descriptions of metabolic responses. An array-based "reactome" could contain a detailed, quantitative profile of the metabolic activity of a cell population—a "metabolic bar code" for a specific micro-organism—and serve as a connection between the genome and metabolome by centralizing the proteome. A metabolome–genome link has already been established in one study by determining the metabolic profiles of *Pseudomonas putida* strain (KT2440) and *Streptomyces coelicolor* strain (M145) on a reactome array (Beloqui *et al*., 2009). By connecting genes and metabolites and determining possible enzymes/proteins on the array, the reactome can be applied towards the detection of foodborne pathogens.

Towards fulfilling the goal of early and faster detection of foodborne pathogens, genomics data are necessary to complement the proteomics and metabolomics approaches. However, proteomics and metabolomics would retain their central positions in functional transcriptomics and genomics. A study published by Trauger *et al*. 2008 correlates the transcriptome, proteome and metabolome in the environmental adaptation of *Pyrococcus furiosus*, a hyperthermophile. Analysing low-molecular-weight metabolites related to proteins, not mRNAs, is essential in determining the nature and site of a toxin, which is presumably the final destination of gene expression. A faster and more reliable detection method for the individual toxin products, the enzymes and/or metabolites, can only be discovered via a joint transcriptomics, proteomics and metabolomics approach (Figure 1).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat229
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

The recently developed bioinformatics tools at http://www.systomonas.de and http://rosy.tu-bs.de may also help to correlate microbial metabolic physiology, genetic profiling and protein profiling on a single platform.

5 CONCLUSION

A variety of microbial toxins have now become diversified in food and related substances due to ongoing microbial tolerance of antibiotics and other environmental factors. Our understanding to trace diversified microbial toxins is limited because of complex microbial physiology. The challenges in understanding of these toxins can be met by integrating functional '-omics'-based technologies such as genetic engineering, transcriptomics, proteomics and metabolomics. In addition, "reactome" offers remarkable, unique platform ahead to understand and detect microbial toxins. The gene-oriented changes are now feasible to explore through proteomics that can determine the microbial virulent state in adulterated food. The expression pattern of intra- and extracellular metabolites from unique gene through protein expression route would promise to predict organisms' metabolic path towards toxin products. The continued technological advancements could ultimately lead to comprehensive approaches in which gene expression, protein and metabolites are analysed to elucidate the functioning of entire organism.

Epigenomic Analysis in Toxicology

Toshikazu Ushijima, Eriko Okochi-Takada and Hideyuki Takeshima

Carcinogenesis Division, National Cancer Center Research Institute, Tokyo, Japan

1 INTRODUCTION

The epigenome, the totality of epigenetic modifications in a cell, plays a fundamental role in development, differentiation, and reprogramming (Law and Jacobsen, 2010). Like the genome and unlike transcriptome and proteome in a cell, the epigenome is replicated upon somatic DNA replication (Ushijima *et al*., 2003; Laird *et al*., 2004; Riggs and Xiong, 2004; Margueron and Reinberg, 2010). At the same time, unlike the genome, the epigenome undergoes dynamic changes during development, differentiation, and reprogramming (Bird, 2007; Cedar and Bergman, 2009). In other words, the epigenome is established as a consequence of interactions between the genome and environmental input (Gan *et al*., 2007), and serves as a cellular memory once established.

From a toxicological viewpoint, agents that induce aberrations in the epigenome are of serious concern. Once an aberrant epigenome is established by some factors, the aberrant epigenome is inherited at somatic cell divisions even if the aberrant status is hazardous to the cell or host. It is well established now that aberration of the epigenome can be causally involved in cancer development and progression (Jones and Baylin, 2007), and it is expected that aberration of the epigenome could be involved in a broader range of acquired disorders (Jones *et al*., 2008; Robertson, 2005). This chapter will introduce what is the epigenome, how it is altered in cancers and other disorders, what induces epigenetic alterations, and essential techniques for epigenome analysis.

2 EPIGENETIC MODIFICATIONS AND EPIGENOME

Epigenetic modifications include DNA methylation and histone modifications. DNA methylation is well known for its high fidelity at somatic cell replication (Ushijima *et al*., 2003; Laird *et al*., 2004; Riggs and Xiong, 2004), and thus is considered as the central player in maintenance of long-term cellular memory in mammalian cells. Histone modifications are more diverse, and individual modifications seem to have their own roles and fidelity in somatic cell replication.

2.1 DNA Methylation

DNA methylation in epigenetics refers to physiological methylation at the 5 position of cytosines at some CpG sites (Figure 1a). This methylation is different from pathological DNA methylations at O^6 and $N7$ positions of guanines, which are abnormal adducts produced by alkylating agents and important in the field of toxicology. DNA methylation at CpG sites is characterized by its inheritance upon somatic cell division, and critical roles in regulation of gene transcription.

2.1.1 Maintenance of DNA Methylation Statuses

When a CpG site is methylated, cytosines on both strands are methylated (Figure 1b). At DNA

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat230
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

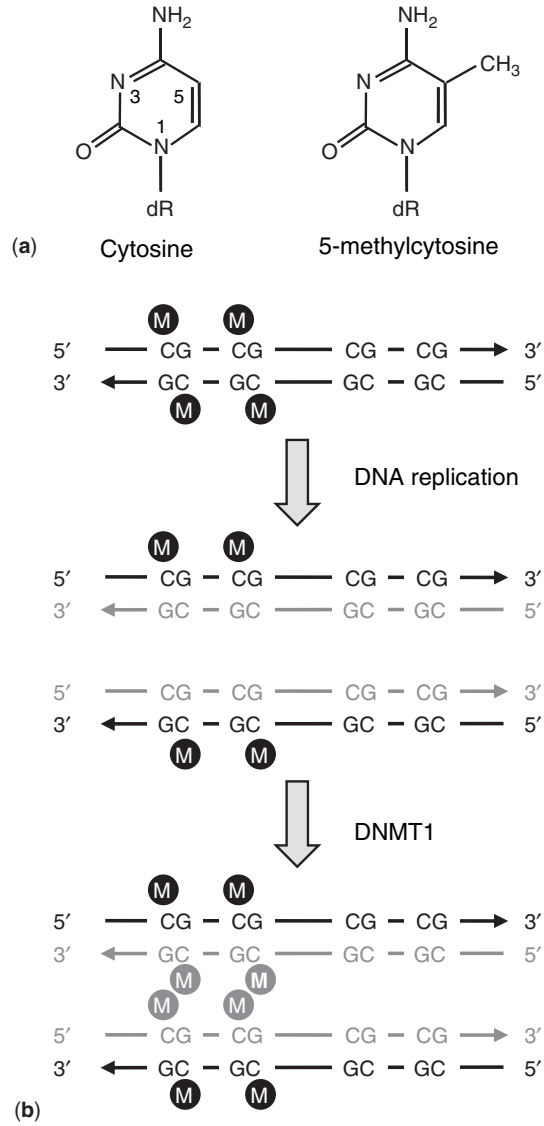

Figure 1. Characteristics of DNA methylation: (a) structure of 5-methylcytosine; (b) maintenance of DNA methylation at somatic cell replication. DNMT1 restores fully methylated statuses by methylating hemi-methylated CpG sites at DNA replication. Methylated or unmethylated statuses are inherited with high fidelity.

replication, cytosines in a newly synthesized DNA strand do not contain methyl groups, and hemi-methylated CpG sites are temporarily formed. However, a maintenance methylase, DNA methyltransferase 1 (DNMT1), associated with a replication fork (Hermann, Goyal and Jeltsch, 2004), restores those hemi-methylated CpG sites into fully methylated CpG sites. DNMT1 has much lower activity on unmethylated CpG sites, and unmethylated CpG sites are kept unmethylated. Therefore, DNA methylation patterns are replicated at somatic DNA replication with a high fidelity (~99.9%), especially in CpG islands (Ushijima *et al*., 2003; Laird *et al*., 2004; Riggs and Xiong, 2004).

DNA methyltransferases are essential machineries to establish and maintain DNA methylation. As mentioned above, DNMT1 has the major role in maintaining DNA methylation upon DNA replication, and homozygous knockout of *Dnmt1* is lethal in mid-gestation (Li *et al*., 1992). In contrast, two *de novo* methylases, DNMT3A and DNMT3B, are involved in establishment of genome-wide DNA methylation patterns (Okano, Xie and Li, 1998; Hermann, Goyal and Jeltsch, 2004). While Dnmt3a cannot methylate nucleosomal DNA, Dnmt3b can (Takeshima *et al*., 2006). Homozygous knockout of *Dnmt3a* causes lethality after birth (Okano *et al*., 1999), and Dnmt3a is essential in establishment of genomic imprinting (Kaneda *et al*., 2004). Homozygous knockout of *Dnmt3b* causes lethality before birth, and germline mutations of *DNMT3B* cause a recessive inherited disorder, ICF syndrome, in humans (Okano *et al*., 1999).

2.1.2 *Gene Silencing Caused By DNA Methylation of Promoter CpG Islands*

DNA methylation of a CpG island in a gene promoter region has been known to be consistently associated with transcriptional repression of its downstream gene (Baylin and Ohm, 2006; Ushijima, 2005). This was further supported by recent genome-wide analyses of DNA methylation and gene expression (Weber *et al*., 2007; Rauch *et al*., 2009; Yamashita *et al*., 2009). As a mechanism how DNA methylation of a CpG island in a promoter region causes silencing of its downstream gene, the role of nucleosome formation, as discussed below, is currently believed to be important (Li *et al*., 2007), in addition to induction of inactive histone modifications and inhibition of binding of methylation-sensitive transcription factors.

DOI: 10.1002/9780470744307.gat230
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2.1.3 *Gene Body Methylation and Increased Transcription*

Recent genome-wide analyses also showed that methylation of CpG islands in gene bodies is often associated with increased gene transcription (Hellman and Chess, 2007; Rauch *et al*., 2009; Yamashita *et al*., 2009). Since the association is much weaker than that between methylation of promoter CpG islands and gene repression, the association observed in gene bodies is considered to have no direct cause-consequence relationship.

2.2 Nucleosomes and Histone Modifications

DNA in the nucleus is not naked, and forms nucleosome structures along with core histones. The critical importance of histone modifications and nucleosomes in transcriptional regulation is now recognized.

2.2.1 *Nucleosome and Nucleosome-Free Region in Promoters*

A core nucleosome is made of 146 ± 2 base-pair stretches of DNA around the histone octamer for 1.65 turns in a left-handed superhelix (Figure 2) (Luger *et al*., 1997). A linker is made of a short stretch of DNA and linker histone H1, and connects two nucleosomes. Thus one nucleosome contains a core and a linker, and is approximately 200 base-pairs long. The histone octamer consists of two of each of four core histone proteins, H2A, H2B, H3, and H4. It is known that DNA in nucleosomes is resistant to micrococcal nuclease and *Sss*I methylase activity, which is experimentally important.

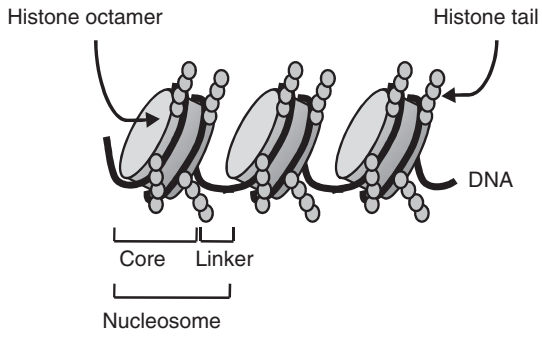

Figure 2. Structure of nucleosome. DNA wraps around the histone octamer, forming a core nucleosome. Core nucleosomes are connected by a linker, and the core and linker forms a nucleosome. Histone tails protrude from the histone octamer.

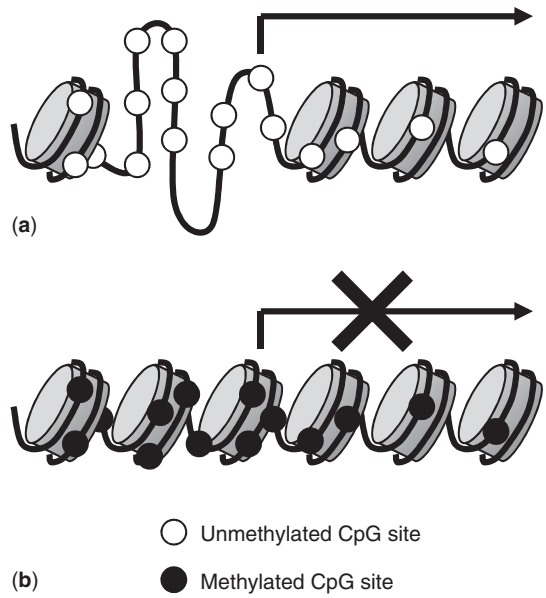

Figure 3. Nucleosome-free region (NFR) and its role in transcription: (a) an approximately 200 bp region upstream of a transcription start site (TSS) lack a nucleosome, and is designated as a NFR. RNA polymerase II and other transcription factors are considered to bind to the NFR; (b) if a NFR in a promoter CpG island is methylated, a nucleosome is formed, and transcription from the NFR is markedly impaired.

It is now known that an approximately 200 bp region just upstream of a transcription start site (TSS) lacks a nucleosome, forming a nucleosome-free region (NFR) (Figure 3a) (Lee *et al*., 2004; Li *et al*., 2007; Ozsolak *et al*., 2007). When a NFR of a CpG-rich promoter is unmethylated, no nucleosomes are formed there, and transcription can be initiated. In contrast, if a NFR is methylated, a nucleosome is formed in the region, and transcription is markedly impaired (gene silencing by promoter methylation) (Figure 3b) (Lin *et al*., 2007).

2.2.2 *Histone Modifications and Their Roles in Transcription Regulation*

All core histones are composed of a histone fold domain and a structurally undefined tail region (Zheng and Hayes, 2003). Tail regions of histones

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat230
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

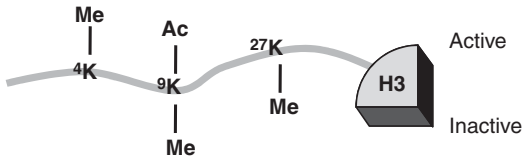

Figure 4. Representative histone modifications. Methylation of H3K4 and acetylation of H3K9 are associated with increased gene transcription, and methylation of H3K9 and H3K27 are associated with gene silencing.

H2A, H2B, H3, and H4 protrude from the histone octamer, and their chemical modifications play important roles in gene regulation (Ruthenburg *et al*., 2007). Histone acetylation can be observed on the tails of four kinds of histones, and is usually associated with active gene transcription. Histone acetyltransferases (HATs) acetylate histones, and histone deacetylases (HDACs) deacetylate histones (Minucci and Pelicci, 2006). Four classes of HDACs are known, and HDAC1, HDAC2, and HDAC4 are considered to be good targets of HDAC inhibitor drugs.

In addition to histone acetylation, histone methylation at specific lysine and arginine residues is now known to have specific meanings (Figure 4) (Ruthenburg *et al*., 2007). Especially, methylation of lysine 4, 9, and 27 of histone H3 (H3K4, H3K9, and H3K27, respectively) is associated with active or inactive gene transcription (Barski *et al*., 2007). At transcription start sites, trimethylation of H3K4 (H3K4me3) is strongly associated with active transcription, and H3K27me3 is associated with silencing of a group of genes (Barski *et al*., 2007; Kondo *et al*., 2008). In transcribed regions, H3K4me1, H3K4me2, and H3K4me3 are associated with active transcription, H3K27me2 and H3K27me3 are associated with inactive transcription, and H3K9me2 and H3K9me3 are weakly associated with inactive transcription. The methylation statuses of histones are finely regulated by histone methyltransferases (Kouzarides, 2007; Hublitz, Albert and Peters, 2009) and demethylases (Shi, 2007; Klose and Zhang, 2007).

2.3 Interplay Between DNA Methylation and Histone Modifications

DNA methylation and histone modifications are often dependent upon each other. For example, DNA methylation is recognized by multiple proteins, such as MeCP2 and MBDs, and these proteins recruit histone deacetylases (Richards and Elgin, 2002) and a histone methyltransferase, SUV39H1 (Fujita *et al*., 2003), which is known to be involved in formation of a heterochromatin structure (Stewart, Li and Wong, 2005). Deacetylated histones are known to be positively charged and to associate tightly with DNA, inhibiting accession of transcription complexes to DNA. On the other hand, H3K9me3 is recognized by heterochromatin protein 1 (HP1), and HP1 recruits DNMT3A and DNMT3B (Fuks, 2005). It helps that inactive histone modification is re-enforced by DNA methylation.

3 EPIGENOME ALTERATIONS IN CANCERS AND OTHER DISORDERS

Epigenomes of normal cells are precisely established and maintained according to developmental stages (Meissner *et al*., 2008; Rauch *et al*., 2009). The vast majority of CpG islands are kept unmethylated, and repetitive sequences, which consist of more than 40% of the genome (Lander *et al*., 2001), are heavily methylated. In cancer cells, an altered epigenome, characterized by "global hypomethylation and regional hypermethylation", is observed (Figure 5).

3.1 Global Hypomethylation

Global hypomethylation, defined as a decrease in 5-methylcytosine content in the genome, is proposed to be present in almost all types of cancer cells (Feinberg and Tycko, 2004). Global hypomethylation is closely associated with hypomethylation of repetitive sequences (Feinberg and Tycko, 2004; Kaneda *et al*., 2004), but can involve demethylation of normally methylated CpG islands. Demethylation of normally methylated promoter CpG islands leads to aberrant transcription of cancer-testis antigen genes, such as melanoma antigen genes (*MAGE*s) (de Smet *et al*., 1999), and potentially oncogenes. Also, hypomethylation of a differentially methylated region (DMR) of *IGF2*, known as loss of imprinting, can lead to increased expression and tumor development (Cui *et al*., 2002). A mouse strain with global hypomethylation demonstrated increased rates of chromosomal loss

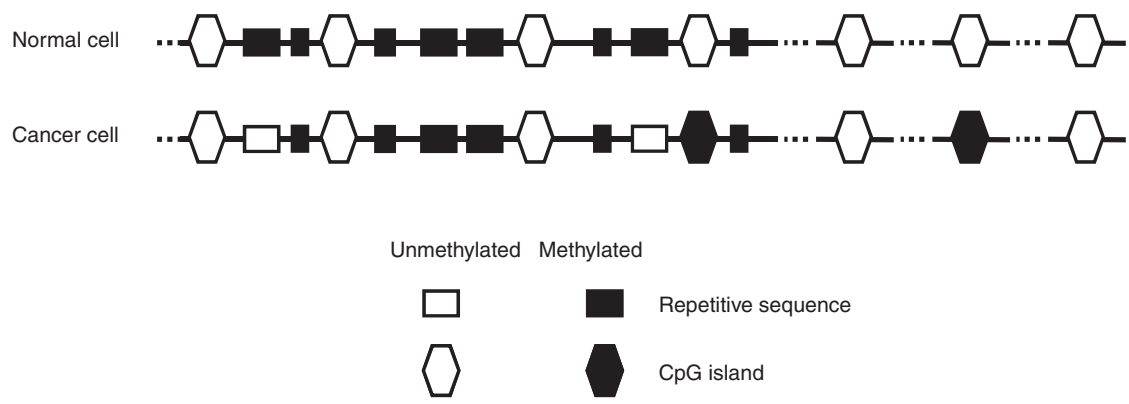

Figure 5. Epigenomic alterations in cancers. Normally methylated repetitive sequences are hypomethylated, and a fraction of normally unmethylated CpG islands are methylated.

(Chen *et al*., 1998) and increased incidences of lymphomas, colonic microadenomas and liver tumors (Chen *et al*., 1998; Eden *et al*., 2003; Yamada *et al*., 2005). At the same time, global hypomethylation led to suppression of macroscopic tumors of the intestine (Laird *et al*., 1995; Yamada *et al*., 2005).

3.2 Regional Hypermethylation – Aberrant Methylation of CpG Islands

"Regional hypermethylation" denotes methylation of CpG islands that are normally unmethylated. If such methylation is induced in the promoter CpG island of a tumor-suppressor gene, the gene is permanently silenced, and the silencing can be causally involved in cancer development and progression (Baylin and Ohm, 2006; Jones and Baylin, 2007). Now, many tumor-suppressor genes involved in various cellular processes, such as cell cycle regulation (*CDKN2A*), WNT signalling (*SFRP* family and *CDH1*), and DNA repair (*MLH1* and *MGMT*), are known to be inactivated by promoter methylation (Baylin and Ohm, 2006). In some cancer types, such as gastric cancers, tumor-suppressor genes are inactivated more frequently by promoter methylation than by mutations (Ushijima and Sasako, 2004). Importantly, CpG islands aberrantly methylated in cancers are not limited to those in promoter regions, and can be present in CpG islands in gene bodies. Methylation of such regions is often associated with increased gene expression (Ushijima, 2005; Rauch *et al*., 2009; Yamashita *et al*., 2009).

3.3 Driver Methylation and Passenger Methylation

Now it is known that several hundred to one thousand promoter CpG islands are methylated in cancer cells (Rauch *et al*., 2009; Yamashita *et al*., 2009). Most of the genes methylated in cancers have no or only low expression, have H3K27me3 modification, and lack stalled RNA polymerase II in normal counterpart cells (Takeshima and Ushijima, 2010; Takeshima *et al*., 2009). Therefore, it is considered that most of the promoter CpG islands aberrantly methylated in cancers are not causally involved in carcinogenesis, but methylated in association with it. As mutations are classified as driver and passenger mutations, methylation causally involved in carcinogenesis is designated as "driver methylation", and methylation that simply accompanies the process is designated as "passenger methylation".

3.4 Aberrant Histone Modifications

Histone modifications are also known to be altered in cancers. The global decrease in acetylation of lysine 16 and trimethylation of lysine 20 of histone H4 is known as a hallmark of cancer cells (Fraga *et al*., 2005a). A global decrease in H3K4me1, H3K9me2, and H3K9me3 and acetylation of histone H3 and H4 are reported in prostate cancer cells (Ellinger *et al*., 2010; Seligson *et al*., 2009). A decrease in H3K4me2, H3K9me2, and acetylation of H3K18 is present in pancreatic cancers,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat230
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

and is the most significant predictor of overall survival (Manuyakorn *et al*., 2010). In addition to these alterations, EZH2, a histone methyltransferase involved in H3K27me3, is known to be overexpressed in breast and prostate cancer cells (Kleer *et al*., 2003; Varambally *et al*., 2002). In accordance with EZH2 overexpression, H3K27me3 is increased in many genes in prostate cancer cells (Kondo *et al*., 2008). Since H3K27me3 is involved in gene silencing independently of DNA methylation (Kondo *et al*., 2008), it is expected that H3K27me3 can be causally involved in gene silencing of tumor-suppressor genes.

3.5 Epigenetic Field for Cancerization

Aberrant DNA methylation is present in non-cancerous tissues of cancer patients, forming an epigenetic field for cancerization (epigenetic field defect) (Figure 6) (Ushijima, 2007). High levels of methylation of specific CpG islands, if appropriately selected, are observed in non-cancerous tissues of cancer patients, but not in the corresponding tissues of age-matched individuals (Maekita *et al*., 2006). The methylation level is correlated with risk of cancer development (Nakajima *et al*., 2006), and the accumulation can be considered to be associated with cancer development. In an animal model, it was clearly demonstrated that aberrant DNA methylation was induced as a result of exposure to an environmental factor, and accumulation is associated with cancer development (Niwa *et al*., 2010). Epigenetic field defects are now attracting attention as a target for cancer risk diagnosis and cancer prevention.

3.6 Comparison Between Point Mutations and Aberrant DNA Methylation

Aberrant DNA methylation of promoter CpG islands, especially in NFRs, is now accepted as an equivalent of inactivating mutations, such as inactivating point mutations and chromosomal losses. However, when compared with point mutations, sharp contrasts have been clarified (Table 1) (Ushijima and Asada, 2010). The number of alterations in a cancer is estimated to be approximately 80 for mutations and several hundred to 1,000 for methylation (Gao *et al*., 2008; Hayashi *et al*., 2007; Keshet *et al*., 2006; Rauch *et al*., 2008; Wood *et al*., 2007; Yamashita *et al*., 2009). The fraction of cells with alterations in non-cancerous (thus polyclonal) tissues is very small for mutations (usually at 1×10^{-5}/cell) and can be large for methylation

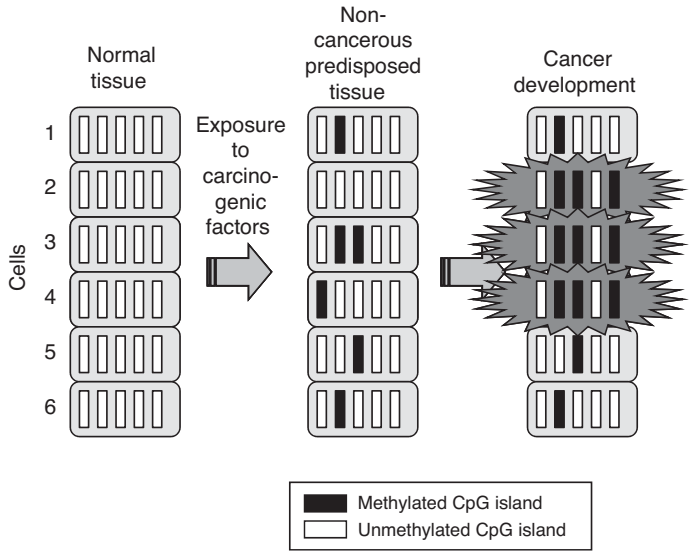

Figure 6. Epigenetic field for cancerization. By exposure to carcinogenic factors, methylation of various, but specific genes, involving both passenger and driver genes, is induced in normal appearing tissues. However, the accumulation level is correlated with cancer risk, and the status is designated as an epigenetic field for cancerization or epigenetic field defect.

Table 1. Comparison between aberrant DNA methylation and point mutations.

	Point mutation	DNA methylation	References
Number of alterations per cancer cell	~80	Several hundred to 1,000	(Gao *et al*., 2008; Hayashi *et al*., 2007; Keshet *et al*., 2006; Rauch *et al*., 2008; Wood *et al*., 2007; Yamashita *et al*., 2009)
Frequency of alterations of a specific gene in non-cancerous tissues	10^{-5}/cell up to 10^{-3}/cell	0.1 to several % up to several 10%	(Maekita *et al*., 2006; Nagao *et al*., 2001)
Target gene	Random	Specific	(Costello *et al*., 2000; Keshet *et al*., 2006; Loeb, 2001; Wood *et al*., 2007)
Reversibility	Irreversible	Reversible	(Gan *et al*., 2007; Issa and Kantarjian, 2009; Jones and Taylor, 1980; Loeb, 2001; Meissner *et al*., 2008; Wood *et al*., 2007)

Modified from (Ushijima and Asada, 2010).

(up to several 10% of cells) (Maekita *et al*., 2006; Nagao *et al*., 2001). Regarding target genes, mutations are induced mostly in random genes, but methylation is induced in specific genes depending on tissues and inducers (Costello *et al*., 2000; Keshet *et al*., 2006; Loeb, 2001; Wood *et al*., 2007; Nakajima *et al*., 2009; Oka *et al*., 2009). Although mutations are essentially irreversible, methylation is potentially reversible, and is now used as a therapeutic target (Gan *et al*., 2007; Issa and Kantarjian, 2009; Jones and Taylor, 1980; Loeb, 2001; Meissner *et al*., 2008; Wood *et al*., 2007). As discussed in Section 4, inducers of aberrant DNA methylation are markedly different from those of mutations.

3.7 Possible Involvement of Epigenomic Alterations in Acquired Disorders Other Than Cancers

Epigenomic alterations are known to be responsible for some inborn disorders other than cancers, such as Rett syndrome (inborn mutations of *MeCP2*), ICF syndrome (inborn mutations of *DNMT3B*), and Beckwith-Wiedemann syndrome (imprinting disorder). From toxicological viewpoints, involvement of epigenomic alterations in acquired human disorders other than cancers is of great interest. As described above, aberrant methylation of specific genes can be present in up to several 10% of cells in non-cancerous tissues, different from mutations. Even if one of 10^5 cells in a tissue had lost expression of specific genes by mutations, it does not harm the function of the tissue. However, it is well expected that, if 10% of cells in a tissue had lost expression of specific genes by methylation, it could harm the function of the tissue.

Epigenomic differences become larger as monozygotic twins grow older, and this could explain different disease susceptibility between twins (Fraga *et al*., 2005b). Monozygotic twins with and without multiple sclerosis had exactly the same genome and transcriptome, but a slightly different epigenome (Baranzini *et al*., 2010). Glucocorticoid receptor is reported to be aberrantly methylated in the hippocampus of suicide victims (McGowan *et al*., 2009). Activating epigenetic changes are induced in the nuclear factor kappaB (NF-κB) subunit *p65* gene in aortic endothelial cells after transient high glucose, and the epigenetic changes and altered gene expression persists during subsequent normoglycemia (El-Osta *et al*., 2008). Involvement of epigenetic alterations in autoimmune disorders and atopic disorders is also proposed (Maciejewska Rodrigues *et al*., 2009; van Panhuys, Le Gros and McConnell, 2008). The mechanistic basis and evidence in human and animal studies strongly indicate that epigenomic alterations are involved in common acquired human disorders.

4 INDUCERS OF EPIGENETIC ALTERATIONS

Epigenetic alterations play a major role in cancer development, as described, and possibly in other disorders (Robertson, 2005; Ushijima and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat230
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Asada, 2010). Nevertheless, only limited information is available on the factors that induce epigenetic alterations, including aging, inflammation, virus infection, one carbon metabolism, and chemicals (Ushijima and Okochi-Takada, 2005). These inducers are also in a sharp contrast with those of mutations, such as mutagenic chemicals, radiation, and ultraviolet light. Little information is available on how epigenetic alterations are induced.

4.1 Interpretation of Changes in Epigenetic Modifications

Epigenetic modifications can regulate gene transcription, but can be regulated by it at the same time. Therefore, we have to be cautious in interpreting the meaning of changes of epigenetic modifications. An agent may target epigenetic modifications first, and the epigenetic changes can then lead to permanent changes in gene expression (left panel in Figure 7). This change of epigenetic modifications corresponds to mutations, and can be designated as epigenetic alterations. Inducers of epigenetic modifications are of great concern from a toxicological viewpoint.

At the same time, an agent may induce gene expression changes first, and then the expression changes can lead to changes in epigenetic modifications, such as histone acetylation statuses (right panel in Figure 7). Such changes in epigenetic modifications might be inherited upon cell division, or might not be inherited. It is often observed that DNA methylation of a CpG island in an exon is induced when expression of the gene is reduced, or that DNA methylation of the CpG island is reduced when its expression is induced (see sections 2.1.2 and 2.1.3).

Even limited to regions within a promoter CpG island, methylation outside a NFR is often observed while the NFR is kept unmethylated (Graff *et al*., 1997; Issa *et al*., 2001; Abe *et al*., 2002). A gene is usually kept to be transcribed even if regions outside the NFRs are methylated (Ushijima, 2005). This shows that methylation outside NFRs is relatively easily induced, but does not cause gene silencing.

4.2 Aging

Issa *et al*. (1994) first reported that a *Not*I site in exon 1 of estrogen receptor (*ESR*) was methylated in normal colon mucosa in association with aging (Issa *et al*., 1994). The age-dependent methylation

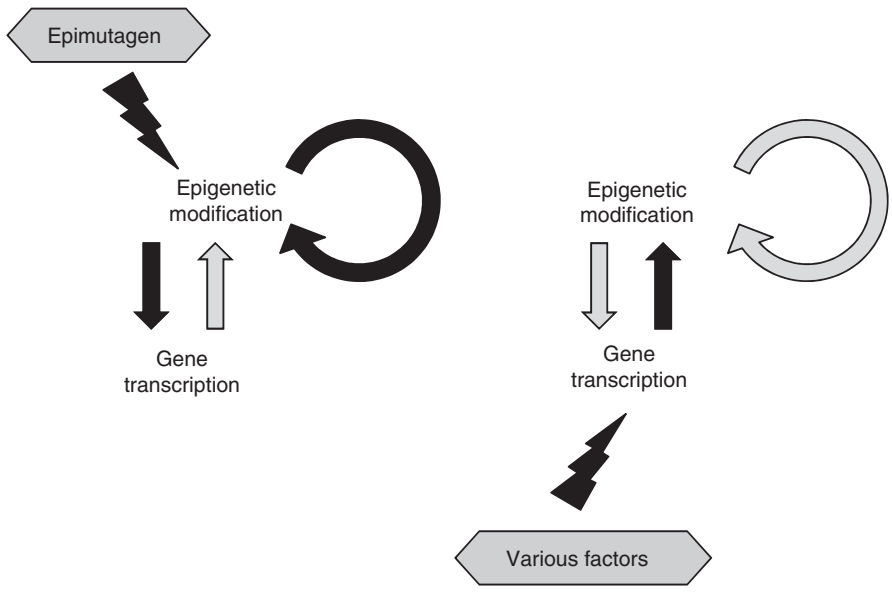

Figure 7. Direct and indirect effects on epigenetic modifications by exogenous factors. *bona fide* epimutagens (defined in Section 4.6) target epigenetic modifications first, and their alterations are inherited and lead to changes in gene transcription. On the other hand, many chemicals induce changes in gene transcription first, and the changes can be accompanied by changes in epigenetic modifications.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat230
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

was later confirmed by many investigators using human and animal samples (Abe *et al*., 2002; Waki *et al*., 2003). It was later shown that age-dependent methylation takes place in specific CpG islands (type A CpG islands) (Ahuja *et al*., 1998; Toyota *et al*., 1999). However, it is often observed that, even within the same CpG island, only peripheral regions are methylated but its central regions, which correspond to NFRs in promoter CpG islands, are kept unmethylated (Graff *et al*., 1997; Issa *et al*., 2001; Abe *et al*., 2002). This suggests that mechanisms for methylation induction are different between NFRs in central regions of CpG islands. As a mechanism of age-dependent methylation, an increase in the cumulative number of cell proliferations is considered to give a higher chance of induction of "aberrant" DNA methylation (Issa *et al*., 2001; Issa *et al*., 1994).

4.3 Chronic Inflammation

Among the poorly characterized inducers, the best-characterized inducer is possibly chronic inflammation. Aberrant DNA methylation is known to be present in colonic tissues with long-standing ulcerative colitis (Hsieh *et al*., 1998; Issa *et al*., 2001; Toyota *et al*., 2002), in the liver with chronic hepatitis (Kondo *et al*., 2000), and in gastric tissues exposed to *Helicobacter pylori* (*H. pylori*) infection (Maekita *et al*., 2006; Park *et al*., 2009). In addition to these associations, we recently demonstrated using an animal model that inflammation triggered by *H. pylori* infection, not *H. pylori* itself, is indeed the cause of methylation induction (Niwa *et al*., 2010). Exact mechanisms of how chronic inflammation induces aberrant DNA methylation are still unknown, but expression levels of *Tnfa*, *Il1b*, *Cxcl2*, and *Nos2* are well correlated with methylation induction.

4.4 Viral Infection and Exogenous DNA

It was noted decades ago that viral DNA is methylated upon infection into mammalian cells (Doerfler *et al*., 1995). It was shown that cells transgenic for an adenovirus type have methylation of not only the transfected viral DNA but also cellular DNA (Muller, Heller and Doerfler, 2001), and the presence of exogenous DNA was suggested to induce methylation of even endogenous genes. The Epstein-Bar (EB) virus infection is occasionally associated with human gastric cancers, and such cancers are known to have more methylated CGIs than gastric cancers without EB virus infection (Kang *et al*., 2002; Chang *et al*., 2006). As a potential mechanism, it was recently reported that DNMT1 is activated by EBV latent membraneprotein 2A (Hino *et al*., 2009). Liver tissues infected by Hepatitis virus C have methylation of multiple genes (Nishida *et al*., 2008). An adult T-cell leukemia virus was also shown to induce methylation of endogenous genes (Yasunaga *et al*., 2004). All these indicate that viral infection and exogenous DNA are inducers of aberrant DNA methylation of endogenous genes.

4.5 Disturbances in One Carbon Metabolism

Disturbances in one carbon (methyl group) metabolism, due to deficiency of folate, vitamin B_{12}, or choline, can influence DNA methylation status by limiting availability of the methyl donor, *S*-adenosylmethionine (Poirier, 2002). In animal experiments, methyl supplementation in maternal diet during pregnancy affected methylation levels of a transposable element of offsprings, and the resultant phenotype persisted for a life time (Waterland and Jirtle, 2003). In human, malnutrition during intrauterine and neonatal periods is known to be associated with the development of obesity, type 2 diabetes, and other related co-morbidities (Kalhan, 2009). This strongly indicates that disturbances of one carbon metabolism can induce changes in DNA methylation, which predispose individuals to disease conditions.

4.6 Chemicals

Some chemicals are considered to induce epigenetic alterations, and are designated as "epimutagens" (Holliday, 1991; MacPhee, 1998; Holliday and Ho, 2002). One of the most well characterized epimutagens is a DNA demethylating agent, 5-aza-2′-deoxycytidine (5-aza-dC), which is widely used in laboratories and has now been approved as a therapeutic drug for myelodysplastic syndrome (Jones, 1985; Issa *et al*., 2005; Issa and Kantarjian, 2009). 5-Aza-dC is incorporated into DNA strands and

Table 2. List of chemicals reported to alter epigenetic statuses.

Action	Chemical	Characteristics	Reference
DNA hypermethylation	Butyrate	Short-chain fatty acid	(Boffa, Mariani and Parker, 1994)
	4-(*N*-Nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK)	Tobacco-specific carcinogen	(Pulling *et al*., 2004)
	Phenobarbital	Antiepileptic agent	(Bachman, Phillips and Goodman, 2006)
	Vinclozolin	Antiandrogenic compound	(Anway *et al*., 2005)
	Diethylstilbestrol	Synthetic estrogen	(Bromer *et al*., 2009)
DNA hypomethylation	5-Azacytidine, 5-Aza-2′-deoxycytidine	Cytidine analog	(Egger *et al*., 2004)
	5-Fluoro-2′-deoxycytidine	Cytidine analog	(Jones and Taylor, 1980)
	5,6-Dihydro-2′-azacytidine	Cytidine analog	(Curt *et al*., 1985)
	Zebularine	Cytidine analog	(Cheng *et al*., 2003; Holleran *et al*., 2005)
	Ethionine	Methionine analog	(Shivapurkar, Wilson and Poirier, 1984)
	Arsenic compound	Metal compound	(Zhao *et al*., 1997;Reichard, Schnekenburger and Puga, 2007)
	Valproic acid	Antiepileptic agent	(Detich, Bovenzi and Szyf, 2003)
	Procainamide	Antiarrhythmic agent	(Lee *et al*., 2005; Segura-Pacheco *et al*., 2003)
	Procaine	Anesthetic agent	(Villar-Garea *et al*., 2003)
	Hydralazine	Antihypertensive agent	(Segura-Pacheco *et al*., 2003)
	6-Mercaptopurine	Anticancer agent	(Hogarth *et al*., 2008)
	6-Thioguanine	Anticancer agent	(Hogarth *et al*., 2008)
	Psammaplins A	Antibiotic agent	(Pina *et al*., 2003)
	(-)-Epigallocatechin-3-*O*-gallate (EGCG)	Major polyphenol from green tea	(Fang *et al*., 2003)
	RG108	DNMT inhibitor	(Brueckner *et al*., 2005)
	SGI-1027	DNMT1 inhibitor	(Datta *et al*., 2009)
	Bisphenol-A	Synthetic estrogen	(Bromer *et al*., 2010)

traps DNMT1, which is subsequently degraded by proteasome (Ghoshal *et al*., 2005). This leads to depletion of DNMT1 in a cell, and passive DNA demethylation is resultantly induced. There are many other chemicals reported to induce changes in epigenetic modifications (Table 2), but their direct action or indirect action through gene expression changes should be carefully evaluated.

5 EPIGENOMIC ANALYSIS IN TOXICOLOGY

Epigenomic alterations are deeply involved in carcinogenesis and possibly in other disorders. In addition, there are a large number of non-mutagenic carcinogens (Snyder and Green, 2001), some of which exert their carcinogenic action by inducing

cell proliferation. It seems reasonable to consider a possibility that some of the non-mutagenic carcinogens exert their action by epigenetic mechanisms. In this context, epigenomic analysis seems essential in toxicology, which has just started. Unfortunately, few reliable and sensitive methods specifically designed for toxicological analysis have been reported yet, and ordinary procedures for epigenetic and epigenomic analysis are used also for toxicological analysis. Their brief principles and efforts in development of convenient assay systems are described.

5.1 Principles of DNA Methylation Analysis

Methods can be divided into those for analysis of specific genomic regions and those for genome-wide analyses. DNA methylation at specific genomic regions is analyzed mainly based upon two principles of methylation detection; methylation-sensitive restriction enzymes, and bisulfite modification of DNA (Figure 8). Some restriction enzymes, such as *Hpa*II and *Sma*I, have recognition sequences with CpG sites, and cannot cleave if the CpG site is methylated. Bisulfite

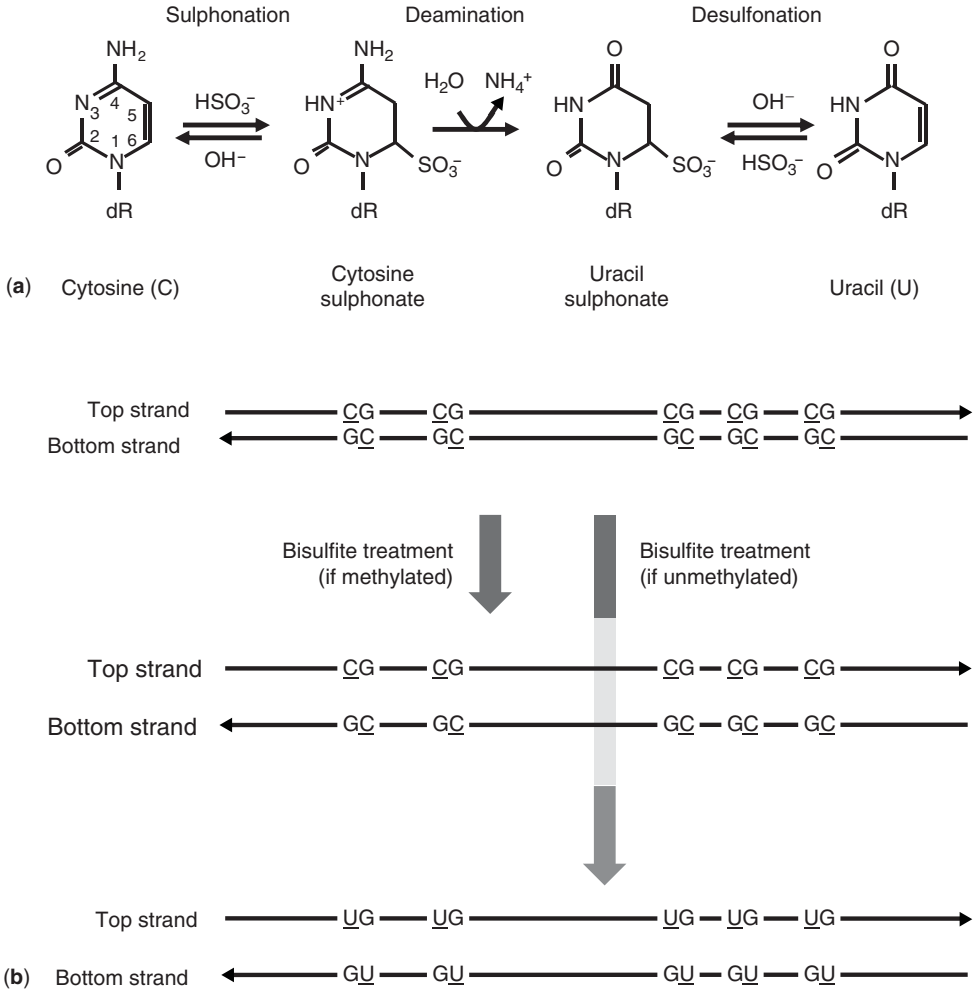

Figure 8. Principle of bisulfite modification: (a) chemical reactions for unmethylated cytosine; (b) sequence changes produced by bisulfite modification of methylated and unmethylated DNA. Different sequences are produced from methylated and unmethylated DNA, and the difference can be detected by various modalities.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat230

modification takes advantage of different efficiency in converting cytosine to uracil, which is very efficient for unmethylated cytosines but very slow for methylated cytosines. After bisulfite conversion, the top and bottom strands are no longer complementary. Methylated and unmethylated DNA will produce different sequences after the conversion, and the difference can be detected by various techniques, such as sequencing, allele-specific PCR, restriction digestion, and pyrosequencing. Depending upon the purpose of experiments, appropriate techniques should be selected, considering the required amount of DNA, flexibility in selection of CpG sites to analyze, how quantitative the method is, technical complexity, and the cost.

Genome-wide analyses are generally composed of a step of detection of DNA methylation and another step of genome-wide analysis (Ushijima, 2005; Laird, 2010). The methylation detection can be performed using affinity-based methods, such as use of anti 5-methylcytidine antibody and affinity column with methylated DNA binding domains, but also using methylation-sensitive restriction enzymes and bisulfite conversion. The detection step can be performed using microarray or next-generation sequencers.

5.2 Principles of Histone Modification Analysis

Methods for histone modification analysis can be divided into: (i) those for analysis of global contents of histone modifications within a cell; (ii) those for analysis of histone modifications for a defined genomic region; (iii) those for histone modifications of defined genomic regions in a genome-wide manner. Global contents of histone modifications within a cell are mainly analyzed by immunohistochemistry and Western blotting. In contrast, histone modifications in defined genomic regions are analyzed by chromatin immunoprecipitation (ChIP). All of these methods are based upon the recognition of histone modifications by antibodies, and their specificity is critical for successful analysis.

The ChIP method can detect physical interactions between histones containing a specific modification and genomic DNA within a cell (Figure 9). The ChIP method is composed of four steps including: (i) preparation of fragmented chromatin from cells; (ii) immunoprecipitation by using a specific antibody; (iii) purification of immunoprecipitated (IP) DNA; (iv) analysis of IP DNA (Lee *et al*., 2006). Fragmented chromatin is usually prepared by cross-linking DNA and histones by formaldehyde, followed by a fragmentation step by sonication or micrococcal nuclease. Immunoprecipitation is performed using a specific antibody, and then the immuno-complex of chromatin and antibody is collected and purified. IP DNA is analyzed by PCR of a specific genomic region, or by microarray or next-generation sequencers for a genome-wide analysis (Barski *et al*., 2007; Lee *et al*., 2006; Wang *et al*., 2008).

5.3 Screening Methods for Epimutagens

A major reason why only a limited number of chemicals are reported to have epigenetic actions (see Section 4.6) is the lack of easy-to-use assay systems for chemicals' capacity to induce epigenetic alterations. For mutagens, there are various *in vitro* assays, using bacterial cultures or mammalian cells, and also *in vivo* assays using genetically-engineered animals (MacGregor, Casciano and Muller, 2000) (Table 3). In contrast, very limited assay systems are available for epimutagens. To construct an assay system for epimutagens, considerations should be given to what target genomic region is used as a marker for epigenetic effects, such as DNA demethylation and methylation, and what reporter

Table 3. Characteristics of assay systems for mutations and epigenetic alterations.

	Mutation assays	Assays for epigenetic alterations
Bacterial system	*Reversion in S. typhimurium* (Ames test)	Essentially impossible
Mammalian cell	*HPRT* or *TK* mutations Chromosome aberration test Mouse lymphoma assay Measurement of UDS	Under development (see text)
In vivo Assay	Micronucleus test Mouse specific locus test Tg mice for a marker gene (Big Blue, gpt-Δ, Muta-mouse etc.)	Not available yet

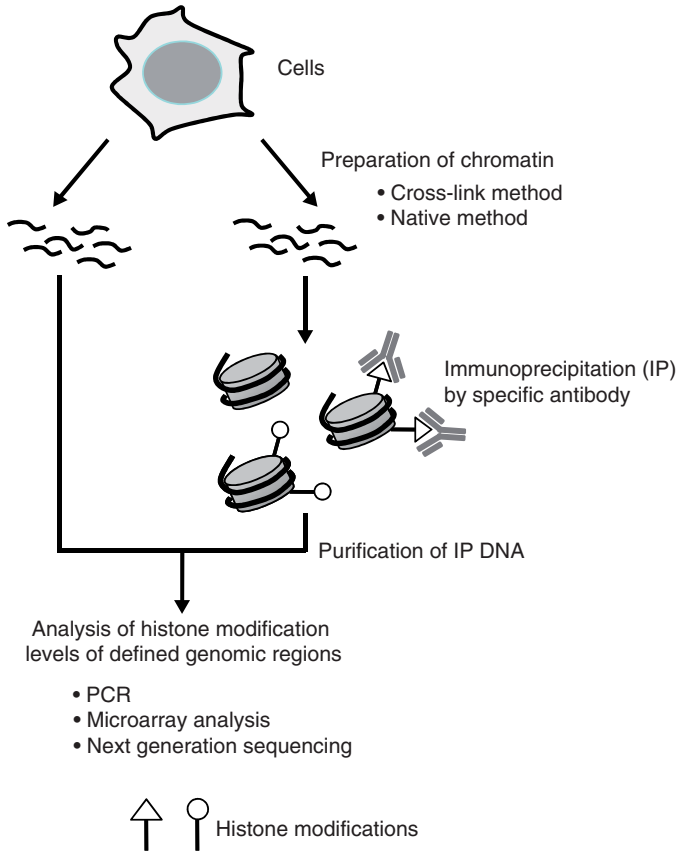

Figure 9. Principle of chromatin immunoprecipitation (ChIP). Fragmented chromatin is prepared, and then immunoprecipitated (IP) by using a specific antibody. DNA purified from the IP chromatin is used for analysis of histone modification levels for defined genomic regions by several technologies such as PCR, microarray, and next generation sequencing.

system is used. For screening purposes, a convenient and reliable assay system is essential.

So far, assay systems only for DNA demethylating agents have been reported. Three systems have been reported using a promoter of an exogenous gene and a reporter gene (Biard *et al*., 1992; Cervoni and Szyf, 2001; Fan *et al*., 2005). Among these, Fan *et al*., 2005 successfully identified 5-bromo-2′-deoxyuridine (BrdU) as an anti-silencing agent without changing DNA methylation status. These exogenous promoters have a concern that they have epigenetic modifications different from endogenous genes. From this aspect, two assay systems are reported using a promoter of an endogenous gene (Okochi-Takada *et al*., 2004; Oyer *et al*., 2009). In addition to these efforts to use specific exogenous and endogenous promoters, hypomethylation of repeat sequences is also proposed as a precursor of toxicity (Carnell and Goodman, 2003).

6 EPILOGUE

Epigenomic alterations are important for cancer and possibly for other disorders. Nevertheless, epigenomic toxicology has just started, and scientists are not armed well yet. Application of findings in epigenetics and epigenomics to toxicology is now an exciting task.

ACKNOWLEDGMENTS

The work was supported by a Grant-in-Aid for the Third-term Cancer Control Strategy Program from the Ministry of Health, Labour and Welfare, Japan.

Sequencing Technology Advances and Toxicology

Luke D. Ratnasinghe

Cytonix, Beltsville, MD, USA

1 INTRODUCTION

The toxicogenomics tool kit has traditionally included quantitative-PCR, microarrays, and capillary sequencing. The first generation Sanger (Sanger, Nicklen and Coulson, 1977) sequencing method developed over 30 years ago has been the core chemistry for nucleic acids sequencing. In first generation capillary sequencing a single reaction generates a single nucleic acids sequence (Turner *et al*., 2009). In second generation methods, fluidics, PCR, and massively parallel sequencing is combined to generate reads from millions of miniature parallel reactions (Figure 1). Third generation methods comprise of truly single molecule sequencing and massively parallel sequence detection with no PCR amplification. The next generation sequencing methods are transforming the tool kit for toxicogenomics by allowing much improved whole-cell transcriptome quantization, micro-RNA analyses, and whole-genome sequencing (Turner *et al*. 2009).

2 PCR, QUANTITATIVE PCR AND DIGITAL PCR

The polymerase chain reaction (PCR) is a proven tool in toxicology because of its ability to amplify specific genes or gene segments directly. Although traditional PCR with gel-based quantization of nucleic acids is very sensitive, it is also time-consuming and only semi-quantitative. Real-time PCR employing techniques such as TaqMan is significantly more quantitative when the goal is to measure two or more nucleic acids. In real-time PCR, quantization is conducted in the PCR exponential phase, where there is a linear relationship between the log of target DNA quantity and the number of PCR cycles to reach a threshold of fluorescence (Heid *et al*., 1996; de Kok *et al*., 1998). The number of PCR cycles required to reach a fluorescence (ΔRn) threshold value is the cycle threshold (Ct). The Ct value for each sample is proportional to the log of the initial amount of target DNA (Higuchi *et al*., 1993). Since Ct values are proportional to the log of the copy number of target DNA, transformations are needed using a calibration curve. The calibration curve can be used to estimate the copy number of target DNA from the corresponding Ct values. The major limitation of real-time PCR based quantization is that Ct value based quantization is not a true quantity, but requires a calibration curve with known reference samples. In addition, the accuracy of quantization assumes that PCR efficiency is the same in all samples including the reference samples; this is often not the case due to PCR inhibitors in some biological samples and toxicology studies. Digital PCR and Digital Gene Expression Analyses are single molecule nucleic acids amplification technologies, which offer a solution to many of the problems faced by Real Time PCR methods.

3 DIGITAL PCR AND DIGITAL GENE EXPRESSION ANALYSES

Digital Polymerase Chain Reaction (digital PCR) is a refinement of conventional polymerase chain reaction methods that can be used to directly quantify and clonally amplify nucleic acids including DNA, cDNA, or RNA. Theoretically, PCR exponentially amplifies nucleic acids, and the number of amplification cycles and the amount of PCR end-product should allow the computation of starting quantity. However, many factors complicate this calculation, creating uncertainties and inaccuracies. These factors include: initial amplification cycles may not be exponential; PCR amplification eventually plateaus after an uncertain number of cycles; and PCR amplification efficiency in a sample of interest may be different from that of reference samples.

Digital PCR overcomes these difficulties by transforming unreliable exponential data from conventional PCR to digital signals that simply indicate whether or not amplification has occurred. Digital PCR is achieved by capturing each individual nucleic acid molecule present in a sample within many separate chambers (or regions or beads) prior to PCR amplification. A count of chambers containing detectable levels of PCR end-product is a direct measure of the absolute nucleic acids quantity. Digital Gene Expression Analyses refers to next generation sequencing of RNA. Digital Gene Expression Analysis methods originate from digital PCR where each captured individual RNA molecule is sequenced in parallel.

4 SEQUENCING TECHNOLOGY

4.1 Roche 454 Sequencing

In 454 sequencing the nucleic acids molecules are ligated to adaptors such that amplification with one set of primers becomes possible. The adaptors are also used to attach the template and daughter amplicons onto 20 μm beads. PCR amplification of each template is conducted in millions of micelles in an emulsion with goal of having one bead with one template and PCR reagents in each micelle. The target ratio of bead to template is 1:1. During PCR a cloned template is generated on the bead surface using an innovative solid surface PCR approach. After PCR the beads are recovered and deposited into plates called Pico Titer Plates (PTP). Each bead with a

clonal population of DNA is deposited into one well in the PTP, which also contains packing and enzyme beads. Each DNA clone on each bead is sequenced in parallel using pyro-sequencing (Margulies *et al*., 2005). The 454 sequencer is capable of generating greater than one giga-base (1 000 000 000 bases) of sequence data per day.

4.2 Life Technologies Solid Sequencing

The template amplification step with SOLiD is similar to that of 454 using beads and emulsions to retain the clone of daughter DNAs on the bead surface. However the beads used in SOLiD are much smaller than 454 with a diameter of $\sim$1 μm and bound to slides at a very high density of 100 000 000 beads. The 100 000 000 beads with DNA clones are sequenced in parallel (although many beads could be filtered out during data analyses due to more than one clone captured per bead). Sequence detection in SOLiD is conducted 8 nucleotides at a time by ligation. To the bead bound clones a sequencing primer is hybridized and 16 8-base probes are introduced. Using an innovative approach of stepwise ligation, imaging and cleavage, sequencing is achieved by generating the color profile of every fifth di-nucleotide (Shendure *et al*., 2005). The Life Technologies SOLiD sequencer is capable of generating greater than two giga-bases (2 000 000 000 bases) of data per day.

4.3 Illumina Genomic Analyzer Sequencing

The Illumina Genome analyzer uses an innovative approach to generate template clones for sequencing. An adapter DNA is ligated onto the template ends. The modified template is then introduced into a flow cell where a random lawn of forward and reverse primers are attached to the interior bottom surface. The template DNA adapter hybridizes to one of the primers and a complementary copy attached to the base surface is generated. The end of the complementary copy folds over and hybridizes to another primer, which in turn is extended to create a new daughter DNA. These new daughter DNA clones act as templates in isothermal PCR to create a surface-attached, clustered clone of the original template.

The double stranded DNA clusters are converted to single strand clusters by selectively removing one strand and the flow cell is transferred to a genome analyzer. In the genome analyzer the clusters are sequenced with reversible florescent terminator deoxyribonucleotides (Bentley *et al*., 2008). During each sequencing cycle, one nucleotide is read with each clone cluster fluorescing in one color. The Illumina sequencer is capable of generating greater than 1.5 gigabases (1 500 000 000 bases) of data per day.

4.4 Helicos Sequencing

The Helicos method is a third generation method that is true single molecule sequencing without PCR amplification of the template. Sample preparation for sequencing is straight forward and fast requiring only the addition of the poly-A tail and fluorescent label. The poly-A tail hybridizes to poly-T strands in the flow cell chamber. The substrate for sequencing is each template and not a clone cluster as is the case with the methods from Roche, Life Technologies and Illumina. Therefore, the flow cell can be densely packed with billions of template molecules. Sequence detection is conducted by adding fluorescent nucleotides, one at a time, and querying one nucleotide per cycle. Sequencing of millions of template molecules occur simultaneously (Braslavsky *et al*., 2003). The Helicos sequencer is capable of generating greater than 2.5 gigabases (2 500 000 000 bases) of sequence data per day.

4.5 Other Next Generation Sequencing

In addition to the currently available next generation sequencing systems by Roche, Life Technologies, Illumina and Helicos there are a number of other very promising platforms. Companies with platforms that are in various stages of readiness include Affymetrix, Base4innovation, Complete Genomics, Dover Systems, Genome Corporation, Intelligent Bio-Systems, NABsys, Oxford Nanopore Technologies, Pacific Biosciences, Reveo, Sequenom, and VisiGen Biotechnologies. The number of researchers and companies involved in the development of next generation sequencing methods illustrates the enthusiasm and promise the new methods. The second generation and third generation sequencing methods will results in very

high levels of data yield and much reduced cost making the $1000 whole genome sequencing goal a reality (Service, 2006).

5 APPLICATIONS OF SEQUENCING IN TOXICOLOGY

Whole genome sequencing has resulted in a biology revolution by facilitating the study of entire cellular systems with the whole cell and sometimes the entire organism in focus. Although many organism model systems have been sequenced and there appears to be consensus that we are in a post genome era, the use of sequencing has only just begun (Pushkarev, Neff and Quake, 2009).

6 SEQUENCE VARIANT SCREENING, PHARMACOGENOMICS AND TOXICOLOGY

Pharmacogenomics is the study of mutations and polymorphism and their effects on drug selection, optimal dose, adverse events, and efficacy. The application of pharmacogenomics principles offers the possibility of personalized medicine with drug therapy delivered based on known susceptibilities. With reduction in adverse events more drugs may be made available by reducing the use of trial error methods. It is also expected that the cost of clinical trials could be reduced.

In the current model of drug development over 75% of prospective drugs fail due to problems with safety and efficacy and also problems with manufacturing (Lesko and Woodcock, 2004). With wider use of pharmacogenomics methods, drugs such as Vioxx, which was taken off the market due to adverse events can be avoided. Individuals susceptible to adverse events could be excluded from taking a particular drug making many more drugs available for non-susceptible patients. The Food and Drug Administration (FDA) has been working on the "Critical Path" to help make product development more predictable and less costly (Lesko and Woodcock, 2004). The FDA has also developed pharmacogenomics data submission guidelines to assist and partner with researchers to better serve the needs of the emerging technologies.

Next generation sequencing has reduced the cost of sequencing the human genome from millions of dollars to approximately $100 000. It is expected that within the next five years the cost will be further reduced to $10 000. Advances in throughput and reduced cost will make whole genome sequencing a reality in clinical trials to identify subgroups of individuals more prone to adverse events and also to better optimize dose. One of the key advantages of next generation sequencing in clinical trials is the ability to potentially whole genome profile polymorphisms and mutations without prior assumptions of which genes modify drug efficacy.

7 MICROBIAL GENOMICS

Next generation sequencing has opened new avenues of exploration in microbial genomics (Hall, 2007). There are many important toxicology implications as microbial-genome diversity is better understood and characterized in the context of their human hosts.

A study of *Streptococcus* strains (Tettelin *et al*., 2005) has shown that after sequencing eight genomes approximately 33 new genes are discovered with each new strain sequenced. This has given rise to the pan genome concept which suggests that most microorganism are made of a core set of essential genes and a set of optional genes that could differ from individual to individual. This genomic diversity is made more complex with mutations and polymorphisms within each gene and their influence on drug susceptibility and host interactions. In light of the pan genome, the sequence of a single reference genome (or transcriptome) maybe a poor representation of the genetic diversity in pathogen populations. To better prepare for emergence of drug resistant or more virulent strains it is increasingly clear that we need deep genome and transcriptome data for a representative population in addition to a reference sequence. One of the most straight forward applications of next generation sequencing is microbial mutation screening. Mutation screening needs to be carried out at the population level to identify correlations between genotype and phonotype with statistical rigor. While whole genome and transcriptome sequencing is still expensive, prices are projected to fall dramatically. Due to the relatively small size of most microbial genomes, next generation sequencing will find fast applications in microbial toxicology.

Metagenomics aimed at characterizing microbial diversity in particularly complex environments such as the gut or skin and how this ecology is influenced by drugs is also an important application of next generation sequencing. There are a number of reports using more traditional methods already examining the metagenomics of the gut (Gill *et al*., 2006; Manichanh *et al*., 2006; Zhang *et al*., 2006). With advances in sequencing, metagenomics studies are becoming easier to conduct and will provide detailed insights into interaction between very complex microbial environments and toxicological outcomes.

8 TRANSCRIPTOMICS, NEXT GENERATION SEQUENCING, AND MICROARRAYS

Microarray technology has made it possible to study thousands of RNA molecules expressed in one experiment. Many advances in toxicogenomics can be attributed to microarray technology. It can be postulated that next generation sequencing can replace most microarray studies (Kato, 2009). In second generation sequencing the level of a particular transcript is inferred by the number of times a specific sequence is identified. Use of second generation sequencing for gene expression studies is referred to as Digital Gene Expression Analyses (Okubo *et al*., 1992). In microarrays, the level of a transcript is determined by the level of hybridization of one target RNA compared to a differently colored reference RNA and it is difficult to compare data from different series experiments (Kato, 2009). It is expected that many of the drawbacks of microarray methods including inter-experiment variation, platform to platform variation and need for extensive reference samples can be overcome with sequencing. For sequencing, RNA is isolated from the cell or tissue of interest and reverse transcribed into cDNA. The cDNA is sequenced and sequence counts used to directly measure RNA levels. It has been reported that changes in expression observed by next generation sequencing is greater than that of microarrays and quantitative PCR (’t Hoen *et al*., 2008) and that the results were highly reproducible with little variation with different sequencer runs (Marioni *et al*., 2008; ’t Hoen *et al*., 2008). Microarray data consist of continuous signals, while sequence sequencing consensus data comprise absolute number of reads (Marguerat, Wilhelm and Bahler, 2008). The digital, countable nature of next generation sequencing data makes it highly suitable for gene expression analyses. The advantages of next generation sequencing over microarrays also include almost unlimited dynamic range and the ability to profile expression without prior assumptions of which genes are expressed. In a comparative study five microarray platforms and digital gene expression analyses it has been shown that next generation sequencing offers major advances in robustness, resolution and inter-lab portability over microarrays (’t Hoen *et al*., 2008).

9 CANCER AND PRENATAL DIAGNOSTICS

Next generation sequencing has found many useful clinical and research applications in detection of cancer and also prenatal genetic abnormalities. In cancer, tumor DNA is split into the circulatory system and mutated DNA can be readily detected by sequencing serum DNA. In prenatal diagnostics, fetal DNA can be detected in the mother’s serum and sequenced. Two very important studies showing the utility of next generation sequencing in prenatal diagnostics have already been published (Fan *et al*., 2008; Chiu *et al*., 2008). The overall sequencing method for cancer and prenatal diagnostics is similar. First DNA from serum is isolated and prepared for sequencing by ligating adapters. A significant amount of DNA in serum from a pregnant mother or a cancer patient originates from the fetus or tumor respectively. The prevalence of mutations, aneuploidy or allele imbalance can be used for cancer and prenatal illness diagnostics.

10 ETHICS

Genetic diagnostics done at very high throughput levels with the new sequencing methods can be hampered by abuse and discrimination both real and imagined (ten Bosch and Grody, 2008). Current fears about genetic testing have largely been about predictive testing such as that for familial cancer. With next generation sequencing hundreds of genes or even the whole genome can be analyzed simultaneously. A person seeking a test for one illness may discover susceptibility to potentially many illnesses.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat231

Table 1. Comparison of next generation sequencing systems.

	PCR	Sequencing	Read length	Read fidelity	Bases read per day	Temp-lates #	Sample Preparation Time
ABI 3730xl	Bacterial cloning	Sequencing by synthesis	1000	>99.9%	1 MB	96	
Roche 454	Bead Capture Emulsion PCR	Pyro-sequencing	~500	99.5%	~1 GB	>1 million	3 days
ABI SOLiD	Bead Capture Emulsion PCR	Ligation-Sequencing	~50	99.9%	~2 GB	>40 million	4 days
Illumina	Microfluidic Isothermal Solid Surface Bridge PCR	Reversible termination Sequencing by synthesis	~50	98.5%	~1.5	>85 million	2 days
Helicos	No PCR	Reversible termination Sequencing by synthesis	~50	99%	~2.5	>100 Million	1 day

A wise course of action with the new very promising methods is to exercise caution by providing extensive pre-test counseling, informed consent and maintenance of stringent privacy rules. It will also be wise to avoid overly restrictive measures to protect patients that may ultimately reduce patient access to the technology (ten Bosch and Grody, 2008). With careful consideration of the potential benefits a proper balance could be struck as next generation sequencing transitions to the clinical setting from the research arena.

11 TECHNICAL CHALLENGES

For all sequencing platforms, ease of sample preparation, read length, read quality, and data processing are very important measures. In all the next generation sequencers, except that from Roche, read lengths are short with about 50 bases read per template (Table 1). When read lengths are short, whole genome sequencing for organisms with large genomes can be difficult and data processing is quite challenging. Short reads are useful for comparative studies to identify polymorphisms after a reference genome has been assembled and for transcriptomics studies. For de novo sequencing, in both read length and quality, Sanger capillary sequencing outperforms all the next generation sequencing platforms (Table 32.1). However as protocols get optimized and data handling software improves the quality measures of next generation sequencing will surpass that of capillary sequencing even for de novo sequencing. In the near term, the major challenge for next generation sequencing is data management and analysis of sequence data (Turner *et al*., 2009).

1 INTRODUCTION

DNA sequencing is a fundamental way for deciphering a broad range of biological phenomena at the molecular level. Although the development of DNA sequencing technologies has a rich and diverse history (Hutchison, 2007; Shendure and Ji, 2008), the dideoxy sequencing established by Sanger, Nicklen and Coulson 1977 has dominated the industry and research community for almost three decades and currently remains the gold standard for decoding DNA sequences.

Many biochemical and technical improvements have endowed modern Sanger sequencers with very low error rates (∼0.001%), relatively long read-length (up to ∼1000 bp), and high-throughput and robust performance. However, the cost of Sanger-based approaches for large sequencing projects remains expensive (on the order of $0.50 per kilobase). This limitation incentivized the National Human Genome Research Institute (NHGRI) of the National Institutes of Health (NIH) to initiate a funding program in 2004 to develop novel technologies that will enable extremely low-cost, high quality DNA sequencing. With a stated goal of reducing the cost of sequencing mammalian-sized genomes by four orders of magnitude to approximate $1000 per genome in 10 years (http://grants.nih.gov/grants/guide/rfa-files/RFA-HG-09-011.html), the initiative has propelled the development and commercialization of novel next-generation sequencing (NGS) technologies.

In 2005, 454 Life Sciences (now part of Roche Applied Science, http://454.com/about-454/index.asp) developed and commercialized its Genome Sequencer (GS) system for ultra-high throughput DNA sequencing (Margulies *et al.*, 2005). As the first commercialized NGS technology, the Roche/454 sequencing system provided a compelling case study for the establishment of a novel, revolutionary technology that enables scientists to carry out massively parallel DNA sequencing reactions at a relatively small cost, as well as at a much faster speed compared to using conventional Sanger's technologies. For example, the sequencing of the first human genome in the Human Genome Project (Collins *et al.*, 2004; Lander *et al.*, 2001) with automated Sanger technology took some 13 years at a cost of about $2.7 billion. In contrast, sequencing a human genome with the Roche/454 sequencer took but five months and approximately $1.5 million (Wheeler *et al.*, 2008). This great stride was enabled by ultra-high throughput, simplified *in vitro* sample preparation, and miniaturization of sequencing chemical reactions (Rothberg and Leamon, 2008).

DOI: 10.1002/9780470744307.gat232
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Illumina, Life Technologies, and Helicos BioSciences quickly followed Roche's lead and launched their own NGS platforms. Concurrently, new DNA sequencing technologies have been advancing at other companies and research institutions, such as Pacific Biosciences (http://www.pacificbiosciences.com), VisiGen Biotechnologies (http://visigenbio.com), Sequenom (http://www.sequenom.com), Complete Genomics (http://www.completegenomics.com), and the Center for Computational Genetics at Harvard Medical School (http://arep.med.harvard.edu/gmc).

Differing in sequencing chemistry as well as technical details, all NGS platforms share a similar technical strategy – miniaturization of individual sequencing chemical reactions to boost sequencing throughput (Metzker, 2010). The miniaturization of sequencing reactions, coupled with other technical breakthroughs, such as overcoming the bottlenecks of library preparation and template preparation (Rothberg and Leamon, 2008) enables millions of simultaneous individual sequencing reactions. Only a single fragment of DNA is sequenced in each miniaturized chemical reaction, but millions of them are spatially arranged so that individual reactions are isolated from one another, and distinctly detected by laser scanning or other approaches. The results are prodigious volumes of short read sequence data, unprecedented detail and resolution of sequence complexity, with consequential challenges in storing, managing, analyzing, and interpreting such wealth of data.

In this chapter, we first describe the fundamental principles of four commercially available NGS platforms, that is, Roche/454 GS FLX, Illumina Genome Analyzer *II*x, Life Technologies SOLiD, and Helicos HeliScope. We then discuss the general difficulties to be overcome in the analyses of NGS data. Next, we outline some main applications of NGS technologies and, finally, we compare the analysis of a toxigenomics study using NGS data with that using microarray data.

2 NEXT-GENERATION SEQUENCING TECHNOLOGIES

2.1 Roche/454 Pyrosequencing

The Roche/454 GS FLX system (Figure 1) relies on pyrophosphate detection (Nyren, Pettersson and Uhlen, 1993) and emulsion PCR (Tawfik and Griffiths, 1998). A library of DNA templates is prepared by a highly efficient *in vitro* DNA amplification method known as emulsion PCR (Figure 1b), where sheared DNA fragments are ligated to specific oligonucleotide adapters, resulting in each DNA fragment binding to a fragment-carrying bead. The beads are then captured in separate emulsion droplets that function as amplification reactors to produce some 10 million clonal copies of the DNA template that are needed for sufficient light signal intensities (Fuller *et al.*, 2009). On completion of the emulsion PCR amplification, the emulsion is disrupted, and the beads containing clonally amplified template DNAs are enriched, and then the beads are again separated by limiting dilution and deposited into individual picotiter-plate wells. The picotiter-plates serve as sequencing reactors to let individual enzymatic sequencing reactions occur without interference from adjacent wells. Visible light emitted from the subsequent pyrosequencing reactions (Ronaghi *et al.*, 1996) are detected by an imaging charge-coupled device (CCD) that is bonded to a fiber-optical bundle. During each cycle of a pyrosequencing reaction, a single species of unlabeled nucleotide is supplied to the reaction mixture to all beads on the chip, so that the complementary strand of DNA is sequentially synthesized. With the incorporation of each base in the growing chain, an inorganic pyrophosphate group is released that is converted to ATP by sulfurylase. During sequencing, the ATP molecule is next used by luciferase to convert luciferin to oxyluciferin, producing a light pulse (Figure 1c). Detecting the light emissions together with knowing the nucleotide identity in each step allows the incorporated base to be determined. Through a series of such pyrosequencing reaction cycles, the sequence of the DNA template carried by individual beads is determined.

Because there is no terminating moiety preventing multiple consecutive incorporations in a given pyrosequencing reaction cycle, the length of homopolymers in sequence reads must be inferred from light signal intensity, with a higher intensity corresponding to more repeats. The error rate of calling consecutive repeats increases when the length of the homopolymers is greater than 3–4 repeating bases. Thus, the main error type for the Roche/454 system is insertions and deletions (or indels), other than substitutions (Shendure and Ji, 2008).

Compared to other NGS platforms, the strength of the Roche/454 system is its longer sequence reads.

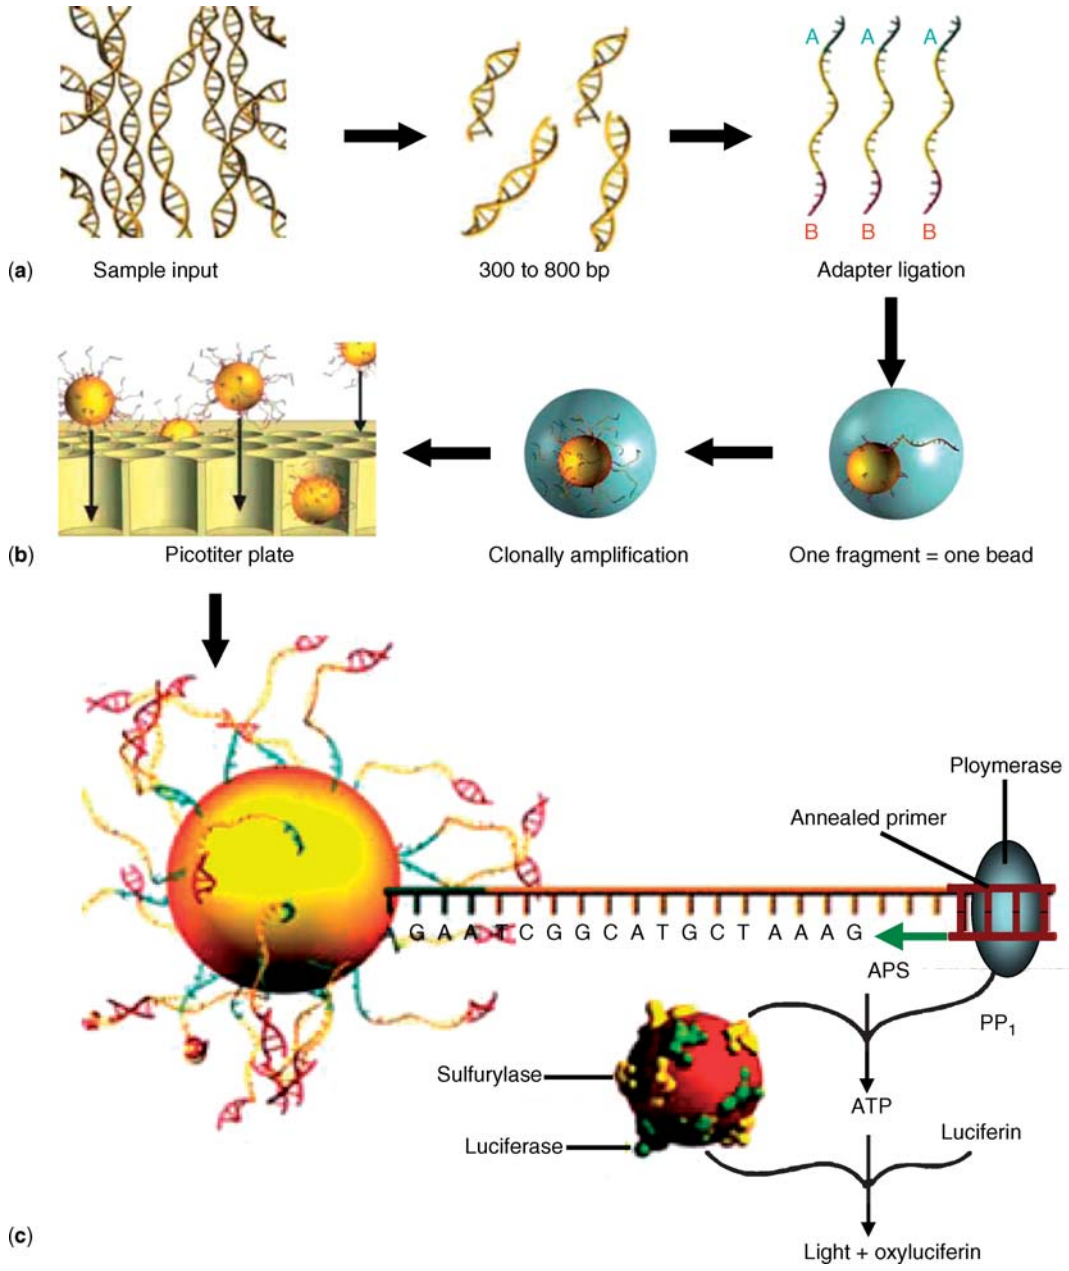

Figure 1. Overview of the Roche/454 GS FLX system workflow: (a) fragmentation of DNA and ligation to Roche specific adapters (denoted as blue A and orange B); (b) clonal amplification by emulsion PCR; and (c) real time sequencing-by-synthesis.

The Roche/454 GS FLX, with its newest chemistry, termed GS FLX Titanium series reagents, can generate more than one million individual sequence reads with read length over 400 base pairs over a 10 h time span (http://www.454.com/products-solutions/system-benefits.asp). Although its per-base cost is much higher than that of other NGS platforms (e.g., Life Technologies/SOLiD and Illumina/Genome Analyzer *II*x), the Roche/454 system is best suited for certain applications such as *de novo* sequencing of new genomes, for which long read length is critical for *de novo* genome assembly.

2.2 Illumina Sequencing Technology

The Illumina GA system is the first short read sequencing platform and currently dominates the NGS market (Metzker, 2010). The first GA system was launched by Solexa in 2006, which was subsequently acquired by Illumina in early 2007 (http://www.illumina.com/technology/sequencing_technology.ilmn).

The Illumina GA system (Figure 2) uses an array technique to achieve cloning-free DNA amplification. Reversible terminator chemistry is the defining characteristic that provides massively parallel sequencing of millions of DNA fragments at low cost. DNA samples are randomly sheared into fragments that are then end-repaired to generate 5′-phosphorylated blunt ends. The Klenow fragment of DNA polymerase is then used to attach a single "A" base to the 3′ end of the DNA fragments, which prepares the DNA fragments for ligation to oligonucleotide adapters (Figure 2a). After ligation to adapters at both ends, the DNA fragments are denatured, and single-stranded DNA fragments are attached to reaction chambers that are optically transparent solid surfaces called a flow cells. To obtain sufficient light signal intensity for the reliable detection, attached DNA fragments are extended and amplified by bridge PCR amplification (Figure 2b). The bridge PCR amplification can create an ultra-high density sequencing flow cell containing hundreds of millions of clusters that, in turn, contains some 1000 copies of the same DNA template. These templates are finally sequenced through the sequencing-by-synthesis technique that applies reversible terminators with removable fluorescent dyes.

For sequencing and DNA synthesis, the reaction mixtures comprising primers, DNA polymerase, and four reversible terminator nucleotides, each labeled with a different fluorescent dye, are supplied to the flow cell. In each sequencing cycle, a specific terminator is incorporated according to sequence complementarity in each template DNA strand in a clonal cluster. After incorporation, the identity (base calling) and the position of the specifically incorporated terminator on the flow cell is determined according to the fluorescence dye emission, and the signal recorded using a CCD camera. In the following cycle, the reversible terminator is unblocked and the fluorescent dye label is removed

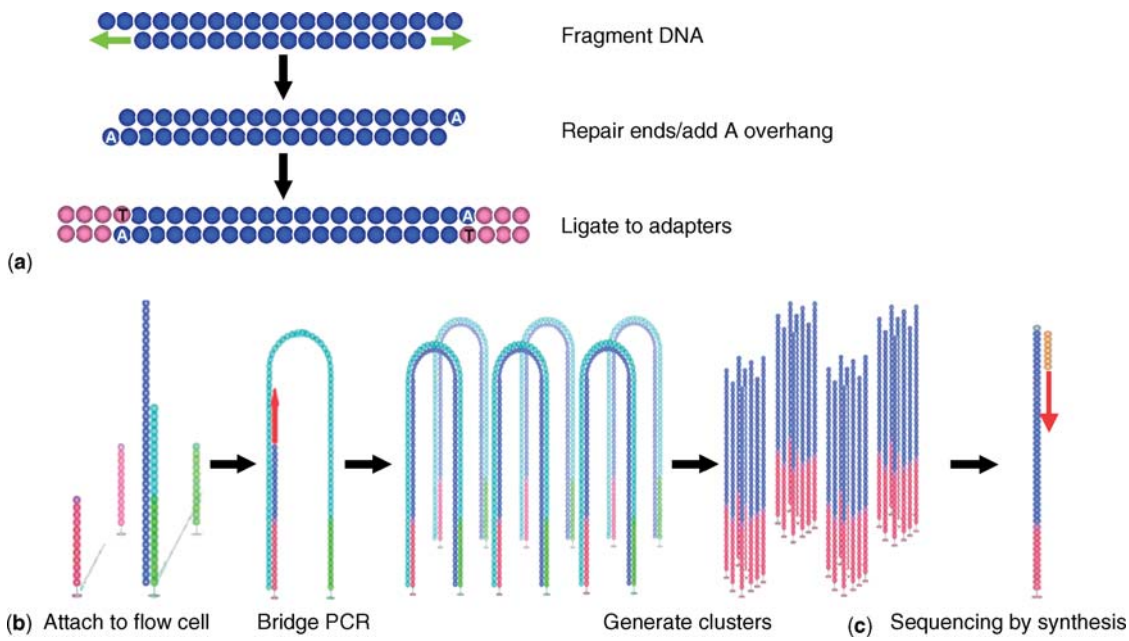

Figure 2. The Illumina Genome Analyzer sequencing strategy: (a) DNA templates are prepared by fragmentation of DNA, end repair, and ligation to adapters; and then are amplified by; (b) bridge PCR in which single-stranded fragments are randomly bound to the inside surface of the flow cell channels and are amplified to generate clusters with some 1000 copies of the same DNA template; and finally DNA templates are sequenced with; and (c) reversible terminator-based sequencing-by-synthesis technique.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat232
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

from the base, so that a new nucleotide can be incorporated and a new base can be detected using the same strategy. This repetitive sequencing-by-synthesis process takes about 2.5 days to generate 50 million reads per flow cell, with a read-length of some 36 bases. The overall sequencing output of the Illumina GA system is more than one billion base (Gb) pairs per analytical run (Bentley *et al.*, 2008).

The upgraded GA *II* that is capable of sequencing both single-read and paired-end (sequencing both ends of the template molecules) libraries, generating some 1.5 Gb of outputs per day, corresponding to 80–100 million reads per flow cell. Moreover, the Illumina's newest version of GA, HiSeq 2000 extends throughput up to 200 Gb per run and two billion 100+ bp paired-end reads.

In a giving cycle of sequencing, any modified nucleotide could be incorporated with a decreased or an increased efficiency, resulting in an under- or over- incorporation and a heterogeneous mixture of synthesis lengths, and concomitant degradation of signal purity and precision. In addition, chemical cleavage of terminating moieties and florescent dye labels are subject to incompletion. Therefore, the Illumina's sequencing strategy generates much shorter reads and its most common error type is substitutions (Shendure and Ji, 2008). The base-call error rate increases with read length due to "dephasing noise" (Dohm *et al.*, 2008). In addition, an underrepresentation of AT-rich and GC-rich regions (Dohm *et al.*, 2008; Hillier *et al.*, 2008; Metzker, 2010) has been observed.

2.3 Life Technologies/SOLiD

The SOLiD (Supported Oligonucleotide Ligation and Detection) system is a short-read sequencing platform relying on ligation chemistry. This platform was developed by Life Technologies based on the strategies described by Shendure *et al*. (2005) and Mckernan *et al*. (2008).

Library construction for the SOLiD system is similar to Roche/454 technology, in which DNA is stochastically sheared into fragments that are subsequently ligated to oligonucleotide adapters (Figure 3a), attached to beads, and clonally amplified by emulsion PCR. After denaturing templates, the template-carrying beads are enriched to separate desired beads from undesired. The templates on the selected beads then are 3′ modified for the purpose of covalent attachment to the slide. Then, 3′ modified beads are deposited onto a derivitized-glass flow cell surface to generate a dense, disordered array (Figure 3b). Sequencing reactions are started by hybridizing a primer oligonucleotide complementary to the adapter at the adapter-template junction (Figure 3c). Unlike the Roche/454 sequencing approach, the sequencing-by-synthesis in the SOLiD system is driven by a DNA ligase rather than a DNA polymerase. Briefly, in the ligation chemistry, a mixture of partially degenerated oligonucleotide octamers is competitively hybridized to the DNA fragments as probes, and a universal primer is oriented to provide a 5′ phosphate group for ligation. The specificity of the probe ligated to a primer is determined by the 4th and 5th bases of the probe that are complementary to the template, and the identities (base callings) of the 4th and 5th bases of probes are characterized by one of four florescent labels at the end of the octamer, so that the interrogation of the 4th base and 5th base is achieved. After ligation, the ligated octamer oligonucleotides are cleaved off after the fifth base and the fluorescent label is removed, so that the next hybridization and ligation cycle can proceed. In such a way, the bases 4 and 5 in the template are determined in the first cycle, and the bases 9 and 10 in the second cycle, and so on. The ligation-sequencing can also be carried out in the same way with another primer offset by one base in the adapter, so the bases 3 and 4, 8 and 9, . . ., in the template can be determined (Figure 3d). By any given five-cycle rounds, each base is interrogated twice with two different fluorescent labels, resulting in significantly reduced base-call error rate (http://www3.appliedbiosystems.com/AB_Home/applicationstechnologies/SOLiDSystemSequencing/OverviewofSOLiDSequencingChemistry).

The current version, SOLiD 3 Plus system, is capable of using both fragments and mate-paired libraries, and of generating in one run over 60 Gb sequence data and one billion reads with read-length up to 50 bases.

By using ligation-based sequencing-by-syntheses, the SOLiD system mitigates homopolymeric sequencing error. The dominant error type is substitutions. Furthermore, according to the manufacturer (http://www3.appliedbiosystems.com/AB_Home/applicationstechnologies/SOLiDSystemSequencing/SOLiD-Accuracy), an

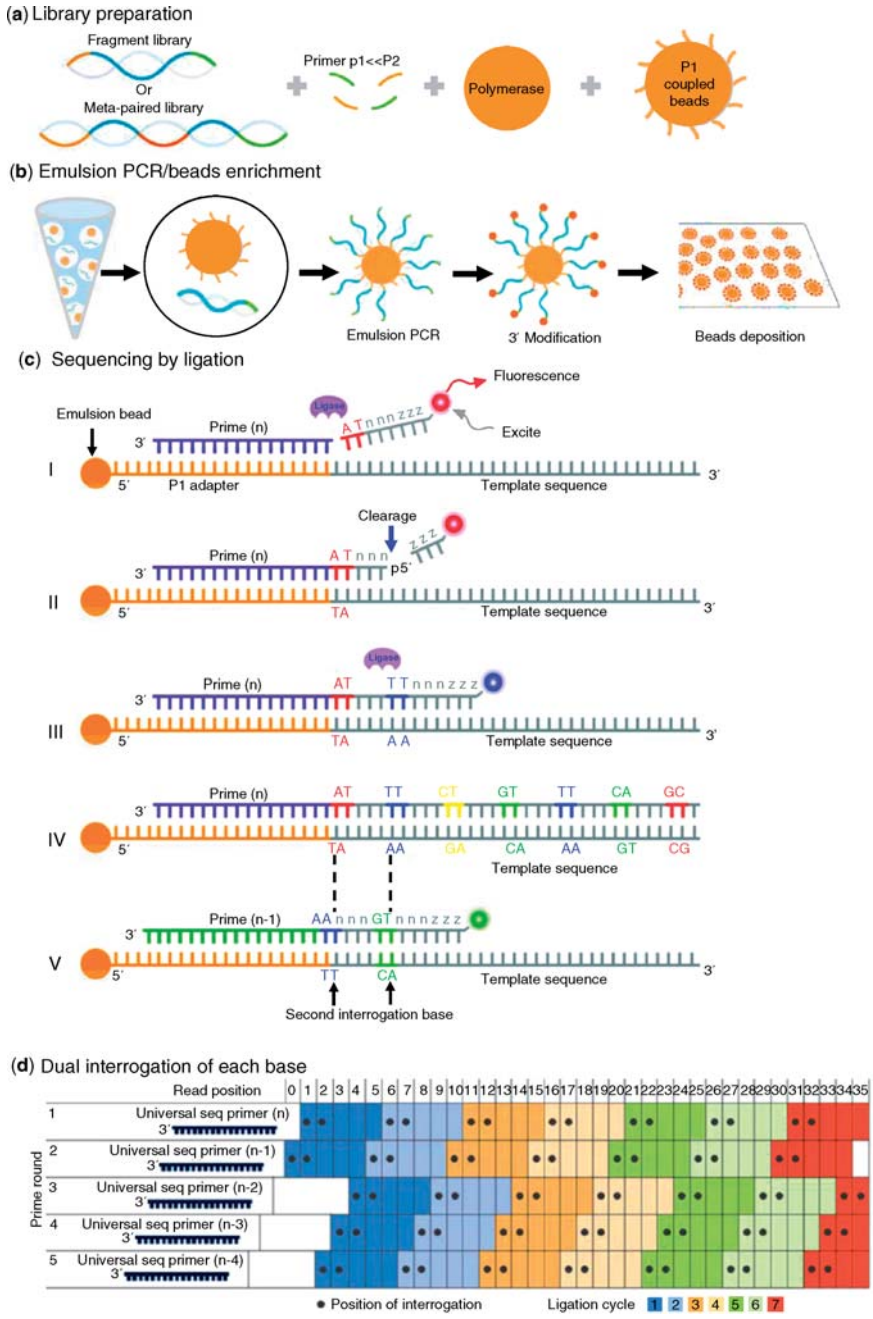

Figure 3. Outline of the Life Technologies SOLiD sequencing: (a) preparation of libraries by ligation of two different DNA adapters, P1 and P2, to the 5′- and 3′- ends of DNA fragments, respectively; (b) emulsion PCR is performed, and DNA templates on enriched beads undergo a 3′ modification, and are deposited onto a flow cell to generate a dense, disordered array; (c) sequencing by ligation: (I) primers hybridize to the P1 adapter on template-carrying beads; a set of four fluorescently labeled di-base probes compete for ligation to the primers. Specificity of di-base probes is achieved by interrogating every 1st and 2nd bases in each ligation reaction. Each ligation is followed by fluorescence detection, after which, (II) the fluorescent label is cleaved and (III–IV) multiple cycles of ligation, detection and cleavage are performed with the number of cycles determining the eventual read length. Following a series of ligation cycles, the extension product is removed and (V) the template is reset with a primer complementary to the n−1 position for the second round of ligation cycles. For each DNA template, (d) a total of five rounds of primer reset are needed, through which, virtually each base is interrogated in two independent ligation reactions by two different primers.

over all accuracy of 99.94% can be achieved by using the two-base encoding system that can recognize and eliminate two-thirds of measurement errors.

2.4 Helicos HeliScope Genetic Analysis System

The HeliScope Genetic Analysis System, developed by Helicos BioSciences (http://www.helicosbio.com) in 2007, is the first commercialized single-molecule DNA sequencer. It is based on the True Single Molecule Sequencing (tSMS) technology stemmed from the work by Braslavsky *et al.* (2003) and relied on the cyclic interrogation of a dense array of sequencing features. By directly sequencing single molecules of DNA or RNA without requiring clonal amplification like other systems, the Helicos' tSMS technology significantly increases the speed and decreases of the cost of sequencing.

In the HeliScope system (Figure 4), a DNA library is constructed by random fragmentation of DNA samples, and 3′ end ploydenylation of DNA fragments with the adenosine terminal transferase (Figure 4a). Denatured poly-A fragments are captured on a flow cell surface by hybridization to surface-tethered poly-T oligomers to yield a disordered array of primed single molecule sequencing templates. In each cycle of sequencing (Figure 4b), DNA polymerase and one of four fluorescently labeled nucleotides are supplied to the flow cell. The template dependent incorporation of single dye-labeled nucleotide is imaged with a CCD camera to make a base calling. Followed by dye-label cleavage and washing, the next cycle of nucleotide extension and imaging is repeated. Each sequencing cycle consists of the successive addition of polymerase and a different type of dye-labeled nucleotide. The total number of sequencing cycles performed ranges from 25 to 55, resulting in read-lengths from 25 to 55 bases. The HeliScope instrument is currently capable of imaging billions of single molecules per run and producing over 1 Gb of usable sequence data per day.

Similar to the Roche/454 platform, the HeliScope system is asynchronous, meaning that some DNA strands will fall behind or ahead of others in a sequence-dependent manner, and some DNA templates just fail to incorporate by chance on a given cycle; therefore, base substitution error is likely to occur. However, the substitution error rate is quite low (0.01–1% with one pass and 0.001% with two passes). On the other hand, there are no terminating moieties present on the labeled nucleotides, so homopolymers could be problematic. Helicos has since developed a Virtual Terminator technology to correct the homopolymer errors, increasing sequencing accuracy (Bowers *et al.*, 2009). In general, as a result of incorporation of unlabeled bases, deletion is the dominant error type in the HeliScope system. The deletion error rate is 2–7% with one pass and 0.2–1% with two passes (Harris *et al.*, 2008).

There are important differences among the aforementioned NGS technologies in terms of costs, advantages, limitations, and practical aspects of use for specific applications. For example, the Illumina and the Life Technologies platforms are particularly well suited for variant discovery by resequencing the human genome (Metzker, 2010), where a reference genome is available. The Roche/454 sequencer may be preferable for *de novo* sequencing due to its longer read-length. The Helicos platform is well suited for RNA-Seq that is relying on tag counting (Wang, Gerstein and Snyder, 2009) or direct RNA sequencing (Ozsolak *et al.*, 2009). Table 1 provides a summary of the characteristics of the NGS platforms from the four manufacturers mentioned above.

3 ANALYSES OF NGS DATA

3.1 Overview of NGS Data Analyses

The new massively parallel sequencing technologies promise to refine and advance science across many fields. Moreover, the now tractable costs enable the powerful systems to reach increasing numbers of hands, thereby, broadly accelerating science. However, the realization of many promises is predicated on progress in overcoming obstacles in handling massive datasets and in developing tools to check and assure sequence quality, conduct sequence alignment and assembly, and biologically interpret and draw inferences from the data. NGS experiments generate immense volumes of short-read sequence data (Voelkerding, Dames and Durtschi, 2009) (Table 1). Data acquisition for such volumes is problematic alone, requiring

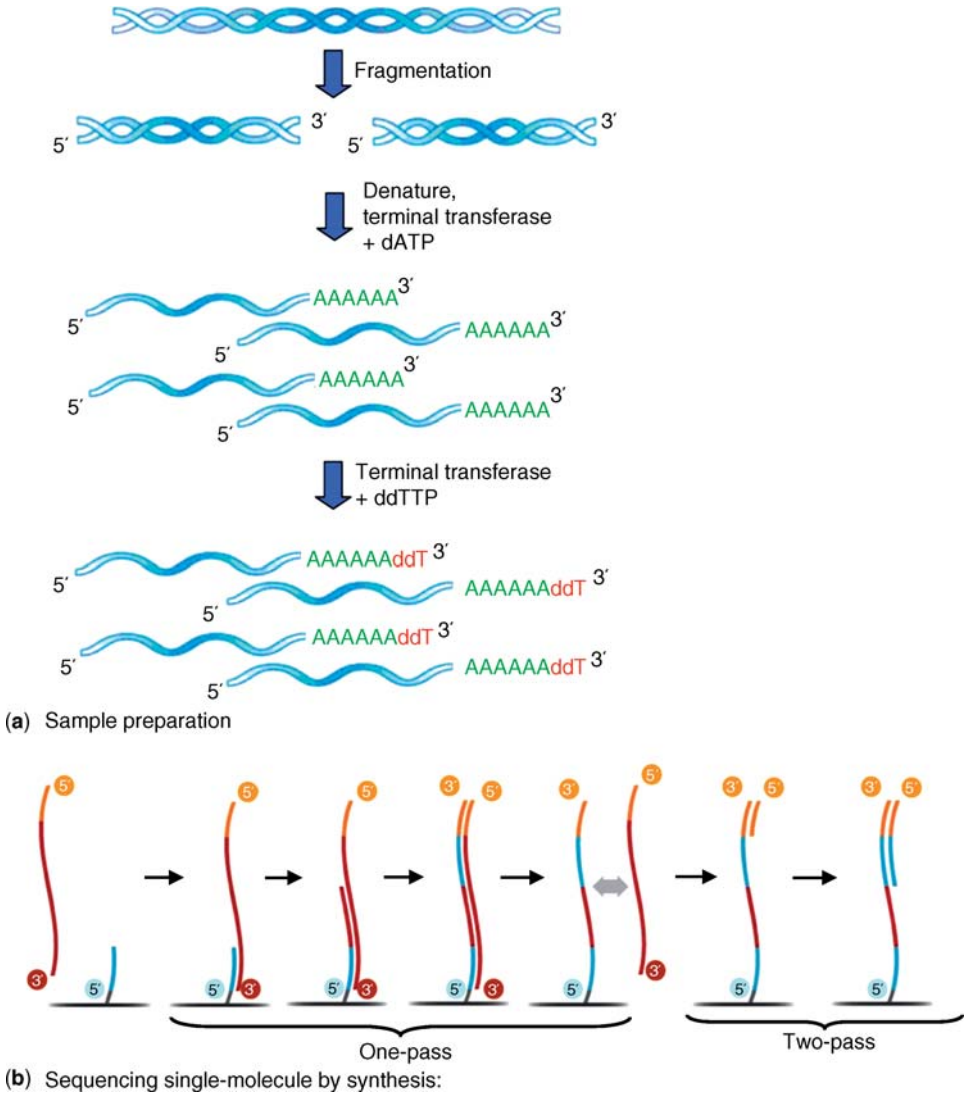

Figure 4. The Helicos true single molecule sequencing (tSMS) system: (a) DNA templates are prepared by fragmentation, 3′ poly (A) tail addition, labeling, and blocking by terminal transferase. In contrast to other NGS technologies, no ligation or PCR amplification is required; and (b) sequencing single-molecule by synthesis: the flow cell is incubated with a mixture of polymerase and one fluorescently labeled nucleotide (C, G, A or T); then the mixture is rinsed away and fluorescent labels are detected. The fluorescent group is finally removed from the incorporated nucleotide and the process continues through each of the other three nucleotides. In such multiple four-base nucleotide addition and detection cycles the sequence of each fragment is determined.

an infrastructure with high bandwidth pipelines between processes that will be computationally intensive.

Translating such volumes of short-read data to biological results can be described as requiring three analysis stages, as depicted in Figure 5. In the first stage, images from NGS sequencers are analyzed and converted into sequence reads using the manufacturer's base-calling system. The reads are filtered and aligned in the second stage. Depending on the intended biological application as well as considerations of the cost, labor intensity and time requirement, the alignment can be done by *de novo* assembly or by mapping to a reference sequence

that can be a complete genome, subsets of a genome (e.g., expressed genes and individual chromosomes of interest), a transcriptome, or an exome. In the final third stage, mapped and unmapped reads can be used to answer specific biological questions, such as the profiling of expression of genes, exons or isoforms; the discovery of novel transcripts, genes, splice variants, or single nucleotide polymorphisms (SNPs); and, the detection of transcription factors, methylation status, and histone modifications.

3.2 NGS Quality Control

The rapid expansion of applications of NGS technologies in solving biological, biomedical, and clinical problems makes the topic of NGS quality control including data quality, reliability, reproducibility, and biological relevance more and more important because of the inherent relatively high error rate in raw sequence data. It is preferable to establish an early consensus of standardized benchmarks for sequencing quality metrics (Editorial, 2008) to avoid the future dilemmas when comparing data from different NGS platforms, such as occurred for microarray platforms the past few years (Shi *et al.*, 2006; Shi *et al.*, 2008). The third phase of the MicroArray Quality Control (MAQC) (Shi *et al.*, 2006) project, also called sequencing quality control (SEQC) is such an endeavor that is aimed at assessing the technical performance of NGS platforms. The SEQC project plans to generate benchmark datasets with reference samples and evaluate advantages and limitations of various NGS platforms and bioinformatics strategies in RNA and DNA sequencing.

3.3 Bioinformatics Tools for NGS Data Analyses

Currently, a number of bioinformatics tools are available for analyzing NGS data (Table 2) that can be grouped in four general categories: (i) base

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat232
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

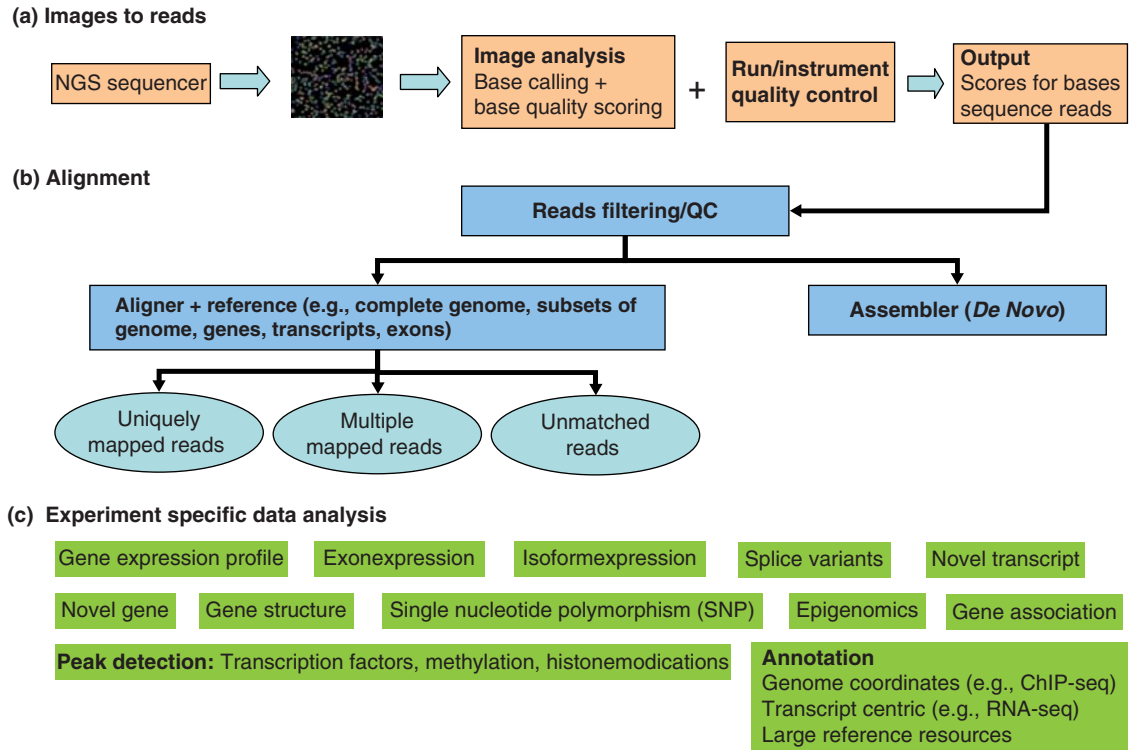

Figure 5. A typical workflow for the analyses of NGS data: (a) conversion of images to sequence reads; (b) alignment of sequence reads (map to a reference or *de novo* assembly); and (c) experiment-specific downstream analyses that depends on the applications.

calling and polymorphism detection, (ii) alignment of reads to a reference, (iii) *de novo* assembly, and (iv) genome browsing and annotation. However, these current tools have some limitations, and many challenges and questions remain. Efficient data analysis pipelines are still needed for many applications and the relative advantages and limitations of existing tools need to be objectively evaluated.

For base calling, most researchers simply use the calls generated with the data-pipeline software provided by manufacturers, but alternative approaches implementing more advanced statistical methodologies are also being developed. For example, Erlich *et al*. (2008) created an Alta-Cyclic approach that uses machine learning to reduce noise factors, substantially improving the number of accurate reads. Rougemont *et al*. (2008) proposed an algorithm using model-based clustering and probability theory to improve base-call quality by identifying and removing ambiguous bases from read ends. However, these improvements must be evaluated for cost effectiveness given the need for substantial investment to handle large volumes of raw image data (Voelkerding, Dames and Durtschi, 2009).

Proper alignment is mandatory to render NGS data biologically meaningful. Because of the short read-length, relatively high error rate in base calling, and a huge volume of data, alignment of data from NGS platforms is much more difficult than that from Sanger sequencing platforms (Trapnell and Salzberg, 2009). One limitation of aligning and assembling of reads is that a large portion of reads cannot be uniquely aligned to a reference when sequence reads are too short and the reference is too complex (Voelkerding, Dames and Durtschi, 2009). In addition, the chance of unique alignment or assembly is reduced not only by the presence of repeat sequences in complex genomes, but also by shared homologies within closely related gene families and pseudogenes (Voelkerding, Dames and Durtschi, 2009).

Conventional alignment solutions like BLAST (http://blast.ncbi.nlm.nih.gov) (Altschul *et al*.,

1990) and BLAT (http://genome.ucsc.edu/cgi-bin/hgBlat) (Kent, 2002) are efficient to align long reads such as those generated by Sanger sequencing, but inadequate to handle NGS short reads. Recently, a variety of sequence alignment algorithms and software packages have been developed specifically for processing a large number of short reads. Table 2 provides an overview of such programs. The algorithms implemented in these software packages vary with the applications, but they include sequence alignment, *de novo* assembly, alignment viewing, and variant discovery. However, the state-of-the-art in short-read alignment and assembly remains the trade-off between speed and accuracy, with a tradeoff needing to be made between ideal alignment and computational efficiency.

4 APPLICATIONS OF NGS TECHNOLOGIES

Over the past five years, the NGS technologies have markedly accelerated multiple research areas, making feasible experiments that previously were not affordable or even technically feasible. Novel fields and applications in biology, life sciences and biomedicine are becoming reality. In this section, we describe some major applications of NGS.

4.1 *De novo* Sequencing or Resequencing of Genomes

The ultra-high throughput and low cost of NGS technologies have made sequencing numerous whole genomes tractable. NGS platforms have been used for *de novo* sequencing many bacterial genomes (Chaisson and Pevzner, 2008; Margulies *et al*., 2005), viral genomes (Harris *et al*., 2008), the giant panda genome (Li *et al.*, 2010c), and resequencing human genomes at dramatically increased speed and decreased cost (Li *et al.*, 2010b; Lin *et al.*, 2008; Pushkarev, Neff and Quake, 2009; Wheeler *et al*., 2008). These applications have demonstrated the power of NGS technologies for *de novo* sequencing or sequencing of personal genomes that will be critical toward moving to the realm of personalized genomics and medicine.

4.2 Target Genomic Resequencing

Resequencing of genomic sub-regions or gene sets is fundamental in basic and clinical research seeking causative and predisposition mutations within populations (Dahl *et al.*, 2007; Ding *et al.*, 2008; Okou *et al.*, 2007). The target resequencing strategy involves comparative analysis of candidate genes or genomic sub-regions from two groups of people with different phenotypes, and requires a high level of accuracy to identify low frequency causative SNPs and structural variants/mutations of diseases that are implicated by linkage studies and whole-genome wide association studies (Porreca *et al.*, 2007; Yeager *et al.*, 2008). Traditional capillary electrophoresis methods provide the highest accuracy and are the best suited for analyzing a limited set of amplicons in a large number of patient samples. However, this is burdensome in cost and labor for investigating a large number of genes or large sub-regions. In contrast, NGS technologies are highly advantageous in terms of both cost and labor, as evidenced by numerous recent studies (Albert *et al.*, 2007; Chou *et al.*, 2010; Hodges *et al.*, 2007; Li *et al.*, 2009b; Okou *et al.*, 2007).

4.3 Chromatin Immunoprecipitation Followed by Sequencing (ChIP-Seq)

ChIP-Seq is a strategy that combines ChIP (chromatin immunopreciptation used to determine the location of DNA binding sites for proteins) technique with the NGS technologies to directly sequence DNA fragments to interrogate DNA-protein interactions, and was an early application of NGS (Barski *et al.*, 2007; Johnson *et al.*, 2007; Mikkelsen *et al.*, 2007). By directly sequencing DNA fragments that interact with proteins, ChIP-Seq provides substantially improved data than microarray-based ChIP-chip method that is the most commonly used for genome-wide profiling of DNA-binding proteins, histone modifications or nucleosomes (Park, 2009). Compared to ChIP-chip, ChIP-Seq has higher resolution, fewer artifacts, greater coverage, and a larger dynamic range. ChIP-Seq can also be used to identify the cistrome of DNA-associated proteins and precisely map global binding sites for any protein of interest (Kaufmann

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat232
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

et al., 2010; Ouyang, Zhou and Wong, 2009; Visel *et al.*, 2009).

4.4 Next-generation RNA Sequencing (RNA-Seq)

Applying NGS technologies to sequence RNA or complementary DNA (cDNA) reverse transcribed from the RNAs offers an alternative methodology for high-throughput transcriptome analysis (Marioni *et al.*, 2008; Wang, Gerstein and Snyder, 2009; Wilhelm *et al.*, 2010). In a typical RNA-Seq experiment, RNAs or cDNAs are first directly sequenced with NGS technologies; and then the sequence reads are mapped to a reference genome to construct a whole-genome transcriptome map (Wang, Gerstein and Snyder, 2009); finally, the transcripts (genes of interest) are characterized (e.g., alternative splicing) and quantified (Wang, Gerstein and Snyder, 2009).

Thanks to the deep coverage and base level resolution provided by next-generation sequencing instruments, RNA-Seq provides researchers with efficient ways to measure transcriptome data experimentally, allowing them to get information such as how different alleles of a gene are expressed, detect post-transcriptional mutations or identifying gene fusions.

By directly sequencing the entire transcriptome without prior knowledge of transcribed regions and at deep coverage and base level resolution, RNA-Seq is revolutionary in its abilities to provide precision in measuring transcriptome data (Li *et al.*, 2010a; Marioni *et al.*, 2008). The far higher resolution improves discovery of novel transcripts, differential allele expression, alternative splice variants, post-transcriptional mutations and isoforms compared with more conventional Sanger sequencing and microarray-based approaches (Chepelev *et al.*, 2009; Hittinger *et al.*, 2010; Jiang and Wong, 2009; Perkins *et al.*, 2009; Richard *et al.*, 2010; Sultan *et al.*, 2008; Tang *et al.*, 2009; Trapnell, Pachter and Salzberg, 2009; Wilhelm *et al.*, 2010). Recent studies (Guttman *et al.*, 2009; Li *et al.*, 2009a; Pan *et al.*, 2008; Porreca *et al.*, 2007; Wang *et al.*, 2008) that used RNA-Seq to characterize the RNA populations have provided more complicated pictures of RNA regulation and expression, through alternative splicing, alternative polyadenylation, and RNA editing. These findings have expanded our traditional view of the extent and complexity of gene expression (Licatalosi and Darnell, 2010), and advanced our understanding of mechanisms of RNA expression regulation in both eukaryotic (Jacquier, 2009) and prokaryotic (Sorek and Cossart, 2010) genomes.

4.5 Comparison Between RNA-Seq and Microarrays

To evaluate the technical performance of NGS technologies on quantifying the expression level of transcripts, we recently used data generated from a rat toxicogenomics study to compare the performance of NGS (Illumina Genome Analyzer *II*) with a microarray-based approach (Affymetrix Rat Genome 230 2.0 arrays) to detect differentially expressed genes (DEGs) (Su *et al.*, 2010). The RNA samples were the same as those used in the MAQC-*I* (Shi *et al.*, 2006) validation study, for which the microarray data already existed (Guo *et al.*, 2006). Eight RNA samples, four treatment and four control, were collected from the kidneys of rats treated/or not-treated (controls) with 10 mg kg^{-1} body weight carcinogen aristolochic acid (AA) (Guo *et al.*, 2006) and then sequenced with an Illumina Genome Analyzer *II* platform. The RNA sample from each rat was sequenced in one lane, generating over 16 million 36 bp reads per sample. Figure 6a shows a scatter plot of NGS log2 FCs (Fold Changes) versus microarray log2 FCs for 11,202 common genes; the Pearson's correlation coefficient (r) is 0.52. Figure 6b plotted the 4169 DEGs that were detected by either NGS or microarrays, where in both cases differential expression of genes was determined by the same two criteria, FC > 1.5 and p-value < 0.05. The 3322 red points and 372 magenta points represent genes detected only by the NGS and microarray, respectively, whereas the 522 blue points and 402 green points represent DEGs commonly selected and either up-regulated, or down-regulated, respectively. One circled point represents a singular common gene with differential expression in the opposite directions. Among all 4619 DEGs, the Pearson's coefficient for log2 FCs is 0.65 (Figure 6b). Although 71% of the DEGs (Figure 6d) selected from microarray data were also selected from NGS data, only 22% of the DEGs selected from the NGS data were selected from the microarray data, supporting conjecture that NGS is

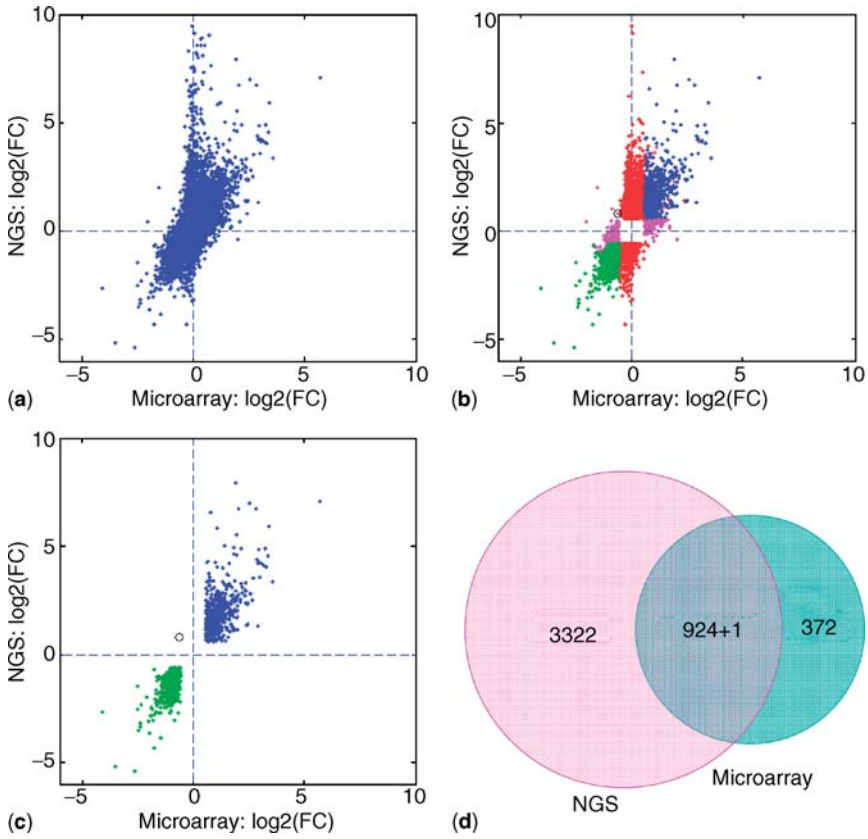

Figure 6. Comparison between NGS and microarray data, based on the log2 fold changes (FCs): (a) all 11 202 common transcripts; (b) 4619 differentially expressed genes (DEGs) identified from either NGS or microarray data; (c) 925 DEGs commonly selected from both NGS and microarray data. For each platform, FCs were calculated by comparing four aristolochic acid treated samples to four control samples and DEGs were selected with an FC cut-off of 1.5 and p-value < 0.05. The magenta and red spots in panel (b) are DEGs determined only by microarrays and NGS, respectively. The blue and green spots in (b) and (c) represent up- or down-regulated DEGs commonly determined by NGS and microarrays. The circle in (b) and (c) denotes a gene up-regulated in NGS but down-regulated in microarrays. The Pearson's correlation coefficients (r) between NGS log2 FCs and microarrays log2 FCs are 0.51, 0.65, and 0.91 in (a), (b), and (c), respectively. The Venn diagram in panel (d) shows the overlap between NGS and microarray DEG lists of panel (b). Of 925 common DEGs (b), 924 are altered in the same directions (c).

more sensitive than microarrays in detecting DEGs under the same selection criteria. The log2 FCs for 925 genes commonly selected by the NGS and microarrays are shown in a scatter plot in Figure 6c with $r = 0.91$. Only one out of 925 genes disagrees in regulated directions. Hence, the concordance between genes commonly detected as differentially expressed by both platforms is very high.

5 FUTURE PERSPECTIVE

NGS technologies are substantially impacting basic genomics research, and many more and far-reaching impacts are anticipated. Over the past few years, NGS technologies have demonstrated their immense potential for enabling scientific advancement in an ever-increasing diversity of biological and medical research areas (Sultan *et al.*, 2008). In the next several years, NGS technologies are anticipated to transition into broader areas including disease etiology, new drug development, clinical-diagnostics, personalized medicine and nutrition, as well as toxicogenomics. Requisite to continuing successful transition will be further sequencing cost reduction, improved read accuracy, more streamlined sample preparation, and perhaps more importantly, computer-based analytics for data

1 INTRODUCTION

Increasing social and economic pressures to develop more effective, safer, and cost-effective medicines make meeting increasingly stringent target product profiles (TPP) and timelines the norm rather than the exception. These very pressures further demand that the way (pre-)clinical experiments are conducted is changed as well. Developments in biological understanding and technology have enabled us to meet some of these expectations. In this chapter, a methodology is proposed for integrating the available knowledge across experiments to predict toxicity in man, thereby making drug development more efficient.

The anticipation is that by utilizing available *in vitro* and *in vivo* (animal) data it will be possible to predict how a molecule will behave in humans. This will allow avoidance of unnecessary human exposure to unsafe or inefficacious drugs as well as reducing lengthy experiments at irrelevant doses by implementing more meaningful designs to deliver more relevant results. Secondly, animal experiments will be designed in such a way that they deliver relevant information – replacing some experiments by simulation and refining the experiments that are conducted to deliver the results required to move to the next phase.

A key piece of information that will enable efficient evaluation of safety and efficacy in man concerns the dose range and regimen to be evaluated and which drug to combine with. The dose and regimen will depend on a molecule's pharmacokinetics, efficacy, and adverse effects. In many ways, these properties will have been evaluated in various experiments before a drug is dosed to humans. Interestingly enough, while the experiments today are largely conducted under a great deal of scrutiny (obeying numerous SOPs and guidelines) – combining all the information and subsequently deciding on a dose and regimes remains a fairly arbitrary process.

Today, we readily board a new plane based on thousands of hours in computer simulation models, we let our politicians decide environmental policies guided by mathematical models that are humblingly complex, and our savings are managed by computer models, yet drug development remains an empirical process, in particular the safety assessment of drugs.

Most experiments conducted today *in vitro*, in animals or man, will have been described by some mathematical equation. Assume for a moment that

any mathematical model that describes some process to which a drug is subjected characterizes that response in parameters that are unique to the physiology of the species tested and also to the drug tested. We can then take this model, add the drug-specific parameters, and replace the species-specific parameters with those of a different species to predict the time course of response in the new species. There are several assumptions in these previous statements, such as the process being similar and the drug-specific parameter being truly drug specific. For example, the regulation of body temperature in rats and humans involves the serotonin-1A receptor; however, it is not so in mice. The validity of the general assumptions therefore needs to be checked case by case. A drug-specific parameter such as affinity is – depending on the receptor – dependent on the species used, something that also needs to be taken into account. However, the concept of scaling results remains valid if the results of any experiment are understood in the context of its environment, be it a Petri dish or the animal physiology. Most often the information collected can be used for reliable predictions.

Key is the understanding of the context in which the drug is evaluated; the mathematical model is merely a tool, a common language to ensure a consistency in our understanding and predictions, but also to visualize highly complex, interdependent non-linear phenomena. This chapter will therefore focus on the following elements to predict in humans: (i) a drug's pharmacokinetics, (ii) drug's toxicity in organs, and (iii) the resulting whole-body toxicity. The pharmacokinetics are essential to the pharmacological process – the "fight" of the body to rid itself off the drug versus the efforts of the drug to distribute itself determine how long the drug will be at the site of action. The second timeline will be driven by the physiology of the actual organ, be it a target of toxicity or pharmacological response. The final timeline will be driven by the overall physiology, or the interaction of the entire system.

Pharmacokinetic information, that is, to predict what might happen to the drug when it is administered to humans, plays a significant role in determining whether a drug will succeed in the clinic (Reigner *et al.*, 1997; Dickins, 2004; Leahy, 2004). This has led to a keen interest in the pharmaceutical industry to develop reliable, high-throughput methodologies to gather PK information. Over the past decade, these methods have been implemented early on in the drug discovery setting to remove compounds with unsuitable PK profiles and only advance those that are predicted to perform well in humans. An accurate prediction of human PK is the basis of a correct calculation of safety margin in human trials for modeling a target or for a given compound. In this chapter, different methods for predicting human PK based on physiochemical properties, *in vitro* and *in vivo* experiments, will be reviewed.

The second part on organ toxicity will focus on the drug-induced prolongation of the QT interval. QT prolongation has become a major regulatory and commercial concern in drug development as the costs associated with late-stage failures, market withdrawals, and patient liabilities have spiralled upwards. Consequently, as a reaction, much work has been invested into computational, simulation, and experimental methods for anticipating QT and proarrhythmic toxicity, thereby allowing drug development programs to mitigate or manage the liability (Sanguinetti and Mitcheson, 2005). To date, regulatory agencies and sponsors are hesitant to embrace such models until clear understanding and agreement on the key proarrhythmia mechanisms emerge (Lawrence *et al.*, 2008). In contrast to *in vitro* and *in vivo* models of cardiac electrophysiology, mathematical system models are presented, which explicitly describe the underlying biophysical processes that are responsible for the genesis of the cardiac action potential. As such, they can be used for two important purposes – to integrate lower-level data to project higher-level possible observations not yet measured and to help interpret and reconcile differences in outcomes or observations across multiple systems.

The final part illustrates the power of combining different models to come to a whole-animal toxicity model. In the example, a model for chemotherapy-induced neutropenia, which represents one of the major limitations during treatment, will be evaluated. The particular example nicely illustrates the high degree of non-linearity in concentration and toxicodynamic-time profiles, which means that mathematical approaches can far exceed our ability to anticipate the events that may occur in humans based on empirical correlations alone.

The three different sections outlined above aim to show that by utilizing available *in vitro* and *in vivo* (animal) data it is possible to get a better understanding and ultimately predict how the molecule

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

will behave in humans at the early stages. These approaches will allow for the evaluation of safe and efficacious doses in humans in an efficient manner. At the same time, it should also help us design more adequate experiments, utilizing less number of animals.

2 PREDICTING HUMAN PHARMACOKINETICS

2.1 Introduction

The primary aim of pre-clinical studies with new drugs is to enter suitable candidates into human clinical trials as quickly and safely as possible. This knowledge, combined with technological advances in high-throughput chemistry enabling numerous compounds to be generated rapidly, has led to a keen focus within the pharmaceutical industry to develop reliable, high-throughput methodologies to gather PK information. In the last decade, these advanced methods have been implemented early on in the drug discovery setting to remove compounds with unsuitable PK profiles and only advance those that are predicted to perform well in humans. The result has been a dramatic shift away from unfavourable PK characteristics being a common reason for attrition of new chemical entities (Theil *et al*., 2003). An accurate prediction of human PK is based on a correct calculation of safety margin in human trials for modeling a target or for a given compound.

The PK profile of a drug is progressively built up using data from a variety of sources and includes considerations such as bioavailability, clearance, and temporal features, such as half-life (Dickins, 2004; Leahy, 2004; Willmann *et al*., 2003). This accumulating information plays a crucial role in the optimization, selection, and development of new drugs from the initial stages of development through to phase 3 clinical trials. Existing methods to generate human PK data fall into three broad categories: *in vivo*, *in vitro*, and *in silico*, and can also be classified into empirical or physiological. Classical empirical methods, such as *in vivo* pre-clinical studies in animals and subsequent allometric scaling to humans, have been utilized for many years to predict human PK parameters. More recently, approaches to human PK prediction of small molecules are increasingly reliant on data generated from *in vitro* studies. With the continuing impetus to improve PK prediction further, strong interest has been sparked into use of *in vitro–in silico* physiologically based PK (PBPK) models (Reigner *et al*., 1997; Poulin and Theil, 2000; Poulin, Schoenlein and Theil, 2001; Poulin and Theil, 2002a; Poulin and Theil, 2002b; Nestorov, 2003). These approaches combine physicochemical properties of compounds and *in vitro* measures, together with information on tissue composition and blood flow, to predict human PK profiles and are increasingly used in compound selection and to simulate clinical outcomes, such as the likely impact of drug interactions and disease, before a drug is administered to man.

2.2 Methods

2.2.1 Construction of PBPK Models

The following section explores some of the key issues associated with the development of PBPK models. More details on the construction of such models are available in a number of reviews (e.g., Clewell, 2008).

Physiologically based pharmacokinetic models divide the body into compartments, including the eliminating organs (e.g., kidney and liver) and non-eliminating tissue compartments (such as fat, muscle, brain, etc.), which are connected by the circulatory system (Figure 1).

The models use physiological and species-specific parameters (such as blood flow rates and tissue volumes) to describe the pharmacokinetic processes. A list of pharmacokinetic parameters with their corresponding definition is provided in Table 1. These physiological parameters are

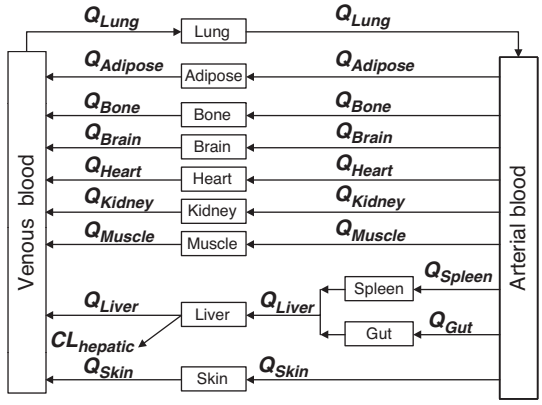

Figure 1. PBPK model.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

coupled with compound-specific parameters such as physicochemical and biochemical parameters (e.g., tissue/blood distribution coefficients and metabolic clearance) to predict the plasma and/or tissue concentration versus time profiles of a compound in an *in vivo* (animal and/or human) system.

Once a model has been developed, the concentrations in the various tissues can be determined by using the mass balance equation below:

Drug concentration in tissue = rate of drug distribution into tissue − rate of drug distribution out – rate of drug elimination within the tissue.

Depending on the drug and tissue, the distribution is perfusion-rate- or diffusion-rate-limited. Perfusion-rate-limited kinetics tend to occur with relatively low molecular weight, hydrophobic drugs that have no problem crossing the lipid barrier of the cell wall. In this case, the process limiting the penetration of the drug into the cells is the rate at which it is delivered to the tissue, so that blood flow is the limiting process. In contrast, diffusion-rate-limited kinetics occurs with more polar drugs that do not freely dissolve in the lipid of the cell membrane and, therefore, have difficulty in penetrating into the cell. In this case the diffusion of drug across the membrane, which is independent of blood flow, becomes the limiting process.

Table 1. Definition of main pharmacokinetic parameters.

PK parameter	Definition	Range of values (human)
AUC	Area under the plasma concentration–time curve following intra- or extravascular administration of the compound	
CL	Total clearance This parameter represents the elimination (metabolism and excretion) of the compound from the body	
CL_H	Hepatic clearance This parameter represents the elimination of the compound through metabolism in the liver and/or biliary excretion	0–20 ml $min^{-1}kg^{-1}$ low: <6 ml $min^{-1}kg^{-1}$ intermediate: between 6 and 14 ml $min^{-1}kg^{-1}$ high: >14 ml $min^{-1}kg^{-1}$
V_d and V_{dss}	Volume of distribution The volume of distribution (V_d) corresponds to the theoretical volume in which the drug would need to distribute to be at plasma concentration. $V_d = C_0$/Dose (iv) V_{dss} corresponds to volume of distribution at steady state	From 0.1 L kg^{-1} (distribution restricted to vascular space) to >50 L kg^{-1} (high volume due to extensive binding)
$T_{1/2}$	Half-life This parameter represents the time taken for the drug concentration in the plasma to decrease by 50% $T_{1/2}$ is a function of the clearance and volume of distribution, and reflects how often a drug needs to be administered. $T_{1/2} = 0.693V_d/CL$	Few minutes to several months, depending on the drug
F_{abs}	Fraction absorbed It is the fraction or percentage of the dose administered, which becomes available in the portal vein after intestinal absorption. $F_{abs} = F/(1 - CL_H/Q_H)$, where Q_H represents hepatic blood flow.	0–100%
F	Bioavailability It is the fraction or percentage of the dose administered, which becomes available in the systemic circulation. Oral bioavailability is obtained by comparison of dose-normalized exposure obtained after oral versus intravenous administration: $F = (AUC_{po}/AUC_{iv}) \times (Dose_{iv}/Dose_{po})$	0 to 100 %

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

For perfusion limitation, the rate of change of drug concentration in a tissue where no elimination occurs can be described as:

$$V\frac{dC}{dt} = Q\left(C_{in} - \frac{C_{in}}{K_p}\right) \quad (1)$$

where V is the physical volume of the tissue, C is the drug concentration in tissue, Q is the blood flow to the tissue, C_{in} is the drug concentration entering the tissue, and K_p is the partition of the drug between blood and tissue.

When diffusion rate limitation occurs, diffusion to and from the extracellular space must be taken into account:

$$V_e\frac{dC_e}{dt} = Q\,(C_{in} - C_e) - P(C_e - C_i) \quad (2)$$

where P is the membrane permeability coefficient, C_e is the free extracellular drug concentration, C_i is the free intracellular drug concentration, and V_e is the anatomical extra cellular volume.

With organs such as liver, where elimination can occur, the rate of elimination must be included in the mass-balance equation. The rate of elimination is described by the equation:

$$\text{Rate of elimination} = CL_H C_t \quad (3)$$

where CL_H is the hepatic clearance of the drug, and C_t is the concentration in tissue (in this case the liver).

This term can then be inserted into the mass balance equation, such as that for perfusion limitation:

$$V\frac{dC}{dt} = Q\left(C_{in} - \frac{C_{in}}{K_p}\right) - CL_H C_t \quad (4)$$

A recent excellent review of whole-body physiological models is provided (Nestorov, 2003). The whole-body model applied in a drug discovery context is described more fully elsewhere (Poulin and Theil, 2002a).

Physiologically based components for prediction of distribution and metabolism may be combined in a whole-body model and linked to an oral absorption model. Thus, plasma and tissue concentration versus time profiles after intravenous and oral administration may be simulated based upon limited data and/or *in silico* estimates (Poulin and Theil, 2002b). In addition, the whole-body model provides a framework for incorporation of additional processes when these can be estimated.

2.2.2 Models to predict distribution

For each organ included in the PBPK model, estimates of tissue/plasma partitioning are required to quantify the distribution for the compound under study.

The tissue plasma partitioning can be estimated in silico using mechanistic tissue composition models (Poulin and Theil, 2000; Poulin, Schoenlein and Theil, 2001) or can be determined experimentally. Semi-empirical methods to estimate tissue plasma partitioning based on *in vivo* V_{ss} were also reported (Ballard *et al*., 2003). These methods are reviewed below:

Tissue composition-based models have been developed to estimate tissue distribution based on *in vitro* and in silico data (Poulin and Theil, 2000; Poulin, Schoenlein and Theil, 2001). These models have greatly extended the applicability of the PBPK approach to early compound research and development. Briefly, these equations assume that the compound distributes homogenously into the tissue and plasma by passive diffusion where two processes are accounted for: (a) non-specific binding to lipids estimated from compound lipophilicity data [$\log P$ (octanol : water distribution coefficient of the unionized drug) and $\log D$ (octanol : water distribution coefficient of the ionized + unionized drug measured at a given pH)] and (b) specific reversible binding to common proteins present in plasma and tissue estimated from the plasma f_u (f_{up}, fraction unbound in plasma). These models have been reviewed in detail (Poulin and Theil, 2000).

2.2.3 Models to Predict Clearance

Models to predict clearance have been reviewed recently and a summary is provided below.

Hepatic Metabolic Clearance

Both empirical and physiologically based approaches have been developed to predict the *in vivo* hepatic metabolic clearance in animals and humans (Lave *et al*., 2002). Because of the improved availability of animal and human liver samples, the number of predictions that include *in vitro* data and are based on *in vitro* to *in vivo* (IVIV) physiologically based direct scaling approaches

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

has markedly increased during the last decade. The attractiveness of these approaches is that they do not require extra information from preclinical studies in animals.

The strategy that allows this extrapolation of *in vitro* clearance to the *in vivo* situation can be summarized as follows: the first step is to obtain CLH,int (hepatic intrinsic clearance) from *in vitro* data; reliable *ab initio* prediction of metabolic clearance for a wide variety of compound structures is not currently available. Thus, *in vitro* CLH,int values determined from various systems (e.g., hepatocytes, liver microsomes, recombinant CYPs), by substrate depletion or metabolite formation, are normalized for cell, microsomal protein, or enzyme concentration to obtain CLint in units of $\mu l\ min^{-1}\ 10^{-6}$ cells or $\mu l\ min^{-1}\ mg^{-1}$ protein and corrected for any non-specific binding. The second step consists of scaling the activity measured *in vitro* to the whole liver. This is achieved by using hepatocellularity numbers (hepatocytes), microsomal recovery (microsomes), or inter-system extrapolation factor (recombinantly expressed CYPs) values. Microsomal recovery and hepatocellularity scaling factors have been reported in the literature for various species including man (Wilson *et al*., 2003). Successful examples of IVIVE using recombinantly expressed CYPs have also been reported (Clausen and Bickel, 1993). However, the accuracy of such clearance estimates relies significantly on the availability of well-defined values for inter-system extrapolation factors (Bickel *et al*., 1987). The third stage involves the use of a liver model that, in addition to CLH,int, incorporates the effects of hepatic blood flow and blood binding, to convert the estimated CLH,int into a CLH. The main liver models used, in decreasing frequency, are: the venous equilibrium (well-stirred) model >the dispersion model >the undistributed sinusoidal (parallel-tube) model (see Figure 2, Lave *et al*., 1999).

Predictions of *in vivo* hepatic metabolic clearance based on *in vitro* data have been reported extensively over the past 30 years (e.g., Ritschel and Hammer, 1980; Yata *et al*., 1990; Yokogawa *et al*., 1990; Kaliszan, Nasal and Turowski, 1996; Reinoso, Telfer and Rowland, 1998; Ballard, Leahy and Rowland, 2000; Ballard *et al*., 2003; Lombardo *et al*., 2002; Wajima *et al*., 2003). The literature indicates variable success with a general trend for underprediction (Abraham, Chadha and Mitchell, 1994) for drugs metabolized by cytochrome P450 (CYP) and UDP-glucuronosyltransferase (UGT), particularly when human liver microsomes (HLM) are employed as the enzyme source (Sawada *et al*., 1984; Nestorov, Aarons and Rowland, 1998; Luco, 1999; Bjorkman, 2002). Accurate prediction requires careful scrutiny of the quality of both the *in vitro* and *in vivo* data, the use of accurate scaling factors, and correction for non-specific microsomal binding (Clausen and Bickel, 1993). Underprediction might arise from the release of membrane long-chain unsaturated fatty acids, which act as potent competitive inhibitors of several UGT and CYP enzymes (Houston, 1994; Houston and Carlile, 1997; Lave *et al*., 1997; Zuegge *et al*., 2001).

Several studies have assessed the predictive performance of physiologically based IVIV scaling based on microsomes or recombinant systems expressing human CYPs or hepatocytes. For example, using Simcyp computer modeling software, to predict median drug clearances for 15 drugs, the predicted values of median clearances fell within twofold of observed values for 78% of the drugs when microsomal binding was disregarded and for 100% when it was considered (Clausen and Bickel, 1993). Overall, the predicted fold variability fell within twofold of the observed variability for 80% (oral) and 67% (intravenous) of the drugs (Clausen and Bickel, 1993). In another study (Mahmood and Balian, 1996), using the standard biological scaling factors alone resulted in a systematic five- to sixfold underprediction of *in vivo* CLH,int. Further empirical adjustments of hepatocyte and microsome human *in vitro* intrinsic clearance values provided more accurate predictions of hepatic clearance with more robust models resulting from incorporation of *in vitro* binding for both hepatocytes and microsomes.

Interestingly, several reports on relatively small numbers of compounds have indicated that data generated from hepatocyte incubations containing serum may yield more accurate, direct estimates of CLH,int, *in vivo* and CLH (Hoener, 1994; Houston, 1994; Houston and Kenworthy, 2000), perhaps by removing the inhibitory effects of long-chain unsaturable fatty acids through serum binding. Combining the results based on cryopreserved human hepatocytes in these studies to obtain an extended data set of 26 compounds, encompassing a 50-fold range of clearance, a range of protein binding from minimal to 90%, and metabolized by a variety of phase I and phase II enzymes, the clear-

ance of 77% of the compounds was predicted within a twofold error in the absence of serum. In the presence of serum, prediction accuracy rose to 85%.

Renal Clearance

Renal excretion involves glomerular filtration and tubular secretion by active transport, both of which occur in the proximal nephron, and subsequent predominantly distal reabsorption, much driven by the extensive reabsorption of water. Despite a detailed knowledge of these factors, and the development of models of renal clearance (Lave *et al*., 1999; Pahlman *et al*., 1999), prediction of human renal clearance has remained essentially empirical, principally because allometric scaling of animal renal clearance has been relatively so successful (Lin, 1995; Ishizuka *et al*., 1999). Still, as with transporters in other organs, species-specific differences in affinity and efficiency of renal uptake and efflux transporters exist (Grass and Sinko, 2002), suggesting that when taken into account some improvement over allometry should result. That said, for some drugs either filtration (especially for large polar compounds) or extensive reabsorption (especially for lipophilic compounds) predominates, processes virtually non-existent in the liver, thereby dampening the impact of any species differences in secretion on renal clearance. For such drugs, *in silico* prediction should suffice. With only unbound drug filtered at the glomerulus, owing to size exclusion of proteins, and with filtration driven by arterial pressure, glomerular filtration is readily predicted as the product of glomerular filtration rates and fraction of drug in plasma unbound. Attempts have been made, with some success, to predict tubular reabsorption based on the physicochemical properties of the molecule (log P, pK_a), taking into account urine flow and pH when, as commonly occurs, reabsorption is passively driven (Norris *et al*., 2000; Agoram, Woltosz and Bolger, 2001). Moreover, when passive tubular reabsorption predominates, renal clearance tends to be low and generally a small component of total clearance, so that even an appreciable error in prediction of the extent of reabsorption is of minor concern. When secretion is a substantial component of renal clearance, allometric scaling tends to underpredict human values (Parrott and Lave, 2002). A model of renal clearance for compounds that undergo extensive active reabsorption, as commonly occurs for many vitamins and essential nutrients, has been developed (Rostami-Hodjegan, 2004).

Biliary Clearance

Common approaches to optimize the key ADME properties of new chemical entities (NCEs) during drug discovery are mainly based on solubility, lipophilicity, permeability, and metabolic stability. The optimization of compound properties for improved metabolic stability often results in more hydrophilic and less membrane-permeable compounds, thereby contributing to a shift in the elimination routes from metabolism toward non-metabolic processes. Thus, besides hepatic metabolism, it is increasingly recognized that hepatic uptake and efflux transport processes have a significant impact on hepatic clearance of many NCEs. For such compounds, hepatic distribution may become sufficiently slow to become permeability-rate-limited and assumptions of perfusion-rate-limited distribution and well-mixed compartments are no longer valid. These permeability limitations, often associated with active transport processes, need to be adequately accounted for in order to better predict clearance from *in vitro* data. This is best performed with physiologically based models by the addition of permeability and by the incorporation of more complex liver models, which include active uptake into the liver, active efflux into the bile, biliary elimination, and enterohepatic recirculation, in addition to metabolism. However, this improvement to current modeling methodologies requires the availability of all the appropriate quantitative input data as well as validation of the corresponding *in vitro* models and the proper IVIV scaling approaches.

Various approaches have been proposed to scale hepatobiliary clearance based on *in vitro* data. A holistic approach, where all processes (uptake, metabolism, and secretion into bile) are integrated, uses hepatocytes in sandwich culture in a single *in vitro* tool to estimate the overall processes driving hepato-biliary clearance (Carlile, Zomorodi and Houston, 1997; Lave *et al*., 1997; Naritomi *et al*., 2001). Whereas the rank order of global biliary clearances in rat was consistent from *in vitro* to *in vivo*, most of the *in vivo* values were underpredicted by more than twofold. A very limited number of drugs have been evaluated for biliary clearance using sandwich-cultured human hepatocytes. Only one was predicted within twofold whereas the two others were underpredicted by 2.2- and 4.6-fold (Carlile, Zomorodi and Houston, 1997).

Another approach, which is entirely mechanistic, involves the determination of intrinsic clearances for each process independently from each other and the integration of these processes in a mechanistic mathematical model to derive the hepatobiliary clearance. The current limitation of this approach is the ability to measure each process *in vitro*, especially efflux transport, as well as the availability of validated scaling factors for individual transporters.

2.2.4 Models to Predict Oral Absorption

Although, in some cases, a simple, first-order model can adequately describe oral absorption, more physiologically representative approaches have been developed and shown to be useful for predicting the fraction absorbed, for example, a compartmental approach such as the Advanced Compartmental Absorption and Transit (ACAT) model (Agoram, Woltosz and Bolger, 2001) and a model describing the GI tract as a tube (Willmann *et al*., 2003). Simulation of oral absorption using physiologically based models represents another challenge because of the many processes involved such as the release, dissolution, degradation, metabolism, uptake, and absorption of a compound as it transits through the different segments of the digestive tract (Semino, Lilly and Andersen, 1997). Oral absorption simulations require *in vitro* and *in silico* input data such as solubility, permeability, particle size, partition coefficient (log *P*), ionization constant (pK_a), and dose.

Physiologically based models to predict oral absorption in animals and humans have recently been reviewed (Agoram, Woltosz and Bolger, 2001; Grass and Sinko, 2002), and several models are now developed to a degree that they are commercially available. The commercial models have not been published in detail because of proprietary reasons, but in essence, they are transit models segmenting the gastrointestinal tract into different compartments with the kinetics of transit, dissolution, and uptake described by differential equations. For example, the model underlying GastroPlus™ is known as the ACAT(Figure 3) and is a semi-physiologically based transit model, consisting of nine compartments corresponding to different segments of the digestive tract. Oral absorption simulations take *in vitro* and *in silico* input data such as solubility, permeability, particle size, log *P*, pK_a (ionization constant), and dose.

2.2.5 PBPK Modeling Strategy for Prediction to Man

A PBPK modeling strategy has been proposed recently and is illustrated on Figure 4.

The proposed modeling strategy attempts to evaluate the data generated in drug discovery and early development in a more integrated way, by combining *in silico* and *in vitro* prediction methods for absorption, distribution, and hepatic clearance to estimate the oral PK profile in humans.

The strategy consists essentially of two major steps. The first step is to predict specific ADME parameters, and then combine their input in a PBPK model to estimate, in a second step, the overall PK after oral and intravenous administration. Before a prediction in humans is attempted, a comparison of the predicted PK parameters and the concentration/time profiles with *in vivo* data from animals (rat, dog or monkey) is performed as a model validation. The rat is usually used because it is by far the most commonly used animal species for the ADME characterization of compound candidates and because tissue composition models are available in rats and humans. A satisfactory prediction for the rat suggests that the prediction in humans might be successful, although this cannot be considered as a full validation.

Thus, the PK in the rat is used to confirm that the PBPK model selected can be used for prediction of human PK. In a first step, disposition PK in the rat after intravenous administration is predicted with a PBPK model by using estimates of tissue:plasma partition coefficients, and hence the derived V_{ss} as well as hepatic clearance as the assumed major

component of clearance. If the predicted plasma concentration/time profile in rat describes the experimental data adequately, the intravenous PK in humans is simulated in a second step. In case of major deviations between predicted and experimental concentration/time profile in the rat, model refinements are necessary prior to prediction of human PK.

During the drug discovery and development process, more and more data become available and the data obtained are characterized by higher quality. The constantly increasing data quantity and quality potentially improve the model predictions as shown in Figure 5.

2.2.6 Commercial Tools Available

A number of user-friendly software packages bringing PBPK modeling to the non-expert are available and have been reviewed recently (Clewell, 2008).

The possible benefits from having PBPK software packages available for scientists who are non-modelers have been a topic of interest for many years. Such a tool would need to meet many criteria to be broadly useful. This tool would need to be user-friendly, fast, flexible, and requiring little mathematical expertise from the user. The import of data into the tool and the export of results from the tool would need to be fast and automatable. The required input would be clearly defined and difficult to enter incorrectly, making consistent use by scientists of varying background possible. The tool would ideally be applicable through all stages of preclinical through clinical development. The pharmaceutical industry now has many tools that meet some or all of these criteria. Tools using physiology-based whole-body models for the simulation of the PK behavior, including absorption, distribution, and elimination, include GastroPlusTM (Simulations Plus Inc., www.simulations-plus.com), Simcyp (Simcyp, www.simcyp.com/), PK-Sim® (Bayer Technology Services, www.pksim.com), MEDICI-PK (AT Computing in Technology GnbH, www.cit-wulkow.de/pdf/Broschueres/MediciPK/Medici-web2.pdf), and Cloe PK® (Cyprotex, www.cyprotex.com).

GastroPlusTM, which is well known in the pharmaceutical industry for its capabilities in predicting oral absorption in preclinical species based on the

ACAT model, has recently expanded to include the capability of PBPK modeling. In the most recent version, GastroPlusTM includes a physiological intestinal model for humans in fed and fasted state as well as models for the rat, dog, cynomolgus monkey, and mouse. Several additional modules are available for parameter optimization, for combining the absorption model with physiological and compartmental PK models, and for PD models. The software also includes clinical trial simulation capabilities and a powerful method of performing sensitivity analysis. Although currently only PBPK modules for the rat and humans are available, the user can create PBPK models for other species by creating input files with appropriate physiological parameters. The performance of GastroPlusTM to predict absorption was evaluated (Parrott and Lave, 2002). In this study, GastroPlus was compared with iDEATM, another software to predict absorption that is no longer commercially available.

Another tool for predicting human PK, Simcyp (Simcyp Ltd, Sheffield, UK), was previously known as a drug–drug interaction clinical trial simulator but has expanded to include PBPK modeling capabilities. Simcyp utilizes fundamental scaling procedures (Houston, 1994), for the prediction of *in vivo* hepatic clearance (CLH) from *in vitro* metabolism data. These *in vitro* metabolism data can be obtained from individual cytochrome P450s (CYP) in human-expressed recombinant systems. These are used for predicting the behavior not only in average individuals, but also in whole populations or in special subpopulations. In order to predict drug–drug interactions involving CYP, Simcyp utilizes the relationship between the inhibitor concentration at the active site *in vivo* and the inhibition constant (K_i) determined *in vitro*. Competitive inhibition, induction, and/or mechanism-based inactivation mechanisms can be investigated within this software, according to the principles described elsewhere (Ito *et al*., 1998; Tucker, Houston and Huang, 2001). Simcyp not only predicts the mean value but also simulates the extremes in the population by applying a Monte Carlo approach. This software comes with a database of physiological properties for specific populations and of PK information for specific drugs on the market (e.g., the CYP3A4 substrate midazolam, the CYP3A4 inducer rifampicin, and the CYP3A4 inducer and inhibitor ritonavir).

Yet another tool, PK-Sim, developed as a user-friendly tool for PBPK modeling, has PBPK models in the mouse, rat, dog, monkey, and humans. In the model, tissue concentrations depend on the blood flow rate to the tissue, the rate of permeation into the tissue, active transport processes into and out of the tissue, and the rate of metabolism within a tissue. Although this detailed description allows significant flexibility and complexity, the user-friendly interface also allows for simple simulations whereby the more complex features are not utilized. In PK-Sim, the GI tract is described as a single tube with physiologically relevant dimensions and spatially varying properties such as pH and surface area. The software has Monte Carlo capabilities, and simulations examining the impact of inter-individual variability can be performed using the population PK module. Physiological parameters for people from 0 to 80 years old are provided, allowing simulations of PK in the young and the elderly. Also, the software has the capability of linking PK to PD behavior with a PK/PD module.

In a fresh approach to PBPK modeling, the new software MEDICI-PK was developed using a novel software concept aimed at providing increased flexibility while maintaining user-friendliness. Instead of adopting the traditional approach whereby user-friendliness is made possible by adopting a static model, in MEDICI-PK the system of differential equations is generated automatically when starting a simulation. This software allows for predictions of parent compound and multiple metabolites, and interactions (metabolic and otherwise) between compounds (Huisinga, Telgmann and Wulkow,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2006). MEDICI-PK has PBPK modeling capabilities for multiple species (e.g., humans, mouse, and dog) that can be extended by the user, and also contains PD modeling capabilities.

Cloe-PK® is a commercial tool aimed at prediction of human PK at the earliest stages of drug discovery. The PBPK model includes 14 organs and tissues, clearance by metabolism and renal excretion, and diffusion-limited uptake in tissues. In each of the organ compartments, the capillary, intracellular, and extracellular spaces are explicitly included. Using *in vitro* and *in silico* data as input, this software can predict human IV and oral AUC from clinical trial data within two- and 3.75-fold, respectively (www.cyprotex.com/products/pk_howwell.htm). Studies on the accuracy of the model for predicting PK behavior in the rat and humans have been published (Brightman *et al*., 2006), and illustrate the utility of this software for predicting PK and ranking compounds based on minimal data and *in silico* parameters.

These software packages are exceptionally useful tools, and we expect them to be increasingly used in the pharmaceutical industry. However, their implementation may require an M&S expert to determine appropriate applications and methods of use and to perform validation exercises to convince the scientists involved in the preclinical development of drugs that the packages do indeed work. Additionally, in-house PBPK expertise and models will still be necessary because these standard tools do not allow the flexibility to simulate every situation that will arise. For example, currently some generic PBPK tools do not yet have the capability to simulate exposures to a parent compound and a metabolite, which could be of interest for simulating the PK of prodrugs or investigating possible PK interactions between the parent and metabolite. Also, generic PBPK software packages have sophisticated capabilities that may require an expert modeler to determine appropriate ways to use (and not misuse) the features (e.g., GastroPlus has the capability of simulating enterohepatic cycling, and PK-Sim can incorporate saturable and non-saturable metabolism in multiple tissue compartments). In addition, the availability of such tools simplifies the technical use of PBPK models; however, a good understanding of the models and underlying equations is still mandatory in order to guarantee good interpretation of output. The different technologies for PBPK modeling discussed have different strengths, making them useful for different purposes within the research and development process in the pharmaceutical industry (see Table 2).

2.3 Applications and Limitations of the Current Methodology

2.3.1 PBPK for Extrapolation of Pharmacokinetics to Man

A number of publications illustrate the potential of PBPK, both for predicting human pharmacokinetics and for examining species differences in pharmacokinetics.

Successful predictions were also reported in the case of epiroprim (Luttringer *et al*., 2003). This was achieved by combining PBPK and allometric scaling. Epiroprim, an antimicrobial agent from the diaminopyrimidine family, was considered a challenging compound for the current extrapolation methods because of large interspecies differences in its pharmacokinetic properties mainly related to mixed elimination pathways, namely hepatic metabolism and biliary excretion of unchanged compound. For the prediction of distribution in man, the tissue:plasma partition coefficients were predicted using the human tissue composition model based on *in silico* input parameters. The human clearance was predicted by using allometric scaling combining animal intrinsic *in vivo* blood clearance and *in vitro* hepatocyte data in animals and humans. Under these circumstances, PBPK led to reasonable predictions of the *in vivo* disposition profile of epiroprim in rat and humans.

Lumped physiologically based models (in which the tissues are subdivided into groups, according to their kinetic properties) have been used to predict human plasma concentration–time curves for the melatonin agonist S20098 (Bogaards *et al*., 2000). By combining *in vitro* metabolism data obtained from human cytochrome P450 enzymes with partition coefficients in fat and liver, the range of plasma concentrations observed in humans could be successfully predicted. In another study (Lave *et al*., 2002), a lumped physiologically based pharmacokinetic model originally developed by Arundel for the rat (Ballard *et al*., 2003) was extended and applied to humans for 10 extensively metabolized compounds. Overall, the results showed that this model might be used to predict concentration versus time profiles in humans. Irrespective of the compounds' pharmacokinetic and physicochemical characteristics, the average error for the predicted pharmacokinetic parameters [CL (total clearance), V_{dss} (volume of distribution at steady state), and $T_{1/2}$ (half-life)] of the 10 compounds was less than twofold (Lave *et al*., 2002).

Recently, empirical and PBPK approaches were compared for the prediction of human pharmacokinetics using 19 diverse compounds taken from recent clinical development projects at Roche (Parrott *et al*., 2005). The original set of compounds included in this analysis represented all the compounds developed at Roche that went into clinical development between 1998 and 2002. From this set of biological compounds, prodrugs and compounds that were not absorbed were excluded. The remaining compounds ($n = 19$) were used in the analysis. The compounds selected covered a wide range of physicochemical and PK properties. All compounds were lipophilic with $\log P$ values ranging between 1.2 and 6.6, with a mean of 4.0. Five compounds were acids with a $pK_a < 8$, seven were bases with a $pK_a > 6$ and seven were neutral or weakly ionized at physiological pH. Half-life in man ranged from short (0.50 h) to long (80 h). Elimination pathways included hepatic metabolism, renal excretion, biliary excretion, or a combination of these. Fraction unbound in plasma (fup) values ranged from extensive (0.00060) to low (0.89). Distribution consisted of both passive and active processes and varied from limited to widespread. In the rat, absorption ranged from 15 to 100%. Predicted values (pharmacokinetic parameters and plasma concentrations) were compared to observed values in order to assess the accuracy of the prediction methods.

Based on the strategy proposed, a prediction would have been made prospectively for approximately 70% of the compounds. The accuracy for these compounds in terms of the percentage of compounds with an average-fold error of less than twofold was 83, 58, 83, 67, 92, and 100% for clearance, volume, half-life, C_{max} [maximal (peak) plasma concentration], AUC (area under the plasma concentration–time curve), and T_{max}, respectively. For the other 30%, unacceptable prediction accuracy was obtained in animals; therefore, a prospective prediction would not have been made using PBPK. The accuracy for these compounds in terms of the percentage of compounds with an average-fold error of less than twofold was 40, 40, 60, 0, 40, and 80% for clearance, volume, half-life, C_{max}, AUC, and T_{max}, respectively. In general, for compounds that were cleared by hepatic metabolism or renal excretion, and whose absorption and distribution were governed by passive processes, the prediction accuracy was very good (average fold error less than twofold) using PBPK. Significant mispredictions were achieved when other elimination processes (e.g., biliary elimination) or active processes were involved. PBPK prediction accuracy was significantly improved when any non-linearities in clearance were incorporated; when both microsomal and plasma binding were included in the scaling of microsomal data; when intestinal metabolism was incorporated for CYP3A4 substrates; and when

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

solubility was measured in physiological media for low-solubility compounds. The poorer predictions or the compounds for which a prediction was not attempted with PBPK were often as a result of processes that were not incorporated into the model due to the lack of *in vitro* input parameters to describe processes such as biliary excretion or enterohepatic recirculation.

The prospective use of PBPK approaches was also described recently (Parrott *et al*., Molecular Pharmaceutics). In recent years, the strategy for prospective predictions of human pharmacokinetics has been applied prospectively and clinical data have been obtained for 10 compounds. Figure 6 shows the correlations of predicted AUC and C_{max} for these compounds in single ascending dose studies. Eighty percent of AUC predictions and 60% of C_{max} predictions are within twofold of the observed mean values.

All in all, there is growing evidence that physiologically based models show improved prediction accuracy for extrapolation of human pharmacokinetics over more empirical methods. The PBPK approach is based upon solid physiological principles and so can often be extended in a rational way to include additional relevant information and data. PBPK model also offers a mechanistic framework that contributes to an improved understanding of the compound's properties, which ultimately should result in better prediction accuracy. The variability and uncertainty associated with the predictions also require some special attention. As is apparent from the literature and available clinical data for the compounds studied, there is a large degree of variability in the population in terms of both physiology (tissue volumes, blood flows, transit times, etc.) and biochemistry (plasma binding, CYP expression, activity, etc.). In order to produce predictions that are more realistic of the target population this variability together with any uncertainty (variations due to assumptions, hypotheses, handling of system, etc.) ideally must be accounted for. The incorporation of these factors can be translated into a measure of confidence in the prediction.

2.3.2 *Early Pharmacokinetic and Pharmacodynamic (PKPD) Predictions in Man Based on PBPK and Preclinical Data*

In a recent study, a mechanistic PBPK and pharmacokinetic/pharmacodynamic approach was reported for the prediction of the human response using the example of a immunomodulator (Meno-Tetang and Lowe, 2005). The example was based on the immunomodulator FTY720 (the first sphingosine-1-phosphate receptor agonist) acting by stimulating the sequestration of lymphocytes into lymph nodes in order to remove cells from blood circulation. A physiology-based pharmacokinetic model

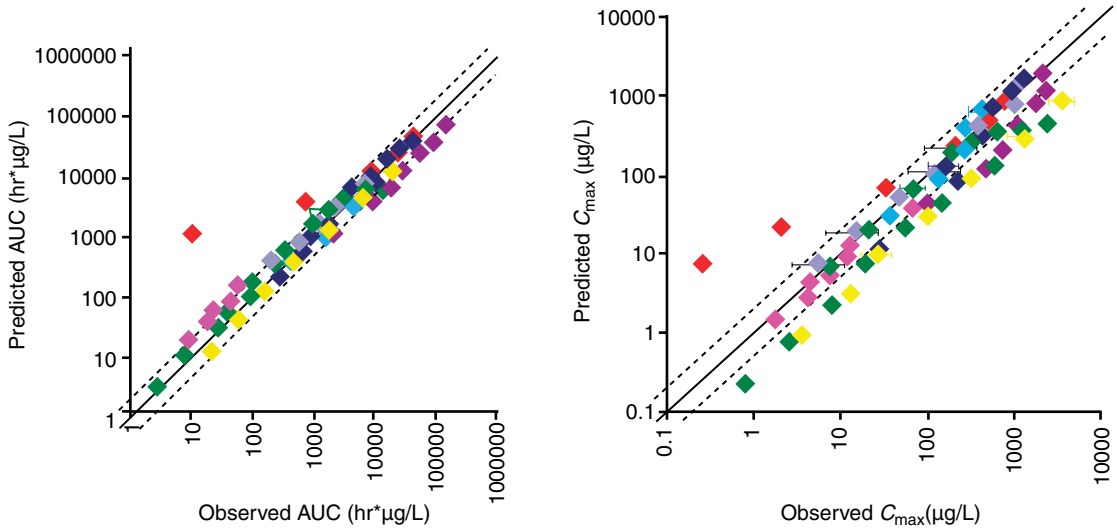

Figure 6. Predicted and observed AUC and C_{max} in humans for 10 diverse compounds. Each compound is represented by a single color and appears multiple times to represent different dose levels.

incorporating permeability limitations in thymus, brain, and lymph nodes was connected to an indirect response model of the lymphocyte system to characterize the cell trafficking effects. Permeability was obtained after fitting *in vivo* tissue data in rats. The IC50 of FTY720 was estimated from monkeys; man was assumed to be similar to monkeys. To make predictions of the pharmacodynamic behavior for man, systemic exposure was obtained from a physiology-based model, and an estimate of lymphocyte turnover in man was obtained from preclinical species using allometric scaling. Predictions compared well with clinical results.

2.3.3 PBPK Applied for Clinical Candidate Selection

In contrast to empirical techniques, an approach based upon a mechanistic framework can lead to greater insights into the behavior of compounds and offers more potential in the early stages of drug development because it does not require animal *in vivo* data in several species as is needed for allometric scaling. Therefore, PBPK has a great potential to assist clinical candidate selection where numerous factors need to be considered and data related to the pharmacokinetics and pharmacodynamics of the compounds need to be combined and compared in a rational way.

An example showing the utility of such an approach was provided recently (Parrott *et al*., 2005). In this example, *in vitro* and *in vivo* data for five potential clinical candidates were combined in PK/PD models to estimate the effective human doses and associated exposures and aid in the selection of the most promising compound. To ensure that the decision was based upon significant differences between the compounds, estimates of variability and/or uncertainty were carried out in the modeling of the PK and PD. The five compounds were from the same structural class and showed similar physicochemical properties. Molecular weights were in the range 406–472 and all compounds were largely unionized at physiological pH. Log *P* values ranged from 2.1 to 2.9 and permeability was good for all compounds whereas solubility ranged from 2.2 to 0.009 mg ml^{-1}. *In vitro* receptor binding and plasma protein binding data in rats and humans and *in vivo* pharmacokinetic and pharmacodynamic data in rats were also available for all compounds.

In the first step, the scaling of intrinsic clearances determined in rat hepatocytes was compared to *in vivo* clearance. When taking account of non-linearity the estimated hepatic metabolic clearance values were in reasonable agreement with observed total clearances, which ranged from 7 to 35 ml min^{-1} kg^{-1}, and it was considered reasonable to estimate the expected clearances in humans by similar scaling of human hepatocyte data. The error around the mean predicted human clearance was based on the variability seen in different batches of human hepatocytes.

Tissue-composition-based prediction of volume on the basis of lipophilicity and plasma protein binding showed an average fold-error of 2.2 and the correlation of predicted versus observed volume for the five compounds was poor. For the prediction of volume of distribution, it was assumed that the volume in 1 kg^{-1} in humans was the same as the observed volume in the rat (ranging from 0.9 to 2.8 l kg^{-1} for the five compounds). Due to the uncertainty in the prediction of volume the error range associated with this parameter was set as a uniform distribution over a twofold range.

The effect versus plasma concentration relationship in the rat pharmacodynamic data was shown to be a direct one and was well described by a simple E_{max} model. Based on preclinical models for efficacy, a 90% effect was considered as the target for therapeutic effect. The effect versus plasma concentration relationship in the rat pharmacodynamic data was shown to be a direct one and was well described by a simple E_{max} model. A 90% effect was considered as the target for therapeutic effect. Finally, the human C90 (human concentration corresponding to 90% effect) was estimated by accounting for the different affinities of each compound for the rat and human receptors and also for the different free fraction unbound in rat and humans.

$$\text{Thus, C90\_man} = \text{C90\_rat}(\text{Ki\_man}/K\text{i\_rat}) \times (\text{fu\_rat}/fu\text{\_man}) \quad (5)$$

Finally, absorption in the rat was shown to be well predicted by GastroPlus™ because good agreement was seen between simulated and observed oral profiles, and so the predicted human pharmacokinetics and pharmacodynamics were combined in a GastroPlus™ model of humans to allow for estimation of the effective steady-state doses and

exposures after repeated oral dosing. Incorporation of variability and uncertainty was achieved using some stochastic simulations. The predicted effective doses and associated exposures including error ranges on the predictions were then provided for the various potential clinical candidates (see Figure 7).

This example showed that the PBPK approach assists a sound decision on the selection of the optimal molecule to be progressed by integrating the available information and focusing the attention onto the expected properties in humans. Importantly, the method is also able to include estimates of variability and uncertainty in the predictions.

2.3.4 PBPK to Prioritize Compounds Prior to In Vivo Experiments

Drug discovery is increasingly "data rich" with high-throughput chemistry generating numerous compounds that are rapidly screened for pharmacological and pharmacokinetic properties. Determination of *in vivo* PK is considerably more costly than *in vitro* screening, and so there is interest in optimizing resources by using simulation to prioritize compounds. However, acceptance of this approach requires extensive validation. The practical value of generic physiologically based models of pharmacokinetics at the early stage of drug discovery was evaluated (Germani *et al*., 2005; Parrott *et al*., 2005). In the study reported below, the validation was carried out with rat data but the ultimate aim is to run these predictions in man.

In the study by Parrott and coworkers, a generic PBPK model was applied to predict plasma profiles after intravenous and oral dosing to the rat for a set of 68 compounds from six different chemical classes. The compounds were selected without particular bias and so are considered representative of current discovery compounds. The physicochemical properties of the compounds are rather different from those of marketed compounds; in particular, they have high lipophilicity (mean log *P* of 4) and low aqueous solubility as well as a tendency to neutrality at physiological pH. The more extreme property values can present measurement difficulties, and so for consistency, all predictions were made on the basis of calculated lipophilicity and protein binding whereas *in vitro* measurements of intrinsic clearance in hepatocytes, ionization, solubility, and permeability were used for all compounds.

In the first stage, distribution was predicted with tissue-composition-based equations and the estimated tissue partition coefficients were combined with clearance estimated by direct scaling of hepatocyte intrinsic clearance in a PBPK model as described earlier.

In the second stage, GastroPlus™ was used to simulate oral absorption and oral profiles were produced by feeding this predicted input into a compartmental disposition model fitted to the mean observed IV data.

For IV dosing simulations, 60% of the clearance and volume predictions were within twofold of the observed values and the ranking of compounds by predicted versus observed parameters showed correlation coefficients of 0.8 and 0.6 for clearance and volume, respectively. For oral dosing simulations, 40% of the predicted AUC values were within twofold of observed values and the mean fold-error was 4.1. For compounds with measured solubility less than 0.012 mg ml^{-1} only 10% of predictions were within twofold whereas for compounds with higher solubility 70% were within twofold (Parrott *et al*., 2005) (see Figure 8).

Overall, this study indicated that generic simulation of pharmacokinetics at the lead optimization stage could be useful to predict differences in pharmacokinetic parameters of threefold or more based upon minimal measured input data. Fine discrimination of pharmacokinetics (less than twofold) should not be expected due to the uncertainty in the input data at the early stages. It is also apparent that verification of simulations with *in vivo* data for a few compounds of each new compound class was required to allow an assessment of the error in

prediction and to identify invalid model assumptions.

The value of PBPK for simulating the First-Time-In-Animal Study was also illustrated previously (Germani *et al.*, 2005). In this study, the model was used to predict the plasma pharmacokinetics obtained in 24 rat and two mouse pharmacokinetic studies. This study was restricted to the prediction of disposition profiles (i.e., profiles observed after intravenous administration of the compounds). The administered compounds were synthesized as part of a number of different discovery programs. The simulated profiles were generally in agreement with the observed ones. Plasma clearance and mean residence times were well predicted: average fold errors were 2.7 and 2.5, respectively, with approximately one half of the cases predicted within a twofold of observed. Some overprediction of plasma clearance was observed in the range of low clearance values, in case of compounds with $\log P = 5$ and protein binding of 99. On the other hand, slight underestimations were observed for molecules with $\log P$ near zero and protein binding of 99.9%. The error in the volume of distribution at steady state (V_{ss}) was higher, but still acceptable (average fold error was 3.7).

2.4 Discussion

For extrapolation of human pharmacokinetics, physiologically based models show improved prediction accuracy over more empirical methods. The PBPK approach is based upon solid physiological principles and can be extended to include additional relevant processes. Also, besides satisfactory prediction capabilities, an approach based upon a mechanistic framework can lead to greater insights into the behavior of compounds and offers more potential in the early stages of drug development because it does not require animal *in vivo* data in several species as is needed for allometric scaling.

When applied at the clinical candidate selection phase the PBPK approach assists a sound decision on the optimal molecule to be progressed by integrating the available information and focusing the attention onto the expected properties in humans. Early prediction is essential to assess the safety of a novel drug target or of novel compounds. Importantly, the method is also able to include estimates of variability and uncertainty in the predictions, which should be considered as an important piece of information for decision making.

The results on the use of generic simulation prior to *in vivo* studies indicate that some caution is required because certain chemical classes were poorly predicted, and it is recommended that generic PBPK models should only be applied for prioritization after verification of the simulations with *in vivo* pharmacokinetics for a few compounds of a given chemical class. Such verification will help to identify invalid model assumptions or missing processes where additional data are needed. In addition, for poorly soluble compounds, the use of aqueous solubility is shown to be inadequate for reliable prediction of oral absorption in physiologically based models.

Important limitations of the generic PBPK approach are realized for compounds that have significant active distribution/absorption processes, where biliary elimination is a major component of the elimination process or where the assumptions of flow-limited distribution and well-mixed compartments are not valid and permeability-limited distribution is apparent. These drawbacks could be addressed by the addition of permeability barriers for some tissues and by the incorporation of a more complex liver model that addresses active uptake into the liver, active efflux into the bile, biliary elimination, and enterohepatic recirculation. However, this will require the availability of appropriate input data for quantification of the various processes involved as well as validation of the corresponding

in vitro to *in vivo* scaling approaches. Finally, the physiologically based methods illustrated in the chapter are used for prediction of small molecules, whereas the prediction of biologics and antibodies is still based on empirical allometric scaling.

Overall, these three examples illustrate how PBPK models can already add value at various stages of the preclinical compound research and development process, although one has to keep in mind a number of limitations. Their use is growing and the potential will be fully exploited as powerful and user-friendly software continues to make these models accessible to non-specialists.

3 MULTISCALE MECHANISTIC MODELS OF CARDIAC ELECTROPHYSIOLOGY FOR ASSESSING QT PROLONGATION AND PROARRHYTHMIC RISK IN DRUG DEVELOPMENT

3.1 Introduction

Over the past decade, drug-induced prolongation of the QT interval in the clinical electrocardiogram has become a major regulatory and commercial concern in drug development as the costs associated with late-stage failures, market withdrawals, and patient liabilities have spiralled upwards. The danger of proarrhythmia accompanying QT prolongation (Figure 1a), in particular the appearance of a ventricular arrhythmia known as torsades de pointes (TdP, Figure 1b), impacts all therapeutic drug classes (Haverkamp *et al*., 2000). In fact, QT concerns are the frequent cause of clinical holds, NDA withdrawals, delays in approval, and restricted labeling (Malik and Camm, 2001). Although QT prolongation was a well known and, for many years, a desired property of antiarrhythmic therapeutics, it was not well appreciated as a dangerous side effect until associated with terfenadine, a non-sedating antihistamine in widespread use. The molecular target mediating terfenadine's QT prolonging effect was identified as the delayed rectifier potassium current I_{Kr} encoded by hERG (human ether-a-go-go related gene) (Roy, Dumaine and Brown, 1996) whose inhibition delays cellular repolarization and induces ectopic early afterdepolarizations. Further cementing this connection between I_{Kr} or hERG blockers and QT prolongation was the finding that fexofenadine (the active metabolite of terfenadine) was devoid of hERG inhibitory activity and also lacked QT prolonging effect clinically (Scherer *et al*., 2002). The result was the initiation of an ongoing tidal wave of research, regulatory concern, and scrutiny over the drug development approach to QT prolongation and how to detect it as early and reliably as possible.

Although generally correlative, the relationship between hERG inhibition, QT prolongation, and incidence of TdP is far from perfect, with a considerable number of false positives (hERG inhibition without TdP) and false negatives (TdP with weak or no hERG inhibition) (Redfern *et al*., 2003). Although a variety of preclinical experimental models are available for assessing the potential of a drug candidate to prolong the QT interval, they are not true surrogates for the human heart. None of the preclinical models (*in vitro* or *in vivo*) have been proven to be fully predictive for QT prolongation and, more importantly, for assessing proarrhythmia and TdP risk (Hammond *et al*., 2001). As a reaction, much work has been invested into computational, simulation, and experimental methods for anticipating QT and proarrhythmic toxicity, thereby allowing drug development programs to mitigate or manage the liability (Sanguinetti and Mitcheson, 2005). Perhaps, not surprisingly, most of the experimental models perform best when comparing compounds within a chemical and/or target class (Cavero, Lux and Steinhoff, 2007), but suffer when comparing across classes. To advance the comparison, Polak, Wisniowska and Brandys (2009) undertook a large-scale curation and meta-analysis of hERG inhibition data. Although this surely helps develop computational chemistry methods and guide teams in reducing the liability, these compounds are not necessarily QT prolonging or torsadogenic. Thus, the continued focus on hERG may miss the overall goal of reducing proarrhythmic risk in development. Correlations of QT prolongation with behavior in the rabbit heart clearly provide value; however, they do not elucidate true torsadogenic risk or provide a mechanistic basis for any effect observed (Dumotier *et al*., 2008).

Current safety assessments of drugs only involve repolarization assays of normal tissue rather than proarrhythmic animal models that challenge current perceptions of appropriate surrogates for TdP in man and call into question existing strategies for preclinical risk assessment (Thomsen *et al*., 2006). Regulatory agencies and thus sponsors are hesitant

to embrace such models until clear understanding and agreement on the key proarrhythmia mechanisms emerge (Lawrence *et al*., 2008). In contrast to *in vitro* and *in vivo* models of cardiac electrophysiology, mathematical system models explicitly describe the underlying biophysical processes that are responsible for the genesis of the cardiac action potential. As such, they can be used for two important purposes: to integrate lower-level data to project higher-level possible observations not yet measured, and to help interpret and reconcile differences in outcomes or observations across multiple systems.

In silico models are created from and validated by reference data from many of the same experimental paradigms they seek to replicate. These *in silico* models can be used to investigate repolarization and QT issues from the scale of a single-ion channel up to the whole heart (for a historical perspective, see Noble, 2001). Importantly, *in silico* model hypotheses can be tested in the setting of various simulated electrophysiological backgrounds and clinical scenarios (e.g., gene mutations in ion channels). Certainly, the mechanistic association between preclinical data and the clinical environment is not entirely clear. However, because the goal of preclinical cardiac safety screening is to identify a signal for QT prolongation and determine the risk associated with that signal, it is important to examine how the novel technique of *in silico* modeling can be used to efficiently accomplish this aim. *In silico* modeling relates quantitative ion channel data to possible clinical outcomes, fills experimental parameter space, integrates across species, highlights study design issues, and explores the impact of risk factors. Indeed, *in silico* modeling in combination with *in vitro* and *in vivo* experimentation appears to be a compelling approach to assessing QT prolongation and proarrhythmia risk at the preclinical stage.

3.2 Review of Cellular and Tissue Models of Cardiac Electrophysiology

Systems models of cardiac electrophysiology can be categorized into those at the cellular level and those at the tissue or organ level. Cellular models describe the electric activity of a single cell using the mathematics of ordinary differential equations that relate the transmembrane potential difference and the function of different ion channels, exchangers, and pumps both on the cell surface and within the cell. These models describe the movement of ions between the cytoplasm and extracellular fluid through ligand or voltage-gated channels (e.g., potassium flux through the I_{Kr} channel), and also between various intracellular compartments (e.g., calcium release from sarcoplasmic reticulum). Importantly, novel voltage-clamp and current-clamp experiments have been used to extract required parameters for describing the mathematics of a particular ion current. In this manner, an integrated *in silico* model of the cardiac cell is assembled from individual "parts" (e.g., ion currents) that are developed with and validated by quantitative experimental data.

Such models, first introduced in the seminal work of Hodgkin and Huxley (1952) to describe the action potential in the giant squid axon, were subsequently adapted to describe the action potential in a cardiac Purkinje fiber (Noble, 1962) and in cardiac ventricular myocardium (Beeler and Reuter, 1977). With further accumulation of experimental data, a growing body of ever-improving cellular models has been created for different types of tissues (ventricular, atrial, sinoatrial node or Purkinje fiber) as well as species (mouse, rabbit, dog, pig, man). In the modern era, the Luo–Rudy model for the mammalian ventricular myocyte (Luo and Rudy, 1991, 1994) and its progeny (Zeng *et al*., 1995; Shaw and Rudy, 1997; Viswanathan, Shaw and Rudy, 1999; Faber and Rudy, 2000) have played a central role in the field. We also recognize the human ventricular cell models developed by ten Tusscher *et al*. (2004) for faithfully implementing heterogeneity for epicardial, mid-myocardial, and endocardial cell types using detailed data from these regions (Figure 9d).

Tissue and whole-heart models describe mathematically the passive diffusion of electrotonic current in tissue composed of (at least partially) excitable cells and, together with the dynamic model of cellular action potential, they belong to the well-studied class of reaction–diffusion systems. These models are broadly categorized as monodomain or bidomain depending on the representation of the intracellular and extracellular spaces. Monodomain models homogenize the two spaces into a single one and only describe the transmembrane potential propagation, whereas bidomain models separately describe the electric potential inside and outside the cells (the transmembrane potential being the difference of these two potentials). Bidomain models are significantly more computationally demanding

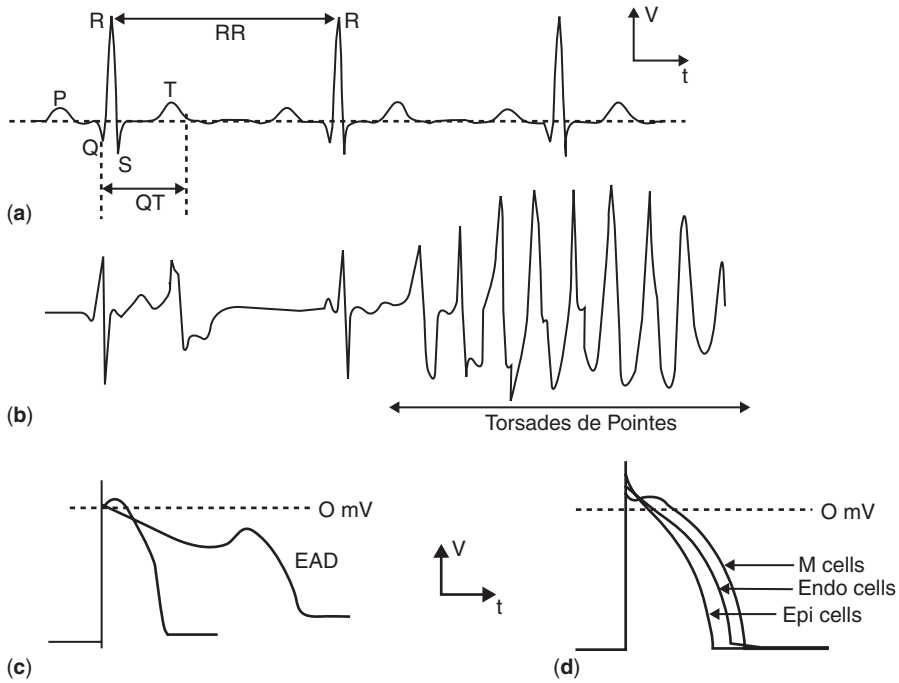

Figure 9. (a) Standard ECG with PQRST complex and QT, RR interval; (b) Torsades de pointes (TdP) event; (c) standard action potential (AP) and action potential presenting an early-after depolarization event (EAD); (d) transmural dispersion of repolarization (TDR) between the endocardial, epicardial, and M ventricular cardiac cells.

versus monodomain ones, but allow for an explicit description of the extracellular potential that electrodes would record and of therapies involving the delivery of an extracellular shock (defibrillation, pacing) (Henriquez, 1993; Potse *et al*., 2006; Trayanova, 2006; Vigmond *et al*., 2009).

Computational speed is highly dependent upon the spatial dimensions of the models, and many techniques exist for increasing the efficiency of more complex calculations (e.g., adaptive spatiotemporal discretization, active region tracking). One-dimensional (1D) models, commonly referred to as "cable models" – because they describe cells oriented in one linear dimension – are computationally efficient models but sacrifice physiological realism, with the exception of models for Purkinje fibers, which are geometrically well-approximated with a 1D structure. Conversely, three-dimensional (3D) models can be geometrically and physiologically very realistic but extraordinarily demanding in terms of computational power (Vigmond *et al*., 2009). Rather than an "arms race" to employ the most complex model, the specific questions being addressed, along with a consideration of the computational power available, should guide the most appropriate model to be used. To address this, Clayton and Panfilov (2008) have provided an excellent guide for building heart tissue models.

For deeper background, several comprehensive book reviews on cardiac electrophysiology are available, including the encyclopedic collection edited by Zipes (2004), Braunwald's classic Heart Disease (Libby *et al*., 2008), and the textbook by Jalife *et al*. (1999) all of which link cardiac function from the subcellular level up to the clinical setting. For specific guidance on the mathematics of cardiac electrophysiological systems and model building considerations, there are reference textbooks on general (Malmivuo, 1995; Gulrajani, 1998; Plonsey, 2007) and cardiac specific (Sachse, 2004; Pullan, Cheng and Buist, 2005; Sundnes *et al*., 2006) bioelectricity and bioelectromagnetism. In addition to providing a historical overview of the development of cardiac electrophysiology models and summaries of heart anatomy and function, these books provide in-depth mathematical formulations and computational techniques that can be employed to model different cardiac time and length scales critical to

describe different cardiac functions. Finally, outstanding journal reviews may provide historical progression and state-of-the-art information on cardiac modeling techniques, as linked to advances in understanding cardiac electrophysiology (Noble, 2001; Muzikant and Penland, 2002; Hunter and Borg, 2003; Belik, Usyk and McCulloch, 2004; Kleber and Rudy, 2004; Holden *et al*., 2006; Rudy and Silva, 2006; Benson *et al*., 2008; Clayton and Panfilov, 2008; Noble, 2008).

3.3 Case Studies

Modeling efforts related to QT prolongation risk have focused on several areas. To be useful, the system models must replicate important markers *in vitro* such as action potential duration (APD), transmural dispersion of repolarization (TDR), early afterdepolarizations (EADs, Figure 9c) and triangulation, reverse use dependence, and instability (TRIaD) advanced by the preclinical models on which they are based. To be accurate, they must incorporate sufficient complexity necessary to describe the phenomena of interest. In broad classifications, one focus has examined the electrophysiologic heterogeneity across the wall of the ventricle to analyze the hypothesis that QT prolongation without an accompanying increase in transmural dispersion of repolarization is not arrhythmogenic. A second focus has elucidated how specific long QT (LQT) syndrome genetic mutations in single ion channels affect the electrophysiologic behavior of the integrated cell and ultimately the whole organ.

Singleton perturbations such as a mutation or exposure to a pure I_{Kr} blocker do not require the use of systems modeling for understanding effects across scales; however, such models are necessitated by the combination of conditions with others in an intrinsically nonlinear dynamical system. In the following text, we review examples of meaningful systems modeling conducted to understand nonlinear factors in the development of drug-induced repolarization delay and cardiac proarrhythmia.

3.3.1 Harmonizing Conflicting Data by Reverse-Engineering an Unknown Pharmacological Effect

A full characterization of drug concentration profiles versus responses of various electrophysiological markers is often necessary to assess the *in vivo* safety of a drug, given the potential modulation of drug concentration *via* pharmacokinetic processes such as protein binding, drug lipophilicity, or liver enzyme inhibition or induction (e.g., CYP3A4) (Bauman, 2001). Due to time and cost constraints as well as experimental difficulties in running electrophysiology assays, only a limited number of conditions may be investigated during the safety assessment of a new compound. *In vitro* and *in vivo* experiments only allow for a small number of drug concentrations to be tested, leading some to use mathematical system models that adequately replicate the experimentally measured AP profiles to simulate the electrical behavior of myocytes at different, non-tested drug concentrations.

All models of biological systems and processes are described by two characteristics: (a) a "structure" or set of mathematical functions for the governing mechanisms and (b) a certain number of parameters. Only the governing equations and parameter values known together allow a computer simulation of the model to be run in a predictive "forward" mode. Although some of the parameters could be measured directly, others need to be inferred from other experimental data using different parameter estimation and mathematical optimization techniques (reverse engineering) (Mendes and Kell, 1998). As an example, Balser, Roden and Bennett, 1990 used such estimation to determine global parameters for a model of potassium channel function directly from rich sets of data by iteratively using the model to simulate the observed data.

Bottino *et al*. (2006) used a combined forward- and reverse-engineering approach to reconcile the inhibition of hERG channel (IC_{50}-values in micromolar range) with the lack of prolongation of AP duration recorded from canine Purkinje fibers (PF) with two compounds. First, a computational model of canine PF was adapted from a published model of the canine ventricular myocyte (Greenstein and Winslow, 2002) using parameter estimation of major ion channels present in both cell types. The parameters estimated were the macroscopic conductances of the 14 ion channels represented in the myocyte model; the data used for the fitting procedure consisted of action potential measurements from samples at multiple pacing rates with either no drug or with different concentrations of the reference compound *dl*-sotalol. The resulting PF

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

model was then used in a forward mode to confirm that model predictions were comparable to independent experimental reference data. Taking the compounds' IC_{50} values on I_{Kr} current as prior information, the authors applied reverse-engineering to derive the remaining ion channel profile for each of the test compounds using experimentally measured action potential traces under different drug concentrations and different pacing frequencies. The fitted parameters were the compounds' IC_{50} values for the cardiac ion currents responsible for repolarization, namely sustained inward sodium current I_{Nasus}, L-type calcium current I_{CaL}, slowly activating delayed outward rectifier potassium current I_{Ks}, transient outward potassium current I_{to1}, and net inward current generated by the calcium/sodium exchanger I_{NaCa}. As proof of principle and a testament to the approach, the estimated IC_{50} values for I_{Nasus} were confirmed in an independent experiment using the patch-clamp technique.

3.3.2 *Role of Multi-Channel Block in Mitigating hERG-Mediated Proarrhythmic Risk*

Preclinical studies (van Opstal *et al*., 2001; Vos *et al*., 2001; Hondeghem and Hoffmann, 2003; Hondeghem *et al*., 2003; Thomsen *et al*., 2006; Hondeghem, 2007) clearly show that despite comparable levels of hERG blockade, the accompanying pharmacology on other cardiac ion channels determines to a great extent the magnitude of the QT prolonging and proarrhythmic effects. Of particular interest discussed here are verapamil, amiodarone, and ranolazine; all of which are marketed compounds with clear hERG inhibition, demonstrating clinical QT prolongation, yet are devoid of significant proarrhythmic risk. The proposed and now accepted hypothesis for this dichotomy centers on these compounds' ability to simultaneously block a number of inward (sodium, calcium) currents while blocking the outward repolarizing (potassium) currents.

Verapamil is a safe, well-known calcium channel blocker with I_{Kr}/hERG blocking capacity that leads to QT prolongation and other ECG changes in the clinic. Given this class III Vaughan Williams effect, many have asked whether verapamil would have been developed and approved in today's climate. Despite its ion channel polypharmacology, verapamil significantly shortened endocardial but not epicardial MAPs, suppressed EADs, reduced ventricular TDR, and ultimately suppressed TdP in a proarrhythmic rabbit ventricle model (Milberg *et al*., 2005). Amiodarone is marketed as an antiarrhythmic drug that blocks sodium, potassium, and calcium ion channels, prolongs the QT interval, yet is only rarely associated with torsade de pointes arrhythmias. Four-week studies in the chronic complete atrioventricular (AV) block (CAVB) dog model of acquired long-QT syndrome clearly showed QT prolongation by both amiodarone (+21%) and its analog dronedarone (+31%). Despite this, amiodarone showed no increase in dispersion of repolarization and did not cause TdP due to its particular balance of blocking both repolarizing (outward) and depolarizing (inward) currents. Highlighting the delicate balance of net repolarization, dronedarone, with a different ion channel blocking profile, increased repolarization dispersion and exhibited ectopic beats and TdP.

Ranolazine is an antianginal agent capable of producing anti-ischemic effects without negative inotropic or hypotensive consequences. However, it does prolong the QT interval, thus raising serious concerns over its long-term safety in cardiovascular patients. *In vitro* studies suggest it is a broad-spectrum ion channel inhibitor that does not trigger any typical risk signals in the nonclinical studies and, in fact, may be ultimately antiarrhythmic (Antzelevitch *et al*., 2004; Schram *et al*., 2004; Wang *et al*., 2008).As additional evidence, the Ranolazine Open Label Experience (ROLE) trial in 746 chronic angina patients treated over 2102 patient-years did not report any TdP- or QT prolongation-related discontinuations, despite having a mean QT interval prolonged by 2.4 ms (Koren, Crager and Sweeney, 2007).

The published ion channel pharmacology for ranolazine (Antzelevitch *et al*., 2004) was applied to *in silico* models of epicardial and midmyocardial cells (Muzikant and Penland, 2002). Findings from these systems models supported the experimental and clinical experience by showing that the action potential was prolonged equivalently in both cell types, leading to no increase in the TDR and therefore no signal for TdP risk. More detailed modeling studies of fast-unbinding sodium channel blockers such as lidocaine, vernakalant, and ranolazine using realistic mathematical models of state-dependent channel block (Hondeghem–Katzung modulated-receptor) have shown how such therapeutics act to terminate vagotonic atrial fibrillation (Comtois *et al*., 2008).

3.3.3 *Role of Gender Differences in Cardiac Proarrhythmic Risk*

The QT interval is well established to be longer in females than in males, and female gender itself is a recognized independent risk factor for development of arrhythmias in the congenital and drug-acquired Long QT syndrome. James, Choisy and Hancox (2007) has summarized a number of drugs having a greater risk of inducing TdP arrhythmia in women than in men. The differences in the ECG between men and women, and in particular those relating to the QT interval, have been explored experimentally and provide evidence of differences in the processes underlying ventricular repolarization (James, Choisy and Hancox, 2007).

A number of investigators have observed small but important differences in the relative strength of cardiac repolarization currents between males and females. In a range of *in vitro* and *in vivo* animal studies by multiple investigators, the application of testosterone at physiological levels either in females or in previously castrated males repeatedly demonstrated augmentation of expression of K^+-channel proteins, reduced the QT interval (where applicable), mitigated the sensitivity to class III agents, and thus protected against arrhythmias *via* increasing net repolarization current (Drici *et al*., 1996; Shuba *et al*., 2001; Fulop *et al*., 2006; Furukawa and Kurokawa, 2007; Ridley *et al*., 2008). These repolarization-enhancing effects of androgens on the human heart were confirmed by dosing a small cohort of hypogonadic men with testosterone (Charbit *et al*., 2009). Conversely, estrogens do not appear to have any appreciable effect on repolarization. Yet other studies have indicated a significant gender difference not only in the inward (I_{K1}) and slow delayed (I_{Ks}) rectifier cardiac K^+ currents but also in the β-adrenergic regulation of those currents in beagle Purkinje fibers (Abi-Gerges *et al*., 2004, 2006).

Investigators at Physiome Sciences (Muzikant and Penland, 2002) integrated these experimentally determined relative differences in repolarizing currents (Drici *et al*., 1996; Liu *et al*., 1998; Liu *et al*., 1999) to create male and female phenotypic responses in their cellular models. In these two gender models, class III agents clearly induced more profound action potential delay in females at lower concentrations. With the latest male and female gender differences in ion channel expression and function, systems models can be used to easily explore possible gender-specific effects of compounds under study. As a final note on the topic, the literature indicates that overall hormonal state – not just adult male or female – is important and thus toxicology should give consideration to patients in categories such as geriatric, menopausal, hormone replacement therapy, (pre)pubescence, or even androgen (mis)use.

3.4 Incorporating Effects of Inherited Cardiac Ion Channel Mutations

A major limitation of the Hodgkin-Huxley formulation used in the previous modeling studies is that it simulates only the macroscopic (i.e. whole cell) currents generated by a large ensemble of individual ion channels. With a growing cohort of experimental evidence characterizing the relationship between ion channel structure and function and the presence of genetic mutations associated with the long QT syndrome, Brugada syndrome, and other inherited arrhythmias (Abriel *et al*., 2001; Keating and Sanguinetti, 2001; Lehnart *et al*., 2007), more sophisticated mathematical representations of individual channel behavior have been developed to investigate how single-channel modifications can modulate electrophysiologic function at whole-cell, and ultimately whole-organ, levels. These models, often Markov by nature, describe the kinetics of individual channel states (i.e., open, closed, inactivated, and subtypes thereof) through experimentally derived probabilities and rate constants. Importantly, they allow for the effect of structural flaws in mutated channels on the gating, ionic selectivity, or conductance properties.

In one well-documented example, Clancy and Rudy developed a Markovian representation for both wild-type and mutant I_{Kr}, and included this channel into whole-cell models (epicardial and M) to study potential proarrhythmia under long QT syndrome (type 2) conditions (Clancy and Rudy, 2001). They showed that a macroscopic effect on the action potential for each of three point mutations in I_{Kr} is highly dependent on the specific mutational effect (i.e., shift in activation, deactivation, or loss of inactivation), and that these effects were more pronounced in M-cells than in epicardium. Detailed models have also been constructed for mutations in the voltage-dependent sodium channel (DeltaKPQ) (Nagatomo, January and Makielski, 2000; Clancy, Zhu and Rudy, 2007), 1795insD (Clancy and Rudy,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2002), D1790G (Abriel *et al*., 2000) and E1295K (Abriel *et al*., 2001). Beyond characterizing the functional consequences of the mutation itself, these studies have also examined the differential effects of the mutation on the channel blockade by known sodium channel antagonists such as flecainide, pilsicainide, mexiletine, and lidocaine (Ono *et al*., 2000; Clancy *et al*., 2007).

To summarize as shown in Figure 10, the systems modeling approach directly represents molecular mechanisms in the context of a higher-order network and therefore is a powerful tool to incorporate the pharmacogenetics and epigenetics of inherited cardiac dysfunction into early proarrhythmic risk assessment for new compounds.

3.5 Discussion and Additional Considerations

In this chapter, we reviewed the application of multiscalar cardiac system models to the anticipation and management of QT prolongation in the clinical electrocardiogram and proarrhythmic risk attending new therapeutic compounds. With a host of unanswered questions, it is natural for investigators using such models to seek to expand the scope, richness, robustness, and complexity as necessary to meet new challenges in the field. To this end, we discuss several promising and tractable extensions that could have considerable impact in the successful industrial application of such models.

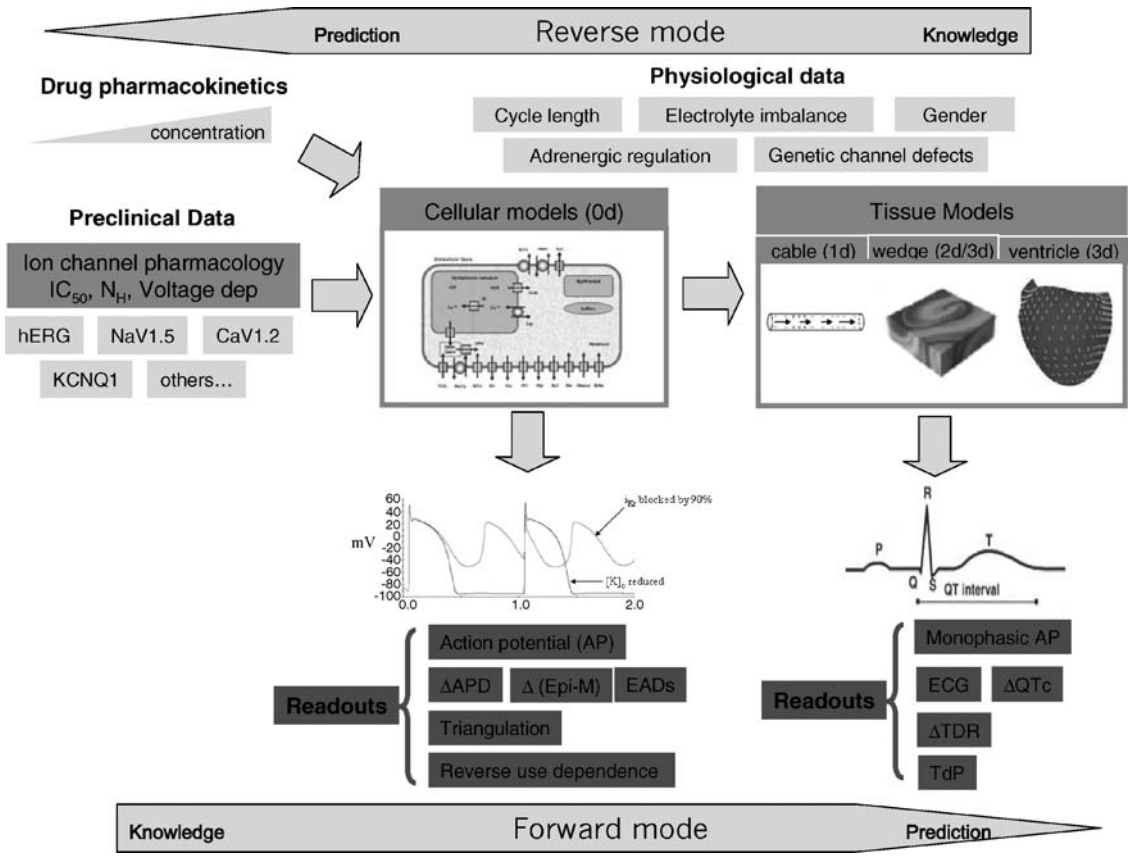

Figure 10. Systems modeling of mechanistic electrophysiological effects in the prediction of cardiac QT prolongation and proarrhythmic toxicity. Direct pharmacological effects on major ion channels are simulated in cardiac cellular models, which are embedded into biophysical models of the heart. Such models produce multiple readouts that are relevant to risk prediction and benchmarking to the analogous experimental system. A range of physiological conditions can be superimposed on the nominal system to explore risk-modifying combinations.

3.5.1 Drug-Channel-Signaling

Historically, models of drug effect on ion channel function have taken the form of a concentration-dependent reduction in available current. In some cases, investigators have had both the motivation and the available data to delve deeper by implementing state-dependent models of drug–channel interaction. Furthermore, it has been clear for some time that relatively few compounds identified as ion channel blockers are in fact pharmacologically restricted to ion channels. Sotalol is a classic example as it is a racemic mixture of enantiomers with β-receptor antagonism but with only the dextro enantiomer having a strong I_{Kr} inhibition. The combined effect on the cardiac action potential cannot be discerned except by implementing a combined model of both mechanisms like that proposed by Levin *et al*. (2002).

It is critical that we remain vigilant for new mechanisms requiring updating of our primary models. Illustrating this clearly are the endogenous (Bai *et al*., 2007) and synthetic (Koyrakh *et al*., 2005) compounds in the sphingophospholipid class that have been shown to have macroscopic electrophysiological effects (reduction in HR) underpinned by newly discovered interaction with important cardiac repolarization channels. Studies showing altered glycosylation and phosphorylation of sodium channel leading to arrhythmia in heart failure (Ufret-Vincenty *et al*., 2001) and those showing the electrophysiological consequences of long-term ionic, pH, and metabolic changes secondary to myocardial ischemia (Cascio, Johnson and Gettes, 1995) also highlight the need to begin incorporating such mechanisms into the cardiac systems models of today.

3.5.2 Intrinsic Variability, "Populations"

The critical question being asked in the assessment of compounds' propensity for QT prolongation and torsadogenesis in the clinic is essentially one of predicting the incidence of rare clinical events given certain typical response data accumulated through preclinical safety pharmacology (Morganroth *et al*., 1993; Fenichel *et al*., 2004). In our opinion, one of the most exciting horizons for systems modeling of cardiac electrophysiology is the growing capacity to include intrinsic biological variability explicitly. The statistical mixture model construct (Rosner and Muller, 1997), already used extensively in clinical pharmacokinetic–pharmacodynamic modeling, is a natural approach to adopt in the systems toxicology models proposed here. The evolution from "mean response" systems models to models that embrace and explicitly represent (*via* stochastics and/or parameter populations, covariates) the underlying biological, physiological, and temporal variation provides the opportunity for a single modeling framework to explain the median response while also capturing the rare combinations that produce toxicological side-effects.

3.5.3 Trafficking and Other Indirect Effects

New evidence has emerged indicating that select but growing number of compounds alter ion channel (hERG in particular, but also others) trafficking and maturation, thus altering the electrophysiological makeup of the cells over a longer term than is typically assessed during *in vitro* screening (Drolet, Simard and Roden, 2004; Wible *et al*., 2005; van der Heyden, Smits and Vos, 2008). In some cases, these same compounds lead to the appearance of QT prolongation disjoint from time of maximum concentration, making management of this risk and assessment difficult. The nature of this emerging trend in compounds with trafficking effects is unclear; perhaps it is a previously intractable mechanism now possible to study or a reflection of new chemical, biopharmaceutical, and target classes in the pharmacopeia. Regardless of the reason, accounting for such effects will require the development and incorporation of new mechanistic understanding and modeling from gene regulation to protein trafficking within the already dynamical cardiac myocyte.

3.5.4 Pharmacokinetics, Getting the In Vivo Behavior Right

The *in vivo* concentration of a novel therapeutic does not remain constant in cardiac tissue over time and thus presents a challenge in using *in vitro* data and systems models to project a compound's clinical characteristics. Point estimates of concentration response using well-known exposures are useful for ranking compounds early on; however, the ultimate toxicological profile and clinical utility are intrinsically tied to the pharmacokinetics of the candidate. The medical literature contains several reports of compounds that are mild ion channel blockers, but are also substrates of particular cytochrome P450 enzymes. The resulting "reality" of risk is that mild

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

hERG I_{Kr} inhibition can amplify manyfold by the co-administration of metabolic blockers of the clearance enzyme in question. Such examples justify research into the union of cardiac mechanistic models with a physiologically based pharmacokinetic model to jointly estimate the human exposure and response in QT or risk of proarrythmia.

4 MECHANISTIC MODELS OF BONE MARROW TOXICITY FOR ASSESSING NEUTROPENIA RISK IN DRUG DEVELOPMENT

4.1 Introduction

Combing pharmacokinetic models with mathematical models that describe whole-animal toxicity observed in *in vitro* and *in vivo* systems to simulate or predict the potential response in humans allows us to better design first-in-man studies, ultimately leading to safer and faster development of new molecular entities.

The systematic use of mathematical approaches is required as the high degree of non-linearity in concentration- and toxicodynamic-time profiles far exceed our ability to anticipate the events which may occur in humans based on empirical correlations alone.

4.2 Example for Small Molecules: Neutropenia Model

Neutropenia represents one of the major limitations during chemotherapy treatment. Consequently, considerable efforts have been undertaken to describe the adverse response – exposure relationship (Egorin *et al*., 1986; Hantel *et al*., 1990; Huizing *et al*., 1993). The single measures of exposure (e.g., dose and AUC) have often been used to explain the observed toxicity (e.g., nadir, grade, etc.), but are limited because they do not take the time-dependent nature of the repose into account, resulting in high levels of variability.

Optimization of drug regimens typically requires extensive clinical trials where a compromise between dose, dosing interval, and safety is sought. As an example, several years of clinical development are needed to find tolerable and efficacious schedules for Taxotere. Taxotere administered once every 3 weeks at the dose of 100 mg m^{-2} gives 70% of grade 4 neutropenia. The median time to onset is day 7, the median duration is 7 days, and the median time to recovery to grade 0 is day 14. This accounts for the need to collect blood samples on days 7 and 14 for every cancer patient receiving this drug following this schedule. The weekly schedule (35 mg m^{-2}) is very safe. At the recommended dose, grade 4 neutropenia is the exception. Blood samples are rarely requested, which is very convenient for cancer patients.

The fine interplay between dosing, drug holiday duration, and timepoints to monitor patients is often the result of empirical and costly clinical research. In the following, we illustrate how semi-mechanistic pharmacokinetic and toxicodynamic modeling can be used to design an animal study that can be used to predict toxicity in clinical trials and design optimal protocols.

4.2.1 Physiology of the Myelopoietic System

Stem cells in the bone marrow with high proliferative capacity are susceptible to chemotherapeutic drugs (Friberg *et al*., 2000; Segura *et al*., 2004). These pluripotent stem cells are at the bottom of the granulopoiesis process for the staged maturation and differentiation to a final cell type, the most prominent being the circulating neutrophils. This transition time in rodents and humans ranges from 3 to 6 days. Circulating blood neutrophils extravasate in peripheral tissue where they undergo apoptosis. They disappear from bloodstream with a first-order process.

The system has a remarkable potential to adapt under stress such as infections, growth colony-stimulating factor (G-CSF) being the most important regulator of granulopoiesis (Friberg and Karlsson, 2003). G-CSF stimulates cell division in the bone marrow. Circulating levels of G-CSF and the peripheral neutrophil count are inversely correlated, implying that mature neutrophils modulate one of the major pathways of G-CSF clearance. This creates a homeostatic mechanism maintaining the level of circulating neutrophils at equilibrium.

In a very schematic way suitable for modeling, one could envision that a chemotherapeutic drug action decreases the stem cell compartment at first with no effect on the circulating cells. The effects on the circulating cells are delayed by the maturation time and are compensated by the feedback loop mediated by G-CSF, which in turn is designed for

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

normalizing circulating neutrophils by promoting proliferation in the pluripotent stem cell compartment. With a certain delay due to maturation, the circulating neutrophils pool will be equilibrated.

Different drugs appear to have a different effect on circulating neutrophils as a result of a number of factors: the PK variability in patients, different sampling times used, and the different antiproliferative effect on the cycling stem cells. When these differences are considered independently, it is possible to separate systems effects (PK, physiology of maturation) from drug effects and build predictive models across species.

4.2.2 *Modeling Approaches: Empirical Versus Semi-Mechanistic Models*

Various modeling approaches have tried to characterize the effect of chemotherapeutics on the myelopoietic system employing different strategies, e.g., correlating drug exposure (Egorin *et al*., 1986) or threshold concentration (Hantel *et al*., 1990; Huizing *et al*., 1993) with the nadir of leukopenia or neutropenia. Typically, such models have been shown to be inadequate and lead to paradoxical predictions of the response *in vivo*. For example, models based on exposure would overestimate the danger of low-dose prolonged infusions versus bolus, whereas models based on threshold concentration or dose would overestimate the safety of prolonged infusions. In general, these models suffer from the following limitations: impracticable scalability from rodents to humans, inability to describe the dynamic response, and inability to re-use prior information.

On the other hand, semiphysiological modeling approaches (Friberg *et al*., 2000, 2002; Friberg and Karlsson, 2003; Segura *et al*., 2004) mimicking the physiological system described previously have been shown to have several benefits. First of all, PK–PD model contributions can be studied in parallel: systems response and drug response are separated and their parameters can be estimated independently. As a consequence, drug parameters can be scalable across species. The systems parameters reflect our knowledge on the physiology. Systems parameters are therefore re-usable across several different drugs. This implies that the more the model is used, the more prior information on the systems parameters is accumulated for more accurate predictions. Finally, this modeling approach allows to study combination therapies where multiple drug effects on the system can be evaluated.

Furthermore, semi-mechanistic models have the advantage of describing the entire time course of leukocyte suppression and rebound phenomena. This is important because for example observed peak drug concentrations and effect, a nadir in neutrophil count occur at different times. The parameters estimated reflect the real concentration–response relationship and schedule-dependent effects can be studied. Hence, an integrated PK–PD model further allows for experimental sampling times to be optimized. Typically, measurement in clinics and in pre-clinical experiments are performed once or twice weekly, and therefore the nadir concentrations are often missed and inter-individual variability could be over- or underestimated. The estimation of optimal sampling times can reduce both the number of animals and subjects in the trials and the burden of blood sampling.

Clearly, such a modeling approach would be very helpful to predict the effect of drugs from rodents to humans and to optimize clinical trials of novel molecular entities with the goal of reducing clinical failures, number of patients, and adverse events. The expected benefits of predicting myelosuppression and efficacy in man are multiple. On the one hand, the modeling approach is expected to reduce the number of animal experiments. A combination of optimal experiment design techniques and modeling can both reduce animals per experiment and make the experiments less invasive (e.g., reducing the number of bleeds). On the other hand, the benefit for the clinical development include a shortening of phase I by choosing the right starting dose with respect to safety and efficacy, a faster optimization of "safe" schedules and combination therapies, and the design of individualized treatments, for instance on the basis of the baseline neutrophil count. Finally, healthcare companies and regulators may re-use the modeling across projects and incorporate competitor data when available expanding the model data sets and improving its accuracy.

4.2.3 *Description of Semi-Mechanistic Models*

Recently, a semi-mechanism-based PK–PD model was proposed, which has been applied successfully across compounds (Friberg *et al*., 2002) and species (Karlsson, Friberg and Sandstrom, 2004).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

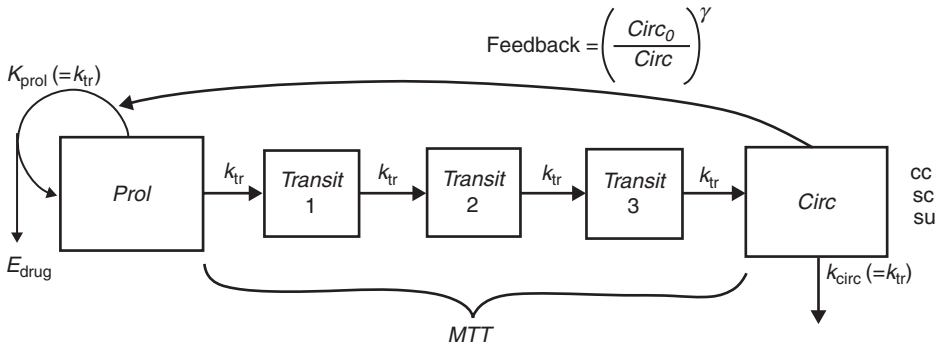

Figure 11. Schematic view of the semi-mechanistic myelotoxicity model. The toxic effect of the drug (Edrug) is exerted on the proliferating compartment of pluripotent stem cells (Prol). The transit compartments (Transit 1, ···, Transit 3) represent the maturation steps to reach the circulating cell compartment. The feedback homestatic mechanism (Feedback) between the circulating compartment and the proliferating pool of cells is also depicted.

This semi-mechanism approach does take the time-dependent nature of cell proliferation into account and allows the myelosuppression to be described in terms of system- and drug-dependent parameters. In the choice of the model, one has to strike a balance between accuracy and complexity. The number of parameters should be low and their interpretation straightforward. Also, the parameter estimation should be tractable. Our preferred model describes the time delay using transit compartments. In contrast to lag-time models, this approach mimics the gradual maturation of cells. Multiple compartments can be added in the delay chain without adding extra parameters because the rate constant between the compartments is the same. The model (Figure 11) consists of five differential equations, one for the proliferating cells in the bone marrow, three to describe the maturation, and one to describe circulating cells.

$$\frac{\mathrm{dProl}}{\mathrm{d}t} = k_{\mathrm{tr}} \cdot \left[\left(1 - E_{\mathrm{drug}}\right) \cdot \left(\frac{\mathrm{Baseline}}{\mathrm{Circ}} \right)^{\gamma} - 1 \right] \cdot \mathrm{Prol} \tag{6}$$

$$\frac{\mathrm{dTransit}_1}{\mathrm{d}t} = k_{\mathrm{tr}} \cdot (\mathrm{Prol} - \mathrm{Transit}_1) \tag{7}$$

$$\frac{\mathrm{dTransit}_i}{\mathrm{d}t} = k_{\mathrm{tr}} \cdot (\mathrm{Transit}_{i-1} - \mathrm{Transit}_i) \quad i = 2, 3 \tag{8}$$

$$\frac{\mathrm{dCirc}}{\mathrm{d}t} = k_{\mathrm{tr}} \cdot (\mathrm{Transit}_3 - \mathrm{Circ}) \tag{9}$$

The drug action is confined to the proliferating compartment where the cell loss term due to the drug action is described using a linear term $E_{\mathrm{drug}} = C_{\mathrm{drug}}$*Potency. The concentration of the free fraction of the drug in plasma C_{drug} is used and the toxicity parameter Potency is estimated for each drug. The parameter k_{tr} represents both the proliferation and maturation kinetics of the system. The feedback mechanism mediated by G-CSF is represented by the term $(\mathrm{Baseline/Circ})^{\gamma}$. The parameter gamma indicates the strength of the feedback response. Interindividual variability is estimated for the parameters k_{tr}, Baseline, and Potency.

In simulations, all the data were estimated using a nonlinear mixed-effects population analysis PK/PD model where data from all subjects were analyzed simultaneously. Lognormal parameter distribution was assumed. The residual error was modeled with an additive and proportional component.

The systems parameters describe time-dependent physiological processes, which are species-specific but drug-independent. Potency, a drug-specific parameter, is assumed to be constant across species. Hence, when a new compound is characterized in a rodent population, the drug-specific parameters are determined.

The same drug parameters are then used together with human system parameter and predicted human PK to predict the myelosuppression in man (Figure 12). The prediction of myelosuppression in man allows for the optimization of candidate selection but also for the optimization of dosing schedules for efficacy in early clinical trials. To date, several

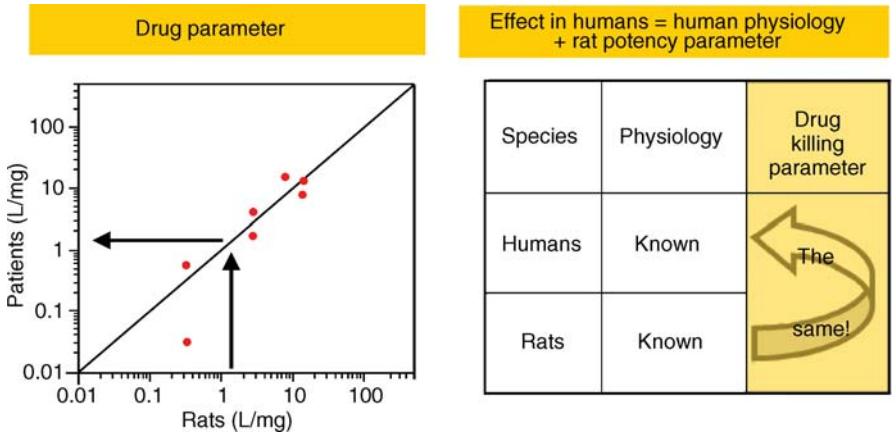

Figure 12. Linear correlation between the drug potency parameter across species. The systems parameters require adaptation when scaling from rodents to humans results to reflect the changes in physiology whereas the drug potency parameter remains the same in a fairly large set of values where most drugs in development or on the market lie.

Roche compounds have been modeled, as well as six compounds from other companies for which clinical and preclinical data are available, which generate a curve that describes the human/rat relationship for the key drug Potency parameter in the model (i.e., kill rate). A log/log plot of this parameter shows an approximate linear relationship that allows prediction of human myelosuppression based on modeling of rat data (Karlsson, Friberg and Sandstrom, 2004). An almost identical Potency parameter between the species has been observed across species, with deviations at the extreme of the range (overestimation if Potency $< 0.3\,\mathrm{l\,mg^{-1}}$; underestimation if Potency $> 12\,\mathrm{l\,mg^{-1}}$).

4.3 An Example in Drug Development

A diaminopyrimidine, which constitutes a new class of cell cycle inhibitors selective for the serine/threonine class of CDK inhibitors undergoing clinical development, has been chosen as case study. Cyclin-dependent kinases (CDKs) play a central role in the control of cell cycle progression. The CDK inhibitor in this study (here referred as CDK-I) has single-digit nM activity against CDK1, CDK2, and CDK4 and is not active against 19 related and unrelated serine/threonine and tyrosine kinases. It has broad-spectrum antiproliferative activity and displays *in vitro* antiproliferative activity across a panel of 14 human tumor cell lines, including a multi-drug-resistant cell line that overexpresses PgP. CDK-I blocks tumor cells in G1+G2 phases of the cell cycle and induces apoptotic cell death in these cells. The compound has been shown to inhibit the phosphorylation of retinoblastoma protein (Rb), a substrate for CDK2 and CDK4 in tumor cells. CDK-I is orally active in 5/5 established tumor models in rodents at or below the maximum tolerated dose (MTD) including an aggressive rat breast tumor model.

CDK-I was developed as an IV administered drug for mono- and combination therapy in a variety of solid tumors. The target product profile requires the adverse events (AEs) to be reversible and manageable. Specifically in monotherapy the AE profiles are required to be comparable or better whereas in combination therapy the AE profiles should allow for the safe combination with other chemotherapeutics.

A placebo-controlled 6-week toxicology study was conducted on healthy rats following once-weekly IV dosing with three doses of 5, 12.5, and $25\,\mathrm{mg\,kg^{-1}}$, three groups per dose (18 rats), and six animals per group bled on day (1, 22, 43) or (4, 25, 43) or (7, 28, 43, 57). The resulting very sparse data set has 4 points per rat for a total of 180 rats. PK data were collected in a satellite group of animals treated intravenously and with oral doses between 5 and $100\,\mathrm{mg\,kg^{-1}}$.

The prediction of myelotoxicity for humans follows the five steps given below:

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat233
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

1. **Analysis of the toxicology study results**
   The analysis of the data from the rat study evidenced two different mechanisms of toxicity for neutrophils and lymphocytes. For neutrophils, a typical delayed suppression has been observed. This effect is compatible with a drug-killing action on the progenitor cells of neutrophils, which becomes evident after the typical maturation time on the circulating neutrophils. The data also show the typical rebound of circulating neutrophils set in place by the feedback mechanism of homeostasis. This dynamic behavior is compatible with the structural model described earlier and can be extrapolated to humans. In the remaining part of this example, we will focus on the prediction of neutropenia but we would also like to emphasize how the modeling can be useful to identify unexpected mechanisms of action as well.
2. **PK in rats**
   PK data have been obtained from oral as well as IV administration of the compound in single doses to cover the range of exposures studied in the toxicology experiment. The plasma concentration–time profiles of CDK-I in Fischer rats could best be described by a three-compartment pharmacokinetic model. Given the limited interindividual variability in the PK of inbred mice, a simple model for the average values was fitted. The current data nonlinearities could not be identified.
3. **Fitting PD model**
   Fitting of myelosuppresion model was performed with NONMEM by linking the PK described above with the semi-mechanistic PD model. The PD model was fitted using reference value as starting point for the physiological systems parameters (e.g., the maturation rate, the feedback loop rebound, and baseline value of circulating cells). The Potency parameter of around $1\,l\,mg^{-1}$ for CDK-I was estimated. This value falls well in between the values reported for other cytotoxic drugs. For other drugs with similar killing potency parameters, the scaling from rodents to humans has been very reliable and this increases the confidence of an accurate prediction for humans.
4. **Prediction of human PK**
   The prediction of PK in humans was performed using a PBPK model with Gastroplus as discussed in Introduction of this chapter. The prediction in humans was based on *in vivo* profiles (IV and PO) at different doses in rats and monkeys. In addition, a set of *in vitro* tests to characterize the physicochemical properties [solubility in simulated fasting and fed intestinal fluids (Fessif, Fassif), $\log P$, $\log D$, permeability] and biochemical properties of the molecule in rats/monkeys/humans (e.g., V_{Max} and K_m for microsomal clearance, protein binding, and blood/plasma ratio) have been carried out. The scaling of PK profiles from rodents to monkeys was tested against real data for the various PO formulations to guarantee the reliability of the PK predictions across species. For humans, the typical variability in PK as seen in phase I oncology trials with patients failing other therapies and at an advanced stage of disease has been used to predict PK. Physiological population parameters and interindividual variability was based on the average parameters of six currently marketed chemotherapeutics. The PK interindividual variability was set to 30% per parameter sampling from normal distribution.
5. **Virtual clinical trials**
   Clinical trial simulations in humans were carried out using the clinical trial simulation software, Trial Simulator (v2.1.2, Pharsight Corporation, Mountain View, CA, USA), and are available upon request. The designs of the studies mentioned below were replicated taking into account the route of administration, the dose, and the number of patients. Each study was replicated 1000 times. The population PK–PD parameters were sampled from a multivariate normal distribution at study level. The individual parameters were based on these new population parameters and a random sample from the distribution characterized by the interindividual variability. On each measurement, a proportional random error was added. Following each replicate, the maximum individual neutropenia grade reached over time was calculated as well as the mean grade per trial using S-PLUS (v6.1; Insightful Corporation, Seattle, WA, USA). The 80% prediction intervals were calculated after simulation of 1000 replicates and represent the 10th and 90th quantiles.

Two scenarios were modeled: the base scenario (IV dose once a week for 2 weeks, 3-week cycle) and the alternative scenario (2 weeks daily dosing, 1 week drug holiday, 3-week cycle) (Figure 13). The baseline value for the occurrence of grade 4

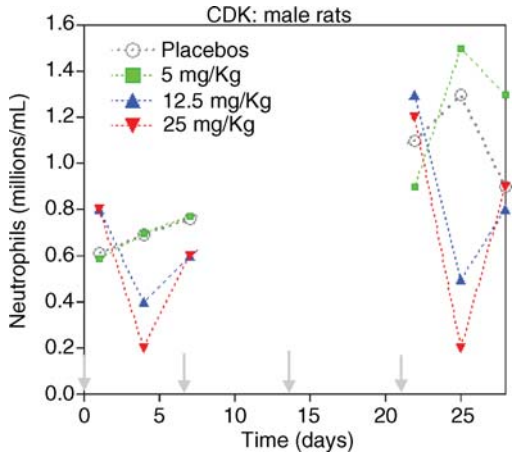

Figure 13. Profiles of circulating lymphocytes and neutrophils after IV administration of CDK-I to Fischer rats. Note the delayed suppression and rebound of neutrophils consistent with the model of Figure 11.

neutropenia in a typical phase I study in oncology is 18% (CI: 0–35%). Based on the assumption that the drug Potency parameter does not vary across species and using the PK predictions in humans, different doses and formulations have been investigated. A significant increase in the incidence of neutropenia grade 4 over baseline is expected to occur at 300 mg m^{-2}, whereas the threshold for efficacy in preclinical models appears to be 200 mg m^{-2} (i.e., average weekly AUC over the 3-week cycle larger than 104 ng h ml^{-1}). In other words, tumor response does not correlate with neutropenia and the drug candidate appears to have a positive therapeutic index.

A regimen where drug is administered either IV or orally continuously for 2 weeks has been investigated (Figure 14). It is expected that the administration of smaller doses will allow the reduction of other acute adverse events. Absorption modeling (GastroPlus) on monkey data (capsules

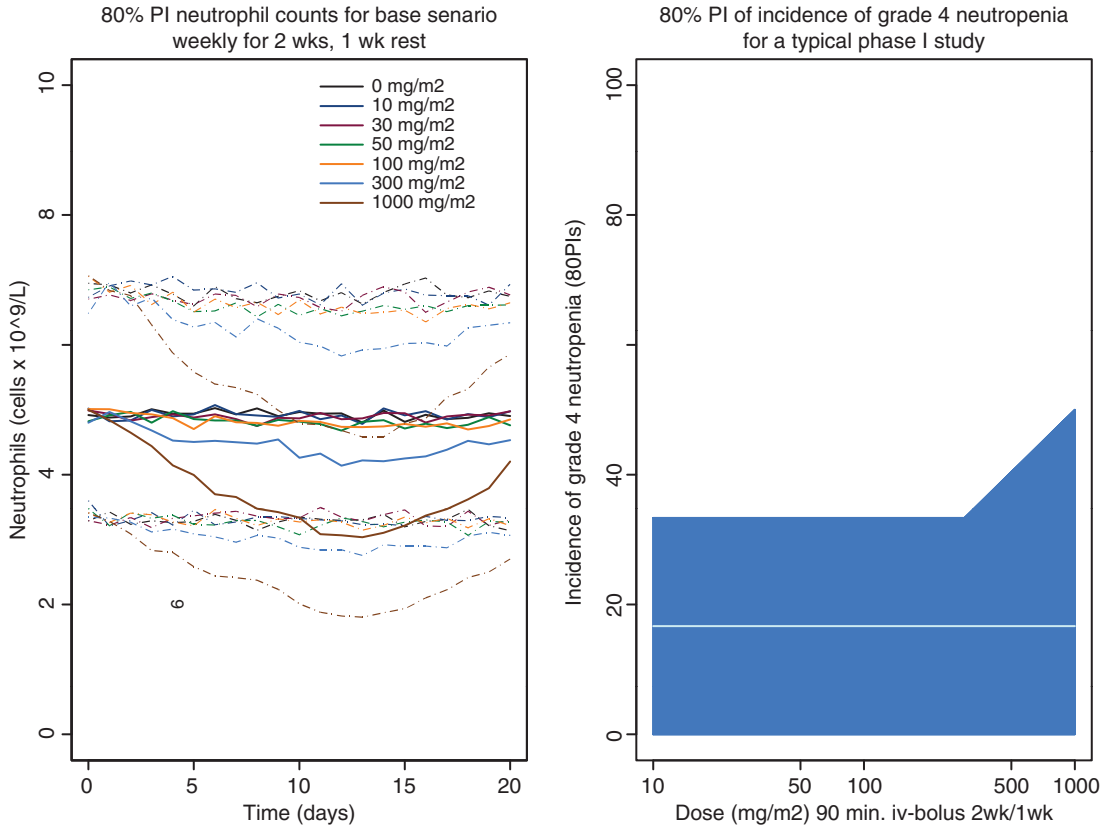

Figure 14. Predicted neutropenia in a human phase I trial in patients with advanced cancer for the base scenario (IV dosing weekly for 2 weeks, 3-week cycle). Typical interindividual variability parameters found in phase 1 cancer trials were used. Simulation indicates that CDK-I is a safe drug candidate and that no increase in neutropenia risk is expected below 300 mg m^{-2}.

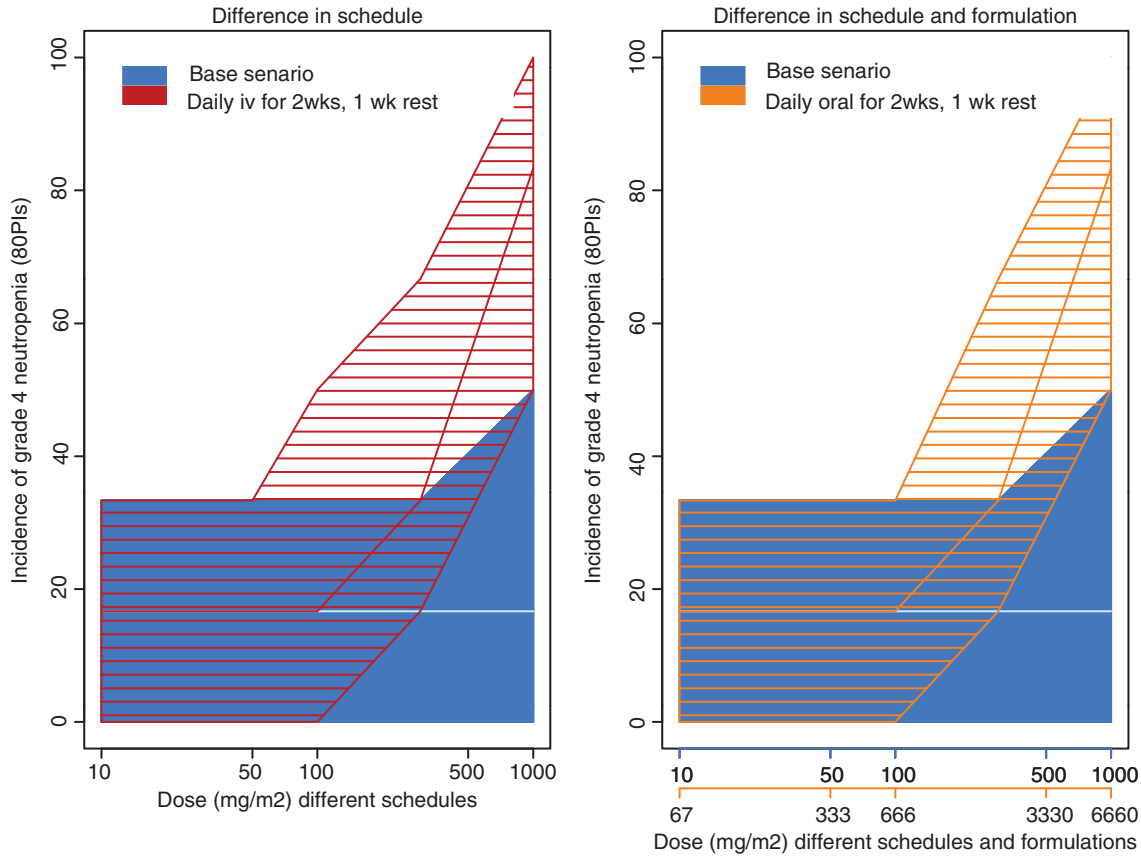

Figure 15. Predicted neutropenia in a human phase I trial in patients with advanced cancer. In the left panel, two different regimes were compared with different schedules: baseline (2 weeks, once-weekly dosing, 3-week cycle) and alternate (2 weeks daily, 3-week cycle). The alternate scenario may reduce other acute toxicities but it has higher risk of increased neutropenia starting at 50 mg m^{-2}. To make the alternate scenario more feasible, administration of oral dosing was explored. Oral dosing appears safe and allows to achieve a drug exposure at which efficacy in preclinical model has been obtained.

with captisol of the mesylate salt) has been used to predict the oral dosing in humans. This study shows a strong dependence on the oral bioavailability of the compound in humans as a function of the dose, mainly due to its limited solubility.

Modeling shows that a dosing of 30 mg m^{-2} IV or equivalently 120 mg PO will not significantly increase the incidence of neutropenia grade 4 over baseline (see Figure 15). Both regimens will deliver an average weekly AUC over the 3-week cycle larger than 104 ng h ml^{-1}. This regimen is expected to have significant antitumor efficacy without increasing the risk of grade 4 neutropenia. In terms of cumulative average exposure, the base and the alternative scenarios are very similar.

5 CONCLUSIONS

The aim of this chapter is to illustrate the ability of physiologically based mechanistic mathematical models to predict pharmacokinetics and toxicity across species. The underlying principle is that toxicity must be interpreted in the physiological context where it is measured (be it *in vitro* or in an animal model). The assumption for scaling and prediction is that the mechanism is the same across species but that the extent and dynamics of the event are dependent on the physiology of the organisms. In other words, the concept is such that physiologically based models account for the underlying biological and scaling differences across systems whereas

the parameters estimated for toxicity remain the same.

In the first section, various methodologies for predicting the PK in man are reviewed. In conclusion, for extrapolation of human pharmacokinetics, physiologically based models show improved prediction accuracy over more empirical methods. As outlined, it is believed that these models ultimately outperform more empirical methods as they characterize the PK in terms of physiological parameters and drug-related properties. Results on the use of generic simulation prior to *in vivo* studies indicate that some caution is required because certain chemical classes were poorly predicted, and it is recommended that generic PBPK models should only be applied for prioritization after verification of the simulations with *in vivo* pharmacokinetics for a few compounds of a given chemical class.

In the following section, the application of multiscalar cardiac systems models to the anticipation and management of QT prolongation in the clinical electrocardiogram and proarrhythmic risk attending new therapeutic compounds is evaluated. The critical question being asked in the assessment of compounds' propensity for QT prolongation and torsadogenesis in the clinic is essentially one of predicting the incidence of rare clinical events given certain typical response data accumulated through preclinical safety pharmacology (Morganroth *et al*., 1993; Fenichel *et al*., 2004). In our opinion, one of the most exciting horizons for systems modeling of cardiac electrophysiology is the growing capacity to include intrinsic biological variability explicitly.

The *in vivo* concentration of a novel therapeutic does not remain constant in cardiac tissue or any organ for that matter over time. Point estimates of concentration response using well-known exposures are useful for ranking compounds early on; however, the ultimate toxicological profile and clinical utility are intrinsically tied to a drug's pharmacokinetics. The last section aims to integrate both predicted pharmacokinetics and toxicokinetics in the chemotherapeutic-induced neutropenia.

The examples outlined above are important in understanding how such approaches can ultimately: (i) make drug development more efficient and (ii) reduce, replace, and refine the animal experiments going into such predictions. The oncology example is a perfect place to start, by knowing where to expect low levels of toxicity – this process being much more efficient than empirical "x times the exposure in y species" rules. Further simulation of the model helped in choosing the right timepoints for collecting blood, in a nearly random schedule. This enabled us, using population-based approaches, to greatly reduce the number of animals used in these experiments.

Overall, it is believed that the methodology proposed for integrating the available knowledge across experiments to predict toxicology in humans will ultimately make drug development more efficient, cost-effective, and socially more acceptable.

APPENDIX

Glossary

ACAT	Advanced compartmental absorption and transit model
ADME	Absorption, distribution, metabolism, and excretion
AUC	Area under the plasma concentration–time curve
CL	Total clearance
CL_{int}	Hepatic intrinsic clearance
CL_{int} (u)	Unbound hepatic intrinsic clearance
CL_H	Hepatic clearance
C_{max}	Maximal (peak) plasma concentration
F_{up}	Fraction unbound in plasma
F_{ub}	Fraction unbound in blood
GFR	Glomerular filtration rate
Iv	Intravenous
log *D*	Log distribution coefficient at a particular pH
log *P*	Measure of lipophilicity; partition between organic and aqueous phases
PBPK	Physiologically based pharmacokinetics
PK	Pharmacokinetics
pK_a	Ionization constant
PO	Per Os
$T_{1/2}$	Half-life
T_{max}	Time of maximal (peak) plasma concentration
V_{dss}	Volume of distribution at steady state

In Silico Tools for Molecular Modeling

Vetrivel Umashankar[1] **and Subramanian Gurunathan**[2]

[1]*Center for Bioinformatics, Vision Research Foundation, Sankara Nethralaya, Chennai, India* and
[2]*Department of Bioinformatics, SRM University, Chennai, India*

1 INTRODUCTION

Molecule is the smallest unit of matter that retains all of the physical and chemical properties of that substance. It is made up of one or more identical atoms or a group of different atoms bonded together. Chemicals, especially drugs, are the well-known examples of molecules. Similarly, proteins such as toxins, enzymes, etc., lipids and carbohydrates are also known as critical biological molecules in living systems. Their physical, chemical and biological properties are commonly studied by employing several *in vivo* and *in vitro* wet laboratory experimental methods. Although the results obtained are valuable, the time and human resources involved in it are huge.

The use of computers has revolutionized the understanding of molecules significantly. In fact, computer-aided calculation has imbibed itself as an important aspect in the field of scientific research. Computers simplify the calculations, which otherwise may take several years to complete through manual effort. The term *in silico* studies encompasses the methods of performing entire experiments "in simulation" or "in virtual reality" in the computer chips. It provides not only faster but also accurate results and can be performed in the absence of animal models and laborious procedures associated with wet laboratory experiments.

2 MOLECULAR MODELING

Molecular modeling is the science of representing molecular structures numerically and simulating their behaviour with the equations of quantum and classical physics. It is the art of mimicking chemical or biological systems to understand the underlying process concerned, frequently with the help of computers. It involves the development of mathematical models of molecules that can be used to predict and interpret their properties.

The common feature of molecular modeling techniques is the atomistic level (i.e. individual atoms or a small group of atoms) description of the molecular systems. Thus, molecular modeling is a collective term refering to theoretical methods and computational techniques to model or mimic the behaviour of molecules.

Molecular modeling methods are now routinely used to investigate the structure, dynamics and thermodynamics of biological, inorganic and polymeric systems. The types of biological activity that have been investigated using molecular modeling include protein folding, enzyme catalysis, protein stability, conformational changes associated with biomolecular function and molecular recognition of proteins, DNA and membrane complexes.

Modeling is an important skill area for exploring several interesting and challenging problems in biological sciences. Physical models give us the best

and most direct view of the molecular world. They are easy to use, inexpensive and safe. Molecular modeling is one of the fastest growing fields in science and is no different than any other field of study. It is a research tool that is no more difficult than traditional research tools such as test tubes, beakers or spectrophotometers. The benefit of molecular modeling is that it reduces the complexity of the system, allowing many more particles (atoms) to be considered during simulations.

3 STAGES IN MOLECULAR MODELING

Most molecular modeling studies involve three stages (Figure 1). In the first stage a model is selected to describe the intra- and intermolecular interactions in the system. The two most common models that are used in molecular modeling are quantum mechanics and molecular mechanics. These models enable the energy of any arrangement of the atoms and molecules in the system to be calculated, and allow the modeller to determine how the energy of the system varies as the positions of the atoms and molecules change.

Molecular mechanics is a classical mechanical model that represents a molecule as a group of atoms held together by elastic bonds. Its methods give predictions of molecular geometries and heats of formation. However, quantum mechanics is a quantum mechanical model of the electronic structure of a molecule. It involves solving the Schrödinger equation. Quantum mechanics can be used to predict electronic properties of molecules, such as dipole moments and spectroscopy.

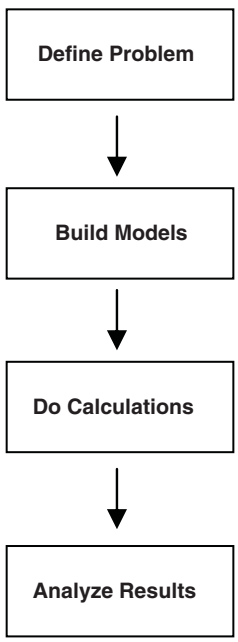

Figure 1. Stages in molecular modeling.

The second stage of a molecular modeling study is the calculation itself, such as an energy minimization, a molecular dynamics or Monte Carlo simulation, or a conformational search. Finally, the calculation must be analysed, not only to calculate properties but also to check that it has been performed properly. For example, a molecular model of a small molecule or protein is built on already known parameters that are known to capture the ideal three-dimensional structure of the molecule. Thus, studied (and averaged) information is used as the stepping-stone in model building and each step needs to be validated.

Classical molecular modeling has dealt with biological molecules which generally have a tree-like structure, but applications to nanotechnology require dealing with more complicated diamond-like structures; it is unclear to what extent this affects the relevant algorithms.

Models using computers are generated using mathematical equations (classical and quantum mechanical) and are evolved based on experimental information that has to be taken into consideration during model building. The basic assumption in mathematical modeling is that the biological properties of any molecule are completely determined by the chemical structure of that molecule. Differences in biological properties ultimately arise from structural differences. A further assumption is that these differences can be expressed in quantitative terms. A modeling study may then be aimed to study an empirical equation that would relate the structures of compounds to their biological properties, for example the strength of a molecular interaction.

Computer models mathematically represent the atomic positions (denoting the coordinates) and molecular geometry, and graphically represent the molecular surfaces and energies of the molecule or a system (critical for evaluating its stability).

4 HISTORICAL OVERVIEW OF MOLECULAR MODELING

History of molecular modeling dates back to mid-nineteenth century during which time the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat234
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

development of the structural theory of organic chemistry was also witnessed. Diagrammatic representations of chemical structures are among the earliest forms of molecular model. "Rational formulas" derived from the molecular formula and knowledge of functional groups, or "radicals', was followed by a variety of conventions in grouping the "radicals" together with brackets or parentheses. The three chemistry researchers Archibald Scott Couper, Friedrich August Kekulévon Stradonitz and Aleksandr Mikhailovich Butlerov (1858–1861) introduced the first written structures involving chains of carbons with lines drawn as "bonds" to substituent atoms and groups. The term "chemical structure" was first used at this time. In 1861, Johann Josef Loschmidt developed a collection of 368 molecular structures as graphic displays with atomic spheres. His structures showed relative atomic size, bond distance and bond multiplicity.

In 1865, August Wilhelm Hofmann first recorded use of a physical molecular model in organic chemistry by using metaphor of croquet balls joined by sticks to describe methane, chloroform and other compounds of carbon. The colour scheme which he employed is still widely used, with occasional variations: white for hydrogen, black for carbon, red for oxygen, blue for nitrogen and green for chlorine. To follow universal colour code for molecular models, The Institute of Physics, in addition to the Hofmann's scheme, introduced the following colour codes: yellowish green for fluorine, light green for chlorine, mid-green for bromine, dark green for iodine, yellow for sulphur, purple for phosphorus, black or grey for silicon, and brown, silver or gold for metals.

Crum-Brown (1865) and Sir Edward Frankland and B. F. Duppa (1867) employed two-dimensional drawn versions of ball and stick models. Suggestions on carbon compounds having tetrahedral geometry in 1869 by E. Paterno, and in 1874 by Jacobus Henricus van't Hoff and Joseph Achille LeBel, helped in expanding three-dimensional molecular structure. Work by C. A. Bischoff (1890) and van't Hoff (1898) introduced the concept of "favoured configuration" about a torsional angle

In the beginning of the twentieth century, the concept of the force field was derived from vibrational spectroscopy. It is the forces acting between every pair of atoms in the molecule, or in a lattice in the case of ionic crystals. In 1946, molecular mechanics method, or the empirical force field method, for calculating molecular structures introduced the idea of the use of force field concept in non-physical chemical community. This method was based upon a combination of steric interactions and a Newtonian mechanical model of bond stretching, angle bending and torsional vibrational modes. Three separate groups proposed this method, namely Hill's, Dostrovsky, Hughes and Ingold and Westheimer and Mayer.

In 1950, the work of Barton on the conformations of steroids influenced the thinking of the chemical community on the three-dimensional nature of molecules. This laid the foundation of conformational analysis. From then onward, an appreciation of the three-dimensional aspect became crucial to understanding the structure, stability, conformation and reactivity. In the following year, Pitzer described the torsional potential govern energetics in simple hydrocarbons.

Double-helical DNA structure presented by Watson and Crick in 1953 is considered to be the most famous physical molecular model of all times. In the same year, a group of scientists from Los Alamos published their work carried out on the advanced MANIAC computer. That laid the groundwork for computer-based Monte Carlo methods, established algorithm for simulated annealing and can be considered as the ancestor of molecular dynamics calculations. In 1960, the work of Kitaigorodsky paved way for applications of non-bonding potentials to organic structure modeling.

The first published use of a computer for empirical force field calculations of molecular structure was in 1961 by Hendrickson, who examined the conformations of medium-sized rings. In 1963, Schachtschneider and Snyder reported the derivation of a set of transferable parameters for a valence force field for hydrocarbons. Transferability is crucial to the development of a general force field with a limited number of parameters.

In 1965, Wiberg employed computer force field calculations to address conformational analysis. His steepest descent algorithm is a scheme for geometry optimization. Wiberg also published algorithms for transforming Cartesian coordinates to internal coordinates, to calculate bond lengths, bond angles and torsional angles from these coordinates. He also provided a geometric algorithm to predict the location of the hydrogens on a methylene carbon.

In 1968, Boyd presented the modified Newton–Raphson method for strain energy minimization, which reached convergence more rapidly than the Wiberg algorithm.

The first computer graphic display of molecular structures was devised at MIT in the mid-1960s. Taking advantage of Project MAC (Multi-Access Computer), one of the first timesharing mainframe computers, Cyrus Levinthal and his colleagues designed a "model-building" program to work with protein structures. This program allowed the study of short-range interaction between atoms and the "online manipulation" of molecular structures. The display terminal (named Kludge) was a monochrome oscilloscope, showing the structures in wireframe fashion.

During the latter half of the twentieth century, force field calculations of molecular structure have developed largely in pace with the development of fast computing machines to carry out the extensive calculations required. Early growth was slow, although, because of unfamiliarity of the average chemist with the programming and use of mainframe computers, and also due simply to lack of access. American scientists made decisive contributions as they had access to computers. Their contributions, such as the Monte Carlo work mentioned above, and the archetypal molecular drawing program ORTEP (Oak Ridge Thermal Ellipsoid Plotter), developed at Oak Ridge National Laboratory in 1965, are clear evidences. Also with the government's support, the first networked computer (the ancestor of the Internet) was demonstrated in October 1969, by establishing a linkage between a computer at UCLA in Los Angeles and another at SRI in Menlo Park.

By the early 1970s, several major force field formulations were reported: ECEPP, UNICEPP, the Consistent Force Field (CFF), the MMI, the EAS, Boyd's and the MUB. These force field models were based on different assumptions, and although they used many of the same or similar potential functions, they were weighted and parameterized differently.

In 1971, Lee and Richards described the molecular surface in the context of protein structure and provided an algorithm to derive it. This involved constructing spheroids about each atom scaled by the van der Waals radius and considering as the surface those portions of these spheroids which were not contained within any other such spheroids. This analysis proceeded through the molecule in a series of planar sections, upon each of which the corresponding projection of the surface was "plotted'. In those days before the advent of modern computer graphics, the surface projection for each planar section was imprinted on a transparency sheet, and these were stacked atop one another to visualize the molecular surface. Expanding upon this work 2 years later, Shrake and Rupley came up with the first dot surface formulation applied to protein structure.

In 1972, Wiberg and Boyd presented an algorithm for exploring conformational interconversions based on systematic modifications of torsional angle. This technique subsequently enjoyed broad use as the dihedral driver method.

Lemieux group first reported computer-aided molecular modeling of oligosaccharides in 1974. Their methodology was much simpler than the other force fields of the time. Also, it was computationally quick and reported satisfactory correlations with the conformational equilibria resulting from NMR studies. Thus, this methodology continues to be popular with carbohydrate chemists even today.

Around the same time, force field formulations for synthetic macromolecules began to appear, such as those used in the conformational analysis of polypropylene by Suter and Flory.

The early 1980s saw the marriage between force field modeling and graphic display on desktop units; the era of personal molecular modeling for the average chemist had begun. A convenient demarcation is the year 1983, when the distribution of the Model (later MacroModel) program by the Still group at Columbia began. This program could be configured to run on a mainframe with a variety of desktop platforms as the user interface. At about the same time, the development of high-quality real-time colour graphics and Connolly's molecular surface program contributed to the rapid evolution of this technique. The graphic presentation of colour-coded molecular surfaces, which displayed at the same time shape, charge and hydrophobicity, provided the modeller with a much higher information density.

In 1986, M. Saunders refocused attention on the central force field model with his STRFIT molecular modeling program. In this method, bond angles and torsional angles are not considered; only forces between pairs of individual atoms are calculated. The resulting structures are quite close to those obtained from MM2. In the following year, Saunders presented the "random kick" algorithm for conformation searching, which was especially helpful in searching over ring conformations.

The history of the World Wide Web began in 1993, when the first graphical browsers became available. Non-graphical Internet applications, such

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat234
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

as electronic mail and file transfer protocol (FTP), had been developing since 1969, but the vast potential of the graphical user interface can encompass and integrate these functions, and provide the additional enhancements of graphic images.

Within the last 10 years, there have been a number of developments. One is the advent of the Class 2 force fields, which contain anharmonic potentials and utilize explicit off-diagonal terms from the force constant matrix. A not unrelated development is the use of structural data obtained from high-end *ab initio* calculations to parametrize these new force fields. The quantum mechanically derived potential surface is then scaled to reproduce experimental data.

A prediction has been made that the Class 3 force fields will be able to model the influence of chemical effects, electronegativity and hyperconjugation on molecular structure and properties. Another ongoing trend is the development and implementation of virtual reality for molecular modeling. Basically, this will enhance the visual third dimension, further developing and enhancing audio sensation, and introducing tactile sensation. It is unlikely that this type of modeling will be implemented on the desktop platform any time soon.

In Virtual Biomolecular Environment (VIBE) system, a massively parallel computational engine runs an interactive molecular dynamics simulation under the CHARMM force field, and this is interfaced with a 3 m cubic "theatre", called the Cave Automatic Virtual Environment (CAVE). The modeller enters this theatre and interacts with the three-dimensional simulation by means of a wand-link remote control device. The modeller's head and hand movements are tracked with a six-degree-of-freedom electromagnetic sensor to maintain the correct perspective in the virtual environment. The wand may be used to dock a ligand into a binding site, and bumps and other interactions are experienced as sounds.

Improvements in the field of molecular modeling have paved ways to combine the higher accuracy of the computer-based methods with the touch of physical models. In one recent report, stereolithography is used to translate computer-designed structures into physical molecular models. The data from molecular orbital calculations or from neutron diffraction studies were used to guide the fabrication of plastic models by laser curing of an acrylate resin blend. The stereolithography apparatus works by building the model iteratively through a series of "slices', from the bottom up. The scales used were 1 Å = 0.19–0.89 cm, depending on the overall size of the molecule. Molecules, transition state complexes, and "molecular impressions" or shape-complementary surfaces were prepared and post-cured for several hours. Such custom-made models can serve a general need and can be especially helpful for the visually impaired. The preparation by stereolithography of a physical model of an inhibitor plus part of the receptor, guided by the use of modeling software, is a recent advancement.

5 APPLICATIONS OF MOLECULAR MODELING

Molecular modeling techniques are used in the fields of computational chemistry, computational biology and materials science for studying molecular systems ranging from small chemical systems to large biological molecules and material assemblies. Molecular modeling covers the areas of automatic structure generation, analysis of three-dimensional structural databases (structural bioinformatics), prediction of the three-dimensional structure of proteins from their sequence (homology modeling), and so on. Computational calculation of energies of a system, energy minimization, molecular dynamics and Monte Carlo simulations also form a part of molecular modeling.

5.1 Designing Drugs for the Future

Molecular modeling has opened up new avenues for scientists to design new drugs against several not so easily curable diseases such as cancer, AIDS and arthritis. Moreover, development of more potent drugs from existing ones is possible only because of molecular modeling methods.

5.2 Designing New Materials

Apart from bringing new drugs to the market, molecular modeling has the potential to bring a vast array of new materials such as fullerenes, nanotubes and superconducting cuprates (as well as other complex inorganic compounds). Similarly, this exciting area is expected to produce new materials in the optics, ceramic, semiconductor and biomaterials markets.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

5.3 Artificial Photosynthesis

Knowledge in molecular modeling has helped scientists to attempt several improvements in photosynthesis machinery of plants. In the near future, one can expect plants or even microbes with better photosynthetic capacity, thus increasing agricultural productivity.

5.4 Understanding Biomolecules Better

Research using molecular modeling will provide greater insights into various molecules, particularly biomolecules and their interactions, so that the basic mechanism behind several biological reactions can be understood clearly.

6 *IN SILICO* TOOLS IN MOLECULAR MODELING

Several programs and software tools are currently available for *in silico* molecular modeling. Using these, one can visualize, rotate, manipulate and optimize models on a computer display. Although some calculations can be performed in a few seconds, other calculations on molecules, using even the largest computers, can take weeks or months to complete. A list of popular softwares for molecular modeling is presented in Table 1.

Discussing all the tools is out of scope of this book. Some of the common and/or important tools used in molecular modeling are discussed in the following section. For our convenience, the tools to be discussed are classified into several categories based on their use in different molecular modeling protocols.

6.1 Tools for Database Searching

Databases are libraries containing sequences/structural information of proteins and small molecules. Database searching is an important protocol in molecular modeling. With reference to proteins, structural information of similar homologues is useful in model building whereas in drug discovery, one of the main use of database searching is in lead optimization. Database searching can be performed either using text or structural details of the compound under study.

Cambridge Structure Database (CSD) (http://www.ccdc.cam.ac.uk/products/csd/) is a database containing information on the experimentally determined three-dimensional structures of low-molecular-weight compounds that are potential ligands. It contains the crystal structures of more than 250 000 molecules. Similarly, PUBCHEM is an open database that contains the chemical structure and certain physiochemical properties of chemical compounds. However, commercially procured chemicals are compiled in a database called Available Chemical Database (ACD). The commercial Asinex database and Open National Cancer Institute (NCI) database also hold computed structures. The Chembridge database contains the highest number of compounds (more than 700 000).

Protein Data Bank (PDB) (www.rcsb.org/) is a database providing information on the structures of proteins. This database is the only player in this kind of information. Research Collaborators for Structural Bioinformatics (RCSB) is an open databank which is a repository of the three-dimensional structure of proteins (around 50 000) solved through X-ray crystallography, nuclear magnetic electron microscopy, electron microscopy and other such methods.

There are some specialized databases such as the SCORPION2 database, which contains more than 800 records of native and mutant toxin sequences enriched with binding affinity and toxicity information, 624 three-dimensional structures and some 500 references.

6.2 Tools for Homology Modeling

Comparative or homology modeling is one of the three different computational approaches for protein structure prediction. Comparative or homology modeling uses experimentally determined protein structures as templates to predict the conformation of another protein that exhibits amino acid sequence homology. Comparative modeling exploits the fact that evolutionarily related proteins with similar sequences, as measured by the percentage of identical residues at each position based on an optimal structural superposition, have similar structures. A structure similar to the native structure can be predicted if sequence similarity is about or above 35%. Homology modeling is a relatively reliable way to generate a model structure for a given sequence, but

Table 1. Some of the popular software for molecular modeling.

Software	Application	Availability
Abalone	Biomolecular simulations, protein folding	Not free
AMBER	Model building, molecular dynamics and molecular mechanics	Not free
Ascalaph Designer	Molecular building, molecular dynamics	Free and commercial
Automated Topology Builder	Automated molecular topology building service for small molecules	Free for academic use
Biochemical and Organic Simulation System (BOSS)	Optimized potentials for liquid simulations	Commercial
Chimera	Visually appealing viewer, amino acid rotamers and other building	Free/commercial
CHARMM	Multiple graphical front, molecular dynamics and molecular mechanics	Not free
COSMOS (software)	Force field with fast semi-empirical calculation of electrostatic and/or NMR properties; 3-D graphical molecule builder and viewer	Free (without GUI) and commercial
Culgi	Atomistic simulations and mesoscale methods	Not free
Desmond	High-performance molecular dynamics	Free and commercial
GROningen MAchine for Chemical Simulations (GROMACS)	High-performance molecular dynamics	Free
GROMOS	Biomolecules	Not free
Large-scale Atomic/Molecular Massively Parallel Simulator (LAMMPS)	Soft and solid-state materials and coarse-grain systems for molecular dynamics	Free
MacroModel	Conformational sampling, minimization, molecular dynamics	Not free
Materials Studio	Materials simulation technology	Closed source/trial available
MDynaMix	Parallel molecular dynamics	Free
Molecular Operating Environment (MOE)	Molecular modeling, molecular dynamics, molecular mechanics, molecular visualization	Commercial
PyMOL	Molecular graphics and modeling package	Free for academics
Sirius	Molecular modeling and analysis system	Commercial
Virtual Molecular Dynamics (VMD)	Fast, parallel molecular dynamics	Free
WHAT IF	Visualizer for MD; interface to GROMACS	Not free
YASARA	Molecular-graphics, -modeling and -simulation program	Not free
Zodiac (software)	Drug design suite	Commercial

is limited to those sequences with high similarity to a structure which has already been solved.

The process of comparative model building is conceptually straightforward (Figure 2). First, an alignment is performed between the sequences for which the structure has been determined by experimental methods (the parent) with the sequence to be modelled (the target). This sequence alignment is used to construct the initial model (sometimes referred to as a framework or template) by copying over some main chain and side chain coordinates from the parent structure based on the equivalent residue in the sequence alignment. Side chains must be built for residues in the target that does not correspond to an identity in the alignment, and for residues where the side chain conformation is thought to vary in the target relative to the parent structure. Main chains must be built in case of insertions, regions surrounding a deletion and other regions of suspected main chain variation. Finally, model refinement and evaluation is carried out in which the structure obtained is refined using energy minimization and validated using appropriate softwares.

6.2.1 Modeller

MODELLER (http://salilab.org/modeller/) is a computer program used to model 3D structure of proteins and for homology/comparative modeling of protein 3D structures. The user provides an alignment of a sequence to be modelled with a known related structure, and MODELLER automatically calculates a model containing all non-hydrogen

atoms. A 3D model is obtained by optimization of a molecular probability density function (pdf). The molecular pdf for comparative modeling is optimized with the variable target function procedure in Cartesian space that employs methods of conjugate gradient and molecular dynamics with simulated annealing. It can also perform many additional tasks. It implements comparative protein structure modeling by satisfaction of spatial restraints.

6.2.2 Swiss-PDB Viewer

Swiss PDB viewer (http://www.expasy.org/spdbv/) is a stand-alone molecular visualization and molecular modeling software. It incorporates many useful functions such as calculating molecular surfaces, electrostatic potentials, high-quality rendering, analysis of torsion angles and energy minimization. It can also be used to prepare input for homology modeling using Swiss-MODEL web server, an automatic web-modeling server (Figure 3).

6.3 Tool for Threading/Fold Recognition-Based Structure Prediction

6.3.1 PHYRE Server

The PHYRE (http://www.sbg.bio.ic.ac.uk/phyre/) is an automatic fold recognition server for predicting the structure and/or function of protein sequence under study. Originally developed in 2004, Phyre was one of the top-performing stand-alone protein structure recognition systems. It combines primary and secondary structure profile information using highly optimized profile–profile comparison algorithms. The predictive power of this server is similar to that of other publicly available software, and the most recent Critical Assessment of Structure Prediction (CASP) competition judged the latest Phyre version to be one of the best servers for preliminary assessment of protein structures.

6.4 Tool for Ab Initio Structure Prediction

6.4.1 Robetta Server

The Robetta server (http://www.bioinfo.rpi.edu/~bystrc/hmmstr/server.php) is an automated protein structure prediction service offered by the Baker laboratory for non-commercial *ab initio* and comparative modeling. It has been rated as performing among the best in the automated server prediction category. It is a protein structure prediction on the Berkeley Open Infrastructure for Network Computing (BOINC) platform.

6.5 Tools for Docking

Molecular docking can be defined as the prediction of the structure of receptor–ligand complexes, where the receptor is usually a protein and the ligand is either a small molecule or another protein. In simpler terms, docking is a process by which two molecules fit together in three-dimensional space.

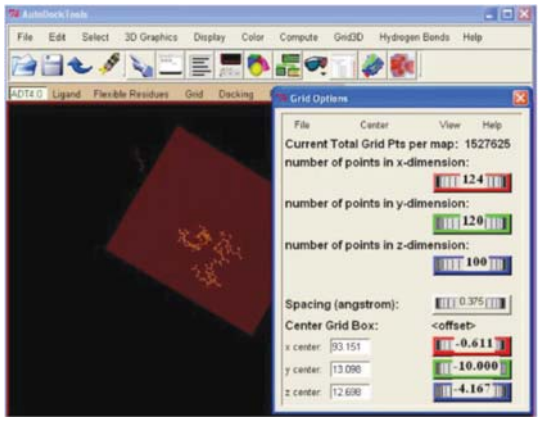

Figure 4. Screenshot of AutoDock tool.

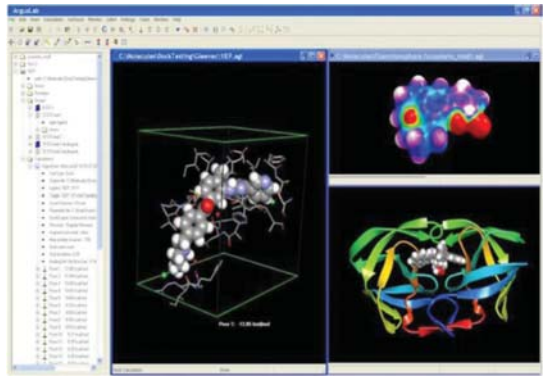

Figure 5. Screenshot of ArgusLab tool.

There are many software programs available (both commercial and free) for docking. Freewares include DOCK 6.1, AUTODOCK and HEX. Commercial includes FLEXX of Tripos Inc. and GLIDE of Schrodinger Inc.

6.5.1 Autodock

AutoDock is a suite of automated docking tools (Figure 4). It is designed to predict how small molecules, such as substrates or drug candidates, bind to a receptor of known 3D structure. It actually consists of two main programs: Auto Dock performs the docking of the ligand to a set of grids describing the target protein; Auto Grid pre-calculates these grids. In addition to using them for docking, the atomic affinity grids can be visualized.

AUTODOCK employs molecular dynamics to predict the docking of a flexible ligand to a binding site of a rigid protein, given the region of the protein containing the binding site and the substrate. It is downloadable from http://autodock.scripps.edu/ webpage.

6.5.2 HEX

HEX is an interactive protein docking and molecular superposition program, written by Dave Ritchie. HEX understands protein and DNA structures in PDB format. HEX will run on most Windows-XP, Linux and Mac OS X PCs. For Academic and governmental users, a runtime version of HEX may be downloaded free of charge. On multi-processor Linux systems, docking calculation times can be reduced in almost direct proportion to the number of CPUs used. This commercial docking tool is available for download at http://www.loria.fr/∼ritchied/hex/ (or) http://www.csd.abdn.ac.uk/hex/.

6.5.3 ArgusLab

ArgusLab is a tool that includes spectroscopy, graphics and visualization, drug docking and high-level *ab initio* calculations (Figure 5). It is a complete molecular modeling system for platforms running on Microsoft Windows operating systems. ArgusLab contains an interactive 3D molecule builder that allows the user to build and manipulate complex molecular structures. ArgusLab also contains a rich suite of computational methods, both quantum mechanical and molecular mechanical, for calculating ground- and excited-state properties. It is downloadable for personal use from http://www.arguslab.com/downloads.htm.

6.5.4 VegaZZ

VegaZZ is a free tool for molecular mechanics. It has rich 3D graphical features and can be employed to build our own databases using specialized tools embedded in VegaZZ. VegaZZ is the evolution of the well-known VEGA OpenGL package. VEGA was originally developed to create a bridge between most of the molecular software packages only, but in the years, enhancing its features, it has evolved to a complete molecular modeling suite. This software is free for non-profit academic uses and can be downloaded from www.ddl.unimi.it after registration.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat234
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

6.5.5 TINKER

TINKER (http://dasher.wustl.edu/tinker/) is a complete package for performing empirical force field molecular mechanics and dynamics calculations. It is intended to serve as a platform for algorithm development and parameterization, while still being efficient enough for most production work. Programs are provided to perform many functions including:

- energy minimization over Cartesian coordinates, torsional angles or rigid bodies;
- molecular, stochastic and rigid body dynamics with periodic boundaries and control of temperature and pressure;
- normal-mode vibrational analysis;
- building protein and nucleic acid structures from sequence;
- location of a transition state between two minima;
- free energy calculations via free energy perturbation or weighted histogram analysis;
- fitting of intermolecular potential parameters to structural and thermodynamic data.

6.6 Tools for Molecular Visualization

Molecules including biomolecules such as proteins, DNA and RNA can be observed on computer screens using specialized tools termed as molecular visualization tools. They help researchers to observe the molecules in three-dimensional structure and also with different formats such as ball and stick, wireframe, ribbon, etc. They help to differentiate different regions of molecules as they use different colours to represent different atoms.

6.6.1 RasMol

RasMol **(**http://www.umass.edu/microbio/rasmol) is a free program developed by Roger A. Sayle (1993). Rasmol is a molecular graphics program for visualization of proteins, nucleic acids and small molecules. The name Rasmol has been derived from Raster (the array of pixels on a computer screen) Molecules. The powerful program is aimed at display, teaching and generation of publication quality images. It is easy to use and produces beautiful, space-filling, coloured, three-dimensional images.

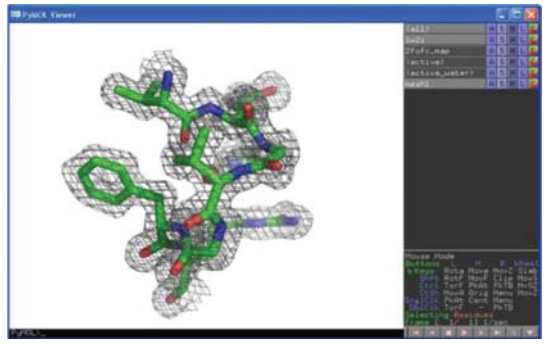

Figure 6. Screenshot of PyMol Viewer tool.

6.6.2 Pymol

The PyMOL application **(**http://pymol.sourceforge.net/**)** was designed to be a molecular visualization system (Figure 6). It is well suited to produce high-quality 3D images of small molecules and biological macromolecules such as proteins. It is equally good for animating molecules dynamically, giving live 3D presentations and sharing interactive visualizations. This open source tool was created by Warren Lyford DeLano. The Py portion of the software's name refers to the fact that it extends, and is extensible by the Python programming language.

6.7 Tools for Molecular Drawing/Editing

6.7.1 ISIS/Draw

Isis/Draw (www.symyx.com/downloads/) is a freely available, chemically intelligent drawing package from MDL Information Systems for Windows and Macintosh. You can insert your ISIS/Draw sketches into documents, Web pages, spreadsheets and presentations. You can also use ISIS/Draw to create structures to register into 2D and 3D molecule, polymer and reaction databases, and to create queries for searching these databases.

6.7.2 Chemsketch

ACD/ChemSketch (www.acdlabs.com/download/) is an advanced chemical drawing tool and is the accepted interface for the industry's best NMR and molecular property predictions, nomenclature and analytical data handling software (Figure 7). ACD/ChemSketch is also available as freeware, with functionalities that are highly competitive with other popular commercial software packages. The freeware contains tools for 2D structure cleaning,

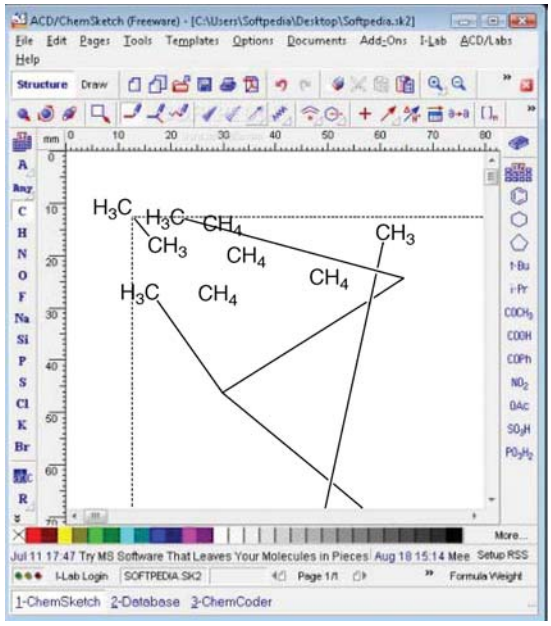

Figure 7. Screenshot of Chemsketch tool.

3D optimization and viewing, InChI generation and conversion, drawing of polymers, organometallics and Markush structures–capabilities that are not even included in some of the commercial packages from other software producers.

6.7.3 ChemDraw

ChemDraw (www.cambridgesoft.com/) is a molecule editor developed by the chemoinformatics company CambridgeSoft. ChemDraw is, along with Chem3D and ChemFinder, part of the ChemOffice suite of programs and is available for Macintosh and Microsoft Windows.

1 INTRODUCTION

Toxicogenomics holds the promise of unprecedented advances in two broad, overlapping fields: mechanistic or investigative toxicology, and predictive toxicology. Mechanistic or investigative toxicology is the area of toxicology focused on biological responses to drug toxicity, and provides important perspectives on risk assessments of various compounds. In contrast, predictive toxicology focuses on identifying the potential toxicity of compounds (Cunningham and Lehman-McKeeman, 2005; Boverhof and Zacharewski, 2006). In previous studies, toxicogenomics has contributed to in-depth investigations of molecular mechanisms and the modes of toxin/chemical/environmental stressor action that was difficult to be achieved by conventional toxicological approaches. At the same time, expanding toxicogenomic data has promoted a valuable platform for the establishment of biomarkers to predict a compound's toxicity.

The progress of toxicogenomics has been supported by DNA microarray technology, a powerful tool for directly monitoring patterns of cellular perturbations through the identification and quantification of global shifts in gene expression resulting from pathological alterations within cells and tissues. Microarrays provide a large amount of transcriptional expression data for thousands of individual genes under various experimental conditions. Bioinformatics technologies can determine which genes are meaningful, facilitating the analysis of huge pools of toxicogenomics data in mechanistic and predictive toxicology. Meaningful genes are referred to as "signature genes" with characteristic gene expression profiles for exposure or toxicological response to specific classes of toxic compounds. This chapter is devoted to computational approaches for the data mining of biomarker genes from toxicogenomics data, leading to toxicity prediction.

2 MICROARRAY DATA FOR TOXICOGENOMICS

Microarray techniques have been applied not only to toxicogenomics but also to various clinical purposes, such as disease classification and patient diagnostics. These applications have revealed the challenges of achieving reproducibility and stability of outcomes with microarray technologies caused by cross-platform chips and differing experimental

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat235
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

conditions. Therefore, data sets for constructing reliable prediction models must be obtained with the same platform and experimental conditions. For this purpose, many public databases for toxicologically relevant microarray data have been developed, including the Comparative Toxicogenomics Database (CTD) (Mattingly *et al*., 2006), Environment, Drugs and Gene Expression database (EDGE) (Hayes *et al*., 2005), and Chemical Effects in Biological System (CEBS) knowledgebase (Waters *et al*., 2003), among others.

In 2002, we began the toxicogenomics project (TGP), a public–private collaborative project of the National Institute of Health Sciences, the National Institute of Biomedical Innovation, and 15 pharmaceutical companies in Japan (Urushidani and Nagao, 2005). With an emphasis on the uniformity of data quality, TGP has generated a large-scale toxicology database of transcriptomes intended to predict the toxicity of new chemical entities in the early stages of drug development. Drug reactions such as efficacy and toxicity are associated with the dosage and time course after treatment, and so precisely monitoring drug reactions requires multiple dose- and time-dependent experiments for each drug. Thus far, about 150 chemicals, primarily medicinal compounds, have been selected for the database. Over 27 000 gene expression profiles have been compiled for multiple doses and times in rat livers and kidneys, as well as rat and human hepatocytes, through comprehensive analysis using the Affymetrix GeneChip® Affymetrix, Inc., Santa Clara, CA, USA. These gene expression profiles, conjugated with histopathological changes, blood biochemical examination results, and the other phenotypic profiles, are stored in our database with a web-based tool for statistical analysis, genomics-assisted toxicity evaluation system developed by the toxicogenomics project in Japan (TG-GATEs). Thirteen of the 150 chemicals were typical nephrotoxicants or drugs showing clinical side-effects (e.g., cisplatin, carboplatin, gentamicin, vancomycin, phenacetin, and bucetin), and 20 chemicals exhibited nephrotoxicity in addition to hepatotoxicity (e.g., phenylbutazone, ethionine, and indomethacin).

3 IDENTIFICATION OF BIOMARKER GENES WITH TOXICOGENOMICS DATA

The first step from toxicogenomics to mechanistic and predictive toxicology is the identification of an individual gene or a cluster of genes detective or predictive of certain types of toxicity; these "signature genes" are employed as biomarkers. A biomarker is defined by the International Programme on Chemical Safety (IPCS) of the WHO as any substance or its product, structure, or process that can be measured in the body and that can influence or predict the incidence of disease outcome. The ideal biomarker provides a sensitive, informative, and reproducible indicator of potential adverse effects at times or doses preceding overt tissue damage, toxicity, or disease initiation. The discovery and validation of biomarkers is useful for application in high-throughput experimental systems to characterize target organ effects and to detect specific toxicity end-points in the early steps of a compound's development. The identification and utilization of biomarkers through toxicogenomics have several further applications: from current use in pre-clinical toxicology to risk characterization and risk assessment of chemicals; from early clinical stages of drug development to the later stages; and even into daily clinical use in diagnostics, disease classification, and therapeutic monitoring.

4 GENE SELECTION FROM MICROARRAY DATA

Identifying biomarker genes in huge sets of microarray data is referred to as the gene selection problem. In selecting genes from a microarray with good separation between toxic and non-toxic drug-treated samples, one seeks the significant genes that are affected by the adverse drug effects, or even those that caused the adverse reaction. This is a key step toward understanding mechanistic and predictive toxicology through the underlying biological process.

Gene selection is also relevant in the classification problems in machine learning, in which the class of toxic response (including non-toxic responses) of a sample (e.g., drug-treated organ or tissue) is determined by a classifier. A sample is represented as a feature vector $\mathbf{x}$. Each dimension in the feature vector $\mathbf{x}$ holds the expression value of a particular gene, which is obtained from a DNA microarray experiment. The classifier is constructed by inputting N feature vectors (called training data) with known toxic response outcomes into the machine-learning algorithms. However, because of the low number of samples (N: the number of the feature vectors)

and the high number of observed genes [dim(**x**): dimension of each feature vector], using all genes to classify the samples into good and bad outcomes incurs a high risk of over-training (or over-fitting). Over-training, in this case, means including the noise in the data, which may increase the generalization error (the error rate of the resulting predictor on samples that were not used during the training phase). This may yield a result that achieves high accuracy levels for the training data, but does not generalize to new data. The underlying problem is that if the sample size is much smaller than the number of genes, then one can distinguish different types of toxicity based on the noise present in these measurements, rather than on distinct biological characteristics of their gene expression levels. One approach to overcome this serious problem is to reduce the number of genes by removing irrelevant and redundant features, a method known as "feature selection" in computer science.

5 FEATURE SELECTION ALGORISMS

Feature selection methods can be broadly categorized into the filter model and the wrapper model. The filter model separates feature selection steps from the machine-learning algorithm, and relies on the general characteristics of the training data to select features (Figure 1a). The wrapper model uses the predictive accuracy of a pre-determined learning algorithm to determine the quality of a selected subset (Figure 1b).

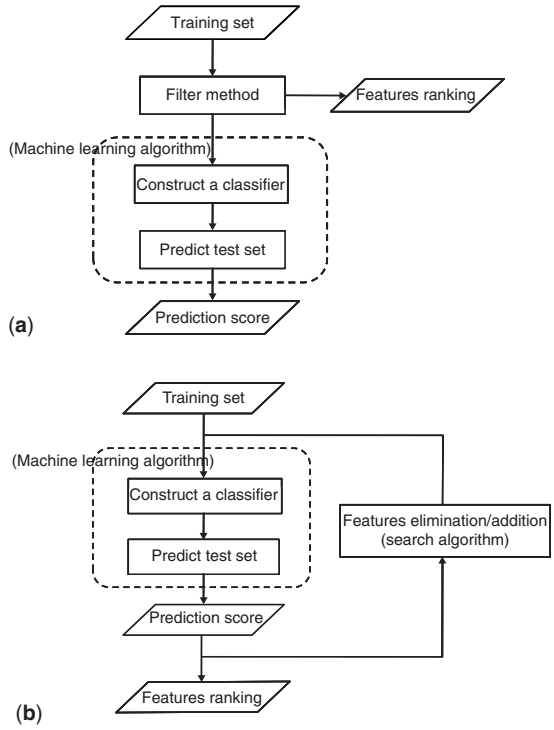

Figure 1. Calculation procedures of filter method (a) and wrapper method (b).

5.1 Filter Methods

Traditional methods in gene selection fall within the filter model. Filter approaches remove irrelevant features based on a ranking of all the genes according to their individual relevance or discriminative power to the target class. Filter approaches generally follow three simple steps (Figure 1a), they: (a) rank all the genes in the microarray data using a filter method, (b) choose the top-ranked $n-1$ genes as the best feature gene subset, and (c) construct a classifier in learning algorithm using the selected $n-1$ genes. The filter-type feature selection (steps 1 and 2) is independent of the classifier-learning algorithm (step 3). One major problem with the filter model is the selection of a threshold for discarding irrelevant features. All the features are given a score by the filter algorithm, but determining the optimal threshold "n" for the data is difficult. We must choose the threshold "n" using some appropriate criteria.

Filter methods are selected to produce the most relevant possible ranking. Many methods have been developed based on statistical tests. They are:

1. t-Statistic: This criterion measures the worth of a feature gene by computing the value of the t-statistic between toxic and non-toxic classes (Thomas *et al.*, 2001; Tsai, Chen and Chen, 2003).
2. ReliefF: This is a feature-weighting algorithm sensitive to feature interactions. The key idea of ReliefF is to rate features according to how well their values distinguish among instances of different classes and how well they cluster instances of the same class (Kononenko, 1994). To this end, ReliefF repeatedly chooses a single instance at random from the data, and then locates the nearest instances of the same class and the nearest instances pertaining to different

classes. The feature values of these instances are used to update the scores for each feature.

3. Correlation-based feature selection (CFS): This method evaluates a subset of features by considering the individual predictive ability of each feature as well as the degree of redundancy among them (Hall, 2000),

$$\mathrm{CFS} = \frac{k\bar{\tau}_{cf}\, f}{\sqrt{k + k(k-1)\bar{\tau}_{ff}}} \qquad (1)$$

where CFS is the score of a feature subset containing k features, $\bar{\tau}_{cf}$ is the average of the correlation coefficients between features and classes, and $\bar{\tau}_{ff}$ is the average intercorrelation among features of the subset.

5.2 Wrapper Methods

Wrapper approaches to gene selection evaluate the prediction performance of a learning machine trained for each given feature subset using a search algorithm to explore possible combinations of features. The strategy of wrapper approaches is composed of four steps (Figure 1b):

1. Choose a machine-learning algorithm to evaluate the prediction score of a feature subset. Many machine-learning algorithms have been developed, including the Naïve Bayes classifier, linear discriminant methods, support vector machines (SVM) (Vapnik, 1998), and artificial neural networks (Bishop, 1995). Cross-validation (CV) is often used for scoring prediction performance.
2. Choose a search algorithm.
3. Perform the search algorithm and note the best subset encountered.
4. Output the encountered subset with the best score.

Search algorithms compare all possible feature combinations, which are usually too numerous to be exhaustively explored. Of these search methods, greedy methods (forward selection or backward elimination) are the most popular. At each round of CV, forward selection adds the best feature; backward elimination deletes the worst feature.

5.3 Recursive Feature Elimination with Support Vector Machine (RFE-SVM)

This is a type of wrapper algorithm that couples recursive feature elimination with linear SVM (Guyon *et al.*, 2002). In a linear SVM, the decision function (classifier) is given as $f(\boldsymbol{x}) = \boldsymbol{w}^{\mathrm{T}}\boldsymbol{x} + b$ or $f(\boldsymbol{x}) = \sum_{k=1}^{n} w_{\mathrm{k}} x_{\mathrm{k}} + b$. For a given feature x_{k}, the absolute value of its weight w_{k} indicates the significance of its contribution to the margin of the linear SVM and to the construction of a linear classifier. Hence, the weight w_{k} is used as a feature-ranking coefficient in RFE-SVM. This algorithm first constructs a linear SVM classifier from the microarray data with n genes; then, the gene with the lowest w_{k}^2 is removed and another classifier is trained on the remaining $n-1$ genes. This process is repeated until only one gene remains.

A gene ranking is produced from the order in which the genes were eliminated, and the last remaining gene is the most relevant gene. However, because of computational cost considerations, the algorithm is often implemented in such a way that several features are reduced at once. In such implementations, the method produces a feature subset ranking instead of a feature ranking. The optimal signature genes are the gene sets with the best prediction performance throughout the elimination process.

5.4 Filter Approaches Versus Wrapper Approaches

The filter methods are useful in practice because they are much faster than wrapper methods. Filters exclude irrelevant genes but cannot remove redundant genes because methods that select important genes based on individual gene information fail to account for mutual information among genes. The problem of redundancy among selected genes is twofold: the selected gene set may less comprehensively represent the target class than one of the same size without redundant genes would and in including all representative genes, redundant genes unnecessarily increase the size of the selected gene set, which will in turn affect the mining performance of the small sample.

In contrast, wrapper methods were developed to select discriminative genes while decreasing gene

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat235
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

redundancy. In theory, the wrapper model should provide more accurate classification results than the filter model (Langley, 1994). Wrappers use classifiers to estimate the usefulness of feature subsets. The use of optimal feature subsets should provide corresponding classifiers with better classification accuracy because the features are selected according to their contribution to the classification accuracy of the classifiers. The disadvantage of the wrapper approach is its computational expense because the classifier must be repeatedly constructed to evaluate a subset during the CV process. Moreover, wrapper-type feature selection is sensitive to training data and runs the risk of over-fitting, leading to a lack of robustness in the selected gene set.

6 ROBUSTNESS OF THE SELECTED GENE LIST

Although many methods have been developed for conducting feature selection on microarrays, these selection methods produce selected gene lists that are insufficiently robust. If the predictor developed with one selected gene set would work well on data from other studies, then we would not have had to worry about list diversity. However, a lack of transferability of predictive power is often observed as a result of the same reason that causes instability of gene lists. Ein-Dor, Zuk and Domany 2006 found that the gene lists developed from microarrays using different methods in prognostic cancer studies differ significantly, even for different subsets of the same microarray data sets. They concluded that thousands of samples are needed for robust gene selection. As generating a more stable gene list will lead to more robust predictors, we must evaluate not only prediction performance but also the robustness of gene sets in feature gene selection. Assessing the stability of selected gene lists is crucial to guarantee their controlled and reliable utilization.

7 APPLICATION OF FILTER AND WRAPPER METHODS TO DIAGNOSTICS OF DRUG TOXICITY USING TOXICOGENOMICS DATA

Our previous study on concurrent diagnosis of drug-induced tubular injury using TGP data demonstrates the application of filter- and wrapper-type methods (Kondo *et al*., 2009). Drug-induced renal tubular injury is a major concern in pre-clinical safety evaluations. In this study, we analyzed 33 nephrotoxicants and eight non-nephrotoxic hepatotoxicants to elucidate time- and dose-dependent global gene expression changes associated with proximal tubular toxicity. The compounds were administered orally or intravenously once daily to male Sprague–Dawley rats. The animals were exposed to four different doses of the compounds, and kidney tissues were collected on days 4, 8, 15, and 29. High-dose groups of 23 compounds that caused necrosis, degeneration, or regeneration in the renal tubules during chronic exposure were defined as the positive set (other high-dose groups of 10 nephrotoxicants were used as the external test set). Low-dose groups of all 41 compounds and high-dose groups of the eight hepatotoxicants that had no histopathological findings were defined as the negative set. To perform supervised classification algorithms after selecting differentially expressed genes, the microarray samples treated with nephrotoxicants and hepatotoxicants were divided into positives and negatives of the training set according to their histopathological findings.

Both filter- and wrapper-type gene selection algorithms with SVM-learning algorithms were used to extract biomarker candidates and construct classifiers using the selected genes. RFE methods were used for the wrapper-type gene selection algorithms and intensity-based moderated *t*-statistics (IBMT; Sartor *et al*., 2006) was used as a filter-type gene selection algorithm (SVM was used as the classifier in this case).

Fivefold CV was executed for optimization of the classifiers and to calculate their prediction accuracies. First, the whole positive and negative training data sets were randomly divided into five subsets of roughly equal size. The SVM was trained with a selection of optimal genes on four subsets and then applied to the fifth subset as the test data set. Before the SVM was trained, optimal genes were selected from the training sets with both RFE-SVM and IBMT-SVM. The 99 top-ranked genes from each selection strategy were used to construct the classifiers. The prediction model using the top-ranked 99 feature genes exhibited saturated prediction performance (Figures 2 and 3). Thus, by tracing the prediction performance of each constructed classifier for the test sets, we determined an appropriate

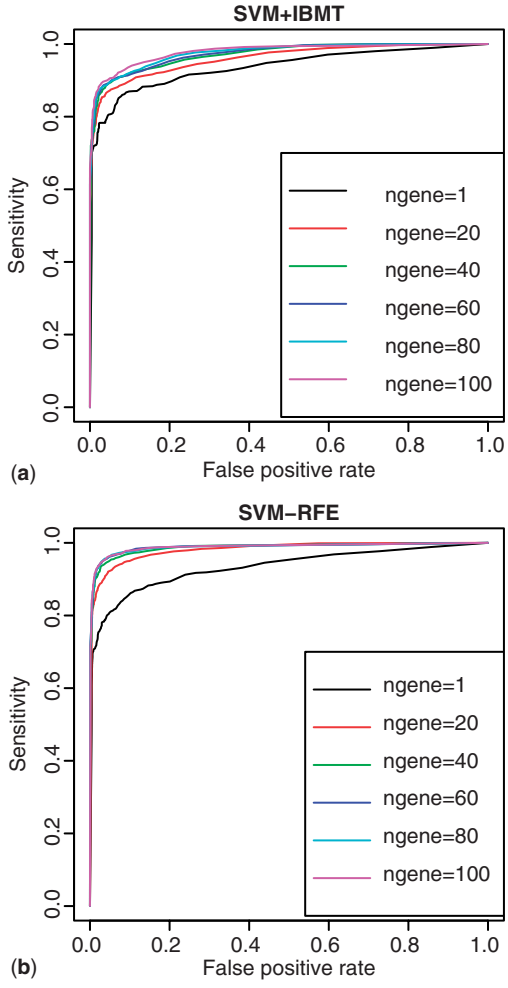

Figure 2. Receiver operating characteristic (ROC) curves for feature gene subsets selected using SVM-IBMT (a) and SVM-RFE (b).

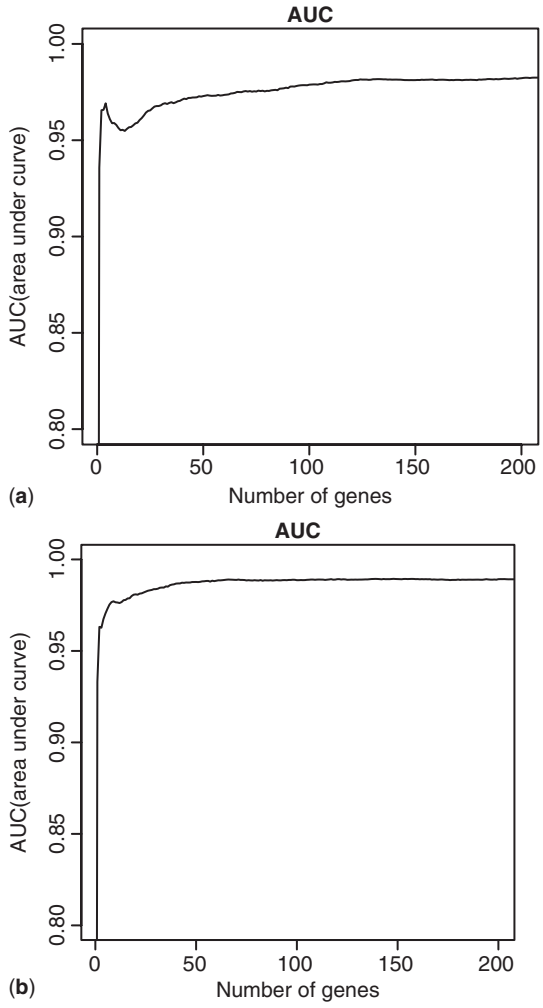

Figure 3. Area under curves (AUC) of the ROC curves by SVM-IBMT (a) and SVM-RFE (b), along with the number of selected feature genes.

threshold number of feature genes, which is one of the challenges in executing search algorithms.

As the result of fivefold CV, we determined the sensitivity of each classifier to be 94% (RFE-SVM; 99 probes) and 93.8% (IBMT-SVM; 99 probes), when we allowed for 10% false positives (Figure 2). Although SVM-RFE exhibited the higher classification accuracy, as we expected, the concordance rate of the feature gene list selected by RFE between the subtraining sets of fivefold CV was lower than that of the filter-type IBMT-SVM (Figure 4). The difference in concordance rate indicates that the RFE-SVM classifier may have over-fitted to the training set, resulting in an insufficiently robust list of biomarkers. In contrast, the feature genes selected by IBMT-SVM were stable between different training data sets generated through fivefold CV. As noted above, in addition to the prediction performance of the constructed classifier, the robustness (stability) of the selected gene sets is critical to successful feature selection. Therefore, in this case using TGP kidney data sets, we concluded that the filter-type IBMT-SVM method was the preferable gene selection and classification algorithm.

Consequently, we determined the appropriate maker gene set using the following criteria: (a) the prediction accuracy was saturated (Figure 3); (b) the

number of support vectors was adequately low (an excessive number of support vectors could indicate over-fitting of the linear SVM classifier) (Figure 5), and (c) the number of feature genes was substantially lower than the number of samples, to avoid over-fitting.

Also, the selected gene list contained enough key genes to interpret their biological relevance in drug-induced renal tubular injury. The gene list contained well-known biomarkers, such as kidney injury molecule 1, ceruloplasmin, clusterin, and tissue inhibitor of metallopeptidase 1, as well as novel biomarker candidates. Most of the genes involved in tissue remodeling, immune/inflammatory response, cell adhesion/proliferation/migration, and metabolism were predominantly up-regulated. Down-regulated genes participated in cell adhesion/proliferation/migration, membrane transport, and signal transduction. This indicates that the gene list provides us with elaborate knowledge about mechanistic toxicology.

8 CONCLUSIONS

Selecting a small gene set from large microarray data sets is critical from both biological and computational viewpoints, and many algorithms have been developed for feature selection. Most studies on feature selection have found that wrapper methods are superior to filter methods, but many of these studies have over-emphasized prediction accuracy and over-looked the robustness of the selected genes. Prediction reliability assumes the stability of the model. In fact, this study illustrates that IBMT-SVM produces more stable gene lists than RFE-SVM. This finding is adaptable to only this training set. In the case of other training sets, we must evaluate multiple methods and choose the best approach. Therefore, we have to carefully gauge not only prediction performance but also the robustness of gene sets in feature gene selection.

1 INTRODUCTION

An individual starts off as a single cell, the progeny of which form complex structures that are themselves integrated into progressively larger systems. Developmental biology is concerned with how this cellular complexity and patterning arises through orchestration of cell divisions, cell migrations, cell interactions, cell death, gene regulation, and differentiation. Any agent interfering with these cellular processes can potentially invoke adverse effects on pregnancy outcome leading to miscarriage, low birth weight, structural malformations, and functional deficits. Windows of vulnerability open and close that render the embryo more or less susceptible to drug and chemical exposure at different times and locations. Developmental toxicology is concerned with understanding these underlying genetic and environmental influences and assessing the health risks from prenatal exposure to drugs and chemicals.

Formal testing of drugs and chemicals for developmental toxicity began following thalidomide, a drug prescribed for morning sickness that went on the market in 1958. In 1961, reports began to appear of children born with a rare limb reduction syndrome (phocomelia) increasing to over 10 000 cases worldwide. Association of these cases with maternal intake of thalidomide led to the establishment of federal guidelines for pre-clinical testing to evaluate reproductive and/or developmental toxicity for compounds regulated by the Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA). The conventional testing paradigm for prenatal safety assessment has since been in use for over 30 years and involves gestational exposure of pregnant dams of two species, usually rats and rabbits, during organogenesis and evaluation of fetal and maternal effects near term (Kimmel, Kimmel and Euling, 2006). The necessity for one rodent and one non-rodent test species was specifically demonstrated in this case; whereas rats displayed systemic toxicity with Thalidomide *in utero*, rabbits exhibited phocomelia, the common human side-effect.

Dozens of compounds that potentially disrupt development in animals and humans have been cataloged over the years (Shepard and Lemire, 2007). Unfortunately, we lack developmental toxicity data for most of the >80 000 chemical compounds to which humans may be exposed (Hartung, 2009). Assessing health risks to the various chemicals alone or in combination is an immense challenge that, under present methods, is hardly tenable. Priorities must be set, leading to an urgent need for strategies to more efficiently test chemicals for a potential risk to human populations. This has led to the critical evaluation of our testing strategy and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat236

in particular the role of conventional *in vivo* animal studies, newer exposure metrics, structure–activity relationship (SAR) models, and high-throughput *in vitro* profiling of chemicals for biological activity.

Toward this end, large-scale efforts are underway to address the data gaps using industrial-scale methods for chemical screening and prioritization, coupled with innovative computational approaches for predictive modeling of human toxicology. The national importance of this effort is evidenced by "Toxicity Testing for the 21st century" (Tox21), a federal consortium between the EPA, National Chemical Genomics Center (NCGC) of NIH, the National Toxicology Program (Collins, Gray and Bucher, 2008) and more recently the FDA. The challenge is significant to generate data in a high-throughput mode and integrate these data into predictive models that can be used to assess *in vivo* toxicity. The vision for toxicology in the twenty-first century (NRC, 2007; Collins, Gray and Bucher, 2008) and its adaptation by EPA for a future toxicity testing strategy (Firestone *et al.*, 2010) draws attention to the current need for a computational framework that can be used to evaluate environmental chemicals based on data from human cell cultures, alternative model organisms, high-throughput testing and systems modeling. This research is in its infancy but holds promise for applications such as identification of potentially toxic chemicals during new product development, prioritization of existing chemical compounds for targeted *in vivo* testing, characterization of chemical targets leading to traditional end-points of toxicity, and pathway-based evaluations of pathogenesis. For all of these reasons, a shift from conventional end-point-based toxicology, where animal models are used to evaluate outcome, to high-throughput chemical biology requires a systems biology approach to integrate all of the toxicological data and biological concepts. This chapter addresses some of the key issues and questions for systems-based approaches in understanding developmental toxicity within the context of this new testing paradigm for environmental chemicals.

2 SCALE OF THE PROBLEM

Environmental chemicals are natural and man-made compounds to which human populations are continually exposed as a matter of individual lifestyle, local geography and community life. The Centers for Disease Control and Prevention (CDC) National Health and Nutrition Examination Survey (NHANES) samples the US population every 2 years to determine which chemicals get into people and at what concentrations (CDC, 2009). The most recent NHANES measured 212 environmental chemicals in blood or urine. Human populations are, however, likely exposed to many more chemicals and even more compounds are synthesized on a daily basis. At least some of these chemicals would be expected to have the potential for adverse developmental consequences if exposure occurs during intrauterine life. EPA's Toxicity Reference Database (ToxRefDB) identified developmental effects relative to maternal toxicity on 53 out of 283 (18.7%) environmental chemicals studied in pregnant rats or rabbits (Knudsen *et al.*, 2009). Developmental or reproductive effects data are available for less than 12% of about 3800 chemicals listed in public databases from the NTP and FDA's Center for Drug Evaluation and Research (CDER) and Center for Food Safety and Nutrition (CFSAN). One of the largest data compilations from multiple resources to date, EPA's Aggregated Toxicology Resource (ACToR), points to any developmental toxicity data, complete or otherwise, for less than 30% of 9912 chemicals in commerce or of relevant environmental interest (Judson *et al.*, 2009). Although the conventional testing paradigm provides qualitative data that are rich in contextual detail and generally regarded as predictive of effects in human pregnancy, it does not scale to the problem of assessing human developmental safety for the $>80\,000$ chemical compounds in commerce or in the environment.

Paucity of relevant data leads to considerable uncertainty that must be accounted for when conducting a risk assessment. EPA's Integrated Risk Information System (IRIS) identifies the 'critical effect' as the basis for setting safe-exposure levels on environmental chemicals to protect public health. Criticality is defined as the first 'observed' effect deemed adverse that is likely to occur in the most sensitive human subpopulation as the dose rate of an agent increases. As of this writing, less than 2% of 533 IRIS assessments report the critical effect for the derivation of a non-cancer reference value (i.e., a safe-exposure level) as being a developmental (five out of 553) or reproductive (four out of 553) effect (http://www.epa.gov/IRIS/). Increased uncertainty in the choice of the critical effect for an IRIS assessment because of inadequate or insufficient

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat236
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

bioassay data is accounted for quantitatively by a database uncertainty factor (UF-D) that when greater than 1 further reduces the safe-exposure values EPAderives to protect public health (e.g., the reference dose (RfD) or reference concentration (RfC)). Many of the older IRIS assessments had only a qualitative rating on the confidence in the database, instead of a UF-D. In these older assessments, a designation of low or medium confidence was often caused by missing reproductive or developmental studies. For assessments where a UF-D was used, a search of the IRIS database resulted in 136 reference values (for 120 out of the 553 chemicals) that had been reduced by a UF-D > 1 as a result of insufficient data. An absence of reproductive or developmental effects data was the sole or major contributing factor for 85% of these higher UF-Ds > 1 (115 out of the 136). To reduce this source of uncertainty and identify potentially sensitive reproductive or developmental targets, a more precise and efficient testing strategy is needed to replace the resource-intensive conventional bioassay approach. Although this low percentage is in part caused by other effects being more sensitive, there is considerable uncertainty in the choice of the critical effect for a number of chemicals because of a lack of developmental and/or reproductive effects data.

The challenge of assessing the potential health risks from 10 000 chemical compounds in Tox21 and 30 000 chemicals under European Registration, Evaluation, and Authorization of Chemicals (REACH) legislation is a significant problem. If, for example, one out of six chemical compounds display adverse developmental activity in conventional testing studies then developmental effects data would be critical for some 1667–5000 chemicals of the broader 10 K–30 K chemical landscape. Because the scope of the toxicity testing problem is too vast to address without a systematic approach to chemical screening and prioritization, high-throughput approaches are needed that can scale to the problem, as well as innovative computational tools for data management, analysis and inference.

3 SCALING TECHNOLOGY TO MEET THE PROBLEM

In 2007, a committee of the National Research Council (NRC) proposed a new vision for toxicity testing in which biologically important perturbations to key toxicity pathways would be evaluated using newer methods in molecular biology, bioinformatics, computational toxicology, and *in vitro* tests based primarily on human biology (NRC, 2007). This new paradigm shifts emphasis from apical end-points of toxicity assessed in conventional *in vivo* studies to *in vitro* profiling, prescribing that profiles of biological activity be used in conjunction with available environmental exposure and human epidemiology data to prioritize chemicals for subsequent evaluation in more targeted animal bioassays. The new paradigm is based on high-content screening (HCS) that arose from revolutionary advances in the genome sciences, enabling parallelized analysis of cellular and molecular features. Together with fast, automated technologies such as high-throughput screening (HTS) of compound libraries (originally developed for drug discovery), *in vitro* profiles are being generated for the biological activity of an increasing number of chemicals, and are being interpreted to predict potential toxicity *in vivo* (Figure 1).

A number of programs are applying HTS–HCS technologies for rapid screening of chemical libraries (thousands of unique structures) for specific molecular pathway and cellular function activity. The NCGC, for example, has the HTS capacity to screen an approximately 100 000 compound chemical library daily in a given specific assay. EPA's ToxCast^{TM} project initially generated rich sets of HTS–HCS data on 309 chemicals across 467 assays (phase I), using chemicals most of which already had extensive animal bioassay data to assess potential toxicity (Judson *et al.*, 2010). In phase II, ToxCast^{TM} is evaluating another $\sim$700 additional chemicals across approximately 500 assays, in this case for chemicals with limited or no pre-existing animal toxicity data as well as several dozens of pharmaceutical compounds that failed for toxicity in human clinical trials (http://www.epa.gov/ncct/toxcast/). The Tox21 program will test $\sim$10 000 chemicals across a few dozen assays (Schmidt, 2009). As such, the new testing paradigm will generate vast amounts of data that can be used to profile the bioactivity of hundreds to thousands of environmental chemicals across multiple pathways of biological activity, thus implementing the NRC vision for the future of toxicity testing (NRC, 2010).

Along with a promising potential for improved human health and disease prevention, the new testing paradigm shifts the focus from an end-point-based risk assessment to a toxicity pathway-based

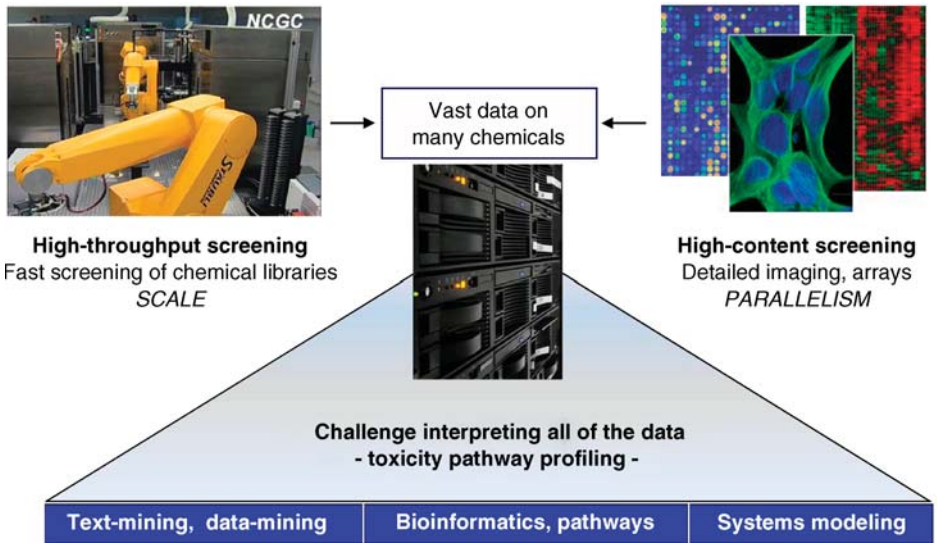

Figure 1. The HTS–HCS paradigm applied to toxicity testing. Applying the HTS–HCS paradigm to toxicity testing turns the drug-discovery process on its side. Rather than starting from a well-defined cellular activity and identifying the targeted chemical biology, compounds of unknown or suspected human toxicity are tested through hundreds of *in vitro* assays. Computers are then used to unlock patterns of biological activity from across the chemical-assay space. Using text-mining tools and bioinformatics, diagnostic signatures are used as the basis to incorporate pathway-level information and predict potential *in vivo* toxicities. This effort, combined with vast biological knowledge, can guide plausibility of biological interpretation to inform testing and hypothesis generation.

risk assessment, and has raised important questions and challenges for researchers. First, the HTS testing paradigm derives primary data from *in vitro* assays intended to coarsely screen compound libraries for biological activity. HTS assay platforms can provide high-quality concentration–response data, although interpreting the significance of a "hit" versus "no-hit" depends on rules that may not easily extrapolate to *in vivo* systems. For example, curve-fitting to *in vitro* concentration–response results can identify the lowest effect concentration (LEC) at which the *in vitro* activity is detected and the concentration at which measured activity has been inhibited or stimulated by 50% (AC50). This can inform design of new *in vivo* or *in vitro* experiments aiming to validate the prediction and the efficacy for a therapeutic or adverse response *in vivo*. Incorporating *in vitro* LEC and AC50 values derived from HTS–HCS data into predictive models of developmental toxicity, however, requires an accounting for, and integration of, higher-order functions that arise in metabolic pathways, signaling pathways or biological networks. This also gives rise to the problem of multiplicity (one-to-many). For example, in the ToxCast^{TM} phase-I results, there were numerous cases where one chemical hit many assay targets (Judson *et al.*, 2010). Because of this complexity, the individual HTS assay target data must be assembled and interpreted within the context of broader pathways and systems level understanding of the biology. In the context of embryogenesis, this means building predictive models that can account for robustness of the developing embryo to genetic or environmental variation resulting from system-level interactions that effectively dampen dynamic response (canalization) or from compensation (adaptive response).

Second, the HTS testing paradigm draws information from assays designed to rapidly screen compound libraries for specific biological activities. As such, the assays must be amenable to high-throughput methods, use of dimethyl sulfoxide (DMSO) as a vehicle, and some degree of automation for measurements. In ToxCast^{TM}, for example, the 467 phase-I assays tested various cell-free extracts (239) and differentiated cells or cell lines (228) mostly of human origin (Dix *et al.*, 2007; Judson *et al.*, 2010). In most cases, target-level responses infer perturbations to the integrity or function of a specific receptor, enzyme, transporter, or cellular feature as measured in a cell-free (biochemical), cell-based (simple culture), or multicellular

(complex culture) platform. Results of these studies have begun to classify pairs of chemicals and their respective toxicity targets based on the assay(s) hit and their pathway-level relationships. The *in vitro* results, however, do not account for *in vivo* chemical disposition, so toxicokinetics and delivery of the chemical to *in vivo* targets at comparable dose levels must also be considered to predict *in vivo* effects.

Third, many HTS assays represent disassembled biological systems that may or may not reflect key events in embryogenesis. One alternative model of embryonic development that is amenable to medium- or HTS is the embryonic stem-cell test (EST). This platform has been approved by the European Centre for Validating Alternative Methods (ECVAM) for developmental toxicity testing. It is configured by embryonic cells that undergo morphogenetic signaling and cellular network responses and was validated using a test panel of 20 compounds categorized as non-, weak, or strongly embryotoxic (Genschow *et al.*, 2002). The ECVAM-approved assay uses mouse embryonic stem (mES) cells where LIF-maintained mES cells are grown through nascent 'embryoid bodies' and scored for beating cardiomyocytes, after being exposed to drugs or chemicals for 5–10 days. Effects on cardiomyogenic differentiation correctly resolved 78% of the 20 chemicals into non-embryotoxic or strong embryotoxic categories (Genschow *et al.*, 2002; Chapin *et al.*, 2008). Incorporating gene expression data into the ES cell assay has been shown to improve the predictivity and applicability domain required to facilitate implementation of these findings into regulatory testing strategies (van Dartel *et al.*, 2010). These investigators recently defined a 'differentiation track' based on 26 genes that correlated with the developmental toxicity of several reference compounds. A human ES (hES) cell metabolomic platform has also been introduced recently to evaluate changes in small molecules and metabolites secreted into the hES cell-culture medium (West *et al.*, 2010). This work showed a correlation between embryoid body formation and changes in the secretome ratio of arginine: dimethylarginine, reflecting imbalances in the urea cycle. Changes in the ratio >10% preceded cytotoxicity, but correlated to embryotoxicity with an accuracy of 88%.

Fourth, apart from advantages in assessing differentiation, HTS systems such as the ES cell platform cannot fully replicate the topological changes in key events that may contribute to a disruption of human development. The *in vivo* dose–response may differ from the ES cell platform dose–response caused by *in vivo* kinetics (ADME: absorption, distribution, metabolism, excretion) affecting the chemical delivery to the comparable maternal or conceptal targets (i.e., dose delivery differences), or to the dynamics of the integrated cellular systems or cell derivatives that are not represented *in vitro*. Placental transport mechanisms and fetal dosimetry are poorly represented, if at all. Methods are also needed to extrapolate risk from dose levels associated with toxicity *in vitro* to estimates of the potential toxicity from low-dose environmental exposures.

Free-living zebrafish (ZF) embryos recapitulate most signaling systems and pathways found in mammalian embryos. In this assay, embryos are exposed to a test solution from 4 to 6 h post-fertilization (pf) and assessed up to 5 days pf for perturbations in embryo structure and function. One study reported an 87% correct prediction of 31 test agents for teratogenic versus non-teratogenic based on LD50 values (Brannen *et al.*, 2010). Among the advantages of ZF models is amenability to genetic methods and cell imaging, which together offer a means to image cellular dynamics during morphogenesis and to digitally reconstruct embryogenesis (Keller *et al.*, 2008). The two main shortcomings of this assay are the lack of pharmacokinetics and species differences (e.g., lack of placentation and pulmonary systems, fin rather than limb development). These factors make it difficult to predict how a compound of unknown or suspected toxicity will behave in a pregnant woman or laboratory animal.

In conclusion, alternative testing methods are promising but in early work have met with mixed results (Chapin *et al.*, 2008). Many developmental effect assays have drawbacks or introduce uncertainties caused by kinetic and dynamic species differences, differences in the complexity of the system (i.e., *in vitro* and *in vivo*), incomplete understanding of mechanisms and signaling crosstalk in a complex developing system, such as the potential for maternal effects and metabolic activation, or uncertainty in extrapolating from high-dose response to the low-dose response of interest when predicting potential for human toxicity (Daston, 2007). The capacity to predict dose-dependent toxicity in alternative HTS models of embryonic development would greatly aid risk assessment and chemical prioritization for further animal testing

(NRC, 2007); however, modeling the HTS data into higher-order functions and control of cellular behaviors (e.g., growth, death, migration) and signaling (e.g., metabolic pathways, signal transduction pathways, gene regulatory networks) is a significant challenge, and must be conducted within the context of normal embryogenesis (Davidson *et al*., 2002) to simulate the key events leading to adverse pregnancy outcome. Both the ES cell and ZF embryo assay systems have potential applicability in this regard and are approved by ECVAM as alternative models for developmental toxicity testing. These two assays have been recently introduced to the ToxCast^{TM} assay panel (Chandler *et al.*, 2010a; Padilla *et al.*, 2010a).

4 COMPUTATIONAL PROFILING OF APICAL END-POINTS

The potential of an environmental chemical to cause adverse effects in the developing embryo or fetus is an important consideration in any health-risk assessment (Gad, 2002; Janer *et al*., 2008). EPA's guidelines for developmental toxicity risk assessment (FRL-4038-3, December 5, 1991) are recorded in the Federal Register 56(234):63798-63826 and were updated in a 1998 workshop (SAP Report No. 99-01C, January 22, 1999). The guidelines state that when experimental data are evaluated, "the agents causing human developmental toxicity in almost all cases were found to produce effects in experimental animal studies and, in at least one species tested, types of effects similar to those in humans were generally seen." When animal bioassay data are available, a number of EPA risk assessments report significant developmental effects in some cases at dose levels within an order of magnitude of the endpoint selected as the critical effect (e.g., acrylamide). Sampling of a subset of 43 toxicological reviews from the IRIS assessment database (http://www.epa.gov/iris) having developmental and/or reproductive effects data resulted in 12 cases (28%) reporting significant adverse developmental effects such as altered birth weight, skeletal variations, neurodevelopmental defects, altered maternal or postnatal weight gains in reproductive organs, or testicular lesions. One might expect that assays focusing on mechanisms or precursor events to observed lesions would detect significant developmental effects at lower exposure levels.

Databases of birth-defect registries (Scheuerle and Tilson 2002; Correa-Villaseñor *et al.*, 2003), prenatal animal studies (Hurtt, Cappon and Browning, 2003; Chernoff *et al*., 2008), and developmental toxicology literature (Julien *et al*., 2004; Matthews *et al*., 2007) have generally attempted to uncover relationships within classes of chemical compounds for developmental effects in laboratory mammals or human populations, rather than profiling developmental effects and mechanisms over a larger chemical space. An internationally harmonized nomenclature designed to standardize the description and classification of such apical end-points (Makris *et al*., 2009) can facilitate registration and aggregation of external abnormalities, visceral abnormalities and skeletal abnormalities during fetal examination of rats, rabbits and mice. This is an important annotation system for profiling developmental toxicity because it enables a computational approach to classifying chemical–target (*in vitro* profiling) and chemical–end-point (*in vivo* profiling) relationships.

In the ToxCast^{TM} project, *in vitro* profiling focused initially on 309 chemicals in phase I, most of which have high-quality and uniformly generated *in vivo* toxicity data. This information has been annotated by a controlled vocabulary in EPA's ToxRefDB. The database, developed at EPA's National Center for Computational Toxicology in partnership with the Office of Pesticide Programs, holds source data from 2073 guideline studies on 480 chemicals, mostly pesticides and antimicrobials, putting 30 years of animal testing bioassays worth >$2B from registrant-submitted toxicology study results as data evaluation records (DERs) into a computable form. The database is the first implementation of its kind for profiling the activity of environmental chemicals based on a comprehensive analysis of source data for a broad range of endpoints relevant to EPA risk assessments, such as chronic cancer studies in mouse and rat (Martin *et al*., 2009a), multigenerational reproductive studies in rat (Martin *et al*., 2009b), and prenatal developmental toxicity studies mostly in rats and rabbits (Knudsen *et al*., 2009). The database and web interface was released to the public in spring 2010 and is accessible online at http://actor.epa.gov/toxrefdb.

ToxRefDB includes 751 prenatal studies on 387 chemicals. A controlled vocabulary of 988 harmonized terms were used to input developmental

effects data, finding 293 end-points across these studies and collapsing them into 18 target embryonic systems. The analysis revealed a spectrum of chemical activity based on administered dose, sometimes broadly active and other times narrowly active. Among the 283 chemicals tested in both pregnant rats and rabbits, the primary expressions of developmental toxicity differed between species. Fetal weight reduction, skeletal variations and abnormalities, and urogenital defects were more frequently noted in rat studies, whereas resorption-pregnancy loss was more common in the rabbit studies as were structural malformations to the visceral body wall and central nervous system (Knudsen *et al*., 2009). ToxRefDB resolved these chemicals into several clusters based on developmental effects noted in rat and/or rabbit studies (Figure 2).

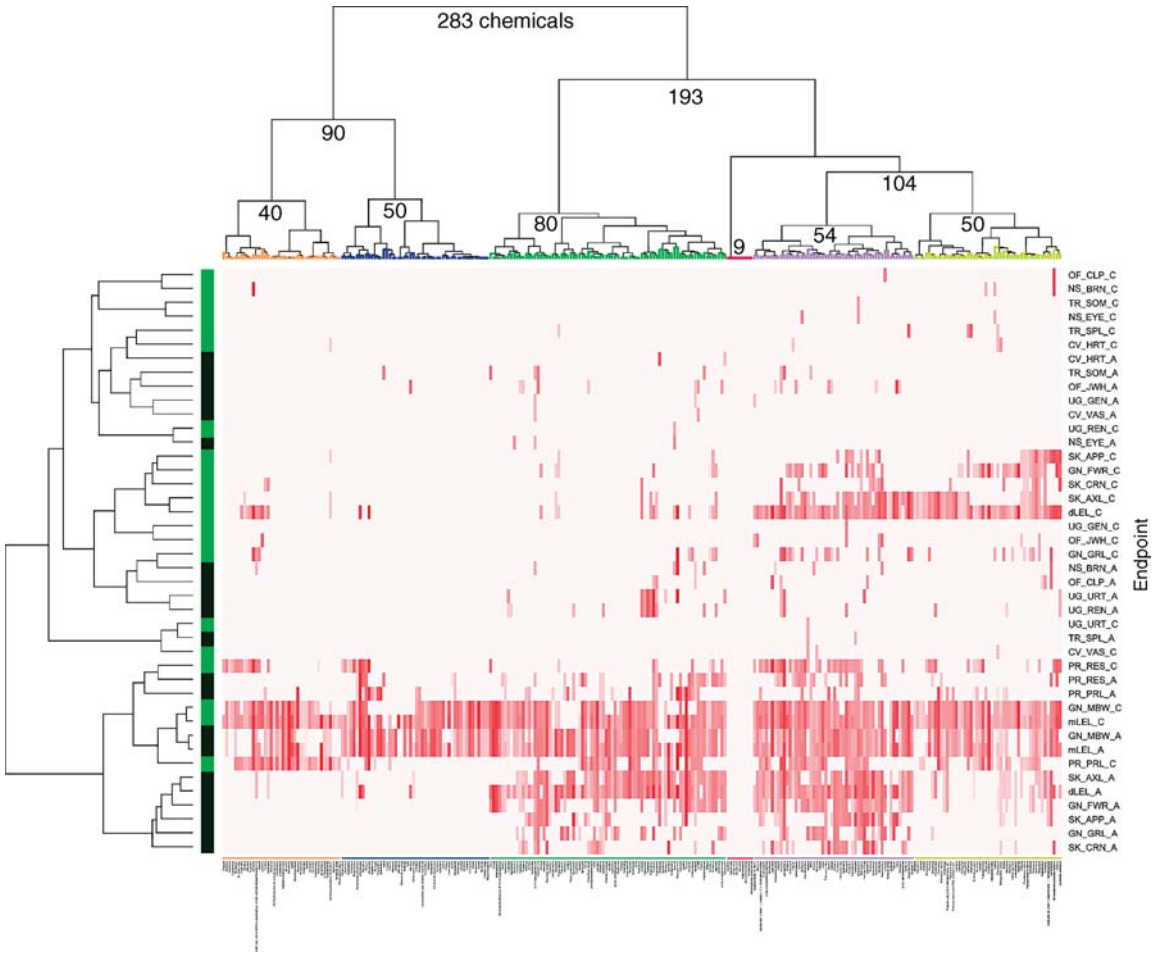

Figure 2. Hierarchical relationship of ToxRefDB chemicals to developmental effects. Chemicals (columns) by effects (rows) for 283 chemicals with developmental activity tested in rat (A, dark green ribbon) and rabbit (C, light green ribbon). Hierarchical clustering was performed by Pearson's correlation and Ward linkage; color intensity reflects potency of a chemical–end-point response based on administered dosage. Variables are maternal LEL (mLEL), developmental LEL (dLEL), and categorical LELs (cLEL) grouped by system: cardiovascular (CV), general (GN), neurosensory (NS), orofacial (OF), pregnancy-related (PR), skeletal (SK), trunk (TR), and urogenital (UG). Abbreviations for specific effects targets: reduced maternal body weight gain (MBW), fetal weight reduction (FWR), maternal-pregnancy losses (PRL), embryo-fetal losses (RES), general fetal pathology (GRL); skeletal defects – axial (AXL), appendicular (APP), cranial (CRN); orofacial defects – cleft lip/palate (CLP), altered jaw/hyoid bone (JWH); defects of the fetal brain (BRN) and eye (EYE); renal (REN), ureteric (URT), genital (GEN); body wall defects (SOM) and abnormal splanchnic viscera (SPL); heart (HRT) and major vessels (VAS) (from Knudsen *et al.*, 2009, © Elsevier, reproduced by kind permission of Elsevier.)

Although species differences as observed for rat and rabbit are important to developmental profiling, the primary risk-assessment objective is to determine concordance between animal-testing and human response. Unfortunately, information on human developmental toxicity is not readily available for most of these environmental chemicals. As noted earlier, phase-II of ToxCast™ will add responses of chemical compounds with less-characterized animal toxicity, and will also include several dozen failed pharmaceuticals. Some studies have addressed animal–human concordance for pharmaceuticals where a good deal of human data is available. A retrospective analysis of several hundred pharmaceuticals tested in both rodent and non-rodent species for general toxicological end-points, reported an overall 71% concordance with true positives in human populations; however, the concordance was lower when non-rodents (63%) and rodents (43%) were considered separately (Olson *et al.*, 2000). With regards to developmental toxicity testing, rat studies detected a signal in 61% of chemicals that showed teratogenic effects in rat, mouse or rabbit studies whereas a rat study and a rabbit study together identified teratogenicity in 100% of these chemicals (Hurtt, Cappon and Browning, 2003). Correlations with teratogenicity in humans for these compounds, however, were unattainable. These findings support a formal laboratory animal-testing procedure in a rodent and non-rodent species for assessing fetal development, an approach that has been adopted since the thalidomide episode, and lend support to the use of systems such as ToxRefDB to anchor *in vitro* profiling data.

In current practice, the animal dose–response data are used to derive safe levels of exposure to humans rather than to predict a specific developmental phenotype in humans. Questions thus arise as to the added value to regulatory agendas of a second test animal species when consideration is given to all four manifestations of developmental toxicity (malformations, resorptions, low-birth weight, and functional deficits), to consequences of maternal toxicity, and to standardized study designs. Resorptions may correlate with malformations, functional deficits may correlate with low birth weight, and all four kinds of developmental defects may result from maternal toxicity with rabbits being somewhat more susceptible than rats (Guittina *et al.*, 2000; Chernoff *et al.*, 2008; Piersma *et al.*, 2008). Piersma and coworkers at the National Institute for Public Health and the Environment of the Netherlands (RIVM) conducted a retrospective analysis to assess the added value of a rabbit developmental test when data from a rat developmental test were available. Both rat and rabbit studies were identified for a number of substances (drugs, chemicals) classified as developmental toxicants. Rat and rabbit studies showed similar sensitivity (NOAEL) and overall the authors did not find evidence that would require the rabbit as an additional test species (Janer *et al.*, 2008). Direct (mechanism) versus indirect (maternal) factors had a greater implication, as some substances induce developmental toxicity in one species at a dose that may induce maternal toxicity in another. From a system perspective, however, interspecies differences can lead to different apical end-points after exposure to the same chemical, even when the mechanism of action is identical (Janer *et al.*, 2008). Thus, one needs to consider whether the application of developmental profiling is for the purpose of predictive modeling or for regulatory decision-making.

Preliminary analysis of ToxCast™ HTS data revealed effects on multiple *in vitro* assays for molecular targets or cellular processes important to vasculogenesis and angiogenesis. A predictive signature built around statistical associations to *in vivo* developmental end-points derived from ToxRefDB revealed a strong correlation between developmental defects and a network of pathways consisting of pro-inflammatory/anti-angiogenic cytokine signaling, vascular endothelial growth factor (VEGF) signaling, and the plasminogen-activating system (PAS) network of enzymes and growth factors mediating matrix remodeling and local signaling during blood vessel growth. Furthermore, relatively robust patterns emerge from the *in vitro* profiling data linked to species-specific *in vivo* developmental toxicity in either rats or rabbits (Kleinstreuer *et al.*, 2010a).

The biological bases for species differences, maternal factors, and study designs are embedded in the principles of teratogenesis (Wilson, 1977). Paraphrased, the principles state that differential teratogenicity depends on: (i) *genotype*: the susceptibility of a developing organism is dependent on genetic makeup with respect to species, strain, or individual genotype; (ii) s*tage*: organ systems asynchronously traverse through critical periods of susceptibility; (iii) s*pecificity*: a wide-range of

initiating mechanisms converge to final limiting pathways of cellular pathogenesis; (iv) *bioavailability*: chemical nature is important to an agent's metabolism, availability to the embryo, and effects on maternal physiology; and (v) *dose–response*: manifestations of abnormal development increase in frequency and extent, from no effect level toward threshold effects and prenatal lethality.

A system-level understanding of development, facilitated by, and coupled with, technological advances in HTS–HCS presents us with a unique opportunity to understand Wilson's principles in a modern context. Many signaling pathways that are important for patterning embryonic growth and differentiation are highly conserved across species, from insects to mammals. Some of the best examples are transcription factors such as Pax6 (eye development), Nkx/tinman (heart development), Hox genes (axial patterning), and Hes1 (somite segmentation clock). In 2000, a committee of the National Research Council issued a report advocating the use of detailed knowledge about cell-signaling pathways to help elucidate mechanisms in developmental toxicity (NRC, 2000). That report compiled evidence for up to 17 canonical cell–cell signaling pathways and two stress response pathways based on conserved roles in animal development. The conserved pathways have been interrogated for quantitative dose–response activity of compounds in the mES cell assay (Chapin and Stedman, 2009). Several dozens of genes representative of key signaling pathways were shown to be disrupted by agents such as retinoic acid or BMP4 antagonists in a manner-dependent upon compound and dose. This indicates at least some conserved cell–cell signaling pathways may be disrupted by environmental exposure and furthermore points to the utility of a pathway-based analysis to identify key events associated with developmental signaling.

5 MODE OF ACTION PROCESSES

As HTS–HCS data are captured *in vitro* and applied *in vivo*, translation into practice will be predicated on two aspects of predictive modeling: mathematical association and biological plausibility. To assess risk to the developing embryo, one must establish a quantitative cause–effect relationship between dose and key events in the path towards an apical endpoint (also known as the mode of action, MoA). Because of the complex and cascading nature of signal–response pathways, for example, a local perturbation in cell-signaling detected in an HTS assay (cause) may result in multiple downstream consequences (effects) only some of which may lead to toxicity, others of which may not. Advanced knowledge of molecular embryology is therefore essential in determining how different signaling pathways interact with one another and how these pathways may govern divergent cellular behaviors during morphogenesis and differentiation. Models based on a system-level understanding can theoretically be useful to interpret the complex responses observed in HTS–HCS assays resulting from genetic errors or exposure to environmental contaminants, and serve as decision-support tools in the effort to predict risk for those critical perturbations that lead to toxicity in the developing embryo.

One way to decipher key events leading to developmental defects is to consider MoA processes, that is, the propagation of chemical lesions to higher levels of biological organization. Perhaps, the most widely exploited practice is genome-scale analysis of signaling pathways and gene networks. Toxicogenomics has become a standard approach to characterize changes in the embryonic transcriptome at critical times during developmental toxicity (Yu *et al.*, 2006; Daston, 2007; Knudsen and Kavlock, 2008; Knudsen and Daston, 2010). The sensitivity of gene expression profiling can reveal more about the potential effects of lower-dose exposure to harmful chemicals than has been possible using traditional techniques. For example, studies by Naciff *et al*. (2005) identified an estrogenic fingerprint of 66 genes in association with the uterotrophic response of rats to low-doses of ethynyl estradiol, bisphenol A, and genistein. This fingerprint was diagnostic of an effect by several weaker environmental estrogens (31 out of 66 genes were affected by diethylstilbesterol, 12 out of 66 genes by methoxychlor), as well as the lack of effect as a result of non-estrogenic chemicals (two out of 66 genes affected by cortisol; and 0 out of 66 genes affected by ethylenethiourea, propylthiouracil, or methimazole).

A genome-wide analysis of gene expression can also provide insight into the genetic basis of differential teratogenic susceptibility. Consider, for example, two closely related murine strains having differential sensitivity to alcohol induced Fetal Alcohol Syndrome (FAS). Gene expression profiles

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat236
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

were determined for the cranial neural folds of day 8 mouse embryos from strains at high risk (C57BL/6J) and low risk (C57BL/6N) for alcohol-induced craniofacial defects, eye defects, and fetal growth retardation (Green *et al*., 2007). This analysis, run 3.0 h after a maternal exposure below the threshold for teratogenesis, revealed a reprogramming of several metabolic, signaling and regulatory pathways, including pathways in tight junctions, focal adhesion, adherens junction, and cytoskeletal pathways all up-regulated in both strains; Wnt signaling and apoptosis pathways up-regulated in both strains; glycolysis and pentose phosphate pathways up-regulated in C57BL/6N only; and ribosomal proteins and proteasome pathways down-regulated in C57BL/6N only. These findings are consistent with the notion that developmental exposure to alcohol alters common signaling pathways linking receptor activation to cytoskeletal reorganization, and furthermore predict at the cellular scale a transition between adhesive and migratory states of precursor target cell subpopulations for high-risk and low-risk embryos, respectively (Green *et al*., 2007). Genes in the focal adhesion/actin cytoskeleton pathway were also shown to be up-regulated in monkey embryos during the early phase of thalidomide embryopathy in conjunction with pro-inflammatory/anti-angiogenic MoA processes (Ema *et al*. 2010).

Integrating these HCS data into predictive models for developmental toxicology can extend conventional testing approaches; however, we are at a relatively early stage in using them to understand MoA processes. Critical details may come from other kinds of assays and experimental designs. For example, Collins and coworkers used whole genome quantitative trait locus (QTL) scans to map the critical chromosomal region for differential susceptibility of two murine strains to 13-*cis* retinoic acid-induced forelimb ectrodactyly: C57BL/6N mice are susceptible to this induced phenotype whereas SWV mice are not (Lee *et al*., 2005). Results based on 88 *Mit*-markers revealed significant linkages to D11Mit39 and D4Mit170 on chromosomes 11 and 4, respectively. Multiple candidate genes could explain the strain differences, with the strongest being RARα and Wnt3/9b that map to the critical region for differential susceptibility on chromosome 11. Thus, a major challenge is to map changes in genomic/proteomic expression, both adaptive and adverse, to sequential cellular behaviors at a systems level and in a manner that is consistent with the underlying embryology and MoA processes.

6 PROFILING DEVELOPMENTAL GENE EXPRESSION

Genome-wide analysis of gene expression is especially powerful when mapped to specific developmental processes (Yu *et al*., 2006). A number of resources for taxonomy of the mouse embryonic transcriptome network have recently appeared for systems such as embryonic kidney development (Brunskill *et al*., 2008), eye development (Lachke and Maas, 2010), and ES cell differentiation (Schulz *et al*., 2009). Nephrogenesis, for example, involves fundamental developmental processes such as mesenchymal–epithelial transition, heterotypic tissue interactions, branching morphogenesis and segmentation (Brunskill *et al*., 2008). These investigators profiled the transcriptome in 54 embryonic kidney samples between gestation day 11.5 and 15.5 encompassing many of the key events in nephrogenesis. Using Laser Capture Microdissection (LCM), they defined taxonomy of gene expression relationships for different components of the kidney, such as the ureteric bud and cap mesenchyme during their inductive interaction and subsequent regional specification. Although some genes displayed component-specific expression, more commonly the profiles between different components showed extensive overlap in gene expression, with differences between components more quantitative than qualitative. Identifying chemically induced perturbations that leads to abnormalities of organogenesis in general, and of the 'developmental nephrome' in particular, requires consideration of this complexity in combinatorial gene expression that comprises the genetic circuitry of kidney development (Brunskill *et al*., 2008). A massive parallelism of transcriptomics and database resources is needed to resolve these patterns.

In a similar vein, a system-level understanding of the genetic circuitry of eye development has progressed from the increasing availability of genome-wide expression data and LCM-based studies. Eye formation, like that of the kidney, is a complex developmental program involving fundamentally conserved signaling pathways that lead to regional specification of the optic vesicle, and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat236
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

that drive reciprocal interactions with presumptive lens ectoderm. A system-level representation of the underlying genetic circuitry has been generated for the mouse embryo by Lachke and Maas (2010) for constructing the network topology of key-signaling molecules, transcription factors, and their targets (Figure 3). The schema provides a framework for understanding network state relationships in the "developmental oculome" as the system undergoes morphogenesis, differentiation and maturation (Lachke and Maas, 2010).

Complexity and robustness inherent to the genetic networks underlying organogenesis in general and eye development in particular make it essential to portray systems in this manner. Systems models like the one depicted in Figure 3 are needed to interpret HTS–HCS data in the context of developmental toxicity, by for example, incorporating the conceptualized linkage of pathway abnormalities specific to the anterior segment (lens-iris-cornea) or posterior segment (pigmented retina, neural retina, optic nerve) (Nemeth, Singh, Knudsen, 2005), and then computationally simulating events that lead to eye-reduction defects (Sipes *et al.*, 2010). As such, a shift in emphasis from the traditional focus on apical endpoints to an understanding of pathways and MoA processes in developmental toxicity requires an understanding of how genes, proteins, and metabolites interact with one another within complex biological networks to maintain normal cell function, and how sub-networks of these interactions can be perturbed in ways that lead to adverse effects on development (Interested readers are referred to Volume 87:2 of Birth Defects Research (Part C), devoted to the topic of gene regulatory networks).

Resources have appeared that allow automatic retrieval and integration of information for the relevant genes and pathways in the embryo and ES cells (Ganter *et al.*, 2008; Bauer-Mehren, Furlong and Sanz, 2009; Schulz *et al.*, 2009). These resources have become particularly relevant in the effort to develop system-level integration of gene expression data on a broad range of cellular pathways, inferring function by taking the entire biological system into consideration. The Edinburgh Mouse Atlas Project (EMAP, http://genex.hgu.mrc.ac.uk/) is a portal for tracking spatio-temporal gene-expression data during normal mouse embryogenesis (Christiansen *et al.*, 2006). The core database contains three-dimensional reconstructions of the mouse embryo at various stages of development (spatial models), a systematic nomenclature of embryo anatomy (anatomical ontology), and defined embryonic territories (domains) (Baldock *et al.*, 1992, 2003; Ringwald *et al.*, 1994).

7 COMPUTATIONAL MODELS

As previously discussed, there are several challenges in developing predictive models of developmental toxicity: correlating *in vitro* concentration–response with *in vivo* dose kinetics and response, understanding how bioactivity profiles extrapolate from one cell-type or technology platform to another, and interpreting individual *in vitro* bioactivity data within the context of complex ontogenetic networks and controls. Two categories of computational tools can facilitate understanding. One category is based primarily on statistical approaches, and includes benchmark dose (BMD) models and quantitative structure–activity relationship (SAR) models. BMD models incorporate all of the available data in the characterization of the dose–response, and the derivation of a point of departure to establish safe levels of exposure; and SAR models attempt to bridge data gaps for data poor chemicals by application of various algorithms to correlate physico-chemical properties with estimates of pharmacokinetic behavior or biological response. These have been reviewed elsewhere (Knudsen and Kavlock, 2008) and will not be further discussed here.

The second category of computational tools involves greater consideration of biological processes and includes physiologically based pharmacokinetic (PBPK) models[a], biologically based dose–response (BBDR) models[b], and looking to the future, *in silico* models that simulate normal biology at various levels of organization (e.g., "virtual embryos"). PBPK models are chemical-specific models that estimate a chemical's internal disposition and dose at a specific target (or an appropriate surrogate dose metric) following a specified external exposure. PBPK models do this by mathematically representing biological tissues as compartments with physiological properties and flows that are characteristic of a species, individual, or population, as well as the processes that determine the internal disposition of a chemical based on chemical specific parameters for key-kinetic processes

(ADME). Because PBPK models are biologically based representation, they can be parameterized to estimate a chemical's internal disposition for a variety of different species, dosage regimens, and exposure routes; and can extend predictions beyond the limitations of the available empirical data (US EPA, 2006). The estimate of the internal dose metric (sometimes called the biologically effective dose) replaces the administered dose in the derivation of the quantitative characterization of the dose–response relationship used to develop regulatory standards for safe exposure levels. Chemical-specific PBPK models are increasingly being used in risk assessment to extrapolate beyond the available bioassay and kinetic data, to reduce uncertainty in estimating safe-exposure levels, and to develop levels where limited or absent data preclude establishment of safe levels by less sophisticated approaches (DeWoskin *et al.*, 2006).

Physiologically based pharmacokinetic models that simulate internal disposition for prenatal developmental exposures must account for changing maternal and fetal compartment sizes or metabolic activity during pregnancy as well as differences in placental physiology or exposures that extend into the lactational period. PBPK models have been developed for gestational (14 chemicals) and lactational (three chemicals) exposures that address these challenges (Corley *et al.*, 2003). By providing a quantitative framework for simulating target concentrations of a chemical, or of its metabolites, the administered dose can be more rationally coupled to the target tissue response. This can infer clues as to the MoA, point to new experiments that would fill gaps, and promote understanding of the human relevance of exposures in laboratory animal models. PBPK model simulations for a variety of exposure conditions where data are limited is especially important when predicting the internal dose to a human embryo where the mother may be exposed intermittently or to low concentrations of the chemical for prolonged periods of time (Yoon and Barton, 2008). PBPK models are also critical to the interpretation of the HTS test data, to support extrapolation of AC50 results captured from *in vitro* assays, to the internal dose *in vivo* and to the corresponding exposures required to realistically achieve that level in an intact system. Quality criteria for PBPK models have been addressed with regards to regulatory acceptance (Clark, Setzer and Barton, 2004) and databases of physiological parameter values for early life stages have been compiled to support PBPK model development and parameterization to simulate the kinetics for this critical subpopulation (Clewell *et al.*, 2002; DeWoskin and Thompson, 2008; US EPA, 2009).

Biologically based dose–response models are predictive models that attempt to simulate the biological response that results from a chemical exposure subsequent to the delivery of an internal dose to a target site. BBDR models mathematically represent the biological processes at the cellular and molecular levels, and the key events leading to an adverse response. Similar to PBPK models, a BBDR is developed for specific chemicals and can extrapolate beyond the limits of the available empirical data. Compared with PBPK models, however, relatively few BBDR models have been developed, and none have been used as of 2010 to derive IRIS reference values in large part because of the relatively more complex dynamics that BBDR model's attempt to simulate (i.e., the effect the chemical has on the body) compared with the straightforward mechanics of a chemical's kinetics that PBPK models can simulate (i.e., the effect the body has on the chemical). Development of BBDR models has also been constrained by a lack of data on key molecular and cellular precursor events, and the need generally for a broader based multidisciplinary team to develop the model (DeWoskin *et al.*, 2001).

Biologically based dose–response model development for complex systems like the embryo face an even greater challenge of unraveling the key events leading to a specific developmental end-point. The complexity of prenatal development and the paucity of detailed information on mechanisms of action make construction of BBDR models for developmental toxicity resource-intensive (Leroux *et al.*, 1996; Faustman *et al.*, 1999; Lau *et al.*, 2000). This may be more readily attainable for drugs that have been designed with a unique therapeutic target than for environmental chemicals to which unintended human exposure may give way to a diverse pattern of biological activity. One comprehensive effort to develop a BBDR model for developmental toxicity was the work of Lau and colleagues that focused on the chemotherapeutic agent, 5-fluorouracil (5-FU), with a well-characterized target (thymidylate synthetase) (Lau *et al.*, 2000; Setzer *et al.*, 2001; Lau *et al.*, 2001). Simulation of the proposed MoA for 5-FU proved to be a complex endeavor; consequently, the project advanced only to the stage of empirical

linkages between interim steps in the MoA, where there were sufficient data for statistical models but insufficient data to develop the BBDR mathematical representation of underlying biological processes. Although BBDR models may improve the conceptualization of the underlying biological processes and the input of information into the risk-assessment process (Andersen and Dennison, 2001), and provide explicit handling of the uncertainties in our understanding of normal biology and chemical effects, they have not advanced to a stage where they can be used with confidence to replace default uncertainty factors in quantitative predictions of low-dose human risk (Crump *et al.*, 2010). Similar to the *in silico* models that are discussed next, BBDR models may also benefit from the greatly increasing data resources and understanding of normal biology that marks the advent of the new paradigm for toxicity testing.

In silico models, also called virtual tissue, virtual organ, or virtual whole body models, are designed to simulate normal biological processes with the aim of predicting the effects of a wide variety of drugs or chemicals as perturbation of the normal homeostasis to an extent that results in an adverse effect. The underlying assumption is that drugs and chemicals exert their actions on cells through interactions with proteins and other macromolecules that function as dynamic complexes within cellular-signaling networks. As such, computational systems biology may give rise to novel concepts and tools that could perhaps extend *in silico* models beyond the limitations of chemical specific BBDR models. Computational systems models would then predict a broad range of effects for a multitude of chemicals by incorporating what is known from the vast biology literature, along with specific HTS–HCS databases, and specific representation of biological processes of interest for risk assessment to simulate the properties and behaviors of complex biological systems following various kinds of stimuli and stress (Kitano, 2001). The era of systems biology has heralded the arrival of technology enabling toxicologists to think about developing such system-level models to represent functional networks (Andersen *et al.*, 2005; Singh *et al.*, 2005). Systems biology graphical notation (SBGN) provides a standardized approach for representing signaling pathways and indirect information from genomics, and for describing the processes and relationships that direct the flow of biological information through a system (Le Novère *et al.*, 2009). This complexity can be managed by presenting only what is needed to simulate a specific context of control circuits, functional network representations of the system, state transitions and the control decision rules of interest (D'haeseleer, Liang and Somogyi, 2000).

Consider, for example, somite formation (Lewis 2008; Oates *et al.*, 2009). This process is sensitive to a number of chemicals in mammalian species. The regular pattern of somite formation (120-, 90- and 30-min in mouse, chick, and zebrafish, respectively) is explained by oscillating gene expression known as the 'somite segmentation clock'. Wnt and FGF (fibroblast growth factor) signals produced at the caudal end of pre-somitic mesoderm maintain an undifferentiated state, and as the neuraxis elongates, cells traveling outside of the influence of Wnt and FGF differentiate. A wavefront formed by this space–time interaction casts different fates on cells in the emerging somite block based on the periodic phase of the somite segmentation clock. The molecular basis for control is oscillating *Hes* genes regulated by Notch-Delta signaling through a negative feedback loop. Computational models indicate the lag-time between *Hes* expression and repression is a key factor in the oscillatory behavior of this circuit, driven by protein translation and mRNA lifetime of Delta (Goldbeter and Pourquie, 2008). In this sense, molecular biology has dissected the system into its basic parts and computers are being used to reconstruct the system using sophisticated software and knowledge from patterns of gene expression for cell adhesion/repulsion molecules (e.g., cadherins, ephrins) (Glazier *et al.*, 2008). This example embodies the parody that "molecular biology took Humpty Dumpty apart; mathematical modeling is required to put him back together again" (Schnell, Grima and Maini, 2007).

8 CHALLENGES FOR IMPLEMENTATION

This chapter has briefly covered a broad range of topics pertaining to systems modeling in developmental toxicity, a concept aligned with the complex problems at hand. We must understand development at the molecular and systems level to recognize key events in developmental toxicity whether the pathways to abnormal development are driven by genetic errors, environmental disruptions, epigenetic programming, or a complex combination of

all these factors. The Holy Grail is to reconstruct biologically informed computational models or 'virtual tissues' that can be used analytically to make HTS data useful in a quantitative risk assessment of developmental toxicity (Knudsen and Kavlock 2008; Knudsen and Daston 2010). Whereas numerous models have been developed for cell-signaling pathways in the embryo, fewer models exist for understanding how chemical lesions are propagated during developmental toxicity. Computational (*in silico*) models that execute a morphogenetic series of events may help in this regard, bridging the gap between *in vitro* profiling and *in vivo* response at different chemical concentrations. The general idea is to model the cell of an embryonic tissue as an agent, that is, the smallest fundamental unit capable of an autonomous decision. Individual agents and their interactions are coded into the model based on biological knowledge (Izaguirre *et al.*, 2004). Control of cell behavior results from an integration of within cell processes and processes external to the cell at different organizational levels that are represented in the model such as cell–cell interactions, signal gradients that may result from binding and release among many cells, as well as physical forces and constraints that are represented in the model. The multicellular simulation is run, and emergent properties such as branching patterns or tissue partitioning are then evaluated for biological relevance and insight. Emergent properties are those properties manifested at higher levels of organization that are neither easily intuited by what is known about the behaviors of the parts (individual cells) nor predictable based on the known linear relationships among the parts.

After suitable elaboration and verification, agent-based dynamic models may someday be used to simulate potential adverse effects following exposure to environmental chemicals where there is some information on perturbation to the model input functions. These models can be exercised to predict outcomes for conditions not experimentally practical because of cost, time, scale, or complexity. Newer technologies such as deep sequencing and cell-level transcriptomics, together with genetics and live cell imaging, bring together the potential to collect cell-level information in a dynamic, integrated system. As most teratology data are derived from perturbation of organogenesis, these newer technologies can provide detailed information at all stages of embryogenesis to provide a more complete system-level perspective such that various computational models would be more relevant with regards to human risk assessment. Because morphogenesis is more than a cumulative sum of individual cell behaviors, virtual tissue models that enable interactions of autonomous cells and preserve elements of system-level control can utilize extensive knowledge about the system and rapidly sweep potential developmental trajectories following chemical or genetic perturbation, thus providing deeper insight into mechanisms of toxicity than is possible solely by analyzing the cell-based data.

To date, successful computational models for processes in developmental biology have linked the specific activities of cell-signaling pathways to discrete morphogenetic events including cell-based models for gastrulation, limb-bud outgrowth, chondrogenesis, angiogenesis, and somitogenesis (Chaturvedi *et al*., 2005; Cui *et al*., 2005; Poplawski *et al*., 2007; Glazier *et al*., 2008; Mahoney *et al*., 2008). These models were implemented as hybrid cellular automata using CC3D open-source tissue simulation environment (www.CompuCell3D.org). An ideal virtual embryo platform will use software, tools, methods and models that can be extended to developmental toxicity. Such a platform fits neatly into EPA's strategy on the future of toxicity testing (Firestone *et al*., 2010) and can leverage unique pathway-based data for numerous chemicals from ToxCast™ (Knudsen and Daston, 2010). Using these resources, experimental–computational models can be built to: simulate key-signaling pathways, interlocking genetic networks, and cellular dynamics in developing tissues; model how embryonic cells react to chemical exposure both individually, and collectively as a complex system; analyze emergent behaviors and canalizing influences following stimulus/injury/perturbation; and understand how this complexity contributes to the differential susceptibility of embryonic tissues across dose, stage, time, and species.

1 INTRODUCTION: AN INTEGRATIVE FRAMEWORK FOR COMPUTATIONAL TOXICOLOGY

Extending "state-of-the-art" whole-body physiologically-based pharmacokinetic and toxicokinetic models, for humans and other organisms, to explicitly incorporate toxicodynamic processes, presents various challenges: The biological information incorporated in these models has to be enhanced substantially, and across many levels of organization, in order to account for pertinent changes in biological function, especially changes that can be linked to observable/measurable markers (biochemical, histomorphological, etc.). Since the function of cells depends critically on intercellular interactions and on the dynamics of their biological microenvironment, it is important to model explicitly these interactions and dynamics in order to understand changes of function taking place at both the cell and tissue levels. The following sections provide a summary of the foundations of a modular "whole body" computational framework that incorporates a hierarchy of alternative formulations representing biological processes within "virtual" (or "in silico") tissues and organs at various levels of detail, in order to achieve the above-mentioned mechanistic integration of toxicokinetics and toxicodynamics. The computational implementations of "virtual" tissues and organs allow the mechanistic consideration of multiple scales of interlinked processes that include: molecular interactions (e.g., ligand-receptor interactions with emphasis on the receptors involved in the transport and biotransformation of xenobiotics); dynamics of intracellular biomolecular (regulatory, metabolic, signaling) networks; spatial and stochastic aspects of cell biochemistry; integrative coupling of cellular-level

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

processes related to common biological endpoints; extracellular signaling and cell-cell communication and interaction; aspects of microscopic and mesoscopic morphological, biochemical and functional heterogeneity within multicellular assemblies and functional physiological or pathophysiological units (e.g., hepatic sinusoids, kidney nephrons, tumors, etc.); dynamics of histomorphological and histopathological processes at the macroscopic tissue level; and integrative coupling of processes at the organismic level, representing the spectrum of physiosystem phenotypes for health and disease states. A critical component of the computational framework presented in this chapter, is a set of approaches for coupling processes and "transferring and integrating" information across different scales of biological organization, from biomolecules to tissues. This set includes a combination of formal methods of multiscale analysis (deriving from fields such as statistical physics), including master equation based descriptions of multicellular kinetics and dynamics, as well as simple "top-down" approaches, both mechanistic and phenomenological. The computational implementation of the framework employs agent-, network-, and field-based modeling methods that have been individually and systematically compared with respect to their strengths and limitations in supporting biological systems modeling and then "merged" in order to achieve a flexible general operational framework for supporting toxicological and environmental health risk analyses.

So, the resulting framework is based on the integrative representation of biological dynamics in terms of (i) interacting networks; (ii) agents that "move across" different networks; and (iii) fields capturing the spatiotemporal relations and variations of a range of physicochemical attributes within a functioning biosystem or biological unit (membrane, organelle, cell, multicellular module, tissue, organ, etc.). This representation is supplemented by rules governing constraints and interactions among components of the biological systems and subsystems, and "actors" that make decisions affecting the state of these systems. A suite of deterministic and stochastic modeling approaches, utilizing a bi-directional coupling between rule-based or stochastic differential equation-based agent approaches on one hand and ordinary and partial differential and integrodifferential equation-based methods, either stochastic or deterministic, that govern the dynamics of fields, on the other hand, is used to achieve the objective of integrative multiscale implementation within this framework.

Interfacing/communication "layers" provide the rules (master equations and so on) for assembling the information from the finer resolution scale and organizing it in a form that is determined by the structure and dynamics of the coarser resolution scale.

2 BASIC CONCEPTS AND METHODS

2.1 Source-to-Dose-to-Effect Analysis of Exposure to Xenobiotics

Xenobiotics such as environmental contaminants have been established as the causes of numerous diseases, from various cancers and neurological degeneration to respiratory, cardiovascular, and metabolic (e.g., diabetes) disorders. Assessment of health risks associated with exposures to specific contaminants (chemical, radiological, biological) present in various *media* (air, water, soil/dust, food, consumer products, etc.), taking place through one or more *routes* (inhalation, ingestion, dermal absorption) requires understanding the events and processes in the sequence from "source" (e.g., the release or formation of the contaminants in the environment) to "outcome" (e.g., the development of an adverse biological effect). *Exposure biology*, as an integrative "systems approach" considers human health state as reflecting multiscale body "system dynamics" (across the genome, transcriptome, proteome, metabolome, cytome, physiome) as they are affected by various environmental (extragenomic) factors that include environmental stressors (e.g., chemical, radiological, and biological contaminants); developmental/aging state and behavior/activities (Figure 1). Of particular importance is the incorporation in this computational framework of dietary/nutritional factors (see, e.g., de Graaf *et al.*, 2009) and of interactions with the "gut microbolome" (see, e.g., Fox *et al.*, 2010), as they can both affect substantially body system dynamics in relation to the response to environmental stressors. These dynamics are modeled through a combination of network, agent, and field representations that incorporate available mechanistic and phenomenological information on the various

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

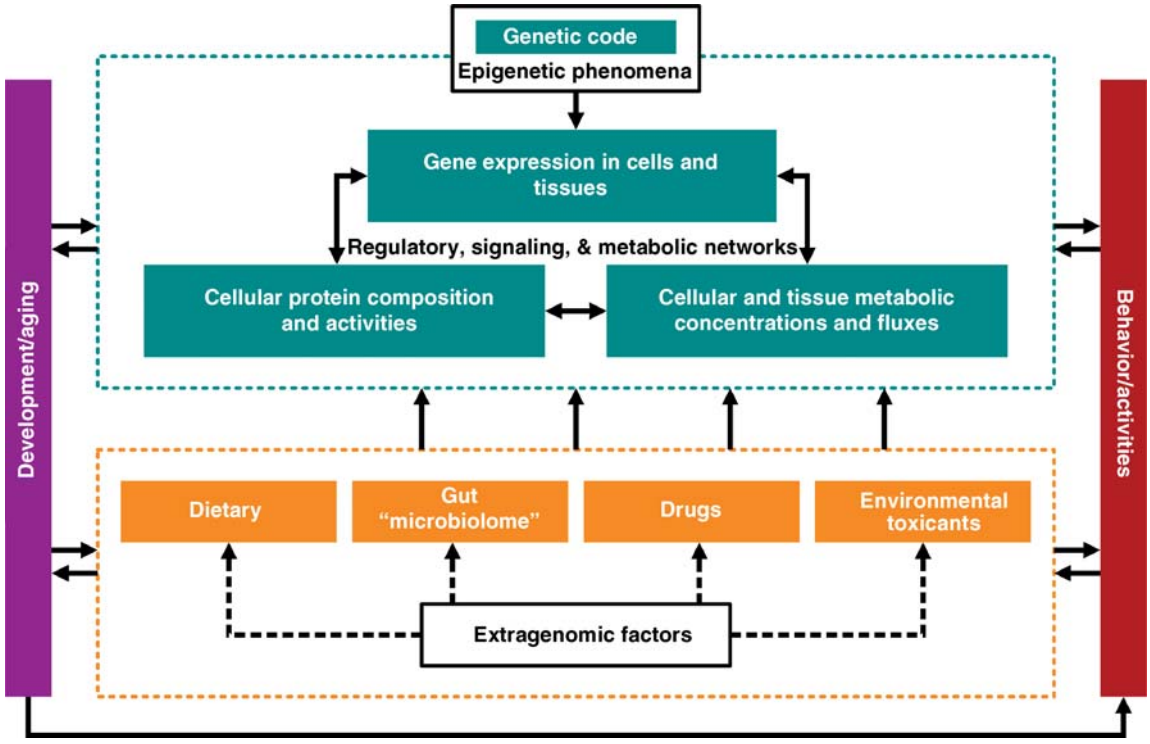

Figure 1. Human health state reflects multiscale body "system dynamics" (across the genome, transcriptome, proteome, metabolome, cytome, physiome) as they are affected by various environmental (extragenomic) factors that include contaminants (chemical, radiological, and biological); developmental/aging state, and behavior/activities (adapted from Georgopoulos, 2008; reproduced with permission from Springer). These dynamics are modeled through a combination of network, agent, and field (continua) representations that incorporate available mechanistic and phenomenological information on the various system components.

system components. This integrative framework allows significant improvements over the "traditional" approaches of studying risks. The traditional approaches generally involve individual contaminants and environmental media (e.g., atmosphere, groundwater, soil, etc.) typically associated with a single exposure route. Recent developments in risk analysis include the evolution of integrative anthropocentric approaches that account for total (cumulative and aggregate) exposures of individuals and populations, to co-occurring contaminants in air, water, soil, food, and so on (Georgopoulos and Lioy, 2006; Georgopoulos *et al*., 2008; 2009b). The framework and applications presented in this chapter are the outcome of a continuing research effort, funded primarily by the US Environmental Protection Agency (USEPA) and the National Institute of Environmental Health Sciences (NIEHS), to develop, evaluate and apply mechanistic and diagnostic computational modeling tools intended to support comprehensive analyses of all the steps in the "environmental health sequence" from the release and transport/fate of environmental contaminants to human exposure/dose and subsequent development of disease (Figure 2). This effort has resulted in two continuously evolving software "libraries," developed primarily in Matlab (The Mathworks, 2010), with various routines in C++ and Java, and with links to an extensive set of data management and analysis tools linking relational databases (such as Oracle [Oracle, 2010], PostgresSQL [PostgreSQL, 2010] and MySQL [MySQL, 2010] and Geographic Information Systems (such as ArcGIS [ESRI, 2010]), that store and manage environmental and biological information, on customized Linux clusters (Georgopoulos, 2008). These software libraries constitute the *M*odeling *EN*vironment for *TO*tal *R*isk studies (MENTOR), that addresses the sequence of environmental "source-to-dose" processes, and

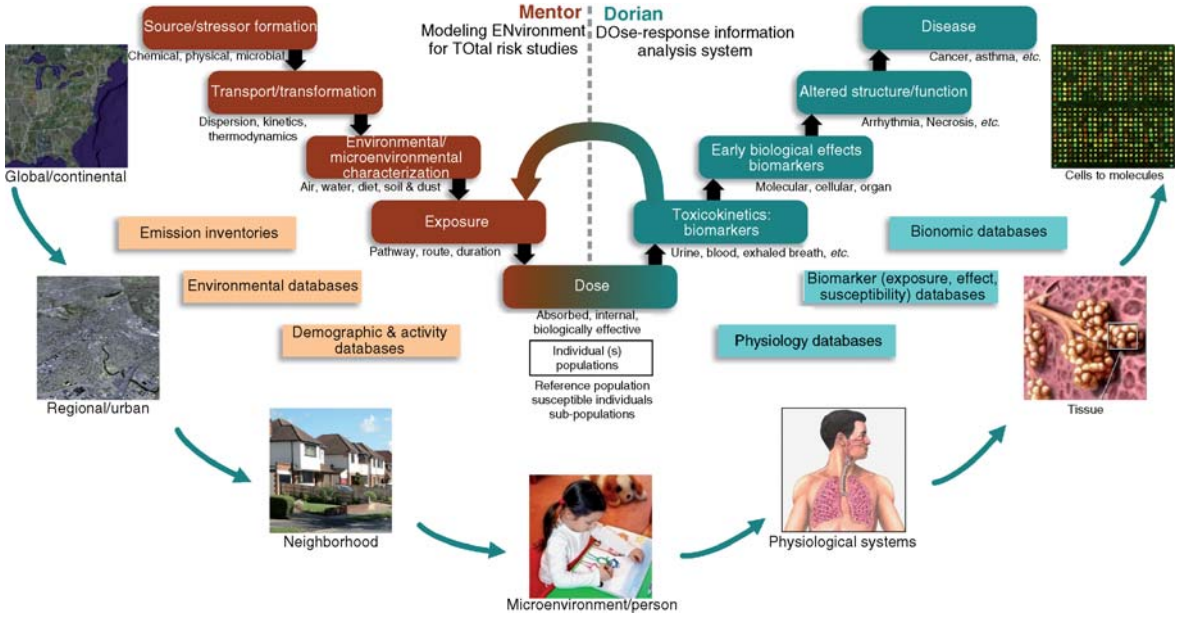

Figure 2. Schematic representation of the "environmental health sequence" from "source" of a stressor (chemical, biological, radiological) to biological "outcome," involving a series of environmental and biological "steps" (Figure source: Georgopoulos *et al*., 2009a).

the *DO*se-*R*esponse *I*nformation *AN*alysis system (DORIAN), focusing on the sequence of the biological "dose-to-effect" steps, to provide, in combination, integrative "exposure biology framework" for the analysis of human health risks from xenobiotics and other environmental stressors. Figure 2 contains a schematic representation of the "environmental health sequence" from "source" of a chemical, biological, stressor, to biological "outcome," involving a series of environmental and biological "steps." It should be noted that the models within MENTOR and DORIAN in principle allow not only calculations of dose and biological response or effect from information on environmental conditions, but also, under certain constraints, reconstruction of environmental exposure patterns from appropriate biomarker data (Georgopoulos *et al*., 2009b).

A series of recent publications have focused on MENTOR, presenting its overall framework and applications covering the "source-to-dose" steps for various environmental problems (Georgopoulos *et al*., 2005; Georgopoulos and Lioy, 2006; Georgopoulos, 2008; Georgopoulos *et al*., 2008; 2009b; Xue *et al*., 2010). Here, in the sections that follow, the focus is on the evolving framework and applications of DORIAN, which provides tools for mechanistically linking contaminant dosimetry with specific adverse biological outcomes.

Figure 3 presents a simplified schematic description of toxicokinetic and (initiation of) toxicodynamic processes in the human body. In this example, only the ingestion exposure route is considered, where a xenobiotic is absorbed in the gastrointestinal tract and, through systemic circulation, is transported to the liver, which is assumed to be the primary site of metabolism and target effects. The xenobiotic (ligand) will interact with various biomacromolecules ("receptors") during the various toxicokinetic steps of absorption, distribution, metabolism, and elimination (ADME); more complex patterns are generally expected in the interactions of the xenobiotic (or its metabolites) with cellular signaling and regulatory networks, resulting in the initiation of toxicodynamic effects. Structure-activity differences in the various receptors, reflecting genetic polymorphisms within a population, may result in different "strengths" (phenotypic polymorphisms) of various

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

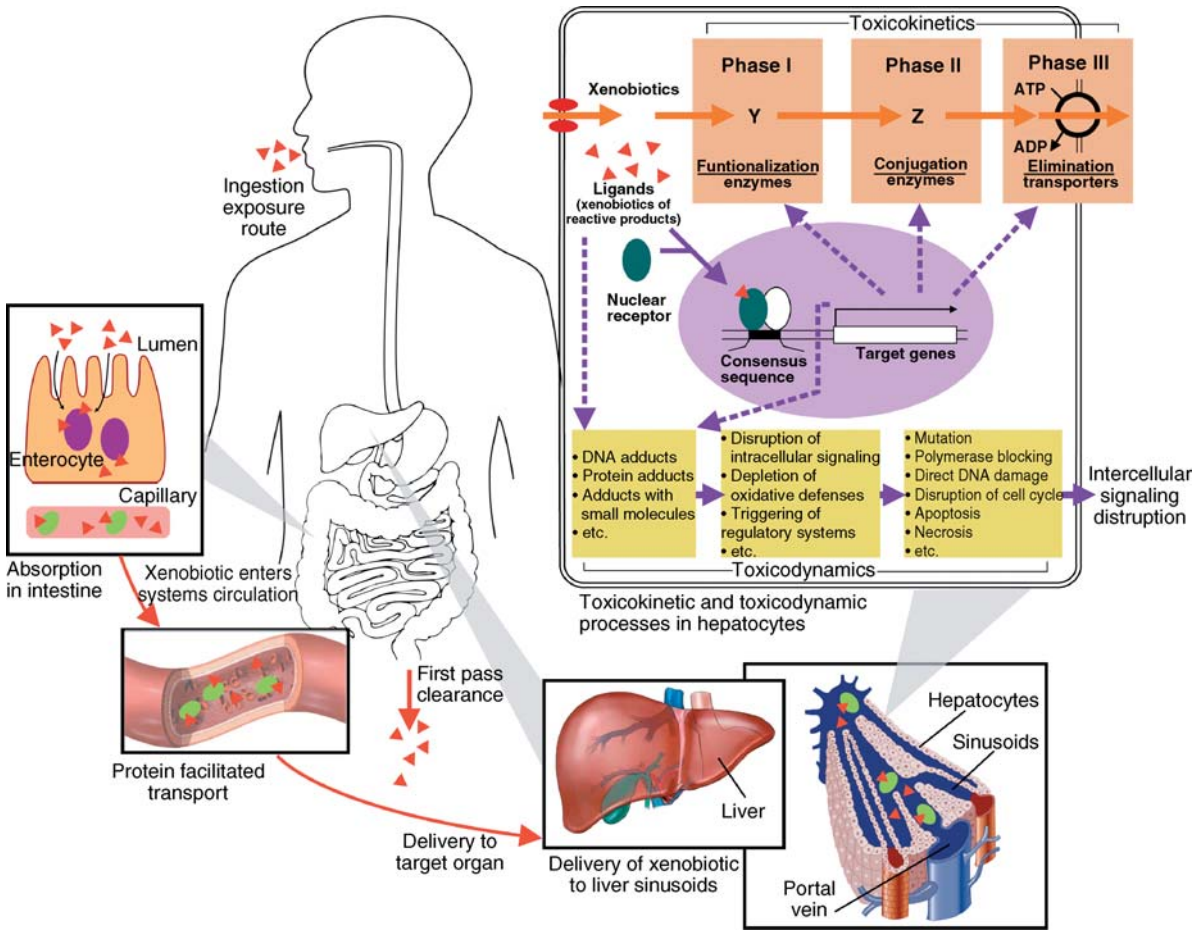

Figure 3. A simplified schematic description of toxicokinetic and (initiation of) toxicodynamic processes in the human body. In this example, only the ingestion exposure route is considered, and the xenobiotic is transported to the liver, which is assumed to be the primary site of metabolism and target effects. The xenobiotic (ligand) will interact with multiple biomacromolecules (receptors) in toxicokinetic (absorption, distribution, metabolism and elimination – ADME) and toxicodynamic processes. Structure-activity differences in the various receptors, reflecting genetic polymorphisms within a population, may result in different "strengths" (phenotypic polymorphisms) of various bioactivation and/or detoxification pathways, potentially resulting to different susceptibilities of effect for individuals of this population.

bioactivation and/or detoxification pathways, potentially resulting to different susceptibilities of effect for individuals of this population. Figure 4 shows schematically typical toxicokinetic and potential toxicodynamic processes taking place, or commencing, in the human hepatocyte. However, in spite of the significance of the individual cell with respect to this process, it should be emphasized that toxicity is a result of a cascade of events that involves multiple scales, both intra- and extracellular. To emphasize the fact that cells never "act" as isolated individuals but rather as members of complex "communities," Figure 4 presents a simplified overview of interlinked intercellular and intracellular signaling networks reflecting biological communication processes among the different types of liver cells (hepatocytes, Kupfer cells, endothelial cells, hepatic stellate cells) as well as components of the extracellular matrix.

DORIAN incorporates toxicogenomic information that is becoming available from various high throughput bionomic (transcriptomic, proteomic, interactomic, metabolomic, etc.) laboratory studies and links a mechanistic analysis framework

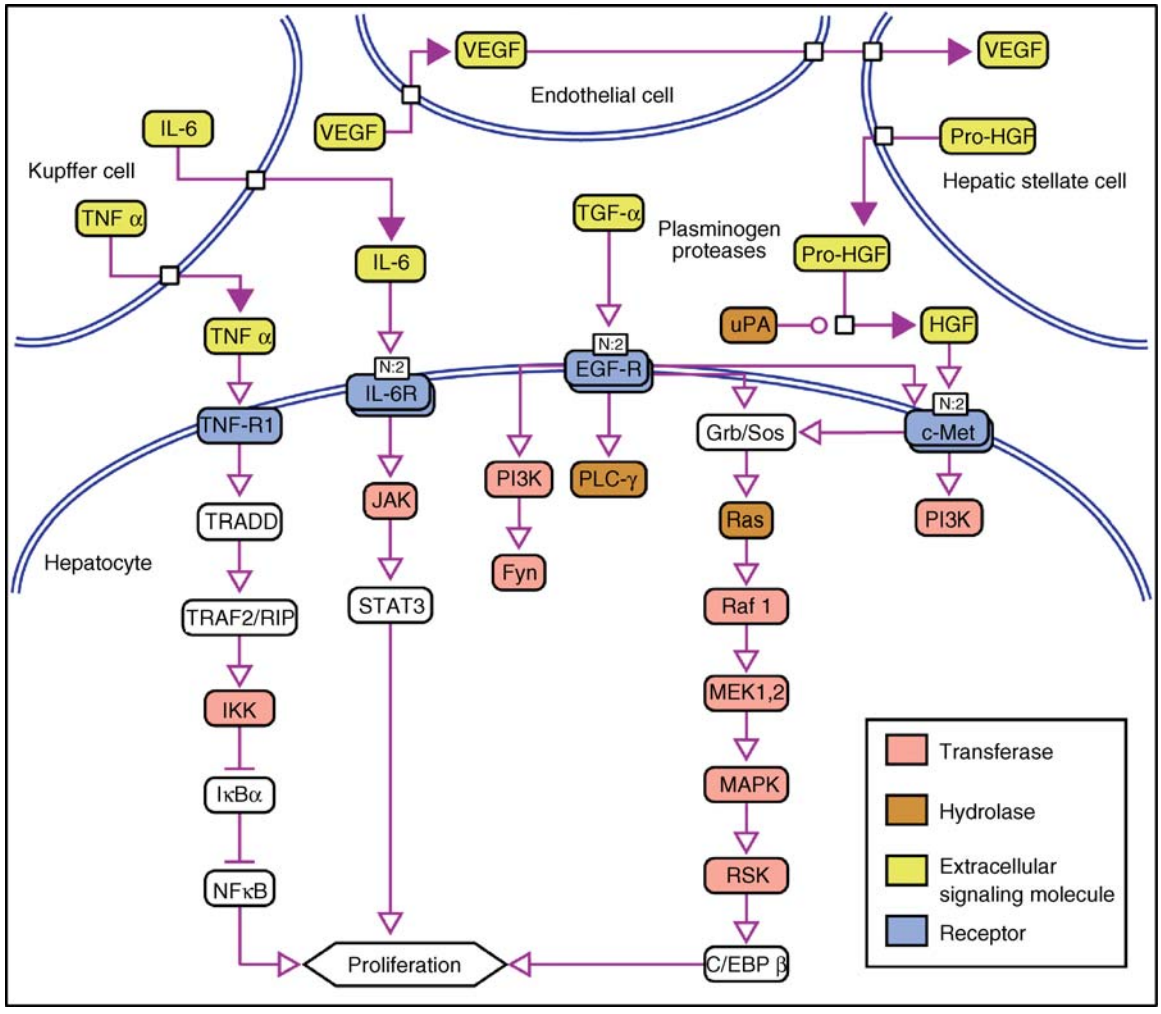

Figure 4. A simplified overview of interlinked intercellular and intracellular signaling networks reflecting biological communication processes among the different types of liver cells (hepatocytes, Kupfer cells, endothelial cells, hepatic stellate cells) as well as components of the extracellular matrix. Systems Biology Graphical Notation (SBGN – Jansson and Jirstrand, 2010) is used to depict molecular interactions; the interactions shown are based on information from Pagano *et al.* (2007).

to ebTrack (Chen *et al.*, 2009). ebTrack is a new user-oriented platform that expands the features of ArrayTrack (Tong *et al.*, 2003) by incorporating a range of options for the analysis of data from a wide range of new technologies, in addition to providing options (beyond those already available in ArrayTrack) for studying microarray gene expression data (e.g., Ouyang, Welsh and Georgopoulos, 2004). The objective of DORIAN is the mechanistic *in silico* replication and interpretation (including cross-species extrapolation) of heterogeneous information from *in vivo*, *in vitro*, and *ex vivo* studies from high-throughput (HT) technologies, from bioengineering applications, and from traditional toxicology experiments (see Figure 5). *In silico* models and model organisms both play a critical (integrative) role in interpreting information from diverse sources and raise the requirements for data and for data management and analysis techniques (Joyce and Palsson, 2006; Ryan, 2008). To support usage of DORIAN in real-world applications, an "environmental bioinformatics Knowledge Base" (http://ebKB.org – Figure 6), has been developed and is available

through a web portal; ebKB is being updated regularly to include continuous advancements in this field.

2.2 Combining Field, Agent, and Network Based Approaches for Biological Modeling

The integrative DORIAN approach to mechanistic toxicokinetics and toxicodynamics considers inter- and intra-cellular *networks* (i.e., regulatory, signaling, and metabolic cascades), as well as physiological (multicompartmental) networks coupled with spatiotemporal *fields* or *continua* (either random or deterministic) of biophysical attributes, and with biological entities that mathematically are identified as "agents" that are affected by and affect other components of the biosystems under study. Additional mathematical entities are "actors" that implement mechanistic or semiempirical "rules" constraining the functions of these biosystems (Figure 7). The above types of mathematical constructs span multiple hierarchical strata and spatiotemporal scales, and they interact at various levels. For example, a coarser-level component can provide boundary conditions or forcing functions to a finer-scale component, while "aggregates" or "assemblies" of finer-scale components can provide parameter values (or distributions of parameter values) to a coarser-scale component.

At each hierarchical stratum, each of the generalized bionetworks under consideration is defined through (i) network nodes (compartments); (ii) network edges or links (relationships, interactions); and (iii) network function (states, dynamics). The nodes can be defined as static (e.g., tissues within an organism) or dynamic (e.g., cells involved in an inflammatory process, in which case they can also be represented as agents). *Each node of a bionetwork can itself be a network, an agent, an actor, or a combination of them*. Interactions among the networks (and associated agents) and processes governing the states of the networks are defined in relation to spatiotemporal "fields" or "continua" (random or deterministic) of biological (i.e., biophysical and biochemical) properties. The constraints on the types of interactions (thermodynamically allowable chemical reactions, transport of molecules across membranes and biocompartments, probabilities associated with migration of agents from one network node to another, etc.) constitute the rules governing the evolution of the networks and associated agents. Considering the cell as the "middle level" of critical biological organization, the above approach distinguishes two major groups of bionetworks, that is:

- *Intra-cellular networks* (where network nodes are biomolecules, biocomplexes, organelles) that include intra-cellular signaling networks, transcriptional regulatory networks, and metabolic networks. For example, components of transcriptional regulatory networks are binding sites, transcription factor molecules, riboswitches, and so on, while corresponding network links include DNA-protein, protein-protein and metabolite-RNA interactions.
- *Intra-organism networks* (where network nodes are cells, cellular assemblies, multicellular functional modules, tissues, organs, physiological systems), that include inter-cellular signaling networks and physiological level networks that reflect connections of organs and physiological systems through the transport of matter and information (signals) by the circulatory, lymphatic, and nervous systems.

Network dynamics coupled with the properties/dynamics of biophysical and biological fields

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

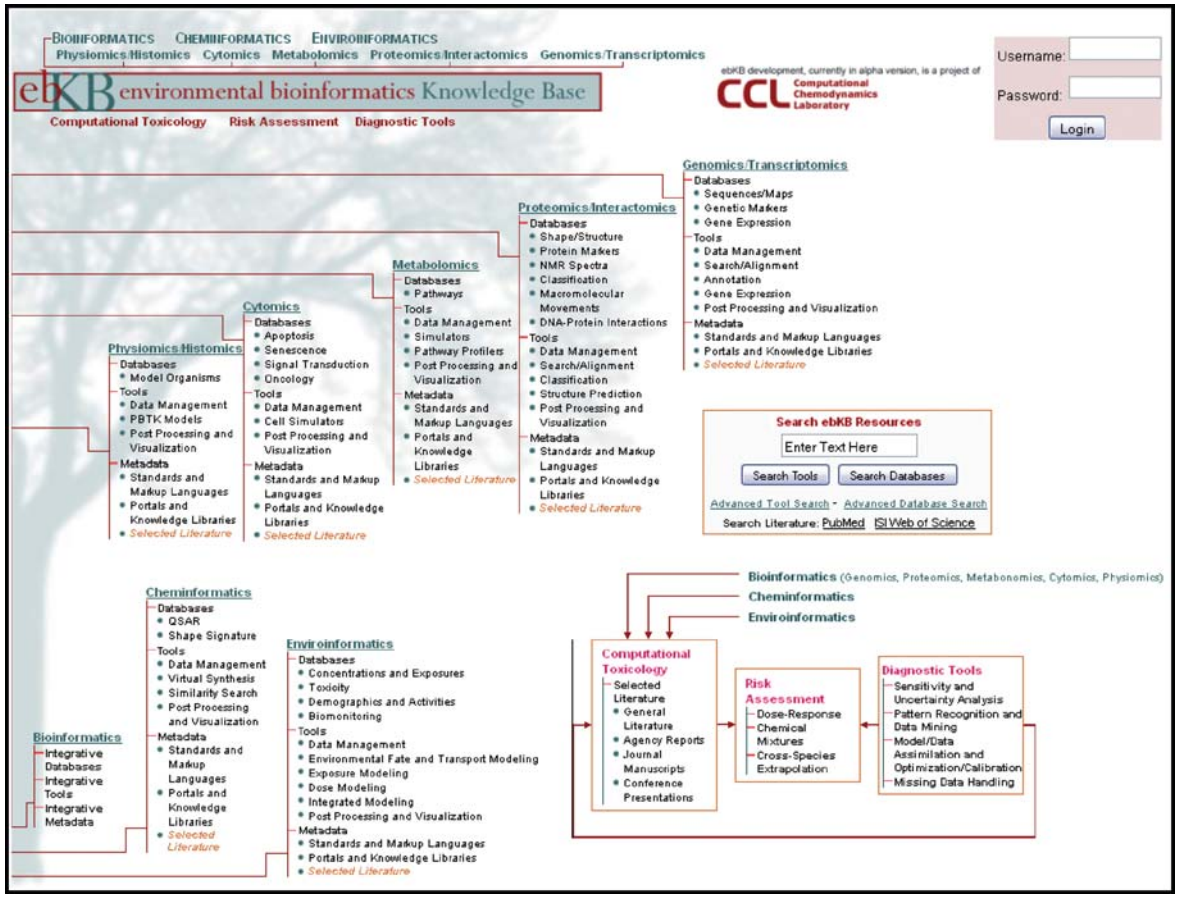

Figure 6. Structure of the Environmental Bioinformatics Knowledge Base (ebKB) for supporting modeling and analysis efforts for assessing human health risks from xenobiotics.

(density, pressure, concentration, electrical charge, etc.) can be described by various combinations of descriptive (phenomenological) and predictive (mechanistic) models, depending on the available data and scientific knowledge. When the number of constituents in a network is large, it may be more appropriate to represent the states of the system in terms of (probability) distributions of key parameters.

Movement of agents within a system is typically modeled as a stochastic process, using constrained random walk models with associated transition probabilities from one network node to another. Critical variables in toxicological and environmental health risk assessment include concentrations of contaminants within a specific biological compartment (e.g., a tissue, etc.), which are scale dependent, and distributions of other factors affecting the system (e.g., probabilities of occurrence of specific genetic polymorphisms). However, networks of different scales, and nodes within a network, will interact with a variety of fields; simulation of these fields requires process-based models with inter-network boundaries defined via differential gradients.

3 IMPLEMENTATION OF A MODULAR MULTISCALE WHOLE BODY FRAMEWORK

The *DO*se-*R*esponse *I*nformation *AN*alysis (DORIAN) framework is being implemented as an expandable software library that systematically collects and organizes methodological research

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.
This article is © 2011 John Wiley & Sons, Ltd.
DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

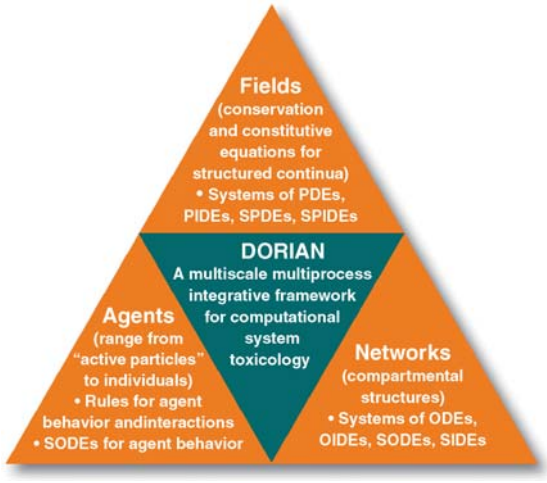

Figure 7. The multiscale modeling framework of DORIAN employs a combination of field-, network-, and agent-based approaches spanning multiple strata of biological organization: the mathematical implementation involves systems of deterministic and/or stochastic ordinary and partial differential and integrodifferential equations [(S)ODEs, (S)PDEs, (S)IDEs] as well as rules (or, in some cases, SODEs) for agent behaviors and interactions.

outcomes from the various completed and ongoing efforts within ebCTC (ebCTC.org). DORIAN aims to provide an integrative but highly modular framework for multiscale modeling of "environmentally induced" effects on biological systems, and in particular on the human organism; this framework also aims to explicitly incorporate variability in human susceptibilities due to genomic factors (e.g., genetic polymorphisms), epigenetic phenomena, and so on. The modules of DORIAN are organized across a sequence of "levels or strata of biological organization," and range from computational descriptions of the toxicologically relevant properties of individual biomolecules and xenobiotics, to models of molecule-molecule (e.g., ligand-receptor) interactions, and, eventually, to whole "virtual cell", "virtual organ," and "virtual organism" models. Figure 8 shows the general structure of the DORIAN framework for the multiscale analysis and modeling of biologically-based toxicokinetic and toxicodynamic processes. "Integrative modules" of intra- and extracellular event dynamics within the DORIAN "library" incorporate

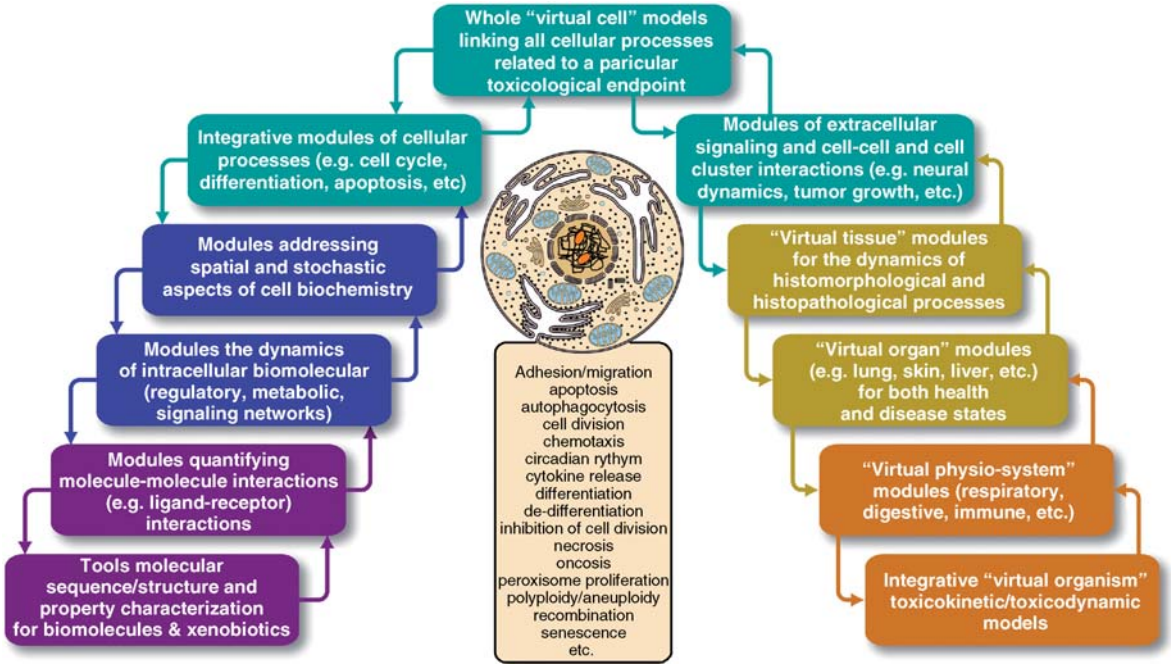

Figure 8. The general structure of the DORIAN framework for the multiscale analysis and modeling of biologically-based toxicokinetic and toxicodynamic processes. "Integrative modules" of intra- and extracellular event dynamics within the DORIAN "library" incorporate pathway and network information related to cascades of processes that can be disrupted by the presence of specific xenobiotics (or other environmental stressors) of concern.

pathway and network information related to cascades of processes that can be disrupted by the presence of specific xenobiotics and other environmental stressors of concern. *Biomodules* (i.e., functional biological subsystems) affected by the biological action of selected stressors (that may have synergistic or antagonistic interactions with respect to particular toxicological endpoints) are "constructed" from plausible biological hypotheses (or "reconstructed" from observational evidence), by applying available physicochemical principles and relevant information from experimental data, for each of these "levels" or "strata." "Reduced" (or simplified) versions of biomodules from each stratum that, based on the outcomes of detailed robustness and sensitivity analyses, maintain the most essential (and relevant) attributes of the original biological systems, are derived and are either "coupled" dynamically to, or, alternatively, provide parameterizations of components for biomodules of the next higher level.

As stated in Section 2.2, the mathematical (and subsequently computational) implementation of DORIAN describes the above biomodules in terms of generalized bionetworks coupled with biologically relevant property fields (structured continua) and discrete mathematical entities (agents). DORIAN employs a combination of (i) "mechanistic (biochemical) interaction"; (ii) "phenomenological (statistical) influence" descriptions, depending on the extent of available biochemical/biological knowledge and of related data. In some cases a "hybrid" approach is employed, that utilizes, for example, Bayesian model-data "fusion" techniques, to obtain optimal or quasi-optimal parameterizations of "postulated" mechanistic models from related "experimental" observations. The mathematical formulations employed in the above implementations include, depending on the specifics of the problem at hand, deterministic, or stochastic (and, in some cases, qualitative) ordinary and partial differential and integrodifferential equations; deterministic and stochastic Boolean logic networks; Bayesian networks, and so on. (Price and Shmulevich, 2007; Thai, Cai and Du, 2007). DORIAN utilizes a wide range of computational tools (i) for physics-based modeling (i.e., modeling of lumped- and distributed-parameter systems represented by deterministic and stochastic ordinary and partial differential and integrodifferential equations for the various conservation/balance equations [mass, energy, momentum] and the associated constitutive equations [reaction rates, transport properties] governing the systems); (ii) for object-oriented modeling of agents and actors; and (iii) for event-driven simulations. DORIAN modules make extensive use of publicly available software packages for systems biology (e.g., Matlab toolboxes such as SimBiology [The Mathworks, 2010] and CellNetAnalyzer [Klamt, Saez-Rodriguez and Gilles, 2007]), supplemented by additional computational tools, developed within ebCTC, on platforms that include Matlab, Java, and R (e.g., Feng and Rabitz, 2004; Chen *et al*., 2009). Various available software tools (such as Virtual Cell [NRCAM, 2010] and Compucell 3D [Cickovski *et al*., 2007; CompuCell 2010]) are also being utilized for application development and for cross-comparison purposes. Computational environments appropriate for handling specific aspects of spatiotemporal data and continuous dynamics are also employed; these include ArcGIS (ESRI, 2010) and Comsol Multiphysics (Comsol, 2010) in combination with selected Agent-Based Modeling (ABM) platforms that include Netlogo (Wilensky, 2010) and Repast (Repast, 2010).

Selected examples of issues related to specific "biological levels" within the DORIAN framework, and of corresponding implementation approaches, are presented in the next Section. A brief overview of the DORIAN framework formulation is presented here in the following two subsections.

3.1 Modularity and Hierarchical Multiscale Structures

The DORIAN system, extending the approach already employed in MENTOR (Georgopoulos, 2008), provides a modular bi-directional framework linking multiple levels and scales of physical, chemical, and biological phenomena (Figure 9). Both formal and heuristic "bottom-up" and "top-down" formulations are supported in this framework, often in combination, so as to allow flexibility of model structure and parameterizations, and to facilitate alternative model implementations that are optimized for specific applications. Interfacing/communication "layers" provide the rules (ranging from semiempirical allocation factors to master equations governing the distributions of parameters of key biological properties) for

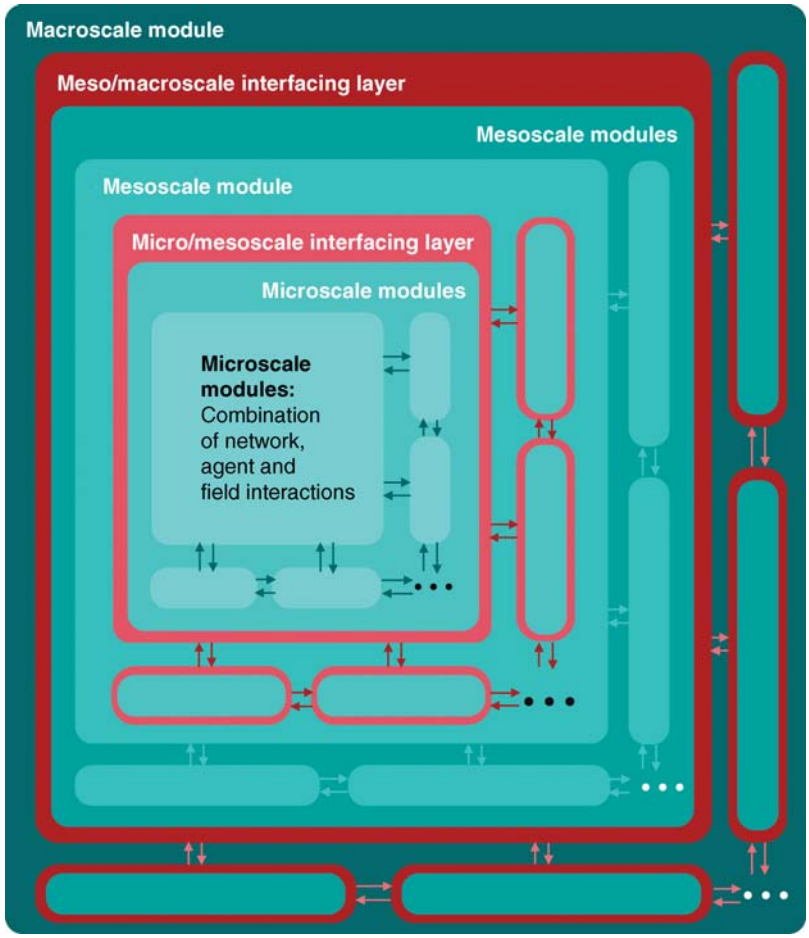

Figure 9. DORIAN provides a modular bi-directional framework linking multiple scales of physical, chemical, and biological phenomena. Both formal and heuristic "bottom-up" and "top-down" approaches are supported in this framework, often in combinations, so as to allow alternative model structure and parameterizations and to facilitate formulations that are optimized for specific applications. Interfacing/communication "layers" provide the rules for "assembling" the information from the finer resolution scale and organizing it in a form that is determined by the structure and dynamics of the coarser resolution scale.

"assembling" the information from the finer resolution scale and organizing it in a form that is determined by the structure and dynamics of the coarser resolution scale.

It is beyond the scope of the present chapter to review the rapidly expanding field of mathematical and computational modeling of complex multiscale (biological and other natural as well as engineered) systems, that is actually becoming a major component of efforts in systems biology (e.g., Auffray and Nottale, 2008; Boissel *et al*., 2008; Clermont *et al*., 2009; Hunter *et al*., 2006; Mesarovic, 1968; Mesarovic and Takahara, 1975; Mesarovic, Macko and Takahara, 1970; Mesarovic, Sreenath and Keene, 2004; Noy *et al*., 2009; Ockner, 2004; Uhrmacher, Degenring, and Zeigler, 2005; Walz, 2005; Woods and Mulholland, 2008; Yaliraki and Barahona, 2007). Only a brief discussion of selected issues that are of primary importance to the implementation of DORIAN is presented in this subsection.

A major challenge associated with multiscale biological system modeling is the consistent linking of different scales for simulating the states and dynamics of network components, agents, and actors (Lavelle *et al*., 2008), while accounting for the uncertainties and the "noise" that typically exist within these subsystems. However, the

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

level of complexity required to adequately represent a system is primarily dependent on the specific problem being studied and on the metrics of importance for the phenomena studied. In general, the techniques for studying complex systems employ simplification procedures, such as "rational" model reduction techniques (resulting from a hierarchical evaluation of modeling assumptions) complemented by encapsulation approaches for identifying coherent functioning "biomodules" within the system of concern. For example, Hartwell *et al*. (1999) discuss the issue of the decomposition of biological systems into interacting subsystems (biomodules). A biomodule is identified so that there is "strong" coupling among those processes and interactions that are internal to the module, while there is "weaker" coupling of these processes with external events; it should be emphasized that each module involves mathematical representations consisting of (or combinations of) networks, agents, and fields. Within DORIAN, module identification and characterization techniques are also complemented by model-structure independent tools for diagnostic analysis, such as (i) model-data fusion through Bayesian parameter estimation and numerical inversion (Georgopoulos *et al*., 2009b); (ii) systematic simplification of models through perturbation-analysis (Gerdtzen, Daoutidis and Hu, 2004), deterministic and Stochastic Response Surface methods (Isukapalli and Georgopoulos, 2001), and High Dimensional Model Representation methods (Wang *et al*., 2005; Li *et al*., 2008).

Typically, "top-down" approaches model macroscopic phenomena in biological tissues via methods of continuum mechanics, through the derivation of evolution equations for the macroscopic variables that describe the physical state of the system. This derivation usually follows the principles of continuum mechanics, that is, conservation of mass, momentum, and energy equations; these equations require "closure" that is usually provided by phenomenological models ("constitutive relations") describing the material behavior of the system. It may be stated that top-down approaches aim to "reverse engineer" underlying mechanisms from coarser scale observations.

"Bottom-up" approaches can be either analytical, employing methods from statistical physics and kinetic theory, or numerical "semi-mechanistic" techniques, that is, agent-based, employing mechanism-based or data-driven rules for the behavior of individual "biological units" (macromolecules, cells, etc.). Asymptotic methods are typically used in conjunction with the analytical approaches to derive macroscopic equations from the underlying microscopic description; these equations govern the evolution of (probability) distribution functions over the microscopic states of large collections of interacting entities. A simple standard example from mathematical kinetic theory is the (continuous or discrete) Boltzmann equation, governing the evolution of a system of identical particles considered as point masses with a microscopic state simply identified by position and velocity. Other examples involve asymptotic methods that expand the distribution function in terms of dimensionless parameters related to the inter-particle distances. Similar procedures have been implemented to derive macroscopic equations for "generalized" or "active" particles and applied to biological systems such as large assemblies of interacting cells. The microscopic state or "microstate" of an "active particle" is characterized not only by mechanical parameters (e.g., position and velocity), but also by parameters determining biological functions at a cellular or sub-cellular level. Microscopic interactions may not only modify the microscopic state, but may also result to proliferation and/or destruction phenomena, that is, to the generation or loss of generalized/active particles (non-conservative interactions). The macrostate of the whole system is described by the probability distributions of the various relevant parameters over the microstates of the constituent particles. Derivation of the equations describing the time-space evolution of the stochastic variables defining the states of the systems follows the general classical statistical kinetic theory, that is, it is based on balance equations for net flow of generalized particles in the elementary volume of the microscopic *state space*, as affected by transport intra-particle factors, and inter-particle interactions. Such derivations have been pursued for multicellular biological systems by many researchers (e.g., Alt, Deutsch and Dunn, 1997; Bellomo and Bellouquid, 2004; Hadeler, Hillen and Lutscher, 2004; Hillen and Othmer, 2000; Lachowicz, 2005; Othmer and Hillen, 2002; Bellomo and Bellouquid, 2006, etc.). The analysis of Bellomo and Bellouquid (2004, 2006) for systems of one and of two interacting populations (limited to the

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

case of mass conservative encounters) showed that interactions affecting the biological functions of cells can substantially modify the structure of the macroscopic governing equations. Effects of external factors have also been modeled, either at the macroscopic scale or at the microscopic scale through the probability distribution of the microstates (Bellomo, Bianca and Delitala, 2009; Bertotti and Delitala, 2008).

The relative advantages of "top-down" versus "bottom-up" approaches for coupling of biomodules across multiple scales have been discussed in the literature (e.g., Meier-Schellersheim, Fraser and Klauschen, 2009). A limitation of top-down approaches is that often a higher/coarser scale phenomenon may have multiple potential underlying explanations arising from the dynamics of the lower/finer scales. On the other hand, bottom-up approaches, that describe system behavior by "aggregating" the dynamics of the finer scales to explain phenomena at the coarser scales, in general require higher computational resources and more detailed information bases. Nevertheless, both approaches can identify potential knowledge and data gaps and provide insight into targeting new studies (Xu *et al*., 2007).

The ongoing development of DORIAN has embraced a combination of "top-down" and "bottom-up" approaches resulting in the bi-directional framework mentioned earlier. The "whole-body framework" that is presented in the next subsection defines a set of "top-down" constraints, while an evolving software library of alternative algorithmic formulations for numeric agent-based models provides an expanding array of options for calculating macroscopic properties from microscopic dynamics.

It should also be noted that specific implementations of the general DORIAN framework are typically hybrids, containing "standard" semi-mechanistic toxicodynamic models (Mager, Wyska and Jusko, 2003; Mager and Jusko, 2008) or even phenomenological elements, complementing detailed mechanistic parts. In some cases, the phenomenological components are necessary "functional placeholders" for unknown or partly known mechanisms, while in other cases an implementation may employ phenomenological simplifications to "avoid the effort of explicitly modeling causal relationships or processes that lie outside of the focus of the overarching biological question" (Meier-Schellersheim, Fraser and Klauschen, 2009).

3.2 The Whole Body Modeling Framework: Representation of Organs and Tissues

The challenges for extending physiologically-based toxicokinetic models to incorporate toxicodynamic processes were summarized in the Introduction (Section 1) of this chapter. To address these challenges DORIAN complements and extends the MENTOR framework by providing a new, modular "whole body" platform for consistent integrative characterization of multicontaminant toxicokinetic and toxicodynamic processes in individuals and populations. Figure 10 shows a schematic overview of an implementation of the multicompartmental (network) structure of this platform for the human organism; the general structure incorporates sufficient physiological and biochemical information for the various organ systems to address the modeling needs for a wide range of xenobiotics. The operational model incorporates links to physiology and biochemistry databases, to account for intra- and inter-individual variation and variability in properties of the different physiological components. The structure of individual tissues and organs is macroscopically described by multicompartmental network formulations that reflect the specific attributes of intracellular and extracellular media comprising the tissue; this description is complemented, as dictated by the needs of specific applications, by a hierarchy of more detailed (virtual tissue) models that span multiple scales of biological organization. Consistencies with ontologies for physiology, anatomy, histology, cytology, and so on (Noy *et al*., 2009; Burger, Davidson and Baldock, 2008) is an important aspect of these formulations.

PBTK/TD model structures for specific chemicals, or mixtures of chemicals, can be "mapped" to subsets of the general "compartmentalized" physiological network structure presented in Figure 10. Tissues that are not explicitly modeled in chemical-specific implementations of the generalized PBTK/TD structure can be "lumped" into rapidly or slowly perfused groups while maintaining overall physiological consistency. Blood flow rates and volumes of physiological compartments are chemical-independent; however, parameters of

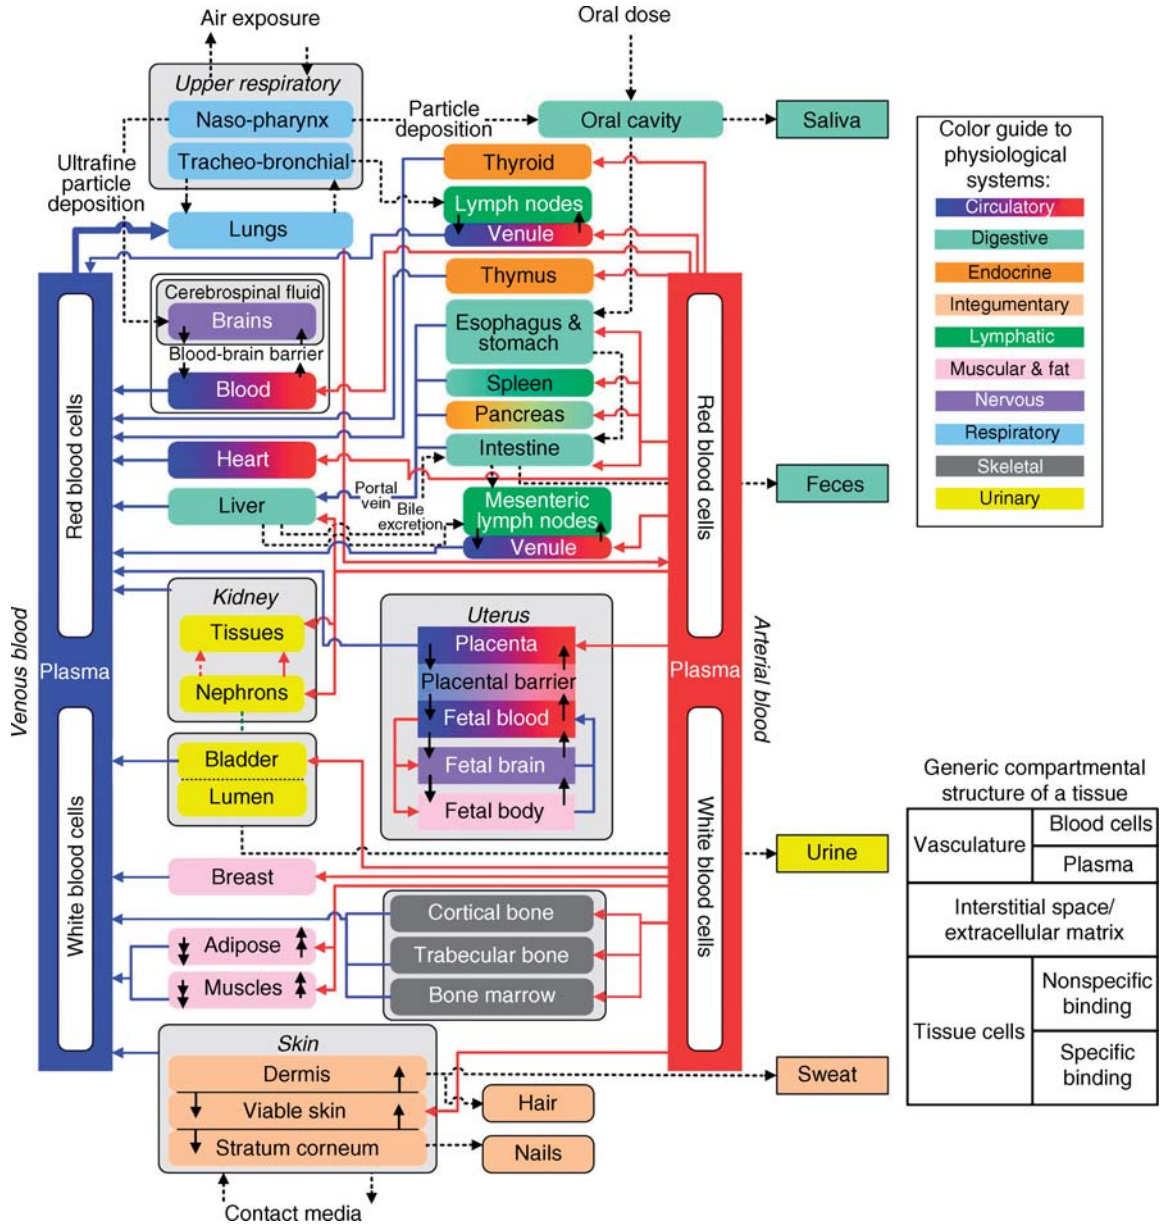

Figure 10. The MENTOR/DORIAN exposure biology framework provides a new, modular "whole body" platform for consistent characterization of multicontaminant toxicokinetic and toxicodynamic processes in individuals and populations; it incorporates links with physiology and biochemistry databases to account for intra- and inter-individual variation and variability. The structure of individual tissues and organs is described by multicompartmental formulations that reflect the specific attributes of intracellular and extracellular media complemented by more detailed (virtual tissue) models that span multiple scales of biological organization. The schematic of the whole body structure presented in this figure is customized so as to facilitate the study of the toxicokinetics and toxicodynamics of nanoparticles (see example in Section 4.7.1) (Figure source: Sasso *et al.*, 2010).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

lumped compartments in some implementations of the general formulation (e.g., flow rates and volumes of slowly perfused and rapidly perfused tissues) may vary based on the particular model structure and the toxic endpoints of interest, and these appear as chemical-dependent. However, all physiological parameters of a compartment need to be constrained so as to be consistent with the values of those quantities for the other compartments. Chemical-specific models for a wide variety of xenobiotics, including volatile and semi-volatile organics, metals and metal compounds, nanoparticles, and so on, have been deduced from this general formulation, allowing for simultaneous toxicokinetic and, in certain cases, toxicodynamic modeling, that may also consider metabolic interactions among the different chemicals (Sasso, Isukapalli and Georgopoulos, 2010).

As mentioned above, physiological variability in a population is consistently considered through linking with current biological databases that provide physiological values for a majority of the tissue groups (i.e., National Health and Nutrition Examination Survey [NHANES – Borrud *et al.*, 2010; CDC, 2010] and the P3M physiological database [Price *et al.*, 2003]). The generalized model offers the option to obtain parameters from databases for the general population and for susceptible populations (e.g., the elderly and health-impaired [Thompson *et al.*, 2009a]). Other sources of whole-body physiology include the PK-Pop scaling algorithm used by PK-Sim (Willmann *et al*., 2007), and the polynomial relationships used by PostNatal (Young *et al*., 2009). The combined MENTOR/DORIAN environment allows the definition of populations of "virtual individuals" with consistent physiology using any of the above databases.

With respect to the terminology for the entities in Figure 10, it should be mentioned that the term "tissue" is typically used (both in the present discussion and in general) in two different contexts, that is, to either signify aggregates of specialized cells of a common type (i.e., muscle tissue, nerve tissue, epithelial tissue, connective tissue) or to refer to the "cellular fabric of any organ or structure" (e.g., kidney tissue or lung tissue – each of which in fact usually contains the four classes of tissue listed in the previous context [Widmaier *et al*., 2008]). Figure 10 identifies the "standard" compartments defined by the present modeling framework for each organ. The microenvironment surrounding each cell in a tissue consists of the extracellular fluid, which is interspersed within the extracellular matrix (ECM), consisting of a mixture of protein molecules and other compounds, including minerals, that are specific for each tissue. The ECM provides a scaffold for cellular attachments and transmits information to the cells regulating their activity, migration, growth, and differentiation. The proteins of ECM consist of ropelike collagen fibers, rubberband-like elastin fibers, and various nonfibrous carbohydrate-containing proteins. The latter also function as communication links between extracellular messenger molecules and cells. The term "extracellular fluid" also refers to the fluid present in blood. Overall, about 20% of extracellular fluid is blood plasma, in which the various blood cells are suspended; the remaining 80%, which is distributed in the spaces between tissue cells, is the interstitial fluid (IF). Concentrations of dissolved substances are virtually identical in the plasma and the IF, except for protein concentrations, which are higher in plasma. In general, the entire extracellular fluid is considered to have homogeneous composition (except for proteins); however, the composition of the extracellular fluid is very different from that of the intracellular fluid. Two-thirds of it is intracellular fluid and the remaining one-third is extracellular fluid, 80% of this overall being interstitial fluid and 20% being plasma.

Organs are often organized into similar "functional units" (Widmaier *et al*., 2008). For example, functional units of the kidneys are the nephrons and the total urine from the kidneys is the sum of the amounts produced by the two million individual nephrons. Organ systems are collections of organs performing a common function: Figure 10 shows a schematic view of the "network interconnections" among the major components of the ten organ systems in the human body as implemented in the present modeling framework.

Various approaches are available to model the processes governing biological transport, biochemical transformation, and biological response in different tissues and/or organs. These approaches span a wide range, from simple, single compartment formulations for an organ to network (multicompartmental), field (structured continuum), agent-based, and hybrid formulations: Table 1 presents a general classification of these approaches and lists representative examples from the literature.

The simplest mathematical formulations involve a single, well-mixed (continuous stirred tank reactor; CSTR) compartment, in which the concentration of a chemical in the blood within an organ is assumed to be in equilibrium with its concentration in the tissue, and this concentration is assumed to be uniform throughout the organ (Abu-Zahra and Pang, 2000; Ridgway, Tuszynski and Tam, 2003). For models focusing on macroscopic properties this approach has often been sufficient because the microcirculatory networks in many organs can result in a high degree of mixing (e.g., Weiss, 1997), and there is often minimal change from using a more detailed model (Ito and Houston, 2004). This simplified approach is generally adequate for environmental toxicants when these are present at low concentrations and have relatively slow rates of uptake and metabolism. In some situations, spatial variation or heterogeneity at the macroscale can be modeled via single compartment models that represent "plug-flow reactors" (Anissimov, Bracken and Roberts, 1997; Ridgway, Tuszynski and Tam, 2003). Physiological network formulations involve descriptions of an organ or tissue via sets of reactors in series (Abu-Zahra and Pang, 2000; Anissimov and Roberts, 2002; Ridgway, Tuszynski and Tam, 2003), in parallel (Abu-Zahra and Pang, 2000; Anissimov, Bracken and Roberts, 1997), or in a combination of both. "Dispersion models" offer another approach for considering incomplete mixing within a single compartment formulation (Anissimov, Bracken and Roberts, 1997; Ridgway, Tuszynski and Tam, 2003). More detailed characterizations of variation within an organ at the macroscale employ Residence Time Distribution (RTD)-based circulatory models, which can account for concentration differences between the vascular space and the sampling compartment (Pang, Weiss and Macheras, 2007; Weiss, Krejcie and Avram, 2007), and fractal models, which represent the heterogeneity of the flow within an organ by employing fractal geometry (Ditlevsen and de Gaetano, 2005; Fuite, Marsh and Tuszynski, 2002; Pang, Weiss and Macheras, 2007). Agent-based descriptions focus on organ behavior through the collective dynamics of agents representing either cells or multicellular structures within the organ (e.g., An *et al*., 2009; Hunt *et al*., 2006; Kawazu *et al*., 2006; Yan *et al*., 2008). Field (or structured continua) formulations include models such as computational fluid dynamics (CFD) applications that focus primarily on detailed characterization of flows within the organ (e.g., Rani *et al*., 2006). Finally hybrid models, such as those developed or under development within the DORIAN framework, employ various combinations of compartmental, field, and agent approaches (Anderson *et al*., 2006; Georgopoulos and Isukapalli, 2009; Wambaugh and Shah, 2010; Zhang, Athale and Deisboeck, 2007).

4 REPRESENTATIVE FRAMEWORK COMPONENTS AND APPLICATIONS

This section consists of a series of examples demonstrating the implementation of various components along with selected applications of the general ebCTC DORIAN framework of analysis, spanning the entire molecule-to-bionetwork-to-cell-to-organism range.

4.1 Computational Chemistry Techniques for Molecular Scale Problems

Various computational chemistry techniques are used in predictive modeling of properties of individual molecules and of molecule-molecule interactions. These techniques typically rely on quantitative molecular descriptors (MDs) of xenobiotics (ligands); the MDs include metrics of various constitutional, topological, geometrical, electrostatic, and quantum mechanical properties (Welsh, Tong and Georgopoulos, 2007), and can be calculated directly from the molecular structure of a chemical. Once appropriate MDs are selected, Quantitative Structure-Activity Relationship (QSAR) models can be constructed to "predict" target properties of untested chemicals by associating specific molecular features with chemical toxicity and potentially with specific modes-of-action. In general, these methods provide a phenomenological mathematical association and not a cause-effect (i.e., mechanistic) relationship between the target property and the descriptors: typically they are derived via statistical "pattern recognition" methods such as clustering, classification, and regression. In general, clustering applies unsupervised learning techniques to explore data patterns on the basis of MDs, without ascribing these patterns to specific categorical endpoints. Classification typically employs supervised learning

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

techniques that group chemicals into known categorical endpoints (e.g., highly active, moderately active, inactive). Regression is used to establish quantitative relationships between structure and activity, typically through multivariate linear methods and, more recently, via machine learning approaches such as artificial neural networks (ANNs). A concise review of specific QSAR models that have been developed or are under ongoing development within the ebCTC framework can be found in Welsh, Tong and Georgopoulos (2007).

Modeling of ligand-receptor interactions can take place at different levels of detail. For example: (i) values of ligand-receptor binding energy (BE) calculated through physical chemistry methods (and that include solvation, etc., effects) can be used to predict the relative binding affinity of untested small-molecule compounds; (ii) calculated BE values can be used as receptor-based molecular descriptors to produce QSAR models for the ligands; (iii) models of ligand-receptor kinetics can be formulated based on biochemistry parameterized with experimental data; (iv) 3-D models of ligand-receptor "docking" can be developed using computational chemistry techniques. The ligand binding domain (LBD) of a receptor is responsible for both ligand recognition and regulation of protein–protein interactions (Shiau *et al*., 1998). Recent advances in computational hardware and in rapid ligand-receptor docking algorithms have produced successful results in various studies, involving chemicals of environmental concern such as estrogenic compounds, including steroids, phytoestrogens, and polychlorinated biphenyls (see Welsh, Tong and Georgopoulos, 2007).

4.1.1 Example: Modeling Nuclear Receptor Activity in Hepatocytes to Assess Differences in Functionality of the Pregnane X Receptor (PXR) Variants

This example focuses on the disruption of the normal function of nuclear receptors (NRs) in hepatocytes, where the majority of "detoxification" of xenobiotics takes place through metabolism (Phase I and II) and transport (Phase III). Figure 11 presents a schematic classification of pharmacogenomic/toxicogenomic regulation and signaling of phase I and phase II metabolizing enzymes participating in hepatic metabolic and detoxification processes for xenobiotics. NRs typically function as ligand-activated Transcription Factors (TFs) that regulate expression of genes involved in various metabolic disorders and cell death.

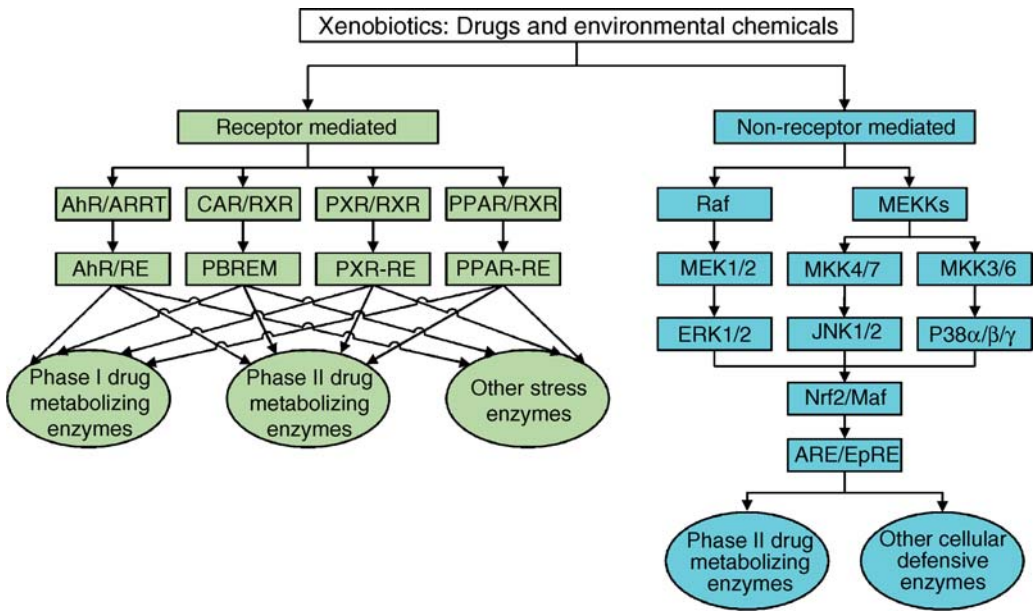

Figure 11. Schematic classification of pharmacogenomic/toxicogenomic regulation and signaling of phase I and phase II metabolizing enzymes participating in hepatic metabolic and detoxification processes for xenobiotics (adapted from Rushmore and Kong, 2002).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Forty-nine members of the "mammalian NR family" include classical endocrine receptors (ERs) as well as "orphan" receptors. Receptors that bind to a ligand become "adopted orphan" NRs and function as a dimer with retinoid X receptor (RXR); they include receptors for fatty acids (PPARs), oxysterols (LXRs), bile acids (FXR), and xenobiotics (PXR).

Dysfunction of NR signaling is linked to proliferative, reproductive and metabolic diseases (e.g., cancer, infertility, obesity, diabetes) (Aranda and Pascual, 2001; Smith and Muscat, 2005; Ai *et al*., 2009; Hotchkiss *et al*., 2008). Maintaining a normal physiological state requires controlling (temporal and spatial) tissue-specific activity of NRs. Understanding how the presence of related environmental chemicals alters NR signaling is a major objective of the DORIAN project.

Different computational methods have emerged aiming at understanding and modeling the functional activities of NR modulators at the molecular level. Generally these computational approaches fall into two categories, ligand-based and receptor-based approaches. Ligand-based methods essentially focus on molecular similarity, which implies molecules with similar features exhibit similar biological responses. It is a particularly valuable approach to identify compounds if structural information for a receptor is unavailable. By contrast, receptor-based (also synonymous with target-based) methods require the three-dimensional structure of the protein targets predominantly generated from X-ray crystallography, NMR structures or homology modeling, to address the fundamental question of how a potential ligand might bind to the receptor (Ai *et al*., 2009).

Multiple QSAR and machine learning models have been published for several NRs, including estrogen receptor (ER), androgen receptor (AR) and pregnane X receptor (PXR), primarily to address the increasing need not only for high throughput endocrine disruptor risk assessment (Ai *et al*., 2003; Jacobs, 2004; Tong *et al*., 1997), but also for toxicological screening (Zhu *et al*., 2006) in combination with crystal structures and other in silico methods. Figure 12 shows the results from molecular dynamics simulations of the ligand binding domain (LBD) and functional sites of the estrogen receptor (ER). The simulations identified a possible steroid receptor-specific functional site for the ER.

The pregnane X receptor (PXR; PXR.1) is highly expressed in the liver as well as in other tissues involved in detoxification (e.g., intestine) and in steroid-sensitive tissues such as breast (Fukuen *et al*., 2002). It is implicated in cholesterol and bile acid synthesis and metabolism, steroid hormone metabolism, and bone homeostasis (Jones *et al*., 2000; Kliewer and Willson, 2002). PXR shows broad ligand binding specificity because its ligand-binding domain (LBD) contains a novel insert that expands its size. Upon ligand activation, PXR forms a heterodimer with the retinoid X receptor (RXR) to bind to DNA response elements in regulatory regions of target genes. PXR is widely known to be a key regulator of many enzymes (Kliewer and Willson, 2002) and transporters (Synold, Dussault and Forman, 2001) involved in drug detoxification and endogenous homeostasis. There are striking species differences in PXR activation as a result of sequence differences in the LBD.

Alternatively spliced PXR mRNAs have been detected in human liver, breast tissue, colon, and small intestine (Dotzlaw *et al*., 1999; Fukuen *et al*., 2002; Lamba *et al*., 2004). For example, PXR.2 is

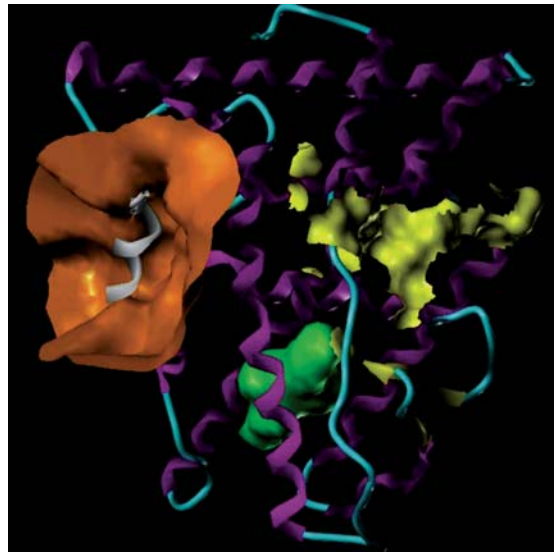

Figure 12. Functional sites on the ligand binding domain (LBD) of nuclear receptors (NRs). The endocrine receptor (ER) is used here as an example. The ligand-binding pocket is shown as a green surface. The cofactor protein-binding site is colored in orange. The computationally identified possible steroid receptor-specific functional site is shown with a yellow surface. The helices of ER are rendered by a ribbon representation and colored in magenta, while the coactivator motif is in white. (Figure source: Ai *et al*., 2009; reproduced with permission from Elsevier).

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

also the most abundant alternatively spliced transcript in human liver, accounting for nearly 7% of total PXR mRNA transcripts (Lamba *et al*., 2004). It lacks 111 nucleotides, resulting in a deletion of 37 amino acids from the LBD.

In this example, the differences in the functionality of PXR.2 compared with PXR.1 are studied *in silico* using homology modeling (Krieger, Nabuurs and Vriend, 2003) and intrinsic disorder (ID) analysis (Iakoucheva *et al*., 2002). Hyperforin (a phytochemical commonly known as St John's wort) was used as a ligand in this study. ID analyses of PXR.1 and PXR.2 were performed using the PONDR VL3H algorithm (Peng *et al*., 2005). Information on various PXR ligand bound structures (Watkins *et al*., 2001, 2003a, 2003b) was used as a basis to model the PXR.2 interaction with hyperforin. The deletion of 37 amino acids (Figure 13a, b) causes a wide opening in the binding pocket of PXR.2 (Figure 13c), and it is likely that hyperforin or other similar-sized molecules cannot be kept inside the flexible binding site when this loop is missing. The white hairline next to the red tube (Figure 13b) represents the Leu209 residue that is important for interaction with hyperforin in PXR.1. As PXR.2 has a wide opening in the binding pocket, and does not contain Leu209 residue (Figure 13c), it is likely that hyperforin will have a weaker interaction with the LBD; this could contribute significantly to the lack of function of PXR.2.

Although it would be difficult to predict the functionality of PXR.2 in relation to the multitude of structurally different PXR ligands, this example demonstrates the application of computational modeling to explain the functional differences between PXR.1 and PXR.2. Lin *et al*. (2009) present these results along with experimental data to corroborate the findings. Such uses of complementary computational and *in vitro* approaches are generalizable to study splice variants of other nuclear receptors.

4.2 Analysis, Reduction and Optimization of Bionetworks (Regulatory, Signaling, Metabolic)

A wide range of classical and novel methods are incorporated within the DORIAN framework for the analysis, reduction, and optimization of complex bionetworks; these include:

Lumping of Networks into Modules: This is a commonly used approach in dosimetric and toxicokinetic modeling. For example, sets of heterogeneous cells, tissues, and organs are represented in terms of "rapidly perfused" or "slowly perfused" compartments to represent transport and accumulation, while Michaelis-Menten kinetics are used to "lump" networks of often multiscale, biochemical processes. At the metabolic level, a large, dynamic system of metabolic reactions can be simplified through the use of pseudo steady-state assumptions (Sharma, Ierapetritou and Yarmush, 2005), and can sometimes be expressed in terms of macroscopic reactions relating to extra-network parameters (Haag, Wouwer and Bogaerts, 2005). Techniques such as perturbation analysis allow the

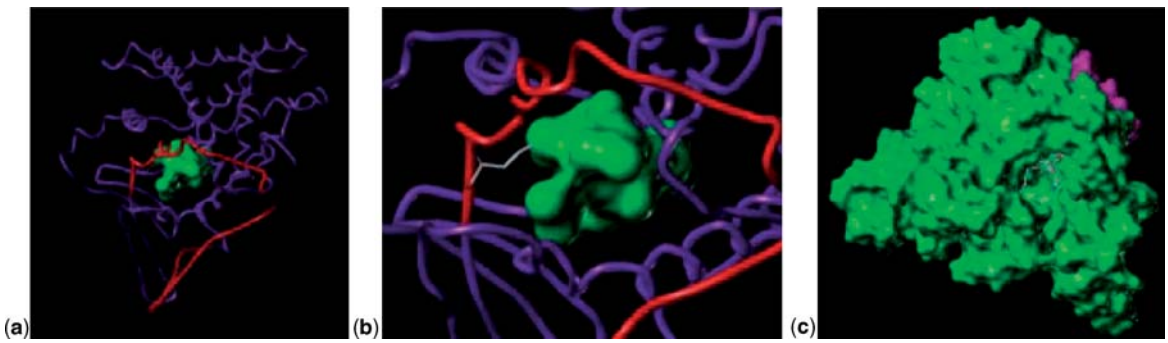

Figure 13. (a) Homology modeling of pregnane X receptor (PXR.2). The trace of PXR.1 full-length in magenta. The 37 amino acids missing from PXR.2 are depicted in red. The green surface of hyperforin is shown behind; (b) close-up view of Leu209 involved in the interaction with hyperforin in PXR.; and (c) the PXR.2 homology model surface is displayed and colored in green, whereas the helix 12 is colored in magenta. The ligand hyperforin is displayed in ball-and-stick representation and colored by atom type (carbon gray, oxygen red) (Figure source: Lin *et al*., 2009, reproduced with permission from the American Society for Pharmacology & Experimental Therapeutics).

identification of slow and fast processes within the network (Gerdtzen, Daoutidis and Hu, 2004), allowing for an a priori filtering of fast processes, thus significantly reducing data requirements associated with identification and estimation of parameters describing fast processes. The identification of self-contained functional modules also facilitates lumping of different networks (Hartwell *et al*., 1999), as these modules typically do not have large links to external nodes, and only affect a limited set of system variables. The original system can then be described approximately in terms of "networks of modules." The coupled bionetworks of biochemical interactions (metabolic, signaling, etc.) can then be "assembled" into integrative modules (e.g., cellular dynamics) related to specific events/endpoints, shown schematically in Figure 8.

"Collapsing" a Network by Reducing the Number of Possible States and Interactions: This approach allows for substantial simplification of interactions among different networks. The most common technique is to employ a one-way nesting of network interactions (i.e., the properties of a coarser-scale network are assumed to be unaffected by the properties of a finer-scale network). However, assumptions that lead to neglecting the influence of finer-scale components on coarser-scale properties need always to be evaluated on a case-by-case basis. An example is neglecting the impact of toxicant fraction bound to ligands in a tissue when calculating tissue-level concentrations of the chemical. A useful technique for further collapsing the network based on reduction in the number of possible states is via qualitative simulations (Eisenack, Welsch and Kropp, 2006), which can overcome the computational demands associated with combinatorial explosion in the number of possible states and the limitations that arise from sparse data.

Representing Network Heterogeneity Via Uncertainty Distributions: This approach is based on representing heterogeneity in terms of variables that are "unknown" but random. The aggregate properties of random distributions present a global picture while finer-scale detail can be reflected in different statistical moments of the joint distributions. For example intra-individual variability in physiological parameters for populations is often described in terms of probability distributions of inhalation rates, metabolic rate constants, and so on.

Two examples demonstrating the characterization and analysis of bionetworks (a transcription factor network and a set of metabolic networks) follow.

4.2.1 Example: Transcription Factor Network Reconstruction From In Vitro Living Cell Array (LCA) Data Using Reverse Euler Decomposition (RED)

As the spectrum of techniques for obtaining high throughput *in vitro* data is expanding rapidly, new computational approaches are also needed to take full advantage of them. This example describes transcription factor network reconstruction from *in vitro* data from one such technique, the Living Cell Array (LCA). LCA is a microfluidics device that utilizes cells transfected with reporter plasmids. These reporter plasmids consist of an unstable green fluorescent protein (GFP), a minimal promoter, and 4 repeats of a transcription factor's consensus sequence (Wieder *et al*., 2005).

The LCA allows for studying the levels of transcription factor activity under multiple stimuli at high temporal resolution. This improves the ability to decipher the interactions between different transcription factors (TFs) by alleviating data limitations commonly encountered in reconstruction of transcriptional networks from microarray data (Somorjai, Dolenko and Baumgartner, 2003), where the number of genes measured is typically much greater than the number of experimental conditions or time points in which they are measured.

Reverse Euler Decomposition (RED) offers a computational approach for utilizing LCA datasets for isolating TF interactions and for quantifying nonlinear phenomena that are present in biological systems (Hemberg and Barahona, 2007). Identifying these nonlinear interactions is important because they provide evidence of specific mechanistic effects that govern transcriptional activation.

The network reconstruction example here assumes that the dynamics of TF activity can be described through an appropriate, yet to be determined, function (F) which is dependent upon the TF activity itself, and a forcing function, s, which may or may not be a function of time, indicating a specific and direct activation of a TF. In the context of LCA, the forcing function is assumed to be independent of time since it is presumed that the soluble factors continuously activate the TFs through infusion. The activity of the TFs is quantified by monitoring of the expression of the corresponding reporter genes.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

To convert the bi-partite network into a form usable by RED, it was assumed that the direct stimulation of a reporter can only occur via its associated soluble factor, and all other interactions were assumed to be secondary (Yang, Yarmush and Androulakis, 2009). Therefore, if a bi-cluster contains a stimulatory factor of TNF-α and was found to stimulate both NFκB and STAT3, one can assume that there is a direct link between TNF-α and NFκB, while the stimulation of STAT3 must occur downstream of NFκB. Because STAT3 must occur downstream of NFκB, it was assumed that a single process exists that links NFκB to STAT3 and the mechanism and dynamics of interest (Yang *et al*., 2007).

The overall hypothesis behind utilizing the RED is that the numerical response *f(i,j,t)* provides insight as to the underlying processes driving the observed changes in the activity of transcription factors. The functions *f(i,j,t)* essentially represent how the various mechanisms transform the amount of active transcription factors into a signal which is then used to activate a secondary transcription factor. Treating the transcriptional network as a circuit analog, one can exploit the fact that many of the simple network architectures that are obtained have well characterized step responses. Because the LCA utilizes a step input as the stimulatory profile for its soluble factors, one should be able to draw direct comparisons between the observed responses and the characteristic inputs. Figure 14 shows these basic interactions and the expected responses of the system to a step input. By combining these simple components, composite components can be generated that can capture profiles that have both a time delay and tolerance effect. It is then possible to predict important underlying mechanistic properties such as feed forward networks, tolerance

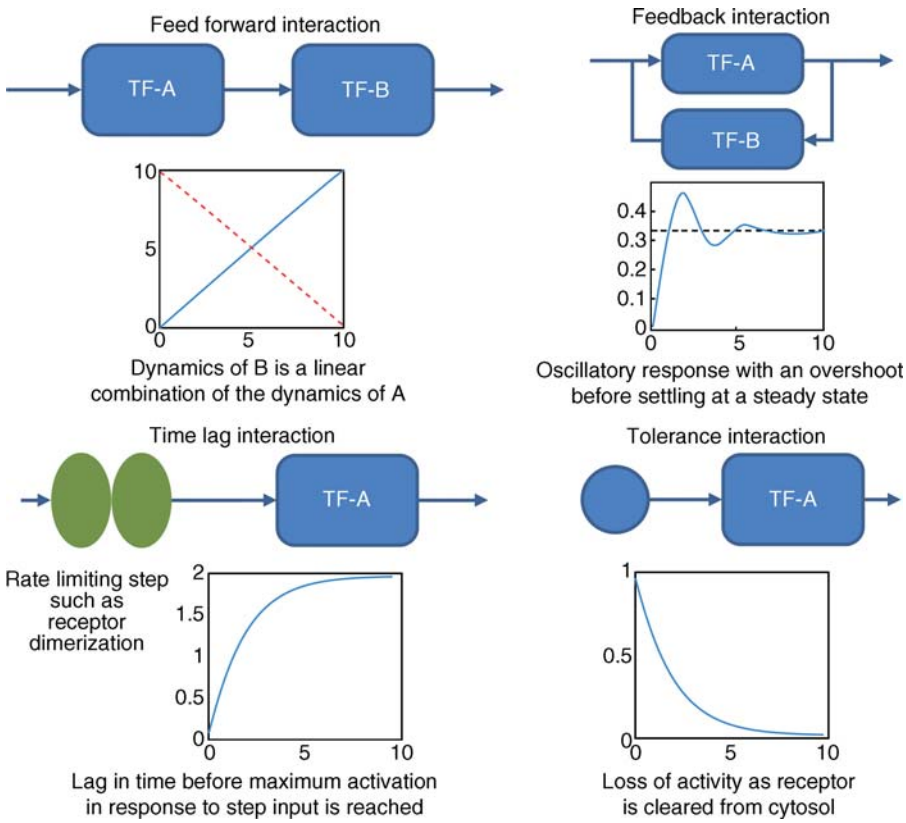

Figure 14. Typical network motifs and their expected responses for a unit step input. Shown are the interaction strengths along the y-axis and time on the x-axis. TF-A and TF-B represent two transcription factors. (Figure source: Yang, Yarmush and Androulakis, 2009; reproduced with permission from Elsevier).

mechanisms, feed-back networks, and time delay properties.

In the RED approach, the results from an LCA experiment can be reconstructed in a simplified manner using a Forward Euler Integration. One limitation of this reconstruction is the significant error propagation, that is, errors from previous time points are propagated into the predictions for later time points (Dunn, Constantinides and Moghe, 2006). However, for many cases, the reconstructions provide satisfactory representations of the underlying data patterns.

Along with simple network building and determining which transcription factors actively regulate each other, the LCA combined with RED allows for the assessment of possible network connectivity structures as well as provides insight into the dynamics of the interactions. In problems involving optimization of network structures, substantial computational savings can be obtained by using the simplified representation instead of the full network, since the simplified representation can adequately represent the overall dynamics. In cases where major dynamics are not captured, the system response will still degrade gracefully instead of failing completely.

Figure 15 shows results from bi-clustering of LCA data on hepatic inflammation (see Section 4.3 for a discussion of inflammatory response modeling). The LCA data were collected from experiments where soluble stimuli were applied to capture major cellular response profiles relevant to inflammation (Thompson *et al*., 2004). The RED approach was able to adequately capture the original responses using a simplified network, as shown in Figure 16.

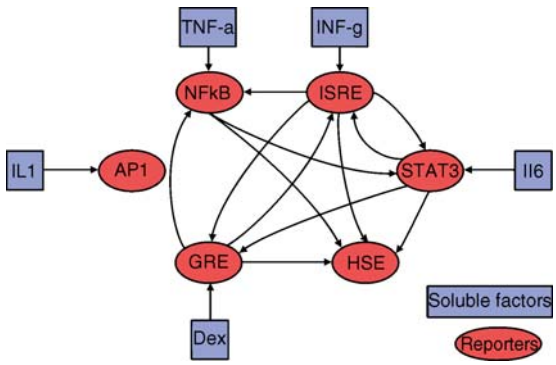

Figure 15. Directed Graph associated with the bi-clustering analysis of Living Cell Array (LCA) data for identifying key processes in hepatic inflammation. In the simplified model, AP-1 is unconnected because it was not found to be part of any bi-cluster. (Figure source: Yang, Yarmush and Androulakis, 2009; reproduced with permission from Elsevier).

4.2.2 Example: Analysis of Xenobiotic Metabolism and Interactions - Construction of Optimized Metabolic Networks via Metabolic Flux Analysis for APAP and Ethanol

This example focuses on the analysis of the metabolic networks of two widely encountered xenobiotics, acetaminophen and ethanol. Given the complexity and interconnectedness of pathways relevant to hepatocyte metabolism, various approaches integrating experimental data with mechanistic mathematical modeling have been applied to understand the dynamics of the various metabolic networks. A commonly used approach is metabolic flux analysis (MFA). MFA can infer the rate of intracellular fluxes from the flux of consumed or secreted metabolites. This approach has been used to quantify the fluxes of cultured rat hepatocytes exposed to different media conditions, to predict what media modifications may optimize hepatic functions, and to identify the metabolic changes associated with toxicity induced due to free fatty acid exposure (Chan *et al*., 2003;Sharma, Ierapetritou and Yarmush, 2005; Srivastava and Chan, 2007). Energy balance analysis (EBA) considers energy balance constraints along with the stoichiometric and mass balances used in MFA and has been used to investigate various liver-specific objectives in gluconeogenic and glycolytic hepatocytes (Nagrath *et al*., 2007). For systems that lack network-wide experimental measurements, Thermodynamic Based Profiling (TBP), an approach that applies thermodynamic constraints for each biochemical reaction, can be used. Yang and Beard (2006) used this method to predict pathways important for drug-drug interactions in hepatocytes.

Figure 17 presents a biochemical network that was reconstructed so as to reveal interactions of acetaminophen and ethanol with hepatic metabolic processes. This network considers the main pathways of para-acetylaminophenol (APAP) metabolism as well as the formation of conjugative species from amino acids, salts, and carbohydrates, ethanol metabolism, and central hepatic metabolism. The xenobiotic metabolism reactions

that are considered are specific to APAP, representing three parallel pathways: glucuronidation, sulfation, and CYP oxidation; however, this network may be expanded in a straightforward manner to include other Phase II pathways, if desired.

Based on the assembled metabolic network of Figure 17 and on values of *in vitro* kinetic parameters and flux bounds taken from the literature, the feasible metabolic fingerprint was calculated for the hepatic metabolism of APAP under different physiological conditions in the rat. Optimization methods were used to determine the flux distribution for maximal xenobiotic detoxification, to understand the pathways that participate in the competition between ethanol and APAP metabolism that contributes to increased drug-induced liver damage, and to evaluate the robustness of the complex network. Treated cultured cells were used to verify those pathways that are most important in APAP detoxification, metabolism of ethanol, and coupling with hepatic functions, and to assess the extended xenobiotic -metabolizing capabilities of the cell.

A kinetic model of the major pathways involved in APAP metabolism was constructed by assembling data from a number of different sources. In this example, concentrations are expressed in terms of nmol per 10^6 cells. The relative importance of the individual APAP metabolism pathways was investigated by simulating a dose-response experiment (Figure 18). When APAP is administered at a low

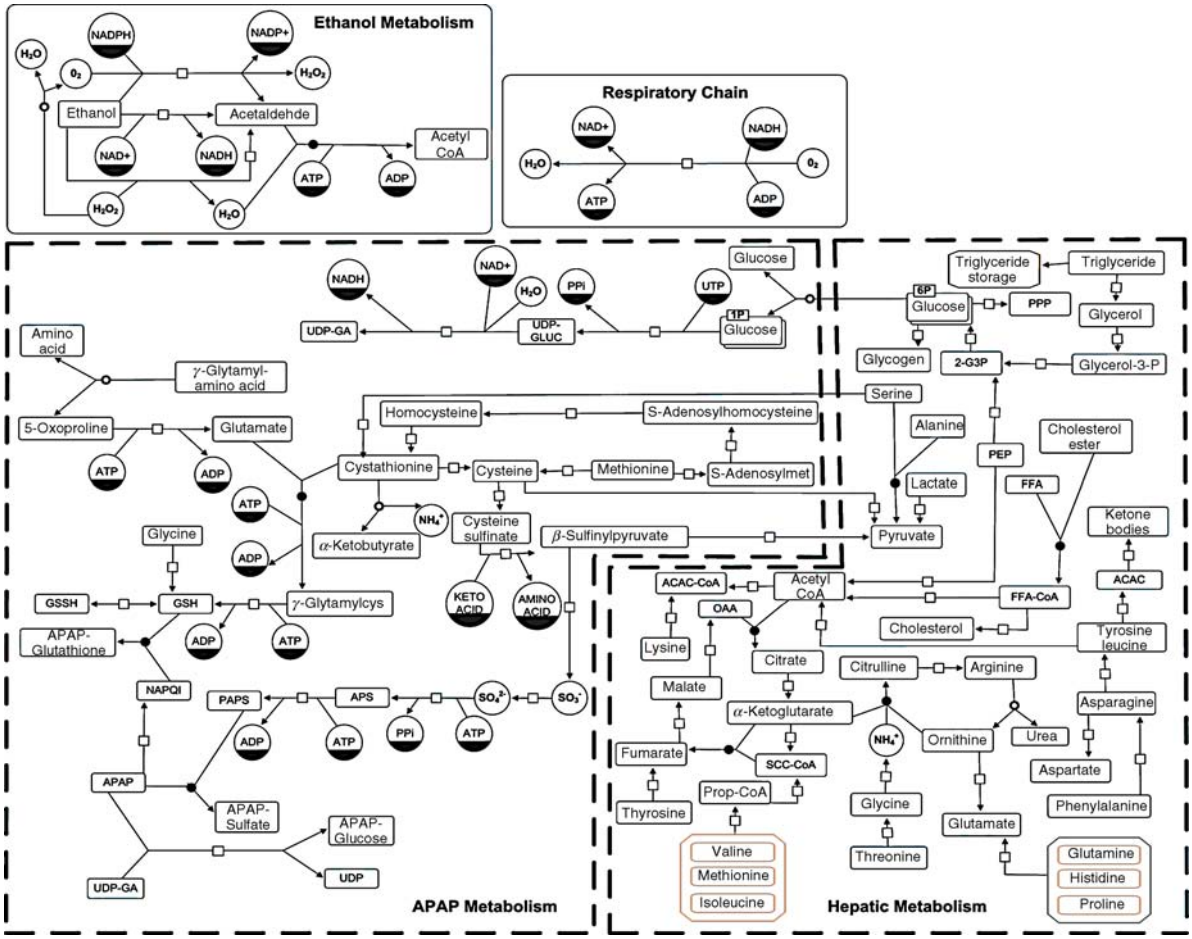

Figure 17. Pathways for central hepatic, APAP, and ethanol metabolism: the network that is schematically summarized in this figure in SBGN format includes 112 reactions and 73 internal metabolites.

dose, the majority is conjugated with the activated sulfate and to a lesser extent with UDP-glucuronidic acid. Oxidation of the xenobiotic leads to the formation of a minor amount of NAPQI that is quickly detoxified through glutathione conjugation (Figure 18a). As the dose increases, the rate of sulfation is limited by the availability and formation of PAPS; above a dose of 1 mmol kg^{-1} of rat body weight glucuronidation becomes the predominate pathway (Figure 18b) (Klaassen and Boles, 1997).

To simulate the effect of fasting on the formation of the oxidative product, kinetic information from a study comparing the potentiation of APAP hepatotoxicity for fasted and fed rats was incorporated into the model (Price, Miller and Jollow, 1987). This study reveals that at high doses the apparent rate constants of the glucuronidation and sulfation reactions were decreased by 40% and 30%, respectively, while the formation rate of the glutathione conjugation remained unchanged. Decreased glucuronidation and sulfation, attributed to the depletion of conjugative species, leads to longer elimination of the parent compound. Indeed, altering these two rate constants in the model leads to a prediction of an approximately 50% increase in the production of the toxic metabolite. As toxic doses quickly deplete stores of glutathione, PAPS, and UDPGA, their re-synthesis becomes the rate-limiting step in subsequent conjugation reactions (Figure 19a).

Simulations on the effect of ethanol pretreatment were executed by substituting the model's CYP450

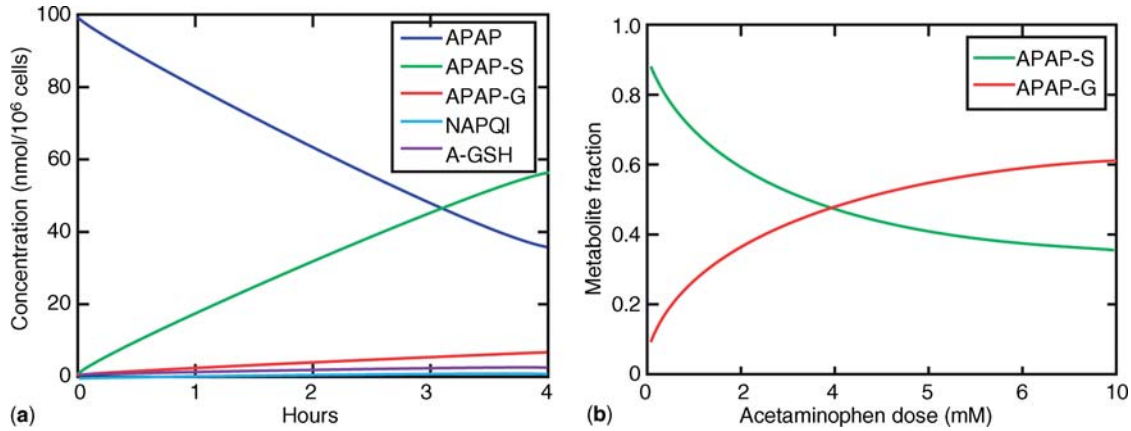

Figure 18. Simulations using the combined metabolic network for acetaminophen (APAP) and ethanol. (a) Time course profiles of APAP metabolites at low APAP doses (40 nmol/10^6 cells); (b) impact of increasing doses of APAP on the metabolite fractions.

kinetic parameters of the model. The values used to describe the system in the absence of ethanol are the mean values taken from rat liver microsomes studies (Patten *et al*., 1993; Thummel *et al*., 1993) without ethanol pretreatment. To investigate the effect of ethanol pretreatment, these values were substituted with the ethanol condition values obtained from Patten *et al*. 1993, who administered ethanol to male rats as a 15% solution (v/v) in drinking water for three days prior to microsome preparation followed by *in vitro* APAP dosing. The results of the simulation for APAP-GSH concentrations in response to increased APAP levels for control and ethanol pretreatment conditions are shown in (Figure 19b).

4.3 Multiscale Modeling of Systemic Endotoxin-Induced Inflammation in Humans Employing Network and Agent Methods

The examples in this subsection demonstrate applications of network- and agent-based approaches in the study of a "prototype" stressor/response problem: endotoxic-induced inflammation.

The acute inflammatory response (AIR) is the initial response of the host to a diverse array of biological stressors including infection, burns, trauma, and invasive surgery. The regulation of human inflammatory response involves not only the local release of anti-inflammatory cytokines

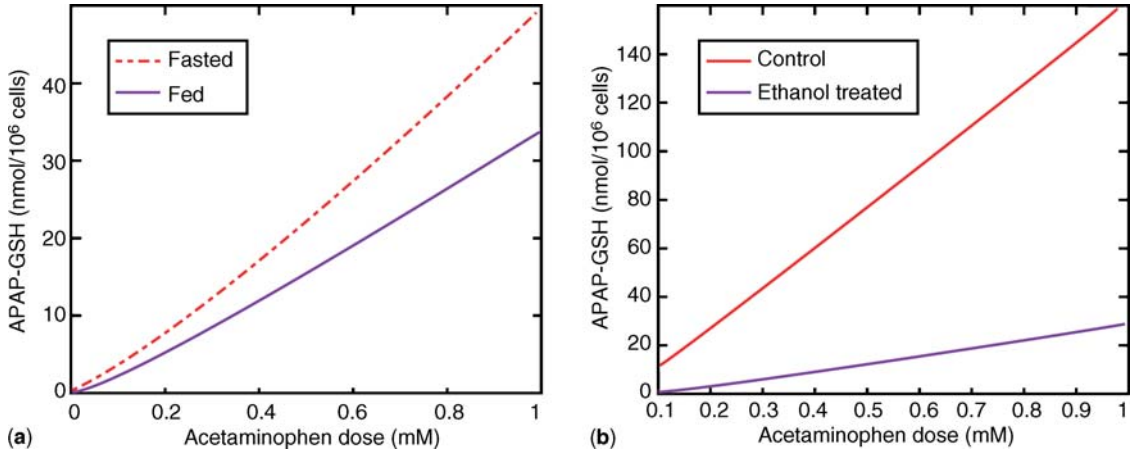

Figure 19. (a) Effect of fasting on APAP metabolism, calculated by changing the values of enzyme parameters in the combined metabolic network for APAP and ethanol; (b) impact of ethanol pretreatment prior to APAP treatment.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

but also other hormonal influences (Lowry, 2009). Under normal circumstances the dynamics of acute inflammation are tightly regulated and self-limited (Hotchkiss and Karl, 2003). However, when anti-inflammatory processes fail, an amplified inflammatory state is reached that is characterized by severe, uncontrolled systemic inflammation leading to multiple organ dysfunction (Bone *et al*., 1992). Mechanistic simulations of inflammation (Vodovotz *et al*., 2009), especially multiscale modeling approaches have the potential to generate alternative testable hypotheses for assessing how cellular events and inflammatory processes mediate the links between patterns of autonomic control (HRV) and clinical outcomes.

Various studies have indicated that the central nervous system (CNS) is a pivotal regulator of the immune response and controls inflammation at various levels (Blalock, 2002; Elenkov, 2008; Elenkov *et al*., 2005; Jara *et al*., 2006; Taub, 2008). As discussed in the previous sections, research at ebCTC pursues the development of a systems-based approach that integrates processes across multiple scales and subsequently models the emerging host response as the outcome of orchestrated interactions of critical modules. The new models of human inflammation detailed here utilize indirect response and agent-based modeling (ABM) for bridging the initiating signal (LPS) and phenotypic expressions (HRV) through semi-mechanistic host response models that include transcriptional (cellular) dynamics, signaling cascades and physiological (hormonal) components.

Human endotoxin challenge is a well-accepted surrogate model for studying the acute inflammatory response, as it captures many of the clinically observed features of the systemic inflammatory phenotype (Calvano *et al*., 2005; Fannin *et al*., 2005; Lowry, 2005; Talwar *et al*., 2006; Wittebole *et al*., 2007). Endotoxin is a major component of the outer membrane of gram-negative bacteria, and the inflammation caused by the activation of the innate immune system by this moiety can be a complicating factor in a variety of situations, including trauma, invasive surgery, and organ-specific illnesses. The prototypical examples of endotoxin are lipopolysaccharides (LPS). The response following endotoxin administration in human subjects includes core temperature, cardiac, vasomotor, hematologic, metabolic, hormonal, acute phase reactant, and cytokine components that have been well described (Copeland *et al*., 2005; Lowry, 2005; van Deventer *et al*., 1990; Van Zee *et al*., 1995). In particular, innate immune cell activation leads to the production and release of pro-inflammatory cytokines, which are proximal mediators of the systemic inflammatory response. Although the bulk of this pro-inflammatory mediator release likely originates in cells of the reticuloendothelial system (Fong *et al*., 1990), the leukocytes present in peripheral blood are also activated and, importantly, are available for sampling with minimal invasiveness.

4.3.1 Example: Network-Based Simulation of Systemic Response to Human Endotoxin Challenge

This example focuses on direct communication links from the cellular to the systemic host response level, integrating bi-directional influences between systems (Foteinou *et al*., 2010), via the following steps: *First*, analysis of leukocyte gene expression data allowed the identification of essential responses characterizing the cellular (transcriptional) dynamics. *Second*, physicochemical modeling (Aldridge *et al*., 2006) was employed to express the relations and dynamics that connect extracellular signals and intracellular signaling cascades, eventually leading to the emergent transcriptional dynamics (identified in the previous step). *Finally*, an indirect response (IDR) model (Jusko and Ko, 1994) was used to describe the toxicodynamics by establishing implicit interactions among signaling molecules and emerging transcriptional responses. A schematic illustration of the network architecture that constitutes the multi-level host response model is presented in Figure 20. At the cellular level, interacting components involve the propagation of LPS signaling on the transcriptional response level (P, A, E) through the activation of endotoxin signaling receptor (R) and elementary signaling pathways (NFκB signaling module). At the level of circulating hormones, essential modules are associated with the release of endocrine stress hormones from neuroendocrine axis (HPA, SNS) coupled with their anti-inflammatory influence on the host. The dynamics of cortisol and epinephrine signaling involve components interacting at the cellular level. At the systemic level, physiologic deterioration of the host is quantified by HRV.

In the injury model, the inflammatory response is activated when endotoxin is recognized by pathogen

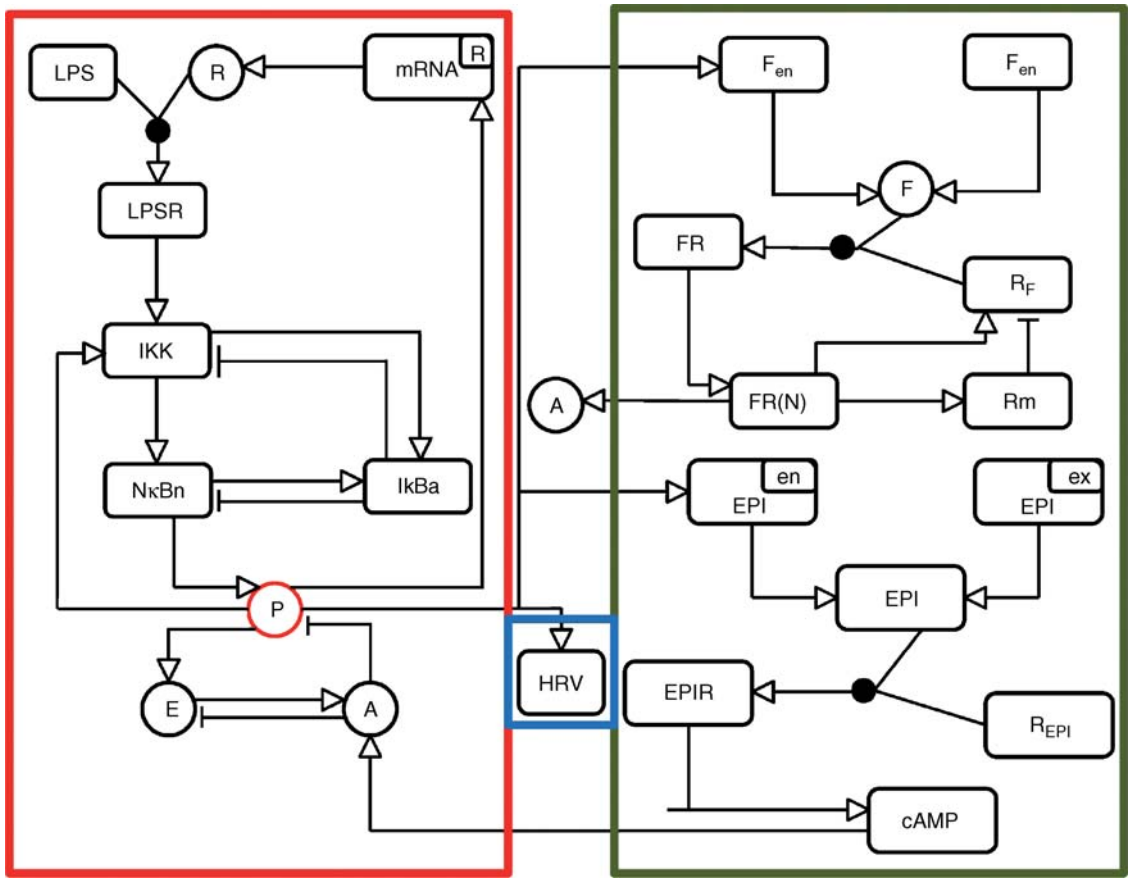

Figure 20. Topological interactions composing the multiscale model of inflammation. At the cellular level, interacting components involve the propagation of LPS signaling on the transcriptional response level (P, A, E) through the activation of endotoxin signaling receptor (R) and elementary signaling pathways (NFκB signaling module). At the level of circulating hormones, essential modules are associated with the release of endocrine stress hormones from neuroendocrine axis (HPA, SNS) coupled with their anti-inflammatory influence on the host. The dynamics of cortisol and epinephrine signaling involve components interacting at the cellular level. At the systemic level, physiologic deterioration of the host is quantified by HRV.

recognition receptors (Wells, Ravasi and Hume, 2005). The LPS-induced stimulation initiates a complex signaling cascade that ultimately targets the transcription initiation of pro-inflammatory cytokines (Kishore *et al*., 2004). During the recognition process LPS binds to the LPS-binding protein in plasma and is delivered to the surface receptor CD14. Subsequently, LPS is transferred to the signaling toll-like receptor 4 (TLR4) with the recruitment of its essential accessory protein MD2 (Du *et al*., 1999; Guha and Mackman, 2001;Van Amersfoort, Van Berkel and Kuiper, 2003), eventually leading to the translocation (activation) of pro-inflammatory transcription factors (e.g., NF-κB) (Calvano *et al*., 2005).

In this example, it was hypothesized that the pro-inflammatory response acts as the stimulatory factor for the energetic response while a dysregulation in the cellular bio-energetics can serve as a positive feedback danger signal to the pro-inflammatory response. The anti-inflammatory response serves as the essential immunoregulatory signal that aims to restore homeostasis in the host defense system. Therefore, a single compartment toxicodynamic model was employed for LPS assuming a homogeneous circulating blood compartment; this model contains pro-inflammation components and energetic responses that inhibit the pro-inflammation response. In human subjects the endotoxin is cleared within the first 1–2 h after LPS

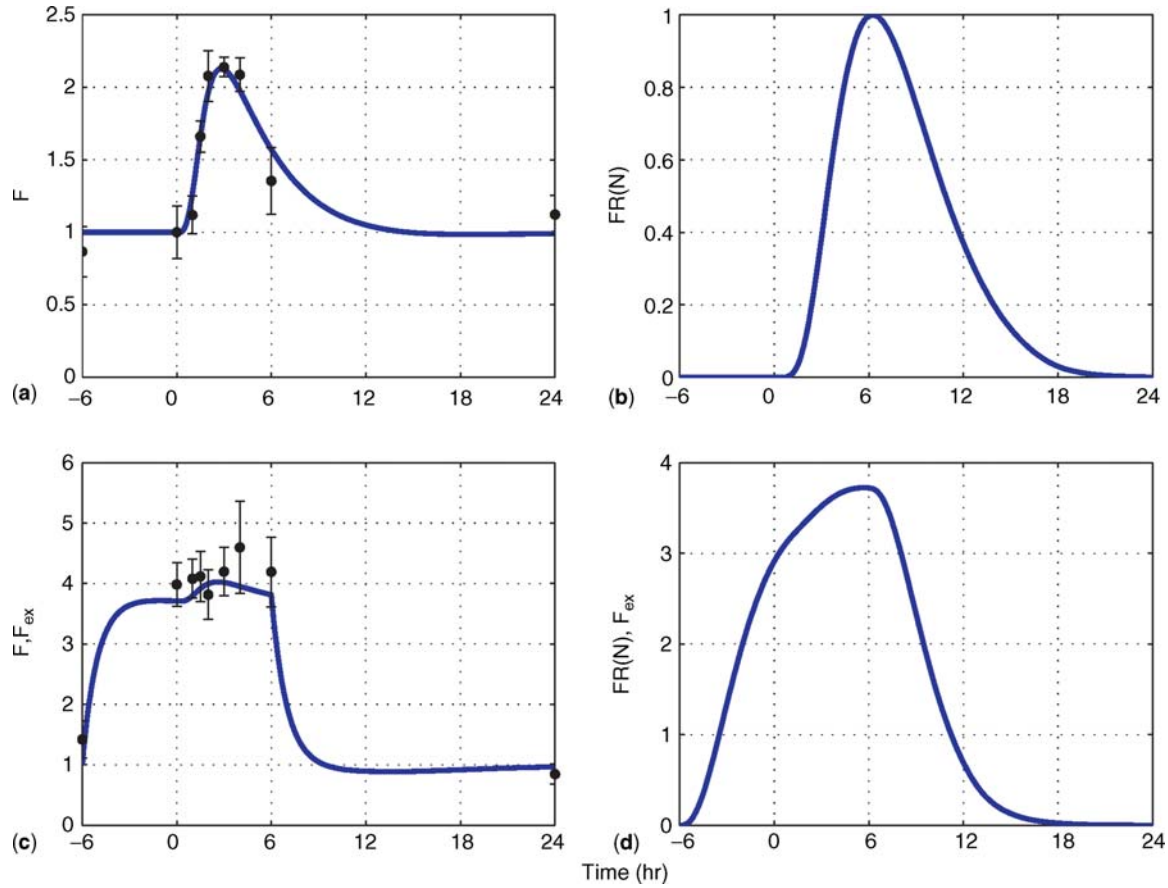

Figure 21. (a) Plasma cortisol levels (F) and (b) steroid active signal (FR(N)) under conditions of acute endotoxin injury (LPS(t = 0 h) = 1); (c) Simulated plasma cortisol levels (FFex) and (d) steroid active signals FR(N)Fex under conditions of low-dose steroid infusion (wFex = 1) which is initiated at t = −6 h before LPS and continued for 6 h after LPS. Solid lines correspond to model predictions while solid markers represent experimental data expressed as mean ± SEM. (Figure source: Foteinou *et al*., 2010.)

administration with an approximate average half time of 8–15 min (Greisman *et al*., 1969). The model parameters have been independently estimated so that the LPS profile decays within two hours in the absence of any complications (Greisman *et al*., 1969).

Figure 21 shows the persistent inflammatory response, which corresponds to an increased exposure of the host response to the inflammatory stimulus (LPS). Since increased catecholamine secretion accompanies modest infection and the effect of EPI in inhibiting LPS-induced pro-inflammatory response has been documented, exploratory simulations were conducted to study whether antecedent EPI infusion would alter the cytokine responses to endotoxin as shown in Figure 22, in order to identify potential protective measures against inflammation.

4.3.2 *Example: Agent-Based Modeling of Endotoxin Induced Acute Inflammatory Response in Macrophages*

In this example, an agent-based modeling (ABM) approach was used to study the dynamics of acute human inflammation. Interacting agents are either inflammation specific molecules or cells essential for the propagation of the inflammatory reaction across the system (Dong *et al*., 2010). Spatial orientation of molecule interactions involved in signaling cascades, coupled with the cellular heterogeneity is further taken into account.

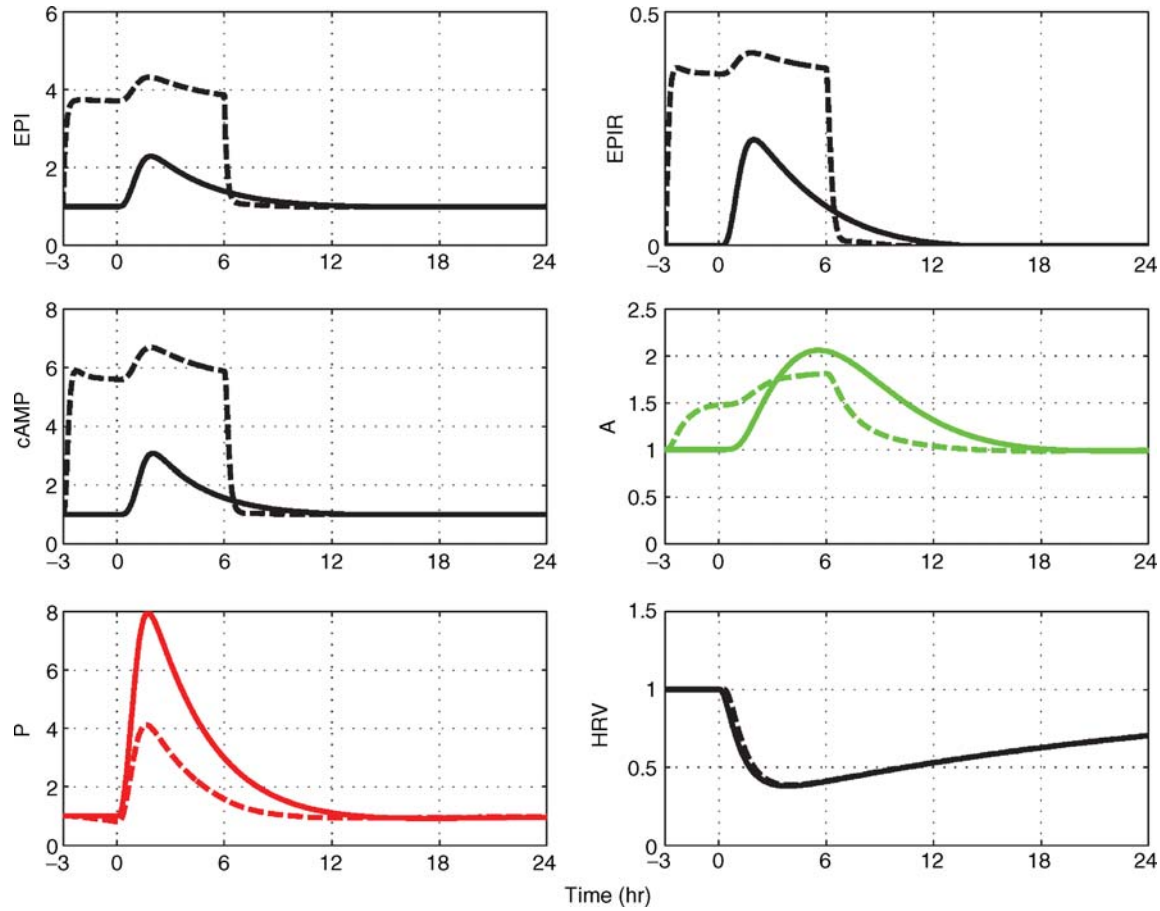

Figure 22. Modulation in the progression of the inflammatory reaction due to short-term epinephrine infusion (initiated 3 h before lipopolysaccharides (LPS) exposure and continued for 6 h after LPS exposure). Such intervention potentiates the secretion of epinephrine from SNS that through cAMP anti-inflammatory signaling can protect in part the host response attenuating the pro-inflammatory response (P). Solid lines simulate a self-limited endotoxin-induced inflammatory reaction while dashed lines reflect the scenario of prior epinephrine infusion ($w_{EPIex} = 1$, $R_{in,EPI} = 20$). (Figure source: Foteinou *et al.*, 2010.)

The agents in this model represent different aspects of the system under study, including families of cells and/or molecules that are able to adapt and interact with the environment and with each other based on a specific set of rules (Vodovotz *et al.*, 2008). While agents within a class will have the same rules for behavior, the behavior of individual agents varies because of differences in local conditions and because of probabilistic application of rules to simulate agent dynamics. The individual interactions then aggregate to engender the overall behavior observed in an experimental setting. The advantage of the ABM approach lies in the fact that the rules governing interactions of agents can be developed in an intuitive manner based on fundamental occurrences in biological processes (e.g., binding of molecules).

This example is based on the premise that peripheral blood leukocytes (PBLs) are major effectors in response to endotoxin and that PBLs represent a composite mixture of several cellular subpopulations. During the onset of the inflammatory response, the secretion of pro-inflammatory cytokines from macrophages stimulates the activation of precursor T helper cells (Th0) and induce them to exhibit the type 1 T helper cell (Th1)

Red polygons refer to the endotoxin (LPS) receptor and blue polygons refer to the TNF-α receptor. Light green polygons correspond to IL-4 receptors and dark green polygons reflect the presence of kinase (IKK). Blue + orange squares represent the inactive (bound) NF-κB with its inhibitor, IκBα while the grey area refers to the nucleus. (Source: Dong *et al*., 2010.)

phenotype, which in turn facilitates the secretion of various pro-inflammatory cytokines (McKnight *et al*., 1994). Additionally, Th0 can also transform to type 2 T helper cells (Th2) and produce anti-inflammatory cytokines that are essential for restoring homeostasis (Kidd, 2003).

The overall host response to endotoxin is simulated via interacting molecules and cells based on the ABM model shown in Figure 23. Each macrophage possesses a cell membrane comprised of agents arranged in a circle around the center of the cell, which constitutes the nucleus. Receptors for LPS, IL-4, and TNF-α are embedded in the membrane while the inhibitor protein IκBα, IKK, and NF-κB are located in the cytosol. This model considers the pro-inflammatory response (P) consisting of the early increased expression of cytokines and chemokines; the anti-inflammatory response (A) that serves as the immunoregulatory arm of the host defense system; and the energetic response (E) that involves the expression of genes that participate in cellular bioenergetic processes. It also considers an NF-κB dependent physicochemical host response model (Foteinou *et al*., 2009). The model is implemented using NetLogo software (Wilensky, 2010) and is evaluated through its ability to successfully reproduce a self-limited inflammatory response as well as a series of scenarios involving either a persistent (non)infectious response or innate immune tolerance and potentiation effects followed by perturbations in intracellular signaling molecules and cascades.

Prior to any external perturbation, NF-κB is inactive in the cytoplasm forming a complex with its primary inhibitor, IκBα. Upon stimulation, NF-κB translocates to the nucleus activating the transcriptional machinery for the up-regulation of the critical transcriptional events (Folcik, An and Orosz, 2007; Kidd, 2003; McKnight *et al*., 1994). During the recognition process of LPS from its signaling receptor (R), a signal transduction cascade is triggered that up-regulates the transcription of TNF-α. The presence of pro-inflammatory mediators (P) promotes the migration of mature T helper cells (Mackay, 2000) where Th0 cells become Th1, while the production of anti-inflammatory mediators (A) incites formation of Th2 cells which further potentiate the anti-inflammatory response (A) (Kidd, 2003). Since the anti-inflammatory arm of the host defense system restores homeostasis, the anti-inflammatory component of the model, including anti-inflammatory mediator agents (A), is assumed to exert its counter-regulatory properties by stimulating the degradation rate of the early potent pro-inflammatory mediator TNF-α, coupled with the active populations of T helper cells. In particular, the Th2 agents continuously produce anti-inflammatory mediators to ensure that the population of (A) agents is sufficient to attenuate TNF-α production in macrophages. Since circulating pro-inflammatory (P) agents have the ability to turn Th0 into Th1, instead of Th2, the population of Th2 cells is primarily affected by the concentration of (P) agents. All the interacting components constituting the agent-based model of inflammation are shown in Figure 24.

The agent-based model predicted the situation where the initial levels of LPS are increased in Figure 25. It was observed that when the concentration of the inflammatory stimulus exceeded a critical threshold, the inflammatory response did not abate. Such a response is characterized by overwhelming production of the pro-inflammatory instigator, TNF-α, which amplifies the activity of NF-κB. In

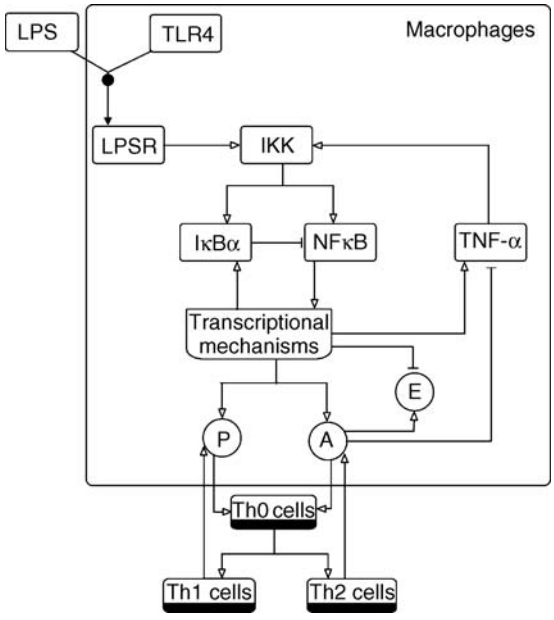

Figure 24. Schematic illustration (in SBGN format) of elements and interactions involved in the Agent Based Model of endotoxin-induced inflammation.

particular, high LPS concentration potentiates the secretion of pro-inflammatory mediators (P), which in turn may increase the probability of Th0 cells to differentiate into Th1 cells rather than into Th2 cells. Additionally Th1 cells further increase (P) population; thus disturbing the balance between Th1/Th2, accounting for the progression of an unconstrained inflammatory response.

While comparing the output of the agent-based model with the output of the deterministic models, it should be noted that both modeling approaches may not be characterized by the same network topology. However, the two modeling approaches predicted responses (e.g., P, A, E) with reasonable qualitative agreement.

4.4 Cellular Level Modeling of Toxicokinetics and Toxicodynamics

4.4.1 Example: Arsenic Toxicokinetics and Toxicodynamics in Mammalian Hepatocytes

This example presents a semi-mechanistic model of combined cellular arsenic toxicokinetics (TK) and toxicodynamics (TD). The model describes the uptake, biotransformation and clearance (TK) of multiple arsenical species in mammalian hepatocytes, along with subsequent cellular adaptive response (TD). Arsenic is an environmental pollutant, potent human toxicant, and oxidative stress agent with a multiplicity of health effects associated with both acute and chronic exposures; effects include cancers of the liver, bladder, skin, and lung (ATSDR, 2007).

The cellular level TK model describes arsenic transport across the cellular membrane and subsequent multistep metabolism in hepatocytes according to the reaction cascade proposed by Hayakawa *et al.* (2005). This model predicts the concentrations of trivalent and pentavalent arsenicals in hepatocytes by simulating uptake of arsenite (iAs^{III}) via aquaporin isozymes 9 (AQP9s), glutathione (GSH) conjugation, methylation by arsenic methyltransferase (AS3MT), efflux through multidrug resistant proteins (MRPs) and the induced antioxidant response via thioredoxin reductase (TR) activity. Methylation reactions are described through a hybrid approach of Hill and Michaelis-Menten kinetics, while the GSH-bound hydrolysis and clearance of methylated arsenicals was described by a threshold-dependent formulation using a sigmoidal function.

Figure 26 illustrates a simplified overview of cellular toxicokinetics and toxicodynamics of arsenic (for the mammalian hepatocyte). The toxicokinetics of arsenic include both "traditional" metabolism (methylation) via AS3MT (methyltransferase) as well as a new metabolic pathway of inorganic arsenic biotransformation via arsenic-GSH complex formation. This pathway includes two separate branches of arsenic biotransformation: $MADG \rightarrow MMA^{III} \rightarrow MMA^{V}$ and $MADG \rightarrow DMAG \rightarrow DMA^{III} \rightarrow DMAV$ (based on Hayakawa *et al.*, 2005). The toxicokinetic pathway carries reactive oxygen species (ROS) formation and corresponding DNA damage, as well as DNA repair.

The model parameters were estimated using data on low doses from Styblo *et al.* (1999) and dose-response data from Drobna *et al.* (2004) (data at 24 h post exposure for doses ranging from low to high: 0.1–10 μM). As shown in Figure 27, the model was able to capture the three distinct modes of the time course patterns corresponding to experimental data. Also, as shown in the figure, the TK model,

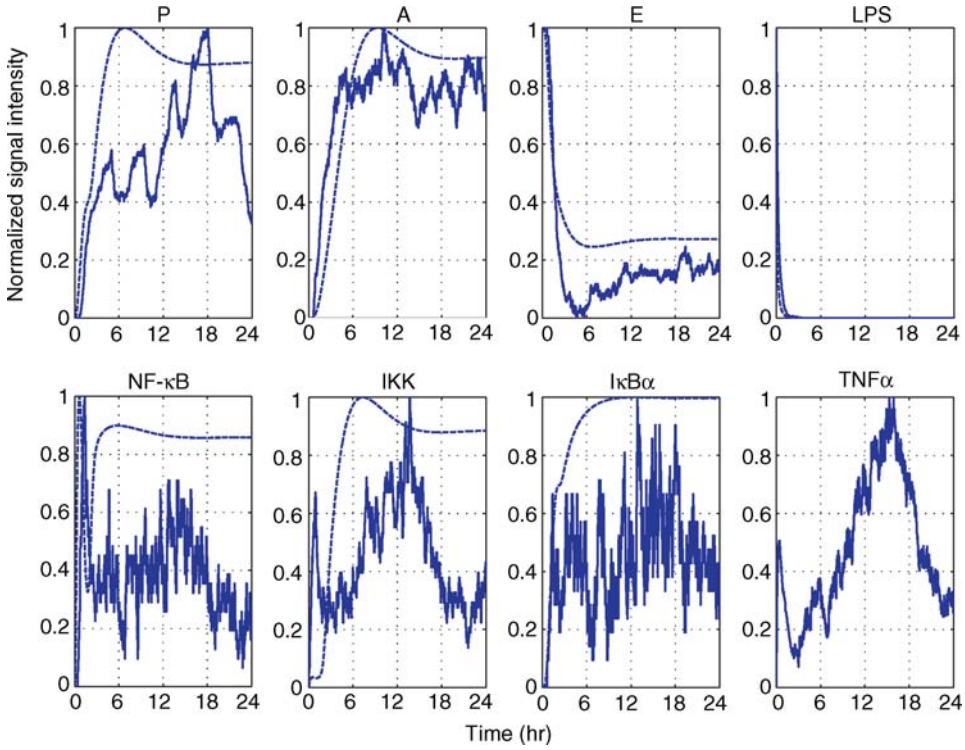

Figure 25. Temporal responses of an unresolved inflammatory response due to high LPS concentration. A high concentration of LPS (LPS(0) = 750) can cause a malfunction in the dynamics of the host leading to an exacerbated inflammatory response (solid lines). Dashed lines refer to the implications of high concentration of LPS as simulated by a deterministic (ODE) approach. For the purpose of comparing the simulated output between the ABM and the ODE model, all responses are normalized so that numerically they are in the range (0,1). (Figure source: Dong *et al*., 2010.)

parameterized using data from Drobna *et al.* (2004), was also able to capture the significant decrease in DMA amounts at higher arsenite doses. This TK model in a stand-alone manner can be incorporated into a larger-scale physiologically based toxicokinetic (PBTK) model of arsenic for improving the estimates of PBTK model parameters, as well as in characterizing inter-individual variability in arsenic metabolism.

The cellular level TK model was linked to a toxicodynamic (TD) model that describes the cellular adaptive response following the metabolism of arsenic and the corresponding increase in the levels of ROS. This adaptive response is governed by a core feedback loop mechanism (Krishna, Jensen and Sneppen, 2006) involving the transcription factor Nrf2 via higher anti-oxidant response in the form of increased GSH biosynthesis and MRP expression. The core elements considered in the TD model are ROS, nuclear Nrf2, mRNA, in addition to MRPs and protein levels of Glutamate cysteine ligase catalytic subunit (GCLC), which catalyzes the rate-limiting step for GSH biosynthesis. This model describes DNA lesions caused by arsenic-induced ROS increase as a first-order process, and also includes the BER pathway for predicting the extent of DNA repair (Sokhansanj and Wilson, 2004).

The TD model was parameterized using experimental data on the expression of GCLC following exposure to 10 μM iAs^{III} (Thompson *et al*., 2009b). The integrated TK/TD model was then independently evaluated with experimental data on DNA repair following exposure to 5–100 μM iAs^{III} (Dopp *et al*., 2008). As shown in Figure 28, the integrated TK/TD model was able to adequately explain the temporal dynamics of GCLC expression and the dynamics of arsenic-induced DNA damage and repair.

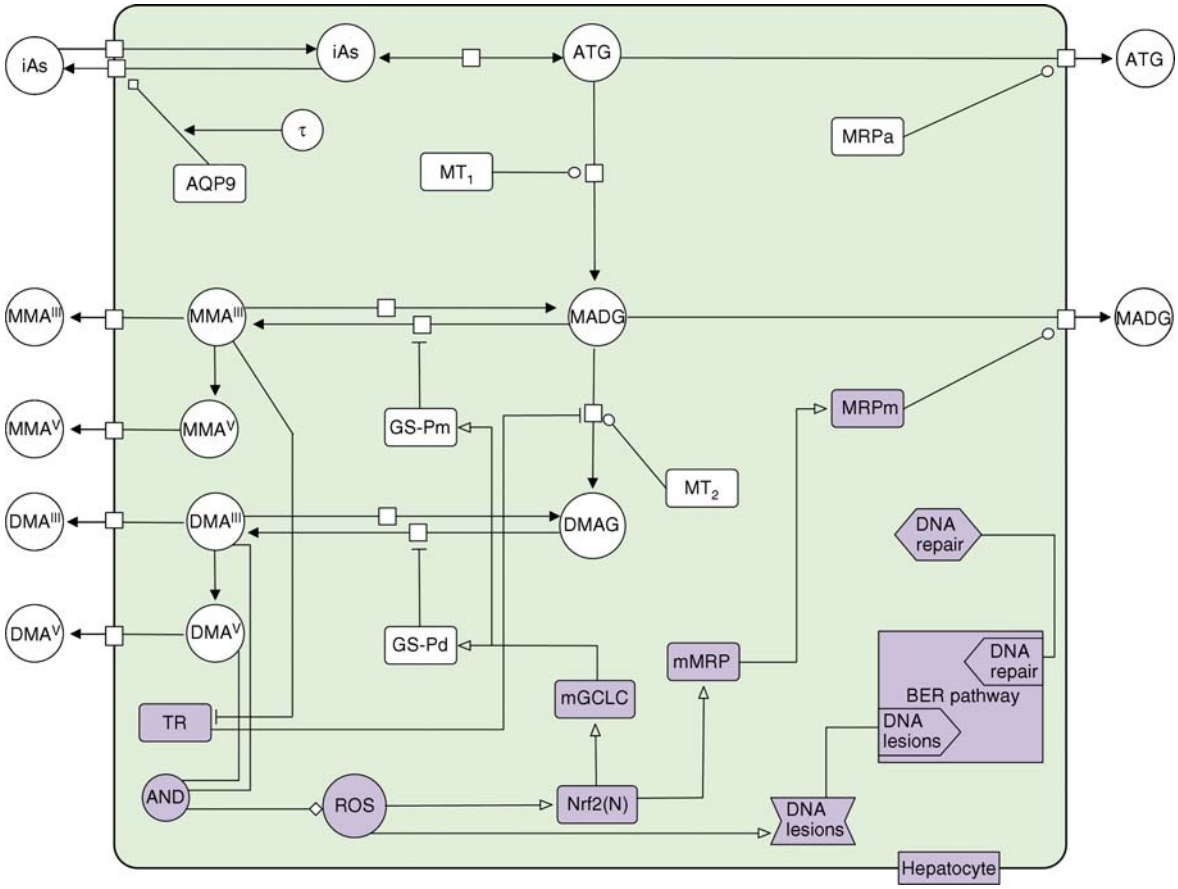

Figure 26. A simplified overview of cellular toxicokinetics and toxicodynamics of arsenic (for the mammalian hepatocyte). The toxicokinetics of arsenic include both "traditional" metabolism (methylation) via AS3MT (methyltransferase) as well as a new metabolic pathway of inorganic arsenic biotransformation via arsenic-GSH complex formation. This pathway includes two separate branches of arsenic biotransformation: MADG → MMA^{III} → MMA^{V} and MADG → DMAG → DMA^{III} → DMAV (SBGN representation based on information from Hayakawa *et al*., 2005). The toxicokinetic pathway carries ROS formation and corresponding DNA damage, as well as DNA repair.

4.5 Modeling of Biochemical Heterogeneity within Tissues and Organs

4.5.1 Example: Distribution-Based Characterization of P450 Induction by TCDD in the Human Liver

This example demonstrates the process of "model reduction" via representing spatial heterogeneity in terms of frequency distributions focusing on the challenges posed by the fact that the liver shows heterogeneous hepatic cytochrome P450 (CYP) induction following exposures to some toxicants. Specifically, the hepatic metabolism of TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin) is addressed here, because TCDD is an ubiquitous contaminant (ATSDR, 1999; Son and Rozman, 2002) that has also been shown to result in significantly higher CYP induction in the centrilobular region compared to the periportal region of the liver (Andersen *et al*., 1995; Santostefano *et al*., 1999).

Existing zonal (i.e., multicompartmental) models for the liver represent the entire organ in terms of discrete zones by making assumptions regarding volumes and toxicodynamic properties of different liver regions (Andersen *et al*., 1997). An alternative statistical distribution-based modeling approach has been developed and applied to the study of this heterogeneity. This approach maps multiple parameters from the zonal model into a single distribution.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

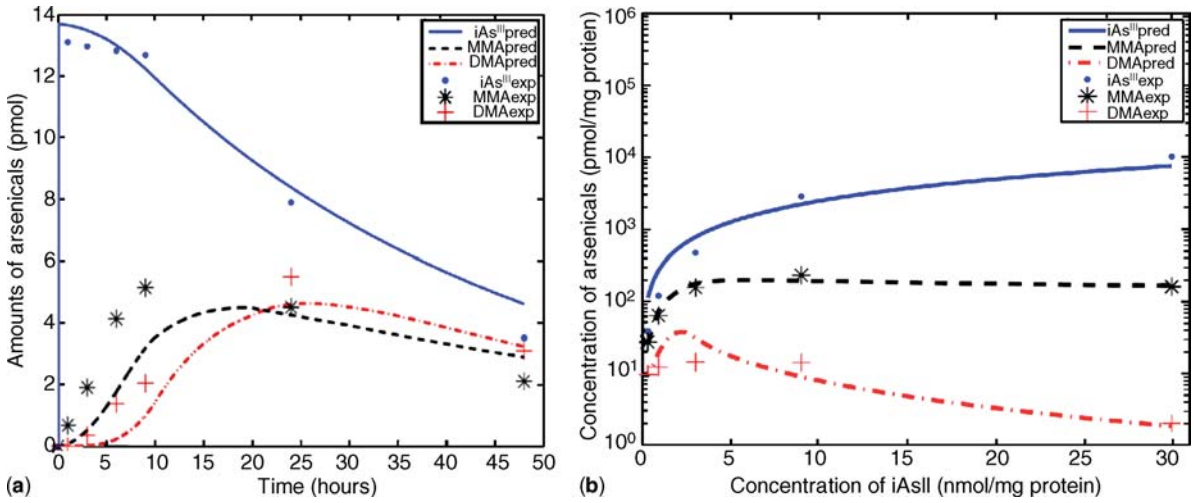

Figure 27. Time course profiles of arsenicals in human hepatocytes predicted using the cellular level TK model. (a) Levels of intracellular arsenicals following exposures to 0.1 μM arsenic for 2 days compared to experimental data from Styblo *et al*. (1999); (b) total amounts (in hepatocytes and the medium) of iAs^{III}, MMA and DMA compared to experimental data from Drobna *et al*. (2004) (hepatocytes from a 63 year old white female).

For scenarios reported in the literature, estimates from the distribution-based model predicted realistic distributions of enzyme induction (as shown in Figure 29a), while the zonal model can provide unrealistic estimates, especially at low and high doses.

Subsequently, key model parameters in the zonal and distribution-based models were estimated using available experimental data. Experimental measurements of CYP 1A1/2 mRNA by Santostefano *et al*. (1997) were converted to total protein concentrations by relating CYP levels to mRNA expression and using data from Santostefano *et al*. (1997). Based on the experimental setup, the data for periportal and centrilobular zones were assumed to represent two liver regions that have volume fractions of 50% each.

Figure 29b presents a comparison of estimates of CYP induction in centrilobular and periportal regions from a single-compartment, a zonal,

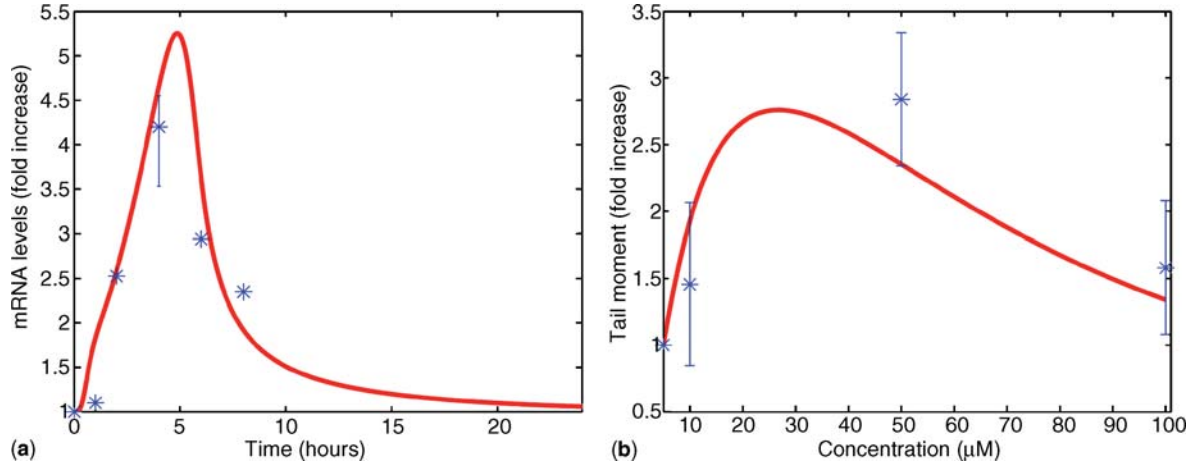

Figure 28. (a) predicted dose-response profiles of mRNA levels following exposure of hepatocytes to 10 μM arsenic, calculated with a new cellular level toxicodynamic model (experimental data from Thompson *et al*., 2009b); (b) estimated levels of DNA damage and repair (fold change) following exposure to 5–100 μM iAs^{III} (experimental data from Dopp *et al*., 2008).

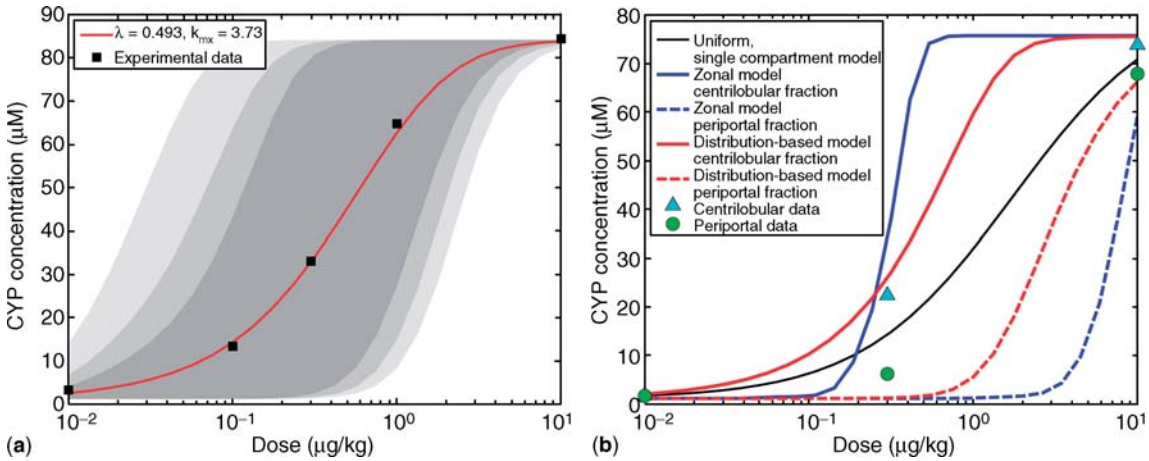

Figure 29. (a) predictions of CYP induction from TCDD compared to measurements of Santosefano *et al*. (1998). Shaded areas represent the 5/95, 13/87, and 25/75th percentiles. (The centrilobular and periportal zones are assumed to be 27 and 39% of the liver, as per Andersen *et al*., 1997.); (b) comparison of the zonal and distribution-based models with experimental measurements of CYP induction from TCDD in fractionated livers as measured by Santostefano *et al*. (1999). The parameter values for each model formulation are optimized based on the experimental data. The distribution-based model more closely represents the variation in liver zones than the zonal model.

and a distribution-based model, with experimental data from fractionated livers, showing that the distribution-based model explains the data better than the zonal model.

In the context of risk assessment, this approach provides a quantitative estimate of the fraction of the organ that experiences high levels of toxicity, providing an overall "spectrum" view of dose-response, instead of the spatial patterns. An advantage of this approach is that distribution-based models can be evaluated by using data from homogenized organs analyzed in conjunction with flow cytometry experiments (Broccardo *et al*., 2004, 2005) that measure the distribution of enzyme induction resulting from exposing a population of hepatocytes. In contrast, the corresponding evaluation of traditional zonal models requires studying an intact organ.

4.6 Whole-Body Combined Toxicokinetic and Toxicodynamic Modeling

4.6.1 Example: Predicting Oxidative Stress in Rats Due to Trichloroethylene Exposures

This example presents a combined physiologically-based toxicokinetic and toxicodynamic model for trichloroethylene (TCE) that predicts the amount of oxidative stress due to exposures to TCE and its metabolite trichloroacetate (TCA) in rats. TCE is a known carcinogen in rodents and suspected carcinogen in humans, while human exposures to TCE are common because it was a widely used industrial solvent. TCE is metabolized in liver tissue where TCE and its metabolites cause oxidative stress. Oxidative stress is a well-known mechanism of cellular injury and plays a major role in the development of chronic diseases including carcinogenesis (Klaunig and Kamendulis, 2004). It results from an imbalance favoring oxidants rather than antioxidants, resulting in an overall increase in cellular levels of ROS. The most common metric of oxidative stress is provided by the thiobaric acid reactive substances (TBARS) assay, which measures lipid peroxidation, and by assays for 8-hydroxydeoxyguanosine (8OHdG), which measure the amount of oxidized DNA that has been repaired.

Many of the toxic effects of TCE are hypothesized to be due to the oxidative metabolism of TCE to TCA (Bull, 2000). Specifically in mice and mouse cells TCE and TCA are both known to cause increases in free radical production (Steel-Goodwin, Pravecek and Carmichael, 1996), lipid peroxidation (Austin *et al*., 1995; Byczkowski, Channel and Miller, 1999; Larson and Bull, 1992), and DNA damage (Austin *et al*., 1996). A weight of

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

evidence analysis has determined that activation of the nuclear receptor peroxisome proliferator-activated receptor α (PPARα) has a dominant role in TCE and TCA induced hepatocarcinogenesis in mice (Corton, 2008).

The PBTK model predicts the distribution of TCE and its metabolites in tissue compartments and the TD model uses those concentrations in the liver as inputs to calculations of oxidative stress metrics. The PBTK model is based on an adaptation of the Hack *et al*. 2006 model, to predict concentrations of TCE and its metabolites in various tissues including blood and liver, following exposures to TCE and/or TCA. The TD model uses Michaelis-Menten type kinetics formulations to describe the production of TBARS, as well as the feedback mechanism reflecting biological response to oxidative stress. Model parameters have been estimated using literature data on mice and mouse liver slices exposed to TCE and its metabolites. These data include *in vitro* mouse liver slice measurement of free radicals and lipid peroxidation and *in vivo* measurements of lipid peroxidation and DNA damage. As shown in Figure 30 (right panel), the new model predicts oxidative stress levels as well as replicates estimates of the Byczkowski, Channel and Miller 1999 model for short times, while it also produces reasonable predictions of oxidative stress at long times (that cannot be calculated by the Byczkowski, Channel and Miller 1999 model).

The new toxicokinetic/toxicodynamic model for TCE presents a substantial improvement over existing models since it can (i) successfully predict oxidative stress produced in the liver over time periods ranging from hours to weeks, (ii) consistently describe effects of exposures to TCE and direct exposures to its metabolites, and (iii) combine events from exposure to toxicodynamic responses. Ongoing work considering the applicability of this model to humans focuses on scaling issues and relevance of additional toxic endpoints of TCE.

4.7 An Integrative Approach to Multiple System Interactions and Effects

4.7.1 Example: Exposures to Fine Particles and Nanoparticles

A prototype generalized risk analysis framework for fine particles and nanoparticles concludes this series of demonstrative examples for toxicokinetic-toxicodynamic process integration. This example, which summarizes various aspects of ongoing collaborative work at ebCTC, aims to emphasize the need for a "systems" approach to characterize the complex nature of interactions of fine and ultrafine particulate matter with biological organisms; these interactions include a wide range of toxicokinetic and toxicodynamic processes, schematically

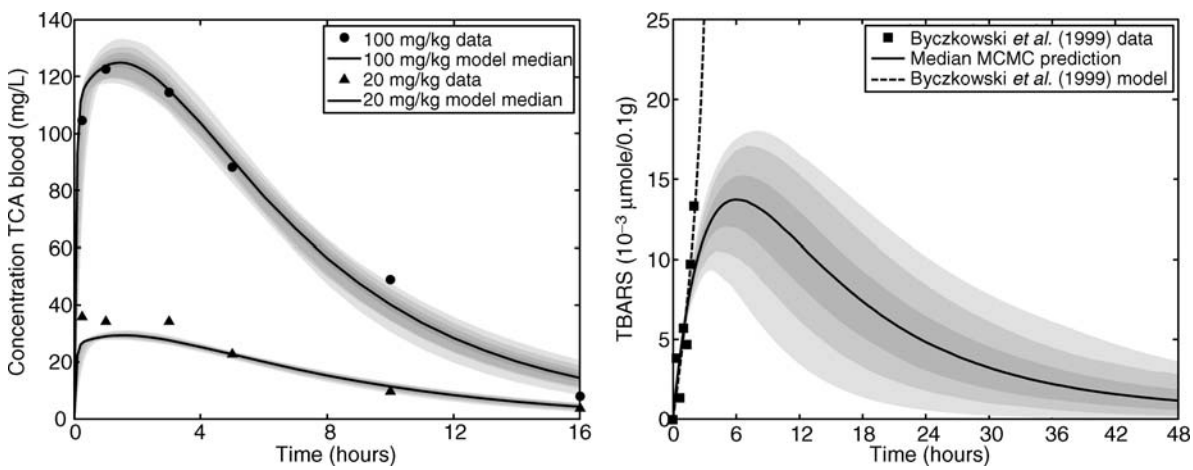

Figure 30. Evaluation of the new PBTK model using data from Larson and Bull (1992) and the TD model using data from Byczkowski, Channel and Miller (1999). Parameters for the PBTK and TD models were estimated through optimization of the model using the Markov Chain Monte Carlo technique (shaded regions represent 1, 2 and 3 standard deviations from the median value). The new TD model predicts realistic levels of TBARS in liver slices from *in vivo* experiments for both short- and long-time periods.

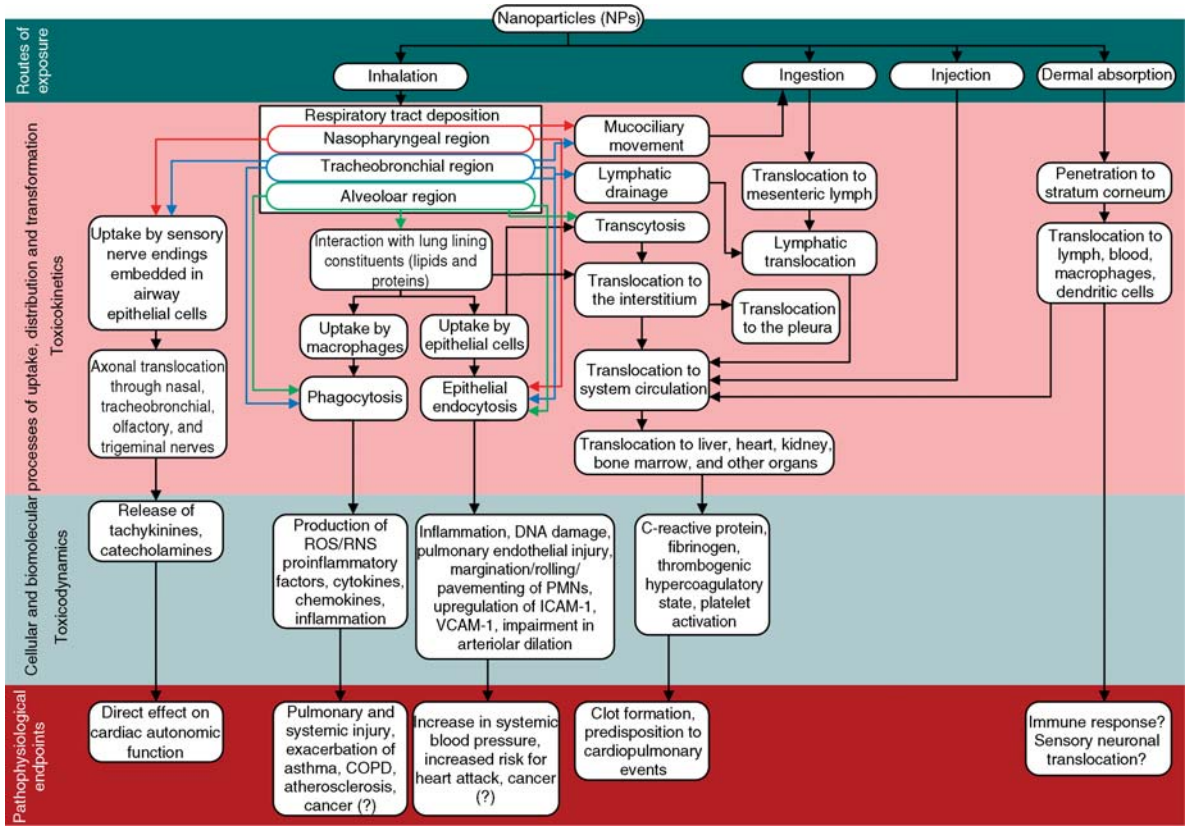

Figure 31. The ebCTC systems framework to support integrative toxicity assessments of nanoparticles through combined whole-body toxicokinetic and toxicodynamic models: the chart provides a simplified partial listing of relevant toxicokinetic and toxicodynamic processes considered in this framework.

depicted in Figure 31, involving multiple mechanisms and physiological systems.

Known adverse health effects of air pollution are numerous and typically involve multiple organs and systems. For example, when airborne particulate matter (PM) enters the lungs it interacts with the respiratory epithelium to mediate respiratory as well as systemic and cardiovascular effects. Furthermore, PM, or its reaction products, stimulate airway sensory nerves, leading to changes in lung function and in autonomic tone, which influence cardiac function. Ultrafine PM, due to their very small size, can enter pulmonary capillary blood and be rapidly transported to extrapulmonary tissues such as liver, bone marrow, and heart, with either direct or indirect effects on organ function (see Figure 31). The DORIAN effort pursues the development of interlinked "virtual organs" within a modular physiologically based toxicokinetic/toxicodynamic "whole body" framework for the systematic study of such complex effects.

The enhanced toxicity of fine particles and nanoparticles (compared to bulk material or coarser particles of the same chemical composition) is typically attributed to the small size that allows deposition in the alveolar region as well as facilitates the penetration of various biological barriers/membranes. However, it is important to note that even when nanoparticles are present in the form of larger aggregates and/or agglomerates, they may still retain the toxicity of individual nanoparticles they consist of, due to the large surface area they maintain (Borm *et al*., 2006; Schleh and Hohlfeld, 2009). For example, the enhanced toxicity of carbon nanotubes (CNTs) (compared to graphite, etc.) is in fact attributed to their enhanced surface area even when they are not present as isolated nanoparticles. Due to the rapidly expanding use of carbon

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237

nanoparticles (and in particular CNTs) and the anticipated widespread exposure of large segments of the population, a systematic attempt for an integrative model of their toxicokinetics and toxicodynamics has been initiated at the ebCTC.

There is a growing number of *in vitro* and *in vivo* studies of carbon nanoparticles, and especially CNT toxicity. Lam and co-workers (Lam *et al*., 2006) provide an overview of the field, comparing the outcomes of a number of toxicological studies performed prior to 2006. These, as well as various more recent investigations (e.g., Pacurari *et al*., 2008; Ryman-Rasmussen *et al*., 2009) discuss a variety of local (pulmonary) and systemic adverse effects. Many of these studies and various other reviews (Gwinn and Vallyathan, 2006; Oberdorster, Oberdorster and Oberdorster, 2005) point to the fact that CNTs and other nanoparticles may evade phagocytosis and translocate to other organs, with systemic toxic effects. Pacurari *et al*. (2008) state that "toxicity studies of nanoparticles should not be limited to a single lung cell or only to the lung, but should involve other systemic targets." CNTs are neither soluble nor biodegradable, so, even when they do not evade phagocytosis, their biopersistence potentially raises the risk associated with exposures to them. Indeed, when the lung is not overloaded, macrophages containing nanoparticles will migrate upward on the alveolar surface and will be carried by the mucociliary escalator system up the trachea, thus cleared into the esophagus (McClellan, 1997). CNT-laden macrophages, however, have been found to move to centrilobular locations, where they enter alveolar septa and cluster to form epithelioid granulomas. When particles enter the interstitial or subepithelial space, clearing them from the lung is very difficult, resulting, in the case of irritating or toxic particles, to more severe histological effects (Lam *et al*., 2006). In addition to inducing histopathological changes, including granuloma formation and fibrosis, both single wall CNTs and multiple wall CNTs have been found to release toxic cytokines and biomarkers of inflammation, oxidative stress, and cytotoxicity (Muller *et al*., 2005; Shvedova *et al*., 2005).

Various modules specific to exposures, dosimetry, toxicokinetics, and toxicodynamics of nanoparticles have been incorporated in the MENTOR and DORIAN systems. These modules in fact provide improved estimates compared to corresponding available agency models. The respiratory dosimetry modules of MENTOR have been formulated incorporating available information relevant to nanoparticles in relation to realistic exposure situations. Figure 32 compares predictions from two different "standard models" and from an inhalation dosimetry module of MENTOR, with the available experimental data on fine and ultrafine

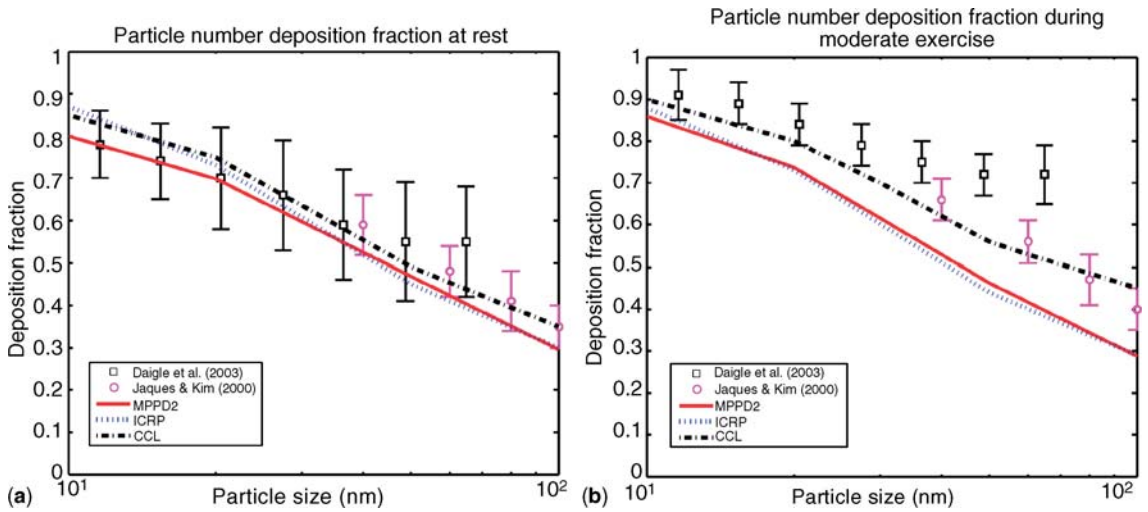

Figure 32. Experimental ultrafine and nanoparticle dosimetry data under: (a) resting conditions and (b) moderate exercise conditions (Daigle *et al*., 2003; Jaques and Kim, 2000) compared to predictions of the Multiple Path Particle Dosimetry (MPPD2 – CIIT, 2006), the International Commission of Radiological Protection (ICRP – Jarvis *et al*., 1996) models, and the inhalation dosimetry module of MENTOR/DORIAN (Source: Georgopoulos, 2008; reproduced with permission from Springer).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237

(nanoparticle) lung deposition from the studies of Jaques and Kim (2000) and Daigle *et al*. (2003). The two standard models, that is, the Multiple Path Particle Dosimetry model (MPPD - CIIT, 2006) and the International Commission of Radiological Protection (ICRP - Jarvis *et al*., 1996) model, perform comparably with each other, and their predictions, as well as the predictions of the MENTOR module, demonstrate acceptable agreement with the measured values in the case of deposition measured under resting conditions. However, the MPPD and the IRCP models substantially underpredict the deposited fraction of nanoparticles under conditions of moderate exercise for the subject considered, whereas, the MENTOR inhalation module achieves much closer agreement with the experimental data.

In current and ongoing work, a generalized, integrative, physiologically based toxicokinetic/toxicodynamic model (PBTK/TD), that incorporates modules from both the MENTOR and DORIAN systems, has been adapted to study the biokinetics and various subsequent effects, from the subcellular to the multi-organ level, of nanoparticles following various types of exposures (inhalation, ingestion, dermal absorption, and injection). The structure of the whole-body PBTK/TD model for fine and ultrafine (nanoparticle) exposures is shown in Figure 10. This generalized structure incorporates multiple routes of exposure, as well as organs/tissues and translocation/distribution pathways relevant to reported fine and ultrafine particle properties. So, for example, in addition to respiratory tract deposition of inhaled particles in the nasopharyngeal (N), tracheobronchial (T), and alveolar (A) regions, this model structure is also designed to account for processes such as the uptake of nanoparticles by sensory nerve endings embedded in airway epithelia (in the N,T areas) with subsequent axonal translocation to the central nervous system (CNS), through the nasal, tracheobronchial, olfactory, and trigeminal nerves. Processes leading to the translocation of nanoparticles to systemic circulation and subsequent distribution to different organs/tissues are incorporated explicitly (e.g., translocation from the lung epithelium, lymphatic drainage, etc.)

As a specific example, the MENTOR/DORIAN whole-body PBTK/TD model was adapted to simulate the absorption, distribution, and elimination of fullerenes (carbon nanoparticles) labeled with 99 m-technetium. The assumptions and parameter values used in the PBTK module were based on the study by Pery *et al*. (2009). The simulation results presented here, as shown in Figure 33, consider an inhaled gas mixture of "small" particles, "large" particles, and free unbound 99 m-technetium. The small particles represent fullerenes that can translocate from the lung to the systemic circulations,

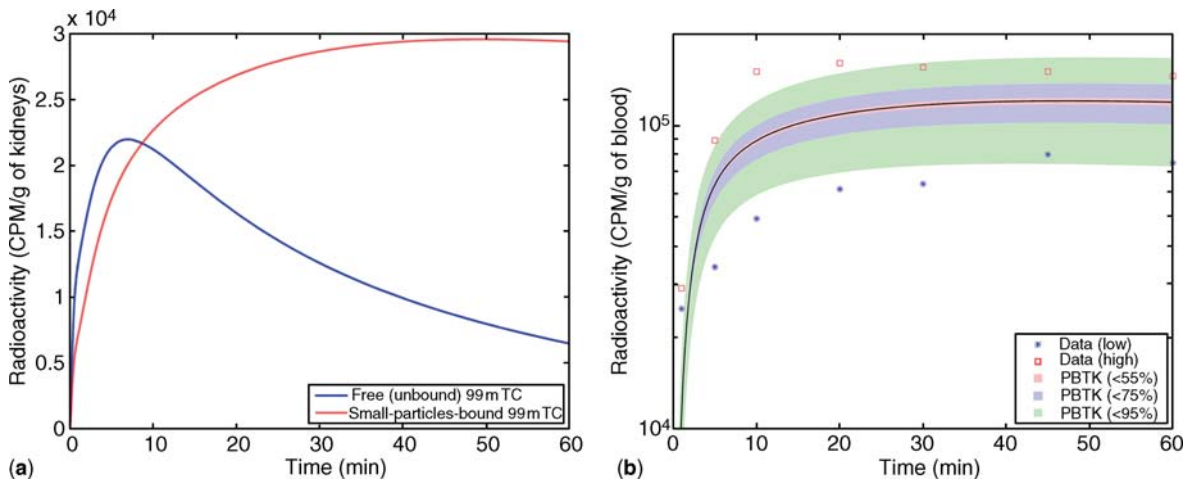

Figure 33. Time-course profiles of radioactivity levels in humans following exposures to carbon nanoparticles labeled with 99 m-technetium, as estimated by the generalized PBTK module of MENTOR/DORIAN. The assumptions and parameter values used in the PBTK module were based on the study by Pery *et al*. (2009). The data used for evaluating the modeling predictions are from Nemmar *et al*. (2002). (a) The calculated time course profile of radioactivity in the kidney; (b) model estimates and confidence intervals for total radioactivity measured in blood, along with the corresponding experimental data.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat237
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

while the large particles are deposited into and rapidly cleared from the lung. Large particles do not enter systemic circulation, whereas small particles and free 99 m-technetium are capable of absorption and organism-wide distribution, with different toxicokinetic properties. In the case study that was simulated, the composition of the mixtures the subjects were exposed to was unknown. A Monte Carlo analysis (1000 model runs) was performed using the MENTOR/DORIAN PBTK module to evaluate the sensitivity of the model predictions to assumptions regarding the relative magnitude of the large and small particle fractions.

Inhaled particle dynamics such as coagulation and agglomeration have been modeled in the past (Broday and Georgopoulos, 2001; Lazaridis *et al*., 2001) for airborne particulate matter of variable chemical composition, employing the aerosol General Dynamic Equation (GDE) for respiratory tract processes, but have not been implemented in the context of nanoparticle dosimetry. However, in the case of nanoparticles, dynamics of agglomeration and aggregation are relevant not only for the inhaled air flow, but also for the physicochemical dynamics of the particles within extracellular and intracellular biological fluids. The ongoing incorporation of the GDE description in the various biokinetic steps of nanoparticle distribution in mammalian organisms is currently being pursued within ebCTC.

5 CONCLUSION

This chapter presented a summary overview of the general approach, and of various components and demonstration applications, resulting from efforts that are being pursued at the *environmental bioinformatics and Computational Toxicology Center* (ebCTC) towards developing a comprehensive DOse Response Information ANalysis system (DORIAN). DORIAN has been designed to complement the Modeling ENvironment for TOtal Risk studies (MENTOR), which provides an extensively tested library of software components, for "source-to-dose" analysis of environmental stressors (chemical, biological, radiological), by adding tools for novel "dose-to-biological outcome" analysis. DORIAN employs a bi-directional approach to provide the framework for linking phenomena occurring across multiple scales of time/space and biological organization: this is achieved by implementing a set of alternative "bottom-up" approaches that model the dynamics of "microscopic entities" such as biomacromolecules and cells to derive macroscopic properties of the coarser/higher scales; however, these dynamics are constrained by the requirements of a whole-body "top-down" framework. The procedure of developing application-specific models involves reducing or decomposing the biological system into suitable functional subsystems (biomodules) according to criteria that take into account the biophysics/biochemistry of the specific problem at hand and the objectives of the analysis that is pursued. The process of *encapsulation*, that is, of dividing a complex biological system into different scales or functional subsystems with limited exchange of information between the "internal" components of separate scales or subsystems, is often the most challenging step in model development. Once the scales and the boundaries of the biomodules/subsystems for a specific application have been defined, along with the selection of "bottom-up" and "top-down" algorithms for model linking, a systematic approach has been established to translate the conceptual/qualitative description of the system into a quantitative formulation: within this framework, computational chemistry methods are being applied and/or developed to quantitatively characterize biomodule components and interactions at the molecular (e.g., ligand-receptor) scale, while deterministic and stochastic system process analysis and optimization techniques are applied to determine "larger" biomodule structures (ranging from interlinked signaling, regulatory and metabolic pathways to networks of multicellular functional subsystems, to tissues, and to multi-organ systems). This process relies on interpretation of data (e.g., transcriptomic, proteomic, metabolomic, cytomic, physiomic, etc. data) from "biomodule perturbation" experiments, that may include (i) genetic perturbations (polymorphisms, gene knockouts, gene silencing, etc.), (ii) environmental perturbations (exposures to environmental toxicants, nutrient availability, etc.) and (iii) disease state (pathological vs. normal). Outcomes provide information that aims to enhance the understanding of (i) molecular mechanisms of environmentally-induced disease (toxic responses); (ii) differences in responses between humans and model species (for improved cross-species extrapolation); and (iii) interindividual variability in responses (for

improved understanding of genetic susceptibility to environmental disease).

Together, MENTOR and DORIAN provide the basis of an evolving integrated, "systems-based" *exposure biology framework* that aims to support (i) more realistic risk assessments for contaminants in a variety of media (air, water, soil/dust, food, beverages, cosmetics, various consumer products, etc.); (ii) improved "population-wide" risk assessments that take into account the specific behavioral patterns and the genetic susceptibility factors which "elevate" the risk for specific subpopulations; and (iii) development of rational and cost-effective "targeted" protection and restoration strategies in relation to exposures involving a wide range of xenobiotics and other environmental stressors. The consideration of "individual-specific" toxicoinformatic (transcriptomic, metabolomic, proteomic, etc.) data is expected to allow development of more accurate, and eventually even "personalized," assessments of risk due to toxic xenobiotics.

Clearly, the ongoing efforts of ebCTC are only starting to address many of the complex challenges related to the multiscale integrative modeling of toxicokinetic and toxicodynamic processes. It may be claimed, however, that the methods that were briefly overviewed in this chapter, along with the selected application-specific examples, demonstrate the potential future benefits of a consistent integrative exposure biology modeling framework.

ACKNOWLEDGMENTS

This work was supported through the USEPA funded Environmental Bioinformatics and Computational Toxicology Center (GAD R 832721-010) and the NIEHS sponsored UMDNJ Center for Environmental Exposures and Disease at EOHSI (Grant #: NIEHS P30ES005022). The authors are grateful to Prof. C. Roth (Rutgers University) for contributions to the construction of optimized metabolic networks via metabolic flux analysis for APAP and ethanol; to Dr. C.J. Brinkerhoff (UMDNJ) for contributions to zonal and distribution-based modeling for studying TCDD metabolism in the liver; to S. Stamatelos (UMDNJ) for contributions to mechanistic modeling of transport and metabolism of arsenicals in human hepatocytes; to Dr. A. Sasso (UMDNJ) for contributions to the biokinetic modeling of fine particles and nanoparticles; to Dr. P. Foteinou (Rutgers University) for contributions to network-based simulation of systemic response to human endotoxin; to X. Dong (Rutgers University) for contributions to agent-based modeling of endotoxin induced acute inflammatory response in macrophages; to Dr. E. Yang (Massachusetts General Hospital) for contributions to transcription factor network dynamics modeling; and to L. Everett and D. Mukherjee (UMDNJ) for their assistance in creating original illustrations for this chapter.

Biomarkers of System Response to Therapeutic Intervention

Ludmila Danilova and Michael F. Ochs

The Sidney Kimmel Comprehensive Cancer Center at Johns Hopkins, Baltimore, MD, USA

1 INTRODUCTION

There are numerous definitions for a biomarker; however, they all fundamentally describe a measurable quantity that informs us about a hidden state of the biological system that predisposes that system to one of several outcomes. For clinical biomarkers, the most straightforward case is the presence of a molecular entity, such as an antibody, that provides evidence of a disease state, such as infection by a virus. In drug development, such biomarkers could include measurable biochemical species indicating organ toxicity or other critical issues that could block efficacy.

There are many types of biomarkers presently in use. Diagnostic biomarkers provide insight into the probability that an individual has a disease. These biomarkers, often the result of hospital laboratory tests, provide physicians with information on the state of the patient. Such diagnostic markers include tests for the presence of antibodies to known disease-causing organisms, levels of serum chemicals such as glucose that can indicate temporary or chronic failure of bodily systems, and blood counts that can indicate anaemia or inflammatory responses. In addition, there are specialized biomarkers developed that identify subtypes of disease, including biomarkers for the different types of leukaemia or lymphoma. These can be used to choose specific treatments among the different options available.

Prognostic biomarkers differ from diagnostic biomarkers in that they provide a probability of outcome. These biomarkers generally do not lead to optimization of treatment, but provide insight into the potential endpoints of a disease. In cancer, such biomarkers are common and often take the form of Kaplan–Meier survival curves that provide the probability of survival with a given type of cancer, including the cancer stage, over time.

Response biomarkers provide indications of the likely response to treatment. Genetic tests on variants of key metabolic liver enzymes can be considered response biomarkers, as they provide information for adjusting dosing of some therapeutics. Naturally, response biomarkers can be viewed as safety biomarkers as well, because they provide information on the safety of the proposed treatment. Pharmacogenomic and pharmacokinetic biomarkers can also be considered types of response biomarkers, as they predict the response of a patient to a drug based on individual variation.

Screening biomarkers are similar to diagnostic biomarkers; however, they must be suitably designed to assess the probability that an individual does not have a disease given that an entire population will be tested instead of a small group of individuals already suspected of harbouring the disease. The significant difference between these types of biomarkers lies in the number of non-diseased individuals likely to receive the test relative to the number of diseased individuals. We discuss

this in more detail in the section on Statistical Issues.

In clinical practice, the logical endpoint for a biomarker is patient outcome, generally survival time. In many cases, using such an endpoint is impractical, as the time required delays the application of lessons to be learned in the study. In some cases, it is therefore appropriate to utilize a surrogate endpoint, which is itself a biomarker related to the outcome. Because a surrogate endpoint is equivalent to a biomarker, it requires development and validation equivalent to that for a biomarker.

It is useful to consider an ideal biomarker as a baseline for discussion of biomarker development, especially from high-dimensional data. An ideal biomarker would be measured non-invasively and provide a clear high value for an individual in state 1 (disease) and a clear low value for an individual in state 2 (healthy). The distributions of the measurements of these values in the population would not overlap, so a clear threshold would exist between healthy and diseased individuals, as depicted in Figure 1a. In reality, no biomarker fulfils these requirements and even simple single chemical biomarkers generally have overlapping distributions, such as in Figure 1b, which leads to false-positive and false-negative test results.

If we consider a real case, a biomarker for the probability of a heart attack, we get a clearer picture of the situation. Typically, measurements of low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, triglycerides and potentially C-reactive protein are made. These measurements are combined with age, medical history, body mass index, diabetes status, smoking history and family history to create an estimate of the potential for a heart attack over a future time period. This clearly is more complex than the case of a single molecular species, and developing this statistical model required many years. With high-throughput data measuring biological systems, we face a similar need for complex statistical models. However, we now face a difficult problem as these molecular measurements are simultaneously refining our understanding of disease subtypes, leading to fewer individuals fitting into any category for statistical analysis.

In this chapter, we discuss the emerging high-dimensional data in terms of systems biology and implications for biomarkers of system responses to therapeutic intervention. We address a number of standard issues in biomarker development and validation as well, including the use of model systems and statistical approaches that enhance the probability of identifying useful biomarkers during the development process. We conclude with an example of an approach to development of biomarkers from high-throughput, systems-level data.

2 SYSTEMS BIOLOGY AND HIGH DIMENSIONALITY

2.1 Complexity of Molecular Interactions

Biological systems are inherently complex, comprising perhaps the most complex systems studied in science to date. This complexity arises from a number of factors. First, the large number of

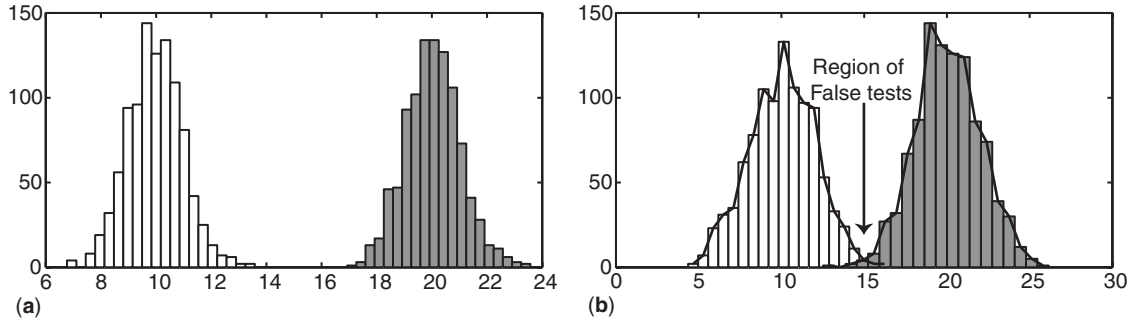

Figure 1. Examples of test results. (a) An ideal biomarker is shown, where the healthy group (white) tests with a mean of 10 and the diseased group tests with a mean of 20, and there is no overlap. (b) An excellent biomarker with good separation between the groups is shown, with a minimal overlap area that generates false positives and negatives depending on the threshold.

DOI: 10.1002/9780470744307.gat238
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

highly interacting molecular species creates very large dimensionality issues in the data. There are roughly 25 000 genes generating hundreds of thousands of protein variants, which undergo post-translational modification to millions of forms. The DNA, mRNA, miRNA and proteins interact with each other and with thousands of chemical species, creating a combinatorial nightmare for modelling and analysis.

Second, these molecular species and interactions take place in a large number of contexts, where epigenetic and environmental changes cause varying subsets of molecules to be produced, leading to different interactions in different cellular and environmental conditions. This makes it difficult to utilize data from model systems or even different human systems (e.g., kidney vs. liver) when analysing data from a specific subsystem.

Third, the interactions, both between different subsystems and between molecular entities, are stochastic and non-linear in nature. This creates serious problems for standard approaches such as perturbation theory, where the underlying assumption is linearity in response, so that a small perturbation does not lead to large changes in the system. In addition, approaches that try to understand the system using deterministic methods are prone to failure.

It is to be hoped that the future of medicine will include detailed models of the full biological system that can guide treatment decisions. This is already the case for some subsystems, such as the function of the heart, where detailed models of nerve firing and mechanics are used to design interventions. However, for molecular interventions such detailed models remain remote in almost all cases due to the underlying complexity. This leads to a requirement for statistical models, where we replace a physico-biological model with a data-driven phenomenological model describing the mathematical relationships between molecular species and system states. These molecular species are then biomarkers for the system state (e.g., disease), and ideally can be shown to have some mechanistic interactions that are involved with driving the state, even though the complete details remain unclear. An example is HDL cholesterol, which has been shown to play a mechanistic role in protecting arteries from plaque formation, although the complete details of the biological process are not yet fully modelled (Rader, 2006).

2.2 Isolation of Signatures

The complexity of biological regulation raises an important issue for biomarker discovery. Recently, analysis of a genome-reduced version of *Mycoplasma pneumoniae* revealed over 200 multi-protein complexes arising under normal growth conditions from less than 700 genes, showing substantial gene reuse in the simplest self-replicating organism under a single condition (Kuhner *et al.*, 2009). Gene reuse is expected to be substantially greater in eukaryotes and studies of cell cycle genes in *Saccharomyces cerevisiae* show that only about 10% of cell cycle-controlled genes are expressed in only one of the four cell cycle phases under rich media growth conditions (Lukashin and Fuchs, 2001; Moloshok *et al.*, 2002), again suggesting extensive reuse of genes for multiple biological purposes. As the goal for a biomarker is to indicate the underlying biological state of interest, generally independent of the present status of other states, it is unlikely that the level of a single molecular component of the system will provide the necessary information across many potential contexts. For example, it is unlikely that the level of a single serum protein will provide a reliable and adequately specific indication of the response of a tumour to therapeutic intervention across the population, which has substantial individual variation genetically and can be expected to have vastly different environmental factors at work (e.g., diet, infection and inflammation, organ status).

The search for a biomarker then becomes a search for a signature comprising the relative levels of multiple molecular species that together provide an indication of the biological state that is robust across many contexts. This is similar to the statistical model for heart attack risk comprising many different indicators, which was noted in the Introduction. Such signatures derived initially from studies utilizing gene expression microarray measurements are already in use to assess the risk of relapse in breast cancer (Ross, 2009). It is not necessary that signatures comprise only a single molecular type, although that is presently the case primarily because microarray-based studies are farther along the development curve. However, there can be substantial advantages of integrating data from different molecular species into a single model to guide biomarker discovery, as demonstrated by the identification of sarcosine as a potential metabolite

biomarker of aggressive prostate cancer (Sreekumar *et al*., 2009).

2.3 High-Dimensional Biological Data

The first widely used high-throughput assay was the gene expression microarray (Schena *et al*., 1995; Lockhart *et al*., 1996), although the name is misleading as it measures only the generation of transcripts (i.e., mRNA) and not the translation of those transcripts to proteins. Early studies were plagued by the failure of researchers trained in low-dimensionality studies to address the 'large p, small n' problems inherent in measuring thousands of variables on only tens of samples (Simon *et al*., 2003). This 'curse of dimensionality' leads to the need for robust statistical analysis that addresses issues of false positives due to chance agreement of measurements. In addition, early studies had issues with proper experimental design, such as randomization of samples, and normalization of signals. The inclusion of informaticists and statisticians in studies and the development of robust normalization techniques greatly enhanced the value of the data as the field matured (Irizarry *et al*., 2003; Tseng *et al*., 2001).

For all high-throughput data, we can consider the normalized, pre-processed data to take the form of a matrix of measurements. The rows comprise different genes (microarrays), proteins (mass spectrometry or protein microarrays), miRNAs (miRNA arrays) or metabolites (mass spectrometry or NMR). The columns comprise different samples, which in general will be different individuals but can also be different time-points in a series or different cell lines or animals in model organism studies. This is depicted in Figure 2a.

Microarrays have become standard tools in probing the molecular variations in disease and therapeutic response (Rhodes and Chinnaiyan, 2004). Processing of the data for standard analyses, such as to identify genes that are differentially expressed between two groups, is routine, and many statistically sound methods to generate lists of such genes now exist. These methods do group genes based on the assumption that two genes grouped together belong together in all samples. From the matrix point of view, this is equivalent to separating out two groups, one in which genes are more highly expressed in one set of samples (e.g., diseased individuals) and a second in which genes

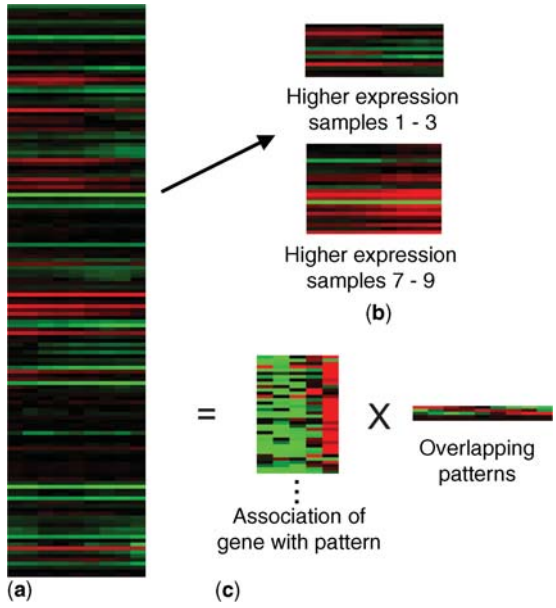

Figure 2. An example of gene expression analysis methods. (a) A portion of the expression matrix is shown, comprising ~50 of the 1300 genes tested. (b) The results of SAM analysis are shown with genes either over- or underexpressed in the first three samples relative to the last three samples. (c) A more complicated analysis where patterns of behaviour are found across the samples and the genes assigned proportionally to these patterns to reconstruct their overall behaviour. See Moloshok *et al*. (2002), for a discussion of this process and the reasons for doing such an analysis.

are more highly expressed in a second set of samples (e.g., healthy individuals), as in Figure 2b. As the expression of genes will be noisy, a weighted average across many genes differentiating the two groups may be more indicative of group membership, which is why commercial biomarkers based on expression have multiple genes.

As gene reuse is widespread, the unique separation into two groups may not reflect the underlying biology in the study in question, and methods have been developed to partition the behaviour of genes into multiple groups. These methods include non-negative matrix factorization, machine learning methods and Bayesian Markov chain Monte Carlo (MCMC) approaches (Kossenkov and Ochs, 2009). The separation then finds patterns with genes assigned to multiple, overlapping groups, as in Figure 2c. The analyses in these cases tend to require multigene biomarkers because the focus is on coordinated changes in sets of genes that differentiate the samples.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat238

As the first widely used high-throughput technology for biomarker discovery, gene expression microarrays are ahead on the development curve. Other platforms are quickly coming into widespread use, however. Proteomics technologies, including tandem mass spectrometry (MS) after fractionation and antibody chip arrays, can generate quantitative measurements of hundreds of thousands of protein species, including tracking of post-translational modifications (Hu, Hood and Tian, 2007). The goal of many of these studies is the ability to measure biomarkers in bodily fluids that are obtainable with minimally invasive procedures, such as blood draws or urine. There are substantial difficulties due to individual variation, the dominance of high-abundance proteins and variation in processing of real clinical samples; however, progress has been rapid in overcoming these barriers (Hanash, Pitteri and Faca, 2008).

Single-nucleotide polymorphism (SNP) microarrays are now in widespread use for genome-wide association studies (GWAS), both for variations in SNPs and for copy number variations (CNV) (Herr *et al*., 2005). The matrix of Figure 2 remains; however, the data may be binary (SNP A or B) or categorical (collection of SNPs in a gene giving allelic variants). The data then must be analysed using different algorithms, which is especially complicated for the Bayesian MCMC approaches that rely on a measure of the model fit to the data during analysis (Favorov *et al*., 2005). Present SNP array chips contain over a million SNPs and the population distribution of many of these SNPs have been measured by the HapMap project (International HapMap Consortium, 2003).

The variation in genomic structure, either through mutation or through CNV, plays an especially critical role in cancer aetiology. As the mutations often occur somatically in the tumour, measurements must be made on tumour samples, which are difficult to obtain and limited in number. The development of tissue microarrays, in which small tumour cores are sliced and arrayed onto a substrate, has greatly enhanced the screening of potential biomarkers in large numbers of tumour specimens (Hassan *et al*., 2008). The measurement techniques are more limited than in the case of a frozen tissue specimen. Generally immunohistochemical staining is the standard, so tissue microarrays are generally most useful as a first validation of prospective biomarkers.

Recently, metabolomic measurements (also termed metabonomic measurements) have emerged as a potential source for biomarkers. Certain metabolites, such as glucose, already serve as clinical biomarkers in practice; however, discovery of new metabolite biomarkers has been hindered by the lack of high-throughput techniques that can identify metabolites in bodily fluids with reasonable dynamic range. The improvement in NMR and MS techniques have resolved some of these issues (Goldsmith *et al*., 2009); however, identification tends to still be limited to hundreds of species rather than the tens of thousands provided by the other high-throughput techniques.

2.4 Integrated Data Sets

The greatest promise for the identification of biomarkers of system response from the emerging high-throughput data sets lies in integration of the different data types prior to analysis. Although this can be performed in a simple manner, essentially allowing measurement of each molecular species to be treated as an independent data point to improve biomarker discovery (e.g., Daemen *et al*., 2008), greater insight and discovery of more powerful biomarkers is likely to result from a model-based integration.

One simple model-based integration is to focus on biological pathways and perform statistical analysis across pathways instead of across genes. This has led to significant insights into the mechanisms underlying cancer aetiology, where amplifications or mutations of different proteins within a pathway drive similar phenotypic development. Multiple studies have now demonstrated that different biological pathways must be altered for cancer development, but within each pathway, different individual proteins carry mutations or amplifications (Parsons *et al*., 2008; Cancer Genome Atlas Research Network, 2008).

More complex modelling relies on inclusion of our knowledge of biological processes in order to link the different molecular species. At its simplest, this is linking of SNP or CNV to the gene, the expression of that gene to the encoded protein and the use of that protein, for instance as an enzyme, in the production of a metabolite. The model can go further, including such information as the function of a protein as a transcription factor, the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat238
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

presence of upstream promoter sequences for that transcription factor in a gene encoding an enzyme and the function of that enzyme in producing a metabolite. Such integration was used to determine the potential ability of the metabolite sarcosine to drive prostate cancer aggressiveness (Sreekumar *et al*., 2009).

One significant advantage of model-based data integration is that potential biomarkers will tend to have an associated biological mechanism identified. This provides a direct link between the molecular biomarker and the actual driver of the system state, which is useful both for further studies aimed at development of therapeutics and for obtaining regulatory approval for clinical use.

An additional advantage of model-based integration lies in the ability to leverage existing biological knowledge during analysis. This is most easily performed through Bayesian methods in which prior knowledge captured in the literature or in data repositories provides prior probabilities for the analysis. Bayesian networks are widely used to capture the relationships that underlie most biological processes, as these can be mapped to a graphical model (Djebbari and Quackenbush, 2008).

2.5 Example: Cell Signalling

Cell signalling provides an excellent example of why model-based integration is important for biomarker discovery. Cell signalling networks comprise a set of proteins that permit a cell to sense the internal and external environments and to respond to maintain homeostasis. The signalling proteins function in a number of ways to transduce a signal; however, the most common is through conformational changes due to phosphorylation that cause a protein to switch from inactive to active conformation. The active protein can then modify a downstream protein target in the signalling cascade, and thus the signal propagates through conformational changes in a series of signalling proteins.

The end result of such a cascade can be modified transcription, translation or metabolism. However, these modifications typically do not affect the expression of the members of the signalling pathway, so simple data integration where a gene is linked to its protein will not lead to an improved analytical result. For example, looking for the coordinated change in protein phosphorylation of a signalling protein and a change in transcript levels of that protein in a microarray measurement is usually a non-sensical approach biologically.

A model-based approach can provide insight, however. In Figure 3, modified from (Ochs *et al*., 2009), the core signalling network underlying growth of gastrointestinal stromal tumours is shown. Growth is driven for most tumours by a mutation in the c-KIT oncogene, which encodes a receptor tyrosine kinase (octagons) governing proliferation. The mutations make the KIT receptor constitutively active, leading to unconstrained growth together with escape from apoptosis due to cross-signalling to the PI3K-AKT pathway. Although the signalling proteins (rounded squares) themselves do not undergo significant transcriptional changes in this system, these signalling pathways link to a series of transcriptional regulators (circles) that drive reprogramming of the cells through up-regulation and down-regulation of a large number of genes, many of which have been studied in detail.

We created the DESIDE (Determination of Signalling from Differential Expression) algorithm to estimate signalling changes during therapeutic intervention from estimates of transcription factor activity deduced from analysis of microarray data coupled to annotations from the TRANSFAC database (Matys *et al*., 2006). By modelling the relationship between the signalling pathways and the transcription factors, as shown in Figure 3, we were able to demonstrate that imatinib mesylate does successfully target the KIT receptor leading to loss of downstream signalling, but that unexpected changes in STAT3 and ELK1 transcription occur, potentially indicating the presence of stem cells. In addition, an off-target effect of IM treatment, DNA damage, was predicted from up-regulation of P53 and verified by immunoblotting of DNA damage response proteins and comet assays (Ochs *et al*., 2009). These predictions could not have been obtained from an analysis that treated transcript levels as surrogates for protein levels for the signalling proteins.

The coordinated change of transcript levels for the targets of transcription factors at the terminal end of signalling pathways can then provide a global, unbiased estimate of pathway activity. As modification of pathway activity is a goal for many modern therapeutics, the statistical inference of transcription factor activity from microarray data can generate proposed multigene biomarkers for the system response. Such biomarkers may include

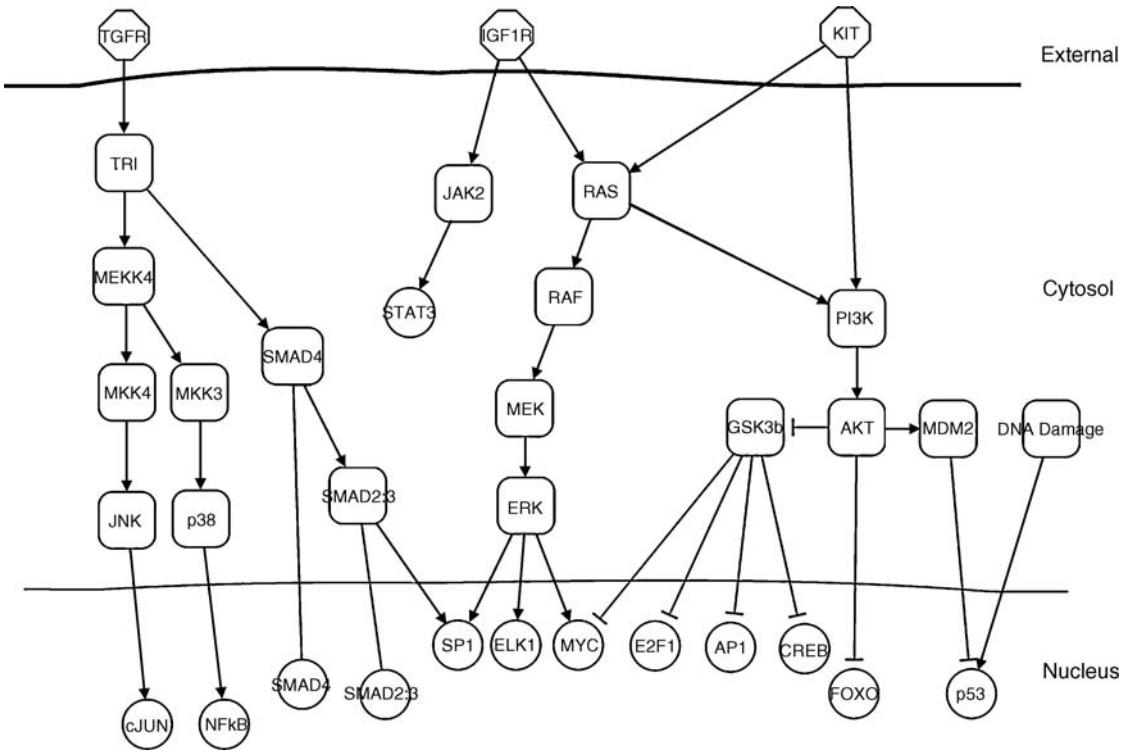

Figure 3. A simple model of a signalling network. Here, the membrane receptors, shown as octagons, transmit external signals to cytosolic signalling proteins, shown as rounded rectangles, which transduce the signals to transcriptional regulators, shown as circles, in the nucleus.

both on-target and off-target effects of the therapeutic, allowing identification of additional pathways requiring therapeutic intervention during treatment. Unfortunately, the present state-of-the-art requires invasive procedures; however, emerging molecular imaging techniques may lead to non-invasive approaches (Shaw, 2009).

3 MODEL SYSTEMS FOR BIOMARKER DEVELOPMENT

3.1 Cell Line Models

The simplest and least expensive systems for biomarker development are cell lines that have been developed out of a variety of normal and diseased tissues. Many well-characterized lines can be obtained from repositories, such as the ATCC. Immortalized lines have limitless replicative potential, allowing them to be maintained indefinitely. For cancer studies, the NCI-60 panel of cell lines have been extensively studied (Shoemaker, 2006), and differences in drug response have been linked to transcriptional variation (Scherf *et al.*, 2000). However, a problem with the use of these lines is that they show dramatic changes relative to early-stage cancers, with chromosomal and genomic instability and expression changes an issue (Li *et al.*, 2008). As such, comparison of responses in immortalized and highly modified cell lines may fail to reflect *in vivo* responses even for similar tissue types.

The development of novel cell lines that more closely match *in vivo* tissues is highly desirable for biomarker development. Recently, transgenic mice and rats carrying the SV40 T-antigen have been produced (Obinata, 2007). These animals ease the establishment of immortalized tissue specific cell lines, and these cell lines show tissue specific expression and behaviour, although it is too soon to know how closely the behaviour of these cell lines will match *in vivo* tissue.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat238
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

3.2 *Ex Vivo* Models

Although cell lines are essentially *ex vivo* models, we wish to separate the discussion of models that are more closely related to the tissue of interest or the *in vivo* system from that of immortalized cell lines. *Ex vivo* systems include use of easily obtained biological samples, such as from blood or serum, and models that permit growth of tissue outside the individual, such as xenograft models. Recently, the use of skin cells, which are easily harvested, has been shown to be indicative of occult systems in some cases (Agulnik *et al*., 2007).

The harvesting of circulating cells from blood can be performed so long as a marker has been identified that can be used in flow cytometry and cell sorting. For blood cancers, it is now routine to isolate the cancerous cells and test them to refine the molecular diagnosis of cancer, and well-known markers are available. However, the markers need not be highly specific in all cases, as, for example, epithelial markers can be used to capture circulating tumour cells from most solid tumours. The cells may be useful for biomarker studies as they reflect the biological characteristics of the source tumour and may therefore reflect molecular characteristics, such as pathway activity, as well (Wong, 2003).

There are also useful primary cell cultures, such as hepatocytes, that can be used to identify biomarkers of drug toxicity (Lavallie, Dorner and Burczynski, 2008). Since the availability of primary hepatocytes can be difficult to maintain, other tools will remain necessary. As pointed out in a review of *ex vivo* systems (Lavallie, Dorner and Burczynski, 2008), a key requirement for any *ex vivo* biomarker discovery system is the presence of pathway activity similar to the target tissue, which may be hard to guarantee in many cases.

An alternative to these approaches is to create xenograft models of the diseased tissue in an animal model to predict response to therapy (Rubio-Viqueira and Hidalgo, 2009). In this case, the xenograft itself becomes the biomarker of response, allowing testing of different treatment options prior to treatment of the patient. Alternatively, a collection of such xenograft models of different tumour subtypes can be used for biomarker discovery, using the high-throughput biological methods discussed in the Systems biology and high dimensionality section on the xenograft tumours. One complication is that the host – tissue interaction will not truly reflect that in the individual from whom the tissue has been harvested.

3.3 Animal Models

Perhaps, the ideal model system is an animal model of the biological system in question. Such models require the development of an orthologous molecular and cellular environment in the model organism. The environment must contain adequate complexity to reflect a significant portion of the function in the human system, and importantly must maintain the likely features of therapeutic intervention. One complexity of any such system is that drug processing can be highly different in different animals, which may complicate pharmacological interpretation of results.

4 STATISTICAL ISSUES

4.1 Statistics for Biomarker Discovery

In the discovery stage, statistical analysis focuses on identifying potential biomarkers with the highest probability of being significant biologically. As data are generally limited at this stage, the process is prone to false discovery, where the molecular species identified as distinguishing the groups (e.g., disease and normal) result from chance variation in the data. The early analyses of microarray data provide a cautionary tale in this regard, as studies were performed with little or no replication and results published without regard for statistical procedures to address false positives.

The statistical needs for biomarker discovery from high-throughput data can therefore be deduced historically from the lessons learned in microarray studies. For identification of potential biomarkers that distinguish two groups, statistical tests were developed that addressed the 'large p, small n' problem by estimating variation using the full data sets rather than the traditional approach of using only single gene variance, as a *t*-test would do. One of the most widely used methods is significance analysis of microarrays (SAM), which uses the framework of a *t*-test but adjusts the denominator by borrowing estimates of variation from genes at similar levels of expression, which corrected unreasonably large estimates of changes at low expression levels (Tusher, Tibshirani and Chu, 2001).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat238
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

More advanced methods were applied for the discovery of multi-gene biomarkers. These techniques looked to discriminate the classes based on signatures in the data, and multiple methods were devised for this, such as support vector machines (Brown *et al*., 2000). A number of issues arose with such approaches as they tend to overfit the data, yielding a signature tuned to the specific idiosyncrasies of the data set. It is important in these cases to apply validation methods, so that the data are trained and tested on different subsets of the data. This can be carried out with repeated splitting of the data into training and test sets (cross validation), with the resulting signature being a weighted average of the signatures discovered in this way.

It is critical to remember that this approach to validation is still prone to overfit the data, as the same data are used throughout and will therefore potentially display the same systematic behaviours. True validation, even during biomarker discovery, requires independently gathered data. Such data should ideally come from a different laboratory, so that unrecognized biases in the data that might arise from unique sample handling can be identified. It is worth remembering that all additional tests performed during discovery are relatively cost-effective compared to *in vivo* tests for validation, so refining biomarkers at this stage is a logical approach.

4.2 ROC Analysis

A biomarker at its simplest discriminates between two states, for instance disease and healthy. This can be reflected in a 2×2 contingency table (Table 1). Across the top of the table, we can write the status of the test, whereas along the side we have the true condition of the individual. The table then divides naturally into true positives (TP, test positive on diseased individual), true negatives (TN, test negative on healthy individuals), false positives (FP, test positive on healthy individuals) and false negatives (FN, test negative on diseased individuals). The value of a test obviously depends on the relative proportions of TP and TN to FP and FN. However, the definition of a positive or negative test depends on a threshold for the score of that test (e.g., fasting glucose greater than 100, rather than greater than 90).

It is useful when analysing the validity of a biomarker within a data set to consider the effects of a change of threshold on the results. This avoids an additional overfitting problem, as tuning the threshold for identifying hidden states can lead to a false sense of the reliability of a biomarker due to the chance distribution of values within a small data set.

This issue can be addressed through the use of receiver operator characteristic (ROC) analysis (Soreide, 2009). An ROC curve is a measure of the trade-off between sensitivity (true positive rate) and specificity (true negative rate). The sensitivity essentially is the probability that a positive test reflects the presence of the biological state (e.g., disease), whereas the specificity does the same for the absence of the state. Figure 4 demonstrates the trade-off for a realistic test where the range of values measured in healthy individuals overlaps that for diseased individuals. By moving the threshold, a curve of sensitivity and specificity values is generated and these can be plotted to form the ROC curve. The area under the curve (AUC) provides a threshold-independent measure of the test. Note that the expectation for a random test (a coin flip decides disease state) is an AUC of 0.5, so any test that does not significantly exceed this value should be considered useless.

Table 1. A 2×2 contingency table.

	Test positive	Test negative	
Disease positive	True positive	False negative	Total with disease
Disease negative	False positive	True negative	Total without disease
	Total positive tests	Total negative tests	Total individuals

Screening test?	Test positive	Test negative	
Disease positive	45	5	50
Disease negative	50	900	950
	95	905	1000

DOI: 10.1002/9780470744307.gat238
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

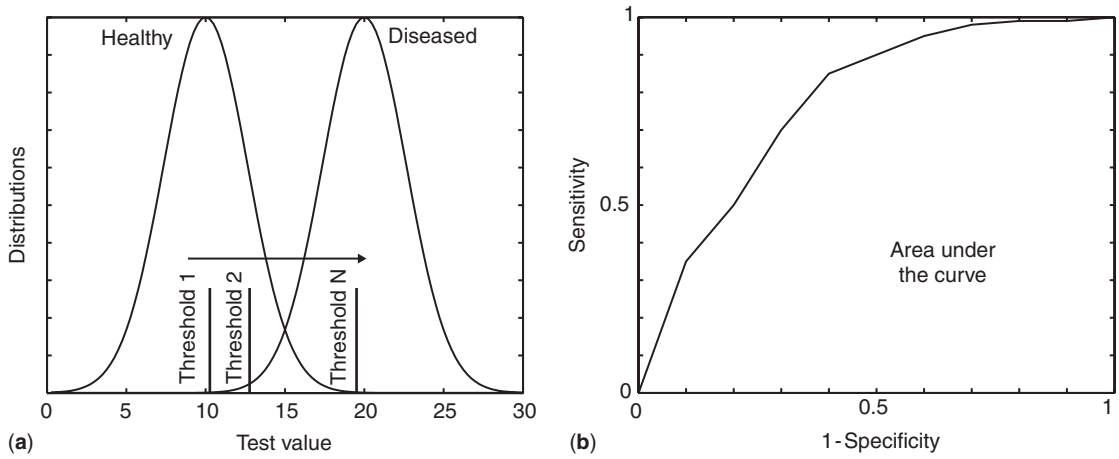

Figure 4. The ROC curve. (a) Overlapping biomarker distributions are shown for the results from healthy and diseased individuals, as in Figure 1. The threshold is shown and this is moved over the range of overlap, leading to different numbers of false positives and negatives and changing specificity and sensitivity. (b) The moving threshold maps out the ROC curve in sensitivity – specificity space.

Although ROC analysis was first used with biomarkers that were a single measurement, the same technique applies to multi-gene or other complex biomarkers. The biomarker results in a single score, such as from a weighted average of relative expression levels in multi-gene expression biomarkers, and the threshold for this score is varied to generate the ROC curve.

4.3 Biomarker Validation

Validation of biomarkers in the sense of moving them from discovery into clinical utility requires establishing their validity in a clinical setting with normal sample processing and within a population. As discovery inevitably is performed in a limited data set, potentially without *in vivo* tests, there are multiple stages to this validation. First, it must be verified that the biomarker is measurable *in vivo* with similar or adequate accuracy. Second, the usefulness of the biomarker across the target population must be validated. Third, the reliability of real-world clinical measurements of the biomarker must be established (e.g., with varying times and temperatures following a blood draw).

It can be useful to stress the difference between validation of the analytic method for biomarker development, including sample processing, and the validation of clinical usefulness, which is also termed qualification (Chau *et al*., 2008). The validation process aims to confirm a potential biomarker in an analytic system with a proven track record in order to confirm that the measurement of the biomarker is feasible in clinical settings. The qualification process involves a number of steps, outlined in (Chau *et al*., 2008), and verifies that the biomarker makes appropriate predictions in different settings and institutions. The FDA reviews proposed biomarkers and looks for scientific consensus from the community on the reliability of the biomarker.

For prognostic biomarkers, the statistic of interest is captured well by the ROC curve and the sensitivity and specificity. The sensitivity, or true positive rate, provides a measure of how good a test is at identifying individuals with the disease. The specificity, or true negative rate, meanwhile, indicates how good the test is at identifying individuals without the disease. When looking at prognosis, this provides an indication of the reliability of the prediction of outcome.

For diagnostic biomarkers, the goal is often to choose treatment based on the biomarker. In this case, the question of interest is what the probability is that a positive test indicates that the individual has the disease. This is known as the positive predictive value (PPV), with a corresponding negative predictive value (NPV) for a negative test predicting that the individual is disease-free. The distinction between PPV and sensitivity is important, as treatment will likely be chosen based on the biomarker test result, so the likelihood that the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat238
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

choice of treatment is correct is given by the PPV, not the sensitivity.

4.4 Special Considerations for Screening Biomarkers

A biomarker for screening the population to identify individuals who have a disease is an extension of a diagnostic biomarker to the case where we expect the number of individuals without disease to vastly exceed the number with disease. In this limit, it is often useful to focus on the PPV in terms of the sensitivity and specificity, which is given by

$$\mathrm{PPV} = \frac{\text{Sensitivity} \bullet \text{Prevalence}}{(\text{Sensitivity} \bullet \text{Prevalence}) + ((1 - \text{Specificity}) \bullet (1 - \text{Prevalence}))}.$$

The sensitivity is the true positive rate, the specificity is the true negative rate and the prevalence is the fraction of the population that harbours the disease. A PPV of 1 indicates a perfect test, and this can only result with perfect specificity, which requires every individual without the disease to test negative. As the specificity declines, the prevalence becomes critically important to the value of the test. For example, a test with excellent specificity (95%) and sensitivity (90%) will have a PPV of only 47% if the prevalence of the disease in the population is 5% (see Table 1). This is relatively high prevalence for many diseases, and it means that for every individual with the disease treated based on the test, another individual without the disease will also be treated. In addition, this test is unreasonably good, and most tests with such high specificity would have lower sensitivity.

This issue is important when developing a screening test. The goal is to maximize specificity in most cases, and the effect of a positive test on non-diseased individuals must be considered. In addition, if there is a relatively low PPV, then it is important that any follow-up tests be non-invasive and inexpensive as well, to minimize risk and cost.

5 SYSTEM RESPONSES

As the Systems biology and high dimensionality section makes clear, we have emerging technologies providing global coverage of the molecular species present in biological samples. However, these measurements still cannot cover the full range of biological variation, especially when the context of cell type, organ system, environmental influence and potential somatic mutations and epigenetic modifications are included. We are therefore required to build statistical models, including as much biological modelling as possible in the data integration, in order to identify biomarkers of system responses to therapeutic intervention.

We can identify a series of steps to be taken in developing such biomarkers. It is best to begin in *ex vivo* systems, where it is possible to perform time series measurements on the system during treatment. Naturally, a cell line that retains features of the system of interest is the logical point of departure for the study. Data can be gathered for the dynamic molecular components during treatment, including mRNA exon microarrays, miRNA arrays, proteomic measurements and potentially metabolomic measurements.

Analysis of the data should take place in a model-based fashion, leveraging the substantial amount of prior biological knowledge encoded in national and international repositories on pathways, transcription factors and binding sites, protein structure, drug targeting and other emerging resources. This model will be moderately complex, though not fully mechanistic in the sense of tracking all molecular interactions. Each analysis will be somewhat different, based on the system of interest, and will require substantial effort.

The result of the analysis will be a set of potential biomarkers. Ideally, a single molecular entity may be identified as a potential driver and biomarker of the state of interest, but it is more likely that a combination of molecular species will provide a signature of the state. This signature needs to be defined, perhaps through normalization invariant relationships to common species (i.e., mRNA level always greater than gene X), as in the Top Scoring Pair method (Geman *et al*., 2004).

This proposed biomarker must then be validated and qualified in independent samples obtained in different institutions. The appropriate test statistic for the proposed biomarker will depend on the purpose, whether diagnostic or prognostic. Naturally, a biomarker of treatment response will not fall into the

category of a screening biomarker. One significant advantage to this rather complicated approach is that biomarkers may be proposed for system responses, such as off-target effects, that would be missed in strategies that rely only on targeted, non-global approaches. These novel off-target effects can suggest biomarkers for treatment failure, if they are accurate surrogate endpoints, and also can suggest new targets for adjuvant treatment.

1 INTRODUCTION OF NANOMATERIALS AND NANOTOXICITY

1.1 Categories of Nanomaterials

Nanomaterials (NMs) are officially defined as "materials that have at least one dimension in the range of 1- to 100 nm" by US National Nanotechnology Initiative, and nanotechnology as "the understanding and control of matter at dimensions of roughly 1–100 nm, where unique phenomena enable novel applications." According to their shapes, nanomaterials could be nanoparticles, nanotubes, nanorings, nanocages, or nanowires, and so on. According to their composition, nanomaterials can be liposomes, emulsions, polymers, ceramic nanoparticles, metallic nanoparticles, carbon nanomaterials, ultrafine particulate pollutants, gold shell nanoparticles, and quantum dots. As a subset of nanomaterials, NMs are also variably called ultrafine particles (UFPs) by toxicologists.

1.2 Applications of Nanomaterials - Nanotechnology

Over the past ten years, nanotechnology and applications of nanomaterials have become one of the leading technologies due to their unique physical and chemical characteristics (Stix, 2001). Nanomaterials are increasingly being used in catalysts, pigments, resins, cosmetics, electric devices, and so on. In recent years, the use of nanomaterials has been extended to the biomedical and biotechnological fields for the purposes of drug/gene delivery, disease diagnosis, tumor cells tracking and recognition diagnosis, and imaging. Different nano-sized carriers, such as biodegradable polymeric micelles (Zhang and Feng, 2006; Win and Feng, 2005), liposomes (Bochot *et al*., 2002), surface-modified nanomaterials (Gupta and Gupta, 2005; Xing *et al*., 2005; Illum and Davis, 1984), and solid lipid nanomaterials (Muller, Mader and Gohla, 2000), have been developed and studied for achieving these goals.

Table 1 shows the estimated global production for specially-engineered nanomaterials and their accelerating production in the near future (Borm *et al*., 2006).

1.3 Potential Impact of Nanomaterials to Human Health and Environment

As the particle size decreases, the surface area increases, which allows a higher proportion of its atoms or molecules to be displayed on the surface rather than being confined to the interior of the material. Figure 1 clearly shows the inverse relationship between the particle size and the number of molecules expressed on the particle surface. The increase in surface area determines the potential number of reactive groups on the particle surface and makes nanomaterials very reactive

Table 1. Estimated global production for engineered nanomaterials. Reproduced from Borm (2006) © BioMed Central.

Application	Nonmaterial/device	Estimated global production (tonnes per year)		
		2003/04	2010	2020
Structural applications	Ceramics, catalysts, films & coatings, composites, metals	10	10^3	10^4–10^5
Skincare produces	Metal oxides (eg., TiO_2, ZnO)	10^3	10^3	10^3
Information & Communication Technologies	SWNT, nanoelectronic and optoelectronic materials (excluding CMP slurries), organic light emitters and electronics, nanophospliors	10	10^2	$>10^3$
Biotechnology	Nanocomposites and encapsulates, targeted drug delivery, diagnostic markers, biosensors	<1	1	10
Environmental	Nanofiltration, membranes	10	10^2	10^3–10^4

in the cellular environment. Thus, nanomaterials may impose dramatically different biological effects from their parent forms (Oberdorster, Oberdorster and Oberdorster, 2005; Kipen and Laskin, 2005; Nel *et al*., 2006). As a result, new toxicology data on the nanomaterials is likely to result in a different hazard assessment for the nanomaterials, and the applications of nanomaterials may be limited because of concerns about their toxicity (Service, 2004).

The remarkably large amount of nanomaterials production and use in our daily lives raises the concerns of the materials' toxicity to occupational workers and end product users, who may undergo exposure to nanomaterials via inhalation, dermal absorption, and gastrointestinal tract absorption. When inhaled, nanomaterials may be deposited in any region of the respiratory system, be taken into cells, enter into the bloodstream, and circulate to potentially sensitive target organs (Oberdorster, Oberdorster and Oberdorster, 2005).

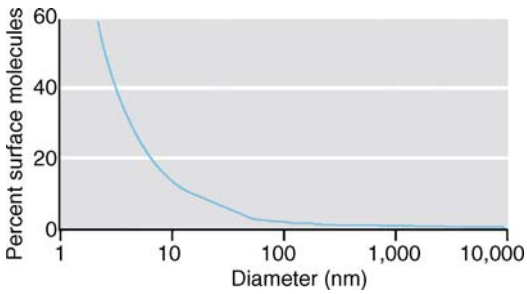

Figure 1. Surface molecules as a function of particle size. Surface molecules increase exponentially when particle size decreases to <100 nm, reflecting the importance of surface area for increased chemical and biological activity of nanomaterials. The increased biological activity can be positive and desirable (e.g., antioxidant activity, carrier capacity for therapeutics, penetration of cellular barriers), negative and undesirable (e.g., toxicity, induction of oxidative stress or of cellular dysfunction), or a mix of both. Reproduced from Oberdorster, Oberdorster and Oberdorster (2005) © National Institute of Environmental Health Sciences.

For most manufactured nanomaterials, knowledge of their toxicity and guidelines for their safe use are very limited. The reasons are due to (i) the new nanomaterials are emerging very fast; (ii) investigations on toxicity of nanomaterials have been carried on for only decades; and (iii) the toxic assessment of nanomaterials is a very complicated issue because of the many particle parameters involved. Also, oftentimes, the interpretation of the toxicity data (*in vitro* and *in vivo*) is difficult because particles of different chemical compositions were used, target animals or cells were different, and duration, end points, and dose levels also differed.

Although the potential effects of nanomaterials on human health remain unclear, considerable preliminary studies have demonstrated toxic effects of nanomaterials, including effects caused by carbon nanomaterials (carbon black, nanotubes, C_{60} and fullerene) (Warheit *et al*., 2004; Oberdorster, 2004; Shvedova *et al*., 2003; Lam *et al*., 2004; Kamat *et al*., 1998; Manna *et al*., 2005; Sayes *et al*., 2005; Jia *et al*., 2005; Kolosnjaj, Szwarc and Moussa, 2007; Kato *et al*., 2009), titanium dioxide (Warheit, Webb and Reed, 2006; Warheit *et al*., 2005; Warheit, Webb and Reed, 2006; Gurr *et al*., 2005; Sayes *et al*., 2006; Xia *et al*., 2006; Grassian *et al*., 2007; Koeneman *et al*., 2009; Kobayashi *et al*., 2009), quantum dots (Green and Howman, 2005; Hardman, 2006; Cho *et al*., 2007; Hsieh, Shiao and Chan, 2009; Pelley, Daar and Saner, 2009), ultrafine polystyrene (Brown *et al*., 2001; Hamoir *et al*., 2003), nanometer

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

sized diesel exhaust particles (Block *et al*., 2004; Zhao *et al*., 2009; Sgro *et al*., 2009; Nemmar *et al*., 2009), and ultrafine particulate pollutants (Li *et al*., 2003a; Hwang *et al*., 2008; Valavanidis, Fiotakis and Vlachogianni, 2008). Some nanomaterials, such as carbon black (CB), TiO_2, iron oxides and amorphous silica, have been manufactured by the chemicals industry for several decades and are produced in quantities of many tons per year. Toxicity studies on animals (mostly rodents) by using a variation of nanomaterials revealed that nanomaterials consistently induced mild yet significant pulmonary inflammatory responses, effects in extrapulmonary organs with the analysis of lung lavage parameters and lung histopathology, effects on the blood coagulation cascade and to extrapulmonary tissues. In addition to *in vivo* and *in vitro* studies, some studies of eco-toxicity of nanomaterials were also carried out (Adams, Lyon and Alvarez, 2006; Hund-Rinke and Simon, 2006) to contribute to a complete understanding of toxicity mechanism.

2 PHYSICOCHEMICAL PROPERTIES OF NANOMATERIALS AND CHARACTERIZATION

Before conducting *in vitro* nanotoxicity testing, one needs to gather all of the physicochemical properties of nanomaterials. The reason is that the physicochemical and structural properties of nanoparticles play a major role in their interactions with cells, which could lead to quite different toxicological effects (Oberdorster, Oberdorster and Oberdorster, 2005; Lewinski, Colvin and Drezek, 2008; Kreyling, Semmler-Behnke and Moeller, 2006; Donaldson and Tran, 2002). The major parameters of nanoparticles to be considered, before conducting *in vitro* testing, include sizes of the particles, extent of their size distribution, surface area, porosity, charge density on the surface, solubility, morphology, function groups on the surface, purity, stability, and so on. Table 2 shows that common physical and chemical properties that should be known before nanotoxicology testing (Sahu and Casciano, 2009).

The particle size plays one of the most important roles in causing cytotoxicity of nanoparticles even though other parameters may also contribute significantly. For instance, shrinkage in size may create discontinuous crystal planes that increase the number of structural defects, as well as disrupt the well-structured electronic configuration of the nanoparticle; thereby, altering its electronic properties (Oberdorster, Oberdorster and Oberdorster, 2005; Donaldson and Tran, 2002; Kipen and Laskin, 2005). The exposed specific surface groups can function as reactive sites. Therefore, the sizes of the nanoparticles must be accurately measured before nanotoxicity is conducted. Several techniques that can be used to determine the sizes and

Table 2. Important properties in nanomaterials characterization for toxicity studies. Reproduced from Sahu and Casciano (2009) © John Wiley & Sons, Ltd.

Property	Importance for toxicity testing	Comments
Particle size distribution	Essential	
Degree/state of agglomeration	Important	
Particle shape/shape distribution	Important	
Chemical composition/purity	Essential	
Solubility	Essential (where applicable)	
Surface properties		
Specific surface area/porosity	Essential	Surface roughness may be important
Surface chemistry/reactivity	Essential	
Surface adsorbed species	Important	In some cases may be the mechanism of toxicity (e.g., complement)
Surface charge/ Zeta potential	Important (essential under aqueous conditions)	Especially in aqueous biological environments, may change according to the environment
Physical properties	Important	
Density	If applicable	
Crystallinity	If applicable	
Microstructure	If applicable	
Optical and electronic properties	If applicable	
Bulk powder properties	If applicable	May be important for dosimetry/exposure
Concentration	Essential	Can be measured as mass, surface area, or number concentrations

size distributions of nanoparticles include Atomic Force Microscopy (AFM), Transmission Electron Microscope (TEM), Scanning Electron Microscope (SEM), Light Scattering (static or dynamic), and Zeta-meter. The most commonly used techniques used by nanotoxicity researchers for size measurements are the AFM and TEM, even though their use depends on the availability of these instruments. Conventional TEM instruments can provide two-dimensional images of nanoparticles as shown in Figure 2a and b (Lin *et al*., 2009). The TEM software allows one to calculate the size distribution of the nanoparticles by using the imaging data. AFM not only provides particle size information, but also provides particle height and volume because it directly produces three-dimensional images, which is the unique advantage of AFM over SEM and TEM.

The specific surface area (SSA, $m^2\,g^{-1}$) of the nanomaterials is also an important factor that can affect their cytotoxicity significantly because the interactions of nanomaterials with cells may increase greatly as SSA increases. Even though the SSA is inversely proportional to the nanoparticle size, the nanopores on the nanomaterials may vary dramatically from one type to another. The SSA of the nanoparticles is normally measured through using the Brunauer, Emmett, and Teller (BET) technique. In addition, the BET technique can also provide particle porosity information, even though other techniques can be used to measure porosity, such as the porosity analyzer. The fundamental

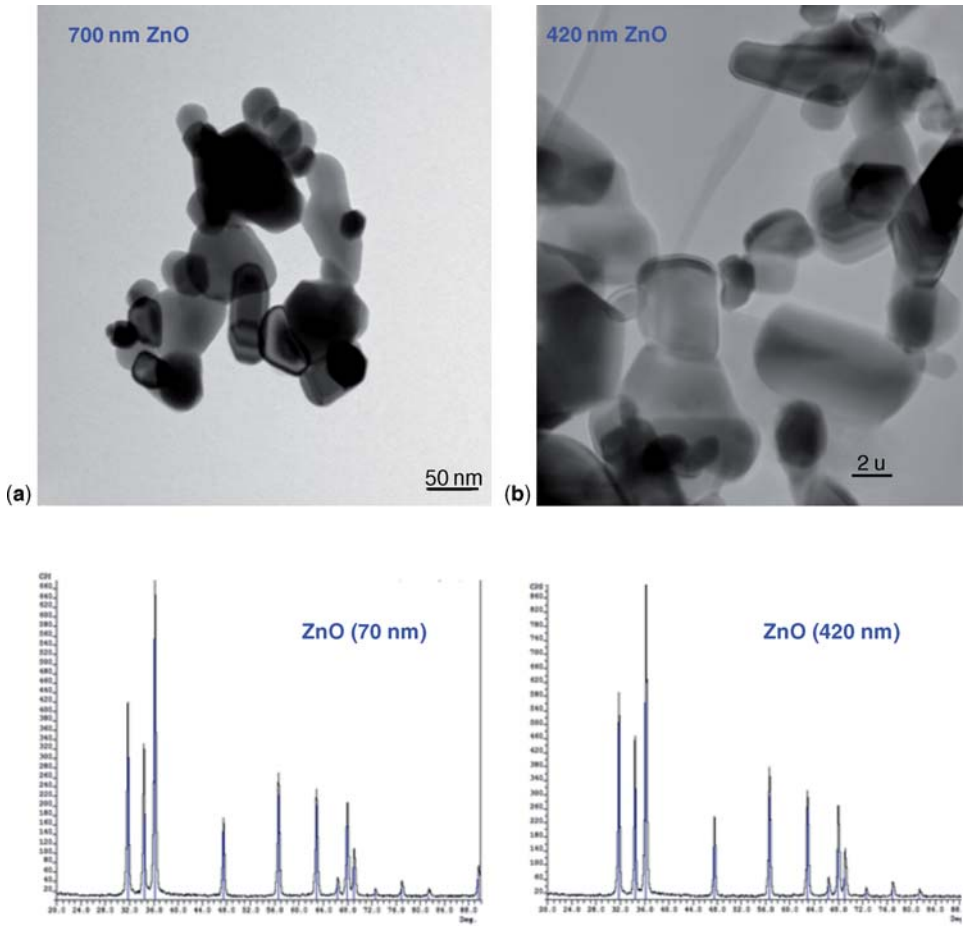

Figure 2. TEM images and X-ray diffraction (XRD) analysis of ZnO nanoparticles. (a) 70 nm ZnO particles; (b) 420 nm ZnO particles. XRD analysis indicated both particles were hexagonal. Reproduced from Lin *et al.* (2009) © Springer.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

principles of the BET technique for measuring the SSA can generally be found in many literatures.

Studies have demonstrated that different nanomaterial structures (amorphous versus crystal structure or different crystal structures) can have different levels of cytotoxicity. Therefore, pertinent information on particle structures, or crystal structures, must be known before conducting a cytotoxicity study. X-ray diffraction (XRD) is a commonly used instrumental technique for this purpose. A representative XRD analysis of ZnO nanoparticles is shown in Figure 2.

Impurities in nanomaterials or on the nanomaterial surface can significantly affect the cytotoxicity of nanomaterials. Sometimes, they may be the major contribution to the cytotoxicity of the nanoparticles, which may provide misleading information about the level of cytotoxicity of the nanoparticles. Therefore, the impurity information should be known before a nanotoxicity study is undertaken. To get the inorganic impurity data, Inductively Coupled Plasma - Mass Spectrometry (ICP-MS) instrument is the most commonly used technique to quantitatively measure the metal impurities in many nanoparticles because of its high sensitivity and specificity. For example, the impurity results in one type of silica nanoparticles are shown in Table 3 (Lin *et al*., 2009).

Due to their nanoscale size and surface properties, nanomaterials tend to aggregate or precipitate in suspensions. This process will change the nanomaterials surface area and physicochemical properties and can affect the levels of cytotoxicity of nanomaterials. Therefore, the average hydrodynamic size and distribution of nanoparticles in suspension must be determined. Dynamic laser scattering (DLS) and Zeta-meter (or zeta-sizer) are commonly used to determine the hydrodynamic sizes of nanoparticles. In addition, a Zeta-meter can also provide zeta potential and surface charge information of the nanomaterials, which are essential pieces of information for nanotoxicity testing. To acquire accurate data on the hydrodynamic sizes of nanoparticles, as well as the charge density on the surface, it is recommended that hydrodynamic size measurements be taken in the cell media used for an *in vitro* study. In summary, the physicochemical properties of the nanomaterials should be known as much as possible before a nanotoxicity study is conducted. Otherwise, the cytotoxicity data acquired through the nanotoxicity study may be difficult to explain or may not be useful at all in trying to conduct a comparison on the levels of cytotoxicity.

Table 3. Metal impurity levels in ZnO particles of 70 nm and 420 nm tested in an ICP-MS system. The method detection limit is 0.04 ppm[a]. Reproduced from Lin *et al.* © (2009).

	Metal impurity levels (ppm)	
Elements	70 nm ZnO	420 nm ZnO
Na	45.4	7.5
K	44.9	4.4
Cu	37.9	9.3
Se	18.2	18.7
Ca	8.6	1.7

[a] One part per million (ppm) of a specific metal is defined as 1 gram of that metal per 10^6 gram of ZnO.

[b] Not detected.

3 NANOPARTICLE MORPHOLOGY AND CITOTOXICITY

Considerable existing data have shown that the internal structure and the external morphology of nanomaterials have a significant influence on their practical applications and cytotoxicity, even though the sizes of nanomaterials may be the same. Therefore, it is important to investigate the nanomaterials toxicity and morphology. In this section, the cytotoxicity of several classes of nanomaterials and morphological effects on their applications will be discussed.

Nanomaterials generally fall into several categories: carbon-based nanoparticles, such as fullerenes, single-and multi-wall carbon nanotubes (SWNTs and MWNTs); metal-based nanoparticles, such as colloids, nanoshells, nanorods and superparamagnetic nanoparticles; semiconductor-based

nanoparticles such as quantum dots. *In vitro* cytotoxicity studies of different types of nanomaterials using different cell lines, incubation times, and colorimetric assays are increasingly being reported (Lewinski, Colvin and Drezek, 2008).

Carbon nanomaterials refer to carbon with one or more dimensions at 100 nm or less, including fullerenes, SWNTs and MWNTs of which fullerenes is the most widely used and well developed of the carbon nanomaterials (Lewinski, Colvin and Drezek, 2008; Sun *et al*., 2006; Schrand *et al*., 2007; Service, 2004; Bandow *et al*., 2000). In terms of cytotoxicity for fullerenes, the most significant factor influencing cytotoxicity is their complexity and cell type (Bandow *et al*., 2000). A review paper summarized the experimental setup and results on fullerenes in Table 4 (Lewinski, Colvin and Drezek, 2008).

Compared to the cytotoxicity on fullerenes, SWNTs were reported to be more toxic than the other two major types of carbon nanomaterials (Smart *et al*., 2006; Tian *et al*., 2006; Pulskamp, Diabate and Krug, 2007). One of the hypotheses to explain the cytotoxicity of SWNTs is due to the mode of production because the synthesis of SWNTs requires the use of metal catalysts which can be toxic themselves. Both time-and dose-dependent cytotoxicity in human epidermal cell lines have been studied. Lewinski, Colvin and Drezek (2008) summarized the cytotoxicity studies on SWNTs as in Table 5. Also, similar studies have been done with those of SWNTs as shown in Table 6. The numbers of publications of *in vitro* cytotoxicity studies of metal nanoparticles using different cell lines are increasing exponentially, of which gold nanoparticles have been widely studied due to their potential medical applications. Due to their small sizes, they have greater potential to travel through the organism than other material or larger particles (Donaldson *et al*., 2004). However, cytotoxicity may not be the only adverse effects of gold nanoparticles; they may also affect the immunological response of cells. One group tested the effect of gold nanoparticles on the proliferation, nitric oxide, and reactive oxygen species production of RAW264.7 macrophage cells (Shukla *et al*., 2005).

In terms of cytotoxicity, while bare iron oxide nanoparticles exert some toxic effects, several coated iron oxide nanoparticles have been found to be relatively nontoxic (Lewinski, Colvin and Drezek, 2008). Cell lines used in the study of iron oxide nanoparticles include: COS-7 cells, Human fibroblasts, Melanoma cells, HTERT-BJ1, BRL3A, MSTO21H, EC219, RAW264.7, SK-BR-3, PC12M, and some others (Cheng *et al*., 2005; Gupta Ajay and Wells, 2004; Petri-Fink *et al*., 2005; Gupta and Gupta, 2005; Hussain *et al*., 2005; Brunner *et al*., 2006; Cengelli *et al*., 2006; Hu *et al*., 2006; Yu *et al*., 2006; Muller *et al*., 2007; Pisanic *et al*., 2007; Wan *et al*., 2007; Adams, Lin and Ma, 2007; Lin *et al*., 2006; Lin *et al*., 2006; Lin *et al*., 2007; Lin *et al*., 2008). The results demonstrated clearly that surface groups on the nanomaterials play major roles in the levels of cytotoxicity.

Another class of nanomaterials is semiconductor nanoparticles, better known as quantum dots. Actually, the concern of their cytotoxicity is due to the composition of known toxic elements. The sizes of quantum dots (QDs) are ranging from 2 to 100 nm in diameter depending on the types of surface coating or functional group added. QDs typically have a core/shell conjugate structure. The core of the QD is composed of atoms from groups II–VI (e.g., CdSe, CdTe, CdS, PbSe, ZnS, and ZnSe) and groups III–V (Lewinski, Colvin and Drezek, 2008). The *in vitro* study of this class involve cell lines: BALB/c, Vero cells, Hela cells, WTK1, and B16F10 (Akerman *et al*., 2002; Dubertret *et al*., 2002; Hanaki *et al*., 2003; Hsieh *et al*., 2006; Larson *et al*., 2003; Ballou *et al*., 2004; Chen and Gerion, 2004;Derfus, Chan and Bhatia, 2004; Hoshino *et al*., 2004; Shiohara *et al*., 2004; Voura *et al*., 2004; Green and Howman, 2005; Kirchner *et al*., 2005; Selvan, Tan and Ying, 2005; Chang *et al*., 2006; Fischer *et al*., 2006;Zhang, So and Rao, 2006; Cho Sung *et al*., 2007; Duan and Nie, 2007; Guo *et al*., 2007; Liang *et al*., 2007; Ryman-Rasmussen, Riviere and Monteiro-Riviere, 2007; Lovric *et al*., 2005; Liu *et al*., 2006; Choi *et al*., 2007).

Many nano-factors enable nanomaterials to present possible dangers, both medically and environmentally, among which nanoparticle morphology play an essential role in toxicological or biomedical activities. Different nanosizes or crystal types are not only able to present different surface-to-volume ratios and surface active sites, but lead to aggregation of different levels. All these features can make the particles very reactive or catalytic in their interactions with biological systems. Although it was suggested that nanoparticle size can alter cellular uptake, subcellular localization, and an ability

to produce ROS (Hussain *et al*., 2005), the cytotoxicity could also depend on the morphology of the particles (Gurr *et al*., 2005).

Particle surface and interfaces are important components of nanomaterials. As the morphology changes, the proportion of atoms found at the surface relative to the proportion inside its volume may also change. This may increase or decrease the reactivity. From the health implication perspective, reactive groups on a particle surface are likely to modify the biological (potentially toxicological) effects. In addition, it should be noted that two different nanoparticle-types may not be biologically equivalent from a toxicological perspective. There can be differences in crystal structures, nanosizes, and aggregation status. These morphology differences are manifested in different pulmonary inflammatory and cytotoxic effects ranging from benign to more moderate health impacts.

Although the morphology of the nanomaterials is not likely to change greatly in *in vitro*/cell culture conditions, one fact should be not ignored. Nanotoxicity assessments can be affected by their solution dynamics. The nanomaterials may precipitate, diffuse, agglomerate, and change surface charge/chemistry over time in solution, which changes the nature of the nanomaterials and their transport to cells. In addition, these processes are also affected by the properties of solutions (viscosity, density, presence of proteins, etc). For instance, nanoparticles of different morphology settle at different rates and these differences may lead to differences in transport to adherent cells in culture. The extent of these differences and their impact on the toxicity assessment of particles in general is not widely investigated. That's why in *in vitro* toxicity studies, particle morphology in solution is an important factor which needs to be accurately investigated as a prerequisite for implementing nanoparticle toxicity studies.

4 TOXICITY MECHANISMS OF NANOMATERIALS

The detailed toxicity mechanism induced by nanomaterials is not completely clear. However, several mechanisms have been proposed based on reported results. The mechanisms are shown schematically in Figure 3 (Nel *et al*., 2006). The shrinkage of size of nanomaterials and subsequent change of the physicochemical and structural properties may cause toxicological effects (Oberdorster, Oberdorster and Oberdorster, 2005; Donaldson and Tran, 2002). For example, when material size decreases to nanolevel, the discontinuous crystal planes and structural defects may increase significantly, further changing the electronic configuration of the nanomaterials (Oberdorster, Oberdorster and Oberdorster, 2005; Donaldson and Tran, 2002). This change could cause more surface sites to be active. These reactive sites act as electron-donors or electron-acceptors and work with oxygen to induce superoxide radical ($O_2^{\bullet -}$), which can then generate Reactive Oxygen Species (ROS) by dismutation or the Fenton reaction.

Nanomaterials may contain transition metals such as Fe, Cu, Cr, V, and Co, on their surface. These transition metals are closely related to the generation of reactive oxygen species and reactive nitrogen species (RNS) due to redox-cycling reactions (Valko, Morris and Cronin, 2005). For instance, carbon nanotubes contain metal impurities that can amplify chemical changes in the nanomaterial's environment and induce ROS and oxidative stress (Shvedova *et al*., 2005). Currently, ROS and oxidative stress induced by nanomaterials has been one of the best-developed paradigms for nanoparticle (NP) toxicity. Other metals such as mercury (Hg), cadmium (Cd), and nickel (Ni) may cause toxicity by depleting glutathione (GSH) and binding to the sulfhydryl groups of proteins (Valko, Morris and Cronin, 2005).

As one of the most important toxicity mechanism of nanomaterials, oxidative stress is defined as a disturbance between the prooxidant and the antioxidant balance in favor of the former and is implicated in the pathogenesis of many disease states including aging, atherosclerosis, carcinogenesis, and acute and chronic inflammatory disorders (Kehrer and Lund, 1994). Oxidative stress can result from depletion of antioxidants due to malnutrition and/or excess production of ROS. The Figure 4 shows the hierarchical oxidative stress hypothesis; the lowest level of oxidative stress induces antioxidant and detoxification enzymes, higher levels of oxidative stress causes inflammation and apoptosis.

From a mechanistic perspective, ROS generation and oxidative stress is the best-developed paradigm to explain the toxic effects of nanomaterials at the present time (Oberdorster, 2004; Xia *et al*., 2006;

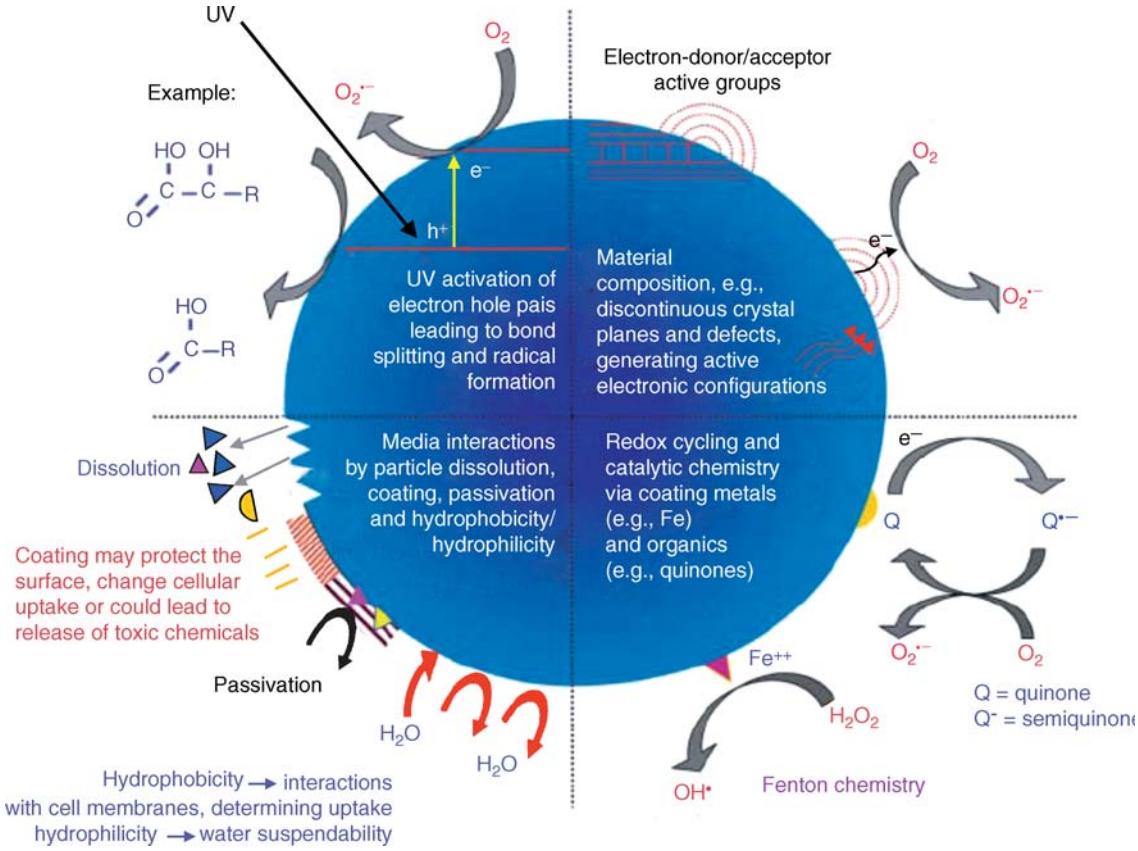

Figure 3. Possible mechanisms by which nanomaterials interact with biological tissues. Examples illustrate the importance of material composition, electronic structure, bonded surface species (e.g., metal-containing), surface coatings (active or passive), and solubility, including the contribution of surface species and coatings and interactions with other environmental factors (e.g., UV activation) Reproduced from Nel *et al.* (2006) © American Association for the Advancement of Science.

Li *et al.*, 2003a). Under normal coupling conditions in the mitochondrion, ROS are generated at low frequency and are easily neutralized by antioxidant defenses such as glutathione (GSH) and antioxidant enzymes. However, when under serious oxidative stress, free radicals can deplete antioxidants and cause severe cellular damage such as lipid peroxidation (Nordberg and Arner, 2001).

Because of the importance and significance of oxidative stress in toxicity studies, investigations both *in vivo* and *in vitro* have been carried out on selected nanomaterials such as carbon nanomaterials (nanotubes and fullerene) (Lam *et al.*, 2004; Kamat *et al.*, 1998; Manna *et al.*, 2005; Sayes *et al.*, 2005), titanium dioxide (Gurr *et al.*, 2005; Liang *et al.*, 2009; Wu *et al.*, 2009; Bhattacharya *et al.*, 2009), quantum dots (Green and Howman, 2005; Funnell and Maysinger, 2006; Li *et al.*, 2009), ultrafine polystyrene (Xia *et al.*, 2006; Brown *et al.*, 2001; Stone, Johnston and Clift, 2007), and ultrafine particulate pollutants (Li *et al.*, 2003a; Valavanidis, Fiotakis and Vlachogianni, 2008; Brauner *et al.*, 2007; Alessandrini *et al.*, 2009). The results demonstrated that the toxicity of these nanomaterials was related to ROS generation and oxidative stress, which caused membrane damage, DNA damage, and possible protein denaturation and immune reactivity.

Figure 5 shows a typical diagram depicting how C_{60} fullerene induces ROS and interacts with the antioxidant defense system (Yamakoshi *et al.*, 2003). The exact mechanism by which C_{60} and other nanomaterials cause ROS is not yet fully understood, but a possible mechanism has been proposed as follows: (i) photo excitation of fullerenes and Single-wall Carbon Nanotubes (SWNTs),

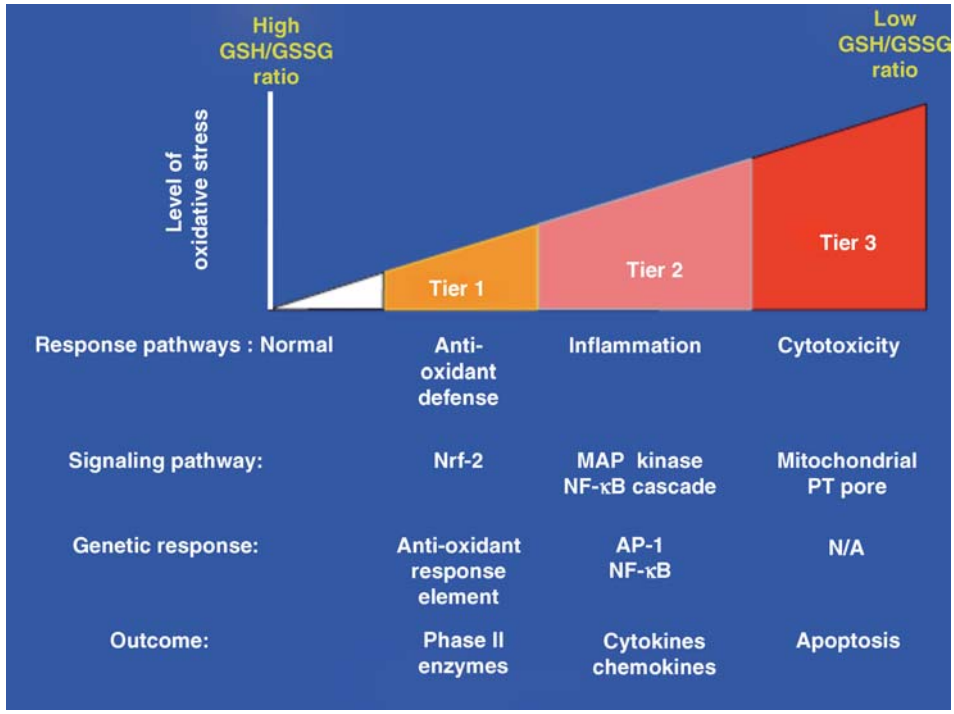

Figure 4. The hierarchical oxidative stress model. At a lower amount of oxidative stress (tier 1), phase II antioxidant enzymes are induced via transcriptional activation of the antioxidant response element by Nrf-2 to restore cellular redox homeostasis. At an intermediate amount of oxidative stress (tier 2), activation of the MAPK and NF-kB cascades induces pro-inflammatory responses. At a high amount of oxidative stress (tier 3), perturbation of the mitochondrial PT pore and disruption of electron transfer results in cellular apoptosis or necrosis. Reproduced from Nel *et al.* (2006) © American Association for the Advancement of Science.

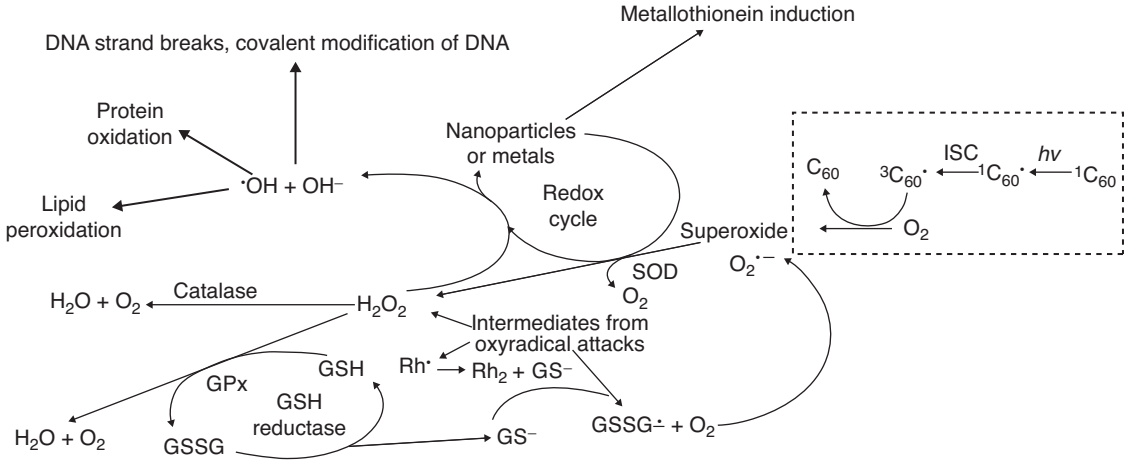

Figure 5. Nanomaterials have been shown to release oxyradicals [pictured here is the mechanism of C60 as determined by Yamakoshi et al. 2003, which can interact with the antioxidant defense system. Abbreviations: GPx, glutathione peroxidase; GSH, reduced glutathione; GSSG, oxidized glutathione; ISC, intersystem crossing; R, any organic molecule; SOD, superoxide dismutase. In addition to fullerenes, metals such as cadmium, iron, or nickel quantum dots, or iron from SWNT manufacturing, could also act in Fenton-type reactions. Phase II biotransformation, ascorbic acid, vitamin E, beta carotene, and other interactions are not shown. Reproduced from Oberdorster, Oberdorster and Oberdorster (2005), National Institute of Environmental Health Sciences.

causing intersystem crossing to create free electrons (Yamakoshi *et al*., 2003); (ii) metabolism of nanomaterials to create redox-active intermediates, especially if metabolism is via cytochrome P450s; (iii) inflammation responses *in vivo* that may cause oxyradical release by macrophages; and (iv) the presence of transition metals such as Fe, Cu, Cr, V, and Co, may induce ROS by redox-cycling reactions (Oberdorster, Oberdorster and Oberdorster, 2005; Nel *et al*., 2006; Adams, Lyon and Alvarez, 2006; Yamakoshi *et al*., 2003).

For the reason of biocompatibility, surface coatings, and covalent surface modifications were commonly applied to nanomaterials in drug/gene delivery, imaging, and diagnostic applications. In this case, chemicals from the coating or surface modifier may cause toxicity. Other nanomaterial properties such as shape, aggregation, and solubility may also affect the specific physicochemical properties, with the possibility of negating or amplifying the size effects.

Figure 3 also gives one possible toxicity mechanism induced by nanomaterials: toxic chemicals released from nanomaterials. Hull *et al*. (2009) studied the aquatic toxicity caused by low-purity, as-produced fullerenes (C60) and metallofullerene waste solids. Release of metal impurities from carbon nanomaterials influences aquatic toxicity. They applied SEM and ICP-MS to characterize the metals compostion of the solid test materials and of aqueous leachates. The results indicated that metals associated with the solid test materials were mobilized upon interaction with waters of circumneutral pH and reached concentrations sufficient to induce toxicity in both test species. The experiment of adding the chelator EDTA to eliminate the toxicity proved that the divalent transition metals were the toxicity source. Some products and byproducts of nanomanufacturing may contain relatively high levels of metal impurities. Their potential toxicity to human beings and the environment needs more attention.

Due to their nanometer size, the cytotoxicity of nanomaterials may be related to the cellular uptake of nanomaterials and the interaction of nanomaterials with individual cellular components, which leads to their malfunction and ultimately to cell death (Jia *et al*., 2005; Xia *et al*., 2006; Cho *et al*., 2007; Li *et al*., 2003; Long *et al*., 2006). The uptake of nanomaterials may be significantly affected by particle composition, particle size, shape, surface charge, temperature, and time.

Because some nanomaterials have the potential to be used as drug carriers or probes, their possible interaction with cellular components are very important to evaluate their toxicity. The binding of cellular proteins on the surface of nanomaterials such as SiO_2, TiO_2, and polystylene particles was studied by Morton Ehrenberg (Ehrenberg and McGrath, 2005). The Brownian motions of embedded polystylene particles and SiO_2 particles were used to infer the micromechanical properties of cells and protein network. They found that among all the proteins in cytoplasmic and cell-rich tissue extracts, nanoparticles bind most abundantly to cytoskeletal protein including actin and intermediate filaments, and the protein binding was strongly dependent on the surface chemistry of nanomaterials.

5 ANALYTICAL METHOD TO EVALUATE TOXICITY OF NANOMATERIALS

To clarify the toxicity and the toxic mechanism of nanomaterials, it is very important to use appropriate analytical techniques to determine the relationship of characteristics of nanomaterials and their toxicity. These relationships are very helpful to set up the safety regulations for these nanomaterials. With the tremendously increased manufacture of nanomaterials, this kind of requirement is urgent and large numbers of significant challenges must be overcome. From an analytical chemistry perspective, this emerging discipline requires both characterization of nanomaterials and bioanalytical chemistry expertise. The following part is to introduce some typically and widely used analytical techniques in nanotoxicology and gives critical vision into this field. The major analytical techniques used by scientists and researchers are listed and discussed in detail. The strengths and limitations of each technique are discussed. These techniques are categorized by the *in vitro* or *in vivo* applications including characterization of cellular uptake of nanomaterials, *in vitro* toxicity study and *in vivo* toxicity study.

5.1 *In-vitro* Uptake and Localization

In defining the mechanistic features of nanomaterials toxicity, a key question is the cellular uptake and subcellular localization of nanomaterials. The

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

cytotoxicity may be caused by NMs uptaken and the subsequent interaction of NMs with individual cellular components, which leads to cell malfunction and ultimately cell death. In addition, the uptake of NMs may be significantly affected by particle composition, particle size, shape, surface charge, temperature, and exposure time. Quantification of the amount of uptaken NMs by cells currently may be resolved by several analytical techniques such as TEM, ICP-MS, Fluorescence, and so on. However, because of the limitations of these techniques, complementary techniques should be used for complete understanding of NMs uptake by cells.

5.1.1 Transmission Electron Microscopy (TEM)

Transmission electron microscopy (TEM) is a microscopy technique whereby a beam of electrons is transmitted through an ultra thin specimen, interacting with the specimen as it passes through. An image is formed from the interaction of the electrons transmitted through the specimen; the image is magnified and focused onto an imaging device, such as a fluorescent screen, on a layer of photographic film, or to be detected by a sensor such as a CCD camera. TEMs are capable of imaging at a significantly higher resolution than light microscopes, owing to the small de Broglie wavelength of electrons. This enables the instrument's user to examine fine detail – even as small as a single column of atoms, which is tens of thousands times smaller than the smallest resolvable object in a light microscope. It is a major analysis method in a range of scientific fields, in both physical and biological sciences.

TEM is a powerful tool to provide the *in-vitro* NM uptake and localization by imaging of NM locations within a cell. TEM has been widely employed in cellular uptake and localization determination of particles with wide range size (nm $\sim$ μm). Here are some examples for the cellular uptake mechanism and subcellular localization of NMs. One typical example is TiO_2 NMs, which is one of the most important nanomaterials in industrials and is produced in millions of tons per year. TiO_2 NMs can exist in several crystalline forms: anatase, rutile, and amorphorous. TiO_2 NMs have been widely used in manufacturing, as a photocatalyst to decontaminate air, soil, and water (Maness *et al*., 1999), and more recently in consumer products (e.g., toothpastes, sunscreens, cosmetics, and food products, etc.). In addition, TiO_2 NMs have been used in various polymeric materials as additives to enhance the material properties. The wide applications and its potential entry through dermal, ingestion, and inhalation routes suggest that nanosize TiO_2 may pose considerable exposure risk to humans and environment. Numerous *in vitro* studies reported that TiO_2 NMs cause oxidative stress-mediated toxicity in diverse cell types, including immortalized brain microglia (Long *et al*., 2006), epithelia (Gurr *et al*., 2005), skin fibroblast (Wamer, Yin and Wei, 1997). *In vivo* studies showed that TiO_2 NMs induced emphysema-like lung injury in mice (Warheit *et al*., 2005).

As we know, like other metal oxide NMs, TiO_2 NMs are neither coated nor modified nanomaterials, thus they are insoluble in water or medium and generally exist in aggregation forms. In addition, they have no fluorescence activity or radioactivity. So the microscopy techniques based on fluorescently or radioactively labeled NMs are not appropriate to study the cellular uptake of TiO_2 NMs. Fortunately, TiO_2 NMs can be easily visualized in cells by TEM due to the high electron density of their inorganic domains, which exhibits different contrasts, sizes, and shapes from those of cellular organelles. The study of Xia *et al*. (2006) indicated that 20–30 nm TiO_2 NMs were taken by RAW 264.7 cells but with no obvious mitochondrial damage (Figure 6).

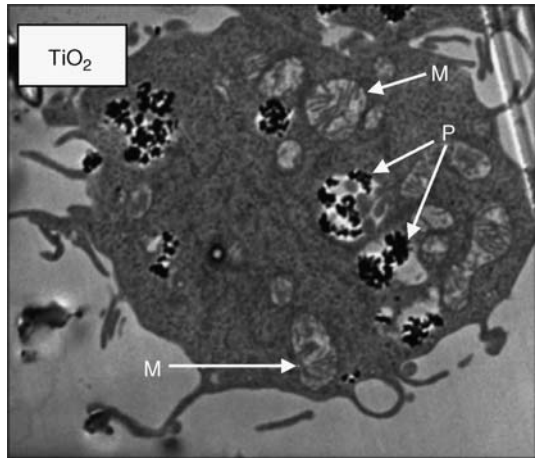

Figure 6. Use of transmission electron microscopy to determine the uptake and subcelluar localization of TiO_2 NMs. Cells were treated with 10 μg ml^{-1} NMs for 16 h. Lables: M=mitochondria, P = TiO_2 NMs. Reproduced from Xia *et al.* (2006) © American Chemical Society.

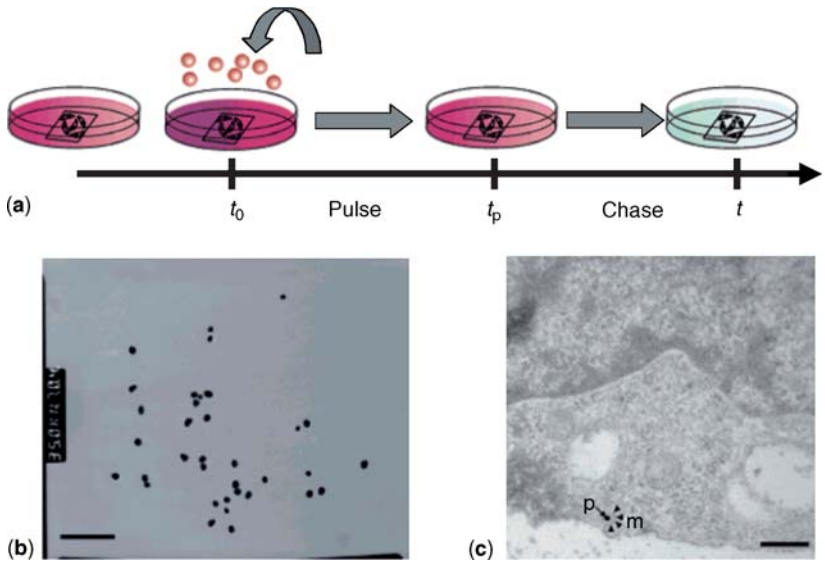

Figure 7. Schematics of the experiment: (a) gold nanoparticles were applied with the cell culture medium at time t_0 as a pulse of duration t_p, followed by incubation in medium without nanoparticles for different time t, at which the Raman experiments were carried out in PBS buffers; (b) transmission electron micrograph of gold nanoparticles immersed in cell culture medium (DMEM with 10% FCS). Scale bar: 500 nm; (c) transmission electron micrograph showing the endocytotic uptake of individual gold nanoparticles by an IRPT cell. The cell membrane (arrowheads, labeled m) encloses the particles (arrow, labeled p), thereby forming a vesicle in the cytoplasm. Scale bar: 500 nm. Reproduced from Kneipp *et al.* (2006) © American Chemical Society.

Kneipp *et al*. (2006) found that the individual gold NMs were cellularly taken up by an endocytosis process. During the endocytosis process, a part of the cellular membrane underwent invagination; thereby, enclosing a gold nanoparticle that was contained in the cell culture medium. Therefore, in the cellular interior, the particle was surrounded by a membrane vesicle. The TEM image displayed a snapshot of this enclosure process as the authors observed it in a cell of the epithelial cell line IRPT (Figure 7). Li *et al.* (2003) used TEM to study the cellular localization of CAP's (concentrated ambient particles) with different sizes (Figure 8). Coarse particles were seen in large cytoplasmic vacuoles in macrophages, while the ultrafine ones were seen to localize inside damaged mitochondria. The same mitochondrial effects were also observed in human bronchial epithelial cells treated with ultrafine particles.

Endocytosis processes were believed to be the most common uptake mechanism for cell to uptake macromolecules, particulate matters, and NMs. Endocytosis is a process whereby cells ingest a part of their cell membrane continually to form endocytic vesicles into which external objects are swallowed. Under its wide definition, endocytosis includes various uptake methods, including phagocytosis (cell eating), pinocytosis (cell drinking), clathrin-dependent endocytosis and caveolae-mediated endocytosis. All the endocytic processes are energy dependent; therefore, endocytosis processes are at least partially inhibited either at low temperature (usually 4 °C) or by cellular ATP depletion. Another feature of endocytic pathways is the formation of vesicles, which usually originate from the peripheral cell membrane, bud off from the membrane, and move towards the interior. Depending on the nature of the cell (phagocytic or non-phagocytic) as well as the nature of the NMs (size, surface characteristics, and presence of ligands on the surface), the uptake process may vary.

5.1.2 Fluorescence Spectroscopy

Fluorescence spectroscopy is a type of electromagnetic spectroscopy, which analyzes fluorescence from a sample. It involves using a beam of light, usually ultraviolet light, that excites the electrons in molecules of certain compounds and causes them to emit light of a lower energy, typically but not

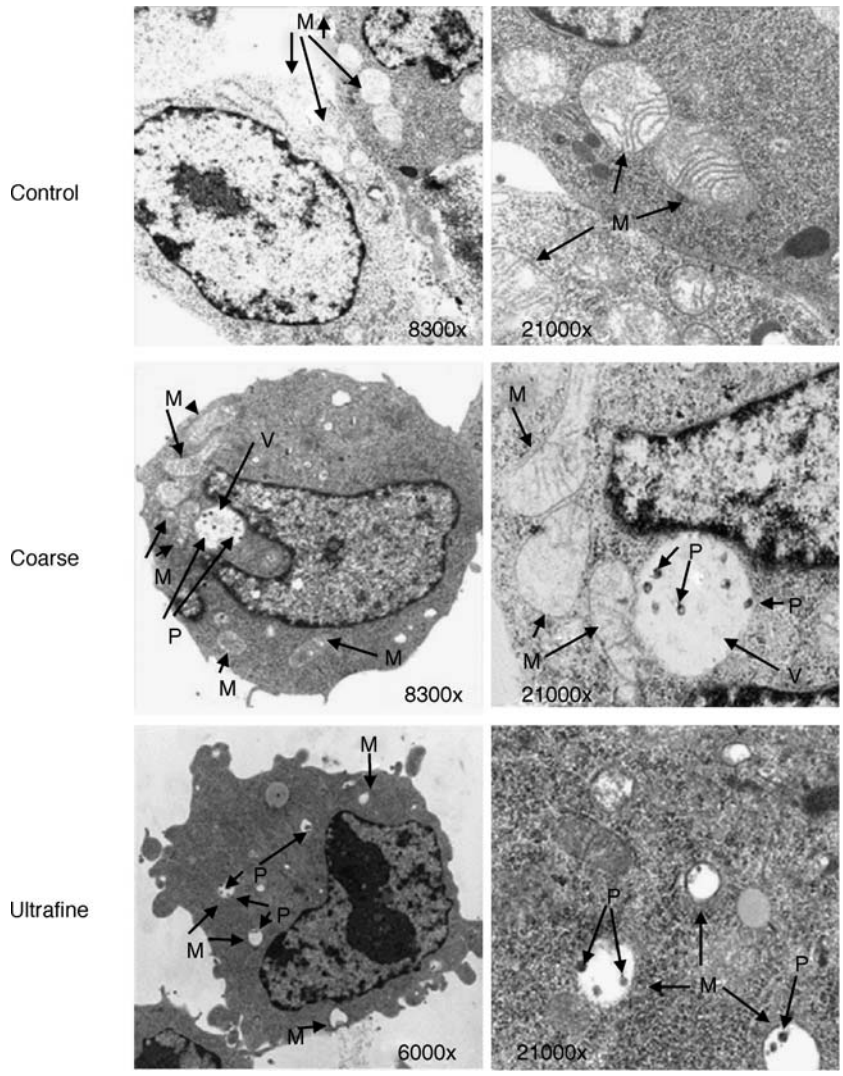

Figure 8. Electron microscopy (EM) showing select subcellular localization of ultrafine and coarse particles. Coarse (2.5–10 μm) and ultrafine (<0.15 μm). CAPs were collected in an aqueous medium in Claremont, CA, using the VACES. RAW264.7 cells were incubated with these particles for 16 h before fixation. EM was performed as previously described. While coarse CAPs are localized in large vacuoles and do not damage mitochondria, ultrafine particles often induce structural damage as demonstrated by the disappearance of cristae. In addition, ultrafine particles appear to lodge inside damaged mitochondria. M, mitochondria; P, particles; V, vacuoles. necessarily visible light. A complementary technique is absorption spectroscopy.

Fluorescence spectroscopy is useful in both the quantitative analysis of nanoparticle uptake and the qualitative analysis of nanoparticle subcellular localization. Using a flow cytometry technique is a typical approach for quantitative assessment of NM uptake. In addition, bulk fluorescence or confocal fluorescence fluoresecne are also used. Detection efficiency is strongly dependent on the fluorescence properties of the NMs.

Until now, the intense investigations of cellular uptake of NMs were mainly focused on drug/gene delivery, disease diagnosis, tumor cells tracking and recognition. In order to study cellular uptake of NMs *in vitro* or *in vivo*, the use of fluorescently

or radioactively labeled NMs is the most common experimental approach reported in the literature. Different nano-sized carriers, such as biodegradable polymeric micelles (Zhang and Feng, 2006; Win and Feng, 2005), liposomes (Bochot *et al*., 2002), surface-modified NMs (Gupta and Gupta, 2005; Xing *et al*., 2005; Illum and Davis, 1984), and solid lipid NMs (Muller, Mader and Gohla, 2000), have been developed to achieve the goal. To improve efficiency of cellular drug delivery, one strategy is to modify or conjugate a drug with a ligand that can be efficiently taken up by target cells via receptor-mediated endocytosis (Sonvico *et al*., 2005; Yang *et al*., 2005). Fluorescent labeling makes cellular uptake of NMs readily detectable by fluorescence microscopy or confocal laser scanning microscopy (CLSM). The extent of particle uptake can then be determined by flow cytometry, fluorometry, or quantitative extraction of the markers from the cells (Win and Feng, 2005; Davda and Labhasetwar, 2002; Azarmi *et al*., 2006). While these labeling approaches facilitate fluorescence quantitation, the conjugated dyes or groups may significantly change the physical and chemical properties of NMs, and even their uptake mechanism and efficiency. So this effect needs to be considered and controlled carefully during experiment design and carryout.

Cellular uptake of quantum dots (QDs), which is applied in cellular probing and imaging, has also attracted considerable studies. QDs are fluorescent semiconductor nanocrystals with unique optical properties such as high quantum yield, high molar extinction coefficients, narrow emission spectra, size-depending emission, and high photostability. QDs are emerging as an attractive alternative to organic fluorophores as fluorescent, nonisotopic labels (Gao *et al*., 2004; Osaki *et al.*, 2004; Zhang, So and Rao, 2006). In general, all the QDs and nanosize drug carriers are water-soluble to improve the cellular uptake and prevent aggregation. Lovric *et al*. (2005) studied the subcellular localization and toxicity of cadmium telluride (CdTe) QDs. Their research indicated that localization of red and green cationic CdTe QDs in PC12 and N9 cells were significantly dependent on QD size. Confocal microscopy was used to observe the QD localization in the nuclear vs. cytoplasmic compartments. Red QDs (5.2 ± 0.1 nm) were only localized throughout the cytoplasm of N9 cells within 1 h; in contrast, green QDs (2.2 ± 0.1 nm) were distributed mainly in the nuclear compartment within the same time (Figure 9). In addition, authors assumed there are several other factors which may also affect the distribution of green and red QDs except the particle size, including aggregation forms, aggregation size, aggregation stability, and complex formed with cell proteins. In 2006, Ron Hardman (Hardman, 2006) published a review paper about the toxicology of quantum dots.

5.1.3 ICP-MS

Inductively coupled plasma mass spectrometry (ICP-MS) is a type of mass spectrometry that is highly sensitive and capable of the determination of a range of metals and several non-metals at concentration levels of parts per billion (ppb). It is based on coupling together inductively coupled plasma as a method of producing ions (ionization) with a mass spectrometer as a method of separating and detecting the ions. ICP-MS is also capable of monitoring isotopic speciation for the ions of choice.

Gojova *et al*. (2007) studied the inflammation in vascular endothelial cells induced by metal oxide nanoparticles (Fe_2O_3, Y_2O_3, and ZnO). They used ICP-MS to measure the delivery of the metal oxide nanoparticles to the cell surface and the cellular uptake of nanoparticles. After the human aortic endothelial cells (HAECs) were exposed to nanoparticles for 4 hs, the cells were washed and detached. The cell pellet was resuspended in buffer and treated with concentrated HNO_3. After heating 3 hs at 80 °C to dissolve cell contents, the solution was diluted and analyzed using ICP-MS. The results clearly demonstrated that the amount of metal uptake correlated directly to the nanoparticle concentration in cell culture medium (Figure 10).

Using ICP-MS to study and quantitate the cellular uptake of NMs was also reported by Yang *et al*. (2005). The disadvantage of using ICP-MS to study cellular uptake is that the method requires large amount of cells (millions) to obtain the detectable metal concentrations.

5.1.4 Other Advanced Techniques for Cellular Uptake Study

Except for those techniques described above, other advanced techniques have recently been used to investigate the cellular uptake and distribution of NMs. Alexander G. Tkachenko etc. (Tkachenko *et al*., 2004) applied video-enhanced color differential interference contrast (VEDIC) microscopy and

TEM to study the ability of peptide-gold nanoparticle complexes to cross the cell membrane and reach the nucleus. Three kinds of cell lines were used: HeLa human cervical epithelium cells, 3T3/NIH murine fibroblastoma cells, and HepG2 human hepatocarcinoma cells. The results showed that particle uptake and nuclear translocation were strongly dependent on the surface-bound peptide sequence and cell types. Figure 11 demonstrates that the gold nanoparticles carrying peptide M2 gradually reached the cytoplasm and nucleus of HeLa cells after 1–3 h. Nanoparticles-peptide M3 complexes reached the nuclear membrane of HeLa cells after 2 h of incubation and after 3 h M3 nanoparticles were observed inside of the nucleus. M4 nanoparticles were also able to reach nucleus.

Transferrin-mediated gold nanoparticles were used as a prospective drug delivery vehicle for specific cellular uptake and targeted drug delivery (Yang *et al.*, 2005). With its high-resolution imaging

capability with a nondestructive approach, Atomic Force Microscopy (AFM) was used in this study to visualize the cellular uptake of transferrin-mediated gold nanoparticles on the surfaces of live cells. The AFM images (Figure 12) vividly showed the endocytosis during the process of internalization. This uptake process was also confirmed by authors using confocal scanning imaging experiments.

Additionally, two-photon luminescence (TPL) microscopy was used to study the cellular uptake of gold nanorods coated with cetyltrimethylammonium bromide (CTAB). The NMs were internalized by KB cells through a nonspecific uptake mechanism and then formed permanent aggregations within the cell (Huff *et al*., 2007).

In addition, measurement of the radioactivity of radiolabeled NMs was also used to study the cellular uptake of NMs (Block *et al*., 2004).

5.2 *In-Vitro* Toxicity Assessment

In vitro toxicity assessment of NMs is the vitally important tool for toxicity evaluation, biomaterials testing and environmental materials exposure testing, despite the results of *in vitro* and *in vivo* sometimes lacking consistency and explanation. In addition, reliable and comparable conclusions require corroborating the results from many different assays. The most commonly used *in vitro*

assessment techniques include the cell viability test and further mechanism studies. Viability based assays can be categorized into different proliferations: apoptosis or necrosis. The most important toxicity mechanisms of NMs are either oxidative stress or DNA damage. It should be noted that these assays may be closely related to each other, and comprehensive *in vitro* toxicity assessment and mechanism studies should rely on comprehensive assays. These techniques and their applications are introduced shortly below:

5.2.1 Cell Viability Assays

Cell viability assay provides a most important assessment method for toxicity of NMs. In general, the percentage of dead cells is directly proportional to the toxicity of NMs. Some widely used dye-based viability assays apply the differential inclusion, exclusion, or conversion of a dye, or a dye precursor which can only be enzymatically converted to detectable dye in living cells instead of dead cells. In this case, the toxicity can be evaluated by measuring the colorimetric or fluorescence signals. These methods include MTT, MTS, Alamar blue, Lactate Dehydrogenase (LDH), live/dead assay, neutral red, trypan blue, and so on.

The MTT (3-[4,5-dimethylthiazol-2-yl]-2,5-diphenyltetrazolium bromide) assay measures the metabolic activity of viable cells; it is based on the reduction of the tetrazolium salt MTT by viable cells. The reaction produces a water-insoluble formazan salt, which must be solubilized. The procedure is very simple: first culture the cells in a 96-well microplate and then incubate them with MTT solution for approximately 4 h. During this incubation period, viable cells convert MTT to a water insoluble formazan dye. Dissolve the

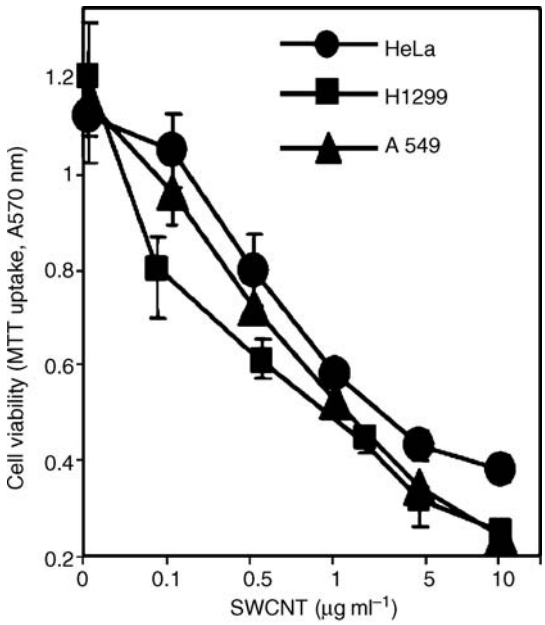

Figure 13. Effect of SWCNT particles on cell viability in different cells. HeLa, H1299, and A549 cells (5000/well in a 96-well plate) were incubated with different concentrations of SWCNT for 72 h. Cell viability was determined by MTT assay. Reproduced from Manna *et al.* (2005) © American Chemical Society.

formazan dye with the solubilization solution in the microplate and then quantitate the dye with an ELISA plate reader. The absorbance directly correlates with the cells numbers. For example, Manna *et al*. (2005) used MTT assay to assess the cytotoxicity of Single-Walled Carbon Nanotube (SWCNT) in different cells. Cell viability was determined after exposing the cells to various concentrations of SWCNT particles. The results clearly indicated that the cell viability was dose-dependent as low as 0.5 $\mu g\,ml^{-1}$ and the decrease of cell viability corresponded with increasing concentrations of SWCNT particles (Figure 13). However, the MTT assay may also have its disadvantage; for instance, reduction of MTT by cysteamine-coated quantum dots to formazan was observed by Khandare *et al*. (2006).

MTS assay is based on similar principles to the widely used MTT assay. The active component is a novel tetrazolium compound called MTS, which has a similar structure to MTT. In living cells, MTS is reduced to a colored formazan product. The amount of formazan product is directly proportional to the number of living cells; therefore, cell proliferation or death can be quantified by reading the plate at 490 nm. MTS is a kind of improved MTT assay with the advantage that the formazan product of MTS reduction is soluble in cell culture medium and does not require use of a Solubilization Solution. For example, Braydich-Stolle *et al*. (2005) studied the influence of soluble and nanoparticulate molybdenum species on germline stem cell mitochondrial function and viability (Figure 14).

Alamar blue is also called Resazurin (7-Hydroxy-3H-phenoxazin-3-one 10-oxide), which is a blue dye used mainly as an indicator used to assess proliferation and cell viability (Orosz *et al*., 2004). However, there is evidence, which indicates that high-density cultures or long incubation times may cause a secondary reduction of the Alamar blue dye to a non-fluorescent compound. Hence, all dye-based assays such as MTT, MTS, Alamar assay, and so on, require careful calibration to prevent potential interferences in the presence of NMs.

Lactate Dehydrogenase (LDH) is a cytoplasmic enzyme. Cytotoxicity of NMs may cause lipid peroxidation, which damages the cell membrane and disturbs the integrity of cellular membranes, leading to the leakage of LDH into the cell culture medium. Commercial LDH Kit is available in market. The procedure is mainly based on the method developed by Wacker, Ulmer and Vallee, 1956. Released LDH catalyzes the oxidation of lactate to pyruvate with simultaneous reduction of NAD+ to NADH. The rate of NAD+ reduction is measured as an increase in absorbance at 340 nm. The rate of NAD+ reduction is directly proportional to LDH activity in the cell medium. The LDH measurement in cell culture medium was also described in other studies using different methods (Sayes *et al*., 2005).

Live/dead assay is a quick and easy, two-color assay to assess cell viability/cytotoxicity. This assay identifies live vs. dead cells on the basis of membrane integrity and esterase activity by staining cells with Live/Dead reagent and measuring by fluorescence (Manna *et al*., 2005) (as shown in Figure 15).

Neutral Red uptake assay is another cell viability endpoint. Neutral Red (NR), a weak cationic dye, penetrates cellular membranes by non-diffusion and accumulates intercelluarly in lysosomes. This dye is endocytosed by only viable cells, dead cells do not (Huang, Khor and Lim, 2004).

Trypan blue exclusion test of cell viability is used to determine the number of viable cells. The principle is that live cells have intact cell membranes that exclude trypan blue dye, whereas dead cells don't. Therefore, the cells, which are blue are dead if observed by microscope (Gojova *et al*., 2007; Huang, Khor and Lim, 2004).

ATP assay has the main advantage of providing results quickly and requires fewer sample cells. The assay performs cell lysis and then the following reaction between the assay and ATP content of cells produces luminescence. The intensity of luminescence is then measured by a luminomeneter and can be translated into number of cells alive since the

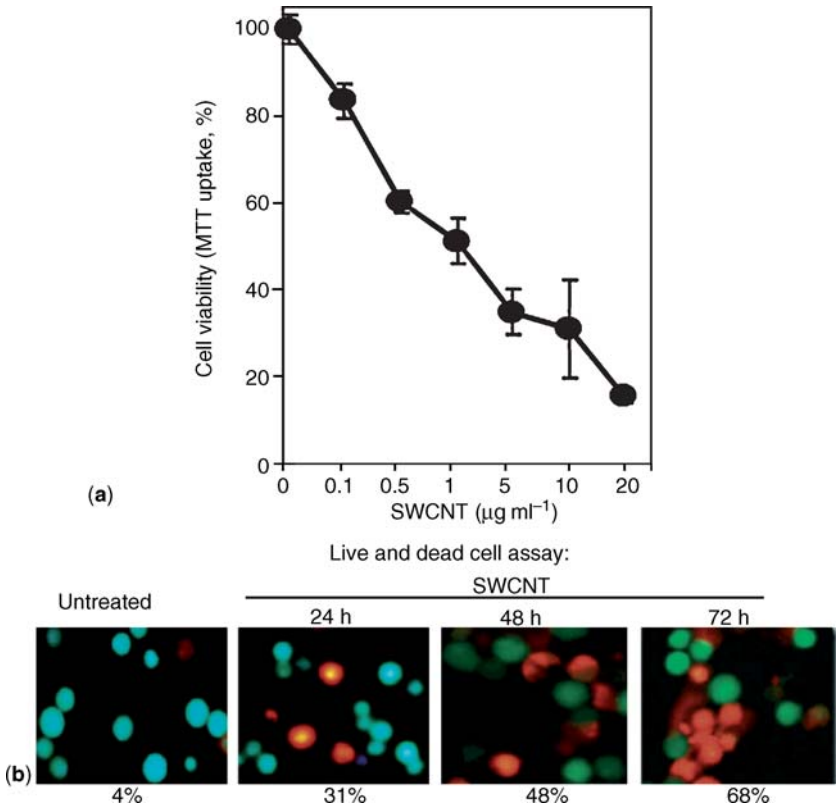

Figure 15. Effect of SWCNT particles on cell viability. HaCaT cells (5000/well in a 96-well plate) were incubated for 12 h and then treated with different concentrations of carbon nanotubes for 72 h. Cell viability was assayed by MTT dye uptake (A). Results are reported as percentage of cell viability and representatives from one of three independent experiments. (B) HaCaT cells were treated with 10 μg ml^{-1} SWCNT for different time intervals, and the dead cell (red color) numbers were counted. The percentage of dead cells is indicated below each photograph. Reproduced from Manna *et al.* (2005) © American Chemical Society.

luminescence intensity is proportional to the ATP content in the sample (Wilson *et al.*, 2002).

5.2.2 Oxidative Stress

As we describe in Section 4, oxidative stress is caused by an imbalance between the production of a reactive species and a biological protection system, which has the ability to eliminate the harmful reactive species. Oxidative stress has been found to be implicated in lots of pathogenesis of diseases such as aging, atherosclerosis, carcinogenesis, and acute and chronic inflammatory disorders (Kehrer and Lund, 1994). Reactive species are generally categorized as reactive oxygen species (ROS) such as superoxide (O_2^-), hydroxyl radical ($HO^\bullet$), peroxy radical ($ROO^\bullet$), and hydrogen peroxide (H_2O_2); or reactive nitrogen species (RNS) such as nitric oxide ($NO^\bullet$), peroxynitrite anion ($ONOO^-$), peroxynitrous acid (ONOOH), and nitrosoperoxycarbonate anion ($ONOOCO_2^-$). Over-production of ROS and RNS would overwhelm the protection system and the capacity of the reducing environment, therefore causing toxic effects within cells. Disturbances in this normal reducing environment can cause toxic effects through the production of peroxides and free radicals that damage all components of the cell, including damage to proteins, lipids, and DNA. The extent of oxidative stress is dependent on the ratio of the amount of ROS/RNS to the cellular reduction capacity. Moderate oxidative stress may cause apoptosis and severe oxidative stress may cause cell death. The detailed mechanisms by which ROS are generated by NMs are still under investigation. However, there is evidence that crystalline silica can induce ROS, such as hydroxyl free radical,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

at the particle surface (Lenz *et al*., 1992; Carter and Driscoll, 2001; Porter *et al*., 2006; Dalal *et al*., 1990). Enhanced production of HO$^{\bullet}$ by adding H_2O_2 to trace iron(III)-containing crystalline silica suggests that a Fenton reaction occurred on the surface of silica particle (Fubini and Hubbard, 2003). The authors suspected that the relatively high metal impurities in crystalline silica may play a key role to yield HO$^{\bullet}$ radicals via the Fenton reaction ($Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH^- + HO^{\bullet}$). On the contrary, some studies indicated that SiO_2 NPs and Cerium oxide containing ultra low levels of metal impurities could induce HO$^{\bullet}$ radicals in the absence of trace metal (Lin *et al*., 2006; Lin *et al*., 2006). Fenoglio *et al*. (2001) also demonstrated that pure quartz and iron-deprived quartz dusts can generate HO$^{\bullet}$ in the absence of trace iron.

Table 7 lists the typical ROS species. The activities of these species are significantly different. Typically, OH$^{\bullet}$ free radical is the most active species. Other species such as superoxide and organic hydroperoxide are much less reactive.

The effects of ROS are controlled by an elaborate antioxidant defense system (Figure 16) (Li *et al*., 2003b). These antioxidants include proteins such as superoxide dismutase (SOD), catalase, glutathione peroxidase (GPx), glutathione reductase (GR), thiol-specific antioxidants, and low molecular weight scavengers such as GSH and α-tocopherol.

Table 7. Ttypical ROS species.

ROS/RNS	Description
$^{\bullet}O_2^-$, superoxide anion	One-electron reduction state of O_2, formed in many autoxidation reactions and by the electron transport chain. Relatively unactive.
H_2O_2, hydrogen peroxide	Two-electron reduction state, formed by dismutation of $^{\bullet}O_2^-$ or by direct reduction of O_2. Lipid soluble and thus able to diffuse across membranes.
$^{\bullet}$OH, hydroxyl radical	Three-electron reduction state, formed by Fenton reaction. The most reactive species to attach cellular components.
ROOH, organic hydroperoxide	Formed by radical reactions with cellular components such as lipids and and nucleobases.
RO$^{\bullet}$, alkoxy and ROO$^{\bullet}$, peroxy radicals	Produced in the presence of oxygen by radical addition to double bonds or hydrogen abstraction.

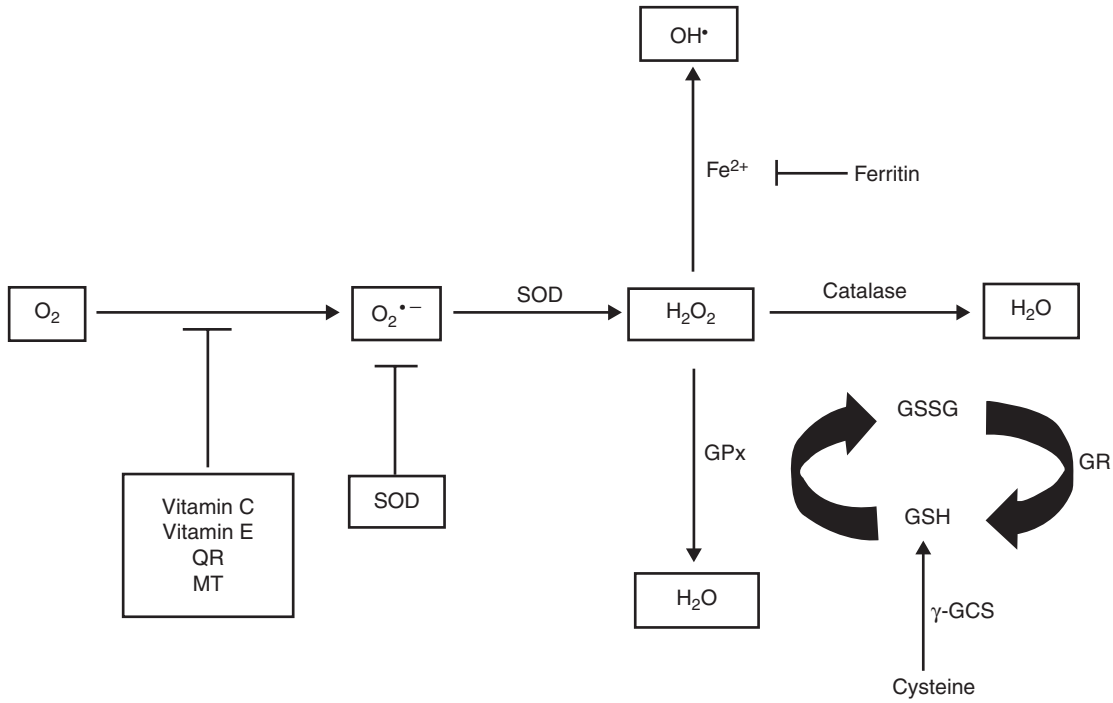

Figure 16. Cellular antioxidant defense mechanisms. The cellular antioxidant defense system consists of antioxidant enzymes, metal binding proteins, and low molecular weight antioxidants. Reproduced with from permission from Li *et al*. (2003b) © Elsevier.

The functions of these antioxidants are to convert high active ROS to less active species and therefore protect the cellular compartments.

Intracellular ROS Measurement

The production of intracellular reactive oxygen species (ROS) was measured using 2′, 7′-dichlorofluorescin diacetate (DCFH-DA) (Block *et al*., 2004; Wang and Joseph, 1999). DCFH-DA passively enters the cell where it reacts with ROS to form the highly fluorescent compound dichlorofluorescein (DCF). Briefly, 10 mM DCFH-DA stock solution (in methanol) is diluted 500-fold in HBSS without serum or other additives to yield a 20 μM working solution. The cells are washed twice with HBSS and then incubated with DCFH-DA working solution for 1 h in a dark environment (37 °C incubator), following by treatment with particle suspension for a certain time. After exposure, the fluorescence is determined at 485 nm excitation and 520 nm emission using a microplate reader.

To prove the presence of free radicals in cell culture medium or solution induced by NMs, electron spin resonance (ESR) is a quick and reliable method. Basically, the sample is dissolved in DI-water and mixed with spin trap reagent DMPO (5,5-dimethyl-1-pyrroline N-oxide) for a certain period. Then the sample is excited with a solar simulator and the ESR signal is recorded. The presence of free radicals would show a significant increase in signal compared to the control. Figure 17 is a typical ESR figure indicating the free radical induced by CdSe/ZnS quantum dots.

The chemiluminescence of luminol can be used to quantitatively measure the presence of reactive species ($\mathbf{^{\cdot}O_2^-}$, $\mathbf{^{\cdot}OH}$) in aqueous nanoparticle solutions (Arnhold *et al*., 1991). In this method, hydrogen peroxide amplifies the chemiluminescence in the oxidation of luminol by sodium hypochlorite. Although this method can't quantify the reactive species, it is a simple and reliable method to evaluate the level of oxidative species.

Some studies measured the RS generations of NMs by determination of their photocatalytic activity. The samples were illuminated by UV light and their capability to induce RS was measured by the degradation of an azo dye. The degradation rate correlated to the rate constant for RS generation in aqueous solution (Sayes *et al*., 2006) (Figure 18).

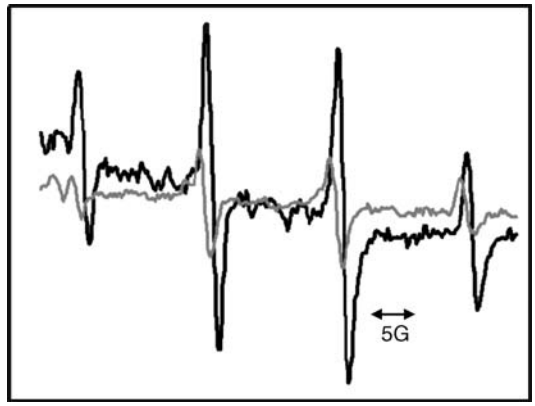

Figure 17. ESR spectrum of water-soluble CdSe/ZnS quantum dots and a spin trap (DMPO) confirming the presence of free radicals in solution. The dark line spectrum represents an illuminated sample; the grey line spectrum represents a sample in the dark. Reproduced from Green and Howmanl (2005) © Royal Society of Chemistry.

GSH Measurement

As one of the most important biomarkers of oxidative stress, GSH (γ-Glu-Cys-Gly) exists abundantly and is widely distributed in living cells, acting as an intracellular antioxidant that is involved in the detoxification of xenobiotics and scavenges free radicals, thereby protecting organisms from the

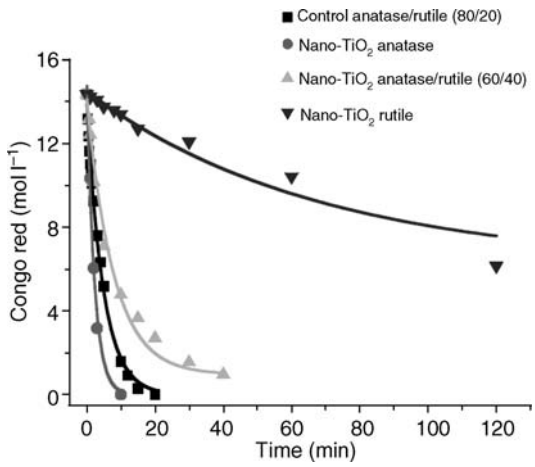

Figure 18. Photodegradation of aqueous Congo red (10 mg l^{-1}, 14 μmol l^{-1}) in the presence of various nano-TiO_2 catalysts (1 g l^{-1}). Based on this plot, the per gram efficiencies of the TiO_2 powders increased in the order nano-TiO_2 rutile particles < nano-TiO_2 anatase/rutile particles < control anatase/rutile < nano-TiO_2 anatase particles. General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

oxidative damage of DNA and lipids. Two GSH molecules yield one GSSG molecules during oxidative stress. Therefore, quantitative measurement of the ratio of GSH and its disulfide oxidative product GSSG provides a very reliable assessment of oxidative stress (Winters *et al*., 1995). The determination methods for the reduced (GSH) and oxidized (GSSG) include using ion-pairing reverse-phase HPLC and a coulometric electrochemical detector (Fernandez-Urrusuno *et al*., 1997) or spectrometric method (Sayes *et al*., 2005), and so on.

MDA Measurement

Malondialdehyde (MDA) is a typical marker for measuring the degree of lipid peroxidation because MDA is the end product from peroxidation of polyunsaturated fatty acids when cells are exposed to NMs. MDA levels increase during oxidative stress due to free radical attacks on cell membrane lipids. The cellular concentration of malondialdehyde (MDA) may be determined by HPLC method (Draper *et al*., 1993; Kumari *et al*., 1989) or by spectrometric method (Sayes *et al*., 2005).

α-Tocopherol Measurement

α-tocopherol is also a kind of antioxidant, and its presence in a cell membrane has been proven to represent the major defense system against peroxidation of membrane lipids, which are highly susceptible to peroxidative degradation. One typical method to extract cellular α-tocopherol was described by Lang, Gohil and Packer (1986).

Other Oxidative Stress Biomarker

Other oxidative stress biomarkers include superoxide dismutase (SOD), glutathione peroxidase (GPx), and Catalase (CT), and so on (Fernandez-Urrusuno *et al*., 1997; Wang *et al*., 2005). SOD is a class of enzymes that catalyzes the dismutation of superoxide into oxygen and hydrogen peroxide. Therefore, SOD is an important antioxidant defense in cellular system. GPx is the general name of an enzyme family with peroxidase activity whose main biological role is to protect the organism from oxidative damage. The biochemical function of GPx is to reduce lipid hydroperoxides to their corresponding alcohols and to reduce free hydrogen peroxide to water. Catalase is a common enzyme which catalyzes the decomposition of hydrogen peroxide to water and oxygen.

5.2.3 DNA Damage Assay

If NMs are able to enter into the body via inhalation, dermal routes, or oral uptake, NMs may penetrate the cell membranes and subsequently enter into different cellular compartments such as mitochondria, nuclei, and so on, via a number of mechanisms. Within the cellular compartments, NMs can cause DNA damage via direct and indirect mechanisms. If NMs have direct interaction with the DNA molecules, they may cause physical DNA damage. There are numerous studies indicating such physical DNA damage can be induced by NMs like TiO_2, Silica, Silver, and quantum dots. Alternatively, NMs may cause DNA damage via indirect mechanisms where the NMs have no physical interaction with the genetic molecules; instead, they induce some cellular responses such as oxidative stress and inflammation, which cause the subsequent DNA damage.

Oxidative stress elevates the cellular ROS. The highly reactive ROS can induce DNA damage by DNA breakage, base modification (e.g., formation of 8-hydroxydeoxyguanosine adducts) and DNA cross-links. Oxidative DNA damage induced by NMs has been shown by many studies as measured by the comet assay and micronucleus assay. Inflammation is a response of a tissue to injury, often injury caused by invading parasites. During inflammation, large amounts of factors such as cytokines (such as interleukins-1, IL-1) and tumor necrosis factors – alpha (TNF-α), RNS and ROS are quickly released. All the cells involved in inflammation have receptors for TNF-α, and are activated by it to synthesize more on their own. IL-1 is one of the first cytokines ever described, which causes fever, controls lymphocytes, increases the amount of bone marrow, and so on. The release of these factors quickly amplifies the response and subsequently helps promote healing. However, these factors can promote DNA damage in the form of DNA fragmentation, mutation, and formation of DNA adducts like 8-hydroxydeoxyguanosine (8-OHdG). In addition, these factors may also inhibit DNA repair and induce aberrant gene expression. To date, there are many studies demonstrating that nanomaterials can induce significant elevated inflammatory responses. Studies have shown that Carbon nanostructure and particulate air pollution (PM10) induce TNF-alpha and oxidative stress *in vivo* and *in vitro* (Manna *et al*., 2005; Li *et al*., 1996). Sayes *et al*. (2006) used human IL-8 enzyme immunometric assay kit

to evaluate the production of the inflammation mediator IL-8 induced by varying concentrations of nano-TiO_2 anatase and rutile particles. The results indicate that nano-TiO2 anatase particles significantly induce the production of IL-8 in both HDF and A549 cells (Figure 19).

To determine the DNA damage, many assays have been developed and applied to study the genotoxicity of NMs, including Comet Assay, Ames test, Chromosome aberration test, Cytokinesis-blocked micronucleus assay, HPRT forward mutation assay, g-H2AX staining, and 8-hydroxydeoxyguanosine DNA adducts.

Comet Assay

Comet Assay is also known as The Single Cell Gel Electrophoresis assay (SCGE). Comet Assay is a quick, universal, sensitive technique for the measurement of DNA single- and double-strand breaks at the individual cell level. Since it was first described by Singh *et al*. (1988), this assay has been used widely as a standard method in toxicity study of NMs. Firstly, the individual cells are suspended in a low-melting-point agarose. Then, the cells are lysed in neutral or alkaline (pH > 13) conditions and the DNA molecules are electrophoresed. During the electrophoresis, intact DNA molecules migrate slower than DNA fragments, resulting in a comet shape. After DNA molecules are stained with common ethidium bromide or other dyes, the fluorescence intensity of the comet tail, which is proportional to the extent of DNA damage, is analyzed. Lin *et al*. (2009) studied the Oxidative DNA damage caused by ZnO particles with micro- sized and nano- sized particles. The data indicated that significant DNA damage was induced by 10–14 $\mu g\ ml^{-1}$ of ZnO suspension after 24 h incubation with human lung epithelial cells (Figure 20).

Ames Test

Ames test is to assess the mutagenic potential of chemical reagents. The chemical might be regarded as a carcinogen if the Ames test result is positive. This method was first described by Ames *et al*. (1972). The test uses several strains of the bacterium Salmonella typhimurium, which carries different mutations in genes involved in histidine synthesis, so they need histidine to grow. The variable being tested is the mutagen's ability to cause a reversion to growth on a histidine-free medium. The bacteria are spread on an agar plate with a small amount of histidine or even without histidine. Only bacteria that have undergone reverse mutations resulting in the histidine synthesis genes will gain the required histidine and survive and then grow. The plate is generally incubated for 48 hs. The measured numbers of colonies would be proportional to the mutagenicity of the potential carcinogen.

Because Salmonella is a prokaryote instead of a eukaryote, the mutagenicity of a chemical reagent may not be applicable for eukaryotic entites like humans. An improved assay using eukaryotic cells has been developed. Another disadvantage of Ames Test is that under some conditions, false

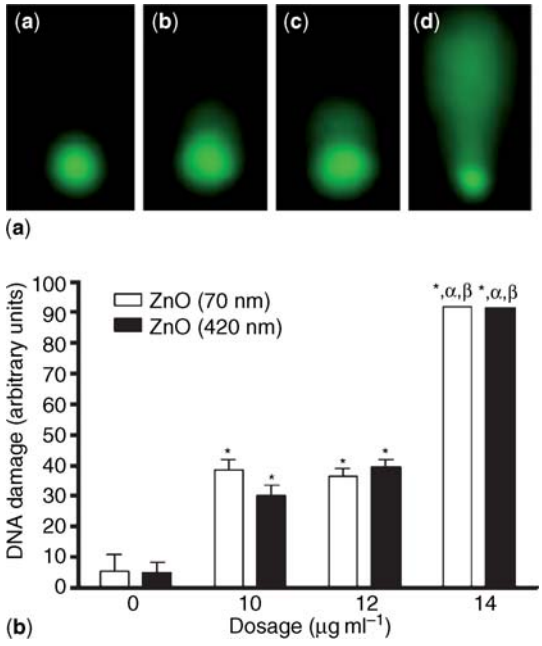

Figure 20. (a) The representative fluorescence images of nuclei treated in the comet assay after 24 h exposure to (a) 0 μg ml^{-1}, (b) 10 μg ml^{-1}, (c) 12 μg ml^{-1}, or (d) 14 μg ml^{-1} of 70 nm ZnO nanoparticles. (b) DNA damage was observed at all dosages. At the same dosage, there was no significant difference in DNA damage between 70 and 420 nm ZnO particles. Values are mean ± SD from three independent experiments. Reproduced from Lin *et al.* (2009) © Springer.

positive results may occur and require additional attention.

Chromosome Aberration Test

This assay includes numerical aberration and structural aberration. Numerical aberration means an abnormal number of chromosomes, which generally occurs when an individual is missing either a chromosome from a pair or has more than two chromosomes of a pair. Structural aberration can occur in several forms: deletions, duplications, translocations, inversions, and isochromosomes.

This test can be performed *in vitro* or *in vivo*. In the *in vitro* test mode, cultured mammalian cells are treated with the testing chemicals for a period of time, then the cells are exposed to a chemical that stops the cell cycle just before the replicated chromosomes are separated into two daughter nuclei. Next step is to stain the chromosome with the dye Giemsa and analyze if the aberration occurs by using microscopy. In the *in vivo* mode, generally, rodents are selected as the targets and are treated with the chemical. Similar to the *in vitro* mode, after the metaphase-arresting period, the bone marrow cells are harvested, stained, and analyzed with microscopy. The assay is a popular method for evaluation of potential carcinogens. However, this assay requires tedious preparation and a skilled person.

Cytokinesis-Blocked Micronucleus (CBMN) Assay

The CBMN assay in human lymphocytes is one of the most commonly used methods for measuring DNA damage. This is an easy, rapid, and sensitive method. CBMN assay measures micronuclei instead of chromosome aberrations because it has several advantages such as speed, ease, reliability, and no metaphase cells are required. Cells that have undergone cell division in the existence of a chemical compound can be easily identified using cytochalasin B. The purpose of cytochalasin B is to block the cell cycle at cytokinesis and make the cell cycle in binucleated cells. If the chemical compound induces DNA fragmentation or loss, then the damaged DNA lags behind during DNA segregation and is not included in either of the resulting daughter nuclei. Instead, they are enclosed within a micronucleus and their frequency in binucleated cells indicates the genotoxicity of the chemical compound (Figure 21). A detailed discussion of this technique and its applications have been described in several publications (Fenech, 1993; Fenech, 1993; El-Zein *et al*., 2006).

HPRT Forward Mutation Assay

The HPRT assay is an *in-vitro* mammalian cell gene mutation test, which is used to evaluate the potential of a chemical, formulation or extract to induce mutations at the HPRT locus of CHO cells. This test system is very suitable for evaluating initially the genotoxicity of a chemical compound (DeMarini *et al*., 1989; Albertini, 2001).

V79 Chinese hamster cells have one functional copy of the gene, which codes for the HPRT enzyme. HPRT enzyme activity is crucial for DNA synthesis. The nucleoside analog named 6-thioguanine (6-TG) is used for treatment. Cells without a mutation are poisoned by 6-TG, while only mutant cells can survive and form colonies. The cells that form colonies are assumed to be mutant cells, which are the result of a spontaneous mutation or an induced mutation by a chemical compound.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

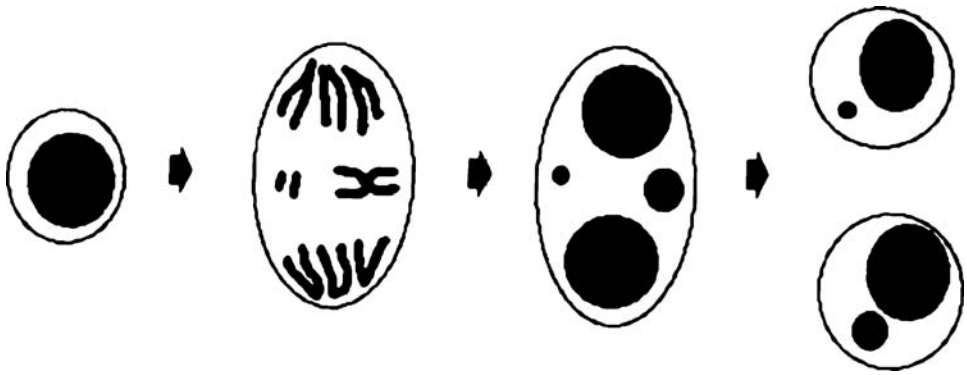

Figure 21. Micronucleus in a dividing nucleated cell. Micronuclei originate from either lagging chromosomes or chromosome fragments at anaphase. Micronuclei are readily identified because they are morphologically identical to but smaller than the main nuclei. A nondividing cell is unable to express its chromosome damage as micronuclei. Cells that have completed one nuclear division can be accumulated and identified as binucleate cells by adding cytochalsin-B, a cytokinesis blocking agent (3,4). Micronuclei are then scored in binucleated cells only. Reproduced from Fenech *et al.* (1993), National Institute of Environmental Health Sciences.

Cells deficient in HPRT are selected by resistance to 6-thioguanine (TG). These cells are exposed to the test substance, both with and without metabolic activation, for 2–4 h or 24–72 h and subcultured to determine cytotoxicity and to allow phenotypic expression prior to mutant selection. Cytotoxicity is determined by measuring the relative cloning efficiency (survival) of the cultures after the treatment period. The treated cultures are maintained in growth medium for three days, characteristic of each selected locus and type, to allow near optimal phenotypic expression of induced mutations. Mutant frequency is determined by seeding known numbers of cells in medium containing the selective agent to detect mutant cells, and in medium without selective agent to determine the cloning efficiency (viability). After a suitable incubation time (ca. 10 days), colonies are stained and counted. The mutant frequency is derived from the number of mutant colonies in selective medium and the number of colonies in non-selective medium.

A result is classified as positive if there is a concentration-related or reproducible increase in mutant frequency observed. Positive results for the HPRT-mutation assay indicate that the test substance induces gene mutations in the cultured cells used. A positive and reproducible concentration-response is most meaningful. There is no requirement for verification of a clear positive response. Equivocal results are clarified by further testing using modified experimental conditions. Negative results need to be confirmed on a case-by-case basis.

8-Hydroxydeoxyguanosine DNA Adducts

Active ROS generated during oxidative stress may attack DNA molecules and generate 8-hydroxydeoxyguanosine (8-OHdG, known as a DNA adduct) due to the modification of the guanine base. Therefore, measurement of this DNA adduct can be used as an important marker for oxidative DNA damage (Loft *et al*., 1992). Figure 22 showed the significantly elevated level of 8-OH-dG after being exposed to C_{60} fullerene (Sera, Tokiwa and Miyata, 1996). So far, approaches developed for direct measurement of 8-OhdG have been developed. The most sensitive and widely used methods are HLPC method and Mass Spectrometry method (Sera, Tokiwa and Miyata, 1996). Other methods like commercial ELISA kit, DNA dot blots, capillary electrophoresis with electrochemical detector (Weiss and Lunte, 2000), or immunocytochemistry staining (Shi *et al*., 2003) have also been reported. Figure 23 shows representative pictures of immunocytochemistry staining in which coarse and fine Particulate Matter induced similar but significant 8-OHdG compared with the control. A unique integrated microfluidic device for 8-OH-dG measure was described by (Dawoud, Kawaguchi and Jankowiak, 2007).

As a very useful marker for oxidative DNA damage, 8-OHdG was measured in numerous toxicity study of NMs such as Titanium Oxide NMs (Bhattacharya *et al*., 2009; Trouiller *et al*., 2009), air pollution particles (Prahalad *et al*., 2001), and fine particulate matter (Shi *et al*., 2003), and so on.

5.2.4 Gene Expression

Gene expression is the process by which information from a gene is used in the synthesis of a functional gene product: mostly protein. The expression of a wide variety of genes has been shown to be sensitive to ROS at the transcriptional level. Among the genes known to be activated by oxidative stress are those for MAP kinase signaling, DNA damage, cAMP/Ca^{2+} signaling, NF-kB signaling, PI3-AKT signaling, and apoptosis (Foncea *et al.*, 2000; Kharasch *et al.*, 2006). NF-kB is a transcriptional regulator that controls expression of a wide variety of cellular and viral genes. These genes include many proinflammatory molecules such as cytokines IL2, IL6, IL8, TNF, cell adhesion molecules such as ICAM-1 and E-selectin, and so on. The gene expression is dependent on cell lines and NF-kB plays a major role in regulation

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

of these genes and contributes significant control over inflammation.

In addition, oxidative stress activates specific signaling pathways such as mitogen activated protein kinase (MAPK). Treatment cells with NMs may induce profound gene expression changes. For example, Ding *et al.* (2005) used whole genome expression array analysis to study the gene expression change induced by multiwall carbon nano-onions (MWCNO) and multiwall carbon nanotubes (MWCNT) on human skin fibroblast cells. The data indicated that the differences in gene expression profiles were highly related to these NMs and their dosage levels. Treatment of the cells with a higher dose of carbon particles caused more gene expression changes than the lower dose treatment. However, the responses were not completely dose dependent. Moreover, MWCNO and MWCNT exposure induced gene expression involved in cellular activities such as cellular transport, metabolism, cell cycle regulation, and stress response. Figure 24 demonstrates the statistically significant gene expression changes in human skin fibroblasts induced by carbon NMs and the Table 8 gives the most significantly changed gene categories after treatment HSF42 cells with carbon NMs.

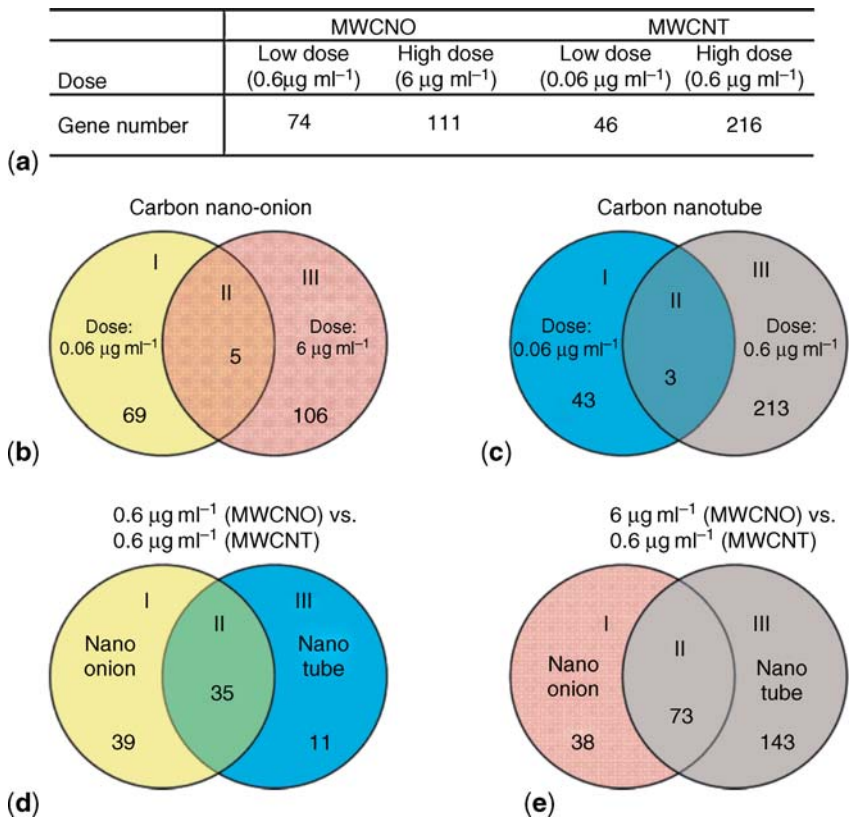

Figure 24. (a) Numbers of genes whose expression levels changed after treatment with carbon nanomaterials at cytotoxic doses. (b-e) Venn diagrams comparing numbers of genes that showed expression changes. Each Venn diagram is divided into three areas and labeled as I, II, and III. Area II is the overlapping area of two circles, representing commonly changed genes in both conditions. Area I and III represent genes that changed only in the condition specified in the circle. Bioconductor software was used to perform significance analysis to determine the difference between expression levels in treated sample, and the control sample possesses statistical significance. The empirical Bayesian model was used with Bonferroni's multitest correction. The cutoff of *p*-values produced through the analysis was determined by at least 10 times less than the *p*-value of the smallest *p*-value of control probe sets on the chip. (b) Comparing different doses for the nano-onions. (c) Comparing different doses for the nanotubes. (d) Comparing different particles at low doses (0.6 $\mu g\,ml^{-1}$ for MWCNO and 0.06 $\mu g\,ml^{-1}$ for MWCNT). [a]The categories are generated by the GoMiner program (Materials and Methods, Supporting Information), using *p*-values as the evaluation criteria of statistically significant changes, for each category. The *p*-value was calculated by conducting a two-sided Fisher's exact test, which reflects the statistical significance for that category being enriched in changed genes. The *p*-values were used to sort categories to identify those gene functional groups that have responded the most after treatments.

6 *IN VITRO* TOXICITY VS. *IN VIVO* TOXICITY

In vitro (Latin: within the glass) refers to an artificial environment outside the living organism. The *in vitro* toxicity study of nanomaterials is to utilize appropriate cell lines to evaluate the toxicity of nanomaterials (cytotoxicity). *In vitro* toxicological assessment is a very important tool for nanotoxicity study. Compared to *in vivo* studies, the advantages of *in vitro* studies include being simpler, easier, faster, lower cost, better experimental control, and significantly minimizing ethical concerns by only using cells. However, *in vitro* study generally applies much higher dosage level and shorter exposure time than *in vivo*, thus it is hard to predict the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

in vivo toxicity based on the results from *in vitro* experiments.

In addition, the test conditions of *in vitro* may not correspond to the conditions inside the organism. This may lead to results that do not correspond to the situation that arises in a living organism. In *in vitro* toxicity study, the liquid cell culture medium contains various components like inorganic salts, amino acids, and proteins, which is the major supplement in serum. The surface physicochemistry of nanomaterials may be changed upon addition into cell culture medium. In fact, several research groups have studied the adsorption of proteins and other molecules on nanomaterial surface and their potential effects on biological activity. Dutta *et al*. (2007) investigated the importance of proteins adsorbed onto the surface of two kinds of nanomaterials: single-walled carbon nanotubes (SWCNTs) and amorphous silica. Their date demonstrated the important role of adsorbed proteins for toxicity change of SWCNTs and nano-sized amorphous silica. Horie *et al*. (2009) studied the influence of adsorption by metal oxide nanoparticles (NiO, ZnO, TiO_2, CeO_2, SiO_2, and Fe_2O_3) on the cell viability *in vitro* and proved the adsorption ability of metal oxide nanoparticles is an important factor for the estimation of cytotoxicity *in vitro* for low-toxicity materials. It should be noted that the absorption by nanomaterials and subsequent toxicity changes may occur in *in vivo* study also so it may be necessary to examine the surface characteristics of nanoparticles that induce a biological response *in vivo*.

Another kind of study for nanotoxicity is to study the impact of nanomaterial exposure within intact living organisms. *In vivo* (Latin for "within the living") refers to using a whole, living organism as opposed to a partial or dead organism, or an *in vitro* controlled environment. Animal testing and clinical trials are two forms of *in vivo* research.

In vivo testing is often employed over *in vitro* because it is better suited for observing the overall effects of an experiment on a living subject. *In vivo* studies of nanomaterials allow investigating the long-term effects, distribution in tissues, retention, and excretion. Therefore, these types of *in vivo* studies provide more relevant information regarding the nanotoxicity in human beings, which is not available through *in vitro* study. These *in vivo* studies are typically undertaken in mice (Wu *et al*., 2009; Kwon *et al*., 2009; Park *et al*., 2009) or rats (Kobayashi *et al*., 2009; Sarkozi *et al*., 2009; Liang *et al*., 2009). Because *in vivo* studies use and sacrifice animals, they have ethical considerations.

The assessment techniques of *in vitro* and *in vivo* studies are also different. The most commonly used *in vitro* assessment is generally either to evaluate viability (proliferation, apoptosis, or necrosis) and/or to study toxicity mechanism (oxidative stress, oxidative DNA damage). However, typically, *in vivo* studies investigate serum/hematological changes, tissue morphology changes, or histology change.

Sayes, Reed and Warheit (2007) designed and studied the methodology to assess the capacity of *in vitro* screening in order to predict *in vivo* toxicity of five fine or nanoscale particle types (carbonyl iron, crystalline silica, precipitated amorphous silica, nano-sized ZnO, and fine-sized ZnO) in rats. For the *in vitro* experiment part, three different cell lines such as rat L2 lung epithelial cells, primary alveolar macrophages, and AM-L2 lung epithelial cell cultures were exposed to these five particles. The following end points were measured: mitochondrial activity (MTT assay), LDH release, and production of MIP-2, TNF-α and IL-6. In the *in vivo* experiment part, after the rats were exposed to these particles by intratracheal instillation, the pulmonary lavage and LDH release were measured. For the evaluation of relevant biomarkers, the authors selected inflammation and cytotoxicity indices as the end points for comparison of *in vitro* and *in vivo* studies. The authors found that *in vitro* and *in vivo* results demonstrated only little correlation. It may be partially due to the different experimental conditions such as cell line types, exposure dosage and time. However, the results solidly demonstrated the limitation of *in vitro* experiments to predict the *in vivo* results. Figure 25 shows the experiment scheme.

7 *IN VIVO* TOXICITY OF NANOMATERIALS

To completely assess and understand the potential adverse effects of nanomaterials in a human being's body, sufficient information on absorption, distribution, metabolism, and excretion (ADME) of the nanoparticles in animal models is absolutely necessary. In addition, newly developed nanomaterials have demonstrated substantial biomedical significance for pharmacology and therapeutics. Their unique characteristics make them very useful in drug discovery, biomarker discovery, drug delivery,

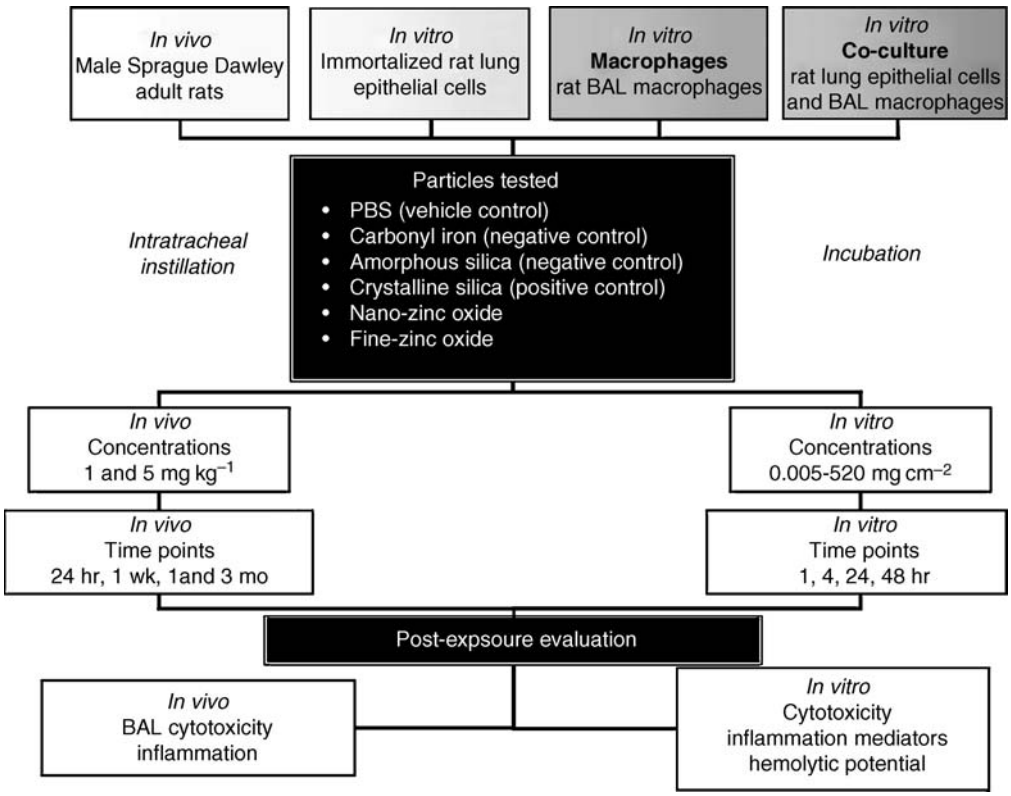

Figure 25. Experimental design. The design of the *in vivo* and *in vitro* experiments. Test systems were exposed to CI, CS (Min-U-Sil 5), AS, NZO, and FZO particles. For each experiment, both dose-response and time-response relationships were established (Sayes, Reed and Warheit, 2007). Reproduced from Ding *et al.* (2005) © American Chemical Society.

and molecular diagnostics. However, development of these novel nanomaterials must proceed in tandem with assessment of their potential side effects to human beings and environments.

Figure 26 shows the ADME scheme of nanomaterials in the body. With the dramatic increase in manufacture and application of nanomaterials, human exposure to nanomaterials is also increasing. Nanomaterials may enter into the human body via inhalatory exposure, oral exposure, dermal exposure and medical intervention. The respiratory system, blood, central nervous system (CNS), gastrointestinal (GI) tract and skin could be potentially targeted by nanomaterials.

7.1 *In Vivo* Toxicity Assessment

Although the assessment technique in *in vivo* has some similarities as that of *in vitro*, such as the measurement of biomarkers (Glutathione, LDH, etc.), *in vivo* nanomaterial toxicity studies typically focus on changes in tissue morphology and changes in blood serum chemistry by using histology.

7.1.1 Histology

Histology is an essential tool to study the *in vivo* toxicity of nanomaterials by observing the morphological changes. It is performed by examining a thin slice (section) of tissue under a light microscopy or electron microscope. The ability to visualize or differentially identify microscopic structures is frequently enhanced through the use of histological stains. Figure 27 demonstrates the morphological change of lung tissue from rats after exposed to $3\,\mathrm{mg\,kg^{-1}}$ of particles for three months postinstillation (Sayes, Reed and Warheit, 2007).

7.1.2 Bronchoalveolar Lavage (BAL) Study

BAL study has gained widespread acceptance as a minimally invasive method that provides important information about immunologic, inflammatory, and infectious processes taking place at the alveolar

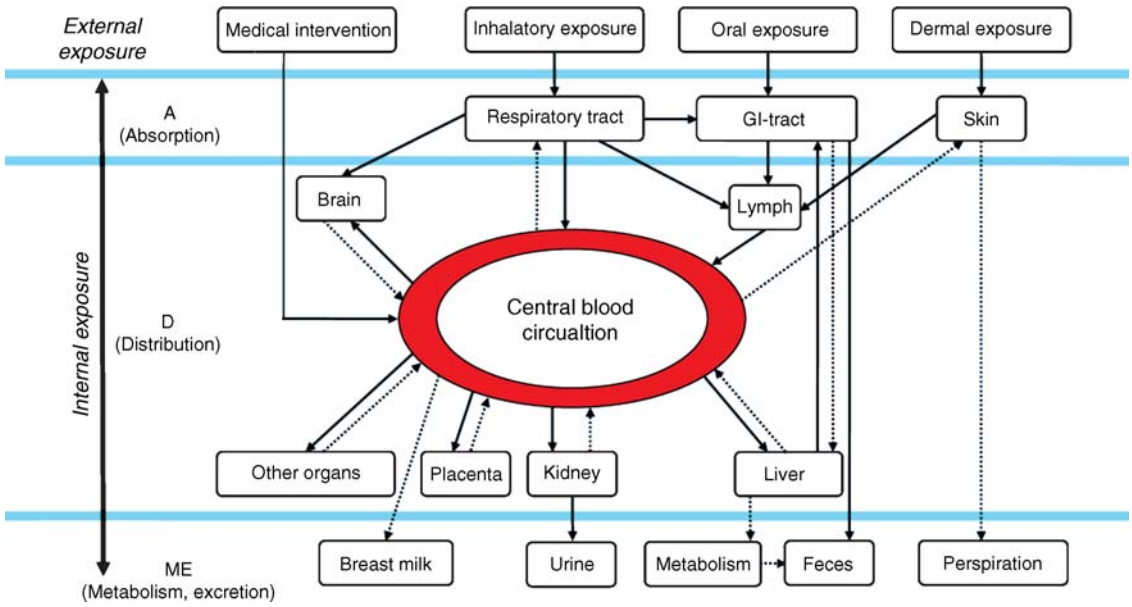

Figure 26. Kinetic properties of nanoparticles in the body. In this scheme, the ADME processes (absorption, distribution, metabolism and excretion) are indicated. The internal exposure is the part of the external dose that reaches the systemic circulation. The black lines represent confirmed routes for nanoparticles; the dashed lines represent hypothetical routes. The transport rates and retention times for the indicated processes are largely unknown (other organs: e.g., spleen, heart, reproductive organs. Reproduced from Hagens *et al.* (2007) © Elsevier.

level. This technique has been widely used for *in vivo* toxicity assessment for nanomaterials such as single-wall carbon nanotubes (Warheit *et al.*, 2004), nanoscale quartz particles (Warheit *et al.*, 2007), and nanoscale TiO_2 rods and dots (Warheit, Webb and Reed, 2006).

7.1.3 Oxidative Stress Biomarkers

Oberdoster *et al.* studied the oxidative stress induced by manufactured nanoscale fullerenes in the brain of juvenile largemouth bass (Oberdorster 2004). In this study, glutathione (GSH) and malondialdehyde (MDA) were selected as the major biomarkers to evaluate the oxidative stress and lipid peroxidation. Based on the significant lipid peroxidation and depletion of GSH levels, it demonstrated that uncoated fullerene can cause oxidative damage *in vivo* (Figure 28).

7.2 Absorption

In this part, different absorption routes of nanomaterials into the human or animal body are described briefly. Table 9 shows some studies of the major exposure pathways (inhalation, oral, dermal, and parenteral) of nanomaterials.

As for the inhalation exposure, the respiratory system is one of the most important portals for nanomaterials to enter and deposit. The alveolar macrophages in the respiratory system play a key role in the response to inhaled nanomaterials. Their essential function is phagocytosis of inhaled nanomaterials and clearance of them. It is well known that lungs are the well target of atmospheric pollutants such as Particle Matters (PM). The deposit, diffusion, and transportation effect may be dependent on various factors such as particle size, composition, shape, charge, solubility, stability, and particle aggregation condition. Other important portals of nanomaterials entry in the body are the GI tract and skin. Nanomaterials can be ingested into the gut by many ways such as from food, water, drugs, and cosmetics (Lomer, Thompson and Powell, 2002).

7.3 Distribution

Due to their nano-size, nanomaterials have the potential to pass through the defenses in the

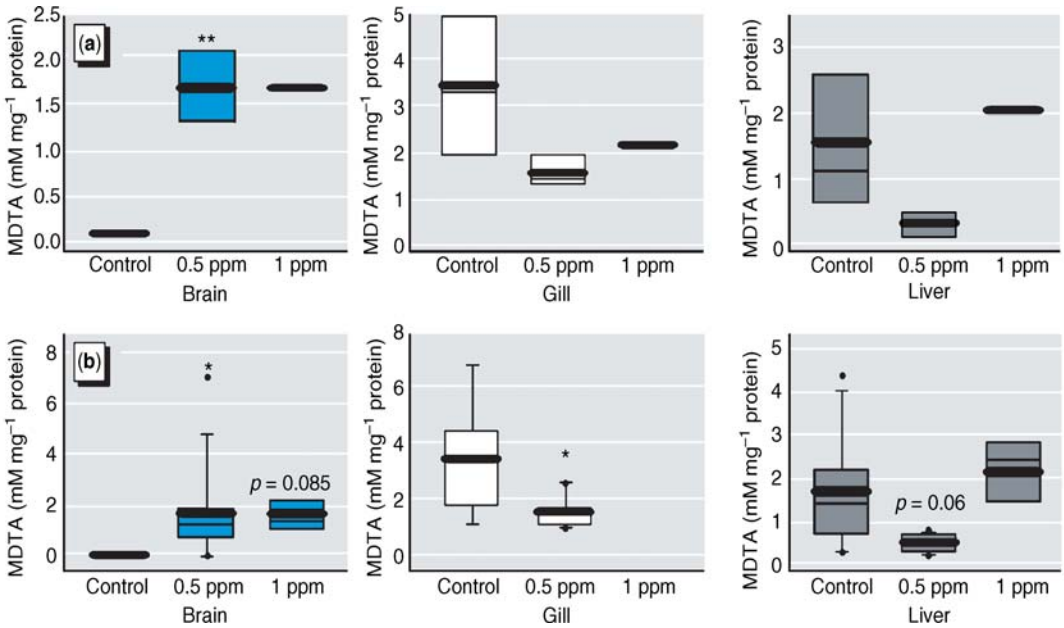

Figure 28. Lipid peroxidation of brain, gill, and liver of largemouth bass after 48 hr of exposure to 0.5 or 1 ppm nC_{60}. MDTA, 1,1,3,3-tetraethoxy propane. (a) Aquarium averages; (b) data using individual fish; in the brain, 0.5 ppm nC_{60} caused a significant 17-fold increase in lipid peroxidation, whereas in gill and liver there is a trend for reduction of lipid peroxidation at 0.5 ppm nC_{60}. Heavy black bands represent the means; thinner lines indicate medians; boxes represent 25th and 75th percentiles; error bars indicate minimum and maximum; and circles represent outliers. Reproduced from Oberdorster (2004) © National Institute of Environmental Health Sciences.

respiratory tract, GI tract, or skin and enter into systemic circulation or even the central nervous system (CNS). Upon entering into systemic circulation, the nanomaterials would be possibly transported and distributed to peripheral organs and tissues. For the first time, Berry *et al.* (1977) showed for the first time that following intratracheal injection of particles of colloidal gold (30 nm) in the rat, particles in the blood platelets of the alveolar capillaries can rapidly be observed. And the presence of the gold was confirmed by microanalysis. Recently, a few studies have shown distribution of particles to several organs including liver, spleen, heart and brain (Brown, Zeman and Bennett, 2002; Sun *et al.*, 2005; Nemmar *et al.*, 2001; Hillyer and Albrecht, 2001; Oberdorster *et al.*, 2002).

7.4 Metabolism

To date, no study on metabolism of nanomaterials has been reported yet. Some nanomaterials with wide applications in industrial work, such as metallic oxide, carbon, silica, are unlikely be metabolized in the body because of their inert chemical properties. However, if nanomaterials contain functional groups or if the nanomaterials are designed as the drug carrier, like liposomes, it is possible that metabolism may be affected.

7.5 Excretion

In general, researchers study the distribution and excretion of nanomaterials in tandem to test the overall process through the human or animal over time and get insight into nanomaterials localization, retention, and passage from human or animal. Excretion studies are accomplished by long-term study of the excretion of the nanomaterials at various time points after exposure. Usually, ICP-MS, radiolabeling and fluorescence are used to quantify the excretion (Lin *et al.*, 2008; Huang *et al.*, 2008).

There are two reviews that describe the effect of nanomaterial properties (size, composition, charge, etc.) on *in vivo* distribution and excretion (Alexis *et al.*, 2008; Owens and Peppas, 2006). However, the information about the excretion route,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat239
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

mechanism, and influence factors of nanomaterials remains largely unknown.

In addition, there remains a great need for a rapid and throughput method for the detection and analysis of excretion of nanomaterials.

8 SUMMARY

Due to exponential increase in the development of many different types of nanomaterials and their wide applications, the health impact of nanomaterials causes great concern. In consequence, nanotoxicology becomes a fast-growing interdisciplinary research involving chemistry, biology, material sciences, physics, and others. To fully understand the toxicity of nanomaterials and determine the mechanisms of nanotoxicity, it is essential that the physicochemical properties of nanomaterials are fully investigated since many physical factors can affect the results of nanotoxicity testing such as composition, impurities, size, shape, surface area, crystal structures, porosity, surface coating, and so on. These factors make characterization of nanomaterials be complicated and time consuming. Before *in vivo* study, a thorough *in vitro* study should be conducted since *in vitro* study is a valuable technique to find the dose response range, the levels of cytotoxicity, and the possible mechanism of cytotoxicity. Many biomarkers and analytical techniques have been developed to assess the levels of cytotoxicity, which can help greatly for future nanotoxicology studies.

1 INTRODUCTION

Nanotechnology is a rapidly developing multidisciplinary field of science which offers the promise of generating new products which will revolutionize diverse areas of our life. Nanotechnology, therefore, is expected to have an enormous impact on economy and it is already so *a la page* to flaunt "nanotech" as a well-established nick name. It deals with materials of extremely small size that due to their high surface area, chemical and biological activities find a wide range of applications.

The fast growth of nanotechnology will undoubtedly be paralleled by an ever-increasing presence of nanomaterials in the environment. The peculiar and unique properties that make these nanomaterials in general and nanoparticles (NPs) in particular so attractive may be associated with potentially new and largely undefined risks (Di Gioacchino *et al*., 2009) for the human health and for the environment. NPs, for example, are readily taken up by the cells (Gornati *et al*., 2009; Papis *et al*., 2009) and stored in cytoplasmic vesicles (Figures 1 and 2) from where they can exert their toxicity. In this context, a new discipline, nanotoxicology, is established to provide answers to the concern about the possible drawbacks of this technology.

In this chapter, after having examined the ecotoxicology of nanoparticles, we will focus on two main concerns that may arise for the human health, that is, cancer and allergy. Last but not least, we will give a glance to the other side of the coin by examining how medicine might take advantage from nanomaterials.

2 ECOTOXICOLOGY

The dispersal of engineered metal NPs in the environment can be accidental, unwanted but unavoidable, or intentional when, for example, used for bioremediation of contaminated sites. Accidental leakages from productive plants or during transport of refined products have never been reported, but exposure to airborne nanomaterials is well documented both at the workplace and in polluted sites. The accumulation of nanometals dispersed in water and soils from consumer products has been predicted to span between few ppt, for

CeO_2, and several tens or even thousands ppb, for ZnO and TiO_2 (Xia *et al*., 2008; Tiede *et al*., 2009). Although in the case of nanomaterials every generalization is difficult and frequently fallacious, these concentrations seem to be potentially harmful (Blaise *et al*., 2008; Cattaneo *et al*., 2009; Farré *et al*., 2009).

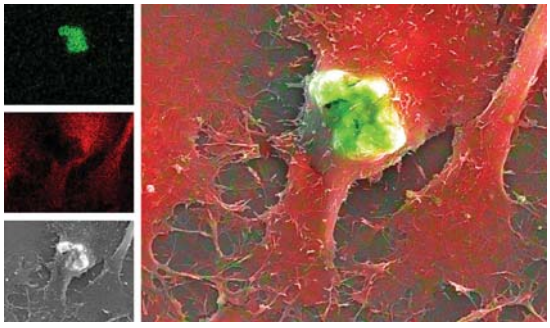

Figure 2. X-ray spectroscopy of cells exposed to Co_3O_4 NPs. On the left, the distribution of cobalt (green) and carbon (red) is shown in false colours in the field of view shown on the SEM image at the bottom left. On the right, the elemental mapping has been superimposed onto the micrograph. The horizontal field of view spans approximately 50 μm. (From Papis *et al*., 2009.)

Among unwanted dispersion of refined nanomaterials of nanotechnology industry, noticeable is the case of silver NPs. The waste of silver in the environment is mainly sustained by the disposal of plastics and textiles functionalized with Ag NPs, in addition to the amount derived from discards of health and dentistry services, silver-containing biocidal products, photographic emulsion and electroplating. The accumulation is mainly expected in sewage sludge and groundwater from which elution into rivers, soil and sea can occur (Blaser *et al*., 2008). The ecotoxicological relevance of Ag NPs has been studied in *Caenorhabditis elegans*: NPs exert considerable toxicity, particularly in reproduction potential, gene expression and oxidative stress (Roh *et al*., 2009).

In addition to silver, other widely used metal nanomaterials could differently affect gene expression in mammals and mammalian cells (Papis *et al*., 2007; Warheit *et al*., 2007; Fowler, Conner and Yamauchi, 2008) and show toxic effects on several other organisms (Adams *et al*., 2006; Hund-Rinke and Simon, 2006; Sun *et al*., 2007; Warheit *et al*., 2007; Zhang *et al*., 2007; Davies, Dodd and Jha, 2008; Griffitt *et al*., 2008; Handy *et al*., 2008; Reeves *et al*., 2008; Velzeboer *et al*., 2008; Vevers and Jha, 2008; Zhu *et al*., 2008; Aruoja *et al*., 2009). Among plants, *Phaseolus radiatus* and *Triticum aestivum* proved to be sensitive to the toxic effects of Cu NPs in a test on agar (Lee *et al*., 2008b), whereas spinach reacted positively to the exposure to TiO_2 NPs with increased germination rate of seeds, growth of plant crops, photosynthetic yield and Rubisco[a] activity (Hong *et al*., 2005; Zheng *et al*., 2005; Yang *et al*., 2007; Gao *et al*., 2008; Su *et al*., 2009). This last result, if compared to those found in algae and plant agar tests, is surprising and, to explain it, a different aggregation of NPs or lower protection against oxidative stress in water has been postulated. Similarly, although no evident toxicity was recorded after NP administration with food to the earthworm *Eisenia foetida* (Oughton *et al*., 2008) and to the terrestrial crustacean *Porcellio scaber* (Drobne, Jemec and Pipan Tkalec, 2009; Jemec *et al*., 2008), the soil nematode *Caenorhabditis elegans* poorly tolerated the exposure to metallic NPs when the experiments were conducted in water (Roh *et al*., 2009; Wang, Wick and Xing, 2009b).

The nanoparticulate present in the air of urban areas or along high-traffic suburban ways is by far

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

represented by the products released from diesel and spark-ignition engines. These technological byproducts have been studied and characterized quite well, and a number of methods to record, measure and characterize ultrafine airborne particulate have been used for several years. Diesel exhaust is, in itself, metal-free while toxic (Lingard *et al*., 2006) and metal NPs are the product of fuel additives or of catalytic converters (Merget and Rosner, 2001).

The main byproducts of catalytic converters are represented by NPs of the platinum group elements (PGE), which, when released in the air, are generally attached to micron-sized aluminum oxide particles. Aged particles can accumulate in dust, soil (Ely *et al*. 2001; Cinti *et al*., 2002; Kylander *et al.*, 2003) and sediments of aquatic systems collecting the urban road runoff (Whiteley and Murray, 2005). PGE NPs seem to be highly mobile in the environment and have been documented even in the Artic snow (Barbante *et al*., 2001). They can enter the food chain through bacteria, fungi and plants with proved toxic effects (Gao *et al*., 2009). Like a great deal of airborne NPs (Duffin, Mills and Donaldson, 2007; Li, Xia and Nel, 2008; Vega-Villa *et al*., 2008), PGE NPs sustain acute or sub-chronic respiratory toxicity when inhaled.

The most important intentional introduction of metal nanomaterials in the environment has been, until now, the injection of products for remediation of groundwater, in particular of nanoparticulate zero-valent iron (nZVI). Remediation has been proposed and tested in artificial systems even with metal oxide NPs, but never used in the field (Table 1). Both nZVI and metal nano-oxides are aggressive agents used to remove, from water and soils, refractory and hazardous pollutants, like those found in oilfield wastewater, polychlorinated biphenyls and other organic and inorganic molecules.

Two recent case studies with nZVI sludge for remediation of groundwater have been conducted on local scale in two industrial sites, one in Southern Finland (Tuomi *et al*., 2008) and the other in Arizona (Bruck, 2007), which were heavily polluted with chlorinated ethanes and ethenes. Although the

Table 1. Examples of proposed uses of metal NPs for remediation of polluted soils. Note the only two cases with intentional dispersion of metallic nanomaterials in the environment.

Nanomaterials	Pollutants	Matrix	References	Toxicity

geology of these sites is very different, positive results were obtained in both cases within 2–3 weeks. The main failure, at a later time, was due to the agglomeration and ageing of NPs, and several efforts have been and will be spent to ameliorate the nanomaterial performances by coating and functionalizing their surface (Keenan and Sedlak, 2008; Lee and Sedlak, 2008; Tuomi *et al*., 2008; Bezbaruah *et al*., 2009; Kim *et al*., 2009, Sirk *et al*., 2009). A different problem arises from the contingency that significant amount of ZVI enters the effluent water, posing a threat for the environment and human health. Although the compound is neurotoxic, it rapidly ages, partially warranting against a serious hazard for humans (Phenrat *et al*., 2009).

Bioremediation of uranium- and heavy-metal-polluted sites is another interesting application of nanotechnology. It involves metabolic properties of bacteria which have been isolated at sites polluted with uranium and other hazardous compounds (Spain *et al*., 2007). In the process of bioremediation, some prokaryotes organize the biogenic metal in NPs which accumulate on the outer side of cells, bound to extracellular polymeric substance (Marshall *et al*., 2006, 2009). Therefore, besides the remediation of the site, there is production of biogenic NPs precious for many technological applications. For example, biogenic Pd and Pt NPs have been found to be active catalysts for dechlorination of polychlorinated biphenyls and lindane (De Windt, Aelterman and Verstraete, 2005; Mertens *et al*., 2007).

3 CANCER

At present, very little is known about the carcinogenic risk posed by NPs and very few studies in this area have been carried out *in vivo* in laboratory animals and in *in vitro* systems, whereas no study is available on the carcinogenic potential of NPs in humans. Furthermore, the existing data on the carcinogenic potential of NPs, the information on the specifications of the test materials used and the relevance of such studies to the human situation are mostly inconsistent, sometimes due to the high-dose exposure used that paradoxically can abolish the biological response, the "obscure route" of exposure (e.g., intramuscularly) and the absence of the chemical purity of the NPs because they may contain "contaminants" such as metals and surfactants used in processing, which may significantly affect their behaviour and reactivity.

Pulmonary exposures to single-wall carbon nanotubes in rats produced multifocal granulomas (Warheit *et al*., 2004) whereas carbon nanotubes introduced into the abdominal cavity of mice show asbestos-like pathogenicity (Poland *et al*., 2008). Intraperitoneal application of multi-wall carbon nanotubes induces mesotheliomas in the p53+/− mouse (Takagi *et al*., 2008). A lung carcinogenic bioassay of CuO and TiO_2 NPs intratracheally instilled into rats showed a tendency to increase the neoplastic lesions compared with the microparticle administration (Yokohira *et al*., 2009).

The development of sarcomatous (malignant connective tissue tumours) lesions has been studied in rats implanted with metallic cobalt, nickel, SiO_2, TiO_2 and PVC (intramuscularly) in comparison to the corresponding bulk materials (subcutaneously) in the same animal (Hansen *et al*., 2006). The strongest carcinogenic effect was observed in nickel-implanted animals. However, it is crucial that there was no significant difference between the implantation sites with bulk metal or NPs. The only group of animals that did show a difference between bulk and NPs was the ones exposed to metallic cobalt. However, it is known for many years that long-term subcutaneous implantation of materials in solid metallic sheets or in particulate form gives rise to fibrosarcomas in rats (Oppenheimer effect – tumours, Oppenheimer *et al*., 1956); there is no evidence of their promoting malignancy in man or other animal species.

Concerning the *in vitro* studies, a wide range of cells have proved useful to examine aspects and mechanisms which may be related to the carcinogenic and genotoxic potential of NPs such as oxidative stress and inflammation (Peters *et al*., 2007; Yang *et al*., 2009). A recent study on genotoxicity and morphological transforming activity of cobalt NPs and cobalt ions (Co^{2+}) in Balb/3T3 cells suggests that cobalt NPs are potential genotoxic carcinogens (Ponti *et al*., 2009). Co NPs can be internalized by human leucocytes and can interact with DNA leading to the observed genotoxic effects, which are, however, modulated both by donor's characteristics and/or by Co^{2+} ions released (Colognato *et al*., 2008). A recent study has highlighted some of the potential confounding factors that need to be considered in order to ensure that *in vitro* genotoxicity assays report true biological impacts in

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

response to nanomaterial (Doak *et al*., 2009). The finding that silver NPs have been observed in the colon of patients with colon cancer (Gatti, 2004) cannot be interpreted as carcinogenic response to such NPs, only proving the presence of NPs in cancer cells.

In conclusion, the existing knowledge on the carcinogenic potential of engineered NPs is of very limited value with regard to human health risk. At present, no animal model is available which is able to predict possible neoplastic effects of NPs in humans and there are no standardized protocols for *in vitro* testing of the carcinogenic potential of such nanosized materials. In addition, no epidemiological study is reported on the carcinogenicity of NPs in humans. There is a great need to meet a level of reliability that would provide confidence in the data generated. However, in spite of the very limited knowledge on the carcinogenic potential of engineered NPs the existing data suggest in any case great caution before introducing such materials into the market if long-term health consequences are to be avoided.

4 ALLERGIC DISEASES

Starting from the concept that all foreign substances that enter the body interact with the immune system, a number of studies on the effects of NPs in humans have been devoted to the evaluation of the immune potential of nanoscale materials. The large majority of studies dealt with the immune toxicity of NPs, whereas very few concerned the modulation of immune function or their sensitizing potential. In particular, literature lacks studies aimed at evaluating the possibility that some form of allergic diseases can be linked to the environmental spreading of NPs. Some manuscripts report a relationship between the increased levels of some metal NPs in the environment and the onset of skin allergies; for example, an increase of allergic contact dermatitis to palladium has been reported, in relation to the increase of Pd emitted from catalytic converters (Merget and Rosner, 2001; Prichard, Sampson and Jackson, 2009). However, it is not demonstrated that Pd NPs rather than Pd ions are responsible for skin sensitization. At present, no metal NPs are demonstrated to induce allergy, while almost all metal ions have been shown to have a strong sensitizing and immune potential, being able to induce, both *in vivo* and *in vitro*, allergic responses and immune toxicity (Di Gioacchino *et al*., 2007), and speciation appears to be the main factor in determining their immune effects (toxic or sensitizing). Sensitizing potential of metals can be studied by evaluating the *in vivo* and/or *in vitro* induction/inhibition of specific cytokine pattern from immune cells. In fact, in experimental animals, it has been shown that exposure of mice to chemicals in general and metal compounds in particular, which are known or suspected to cause allergic asthma or allergic contact dermatitis, provokes the development of selective type 2 (Kimber *et al*., 1999; Hayashi *et al*., 2001; Vandebriel *et al*., 2000) or type 1 (Dearman and Kimber, 1999; Hayashi *et al*., 2001; Vandebriel *et al*., 2000) cytokine expression profiles.

Cytokine profile induced by metal nanoparticles appears to be different from that induced by their respective ions. For example, Co NPs induced an increase of tumour necrosis factor α (TNF-α) and interferon γ (IFN-γ) and an inhibition of interleukin 10 (IL-10) and IL-2 release by cultured PBMCs, differently from Co ions that inhibited the production of all studied cytokines (Petrarca *et al*., 2006). A similar T helper 1 (Th1) stimulatory effect has been shown to be induced by Pd NPs, in particular, increasing (at high concentrations) INF-γ and inhibiting TNF-α and IL-17 release from human peripheral blood mononuclear cell PBMC in cultures stimulated by lipopolysaccharides (Boscolo *et al*., 2010). The cytokine pattern observed in these two studies can mimic that of allergic contact dermatitis (or experimental autoimmunity). However, sensitized patients should be studied to definitely establish whether *in vitro* results can be extrapolated *in vivo*, to demonstrate the ability of NPs to induce a delayed type of immune reaction as the allergic contact dermatitis.

Also atopic dermatitis, a Th2-mediated disease, can be affected by metal NPs, In fact, it has been also reported that the exposure to TiO_2 NPs under skin barrier dysfunction/defect in animals affected by atopic dermatitis can exacerbate symptoms induced by allergens through Th2-biased immune responses (increase of Il4, IgE and histamine release and decrease in IFNγ production). Furthermore, TiO_2 NPs can play a significant role in the initiation and/or progression of skin diseases following the barrier dysfunction/defect by histamine release even in the absence of allergens (Yanagisawa *et al*., 2009).

DOI: 10.1002/9780470744307.gat240
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Inhaled metal NPs show different immune effects, being able to induce immune cells to release Th2 cytokines, typical of the IgE-mediated reactions. Park *et al*. (2009b) demonstrated that in experimental animals, the intra-tracheal instillation of TiO_2 NPs induced a strong release of Th2-type cytokines such as IL4 and IL-5 (typical of allergic asthma) and lower levels of IL-12 and IFN-γ. By the prevalence of Th2-type cytokines, an increased IgE production in BAL fluid and serum was observed. The same authors showed that other engineered nanomaterials are able to favour allergic responses in mice through B-cell activation and production of IgE (Park *et al*., 2009a). However, it has not been demonstrated that NPs can act as apten inducing specific IgE. Rather, it is likely that some NPs can work as adjuvant in inducing patterns of cytokines, antibody and cells that favour allergic sensitization to natural allergens and xenobiotics. Inoue *et al*. (2006) also showed that engineered NP might exert adjuvant effects that resulted in exaggerated eosinophil, neutrophil, and mononuclear cell infiltration, as well as an increase in ovalbumin (OVA)-specific IgG and IgE production. The combination of NPs with OVA also increased the production of IL-5, IL-6, IL-13, eotaxin, monocyte chemoattractant protein-1 (MCP-1) and RANTES in the lung compared with OVA alone.

Through the induced inflammation, NPs can also exacerbate allergic diseases, directly causing cell and epithelial damages and increasing bronchial hyper-reactivity. In fact, subacute exposure of C57B1/6 mice to 2–5 nm TiO_2 NPs in a whole-body exposure chamber caused a moderate, but significant, inflammatory response in the lung within the first 2 weeks of exposure, beyond which the inflammation resolved without permanent damage (Grassian *et al*., 2007). Furthermore, Inoue *et al*. (2007) demonstrated that inhaled NPs have the ability to increase bronchial hyper-responsiveness, especially in the presence of antigen/allergens. The researchers observed that NPs alone or OVA alone moderately enhanced cholinergic airway reactivity, whereas in the NPs + OVA groups, all the parameters for lung responsiveness were worse than those in the control group.

As speciation is the main characteristic of metal ions, particle size and surface area are the most important features of NPs in inducing immune effects. In fact, the adjuvant effect of NPs on allergic immune responses has been shown to increase with decreasing particle size and increasing particle surface area. As shown in experiments made with TiO_2, the ultrafine particles cause significantly more inflammation and were significantly more cytotoxic than the fine-sized particles. Lung burden data indicate that ultrafine TiO_2 appears to migrate to the interstitium to a much greater extent than fine TiO_2 (Sager, Kommineni and Castranova, 2008). However, when doses were equalized based on surface area of particles delivered, the ultrafine particles were only slightly more inflammogenic and cytotoxic compared with the fine-sized particles.

In conclusion, at present there is no clear evidence that some metal NPs can act as apten inducing specific sensitization, both in Th1 and in Th2 allergic-mediated diseases. However, their ability to induce a specific cytokine-mediated inflammation can result in favouring allergen sensitization to environmental allergens or xenobiotics, both favouring allergic contact dermatitis of IgE-mediated sensitization, according to the type of metal NPs. The proinflammatory properties of some metal NPs, mainly related to their size, can also result in exacerbation of allergic diseases.

5 NANOMEDICINE

Colloidal suspensions of gold and silver were used in the traditional medicine (Mahdihassan, 1985; Milot, 2008), and the ingestion of these preparations holds over, despite the possibility of serious side effects (Archer, 2008). The empirical character of medicine anticipates sometimes science: the colloid suspensions of metals were only recently characterized as mostly composed of nanoparticles, and the red colour of colloidal gold used in traditional Indian medicine as a formulation for long life and fertility is now definitely known to be restricted to colloidal gold particles sized >20 nm (Berciaud *et al*., 2005). The colloidal gold, enriched in its radioactive isotope Au-198, entered the history of Western official medicine in 1952. At that time, it was considered an advantageous alternative to radium for the treatment of prostate cancer; its use preceded that of other colloidal radioactive isotopes for the palliative treatment of a wide range of neoplasias (Fountain and Malkasian, 1981, Metz, Stoll and Plenert, 1982) and was abandoned late in the 1970s (Chassagne *et al*., 1985). The colloidal formulation was selectively toxic for neovascularized tissues: this

[b] See Endnote b.

property explained its selective effect on neoplastic growth as well as the powerful anti-inflammatory and analgesic effects of non-radioactive colloidal gold, widely used to treat chronic polyarthritis and knee synovitis (Boerbooms *et al*., 1985). The proclivity of colloidal metals to accumulate in newly formed endothelia is now recognized as a basic pharmacokinetic character of all nanosized compounds, the so-called enhanced permeation and retention (EPR) effect. The availability of newer, safer and more powerful drugs led to the neglect of colloidal gold for these use until recently, when colloidal gold prepared under controlled conditions and functionalized with TNF has been proposed: it is still under evaluation for tumour treatment in humans (Paciotti *et al*., 2004; Visaria *et al*., 2006, 2007; Goel *et al*., 2009) (Table 2).

The colloidal silver suspensions are only minimally characterized as pure nanosized silver: they lack the dimension-dependent colour shift observed in gold, and the element is by far more reactive, leading to the formation of oxides. Its systemic use in alternative medicine, mainly as an antiseptic agent and a supposed immunomodulator, is charged by a

specific set of side effects, known with the name of argyria (Archer 2008; Baral, Dewar and Connett, 2008).

Nanometals recently gained a renewed interest in medicine, after their production in a standardized, industrial and controlled manner. A number of customized products have been introduced in the market for care and diagnosis: several of them are listed in Table 2.

The metals used to this end (i.e., Ti, Fe, Ag, Pt and Au) mainly belong to the transition metal group; it should be remembered, however, that, when organized at nanoscale, transition metals do not behave as metals, but as semiconductors (Mikrajuddin *et al.*, 2000). In addition to transition metals, lanthanides are of interest: the radioactive Ac-225 has been used to develop targeted alpha-emitting atomic nanogenerators (Miederer *et al*., 2004). The first and only clinical study with this new therapeutic is still open at the Memorial Sloan Kettering Cancer Center of New York, USA.

Nano-titanium dioxide ($nTiO_2$), eventually combined with nZnO, has been used in sunscreen protection and proposed for photocatalytic dressing of wounds: its indiscriminate use has been heavily criticized for both health and environmental concerns (Beck 2005; Nohynek *et al.*, 2007; Barker and Branch, 2008). Another nanotechnology-based device undergoing clinical evaluation and containing TiO_2 is a semiconductor toothbrush, which undergoes clinical evaluation in a still recruiting clinical trial (Table 2).

Powders, functionalized textiles, medical implants and devices with antiseptic properties related to the release of silver nanoparticles have been recently introduced in the pharmaceutical market, or undergo clinical evaluation (Ricco *et al*., 2006; Gravante *et al*., 2009; Larese *et al*., 2009). Two open trials on nanosilver are at present registered at the ClinicalTrials.gov (the repository of clinical trials maintained at the National Institute of Health, Bethesda, MA, USA) (Table 2). They will test the benefits against the growth of microorganisms, of a nanosilver-containing gel for hand cleaning (SilvaSorb®, phase III[b], Madigan Army Medical Center, Washington, USA) and of a central venous catheter embedded with nanosilver (AgTive®, phase IV, Policlinico Gemelli, Rome, Italy).

Several preparations containing metal NPs are available or have underwent clinical evaluation as injectable therapeutic agents, mainly for treatment of advanced or refractory neoplasias. The most relevant among them is the nanosized formulations of cisplatinum (*cis*-diamminedichloroplatinum) embedded in liposomes (Lipoplatin®), or in polymeric micelles (NC-6004). These formulations show lower toxicity, better tolerability, longer half-life and higher antineoplastic activity, in comparison with non-nanosized formulas (Uchino *et al.*,2005; Froudarakis *et al*., 2008; Jehn *et al*., 2008; Kim *et al*., 2008; Ravaioli *et al*., 2009).

Other metal NPs have been mainly developed for diagnostic use, including small and ultrasmall superparamagnetic iron oxides (SPIO and USPIO), nanogold and nanosilver prepared as highly regular spheres, rods, triangular prisms and quantum dots. Nanogold and nanosilver are mainly used for "*in vitro*" studies; however, they have been injected into the systemic circulation in animals, as "*in vivo*" staining, bioactive probes. Their advantages in comparison with existing molecules and dyes are a combination of powerful and unique optical properties and compartmentalization into cells and tissues (Hama *et al*., 2007; Yang and Cui, 2008; Millstone *et al*., 2009; Rzigalinski and Strobl, 2009). Unfortunately, the toxic potential of these probes seems to be elevated, and it is not sufficiently documented in pre-clinical studies to admit them to clinical trials.

At present, iron is the most represented of nanometals submitted to evaluation for clinical use: SPIO and USPIO are the subject of 15 registered clinical trials, six of them still recruiting. The signal of these particles is considered more powerful than that of other paramagnetic probes, and the proclivity of both to accumulate in macrophages and in cells of the reticular endothelial system permits to record clean magnetic resonance images of metastasis, inflammatory processes and atheromas (Turvey *et al.*, 2005; Barentsz, Futterer and Takahashi, 2007; Barnett *et al.*, 2007; Tang *et al.*, 2009; Thoeny *et al.*, 2009). The application of superparamagnetic iron oxide to vascular imaging is limited by the short half-life of these compounds in circulating blood: a brilliant solution circumventing this problem could be the recently proposed internalization of SPIO nanoparticles inside functionalized red blood cells (Antonelli *et al*., 2008). Another interesting therapeutic application of USPIO is in the treatment of refractory anaemia, such as those affecting non-dialysed patients with chronic renal insufficiency (Landry *et al.*, 2005; Singh *et al.*, 2008): four trials are registered (Table 2).

NPs, if coated with antibodies or other molecules capable of binding specific tumour biomarkers, can selectively stick to the surface of cancer cells and eventually be endocytosed. So engineered NPs can, in principle, serve for diagnosis allowing a precise localization of cancer cells in the body as well as for innovative treatment methodologies. They could, in fact, be used as shuttles for precisely delivering therapeutic agents and minimizing the damage to the healthy cells or even become themselves the killing agent for the cancer cells. Gold NPs, heated by harmless radio frequencies, could "cook" tumour cells without damaging the neighbouring tissue (Gannon *et al*., 2008; Schmidt, 2008). Similarly, magnetic NPs can be heated by alternating magnetic field, and several efforts are currently being made to improve their heating efficiency (Kline *et al*., 2009). Moreover, after injection in the bloodstream, magnetic NPs could be guided in proximity of the tumour by a magnetic field to facilitate their interaction with the cancer cells.

In conclusion, despite the heavy toxicity of several metals used as therapeutic or systemic agents and the high bioactivity of NPs which are intentionally engineered to interact with cells and are deliberately and directly injected into the body, metal NPs show promising features for medical applications, both for diagnosis and for cure. Although these fields of knowledge are at their beginning in medicine, it is important to ensure that these enhancements do not cause any adverse effects or, at least, to be aware of the risks and benefits.

ACKNOWLEDGMENTS

This study was supported by a "Protein factory" Interuniversity Center grant to G.B.

END NOTES

[a.] Rubisco, ribulose-1,5-bisphosphate carboxylase/oxygenase, is the key enzyme in photosynthesis and photorespiration. Composed by eight small and eight larger subunits (encoded by the nuclear and mitochondrial genome, respectively), Rubisco is considered to be the most prevalent protein on the earth.

[b.] The phases of clinical trials are designed with roman symbols, from I to IV: all are conceived in humans. Phase I: limited to the study of pharmacokinetics and effects in healthy and diseased subjects; Phase II: controlled trials to define indications and short-term side effects; Phase III: uncontrolled and extended protocols to define risk/benefit of molecules retaining a proven efficacy; Phase IV: post-marketing surveillance.

Multifunctional Nanomaterials for Biomedical Applications: The Onset of Nanomedicine

Yang Xu, Meena Mahmood and Alexandru S. Biris

Nanotechnology Center, University of Arkansas at Little Rock, Little Rock, AR, USA

1 INTRODUCTION

The use of nanomaterials in biology and medicine is one of the most intensely researched areas in nanotechnology. The emerging field of nanomedicine bridges the scientific disciplines of nanotechnology and the biological sciences, delivering a valuable set of research tools and medical devices for the diagnosis and treatment of medical diseases and conditions. In the last few years, carbon nanotubes (CNTs) and magnetic nanoparticles have become the most commonly used nanomaterials for medical applications, especially for the prevention and treatment of cancer. Various nanoparticles (diameter < 10 nm) have been used as carriers of anti-cancer drugs and have been observed to penetrate the cells and aggregate around the nuclear membrane – afterward penetrating into the nucleus (Mahmood *et al.*, 2009; Mu, Broughton and Yan, 2009; Xu *et al.*, 2010; Kam, Liu and Dai, 2006; Pantarotto *et al.*, 2004). The majority of published data agree with the endocytosis pathway, which shows that nanoparticles pass through the cell membrane by endocytosis, an energy-independent cell uptake process (Mu, Broughton and Yan, 2009; Kam, Liu and Dai, 2006). Pantarotto *et al.* (2004) have previously indicate the possibility of a mechanism for nanotube penetration through the membrane that is non-endocytotic and is energy-independent. Understanding these mechanisms of the cellular entry of various nanoparticles (such as CNTs), their intracellular translocation, subcellular locations, and excretion (Mu, Broughton and Yan, 2009) are of utmost importance in order to comprehend possible nanoparticle hazards and their potential for drug/gene delivery. Along the most commonly studied applications of nanoparticles as drug and gene delivery vehicles, they also find novel applications as thermal agents for the ablation of cells and tissues. Moreover, the development of radio-frequency devices that excite and heat magnetic nanomaterials delivered into tumors or to cancer cells opens up a new direction in the fight against cancer. Most of the magnetic nanosized materials present large magnetic moments and as a result have ultra-fast responses in the presence of magnetic fields. Moreover they can have low remanence (residual magnetism) and coercivity levels (Xu *et al.*, 2010). This characteristic allows them to easily absorb energy from radio frequency (RF) when they are targeted to certain tumors or cancer cells. This technique permits the destruction of tumors without necessitating their removal (*in situ*) and, in many cases, can be used in place of more invasive and expensive surgical techniques (Scott Gazelle *et al.*, 2000).

2 SYNERGISTIC ENHANCEMENT OF CANCER THERAPY (CARBON NANOTUBES AND ANTITUMOR DRUG COMBINATION)

Carbon nanotubes have unique physical and chemical properties that have caused them to be considered potential drug carriers and delivery vehicles for cancer treatment (Liu *et al.*, 2008; Prato, Kostarelos and Bianco, 2008; Hampel *et al.*, 2008). CNTs can carry therapeutic drugs (Chen, Chen and Zhao, 2008) and apoptotic agents (Hampel *et al.*, 2008) safely and effectively into cancerous cells, thereby becoming ideal candidates for drug delivery. Nonetheless, drug resistance remains a major concern in the process of tumor treatment, due to lack of precise tumor targeting and toxicity. As already known, etoposide is a derivative of podophyllotoxin and a chemotherapeutic agent. In recent studies, it was used as a target for the nano-delivery system (Arimondo *et al.*, 2000; Kim *et al.*, 2002). This drug's apoptotic attribute lies in its ability to inhibit the topoisomerase II enzyme (Bromberg, Burgin and Osheroff, 2003). Etoposide is widely used for the treatment of different malignant tumors of the lung, brain, stomach, testis, and pancreas (Teicher, 2008). Even with advances in treatment protocols, etoposide still has a modest response rate that shows a success rate from 4 to 45% in pancreatic, breast, ovarian, cervical, and small cell lung cancer (Thomas, Dumas and Ajani, 1999; Herbert, Brames, Einhorn, 2006; Hijiya *et al.*, 2004; Perkins *et al.*, 2000; Stefanelli *et al.*, 2002; Smart *et al.*, 2008). It was observed that, using a single combined therapy of etoposide and CNTs on pancreatic (Panc1) and HeLa cancer cells, the anti-tumor activity was increased by about 40–47% when compared with the single administration of each agent (Mahmood *et al.*, 2009). This finding suggests that CNTs can alter the mechanisms of chemoresistance in malignant cells. This discovery could lead to new treatment approaches and improvement of current cancer therapies by using both cytostatic drugs and nanostructural materials (such as CNTs, gold nanoparticles, and silver nanoparticles), which synergistically are more aggressive and possess greater curative effects in the treatment of cancer (Mahmood *et al.*, 2009).

The process of apoptosis is extremely complex and can be induced by a number of intra or extra cellular signals with effects on the cells morphology and structure. Figure 1 shows the schematic of the apoptosis process induced in cancer cells exposed to a combination of CNTs and etoposide, which was found to be responsible for an accelerated death process of the cells and to have a

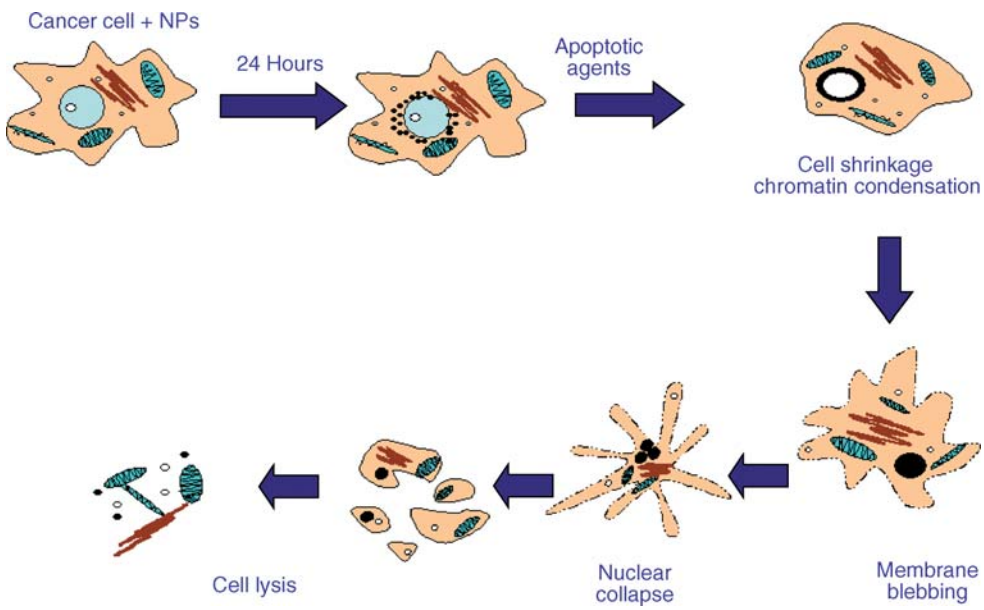

Figure 1. The experimental diagram of the CNT and etoposide delivery to various cell lines (Mahmood *et al.*, 2009).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat241

synergistic effect. Current therapies such as CNTs combined with etoposide exert a therapeutic effect by indirectly promoting apoptosis. This type of regimen induces apoptosis by causing DNA damage. In doing so, the nanotubes stimulate apoptosis through the intrinsic pathway. Figure 1 shows cell shrinkage, membrane blebbing, nuclear collapse, and, finally, apoptotic bodies (cell lysis) resulting from the synergistic enhancement by CNTs.

Two cancer cell lines, HeLa cells and human pancreatic cancer cells (Panc-1), were used to investigate the role of CNTs, etoposide agents, and their combination on the possible necrotic and apoptotic processes (Mahmood *et al.*, 2009). Trypan blue assay was used for the assessment of the viability of cells (dead cells). A very low percentage of dead cells were found in the control culture medium at levels of 2.26% and 5.73% for HeLa and Panc-1 cells, respectively. When CNTs and etoposide were introduced separately, cellular death increased to 14.1% and 7.80% for the HeLa cells. A slightly greater level of toxicity of CNTs was found when compared with etoposide, although the differences are not statistically significant. However, when HeLa cells were incubated with CNTs in combination with etoposide at the same dosage as when incubated individually, a significantly higher cell death rate of 49.1% was observed – an increase of 46.9% over the controls (Figure 2). The combined effect was approximately 2.7-fold higher ($P < 0.05$) than the sum of individual effects of CNTs and

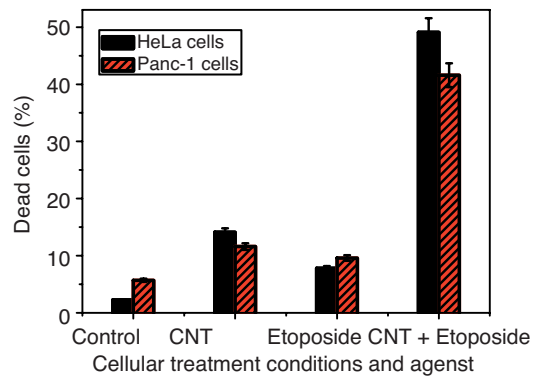

Figure 2. Percentage of dead HeLa cells and Panc 1 cells after exposure to various agents (etoposide, CNTs, and their combination) as a reference to control. The cells were incubated for 24 h with CNT (10 μg ml^{-1}), and an additional 6 h with etoposide (75×10^{-6} M). The experiments for the two cell lines were performed in identical conditions for comparison.

etoposide (17.4%). The percentage of Panc1 cells dead after exposure to the combination of CNTs and etoposide was 41.6%, slightly lower than that for HeLa cells. Furthermore, the number of dead cells was dependent on the concentration levels of CNT and etoposide. By increasing the concentrations of CNTs and etoposide, individually or combined, the percentage of dead cells increased significantly ranging from 62.1% to over 80.0%, respectively. This result suggests that CNTs have a role in decreasing the chemoresistance of cells. In addition, dexamethasone, another commonly used anti-cancer drug, was investigated under the same conditions, and the results showed similar trends.

Microscopic images of single HeLa cells in Figure 3 illustrate that the administration of CNTs alone did not change cell morphology significantly (Figure 3b) as compared with the control (Figure 3a), although a slight decrease (about 10%) in the size and shape of the cells was observed. It can be seen that CNTs appear to cluster inside the various cellular compartments; however, it was the combined CNT–etoposide action that led to significant changes in cellular morphology. The aggregates within the cell presented in Figure 3b and c represent CNT clusters as identified by Raman spectroscopy. Raman signal corresponding to CNTs inside the nucleus was found. As shown in these figures, the difference in the intensities coming from the nucleus and cytoplasm is quite significant, indicating that only a small percentage of the CNTs reached the nucleus. It has been argued that the varied mechanisms of cell uptake could be due to the different surface characteristics of CNTs. Earlier studies have indicated that CNTs can cross the mammalian cell membrane by endocytosis or other mechanisms (Mu, Broughton and Yan, 2009). The ability and kinetics to penetrate inside of cells through the bi-layered cellular membrane have been shown to be a function of their surface charge (Mu, Broughton and Yan, 2009).

Flow cytometry can be used to verify the apoptotic and necrotic effects of CNTs, the chemotherapeutic agent, and their combination by staining the cells with specific fluorescent dyes. Figure 4 shows that the percentage of apoptotic cells increased after the treatment of HeLa cells with etoposide and CNTs. Furthermore, the combined CNTs and agent drastically increased the population of cells undergoing late stages of apoptosis or necrosis. These results strongly suggest that the

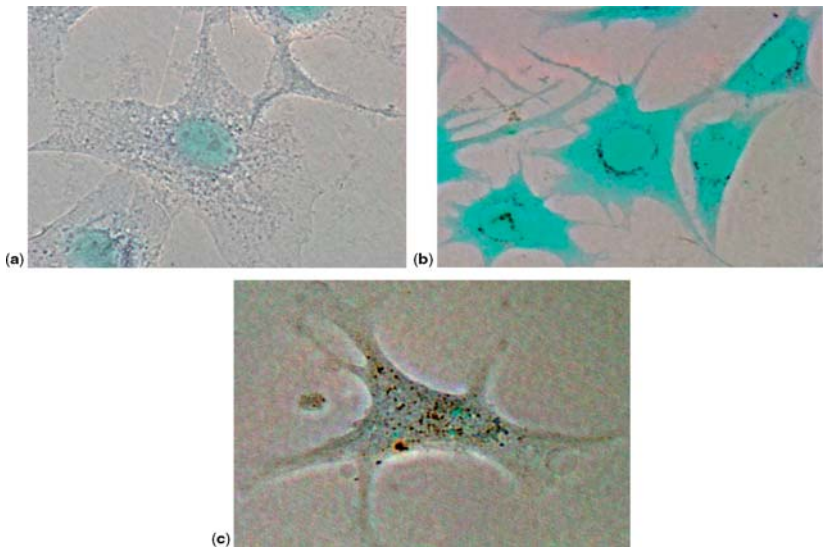

Figure 3. Optical image of a single HeLa cell morphology before (a) and after (b) the delivery of CNTs alone (10 μg ml^{-1}, 24 h incubation time). (c) Image of a HeLa cell that was exposed for 24 h to CNT (10 μg ml^{-1}) and an additional 6 h to etoposide (75×10^{-6} M).

CNTs–etoposide combination therapy achieved a greater cell death response and perhaps may eliminate cancer cells more efficiently.

Caspase-3 assay was the other common method used to assess the possible apoptosis of cells. To confirm the synergistic enhancement of apoptosis by CNT–etoposide, these results were further verified by assessment of the caspase-3 activity performed by staining the cells with Red-DEVD-FMK dye. Sequential activation of caspase plays a central role in the execution phase of cell apoptosis. The fluorescence brightness level of the red stain indicates the caspase-3 activation level in the cells. The control cells (Figure 5a) showed a weak fluorescence, but became brighter when the cells were incubated with CNTs (Figure 5b) and, similarly, with etoposide, alone (Figure 5c). Additionally, these data indicate that CNTs were found to induce a larger number of dead cells compared with the samples treated only with etoposide and to have a strong interaction with the cells via caspase pathways, which is also typical for the etoposide action (Moosavi *et al.*, 2006; Spitaleri *et al.*, 2009). Furthermore, when the cells were incubated with the combination of CNTs and etoposide, the caspase-3 activity expressed by the red stain was extremely intense (Figure 5d) – clearly indicating that the administration of both etoposide and CNTs enhances and activates apoptosis through the caspase cascade.

Etoposide inhibits the enzyme topoisomerase II, which unwinds DNA, and, by doing so, causes DNA strands to break. Cancer cells are less able to repair this damage than healthy cells (Boyer *et al.*, 2001). As previously shown (Morisaki and Katano, 2003), this DNA damaging agent can trigger cell death through the activation of p53-mediated caspase cell death signaling cascade (Li *et al.*, 2001). The ultimate result of these molecular changes induced by etoposide is a process of self-destruction in human malignant cells. In the present study, the low response rate of etoposide alone compared with the untreated HeLa cells (also confirmed by earlier reports (Mirzaie-Joniani *et al.*, 2002; Seminara *et al.*, 2007)) is caused by chemoresistance mechanisms activated inside the cells (Reddy *et al.*, 2003). Apoptotic deficiency is one of the main mechanisms of chemoresistance to anti-neoplasic drugs. It has been shown that etoposide administration leads to the up-regulation of pro-apoptotic proteins such as Bax proteins (Reddy *et al.*, 2003; Panaretakis *et al.*, 2002). These protein families translocate from the cytosol to the mitochondria preceded by the release of cytochrome *c* that contributes to the induction of the mitochondrial permeability transition (MPT). This process is accomplished by the coupling of DNA damages and leads eventually to the necrosis of the cells. The activity of several cofactors in the cytoplasm, including apoptotic protease activating

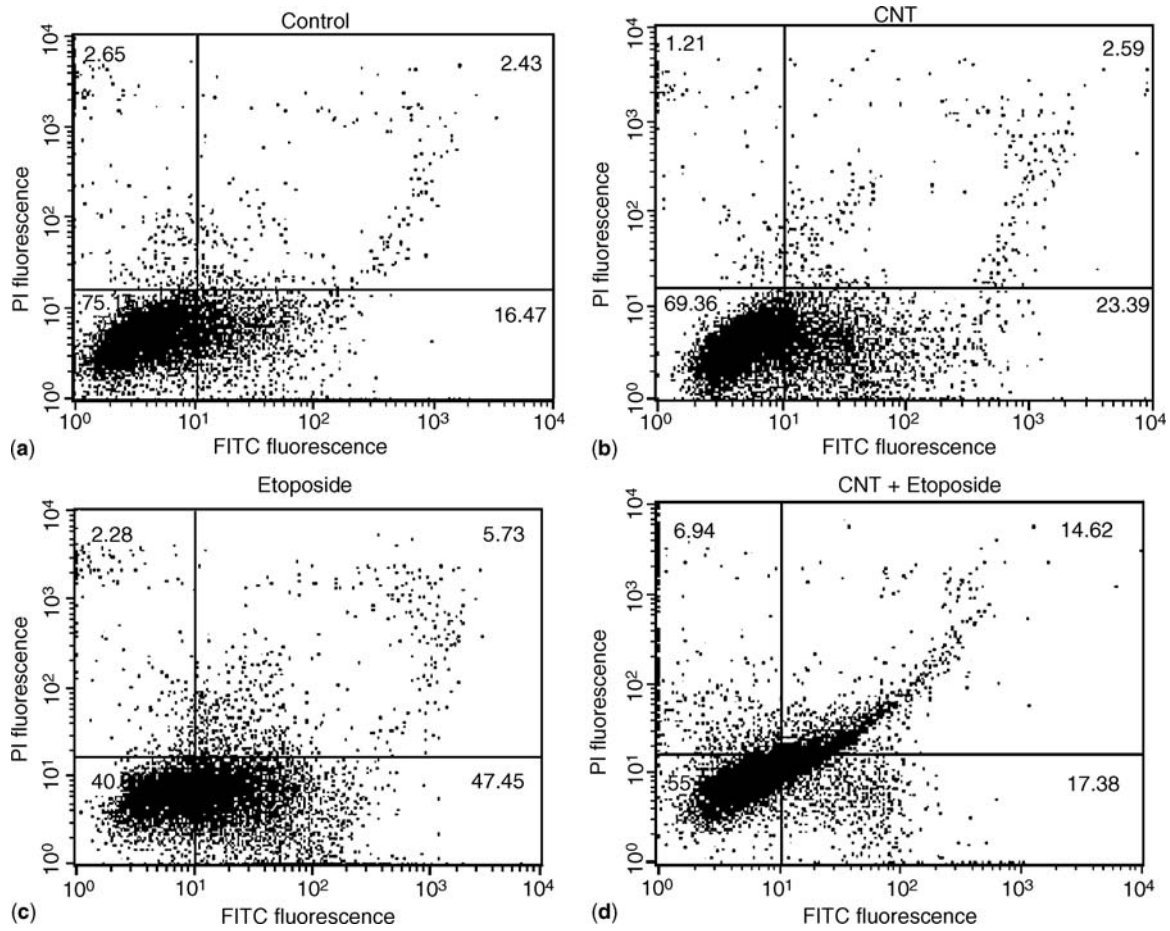

Figure 4. Flow cytometry data indicating the effect of DMSO (as vehicle control) (75×10^{-6} M), CNTs ($10\,\mu g\,ml^{-1}$, 24 h), and etoposide (75×10^{-6} M, 6 h) as mono- and combined therapy of the HeLA cells. Cells were stained with YO-PRO-I and PI dyes from Vybrant viability assay following manufacturer's instructions and analyzed by flow cytometry. Shown in quadrants are live (c), apoptotic (d), and necrotic cells (a and b) (Mahmood *et al.*, 2009).

factor-1 (Apaf-1; protein involved in cellular death) and ATP/dATP, coupled with the presence of some enzymes (pro-caspase-9) could be responsible for the generation of the apoptosome complex in the cytoplasm, which activates caspase-9 responsible for the activation of the caspase-3 proteins. Caspase-3 plays an important role in the apoptosis process being primordially involved in the cleavage of the poly ADP ribose protease (PARP) taking place during cell death and leads to the degradation and fragmentation of the chromosomal DNA inside the nucleus (Van Maanen *et al.*, 1988).

It has been shown that resistance to etoposide is due to molecular changes that affect the apoptotic cascade at different levels (Hwang *et al.*, 2008). Multiple mechanisms that block the activation of caspase cascade have been proposed to explain the acquired resistance of malign cells to etoposide (Hwang *et al.*, 2008). Studies have reported that the inactivation of Apaf1 is associated with chemoresistance in metastatic melanoma (Soengas *et al.*, 2001). Other reports have shown that the activation of various caspases is required for p53-mediated apoptosis and chemosensitivity in cancer treatment, suggesting that the analysis of the p53-dependent caspase activation could predict the chemosensitivity in some cell types (Wu and Ding, 2002). It has previously been shown that

targeting p53 for degradation by the human HPV E6 gene in the ovarian cancer cell line PA1 leads to an increase in the chemoresistant phenotype. Etoposide induces caspase-7 activation (Rothstein, 2000) and it was proved that an endoplasmic reticulum (ER) resident protein over-expression, GRP78, suppresses the activation of caspase-7, both *in vivo* and *in vitro*, and consequently blocks the full activation of the multiple caspase-mediated cell death pathways in drug-treated cells, contributing to the development of drug resistance (Reddy *et al.*, 2003).

It is also possible that CNTs induce cellular toxicity due to the accumulation of peroxidative products, generation of oxidative stress, mitochondrial dysfunction, and modifications in the morphology of the cells (Manna *et al.*, 2005). Several studies have indicated varying mechanisms of CNT uptake into the cells, of which endocytosis is believed to be the most probable process (Shi Kam *et al.*, 2004). CNTs penetration inside the various cellular compartments such as the cytoplasm or the nucleus, can be expected to lead to strong interactions between the CNTs and the protein or DNA structures of the cells which could affect various biological processes related to the cells activity. As a result, CNTs can be responsible for alterations in cellular signaling, metabolism, or motility affecting the mechanisms of chemoresistance, especially cell-cycle-mediated drug resistance. The first response of the cell in contact with CNTs is represented by the activation of antioxidant and detoxification enzymes followed by inflammation, which is a result of the activation of a pro-inflammatory signaling cascade (Andre *et al.*, 2006). The most common responses are the generation of mitogen-activated protein kinase (MAPK) and nuclear factor kB (NF-kB) cascades. The ultimate response is represented by mitochondrial perturbation, activation of caspase cascade, and release of pro-apoptotic factors that leads to cell death. Thus, both agents can induce apoptosis via some similar pathways that can interact and provide synergy leading eventually to cell death as a combination of apoptotic and necrotic phenomena. Some hypothetical processes focused on apoptosis are depicted in Figure 6.

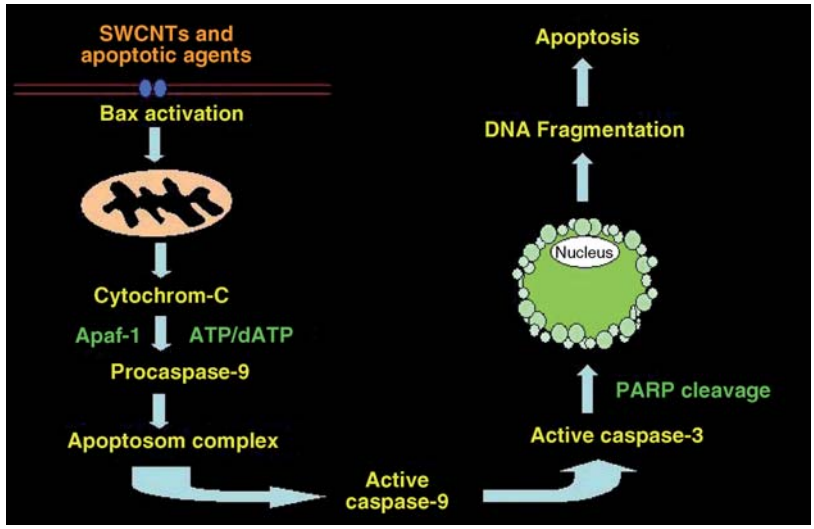

Figure 6. The proposed hypothetical mechanisms for etoposide–CNT combined action for the induction of apoptosis leading eventually to cellular death (Mahmood *et al.*, 2009).

Although this study did not involve targeting molecules, it provides insight into the use of nanomaterials to alter the chemoresistance of cancer cells when exposed to a combination of CNTs and chemotherapeutic drugs. It has been shown (Liu *et al.*, 2008) that CNTs *in vivo* have considerable ability to accumulate in several organs, such as the liver, kidney, and spleen. Moreover, given the intense blood vascularization of tumors, it is expected that the CNTs/drug system delivered in the blood circulation will naturally bio-accumulate in the tumors in larger amounts when compared with the non-cancerous tissues and therefore induce a high rate of cellular death, as shown in the present studies. The attachment of antibodies, folates, and growth factors to the nanomaterials for their specific delivery at the level of either individual or clustered cancer cells is further expected to greatly enhance the killing rate of the cells. Furthermore, the delivery of CNTs/anti-cancer drugs can be followed by other approaches that use the unique properties of the nanomaterials to absorb electromagnetic radiation and provide nanolocalized thermal ablation capabilities, such as laser heating, RF ablation, etc. This could result in the creation of a new treatment involving several steps in a procedure to completely eliminate cancer cells *in vivo*. These processes will have to be studied for various cancer cells lines in order to find the right experimental conditions for maximizing the death rate for each of these biological systems.

3 CARBON-COVERED MAGNETIC NANOMATERIALS AND THEIR APPLICATION FOR THERMOLYSIS OF CANCER CELLS

Magnetic nanoparticles are another group of nanomaterials that are of great interest for a wide range of biological and medical applications, such as magnetic resonance imaging (MRI) (Bulte and Kraitchman, 2004; Corot *et al.*, 2007), as well as medical diagnostics and therapeutics (Douziech–Eyrolles *et al.*, 2007; Reiss and Huetten, 2005), especially for *in vitro* and *in vivo* medical treatments. The stability and activity of these nanostructures in the presence of biological environments could dictate their possible utilisation in bio-medical applications. One cause of concern is their agglomeration, given by the tendency to lower their surface free energy, but which could dictate the level of their interactions with cells and tissues. The larger the agglomerates, the lower the ability to penetrate membranes and biological systems. However, nanoparticles can be easily oxidized in air and therefore lose partially or completely important properties, such as their surface reactivity, structural and magnetic characteristics, and their oxidative states (Lu, Salabas and Schuth, 2007). As a result, lately a significant amount of effort was spent on finding methods to stabilise these nanomaterials by the use of coatings that would limit

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat241

their degradation and possible biological undesired effects. Although most studies have focused on the development of polymer or silica protective coatings, carbon-protected magnetic NPs have recently received more attention (Seo *et al.*, 2006; Wang *et al.*, 2008; Xu *et al.*, 2008) due to carbon's relatively higher chemical and thermal stability, inertness, as well as its enhanced biocompatibility (Lu, Salabas and Schuth, 2007; Geng, Jefferson and Johnson, 2004). For example, carbon coated nanoparticles were reported to remain in the metallic state with positive effects on their magnetic properties (Vilas, Swati and Aharon, 2008). Core-shell nanostructures often exhibit improved physical and chemical properties over their single-component counterparts, which gives them a broader range of applications. Besides their protective roles, these coatings also offer means of attaching the complex structures to biological systems (antibodies, proteins, DNA, etc.) in order to target particular cell lines such as cancer (Xu *et al.*, 2008).

Radio frequency resonance heating is less invasive when compared with other types of electromagnetic radiations (lasers, microwaves, etc.) and possesses higher efficiency for absorption into magnetic structures that are delivered to localized cancer cells or tumors – thus potentially reducing the side effects associated with traditional cancer therapies (Xu *et al.*, 2008). It is known that the capacity of RF energy fields for tissue penetration is excellent (Bernardi *et al.*, 2003). For example, low-frequency RF radiation of 350 kHz has high tissue penetration abilities and therefore can be used for the treatment of both superficial and deep tumors. As a result, the RF treatment of tumors non- invasively should be possible in the conditions in which the heat-generating agents under RF exposure are delivered in sufficient amounts at the site of the tumor. Previous studies have indicated that the used of electromagnetic radiation for thermal ablation of tissues can induce tumor necrosis of over 1.6 cm in diameter (Scott Gazelle *et al.*, 2000). However, most tumors are significantly larger; therefore, in order to accomplish successful results, most of the treatments required several sessions and the used of multiple RF probes. Based on these considerations, the focus of a number of studies was to develop technologies that can generate high enough thermal levels to successfully and reliably induce tissue necrosis after only one application without damaging the healthy tissue (Scott Gazelle *et al.*, 2000).

Researchers have shown that low RF can induce death in HeLa cells containing magnetic nanoparticles after only several minutes of RF application, a process that is greatly enhanced by the aggregation of nanoparticles inside the cells (Xu *et al.*, 2010; Xu *et al.*, 2008). DNA fragmentation further confirmed the thermal damages produced by the nanoparticles under the RF excitation inside the HeLa Cells (Xu *et al.*, 2008).

Fe, Fe/Co, and Co NPs covered with layers of carbon were all synthesized by radio frequency–catalytic chemical vapor deposition (RF-CCVD) (Xu *et al.*, 2010). Atomic force microscopy (AFM) and transmission electronic microscopy (TEM) analysis revealed that the average size of the C–(Fe,Co and Fe/Co) was about 7–10 nm, with the mean and standard deviation of sizes measured by TEM for ∼100 nanoparticles in each sample. The NPs were covered with 2–8 layers of graphitic carbon, as shown in Figure 7b. XPS analysis data (Figure 8) showed that the metallic states of the Fe, Fe/Co, and Co NPs were well protected by the graphitic shells (Xu *et al.*, 2010).

Here, it was found that non-functionalized, graphitic-shelled nanoparticles can be effectively taken up into the cells (Xu *et al.*, 2010; Seminara *et al.*, 2007) The *in vitro* nanoparticles translocation inside the cells occurred mostly due to endocytosis, but also based on other processes that include: diffusion, membrane channels, and various adhesive interactions (Geiser *et al.*, 2005). However, the mechanism of cell uptake and the cellular fate of graphitic structural NPs is not fully understood; moreover, current descriptions are controversial, especially with respect to the cellular uptake of CNTs (Mahmood *et al.*, 2009; Smart *et al.*, 2008; Bulte and Kraitchman, 2004; Koistinen *et al.*, 2001; Douziech–Eryrolles *et al.*, 2007; Reiss and Huetten, 2005), their intracellular translocation, and their subcellular localization (Corot *et al.*, 2007; Lu *et al.*, 2004; Hyeon, 2003; Yavuz *et al.*, 2006; Seo *et al.*, 2006). A popular view is that NPs are taken up by cells through clathrin-dependent endocytosis (Koistinen *et al.*, 2001). Protein- or DNA-coated NPs have been shown to enter cells in an energy-dependent manner. Although the majority of published data agree with the endocytosis model, energy-independent cell uptake has also been reported (Mu, Broughton and Yan, 2009). Among all the properties of the nanoparticles, those that are believed to be the most important for their

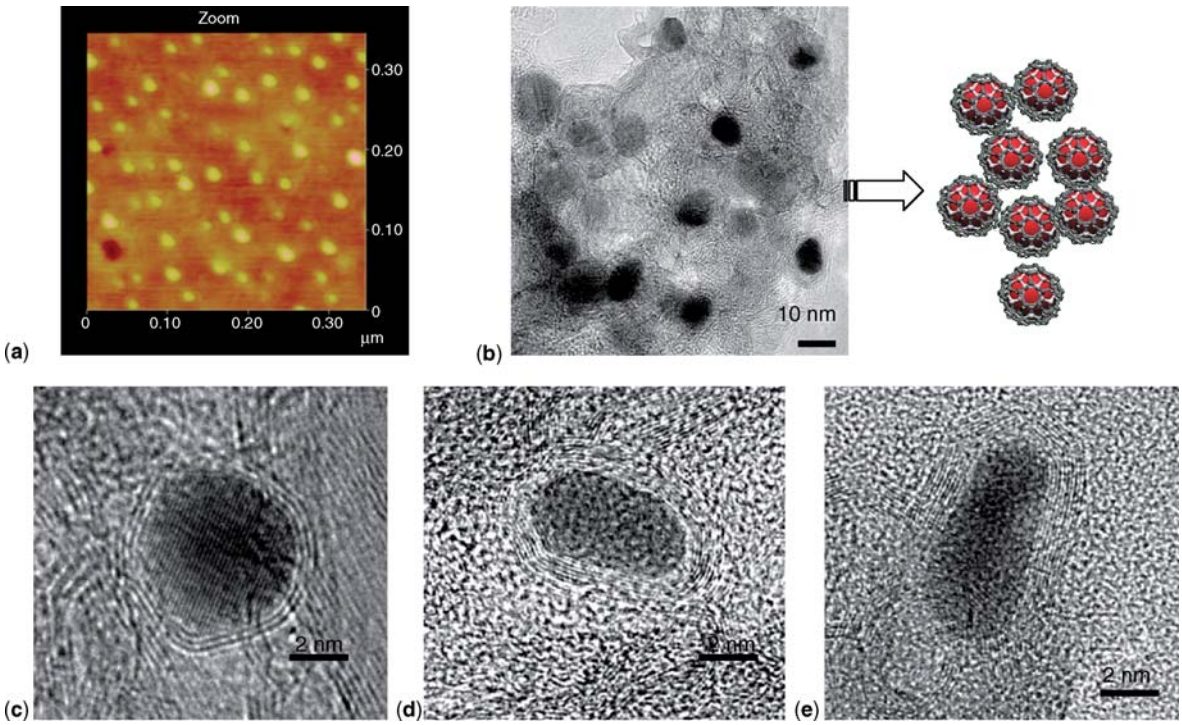

Figure 7. (a) AFM topographic images showing individual C–Co NPs. (b) Low- and (c–e) high-magnification TEM images of graphitic (c) C–Co, (d) C–Fe, and (e) C–Fe/Co NPs obtained by RF–cCVD method (Xu *et al.*, 2010).

translocation inside cells are size, type, and surface charge (Mu, Broughton and Yan, 2009; Rothen-Rutishauser *et al.*, 2006). Individually dispersed NPs in the medium solution used to feed the cells were visualized to aggregate around the nucleus and then penetrate inside (Xu *et al.*, 2008).

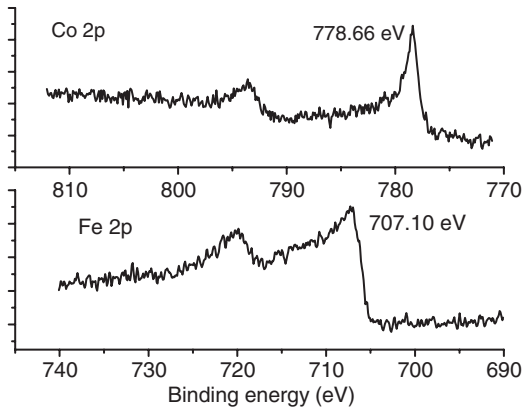

Figure 8. XPS spectra of the Co2p and Fe2p peaks represent the patterns of C–Fe and C–Co magnetic NPs (Xu *et al.*, 2010).

Cytotoxicity studies involving HeLa cells cultured with the C–Fe, C–Fe/Co, and C–Co NPs were carried out by EB/AO staining assay for cell viability. The results indicated that the great majority (99.4–99.7%) of the total cultured cells were alive (below the concentration of 50 $\mu g\,ml^{-1}$), revealing a low level of toxicity of these magnetic NPs – although the toxicity of nanomaterials inside living biological systems is still an intensively studied topic. Furthermore, it was found that RF radiation, alone, had scarcely any effect on the HeLa cells: 93.0–96.2% of these cells survived RF treatment, depending on the radiation time.

HeLa cells cultured with various concentrations of magnetic NPs were introduced inside a water-cooled coil coupled to a radiofrequency generator (Pillar, Brookfield, WI, TX, USA) with the frequency of 350 kHz (as shown in Figure 9), which is far lower than the 10 MHz to 300 GHz that is commonly used (Leea *et al.*, 2005). The depth of penetration of RF radiation in human tissue decreases as the frequency increases. The frequency of the AC electromagnetic field should be chosen

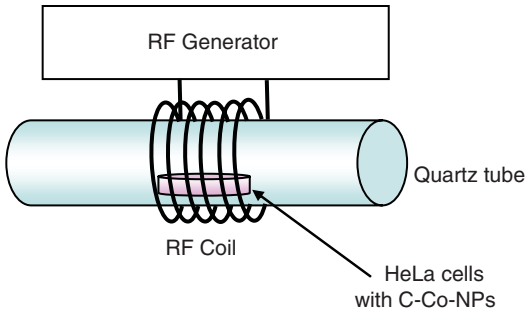

Figure 9. RF excitation setup (350 kHz, 5 kW) used for the thermal ablation of Hela cells (Xu *et al.*, 2008).

based on a compromise; namely, it must be higher than the frequency capable of provoking neuromuscular response and lower than the frequencies causing overheating of healthy tissues. It is believed that the frequency should be in the range 100–1000 kHz; in this case, correctly chosen frequencies and electromagnetic field strengths produce no notable *in vivo* side effects of the AC magnetic field (Nikiforov, 2007).

Three key factors – RF radiation time, concentration of NPs, and the species of NPs—determine the effect of RF exposure on biological cells or tissue. As shown in Figure 10a, after 2–30 min of radiation exposure with constant NP concentration, the number of dead cells gradually increased as RF heating time increased. During RF exposure times longer than 10 min, a rather slow increase in the percentage of dead cells was observed, mostly dependent upon the type of magnetic nanoparticles used in the study. For the C–Fe NP, after only 2 min of RF exposure, 67.0% of cells were observed to have died. Increasing the heating time to 30 min caused the percentage

of dead cells to reach about 74.5%. If the three types of nanoparticle were kept at the same low concentration (about 0.83 $\mu g\,ml^{-1}$), after the RF heating, C–Fe NPs exhibited the highest killing rate of the HeLa cells, as presented in Figure 10a, which is 2.14 and 2.69 times higher than that induced by the C–Fe/Co NPs and C–Co NPs, respectively. The results indicated that the C–Fe NPs were the best RF absorbers and induced cellular death in the shortest time and at the lowest concentrations (Xu *et al.*, 2010). As for the third factor, concentration of NP, if the exposure time was kept constant, the percentage of dead cells was found to be highly dependent on the NP concentration. As shown in Figure 10b, when the NP concentration was increased to 3.33 $\mu g\,ml^{-1}$, C–Fe NP killed almost 98.88–100% of the exposed cells with only 2 min of RF exposure. However, for the C–Co NP, a significantly higher concentration ($\sim$20 $\mu g\,ml^{-1}$) was required to cause the same effect (Xu *et al.*, 2008). From the aforementioned findings, we can conclude that the concentration of NP and the type of NP largely determine the cancer cell death.

The localized heating of NPs inside the cancer cells comes from the hysteresis heating and resistive heating through eddy currents generated under the RF radiation. As known, the resulting magnetic field induces eddy currents in the body, and the power is dissipated into heat by the Joule effect. In order to investigate the heating effects inside the HeLa cells, temperature changes in nanoparticles in powder form and nanoparticles dispersed in solution under RF were studied.

For the purpose of comparison, the surface temperature increase for the NP powder and the Co–NP dispersed in the medium solution with varying concentrations under RF heating for 5 min was continuously monitored and is shown in Figure 10c. The high-sensitivity thermal analysis indicated that the RF-induced temperatures, as well as their heating rates, rose and were found to be dependent mostly upon the mass of the NPs used for the measurements. The C–Fe NPs were shown to be the best hyperthermia agents because they were found to reach temperatures higher than the C–Fe/Co and C–Co NPs under identical RF exposure conditions (Xu *et al.*, 2010). When the NPs were individually dispersed in the medium solution, no significant level of heating was observed, and the temperature relatively constant (only a shift about 5 °C) with increasing the NPs concentration. Based on these experimental results, cell death is not expected to occur due to the bulk heating of the entire cell structures, but rather due to the localized heating where the NPs aggregate. The damage to cell membranes (especially of the nucleus), DNA fragmentation, protein thermal damages and denaturation occurred mostly at temperatures superior to 55 °C (Xu *et al.*, 2008). These studies are in good correlation with previous studies that have reported that, for the *in vivo* heating of up to 42 °C, about $\sim$1.2 mg particles per 1 cm^3 volume of tissue are required (Rothen-Rutishauser *et al.*, 2006). In this study, the NP concentrations used were too low (around 3.3–20 $\mu g\,ml^{-1}$) to allow for exact temperature measurements of the nanoparticles taken up by the cells (Xu *et al.*, 2008). The heat transfer between the nanoparticles and the liquid environment is largely governed by the heat transfer kinetic processes, and, the dimension of the nanoparticles or the size of their agglomerates inside the solution, that can vary from a few nm to several microns. However, RF radiation was found to be highly absorbed by the nanoparticles and which acted as thermal agents creating localized damage in various cellular sub-compartments (10–50 μm), which then induced the death of the cells (Xu *et al.*, 2010; Xu *et al.*, 2008). Besides the thermal effects induced by the RF irradiation inside the magnetic nanoparticles, this type of electromagnetic radiation can also make tissues and cells more susceptible to other types of cancer treatments, since the localized heating and breakage of the nuclear membranes facilitate the administration of various drug molecules (Xiang *et al.*, 2007).

The localized heating of carbon-shelled magnetic NPs that occurs under RF radiation could undergo an 'auto-heating' event–in that the NPs may generate their own heat energy based on molecular rotation. Rotation of particles is usually referred to as the Brownian rotation; rotation of the magnetic moment inside each particle is called the Néel relaxation under application of RF radiation (Kan *et al.*, 2005). The Néel relaxation time τ_N of the magnetic NPs under an external magnetic field is expressed by the following formula (Rosensweig, 2002):

$$\tau_N = \frac{\sqrt{\pi}}{2}\tau_0 \quad \frac{Exp(KV_M/k_BT)}{(KV_M/k_BT)^{1/2}}$$

where τ_0 is the relaxation time constant and has the order of 10^{-9} s, K is the anisotropy constant,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat241
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

and V_M is the magnetic volume of particles. τ_N for the Néel relaxation is determined by the ratio of the energy of magnetic anisotropy of superparamagnetic particles to the thermal energy (Rosensweig, 2002).

In the initial stage from 0 to 60 s, the temperature of the three NPs increased rapidly as shown in Figure 10d. After about 200 s, final temperatures of 65, 70, and 90 °C were reached for Co, Fe/Co, and Co NPs, respectively. This is due to the thermally stable spin rotation of the ferromagnetic NPs caused by the RF-induced hysteresis loss. The ferromagnetic NPs show hysteretic properties under a magnetic field, leading to magnetically induced heating. The amount of heat (power dissipation) generated per unit volume, W, is given by the frequency multiplied by the area of the hysteresis loop in the M–H coordinates caused by the hysteresis loss (Rosensweig, 2002):

$$W = -\mu_0 f_{\text{appl}} \cdot \oint H \cdot \mathrm{d}M$$

For ferromagnetic nanomaterials with sizes greater than those of superparamagnetic ones, there is no definitive frequency dependence with hysteresis loop surface; therefore, the heat generation level can be found from measurements using SQUID magnetometer. Figure 11 compares magnetization loops measured at 5 and 300 K for the C–Fe, C–Fe/Co, and C–Co NPs. C–Co nanostructures were observed to have a larger saturation magnetic induction (M_s), larger residual magnetization (M_r) and smaller coercivity (H_c) relative to C–Fe/Co or C–Fe

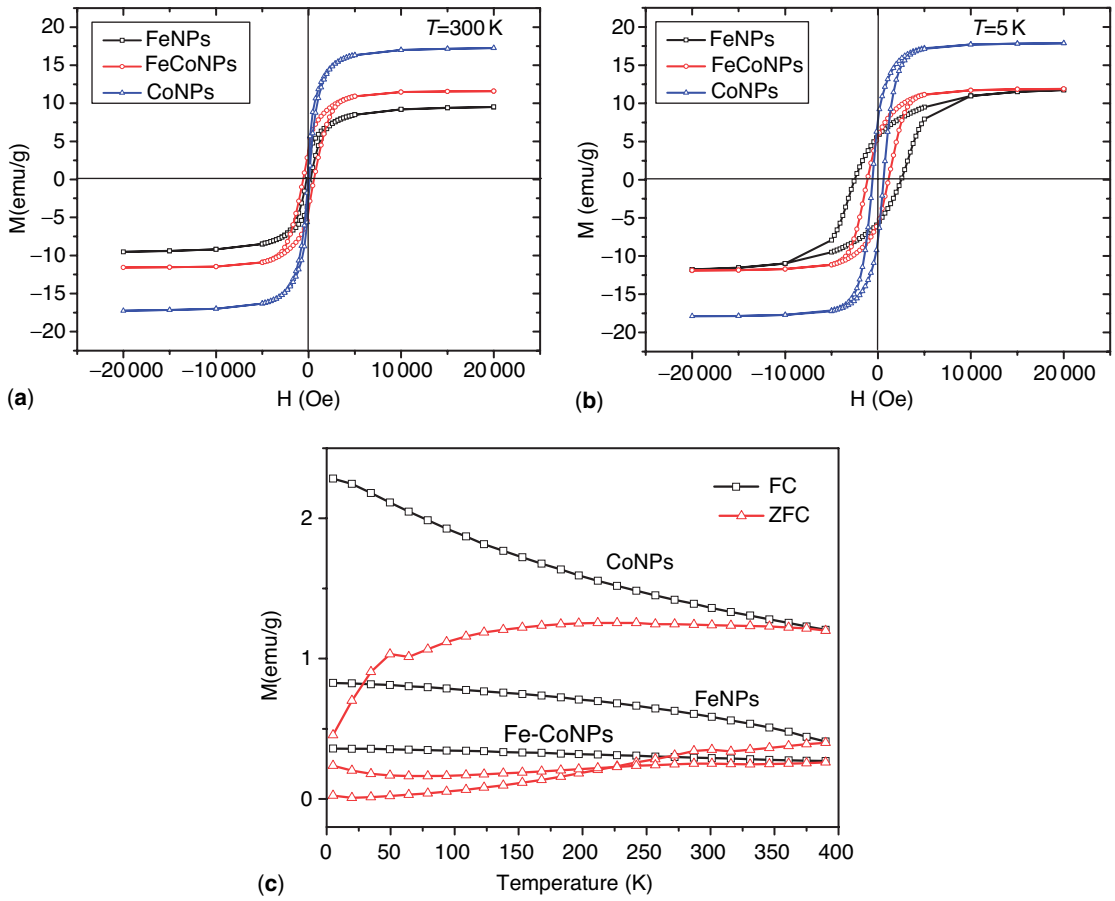

Figure 11. Magnetization curves of different magnetic NPs at (a) 300 K and (b) 5 K; (c) temperature dependence of ZFC and FC measurements recorded at a magnetic field of 30 Oe for these magnetic NPs (Xu *et al.*, 2010).

nanostructures. One cause is the nanoparticle size distribution. The specific energy absorption along with the heat generation capacity and integrated with the particle density will provide the thermal emission power per unit volume *W*, giving the efficiency of heating by using magnetic particles. This allows for the nanoparticles of various sizes to be compared to heat generators. The Fe and Co NPs in this work have sizes ranging from 7 to 15 nm. For this size, the Fe NPs are about the size of the Fe domain (14 nm); however, the Co NPs are much smaller than the Co domain size (70 nm) (Zhao *et al.*, 2008). As the Fe NPs are most probably composed of single domains, they exhibit the maximum possible coercivity for Fe because the Co NPs, which are much smaller compared with Co domain size, show a consequent diminished coercivity. This phenomenon is highlighted by almost no hysteresis loss for the Co NPs. Lately, the magnetically induced hyperthermia was drastically enhanced by the development of superparamagnetic liquids, composed by nanoparticles with one magnetic domain that are suspended in water (Zhao *et al.*, 2008; Jordan *et al.*, 2001). When a ferroliquid is removed from the magnetic field, its magnetization vanishes because of the thermal energy of the environment. Another cause is that the greater pairing of electrons in Co and the stronger nuclear charge of the Co atoms lead to less surface delta multi-bonding of Co surface atoms in the Co NPs relative to the Fe NPs. Such Co–C bonding lowers the coercivity of Co, which results in far more weaker magnetic properties relative to Fe NPs. Note that the magnetic hysteresis of Co NPs is almost zero at 300 K, indicating that the Co NPs are not agglomerated, and the NPs are superparamagnetic. However, the Fe/Co and Fe NPs have more agglomerations, as indicated by the larger hysteresis loops for these particles relative to Co NPs. As a result, Fe and Fe/Co NPs can generate more thermal energy than the Co NPs when they are exposed to the external AC field (Xu *et al.*, 2010).

A ferromagnetic particle becomes 'superparamagnetic' below a critical size of the order of 100 nm, depending on the material. Such a particle cannot develop internal magnetic domains and, therefore, acts as a paramagnetic particle with a magnetic moment of up to 10^7 Bohr magnetons. The blocking phenomenon is a characteristic of the superparamagnetic behavior which is correlated to the particle size and distribution, crystallinity, and interparticle interactions (Prozorov *et al.*, 1999). Each NP then becomes a single magnetic domain and shows superparamagnetic behavior when the temperature is above the so-called blocking temperature, T_B (Prozorov *et al.*, 2007).

At temperatures inferior to T_B, the nanoparticles are 'blocked', indicating that the random magnetic moments of the individual nanoparticles cannot easily align with the magnetic field, since the magnetic Zeeman energy (H) and thermal fluctuation (k_BT) levls are too low to overcome the energy barrier given by the magnetic anisotropy and interparticle dipolar interactions. T_B presents a peak in the $M_{(T)}$ curve developed during the heating process under a magnetic field application. It is well established that T_B is lower for smaller particles and for those with limited crystallinity; both properties are responsible for the reduction of the magnetic moment per particle (Prozorov and Prozorov, 2004). In parallel, it is also possible to analyze the magnetic properties of a superparamagnetic system by measuring its magnetic moment at a given temperature and varying the intensity of the magnetic field. Figure 11c shows the results of zero-field-cooled (ZFC) measurements performed upon warming after a magnetic field of 30 Oe was applied at 5 K after cooling in zero applied fields. Clearly, Co NPs exhibit the lowest blocking temperature at about 50 K. Fe and Fe/Co NPs show an elevated T_B of 300 K. These results were fully consistent with the results of TEM; that is, Co NPs are of a relatively smaller size and lower crystallinity than Fe and Fe/Co NPs (Xu *et al.*, 2010).

As shown in Figure 12a and b, after the NPs were taken up into the HeLa cell cytoplasm, they were able to cross the various intercellular membranes and reach the nucleus (Xu *et al.*, 2008). Due to the localized RF heating provided by the NPs, the cells were found to go through an apoptotic process and, subsequent cellular decomposition (one of the signs of apoptosis process, the cell membrane blebbing) was observed and is shown in Figure 12c. Compared with other NPs, as shown in Figure 12d–f, the C–Fe NPs revealed the highest efficiency for inducing cell death when compared with the C–Fe/Co NPs and C–Co NPs after 2 min of RF exposure. The disintegration of localized cellular environments, such as the nucleus, nuclear membranes, and DNA, was believed to be the effective response resulting from RF heat inducement into the NPs.

This initial cellular death screening process was confirmed by supplementary analyses, including

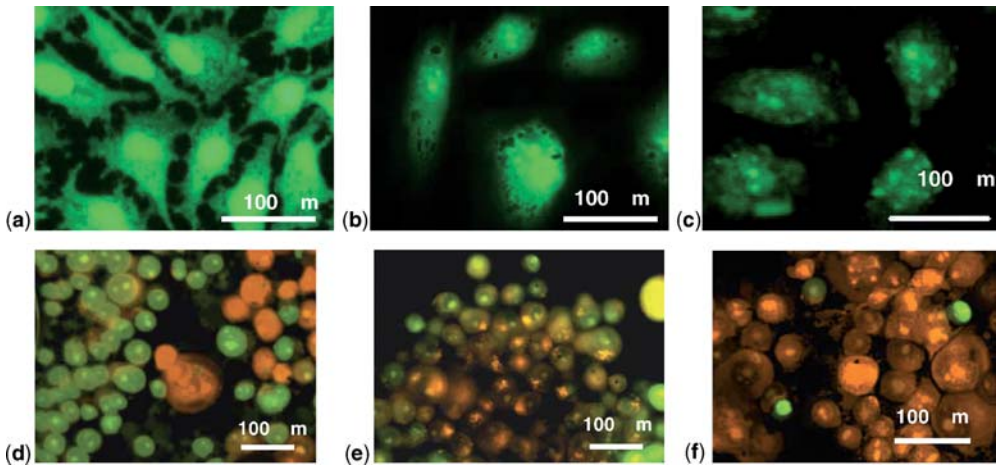

Figure 12. (a) Normal HeLa cells without incubation of magnetic NPs; (b) after 24-h incubation time, the magnetic C–Co NPs were found to aggregate around and further penetrate into the nucleus of HeLa cells. (c) The images took from the Olympus confocal microscopy indicating the membrane blebbing of HeLa cells incubated with magnetic C–Fe NPs after a 350 kHz RF heating for 2 min. Confocal microscopy images indicating the extensive live and dead cells after being incubated with the C–Co NPs (d), C–Fe/Co NPs (e), and C–Fe NPs (f) after exposure to RF radiation for 2 min. The cells were stained to distinguish between the live (green for acridine orange) and the dead cells (orange for ethidium bromide) (Xu *et al.*, 2010).

cellular morphology studies and agarose gel electrophoresis to detect oligonucleosomal ladders – a reliable indicator of the cellular apoptosis. From the gel electrophoresis analysis (Figure 13), it can be observed that, in comparison with that collected from the control cells (unexposed to any treatment) the DNA collected from the cells exposed to the cobalt nanoparticles under RF exposure indicated a significantly greater broadening of the DNA spectra. The nuclear DNA was found to degrade into fragments of about 2000–100 bp as presented in Figure 6. These results indicate chemical and structural modifications (Zhu *et al.*, 2007) of the DNA bases and the probable breakage of the DNA double strands – a process that can induce mitotic recombination, point mutations, and chromosomes loss and translocation.

In conclusion, the area of nanomedicine and cancer treatment will be transformed in the next few years by the use of nanomaterials with advanced bioactivity properties. The use of nanostructures in conjunction with various biological systems, such as drugs, proteins, growth factors, and DNA, will have an extraordinary impact on a broad range of applications for treating diseases and conditions: cancer treatment, tissue regeneration, biological sensors, drug delivery, and others. The selective delivery and molecular tumor cell targeting with high specificity and optimized nanostructure parameters have to be developed for clinically relevant treatments. Further validation of this approach will use more quantitative imaging and biological methods to explore the

1 NANOTECHNOLOGY

Nanotechnology can be defined as the manipulation, precision placement, measurement, modelling or manufacture of materials at the nanometre (nm) scale (Donaldson *et al*., 2001). The era of nanotechnology proposes to provide lighter, stronger, smaller, more efficient and durable products such as stain-free clothing, as well as environmental remediation, and can be further described as the manufacturing of materials or particles <100 nm in size (Reijnders, 2006). Since the naturally occurring or biologically based molecules found within organisms can be used as model nano-sized materials (Oberdorster, Oberdorster and Oberdorster, 2005), a comparison to these molecules and atoms, definitive in their size, can further characterize the scale on which nanotechnology is based. For example, 1 nm, or 1 billionth of a metre (10^{-9} m), is the diameter of 10 hydrogen atoms, 4 nm is the size of a single protein molecule, 1000 nm is equal to the size of a pollen grain and 10,000 nm can be equated to the average length of one human hair follicle (Whitesides, 2003).

It is proposed that nanotechnology involves manufacture at three specific levels: (i) materials, (ii) devices and (iii) systems (Salata, 2004). There have been many recent advances in nanotechnology, although only at the material level, including computer technology and washing machines, as well as lighter, faster and stronger sporting equipment (Mamalis, 2007). The proposed advantages of nanotechnology, however, are still not completely defined or even fully understood (Whitesides, 2003). In addition, increased public attention has further highlighted possible disadvantages of nanotechnology (Bruce, 2006; Rogers-Hayden and Pidgeon, 2006), as well as the potential deleterious and detrimental effects that this new form of technology might pose (Hoet, Bruske-Hohlfeld and Salata, 2004; Borm *et al*., 2006; Gwinn and Vallyathan, 2006; Maynard, 2007; Nel *et al*., 2006).

Despite this, the nanotechnology industry is a rapidly developing field, with the amount of money

invested into its research and development, as well as the economic value of the industry increasing continuously every year (Maynard *et al.*, 2006; Maynard, 2007). Concomitant with this increase is the level of nanotechnology-related products manufactured and distributed for use in a wide and diverse range of consumer, industrial and technological applications, such as clothing, cosmetics, computer technology, household paints, medicine and sporting equipment (Maynard, 2007). Due to the constant influx of nanotechnology-related products in these areas, it is essential that rigorous assessment of their risk to both humans and the environment is conducted, in order to implement a set of stringent safety guidelines for their production, use and disposal, so that the promise surrounding the industry can be realized (The Royal Society and Royal Academy of Engineers Report 2004; Hoet, Bruske-Hohlfeld and Salata, 2004; Maynard *et al.*, 2007).

1.1 What is a Nanomaterial?

Nanomaterials have been defined as "a material that has one or more external dimensions in the nanoscale or which is nanostructured (nanomaterials can exhibit properties that differ from those of a material which does not have nanoscale features)" (BSI PAS: 136, 2007). Although it is recognized that the definition of a nanomaterial is different from that of a nanoparticle (NP), it is often assumed that both are synonymous. The definition of an NP is difficult to confirm and is under constant debate. In some instances, combustion-derived NPs are referred to as "ultrafine (uf) particles" (a term predominantly associated with NPs present within ambient/environmental air pollution), and described as particles with a diameter of <100 nm (BSI PAS: 136, 2007). In addition, a report published by the European Science Foundation, concerning nanomedicine, stated that the NP complexes used in nanomedicine range from 1 to 1000 nm (ESF Report, 2005). Despite this, due to the diverse range of shapes and structures that comprise the many different forms of NPs (Oberdorster, Oberdorster and Oberdorster, 2005), as well as the extensive number of reports on contrasting definitions for nanomaterials (SCENIHR, 2005, 2007; Friends of the Earth, 2006; BSI PAS: 136, 2007) the International Organization for Standardization (ISO), in a recent attempt to develop a more structured approach, provided the following definition (ISO/TS: 27687, 2008). In a document entitled "Nanotechnologies – Terminology and definitions for nano-objects – nanoparticle, nanofibre and nanoplate", the ISO defined an NP as "a nano-object (a material with one, two or three external dimensions in the nanoscale (1–100 nm)) with all three external dimensions in the nanoscale" (ISO/TS: 27687, 2008). NPs, however, comprise a diverse number of materials such as carbon, titanium, gold, polystyrene, cadmium, iron and zinc, and can be either accidentally produced (also referred to as naturally occurring NPs (Section 1.2.1)), or specifically engineered (Section 1.2.2) (Oberdorster, Oberdorster and Oberdorster, 2005); thus, due to this plethora of different shapes, sizes, materials and intended applications, the debate surrounding the definition of an NP will continue. For the purpose of this chapter, NPs will be referred to in accordance with the definition as provided by ISO (ISO/TS: 27687, 2008).

1.1.1 Accidentally Produced NPs

Naturally occurring NPs have been experienced by humans across all evolutionary stages (Oberdorster, Oberdorster and Oberdorster, 2005; Oberdorster, Stone and Donaldson, 2007). Examples of naturally occurring NPs include particles derived from volcanoes and fires (Oberdorster, Oberdorster and Oberdorster, 2005; Oberdorster, Stone and Donaldson, 2007). Over the past two centuries due to industrial development, the invention of the car engine as well as other combustion processes have resulted in a rise in the level of air pollution, as well as the amount of unintentional, or accidental NPs released into the atmosphere (Oberdorster, Oberdorster and Oberdorster, 2005). Within the workplace, NPs have also been found, for example, to be present in the emissions from welding fumes (Zimmer, Baron and Biswas, 2002) and natural gas-powered equipment (Rundell, 2003), whereas in the environment, power plant emissions (independent of being powered by coal, oil or natural gas) have been observed to produce large amounts of NPs into the atmosphere (Oberdorster, Oberdorster and Oberdorster, 2005). The major source of accidentally produced NPs in the environment, however are traffic exhaust emissions (Oberdorster, Oberdorster and Oberdorster, 2005). Also known as combustion-derived NPs, these emissions can

increase the number of particles in the air by up to ten million particles per cm^3 (Kittelson, Watts and Johnson, 2004). The effects of exposure to increased levels of particulate present in polluted air have been well documented over the past 20 years, demonstrating accidental NPs to be associated with adverse health effects, such as cardiovascular disease and chronic obstructive pulmonary disease (COPD) (Donaldson *et al.*, 2003), compared with their larger particle counterparts at the same mass dose (Oberdorster, Oberdorster and Oberdorster, 2005). (The effects following exposure to NPs contained in polluted air are discussed in Section 4.) Findings from studies investigating the toxicity of NPs present in polluted air have prompted concerns regarding the possible hazardous health effects of exposure to engineered NPs on human health and the environment (Colvin, 2003; Moore, 2006; Maynard *et al*., 2006).

1.1.2 Engineered NPs

Engineered NPs can be defined as particles engineered or manufactured on the nanoscale with specific physicochemical compositions and structures to exploit properties and functions associated with their dimensions (Oberdorster, Oberdorster and Oberdorster, 2005; Oberdorster, Stone and Donaldson, 2007). Furthermore, engineered NPs include particles that have either a homogeneous or heterogeneous chemical composition or structure, or are multi-functional and can be of different shapes, for example spheres, fibres, tubes, rings and planes (Oberdorster, Oberdorster and Oberdorster, 2005). Examples of these include: (i) carbon nanotubes (CNTs) – graphite-like carbon tubes with capped ends, which can be either a single graphite-like carbon tube, known as single-walled CNTs (SWCNTs), or a series of SWCNTs that can be either stacked inside one another or a single CNT rolled inside of itself, known as multi-walled CNTs (MWCNTs) (Donaldson *et al*., 2006); (ii) C_{60} fullerenes – complex, semi-conductor, spherical 3D carbon structures (Jensen, Wilson and Schuster, 1996); (iii) superparamagnetic iron oxide nanoparticles (SPIONs) – spherical NPs consisting of an iron (Fe) core, coated with a shell material (usually gold (Au)) (Gupta and Gupta, 2005), and (iv) dendrimers – a symmetrical arrangement of macromolecule branches arising from a multi-functional core (Duncan and Izzo, 2005). In addition, the specific physicochemical properties of engineered NPs can be manipulated to create different surface coatings/charges surface chemistries and surfactants, such as organic (neutral charge), carboxylated (COOH) (negative charge) and amino (NH_2) or amine (positive charge); as well as for the ability to attach polymer groups and biologically based structures (Oberdorster, Oberdorster and Oberdorster, 2005).

Despite the vast array of manufactured NPs already in use for a wide range of applications (Section 1.1), newly engineered NPs are constantly being generated to meet the increased demand for smaller, lighter, faster, more efficient and durable products (Maynard, 2007). The potential toxic and adverse health effects of these "new" NPs, however, are not fully understood (Hoet, Bruske-Hohlfeld and Salata, 2004; Maynard, 2007; Nel *et al*., 2006). Therefore, it is vital that efficient, model ways of analysing the diverse physiochemical components of manufactured NPs are determined, in order to fully understand both the potential detrimental and advantageous effects of engineered NPs (Maynard *et al*., 2006).

2 THEORY OF TOXICOLOGY

Toxicology is the study of the adverse effects of substances on living organisms (Timbrell, 1999). One of the fundamental principles of toxicology is that the "risk" posed by a substance is a function of its potential to cause harm, or "hazard," and the amount of substance a biological system is "exposed" to. This is defined by the following principle:

$$\text{Risk} = \text{Hazard} \times \text{Exposure}$$

It is necessary to consider exposure levels of substances according to the principle that all materials are toxic if exposure occurs in sufficient quantities (Timbrell, 1999). Most commonly this principle is referred to via the quote of *Paracelsus* (CH, 1493-1541). "*All things are poison and nothing is without poison, only the dose permits something not to be poisonous*." These fundamental toxicology principles imply that substances with a low hazard generally pose a low risk. If, however, there is a high enough exposure to these low-hazard substances, even these can be harmful, or even fatal.

3 NANOTOXICOLOGY – A DEFINITION

Based on the principles of toxicology, nanotoxicology can be defined as "the study of the effects of NPs (either accidentally produced or engineered) on living organisms" and further described as a multidisciplinary science including material science, chemistry, physics and medicine (Donaldson *et al*., 2004). The field of nanotoxicology focuses upon gaining a thorough understanding of the relationship between properties such as particle size, surface area and reactivity, dose (concentration), material composition and the potential toxicity of NPs. In relation to this, it is also proposed that nanotoxicology will develop and implement "nano-specific" protocols in order to investigate and gain the knowledge necessary to determine the suggested toxicity (Section 4) of the plethora of different NPs.

4 NANOTOXICOLOGY – A BRIEF REVIEW

As a complete review of nanotoxicology is beyond the scope of this chapter, the following section is only a brief review of the history of nanotoxicology and its current state. For a complete overview of the field of nanotoxicology, the readers may refer to both Oberdorster, Oberdorster and Oberdorster (2005) and Oberdorster, Stone and Donaldson (2007)

4.1 A historical Perspective of NPs and Their Associated Health Effects

The concern surrounding the exposure of humans to NPs (mainly) derives from their small size and emanates from two independent findings that separately recognized that as particle size decreases, toxicity generally increases.

One of the initial studies to demonstrate the potentially harmful effects of exposure to NPs was by Ferin, Oberdorster and Penney (1992). In this study, rats were exposed, via inhalation, to both NP (21 nm diameter) and fine (250 nm diameter) titanium dioxide particles (TiO_2), as well as intratracheally instilled with TiO_2 particles of various sizes (12, 21, 230 and 250 nm in diameter) over a period of 12 weeks. The effects of treatment with each particle size were then observed over a 70-week post-exposure period. It was demonstrated that TiO_2 NPs promoted an acute inflammatory response following both intratracheal instillation and subchronic inhalation techniques compared with the larger particles (230 and 250 nm). The inflammation observed in exposed animals was subsequently found to reduce to control levels post-exposure (64 weeks), with a noted decrease (from peak levels) in the number of neutrophils present in the lung at that time. Ultrafine particles were also found to remain within the lung longer (501 days) than fine particles (174 days). The prolonged retention of TiO_2 NPs in the lung was suggested to be an effect of the finding that at equivalent masses, NPs were able to translocate to the pulmonary interstitium more efficiently than the larger TiO_2 particles. It was suggested that the translocation of NPs to the interstitium was due to the smaller particles (12 and 21 nm) not being taken up by alveolar macrophages and undergoing clearance from the alveoli via uptake by alveolar type-1 epithelial cells instead. In addition to this, it was found that an increased dose (increased number of particles and decreased particle size) promoted movement of particles within the pulmonary system. It was also observed that the number of particles present, particle size, delivered dose and the delivered dose rate also had an effect on the translocation process. Ferin, Oberdorster and Penney (1992) concluded that the observed inflammation was due to the exposure of the rat lung to NPs, impaired lung clearance and NP redistribution.

In a subsequent publication, these findings were supported by Oberdorster, Ferin and Morrow (1992), who showed increased levels of inflammation present in the alveolar space of rats after instillation with 500 μg TiO_2 NPs (20 nm) over 24 h, compared with TiO_2 fine particles (250 nm) at the same mass dose. It was also found, in comparison to Ferin, Oberdorster and Penney (1992), that NPs were able to enter the interstitium more readily than the larger TiO_2 particles. Oberdorster, Ferin and Morrow (1992) further suggested that the increased inflammatory response to acute NP exposure was not due to the movement of particles to the interstitium, but it was related to the larger surface area of the particles and their interaction with alveolar macrophages and interstitial cells. Focusing on alveolar macrophages, it was noted that they were effective inhibitors of the inflammatory response to NPs due to the active uptake of these particles. The findings of both Ferin, Oberdorster and Penney (1992) and Oberdorster, Ferin and Morrow (1992) promoted interest in the effects of NPs in the lung,

as well as the possible adverse effects on respiratory and cardiovascular function that exposure to NPs might pose.

In addition to laboratory investigations, epidemiological studies conducted over the past two decades have shown a positive correlation between the level of particulate air pollution and increased adverse health effects (Dockery *et al*., 1993; Bremner *et al*., 1999; Braga, Zanobetti and Schwartz, 2000), including increased pulmonary diseases (Choudhury, 1997; Pope and Dockery, 1999; Schwartz, 2004), as well as a rise in the number of deaths from cardiovascular disease (Abbey *et al*., 1999; Aga *et al*., 2003; Zanobetti *et al*., 2003; Kaiser *et al*., 2004; Medina *et al*., 2004). It was specifically shown that these adverse health effects manifested predominantly in susceptible individuals who had pre-existing pulmonary or cardiovascular disease following increased exposure to areas of heightened particulate air pollution (Dockery *et al*., 1993; Pope and Dockery 1999). To determine the levels of particulate air pollution, or particulate matter (PM), these studies used the global sampling method of PM. This method collects all airborne PM that has an aerodynamic diameter of $\leq$10 μm, via a machine with a size-selective inlet of $\leq$10 μm and 50% efficiency (Donaldson *et al*., 2001). The composition of PM_{10} is complex and difficult to define exactly; thus, it is termed as a "particle cocktail," comprising a wide variation of particulate materials, including carbon, a complex mixture of metals, exhaust fumes, endotoxins, wind-blown dusts and a mixture of chemicals ranging from $>$2.5 μm to $<$100 nm in size (Wilson *et al*., 2002). All of the components are thought to contribute to the observed toxicity and reducing effects of PM on human health (Donaldson *et al*., 2003). Despite this, the NP component of PM_{10} has been held principally accountable for eliciting the adverse health effects that were highlighted in these epidemiological studies. This led to the generation of the "ultrafine hypothesis" (Seaton *et al*., 1995), whereby NPs ($<$100 nm) were considered to be particularly hazardous and to drive the adverse effects to human health, specifically within the lung. It is also relevant to note that these findings and suggestions were in agreement with those of Ferin, Oberdorster and Penney (1992) and Oberdorster, Ferin and Morrow (1992), whereby smaller particles were potentially of greater risk to health than larger particles of a similar material. This hypothesis was subsequently supported in an epidemiological study by Peters *et al*. 1997, who reported that human respiratory ill health was associated with the number of ambient uf particles inhaled. In the study by Peters *et al*. (1997), 27 non-smoking asthmatics, who resided within a highly polluted city in Central Europe, were examined over a 6-month period. Analysis of the peak expiratory flow (PEF) of the lungs for each individual volunteer demonstrated the number of uf particles in the air to have a significant mean decrease on PEF, compared with the mass of larger particulates in the atmosphere. It was concluded, therefore, that the adverse health effects observed following exposure to PM_{10} could be related to the size distribution of particulates in the environment, thereby supporting the theory that NPs could potentially drive toxicity in the lung. Although there are a number of additional epidemiological studies that have studied particulate effects on human health (Wichmann *et al*., 2000; Schulz *et al*., 2005), further epidemiological studies are still required in order to support the findings of the plethora of laboratory-based investigations.

Despite the shortage of epidemiological studies, the hypothesis of Seaton *et al*. (1995) has been the basis of increased experimental, laboratory-based analysis over the past two decades. In a study by Li *et al*. (1997), PM_{10} samples were examined *in vivo* and *in vitro*. Following intratracheal instillation of PM_{10} in rats for 6 h, an increase in inflammation (increased neutrophil count) and toxicity (increased levels of lactate dehydrogenase (LDH)) was measured in the bronchoalveolar lavage (BAL) fluid, as well as an increase in BAL protein, indicative of increased epithelial permeability. Further analysis of the BAL fluid found depletion in glutathione, indicating an increase in oxidative stress. It was also observed that PM_{10}-treated BAL leucocytes *in vitro* produced a significant increase in the level of tumour necrosis factor (TNF)-α, suggestive of increased inflammation in PM_{10}-exposed lung cells. Due to the diverse range of materials in PM_{10} it is difficult to replicate in a laboratory environment for experimental purposes, and therefore many studies have used surrogates of PM_{10}, such as fine ($>$100nm) carbon black (CB) and its NP counterpart, ufCB. Subsequent analysis of the effects of ufCB *in vivo*, following intratracheal instillation, demonstrated that these smaller particles were able to cause a greater level of inflammation compared with both fine CB and PM_{10}. Subsequent comparative analysis of CB and ufCB by Li *et al*. (1999), in which a

mass of 125 μg of each particle type was instilled into rats, also reported ufCB to induce greater pro-inflammatory effects than CB. A 50% increase in neutrophils was observed in the alveolar region of the lung following BAL of rats exposed to ufCB, compared with CB particles after 6 h of exposure. Subsequent analysis of the BAL profile of the ufCB-instilled rats after 6 h, compared with rats exposed to CB, also showed an increase in LDH, indicative of cell damage (increased cell membrane permeability), as well as a rise in total BAL protein, suggestive of increased epithelial cell permeability. It was shown, however, that both particle sizes (ufCB and CB) caused a decrease in glutathione content in the lung, indicating that both ufCB and CB induce oxidative stress in the lung, although the highest levels of depletion were observed in rats treated with ufCB. In conclusion of these findings, Li *et al*. (1999), in comparison to Oberdorster, Ferin and Morrow (1992), suggested that the biological reactivity of ufCB was related to the size and surface area of the particle type.

The findings of both Li *et al*. (1999) and Oberdorster, Ferin and Morrow (1992) were supported by Brown *et al*. (2001) who examined the effects of the instillation of 64, 202 and 535 nm engineered polystyrene beads (PBs) in rats. It was discovered that treatment of 64 nm PBs induced an increased inflammatory response via an influx of neutrophils, LDH and protein in BAL fluid from the rat lung compared with exposure to both the 202 and 535 nm sized PBs. Further analysis of the BAL fluid found a depletion in glutathione also showed that the surface area of the particles instilled into the rats was relative to the level of inflammation in the rat lung, and therefore a proportional relationship between particle surface area and inflammation existed. Therefore, Brown *et al*. (2001) concluded that as the 64 nm PBs had a greater surface area than both the 202 and 535 nm PBs, NPs have the ability to cause a greater level of inflammation than their larger particle counterparts at the same mass dose due to a greater surface area and reactivity. These findings were subsequently supported by Duffin *et al*. (2002, 2007), who demonstrated a number of low-toxicity particles (TiO_2, CB and PBs), at different sizes *in vivo*, to cause a heightened inflammatory response, via an increased neutrophil count in BAL fluid from the rat lung between 18 and 24 h after exposure to particles <100 nm in size. A recent study by Stoeger *et al*. (2006) also showed the specific surface area of NPs to be related to their potential to induce pro-inflammatory cytokine production in mice. It was observed by Stoeger *et al*. (2006) that mice instilled with 5, 20 and 50 μg of a series of different particles, including flame soot particles, spark-generated uf carbon particles (ufCPs) and diesel exhaust particles (DEP), ranging in their surface area from 30 to 800 $m^2\ g^{-1}$, caused increased levels of LDH, total protein, TNF-α, interleukin (IL)-1β and macrophage inflammatory protein-2 (MIP-2), as well as polymorphonuclear leucocytes (neutrophils) (PMNs) in BAL fluid after 24-h exposure. Investigation demonstrated that the ufCPs were more potent than the other particles tested, and that the inflammatory indicators were not detectable when the instilled dose was $\leq 20\ cm^2$. It was subsequently concluded by Stoeger *et al*. (2006) that although the surface area of particles indicates their ability to cause inflammation, with uf particles causing an increased pro-inflammatory gene expression compared with larger particles, a threshold may exist in relation to the surface area of NPs and their relevant toxicity. The findings of these studies support the hypothesis that NPs have the potential to drive toxicity in the lung, and that they are responsible for the subsequent adverse health effects observed (Seaton *et al*., 1995). In addition, although these studies are limited to only a few specific NP types (predominantly CB, PBs and TiO_2), it is suggested that the specific characteristics of particle size, particle mass dose, surface area and surface reactivity are associated with NP toxicity in general.

Although it is well documented which characteristics influence NP toxicity, the precise mechanism by which this observed toxicity occurs is not fully understood. Despite this, as a result of increased laboratory-based investigations that have been highlighted in this section, a paradigm termed the "oxidative stress paradigm" was proposed suggesting the manner in which NPs can cause adverse effects to cells (Donaldson *et al*., 2003).

4.1.1 The Oxidative Stress Paradigm

Oxidative stress occurs when a greater number of oxidants than antioxidants are present within the cell, causing an oxidant/antioxidant imbalance (MacNee, 2001). Increased oxidation can occur within cells, such as macrophages following activation (Donaldson *et al*., 2003). The activation of

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

macrophage cells can cause the generation of the superoxide anion, which is readily converted into the hydroxyl radical ($^{\cdot}OH$) via the influence of superoxide dismutase (MacNee, 2001). The presence of the $^{\cdot}OH$, as well as the superoxide anion, which are examples of reactive oxygen species (ROS), can thus cause increased oxidation within the cell because these molecules possess unpaired electrons and are highly unstable (MacNee, 2001). Additionally, ROS can be produced via nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, which is the most common form of ROS found in cells, and is usually produced when cells are performing the phagocytosis of xenobiotics (MacNee, 2001). Therefore, this suggests that although cells purposefully clear hazardous particles from the tissue, the phagocytosing cells can unintentionally or intentionally produce ROS. In addition, the potential production of ROS following encapsulation of particles via phagocytosis further emphasizes the necessity to understand the specific uptake mechanism of NPs, in order to determine their potential route within the cell, and how their uptake may relate to their toxicity.

The production of ROS and subsequent oxidative stress in cells can be extremely deleterious, causing a reduction in cell metabolic competence via a reduction in mitochondrial respiration, as well as an increase in pro-inflammatory cytokine production. The effects of ROS production and subsequent oxidative stress can further be associated with diseases and illnesses such as pulmonary and cardiovascular diseases, including asthma, COPD, as well as atherosclerosis and even tumour formation (Donaldson *et al*., 2003).

In a study by Stone *et al*. (1998), the potential for NPs, specifically ufCB, to cause oxidative stress was assessed in A549 epithelial cells. Cells were measured for their glutathione content to determine the level of oxidative stress present. Glutathione is the most abundant non-protein thiol present inside most cells, and it is essential for maintaining cell viability by detoxification of pathogens, as well as by regulating cell cycle and gene expression (Droge *et al*., 1994). A reduction in the glutathione content of cells, therefore, is known to indicate an oxidative stress environment (Stone *et al*., 1998). It is also known that glutathione can have a protective role following the onset of oxidative stress, due to its antioxidant gene characteristics (MacNee, 2001). Antioxidant genes are common throughout cells, such as the c-*fos* gene. This gene is part of a series of growth- and differentiation-related genes that are expressed by cells in response to foreign materials (MacNee, 2001). It is thought that antioxidant genes are "switched on" following NP stimulus, which can thus overwhelm the NP effect (Donaldson *et al*., 2003). Research into these effects, however, is limited and requires further investigation. In relation to the potential for NPs to induce oxidative stress, it was observed by Stone *et al*. (1998) that following treatment of A549 epithelial cells with up to 0.78 $\mu g\ mm^{-2}$ of ufCB and CB, the glutathione levels, as measured specifically in its reduced form (GSH), decreased after 2 h, with a significant decrease also found after 6-h exposure to ufCB, but not to CB. It was subsequently concluded by Stone *et al*. (1998) that ufCB is more potent at inducing oxidative stress than its larger counterpart, CB. Li *et al*. (2003) further studied the potential for NPs to induce oxidative stress in cells. In the study by Li *et al*. (2003), the effects of ambient (25–10 μm), fine ($<2.5\ \mu m$) and uf ($<0.1\ \mu m$) particles on RAW 264.7 macrophage cells and BEAS-2B epithelial cells were assessed. It was observed that NPs, in comparison to both ambient and fine particles, induced an increased cellular expression of heme-oxygenase-1 (HO-1) expression in each cell line, indicative of oxidative stress, as well as a decrease in intracellular glutathione levels. High levels of ROS production were also demonstrated following dithiothreitol (DTT) analysis. Further examination of the different particle types by transmission electron microscopy (TEM) showed the NPs, as well as a small amount of larger particles, to predominantly locate within mitochondria, causing subsequent major structural damage thought to contribute to increased oxidative stress (decrease in GSH) and toxicity previously observed. It was therefore concluded that the increased biological potency of NPs can be associated with the redox cycling of organic chemicals due to their increased ability to damage the mitochondria, causing ROS and oxidative stress.

Recently, Xia *et al*. (2006) also showed ufCB, in comparison to TiO_2 and CB, to cause an increased production of ROS, as measured via the ROS quencher, furfuryl alcohol, as well as by assessment of the level of NADPH peroxidase with RAW 264.7 macrophage cells over a 4- and 16-h period. Subsequent analysis of the oxidative stress levels in these macrophage cells found depletion in GSH levels, as well as toxic oxidative stress after similar

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242

exposure periods. It was further illustrated that the toxic oxidative stress observed was specific to an injury to mitochondria due to increased cytosolic calcium (Ca^{2+}) production and uptake, causing structural damage to the organelle.

Ca^{2+} is an essential and ithe most abundant mineral in the body (Alberts *et al*., 2002). Maintaining normal Ca^{2+} levels ($\sim 155 \pm 9$ nM) within the cell, also known as Ca^{2+} homeostasis, is essential for cell viability (Abbas and Lichtman, 2003). The finding by Xia *et al*. (2006) that an increased Ca^{2+} production (signalling) can occur in cells following exposure to NPs supports previous studies that have suggested the increase of cytosolic Ca^{2+} to be associated with the onset of increased ROS production and subsequent oxidative stress (Stone *et al*., 2000a, 2000b; Brown *et al*., 2000, 2004, 2007a; Donaldson *et al*., 2003). Stone *et al*. (2000b) initially showed that ufCB exposure for 30 min to Monomac 6 (MM6) human macrophage cells induced a 1.6-fold increase in the resting cytosolic Ca^{2+} concentration, measured using the Ca^{2+} chelator Fura 2-AM (Grynkiewicz, Poenie and Tsien, 1985), in MM6 cells at a concentration of 66 $\mu g\, m^{-1}$, whilst no changes were observed following treatment of MM6 cells with CB. Subsequent investigation by Stone *et al*. (2000a) examined the effects of CB, both fine and uf (33 $\mu g\, ml^{-1}$), and latex beads (64, 202 and 535 nm in diameter) (1 mg ml^{-1}) on MM6 cells and primary rat macrophages. Analysis of the latex beads showed a 2.3-fold increase in cytosolic Ca^{2+} concentration (as assessed via Fura 2-AM) in response to thapsigargin stimulation following treatment with the 64 nm latex beads; however, no effects on MM6 cell Ca^{2+} concentration were observed following treatment with either the 202 or 535 nm latex beads. In this study, thapsigargin was used to assess the viability of the cells via Ca^{2+} signalling. This chemical stimulant causes release of Ca^{2+} from the endoplasmic reticulum (ER); a loss of cell viability, via apoptosis, can be related to a loss of Ca^{2+} in the ER store and therefore a reduced Ca^{2+} response to thapsigargin stimulation. Similarly, Stone *et* al. (2000a) showed a 2.6-fold increase in Ca^{2+} in BAL cells (>80% macrophages) following stimulation with thapsigargin and after exposure to ufCB, but not to CB. These latter findings support those previously reported by Stone *et al*. (2000b) that ufCB can cause an increase in cytosolic Ca^{2+} concentration, and further demonstrate that different macrophage types (MM6 and primary rat macrophages) can elicit similar responses following NP exposure. Further analysis by Stone *et al*. (2000a), demonstrated that these effects were attenuated when the MM6 cells were pre-treated with either the antioxidant mannitol or Na-cystelyn, suggesting that the increased cytosolic Ca^{2+} concentrations observed following NP exposure could be mediated via ROS and oxidative stress. Stone *et al*. (2000a) performed further examination of the potential of all sizes of the latex beads to produce ROS, using the dye 2′,7′-dichlorofluorescin diacetate (DCFH-DA), which when oxidized converts into 2′,7′-dichlorofluorescin (DCFH) and shows an increasing fluorescence intensity relative to an increase in ROS production. It was found that the NP latex beads (64 nm) were more potent in causing ROS, with the 202 and 535 nm latex beads showing no oxidative effects after 10 min.

These findings were subsequently supported by Brown *et al*. (2000), who also measured cytosolic Ca^{2+} via the use of the fluorescent marker Fura 2-AM. It was reported that ufCB elicited a heightened cytosolic Ca^{2+} concentration in MM6 cells following treatment for 30 min. Subsequent analysis by Brown *et al*. (2000), which examined the effects of transition metals, specifically Fe in the form of Fe chloride ($FeCl_2$), using the transition metal chelator, desferal, found that these metals had no effect on cytosolic Ca^{2+} concentration after 30 min of exposure. In addition, Brown *et al*. (2000) also investigated the inflammatory potential of the ufCB and CB particles, as well as of the transition metals *in vivo*. It was observed that the ufCB particles, but not the CB particles, induced an increase in the number of PMNs present within the lungs of rats, with a significant increase in the number of neutrophils found within the BAL fluid after 24-h exposure. No inflammatory effects were found with $FeCl_2$. Following inductively coupled plasma–mass spectrometry, it was observed that the $FeCl_2$ particles were detectable in ng mg^{-1} concentrations within ufCB particles. It was subsequently concluded that ufCB does elicit an increase in cytosolic Ca^{2+} concentration, in support of Stone *et al*. (2000a, 2000b), and that ufCB particles induce an inflammatory response from cells, which was suggested to be independent of the transitional metal content of these NPs. The observation by Brown *et al*. (2000) that ufCB can cause increased inflammation supports the suggestion that ROS production, oxidative stress and altered Ca^{2+} signalling

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

caused by these NPs can cause an activation of transcription pathways, via a cascade of events within the cell, including both the nuclear factor-kappa B (NF-κB) and activator protein-1 (AP-1) pathways (Donaldson *et al*., 2003). Activation of these pathways was subsequently proposed to result in an escalated inflammatory response, with an increase in pro-inflammatory gene expression and pro-inflammatory mediator production, such as the cytokines IL-8 and TNF-α (MacNee, 2001; Donaldson *et al*., 2003). Subsequent analysis by Brown *et al*. (2004) further supported this hypothesis, demonstrating that ufCB particles, and not CB particles, cause an increase in resting cytosolic Ca^{2+} concentration (as assessed by using Fura 2-AM) in rat alveolar macrophages. Similar effects were also found on treatment of rat alveolar macrophages in a dose–response relationship (12.5–50 $\mu g\,ml^{-1}$) following thapsigargin stimulation. It is also worth noting that these effects are similar to the findings of Stone *et al*. (2000a, 2000b) and Brown *et al*. (2000), further demonstrating the consistency between different forms of macrophage cells in assessing the toxicity associated with NP exposure. Additional study by Brown *et al*. (2004) also showed that these effects were decreased following addition of antioxidants (Trolox and Nacystelin), further supporting the findings of Stone *et al*. (2000a), who concluded that the increased Ca^{2+} signalling observed in macrophage cells after NP exposure was mediated via ROS. As it was suggested, by Donaldson *et al*. (2003), that subsequent inflammation could occur due to the activation of specific transcription pathways (such as NF-κB and AP-1) following the altered Ca^{2+} signalling caused by ROS and oxidative stress of NP-treated cells, Brown *et al*. (2004) further studied the effects of ufCB on both NF-κB and AP-1 transcription pathways. Investigation of the NF-κB pathway showed ufCB (100 $\mu g\,ml^{-1}$) treated human monocyte cells to show increased fluorescence of the sub-units of NF-κB, p50 and p65 over a 4-h period compared with untreated monocyte cells. Additional analysis of the AP-1 pathway showed no significant increase in the intensity of the AP-1 protein following treatment with ufCB at 200 $\mu g\,ml^{-1}$, after 4 h in rat alveolar macrophages. The findings relative to both these pathways were found to be attenuated following the addition of antioxidants, further supporting the suggestion that these events are mediated via ROS production. Subsequent analysis of the inflammatory potential of ufCB in rat alveolar macrophages found the production of the pro-inflammatory cytokine TNF-α to be dose dependent (25–200 $\mu g\,ml^{-1}$) after 4-h exposure. It was subsequently concluded by Brown *et al*. (2004) that uf particles can exert pro-inflammatory effects by altering Ca^{2+} signalling, activating transcription factors and causing the production of pro-inflammatory cytokines via ROS-mediated mechanism, thus supporting the proposed oxidative stress paradigm.

Although the findings of these studies suggest that the toxicity observed following exposure to NPs is relative to increases in the production of ROS and subsequent oxidative stress, as well as an escalation in Ca^{2+} signalling and inflammation within cells, the oxidative paradigm is only a hypothesis and further research is required to fully understand the mechanisms of NP toxicity and how they may relate to the many "new" and different types of NPs being manufactured.

4.2 Current Status of the Field

As a complete overview of the current status of the field of nanotoxicology is not possible within the remit of this chapter, it is the intention of this section that the major aspects of the field, as it currently stands, as well as the many problems which affect nanotoxicology research are addressed and highlighted in order to provide a foundation for research and understanding within the field.

There has been significant progress in the field of nanotoxicology since the production of nanotechnology applications (Maynard *et al*., 2006; Maynard, 2007; Hoet, Bruske-Hohlfeld and Salata, 2004; Donaldson *et al*., 2006). Despite this, the field has not been able to maintain an even balance in regards to the known effects of NPs and the production of NP-based products and applications (Maynard, 2007). The inability to provide clear and up-to-date knowledge on the effects of newly engineered NPs has caused public perception of the industry to be based upon either a lack of, or incorrect information, creating a repeat of the problems faced, and which inadvertently ended the genetically modified food industry (Gaskell *et al*., 2000). Clear examples of such issues include the "Magic Nano" (Kleinmann, GmbH) bathroom cleaning product which was released in 2006. This product was advertised to keep surfaces clean and dirt repellent due to

the "nano" aspect of the product, thus providing a cleaner area for a longer period of time compared with conventional bathroom cleaners. Following the use of this product (and therefore subsequent exposure), however, increased instances of reduced pulmonary function were reported, including six hospitalizations of individuals reporting respiratory problems. The product was immediately recalled by its distributors, and it was subsequently suggested that such effects were a result of exposure to NPs contained within the product; an assumption based on both uninformed individuals and misunderstanding following the results of the studies previously discussed in Section 4. Although seemingly apparent from the name of the product, it was not completely clear whether the product actually contained NPs, due to the lack of information disclosed by the company (due to patent issues). Subsequent laboratory-based examination of the product concluded that the product did not contain NPs, and thus NPs could not be responsible for the adverse health effects observed following its use.

In addition to this, and most recently, a paper published by the European Respiratory Journal claimed that chronic exposure to NPs not only induced altered cardiovascular and pulmonary function, but also caused human fatalities (Song, Li and Du, 2009). In this study, Song, Li and Du (2009) suggested that seven females who worked within a poorly ventilated print plant were exposed to NPs (polyacrylate ester) for up to 13 months. A range of different biological and immunological tests were performed on the female workers and it was noted that five of the workers showed signs of increased pleural effusion, pulmonary fibrosis and signs of granuloma formation in the lung. It was also suggested that two of the female employees died as a result of the NP exposure, although further assessment is necessary to confirm the subjects' cause of death. Additionally, the study also assessed the effects on one male employee who was exposed to polyacrylate ester from the paint in the workplace for a total of 3 months. It was reported that he only suffered from asthma-like symptoms. There was no association of this health state with NP exposure however, as well as whether he may, or may not, already have been asthmatic prior to working in the print plant. The response to this publication has brought increased scepticism and caution from world leading figures in the field of nanotoxicology, particularly in relation to the lack of confirmation that the employees were exposed to actual NPs (by definition), as well as a clear association of the detrimental health effects observed following exposure to this NP type. It is of the utmost importance, therefore, that it is deduced whether or not the NPs that the workers were exposed to in the occupational setting drove the adverse health effects observed.

Despite these instances in which engineered NPs and their applications have been suggested as driving toxicity in humans without clear association, research into the effects of engineered NPs, based on the findings previously discussed in Section 4 of this chapter, has continued to increase over the past 10 years, obtaining increased yearly funding (Service, 2004) in order to obtain information that will enable the proposed advantages of nanotechnology to be realized (Oberdorster, Oberdorster and Oberdorster, 2005; Maynard *et al*., 2006; Maynard, 2007). In light of this, however, the proposed basis that the testing strategies used to determine the effects of ambient air NPs could be used to determine the potential toxicity of new, engineered NPs is not sufficient (Oberdorster *et al.*,2005). Concurrent with the ever-increasing number of studies published in regards to testing the toxicity of NPs (Section 4.2.5), heightened attention has also been focused upon the novel characteristics of each different type of engineered NP, and how these characteristics might affect the interactions of these NPs with biological systems (Hoet, Bruske-Hohlfeld and Salata, 2004; Oberdorster, Oberdorster and Oberdorster, 2005; Oberdorster *et al*., 2005; Oberdorster, Stone and Donaldson, 2007; Maynard *et al*., 2006; Maynard, 2007). In accordance with this, increased issues have also been raised in regards to the manner in which engineered NPs react in suspension, their specific characteristics and how best to measure/identify these characteristics, as well as the specific exposure routes and scenarios relating to biological systems. The following sections will briefly cover these issues.

4.2.1 Characterization of NPs

As discussed in Sections 4.1 and 4.1.1, there is a plethora of information related to specific NP types in regards to their (adverse) effects on the lung, as well as increased knowledge specific to the characteristics of the particles and the mechanism of toxicity which could potentially drive these observed effects. Despite this, and in addition to

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242

the aforementioned parameters which are associated with NP toxicity (Section 4.1), engineered NPs, as previously mentioned, will also exhibit additional characteristics, including different shapes and structures, as well as a variety of different surface coatings and chemistries, which are thought to contribute to their potential toxicity (Oberdorster, Oberdorster and Oberdorster, 2005).

There is already evidence that NPs, of a variety of compositions and forms, do not behave similarly, indicating that their ability to cause toxicity are not comparable. This was shown by Dick *et al*. (2003) who investigated four different NP types (CB, cobalt, nickel and TiO_2) in order to determine what attributes of particles influenced their toxicity *in vitro* and *in vivo*. It was observed that the inflammatory response elicited by the different particle types was not comparable, so that the toxicity of the different particle types can be ranked in the following order: carbon = cobalt > nickel > TiO_2; therefore, attributes other than their similarity in size were responsible for driving the observed toxicity. Furthermore, Xia *et al*. (2006) compared the toxicity of uf ambient particles, polystyrene microspheres (positively and negatively charged) and a range of engineered nanomaterials (CB, TiO_2, fullerol ($C_{60}(OH)_{24}$)) to RAW 264.7 macrophages *in vitro*. It was reported that the ambient uf particles and positively charged polystyrene microspheres induced the highest levels of toxicity as evident by their ability to induce the production of ROS, glutathione depletion and organelle (mitochondrial) damage. Therefore, it is suggested that the composition and charge of the nanomaterials influence their toxicity in addition to those described previously (Section 4.1). This study however used only one cell type, and it is relevant to highlight that other cell types may be sensitive to the toxicity of the these particles.

Although it is well documented that the composition and charge of NPs affect their toxicity, it is also necessary to take into consideration the effects of size, surface area and reactivity, as well as the chemical composition of the particle (Oberdorster *et al*., 2005). The parameters of size, surface area and surface reactivity have been discussed in detail in Section 4; however, due to the advent of new engineered NPs, these have increasingly been highlighted as vital characteristics relating to NP toxicity (Oberdorster *et al*., 2005). For example, quantum dots (QDs), which are semi-conductor nanocrystals with differing surface charges intended for both diagnostics and therapeutics (Pison *et al*., 2006), can range from 1 to 100 nm (Hardman, 2006), although they commonly differ by a size of 1–10 nm (Pison *et al*., 2006). Within this size range (1–10 nm), QDs, due to their novel fluorescent characteristics, alter significantly in their emission wavelength as well as shape (Hardman, 2006). In addition to the effects of the surface charge (Clift *et al*., 2008), it has been shown that the small change in size (1 nm difference) can significantly alter the ability of QDs to enter the cell and their internal localization as well as their resultant toxicity (Lovric *et al*., 2005a, 2005b). These differences in size will also affect their overall surface area and reactivity, possibly affecting their biocompatibility and potential toxicity potential (Duffin *et al*., 2002, 2007). Further research is required, however, to determine this for QDs and the plethora of engineered NPs available. In addition to these, there are other characteristics that have been recently highlighted as important in relation to the NP–cell interaction, including length and stiffness (Poland *et al*., 2008) as well as aggregation/agglomeration status (Oberdorster *et al*., 2005). All of the characteristics highlighted in this section can be determined via a number of different experimental procedures such as dynamic light scattering (DLS) for particle size, BET measurements to assess the surface characteristics of NPs and mass spectrometry to determine the chemical composition of a material. The reader is referred to Oberdorster *et al*. (2005) for a more, comprehensive review of characterizing NPs as a strategy prior to toxicological testing.

4.2.2 NP Suspensions and Dose

Similar to NP characterization, the manner in which NPs are suspended prior to exposure to biological systems has received increased attention. In a recent paper by Cedervall and colleagues (2007), the ability for NPs to interact with proteins, specifically the protein corona, was described. It stated that once suspended in biological media, the ability for proteins to interact with NPs is significantly increased, subsequently covering or coating the NPs. This process, therefore, has a significant effect on the manner in which the NPs interact with biological systems, such as cells, and also the subsequent effects of these interactions. Additionally, it has also been found that when NPs are suspended in cell–culture media

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

both with and without serum, the toxicity observed is significantly different, with NPs suspended without serum inducing increased toxicity compared with those suspended with serum (Petri-Fink *et al*., 2008). Indeed, there are a number of investigations ongoing which are specifically examining the effects of NPs when suspended in different media and buffers, as well as how these buffers may affect the distribution of NPs in suspension (Wick *et al*., 2007). It is essential that the correct suspension media/buffer is used when forming a NP suspension for biological exposure because it is imperative to obtain an understanding of their interaction with biological systems following realistic exposure.

In addition to the manner in which NPs are suspended for cellular exposure, it is also necessary to take into consideration the specific dose that is being used when investigating the toxicity of NPs. Throughout the history of NP research, the realistic doses of NPs found either in air or within an occupational setting has been debated. Despite the ongoing assessment of the precise, realistic doses at which humans as well as the environment will inevitably be exposed to NPs, it is still an area of concern due to many studies using increased, non-realistic doses and reporting hazardous effects on human health and/or the environment following NP exposure. Also, it is not only the dose that has to be taken into consideration, but the manner in which the dose is expressed (i.e., dose metric) (Teeguarden *et al*., 2007). Therefore, in order to obtain a clear and definitive understanding of how NPs affect humans and the environment, the dose used must be both realistic and expressed without causing confusion.

4.2.3 Realistic Exposure Parameters

Recently, the exposure of NPs to biological systems, specifically cell cultures, has been a basis for increased discussion (Rothen-Rutishauser *et al*., 2009). In most nanotoxicology studies, particles are applied in suspension (for example, suspended in cell culture medium). If NPs are to translocate from the lung to secondary target organs (such as the liver or brain) then it is possible that the interaction between NPs and cells could be relevantly mimicked via the exposure of cell cultures to NP suspension (due to the NPs being translocated within blood). This aspect however requires further in-depth analysis to determine (i) whether and how NPs are translocated from the lung and (ii) at what dose the NPs are translocated and thus interact with the secondary organs. In addition, it is paramount that the specific characteristics of the translocated NPs are determined, as it is possible that they are no longer in the same format as when they entered the lung.

Although research into NP translocation is in its infancy (Kreyling *et al*., 2002a, 2002b), research, as noted throughout this chapter, into the effects of NPs on the lung is well documented. Indeed, exposure to most forms of NPs will initially be via inhalation and thus will affect the respiratory system (Oberdorster, Oberdorster and Oberdorster, 2005). Therefore, in order to achieve a more advantageous correlation between the *in vitro* and the *in vivo* situation, specifically regarding NP–lung interactions, cells have to be cultivated at an air–liquid interface and the particles have to be applied from the air. In order to study particle–cell interactions in cell culture systems representing the airway epithelial barrier, it is important to mimic the *in vivo* interactions of particles with cells as closely as possible. The particles have to maintain their shape as well as their chemical and physical properties when they come into contact with the cell surface to relevantly elucidate which particle properties contribute to toxic effects. As highlighted previously, the majority of existing cell culture models used to assess lung cell–particle interactions use immersed cells in medium, with particles added to the cell cultures as a suspension in liquid (Duffin *et al*., 2007; Gurr *et al*., 2005; Limbach *et al*., 2007; Rothen-Rutishauser *et al*., 2007; Stearns, Paulauskis and Godleski, 2001). This does not, however, reflect the physiological condition of lung epithelial cells, which are exposed to air, separated from it only by a thin liquid lining layer with a surfactant film at the air–liquid interface (Gehr *et al*., 1990; Gil and Weibel, 1971; Schürch *et al*., 1990). In addition, the physical and chemical properties of the particles rapidly change when suspended in medium, and NP aggregation and diffusion determine the transport and uptake kinetics in living organisms (Limbach *et al*., 2007). Other approaches include applying NPs to lung cells that have been cultured at the air–liquid interface by nebulizing particles over the air-exposed system using a spraying device (Lenz *et al*., 2009) or an exposition chamber with an integrated aerosol generator (Bitterle *et al*., 2006; Tippe *et al*., 2006). Another experimental approach is to work with an exposure device based on a cell exposure system, known as the CULTEX (Aufderheide

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

and Mohr, 2000). In addition to this, simulation of accidental exposure of the lung to NPs in a relevant state of agglomeration and surface coating has been achieved by directly combining the synthesis of NPs to the exposure of cell cultures at the air–liquid interface using a glove box (Rothen-Rutishauser *et al*., 2009). Therefore, via the use of such systems, it is possible not only to obtain a clear and defined understanding of the interaction between NPs and the lung as it occurs *in vivo*, but to also mimic a specific exposure route of NPs to the human body.

4.2.4 Exposure Routes of NPs

The availability and toxicity of a substance to an organism is determined not only by the dose the entire organism is exposed to, but via a set of properties referred to as "toxicokinetics," which describe uptake, transport, metabolism, sequestration to different compartments and finally elimination of a substance from the organism. These parameters are essential, since toxicity of substances is dependent on which organs or cell types are exposed, which form the substance is in, for example bound to serum protein, aggregated, dissolved or oxidized, and how long the substance remains at the site of exposure. Therefore, the potential for NPs to exhibit toxicity at their site of entry (such as the lung, skin and gut) is of great relevance.

As described in Section 4.1, the respiratory system was initially identified for research because it was considered to be the primary target organ for particle toxicity due to PM_{10} exposure via inhalation and it was reported that, following epidemiological investigations, uf particles can contribute to reduced respiratory function and health (Peters *et al.*, 1997; Pope, Ezzati and Dockery, 2009). The impact of uf particles on the cardiovascular system was also investigated because mortality associated with exposure to PM_{10} was also associated with a reduction in cardiovascular function (Schwartz, 2004). The lung remains the primary organ for exposure to engineered NPs, specifically in reference to NP exposure during their production (occupational exposure) (Oberdorster, Oberdorster and Oberdorster, 2005). Despite this, due to the influx of many different types of NPs for a diverse range of applications, the routes by which NPs can enter the human body include permeation through the skin, ingestion and injection, in addition to inhalation (Oberdorster, Oberdorster and Oberdorster, 2005; Maynard *et al*., 2006). As it is not within the remit of this chapter to discuss each of these routes in detail, the following paragraph intends to cover the main aspects and current status of research in the field related to these potential routes of entry for NPs.

In contrast to the lung, little is known regarding the effects of NPs on the skin. Research that has been performed, however, widely suggests that the optimal opportunity for NP uptake by the epidermis is when the outer skin cells are broken, such as when the skin is sunburned or diseased (i.e., application of sun cream (which can contain either TiO_2 or zinc oxide) to burned skin) (Mortensen *et al*., 2008). Tinkle *et al*. (2003) has reported that when broken skin is flexed it is more sensitive to penetration by NPs, such as TiO_2, as it forms a more permeable environment, allowing translocation of the NPs, via Langerhans cells, to the lymph nodes and then subsequently into the blood circulation. Investigation into the effects of ingesting NPs is also in its infancy and is perhaps one area for which there is extremely limited amount of knowledge and understanding (Oberdorster, Oberdorster and Oberdorster, 2005). Initial research suggests that following ingestion of NPs (most likely via food) these particles can interact with the cells of the gut causing decreased cellular integrity and function (Oberdorster, Oberdorster and Oberdorster, 2005). Further research is imperative to fully understand the effects of NPs following ingestion, specifically to investigate the characteristics of NPs at this level and the concentration at which NPs interact with the gut. In comparison to NP ingestion, research into the effects of NP exposure via injection is limited, and is specifically concentrated upon their effects associated with medicinal application. The aim of injecting NPs is to target specific organs, tissues and cells; thus, the NPs used will be coated with coatings such as polymers, in order to negate their identification by the immune system, specifically phagocytic cells (such as macrophages) (Oberdorster, Oberdorster and Oberdorster, 2005). Although increased research has been based upon investigating the effects of NPs intended for use in nanomedical applications, there are no current studies focussing upon NP effects in the bloodstream. It is essential, therefore, that research into this area is performed so that the advantages posed by nanomedicine (ESF Report, 2005) are gained.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Despite concentrated efforts to investigate the effects of NPs on the (potentially) primary exposed organ, as previously highlighted, it has become evident that NP localization might not be restricted to their portal of entry (Kreyling *et al*., 2002a, 2002b). It has been reported that NPs can become distributed to organs distal to their site of exposure, so that NP toxicity can be potentially exerted at a number of secondary targets (Oberdorster, Oberdorster and Oberdorster, 2005). Therefore, toxicity at a number of targets (including the liver, brain, spleen and kidneys) is worthy of consideration when assessing the toxicity of NPs on human health. For example, the liver is considered to be a preferential site of NP exposure via a variety of routes (Nemmar *et al*. 2001; Oberdorster *et al*. 2002; Ogawara *et al*. 1999). Thus it is imperative that the ability of NPs to have detrimental consequences on normal liver function is investigated. In addition to the effects of NPs on human health, an area that is receiving increased research interest due to augmented concerns is the effect of the release of NPs into the environment (also via an array of different exposure routes). The release of such particles could increase the concentration of atmospheric particles (Borm *et al.*, 2006), which has obvious human health implications, when considering the epidemiological findings of PM_{10} toxicity, in addition to damaging the environment. Therefore, in order to fully understand the effects of NPs on both human health and the environment, it is essential that increased research is performed in each of these exposure areas in order to fulfil the potential advantages that nanotechnology offers.

4.2.5 Additional Paradigms for NP Toxicity

As previously described in Sections 4.1 and 4.11, the oxidative stress paradigm has been the basis for which increased toxicological research has been performed in relation to NPs (Oberdorster, Stone and Donaldson, 2007). With the constant increase in the production of different engineered NPs, as well as in the number of studies being published which have investigated the potential toxicity of NPs, there are now alternative theories, or paradigms, relating to NP toxicity. Additionally, due to the increased research being performed, it is only a matter of time before numerous theories are produced relative to the many different forms of NPs available.

Recently, the most publicized paradigm is the fibre paradigm (Dörger *et al*., 2001; Donaldson and Tran, 2004). The fibre paradigm was originally formulated in relation to the effects of asbestos fibres and their ability to cause mesothelioma in the lung (Dörger *et al*., 2001; Donaldson and Tran, 2004). Due to the production of more fibrous nanomaterials, specifically CNTs, this paradigm has recently shown NPs, or nanofibres (a nano-object with two similar external dimensions in the nanoscale and the third dimension significantly larger (ISO/TS 27687, 2008)) to fit into the fibre paradigm (Poland *et al*., 2008). Specifically, in relation to CNTs, the fibre paradigm relates to high aspect ratio nanoparticles (HARN), which expresses the possible adverse effects that a material could have in regards to its length divided by its width (with a minimum 3:1 required to fit the paradigm). It is also necessary that the fibre is at least 15 μm in length. It has been shown that this length of nanofibre can cause a process known as "frustrated phagocytosis" (Brown *et al*., 2007b) to occur, due to cells being unable to actively take up these fibres. The repercussions of this are an increased level of oxidative stress and subsequent stimulation of pro-inflammatory cytokines (Brown *et al*., 2007b) (similar to the oxidative stress paradigm). Therefore, it has been shown by these studies, and also in light of the aim of this chapter, that within NP toxicology research it is not just one aspect that affects the interaction and response of NPs to biological systems. It is essential that numerous aspects are taken into consideration when performing any type of nanotoxicology research.

In addition to the fibre paradigm, the theory of genotoxicity has also been extensively explored. The theory of genotoxicity (Schins and Knaapen, 2007) is predominantly based upon the oxidative stress paradigm, and however moves on from the stimulation of an inflammatory response to assess what the stimulation of inflammatory mediators could incur, regarding human health. The theory describes a two-tiered approach: primary genotoxicity and secondary toxicity. In regards to primary genotoxicity, it is suggested that NPs can cause genotoxicity following direct exposure to the biological system. Secondary genotoxicity however describes, initially, the oxidative stress paradigm (in theory: NP exposure = ROS/reactive nitrogen species (RNS) production (also oxidative stress (oxidant/antioxidant imbalance)) = chronic inflammatory response), which causes genotoxicity and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

(possibly) subsequent tumour formation. Secondary genotoxicity however, may not be caused by the NPs alone; it may also be caused via interaction of the biological system and the chemicals contained within the NPs. It is suggested that the NPs might be completely inert but are able to penetrate the cellular membrane, possibly locating within the nucleus. At this stage, due to the high acidic pH, the chemicals present within the NPs could be released (such as Fe within Fe platinum NPs) causing a toxic response. This form of secondary toxicity has also been referred to as the "Trojan horse" effect (Limbach *et al*., 2007). It is also possible, however, in relation to this theory that the cells might undergo cell death and thus not induce genotoxicity and tumour formation. Additionally, the cells might proliferate or undergo repair of the deoxyribose nucleic acid (DNA) chain and negate any NP effects (Schins and Knaapen, 2007). It is prudent to point out that this theory has been based upon biological system exposure to NPs of a size >100 nm and knowledge of how the theory works in relation to NPs <100 nm is not limited at this time. Few studies have investigated the potential for NPs and nanofibres to induce genotoxicity (Knaapen *et al*., 1999; Zhao *et al*., 2004; Bao *et al*., 2006; Jacobsen *et al*., 2008; Takagi *et al*., 2008); however, increased research is still necessary in order to assess the realistic possibility that NPs can induce genotoxicity and subsequently cancer (Poland *et al*., 2008).

5 TESTING NP TOXICITY *IN VITRO*

When assessing the potential toxicity of any form of NP it is important to investigate how the particles enter the specific cells being examined and in which compartments they may be found (or, if the NPs stay attached to the cell membrane, which is also possible). This is of great importance because it has been shown that the uptake behaviour can influence the cellular response following NP exposure (Unfried *et al*., 2007; Maysinger *et al*., 2007). As it is not possible to explore in detail the entry mechanisms of NPs into cells, the reader is referred to the studies of Unfried *et al*. (2007), as well as Rothen-Rutishauser, Schurch and Gehr (2007) and Müehlfeld, Gehr and Rothen-Rutishauser (2008a), Muhlfeld *et al*. (2008), which provide a good overview of these processes. As previously highlighted in this chapter, there are a number of different toxicological endpoints which researchers have used to assess the potential adverse effects that NPs may have on organs of the human body. It is also pertinent to point out that these tests are beginning to be used to assess the impact of NPs on the environment. The following section therefore intends to summarize the majority of the many different tests available to study the toxicity of NPs and how they may be used to provide a clear, thorough and complete assessment of NP toxicity.

5.1 Advantages and Disadvantages of *in vitro* Testing Compared to *in vivo* (*ex vivo*) Testing

Although all the experimental analyses described in Section 5.2 can be performed with cells obtained from *in vivo* experimentation (*ex vivo)* as well as *in vitro*, it is pertinent to highlight the constant debate on the advantages and disadvantages of both *in vitro* and *in vivo* testing. Although *in vivo* (specifically mice and rat models; however also considering research on hamster, guinea pig and monkey models) research is known to enable scientific research to observe almost "first-hand" the effects of a substance as they would occur in Homo sapiens, *in vitro* models provide the possibility to investigate toxic effects on human cells extensively, which cannot be conducted *in vivo* (Rothen-Rutishauser *et al*., 2008a). Cultured human and animal cells can be better controlled and therefore yield more reproducible data than *in vivo* systems; however, they require a high standardization to maximize reproducibility. In addition, there are many efforts to establish more realistic models to study the toxic potential of NP, as for instance the triple-cell co-culture system composed of epithelial cells, macrophages and dendritic cells which has been established, simulating the most important barrier functions of the epithelial airway (Rothen-Rutishauser *et al*., 2005, 2008b; Blank *et al*., 2006).

5.2 Tests Used to Assess NP Toxicity

5.2.1 Cytotoxicity and Cell Death

In order to determine the absolute toxicity, otherwise known as the lethal dose (LD50) (Timbrell, 1999) of a substance, an assessment of the substance's ability to cause complete cytotoxicity and/or cell death is

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

necessary. As highlighted in Section 4, within the field of nanotoxicology, researchers have tended to use an assessment of the permeability or integrity of the cell membrane in order to assess the cytotoxicity of NPs. This has predominantly been achieved by measuring the amount of LDH present within cell supernatants following NP exposure. LDH is contained within the cytoplasm of cells and can be subsequently released following a loss in cell membrane integrity (Kendig and Tarloff, 2007). LDH release from cells has been shown to be a good indicator of cytotoxicity (Henderson *et al*., 1985), as well as associated with necrotic cell death (Kendig and Tarloff, 2007). It must be stressed, however, that assessment of LDH release from cells indicates neither necrosis nor any form of cell death. Quantification of the level of LDH enzyme release from particulate-treated cells into the external cell culture medium (cell supernatant) (this process is also known as membrane leakage) can be achieved by assessing the catalytic interconversion of pyruvate to lactate, concomitantly with an investigation of the interconversion of nicotinamide adenine nucleotide (NADH) to its oxidized form nicotinamide adenine dinucleotide (NAD^+). Predominantly LDH is assessed via spectrophotometry and absorbance. It is suggested, however, that presentation of such data sets is arbitrary (i.e., when expressed as an optical density). In order to provide a realistic observation, results need to be expressed as a function of the total LDH release (positive control), which can be determined by destroying the cell membrane with Triton X-100 (Figure 1).

Indeed, as highlighted in this chapter, nanotoxicology research is dependent upon the performance of multiple assessments in relation to each variable. Therefore, a measurement of LDH to denote the cytotoxicity of a NP is not sufficient. Numerous colorimetric tests are also available to assess the potential cytotoxicity of NPs. These include the MTT, WST-1 and MTS assays. These assays are based upon the ability of living, metabolically active cells to cleave a tetrazolium salt. These assays enable the determination of cell survival, proliferation and activation in a wide variety of cells, including macrophage-like tumour and lymphoma cell lines, as well as stimulated myeloma cells. Similar to the LDH assay, this is achieved via quantification by spectrophotometry of the formazan generation by active mitochondria, indicative of the energy metabolism in mitochondria (levels of mitochondrial succinate dehydrogenase) within living cells (Mossman, 1983). Generally, it is accepted that an observed increase in absorbance is indicative of cell proliferation, whilst a decrease in absorbance suggests either a reduction in metabolic activity and/or a decrease in viable cell number. It is suggested that the data gained from these tests are presented as the percentage of the negative control (Figure 2).

Figure 1. mitochondria, due to its importance in the energy production for cell function and viability. Direct assessment, by both quantitative and qualitative means, can also be performed in order to assess the ability of NPs to disturb the normal homeostasis of this cellular organelle via assessment of the mitochondrial membrane potential. This is generally achieved by purchasing a kit, providing the relative dyes in order to perform both confocal laser scanning microscopy (CLSM) and fluorescent-activated cell sorting (FACS™).

Although the above-mentioned assays take into consideration the effects of NPs on the mitochondria and the cell membrane, the direct measure of the ability of NPs to cause cytotoxicity is via an assessment of cell death. Cell death can be attributed to numerous cell cascades, resulting in different cell death processes. There are, however, two specific forms of cell death which have received increased attention in relation to NP exposure to cells. The first of these processes is apoptosis, also known as controlled cell death. The second, necrosis, is a pathological process because it has been shown to occur in response to externally induced toxicity, including inflammation. Cell death is commonly assessed by the use of specific fluorescent staining solutions/antibodies for both apoptosis and necrosis. Although there are many different kits and tests available, assessment of NP-induced cell death is generally achieved by performing the Annexin-V assay. When cells undergo apoptosis, one part of this process includes the transport of inner cell membrane lipids (such as phosphatidylserine) to the outer side, serving as a marker for macrophages to eliminate these cells. In the Annexin-V assay, the fluorescent dye Annexin-V-Fluorescein binds to phosphatidylserine, thus marking the apoptotic cells. The necrotic cells are also distinguished by the use of a fluorescent dye propidium iodide. Staining with the fluorescent dye propidium iodide identifies the DNA of cells. This method can be achieved, similar to the mitochondrial membrane potential assay, both qualitatively and quantitatively; thus, the result can be observed via both CLSM and FACS™ analysis.

5.2.2 Reactive Oxygen/Nitrogen Species and Oxidative Stress

Due to the oxidative stress paradigm being the foundation for nanotoxicology research, assessment of the formation of ROS and oxidative stress can be achieved by an ever-increasing list of assays and diagnostic kits. Despite this, there are specific parameters that are constantly used in order to denote the production of ROS, the increase in oxidants or the loss in antioxidants within a biological model.

In regards to the production of ROS, the most common parameter used is the fluorescent dye 2′,7′ dichlorodihydrofluorescein diacetate (DCFH-DA), a reliable fluorogenic marker for ROS in living cells. This method assesses the production of ROS via the increase in fluorescence. Upon the production of ROS, the DCFH-DA molecule is cleaved, resulting in a DCFH molecule which is highly fluorescent. The fluorescence signals can be both imaged via CLSM and quantified using FACS™ analysis and fluorescent spectrophotometry. A similar form of testing procedure is also based upon the fluorescent dye dihydroethidium (DHE). Similar to the DCFH-DA reaction) in which ROS production is determined by the level of fluorescence, DHE detects the extent of oxidative stress and ROS production in cells, by oxidizing to ethidium, which is highly fluorescent. These methods are extremely advantageous, as not only they can be performed via multiple approaches, but they can also be used in a cell-free environment. This is important because it provides important information pertaining to the NPs alone, and thus their ability to cause ROS independent of a cellular environment. This, of course, is extremely advantageous in regards to assessing the ability of NPs to cause secondary genotoxicity.

As previously mentioned, there are a number of kits available to measure ROS production and mostly these are based on the DCFH-DA reaction. An example of this is the Image-iT™ LIVE Green ROS Detection Kit (provided by Molecular Probes). In Figure 3, the ability to determine the ROS production in cells following NP exposure is easily identified. This is only an example of the ability to quickly and efficiently identify the ability of NPs to cause ROS production in cells.

As previously mentioned in Section 4.1.1, the production of ROS is concomitant with a reduction in antioxidants, thus causing an oxidant imbalance within the cell and therefore oxidative stress. It is therefore, as also previously highlighted in the chapter, pertinent that an assessment of the antioxidant capacity is performed in order to obtain a thorough and clear understanding of the oxidant-related

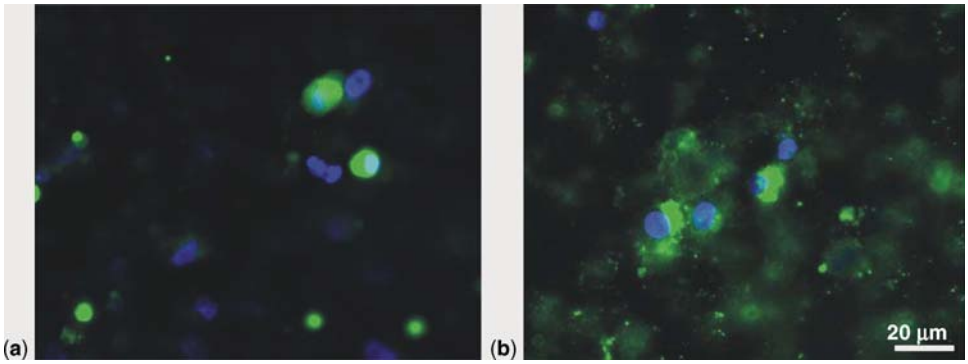

Figure 3. Fluorescent microphages of ROS production in the triple cell co-culture model (Rothen-Rutishauser, Kiama and Gehr, 2005) obtained after using the Image-iT^{TM} LIVE Green Reactive Oxygen Species (ROS) Detection Kit (Molecular Probes). Cell nuclei are shown in blue, ROS in green. In control cultures only few cells with ROS signals could be detected (a) (reproduced with permission from Rothen-Rutishauser, Kiama and Gehr, 2005 © American Thoracic Society), whereas TiO_2 NP induce a higher oxidative response, as the green stain in the cytoplasm shows (b) (reproduced from Rothen-Rutishauser *et al.*, 2008b © Springer).

effects of NPs. This form of analysis has commonly been performed in regards to an assessment of intracellular glutathione levels. Glutathione is an intracellular non-protein thiol readily available in a wide range of living cells, and is a key factor in a number of biological functions, including oxidative stress (Hissin and Hilf, 1976). It is usually present in cells as GSH; however, when existing in cells as its oxidized glutathione (GSSG) form, glutathione is rapidly converted to GSH via an enzymatic reaction using glutathione reductase. In the method originally published by Hissin and Hilf (1976), the levels of both GSH and GSSG were determined via their pH-sensitive reactions with the fluorescent reagent *o*-phthaldehyde. There are of course many alternative ways to determine glutathione levels within cells, including diagnostic kits and microscopy-related assays. In addition, there are numerous ways to assess the antioxidant capacity of cells, such as the trolox equivalent antioxidant capacity method (TEAC); however this is extremely laborious and difficult to optimize.

In addition to determining the antioxidant capacity, it is also possible to determine the level of oxidants present within the biological sample. This is notoriously difficult and time-consuming; however, it provides extremely valid and optimal results in regards to the oxidative potential of NPs. Such testing strategies include assessment of the $^{\cdot}OH$, as well as the superoxide anion via polymerase chain reaction (PCR). These can be determined via diagnostic kits; however, due to the intrinsic nature of these radicals/anions within the cellular system the most reliable method for assessing these aspects is via PCR.

In addition to the measurement of ROS and oxidative stress, it is also prudent to determine the ability for nitric oxide (NO) to be produced. Often, however, NO is not assessed in relation to the radical formation potential of NPs. Increased research should be directed towards this aspect, though, due to the fundamental role of NO in cellular function. A radical gas, NO, is derived from the guanidino nitrogen of the amino acid L-arginine and molecular oxygen in a reaction catalyzed by the enzyme nitric oxide synthase (NOS). There are at least two types of NOS. The calcium-dependent form is present constitutively in a variety of tissues and produces the physiological concentration of NO needed for maintenance of blood pressure. The other, calcium-independent form, is inducible (iNOS) in a number of cell types including macrophages, hepatocytes, neutrophils and endothelial cells, by a variety of immunological stimuli such as interferon-γ (IFN-γ) and bacterial lipopolysaccharide (LPS). iNOS is a high-output enzyme and nitrite concentrations are easily detected. It is possible to measure NO (or iNOS) via spectrophotometry using a colorimetric test known as the Griess reaction, for which numerous diagnostic kits are available. It is important to note, however, that problems have been reported when assessing NO in primary cells, as well as some cell lines (for example A549 epithelial cells). This test is, however, advantageous in

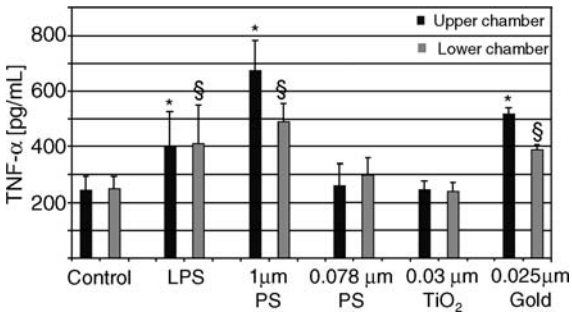

Figure 4. TNF-α release in triple cell co-cultures upon particle incubation. TNF-α levels in the supernatants (upper chamber, lower chamber) were measured by ELISA. TNF-α release in cells exposed to LPS, 1 μm, and 0.078 μm polystyrene particles, TiO_2, and Au NPs. Values are means ± SD. * indicates a statistical difference to the levels in the supernatants in the control of the upper chamber; §indicates a statistical difference to the levels in the supernatants in the control of the lower chamber. Reproduced from Rothen-Rutishauser *et al*. (2007) © Springer.

assessing the ability of NPs only to produce NO (i.e., in a cell-free environment). In order to assess NO in cells therefore, it is also possible to use PCR analysis. This testing strategy, however, as with measurement of both the ·OH and the superoxide anion, is extremely laborious and time-consuming.

5.2.3 Inflammation

Assessment of inflammation *in vitro* is usually achieved via the use of enzyme-linked immunosorbent assay (ELISA) diagnostic kits (Figure 4). Although expensive, these diagnostic kits provide valuable and reproducible testing strategies to measure the plethora of different pro-inflammatory cytokines and chemokines that have been associated with NP exposure to culture cells. In addition to ELISA kits, it is also possible to measure cytokine/chemokine production either via PCR analysis or FACS™ analysis; however, these methods are again laborious and, in comparison to the ELISA method, provide no further advantages.

5.2.4 Cell Signalling

As highlighted in Section 4.1.1, the influence of NPs on cell signalling, specifically upon Ca^{2+} signalling in cells, is a significant factor related to the oxidative stress paradigm. In relation to this, Ca^{2+} signalling is not as well researched as the ability of NPs to stimulate ROS and inflammatory cytokines/chemokines. Although it is possible to measure intracellular calcium levels via a number of means, again including diagnostic kits, the most commonly used indicator of changes in intracellular calcium is the fluorescent marker FURA 2-AM (Grynkiewicz, Poenie and Tsien, 1985). The function of this dye is similar to that of DCFH-DA, as during the incubation period with the cells (and xenobiotic), if there is a change in Ca^{2+}, intracellular esters are able to remove the acetoxymethyl (AM) group from the Fura 2-AM molecule, making the membrane impermeable to Ca^{2+}-sensitive fluorescent dye, Fura 2. It is then possible to determine the level of Ca^{2+} present in samples via spectrophotometry, as well as by CLSM.

In addition to this, and as previously mentioned in Sections 5.2.2 and 5.2.3, PCR is a very useful tool in assessing the effects of cell signalling. Although this method can identify specific proteins and genes (ribose nucleic acid (RNA) transcription/isolation), it is laborious and requires increased optimization time in order to obtain valid and reliable results.

5.2.5 Genotoxicity and Mutagenicity

As previously discussed in Section 4.2.5, the theory of genotoxicity and mutagenicity is initially based upon the oxidative stress paradigm, and thus to initially determine this, the tests discussed in Sections 5.2.1–5.2.4 must be performed first (it is important to note that for an NP to be genotoxic, it must not be cytotoxic (at a specific dose) and therefore it is essential to test for this initially). When determining the genotoxicity of a NP, however, there are numerous tests that can be performed. Specifically, however, research has focused upon a few specific toxicity tests which measure the ability of NPs to inflict DNA damage, mutagenicity and cell proliferation.

DNA damage is commonly investigated via the comet assay. In addition to measuring DNA damage, this assay also assesses other DNA alterations in cells (Jacobsen *et al*., 2008). The extent of DNA damage is revealed via electrophoresis of the agarose embedded single-cell samples, showing both DNA fragments or damaged DNA to migrate away from the nucleus (forming a comet shape). After staining with a DNA-specific fluorescent dye, such as propidium iodide, the fluorescent signal of the gel is then measured in the head and tail and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat242
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

length of tail. The extent of DNA liberated from the head (to the tail) of the comet is directly proportional to the amount of DNA damage. Quantification of the liberated DNA is generally achieved by the use of specific computer software; however, it can also be determined by giving comets a series of numbers related to the severity of DNA damage. This latter method, although original, is flawed, specifically due to the impact of human error; therefore, it is not advisable despite the expense of the computer software. In addition to the original comet assay, alternative testing protocols have been developed in which oxidative DNA damage can be assessed simultaneously. For example, by inclusion of the formamidopyrimidine glycosylase (FPG) enzyme, the assay also allows for specific detection of oxidative DNA lesions (Jacobsen *et al*., 2008) Although this form of the comet assay requires double the samples, it is extremely advantageous to obtain an understanding of the oxidative/genotoxic potential of NPs.

Assessment of an NP's ability to cause mutagenicity is also a prominent testing strategy when determining the genotoxic potential of NPs. A well-defined testing protocol for mutagenicity is the micronucleus assay. This test has been proven to detect both clastogenic and aneugenic events, as well as to be valid for genotoxicity testing of micron- and nano-sized particles (Singh *et al*., 1988; Li *et al*., 2008). In addition to the micronucleus test, a recent testing protocol for NP genotoxicity is the Ames test. This test is based on strains of bacteria that have point mutations on the histidine (*His*) operon. Due to the position of the mutation on the *HIS*-gene, the bacteria are incapable of producing histidine and therefore unable to proliferate unless histidine is present (Ames *et al*., 1973). If chemicals are mutagenic then additional mutations occur on the *His*-gene, known as base substitutions or frameshift mutations, which enable the bacteria to produce histidine and subsequently proliferate. The mutagenicity of the chemical is then determined via quantification of the ability of the histidine-free bacteria to replicate. Previously, this test has been used to screen chemicals; however, recently it has been successfully used to study the mutagenicity of NPs, specifically DEPs (Zhao *et al*., 2004). There is debate, however, on the specificity of this mutagenicity test, due to the interaction of NPs with bacteria and not with cells. The understanding of the interaction between NPs and bacteria is extremely limited, if not unknown, and therefore it is not understood whether the NPs will interact with the bacteria in a similar manner as with a cell, and whether the use of this protocol will provide specific, realistic mutagenic effects of NPs in relation to human health.

Cell proliferation is also a key factor in the genotoxic potential of NPs (Schins and Knaapen, 2007). As previously highlighted, this can be achieved via a number of different assays, such as the MTT, WST-1 and MTS assays. Due to the reported concerns and difficulties of using these assays (Worle-Knirsch, Pulskamp, and Krug, 2006) (Section 5.3), an alternative test for determining the ability of cells to proliferate is the BrdU assay. The BrdU assay is an immunochemistry technique which assess newly synthesized (or partially denatured double-stranded) DNA strands in cells that are undergoing active proliferation via fluorescent microscopy. This technique enables the assessment of cells that have been treated with NPs to actively synthesize and proliferate. Similar to the MTT, WST-1 and MTS assays, this test can be performed via purchasing a diagnostic kit and using spectrophotometry, as well as CLSM, therefore providing a valid and reliable testing strategy for cell proliferation in relation to NP genotoxicity.

5.3 Use of Appropriate Controls When Assessing the Toxicity of NPs

In addition to all of the previously mentioned parameters that can be used when assessing the potential toxicity of NPs (in relation to the specific experimental question), it is also vital that additional and appropriate controls are used throughout.

When choosing a toxicology testing strategy, it is important that a relevant positive control is also chosen. Although negative controls are easily identified (usually cell culture medium/buffer only), determination of the correct positive control must be given more thought. For example, a low concentration of Triton X-100 (such as 0.1% or 0.2%) is able to provide a clear positive reaction in any LDH assay (either diagnostic kit or laboratory protocol); however, this form of compound would not be useful when assessing the potential production of ROS by NPs within cells. It is therefore pertinent that the reaction the test is causing is debated and the most adequate and specific positive controls are used.

As highlighted in Section 4.2.2, the ability for proteins to adsorb onto the surface of NPs is realistic and can significantly affect the ability of NPs to interact with cellular systems. It is, therefore, also essential that the ability of proteins to adsorb onto the surface of particles during toxicological tests is assessed (such as when using an ELISA). This is also true for enzymes such as LDH. It is known that this enzyme can also adsorb onto the surface of NPs, masking their toxicity and thus providing a false-negative toxic result. As with protein adsorption, enzyme adsorption must also be investigated to correlate valid and representative toxicity data. Determination of these aspects is easily performed. Generally, the protocol consists of incubation of the NPs with the protein/enzyme for a period of time followed by the specific toxicological test (Clift *et al*., 2008). Any adsorption of the proteins or enzymes onto the NPs is then apparent via a loss or increase in the specific protein/enzyme being measured. Additionally, it is also necessary to determine the ability of the NPs used to interact in regards to the fluorescent dyes or formazans that are used. An example of this was reported by Worle-Knirsch, Pulskamp and Krug (2006), where it was reported that CNTs interacted with the MTT formazan (tetrazolium salt) used and provided false-negative results. In addition to this, it is also pertinent that an assessment of the toxicity of the suspension media/buffer is performed. Increasingly, NPs are suspended in such buffers as Pluronic F127 and Tween 80 in order to obtain a well-dispersed and characteristic NP suspension. If, however, a toxic response is observed following cellular exposure to NPs suspended in such buffers, it is essential that the toxicity of these buffers is known, in order to assess the specific effects of the NPs only (Wick *et al*., 2007).

6 CONCLUSION

The field of nanotoxicology is complex and requires increased research in order to enable the advantages of the nanotechnology industry to be realized. It is paramount that the findings of environmental air pollution research are taken on board and built upon to assess the potential adverse effects that could occur following exposure to the many new, engineered NPs. This of course is best achieved via *in vivo* research; however, this area of research can be too invasive, time-consuming and expensive. It is therefore prudent that research is driven towards a more *in vitro* approach, where specific cell culture models, mimicking the *in vivo* situation, are constructed and used regularly. By using these models, toxicological screening of engineered NPs can be achieved quickly and efficiently using a series of toxicity tests (as described in Section 5.2). It is important that increased controls and supporting tests are performed concomitantly in order to obtain a clear, definitive and realistic understanding of the risk that NPs might pose.

7 LIST OF ABBREVIATIONS

OH	Hydroxide radical
AM	Acetoxy methyl
AP-1	Activator protein-1
Au	Gold
BAL	Bronchiolar lavage
BSI	British Standards Institution
C_{60}	Carbon 60 (fullerene)
Ca^{2+}	Intracellular calcium
CB	Carbon black
CH	Switzerland
CLSM	Confocal laser scanning microscopy
CNT(s)	Carbon nanotube(s)
COOH	Carboxylated
COPD	Chronic obstructive pulmonary disease
DCFH	2′,7′-dichlorofluorescin
DCFH-DA	2′,7′-dichlorofluorescin diacetate
DEP	Diesel exhaust particles
DHE	Dihydroethidium
DNA	Deoxyribose nucleic acid
DLS	Dynamic light scattering
DTT	Dithiothreitol
ELISA	Enzyme-linked immunosorbent assay
ER	Endoplasmic reticulum
ESF	European Science Foundation
FACS™	Fluorescent-activated cell sorting (Becton Dickinson™)
Fe	Iron
$FeCl_2$	Iron chloride
FPG	Formamido pyrimidine glycosylase
GSH	Reduced glutathione
GSSG	Oxidized glutathione
HARN	High aspect ratio nanoparticles

Toxicity of Selenium Compounds and Nano-Selenium Particles

Jinsong Zhang[1] **and Julian E. Spallholz**[2]

[1]*School of Tea and Food Science, Anhui Agricultural University, Anhui, China* and [2]*Nutritional Sciences, College of Human Sciences, Texas Tech University, Lubbock, TX, USA*

1 BRIEF HISTORY OF SELENIUM

The element selenium was discovered by Jons Jacob Berzelius (1779–1848) in 1817 as a red deposit in a sulphuric acid flue deposit at Gripsholm, Sweden (Berzelius, 1817). Believed at first to have been a tellurium deposit, it was a new element having intermediate characteristics of tellurium and sulphur. Berzelius named it selenium for Selene, goddess of the Moon, as the new element fit within the periodic table above tellurium, which had been discovered in 1783 and named for the Earth, Talus. Berzelius, in addition to discovering selenium, also discovered lithium, silicon, thorium and cerium. He is furthermore credited with establishing the two-letter system (Xx) of elemental identification as used within the periodic table.

Although Berzelius identified and named the element selenium, the Venetian Traveler Marco Polo is the first to have seemingly described the toxic attributes of selenium ingestion by horses along the Silk Road. The observation of sick and ill horses with their hoofs sloughing off was probably made in or about 1265 upon Marco Polo's return trip to Venice from China as he crossed the Silk Road (Rosenfeld and Beath, 1964). This toxicity in horses, as well as in cattle and sheep, was to be rediscovered in the settling of the western United States. In 1857, Dr Madison, an army surgeon, described a fatal condition affecting horses of the US Cavalry near Ft Randall of the Nebraska Territory now located in South Dakota (Rosenfeld and Beath, 1964). Loss of tail and mane hair, appetite and the sloughing-off of hooves of horses are some of the symptoms described by Madison. This condition, affecting grazing livestock throughout the Nebraska Territory, was noticed and the citizens of Boyd County gave it the name "alkali disease", thinking the cause was the mineral salts of water, soils or pasture. In 1929, Franke (1934) working for the experimental station in South Dakota was to discover that grains grown on specific soil deposits imparted to animals "alkali disease" and that they were exceptionally toxic to livestock. Robinson (1933) had been given samples of toxic South Dakota wheat and, at the suggestion of Knight, analysed the wheat for its selenium content. The wheat gluten contained 90 μg Se g^{-1} of the protein which we now know to have been selenomethionine. By mid-1930s, selenium accumulation in plants from soils was known to be the cause of "alkali disease" and the disease had all the same characteristics expressed in livestock that were described in horses by Marco Polo.

The next 20 years or so were spent in the identification of those plant species that took up

and concentrated selenium from soils. Selenium was found in many species of the plant genera *Astragalus*, *Xylorhiza*, *Oonopsis* and *Stanleya*, conspicuous wild flowers of the western United States (300 species) and other arid and semi-arid regions of the world (1200 species overall). Although selenium is not generally recognized as required for plant species, the early growth experiments with *Astragalus racemosus* and *Astragalus beathii* certainly indicated a physiological requirement for selenium. Indeed, some but not all species of *Astragalus* plants are known to only grow on outcroppings of sediments with heavily concentrated selenium. Where these selenium accumulator plants grow, they often volatilize malodorous and nauseous odors of selenium compounds. The selenium concentrated and volatilized by accumulator plants originates primarily as selenates with lesser amounts of selenites in soils. Accumulation in these plants ranges from a few $\mu g\,Se\,g^{-1}$ to thousands of $\mu g\,Se\,g^{-1}$ of dry plant material. Some plants of the *Astragalus* genus highly accumulate selenium; *Asters*, *Atriplex* and other plants moderately accumulate selenium; whereas cereal grains and grasses and most other plant foods accumulate only low levels of selenium (Trelease and Beath, 1949; Rosenfeld and Beath, 1964). Today, speciation of these and other selenium-containing plants and plant foods have revealed the presence of several different selenoamino acids (Pedero and Madrid, 2009).

In 1941, *Astragalus pectinatus* yielded the first unidentified selenoamino acid from a protein, $C_7H_{14}N_2O_4Se$, isolated in association with its sulfur analogue. It had long been suspected since 1916 that selenium might be a replacement for sulfur in plants, as they existed together in the VIA period of the periodic table. Early examination of these plants indicated they contained both sulfate and selenate, but within *Astragalus* plants, only organic selenium compounds were found, most of which were directly soluble in water. In cereal crops and grasses, much of the selenium was not water soluble and could not be readily dissociated from the plant's protein fraction. By 1950, selenomethionine and selenocysteine had been reported to have been identified in plant protein hydrolysates. In 1960, Se-methylselenocysteine was identified in *Astragalus bisulcatus* following the identification of *S*-methylcysteine (Rosenfeld and Beath, 1964).

In 1957, selenium had been identified as a component of a yeast isolate fraction called "Factor-3" which prevented a condition known as "dietary liver necrosis" in rats. Dietary liver necrosis in rats occurred when rats were fed a torula yeast and low vitamin E diet, but not when fed a brewer's yeast. This discovery was made by Schwarz and Foltz (1957) then working at the National Institutes of Health. The other "two factors" preventing dietary liver necrosis were a higher dietary level of vitamin E and additional sulfur amino acids such as cysteine fed to rats. This revelation that toxic old selenium could prevent a nutritional disorder of the liver in rats and also other detrimental disorders and conditions in animals has changed the perception of the biological role of selenium forever.

Soon after the discovery of selenium as the "Integral Component of Factor-3", and by 1964, exudative diathesis in chicks, "stiff lamb disease", white muscle disease in calves, "ill-thrift disease" in cattle and sheep in New Zealand have been determined to be conditionally responsive to very small amounts of dietary selenium supplementation (Scott, 1981). Thereafter, Allaway and Cary (1964) proceeded to map the selenium content of soils throughout the United States by using the identification of selenium in plants. They were able to identify regions of the United States that were sub-adequate in soil selenium leading to animal deficiency conditions, areas where selenium was sufficient and those areas of the country where seleniferous plants accumulated selenium from geologically enriched strata. Prior to the approval of the addition of selenium to animal feeds by the US Department of Agriculture in 1974 (Ullrey, 1980), the selenium map was used in the selection and transport of high-selenium feed stocks into areas such as Florida for their inclusion into animal feeds, raising the natural amounts of selenium consumed by animals. The most extensive and complete selenium map of any country is that of China. With the discovery in 1980 of perhaps the only widespread incidence of selenium deficiency in humans, "Keshan's disease and Kachin-Beck's disease" in China (Yang *et al*., 1984), nearly the entire country, county by county, was assessed for the selenium content of crops.

Just prior to the approval of selenium additives to animal mineral premixes by the US Department of Agriculture, Rotruck *et al*. (1973) discovered that selenium was present within the rat erythrocyte enzyme glutathione peroxidase. This came about through a variety of experiments showing that selenium-sufficient rats but not selenium-deficient

rat erythrocytes were protected against haemolysis in the presence of glucose. Selenium also protected haemoglobin from ascorbate or hydrogen peroxide oxidation and was not able to be dialysed away from the hemolysates. Following injection with 75-SeO_3 rat hemolysates were chromatographed and the 75-Se co-eluted with glutathione peroxidase. Flohe, Gunzler and Schock (1973) showed that glutathione peroxidase contained 4 g atoms of selenium/molecule, a tetramer of approximately 82 kilo dalton. Five years later, Forstrum, Zakowski and Tappel (1978) identified selenocysteine as the catalytic amino acid residue in rat glutathione peroxidase. The second selenoenzyme was initially isolated from pig liver by Ursini *et al*. (1982). It also used glutathione as a cofactor as did glutathione peroxidase, but it exhibited a different spectrum of reducible substrates. This second selenoenzyme was named phospholipid hydroperoxide glutathione peroxidase as it reduced iron-induced phophatidylcholine, *t*-butyl and cumene hydroperoxides to their corresponding alcohols. Selenocysteine would later be named the "twenty-first" amino acid by Böck *et al*. (1991) as it was to be found in additional selenium-containing enzymes and proteins.

Since 1985, 23 additional selenium-containing proteins (Stadtman, 2000) and enzymes have been identified and studied in detail. Common to all proteins is the inclusion of one or more selenocysteine residues. Common to all selenoproteins with catalytic activity is one selenocysteine residing at the active site (Stadtman *et al*., 1996; Toppo *et al*., 2009).

2 SELENIUM COMPOUNDS IN FOODS AND SUPPLEMENTS

The general consensus is that higher plants, exclusive of some algae and bacteria, do not have a growth or biochemical requirement for selenium. The exceptions are the most beautiful flowering selenium accumulator plants of the genera *Astragalus*, *Oonopsis*, *Xylorrhiza* and *Stanleya* (Trelease and Beath, 1949; Rosenfeld and Beath, 1964). Therefore, plant foods, particularly cereal grains, account for providing almost all of the direct animal and human selenium requirements. Selenium in all plant foods is dependent upon the passive accumulation of selenium from soils following most commonly in the metabolic pathway of sulfur. As plants synthesize methionine and other sulfur amino acids and compounds, they also synthesize the selenium analogues to the degree that selenium is present and assimilated at non-toxic levels from soils. Thus, plant foods contain primarily selenomethionine, and as such it is also the major selenoamino acid found in fish, meats and eggs, the major animal and human dietary forms of selenium (Schrauzer, 2003). Lesser amounts of selenocysteine in animal foods and Se-methylselenocysteine are to be found in plant foods. The latter, Se-methylselenocysteine, is the major selenoamino acid found in *Astragalus* and the other selenium accumulator plants *Cruciferous* vegetables (broccoli, cauliflower) and *Allium* plant species (garlic, onions, leeks). The former, selenocysteine, is primarily found in animal foods in association with the various selenium proteins, with trace amounts of selenium from fermented bacterial or yeast-containing foods. Selenocysteine had been reported early on to be present in foods, but it is most likely to have been an artefact of selenocysteine oxidation.

The wide-ranging variability of selenium concentrations in animal feeds and human foods is the cause of a low selenium intake and the many reported selenium-deficiency-associated animal diseases and conditions. With the exception of Keshan's disease and Kaschin-Beck's disease in humans from China, no other selenium deficiency is known to widely occur. Many human populations are known to consume diets below the WHO-recommended minimal adult dietary intake (RDI) of 40 μg selenium each day. European populations are considered marginal and poor people in countries such as rural India, Bangladesh and elsewhere consume less than the WHO dietary standard set for selenium. For such inadequate dietary intakes of selenium, there is provision of selenium supplementation via mineral premixes for animals and multi-vitamin minerals and individual selenium supplementation for people. Animal supplements include selenate, selenite and Se-yeast and, sometimes, pure selenomethionine. Human supplementation is often through normal animal feed supplementation or through the enriched production of high-selenium eggs, milk and meats as occurs in some countries. Individual human supplements run the spectrum of selenium compounds: selenate, selenite, selenomethionine, Se-methylselenocysteine and the first available commercial selenium supplement, circa 1978, a highly enriched Se-yeast.

Whereas in most environmental/natural feed/food situations there is insufficient selenium in diets to cause any toxicity, toxicity is known to occur particularly in fish and birds. The cause is some natural concentration of selenium in water run-off, stream and river contamination from mining or agricultural operations, ingestion of selenium accumulator plants by livestock and misformulations of supplements for both animals and people. The most recent publicized case of selenium toxicity (May, 2009) was that of 21 Polo horses from Argentina in Florida (JAVMA News, 2009).

Table 1. Mathematics of selenium essentiality and toxicity (selenite; rodents).

Selenium	μg Se g^{-1} diet (ppm)	Atoms Se g^{-1} diet
Nutritional deficiency	0.05	38 000 000 000 000 000
Nutritional adequacy	0.20	152 000 000 000 000 000
~Oral tolerance	2.00	1 520 000 000 000 000 000
~Oral toxicity	5.00	3 800 000 000 000 000 000
~Oral lethality	15.00	11 400 000 000 000 000 000

Numbers are approximate depending upon species, sex, age and other dietary factors. Given to the author (JES) by the late Dr Douglas Frost, Schenectady, NY.

3 TOXIC THRESHOLDS OF SELENIUM INGESTION

All selenium compounds are potentially toxic to animals with the toxicity dependent upon the animal species, the chemical form of the selenium compound, the route of administration and the dose. For selenium compounds, the often quoted statement attributed to Paracelsus, Father of Modern Medicine, "The dose makes the poison" is particularly apparent and presently apt in view of the recent deaths of the 21 Polo horses in Florida noted above. To date, we know only that selenite was administered to these horses and that liver and blood tissues contained circa 20 × the normal levels of selenium. Further details will surely determine the amount of selenium in the formulary and the total amount of selenite selenium administered to the Polo horses.

Selenite selenium along with selenate selenium is a common additive to animal feeds present at 0.1–0.2 ppm Se. Experimental rats and mice can tolerate dietary selenite/selenate selenium to about 2 ppm Se, with about 3–5 ppm Se being chronically toxic and 10–15 ppm Se fatal as summarized in Table 1. Organic selenium supplements Se-yeast, selenomethionine and Se-methylselenocysteine are less toxic than the inorganic selenium compounds.

All selenium compounds are potentially toxic to humans. Although there is much less controlled experimental data, there are some mistakes that have been made with human selenium supplements similar to that which has recently occurred in the Polo horses. There is no reason to suspect that the chemical forms of selenium that are toxic to animals are not similarly toxic to humans. Thus, selenite/selenate selenium probably remains as the most toxic selenium dietary supplement available, with Se-yeast, selenomethionine and Se-methylselenocysteine being much less toxic. Very few reports of selenium toxicity have been reported in humans, but they are not unknown. The most extensive environmental human selenium toxicity occurred in China with keratinous tissues affected, loss of hair and cracked nails as found in horses, cattle and sheep, loss of mane, hair, wool along with cracked and deformed hooves. Similar symptoms have been reported in Water Buffalo in the Indian Punjab due to high selenium content of ground waters.

The US RDI is 55 μg Se each day for adults from food and/or supplements. The tolerable upper limit (TUL) is 400 μg Se each day and overt selenosis occurs at 15 000 μg Se each day as observed in China. Table 2 provides dietary intake information about selenium and its effects in humans. The data are presented as it might apply to selenite. The predominant forms of dietary selenium intake from foods are selenomethionine and selenocysteine with much lesser amounts of Se-methylselenocysteine. These latter selenium compounds are less toxic and the tabular data below do not directly apply to the toxic selenium concentrations cited.

3.1 Toxicity of Selenium Compounds

As noted above, selenium toxicity is initially thought to have been first described in horses by Marco Polo while travelling the "Silk Road" of China. A similar description of toxicity symptoms affecting hooves and mane hair in horses given by Marco Polo was also observed in horses in the western United States in the late 1800s. Its cause

Table 2. Selenium essentiality and toxicity in humans.

Se ($\mu g\,day^{-1}$)	Chemical form	Effect
<11	Dietary	Keshan's disease
20	Dietary	Minimum dietary requirement
40	Dietary	WHO adequate dietary requirement
55	Dietary	Adult US RDI
400	Dietary	TUL, tolerable upper limit
600	Dietary	Individual maximum safe limit
819	Dietary	NOAEL, maximum safe limit
1000	Na_2SeO_3	Personal known intake for years
1540	Dietary	LOAEL, low level toxicity
1600	Dietary	Adverse effective level
5000	Dietary	Selenosis; hair and nail loss
15 000	Dietary	Overt selenosis

was to remain undiscovered until the USDA in South Dakota and the Wyoming Experiment Station in the 1930s determined that the cause of the toxicity was the ingestion of seleniferous range plants containing up to several thousand milligrams of selenium per kg dry matter. With great sadness, it was the 21 Argentinean Polo horses that succumbed to acute selenium toxicity in Florida in May 2009 resembling "blind staggers".

In the case of selenium toxicity from seleniferous plants and infrequently from cereal grains, toxicity to horses and other livestock is from organic selenium compounds. In contrast, the Polo horses from Argentina succumbed to selenite, inorganic selenium toxicity, with more than 20 times the normal concentration of selenium found in liver and muscle tissues. Inorganic selenium compounds, selenates/selenites, particularly selenites, are infrequent constituents of ground or well water, but more frequent constituents of leaching from concentrated geological formations and commercial mine effluents. These more highly concentrated inorganic selenium sources enter the food chain through algae and other plants and then up the food chain making their way to birds and fish of all kinds. Although selenium is not necessarily concentrated in the food chain by adults, it may be highly concentrated in eggs by female adults. Selenium toxicity is well known to adversely affect unborn fish, birds and perhaps other ovaripids when it is excessively ingested by females during periods of ovogenesis and egg formation. Such embryos are subject to selenium-induced developmental mutations and malformations of chicks and fish (Hoffman, 2002).

3.2 Inorganic Selenium Toxicity

From the time of the association of seleniferous plants with toxicity in the 1930s and the subsequent experimental confirmation of selenite toxicity in laboratory animals, the reason for selenium's toxicity had been debated for years thereafter. At the second International Symposium of Selenium in Biology and Medicine held in Lubbock, Texas in 1980 the major focus of the meeting was the composition, mechanism and role of selenium in glutathione peroxidase. Two presentations were to progress the understanding of the metabolism of inorganic selenium (e.g., toxicity) in biological systems initially pioneered by Painter (1941), and latter by Tsen and Tappel (1958). The first paper by Kice (1981), System Toxicology Approaches for Evaluating Chemical Carcinogenicity, discussed the detailed reaction of Se IV species, selenite/selenium dioxide, with thiols, as first reported by Tsen and Tappel in 1958. In Nanotoxicology of the Symposium, Bhuyan, Bhuyan and Podos (1981) described their not-too-distant past work on the generation of bilateral nuclear cataracts in rats, rabbits and guinea pigs from a single injection of selenite following the finding that these injections did not protect rabbits from cataracts induced by 3-aminotriazole. Cataract induction in animals by 3-aminotriazole had been shown to be due to the generation of reactive oxygen species (ROS), loss of lens protein thiols and lenticular lipid peroxidation. Ascorbic acid (vitamin C) had been shown to protect from 3-aminotriazole cataract formation in animals, but when "other antioxidant" selenium failed to afford protection but rather induced cataratogenesis, insight into selenium's oxidative role in biological systems further emerged. Selenite, by oxidizing thiols, cross-linking disulphides and forming unstable selenotrisulphides, as originally proposed by Painter (1941), was discussed in the context of cataract formation by injections of selenite.

What Bhuyan *et al*. had alluded to in their 1981 Proceedings publication was the possibility that selenite was generating ROS as the cause of cataract formation. Their supposition could have been more emphatic had they been aware of and cited the paper of Misra (1974). The study by Misra describes the auto-oxidation of various thiols, including glutathione, generation of superoxide and the inhibition of nitroblue tetrazolium (NBT) reduction by superoxide dismutase. The authors

went on to explain how transitions metals, such as copper, might catalyse thiol oxidation generating superoxide and other ROS. Thus, both Kice and Bhuyan, Bhuyan and Podos (1981) had the selenium chemistry, *in vitro* and *in vivo*, nearly correct. What was missing was the "Misra Connection" to the superoxide generation from the auto-oxidation of glutathione. Selenite selenium was just a catalyst of thiol oxidation, as first demonstrated by Levander, Morris and Higgs (1973) and later shown by Seko *et al*. (1989), to produce superoxide.

The "Misra Connection" to selenate-accelerated superoxide generation was directly made by Seko *et al*. (1988) in an unassuming poster presentation at the 4th International Symposium on Selenium in Biology and Medicine in Tubingen, Germany and later published in the Proceedings of the Symposium (Seko *et al*., 1989). This realization that inorganic selenite generated superoxide and likely other ROS seemed to account for the toxicity of selenite *ex vivo* and *in vivo*. Immediately following the Seko paper in the Proceedings were two papers that, retrospectively, evaluated the superoxide-generating effect of selenium that was generating superoxide. Following the Seko paper was a manuscript by Hogberg, Garberg and Stahal (1989) showing that selenite in a dose-dependent manner induced single-stranded DNA fragmentation provided that oxygen was present. Hogberg and coworkers had previously shown that selenite induced cell lysis and speculated that oxidation–reduction (redox) cycles were likely at play contributing to the lysis of hepatic cells. The paper following Hogberg and coworkers, by Frankel and Favey (1989), reported that selenite inhibited DNA and RNA polymerases but only in the presence of a thiol. Again, retrospectively, these authors incorrectly concluded that selenite was toxic by forming a selenotrisulphide (Ganther, 1968), selenodiglutathione, which then served to inhibit the polymerases. In their experiments, non-specific cell depletion of all thiols served to inhibit selenite inhibition of the polymerase whereas specific inhibition of glutathione with buthionine sulfoximine did not prevent polymerase inhibition. This suggests that not only selenite but also other thiols such as protein thiols (cysteine residues)oxidize gluthathione to generate superoxide. From more recent research, it is known that selenite *in vivo* targets and oxidizes the protein thiols of mitochondria (Shen *et al*., 2001; Kim *et al*., 2002; Hail and Lotan, 2009) decreasing the mitochondrial membrane potential. This is the likely cause of mitochondrial swelling, as first observed by Levander, Morris and Higgs (1974), and the inhibition of the mitochondrial permeability transition (MPT) pore followed by the release of cytochrome *c*. As a cellular oxidizer, selenite oxidation is concentration dependent and does not apparently discriminate among thiols. Most cells encounter selenite toxicity exposed to concentrations of 5–10 μM.

3.3 Organic Selenium Toxicity

Toxicity of organic selenium compounds in comparison with selenite is well known to be far less toxic to cells, particularly as studied with cancer cells *in vitro* (Fico *et al*., 1986) and in mice (Poirier and Milner, 1983) as well as in larger animals on a comparative selenium basis (Kim and Mahan, 2001; Tiwary *et al*., 2006). *In vivo*, the study of inorganic and organic selenium metabolism beyond H_2Se formation showed that methylation reactions were the route to selenite and organic selenium detoxification and excretion (Foster, Kraus and Ganther, 1986). The trimethylselenonium ion is excreted in urine and the methylated intermediate of the trimethylselenonium ion, dimethylselenide, is exhaled via the pulmonary system. The latter route of selenite metabolism and excretion occurs under mild to severe toxic conditions where the methylation pathways appear to be compromised and which contributes to the "garlicky to horse radish" smell of the breath from dimethylselenide (Hsieh and Ganther, 1977). Nonetheless, organic selenium compounds are toxic as recorded by the conditions of animals ingesting seleniferous plants and grains, "alkali disease" (chronic selenium toxicity) and "blind staggers" (acute selenium toxicity). To account for the differences in the chronic and acute toxicity of inorganic vs. organic selenium compounds, metabolism has to occur, quite different from that of selenite (SeO_2) directly reacting with thiols such as glutathione, which was thought to be the intervening effect. Although methylation has been viewed as the principal detoxification pathway of inorganic selenium and organic selenium metabolites under physiologic conditions, demethylation of methylated selenium compounds is now viewed as the route to selenium toxicity of the major dietary forms of selenium, selenomethion-

ine and Se-methylselenocysteine (Ohta and Suzuki, 2008; Suzuki, Kurasaki and Suzuki, 2008). Again, the 4th International Symposium on Selenium in Biology and Medicine held in Tubingen, Germany in 1988 serves as the transitional point in time to the understanding that inorganic selenium toxicity involves generating ROS, and that the metabolism of organic selenium compounds results in a more toxic selenium metabolic form. The study by Ip (1989) in those Proceedings foresaw that selenium metabolism was the key to organic selenium toxicity and possibly chemoprevention by dietary supplements.

When present in tissues or cells we know that all the principal dietary forms of selenium, selenomethionine, selenocysteine and Se-methylselenocysteine, are metabolized by enzymes, methioninase and β-lyases, directly or indirectly in the case of selenocysteine via methylation of H_2Se and on to an common metabolite, methylselenol, CH_3SeH. It is also known that like selenite, methylselenol can react with glutathione and generate superoxide as shown *in vitro* from dimethyldiselenide (Spallholz, Shriver and Reid, 2001), and from the methioninase reaction with selenomethionine as substrate (Spallholz, Palace and Reid, 2004). The realization that many organic selenium compounds were toxic because of the same or a similar selenite chemistry generating superoxide immediately became plausible to Spallholz (Yan *et al*., 1991) from the 1988 poster presented at Tubingen. Yan and coworkers showed that selenite and selenocysteine at two different concentrations, 6.25 and 12.5 μM, were most effective in reducing the intracellular levels of glutathione of mammary cancer cells whereas selenate and selenomethionine were not efficient in reducing the cancer cell glutathione. Concurrently, selenite and selenocysteine also reduced the cancer cell growth viability whereas, again, selenate and selenomethionine had much less of an effect. By 1990, the authors knew that in an *in vitro* chemiluminescent (CL) assay that measured superoxide generation, selenite and selenocystine both generated superoxide in the presence of glutathione and other thiols (Yan, Boylan and Spallholz, 1990). Selenate and selenomethionine were not catalytic in the *in vitro* CL assay and were therefore not toxic to cancer cells affecting cell growth at the same concentrations of added selenium compounds. The CL superoxide data and 1991 mammary cancer cell data from these selenium compounds were the same for selenite, selenate, selenocystine and selenomethionine as that reported by Greeder and Milner (1980) against an ascites cancer in mice. Selenite and selenocystine were much more efficacious in mouse survival than selenate or selenomethionine. Thompson and Ip (1991) found that when selenite was injected into Sprague–Dawley rats the hepatic glutathione levels were lowered when measured 2 h later. *In vivo*, feeding 5 ppm Se as selenite in diets increased hepatic glutathione whereas selenomethionine had no effect upon glutathione. It was quite clear that the similarities and differences between the toxicity of selenite and organic selenium compounds to cells in culture, and animals, depended upon the differences in the chemical composition of different organic selenium compounds and how they were being metabolized.

Chaudière, Courtin and Lecalire (1992) described the catalytic and anti-cancer properties of selenocysteine and many other diselenides that were to be later studied. Using the diselenide selenocystamine, these authors were able to demonstrate that thiol reduction of the diselenide would generate much more than stochiometrically oxidized glutathione (GSSG), superoxide and H_2O_2. Their *in vitro* assay required oxygen as had been observed in the catalysis of glutathione with selenite. Spallholz (1994) reviewed both the inorganic and the organic selenium redox chemistry listing those selenium compounds that generated superoxide from glutathione oxidation in an *in vitro* CL assay (Table 3).

Spallholz (1997) reviewed the CL redox chemistry of selenium compounds in physiological phosphate buffer and provided evidence that selenium, covalently attached to an insoluble matrix, cellulose, would also catalyse superoxide generation from glutathione as measured by a CL assay. Attachment of a redox selenium coating to insoluble matrixes to prevent bacterial biofilm formation received US FDA approval as a medical device application in 2008. Prevention of biofilm formation in the form of selenium coated brackets and ligatures has been included in dental adhesives by Class One Orthodontics of Lubbock, Texas. The prevention of bacterial biofilm colonization of surfaces by redox-active covalent selenium has also been demonstrated for silicon contact lenses (Mathews *et al*., 2006) and a dental sealant coating as applied by Class One Orthodontics on cellulose (Tran *et al*., 2008).

Table 3. Redox cycling and non-redox cycling selenium compounds.

Compounds that generate superoxide	Compounds that do not generate superoxide
Selenite	Elemental selenium
Selenium dioxide	Selenate
Selenocystine	Selenomethionine
Selenocystamine	Se-methylselenocysteine[a]
Diselenodipropionic acid	Selenobetaine[a]
Diphenyldiselenide	Dimethylselenoxide[a]
Dibenzyldiselenide	Selenopyridine[b]
1,4-Phenyl-*bis*-(methylene)-selenocyanate[c]	Triphenylselenonium ion[a]
6-Propylselenouracil[d]	K-Selenocyanate
Dimethyldiselenide	Selenourea
Methylseleninic acid	Selenoethionine
Selenocyanopropionic acid	All monoselenides tested (RSeR′)

Original table from Spallholz (1994).
Assay conditions: borate buffer pH 9.2 containing glutathione (4 mg ml^{-1} and lucigenin (20 μg ml^{-1}) at 25 °C or phosphate buffer pH 7.4 containing (1 mg glutathione ml^{-1}) at 36 °C. The CL results are similar. Greater selenium-generated CL activity is measured as the pH becomes more alkaline.

4 SELENIUM: PHASE 1 AND 2 ENZYMES, CHEMOPREVENTION AND APOPTOSIS

Phase 1 and 2 liver enzymes are responsible for the detoxification of non-nutrients, drugs, toxins, carcinogens and other xenobiotics. In general, phase 1 liver enzymes modify the above-cited constituents by adding an epoxide or hydroxyl moiety or preparing molecules as phase 2 enzymatic substrates. The phase 2 enzymes utilize the phase 1 enzymatic modifications adding glutathione, glucuronic acid, acetic acid, amino acids, that is, glycine or taurine, sulfate and other molecules. The net effect of phases 1 and 2 enzymes is to convert water-insoluble molecules into water-soluble molecules for excretion or to neutralize potential toxins and/or carcinogens (Liska, 1998).

Toxicity from the ingestion of compounds often elevates levels of phases 1 and 2 enzymes in order to accelerate molecular modifications for detoxification and excretion. Phase 1 and phase 2 enzymes respond to toxic insults from xenobiotic and phytochemicals, and are referred to as inducible enzymes. Many compounds that induce phases 1 and 2 enzymes do so by generating "oxidative stress", the beyond ambient production of free radicals from normal metabolism. The response of the phase 1 and phase 2 enzymes is dose related prior to induction of toxicity; that is, an increase in "oxidative stress" increases the synthesis of phase 1 and 2 enzymes, most likely through an ROS gene signalling modality. Sulforaphane and other isothiocyanates, derived from the glucosinolates of cruciferous vegetables, are considered potent anti-cancer phytochemicals owing to their ability to induce phase 2 enzymes that metabolize and/or inactivate carcinogens for excretion (Zang and Callaway, 2002). Isothiocyanates in sufficient concentrations are known to also generate "oxidative stress", thereby inducing phase 1 and phase 2 enzymes and lowering cancer risk. As described above for selenite and selenides, these isothiocyanates also initiate redox cycling with glutathione *in vitro*, as determined by CL, and have the inherent potential to induce "oxidative stress" (Sharma *et al*., 2008).

Some selenium compounds are also known to induce phase 1 and phase 2 enzymes and are thought to be a family of potent anti-cancer compounds. These selenium compounds also affect levels of glutathione, increasing glutathione probably do to moderate "oxidative stress" or by decreasing glutathione do to the higher concentrations of redox cycling selenium present in cells, in liver and other tissues *in vivo*, all depending upon the level of dietary intake. Normal dietary intakes of adequate amounts of selenium can maximize the anti-oxidant selenium enzymes: the glutathione peroxidases, thioredoxin reductases, phospholipidhydroperoxide glutathione peroxidases and alike. These selenium selenocysteine enzymes, along with superoxide dismutases and catalases, are in effect "anticarcinogenic" as they protect cells and the cells genome from "oxidative stress" and the ensuing free radical damage that may target nuclear as well as mitochondria and mitochondrial nucleic acids as does selenite. With an understanding that many selenium compounds, in a dose-dependent manner, can oxidize thiols, producing superoxide and other ROS, modest amounts of dietary supplemental selenium compounds, selenite, methylseleninic acid and Se-methylselenocysteine following metabolism, such as sulforaphane and other isothiocyanates,

elevate levels of phase 1 and phase 2 enzymes via "oxidative stress". This is one of only two likely scenarios of why non-toxic levels of sulforaphane, curcumin, selenium and other supplemented phytochemicals may be anticarcinogenic (Hail *et al*., 2008; Hail and Lotan, 2009). The other scenario for selenium is that supplements are raised to such dietary levels that their metabolites, most likely the methylselenide anion (methylselenol is fully ionized at physiological pH), are high enough to induce multiple "oxidative–signalling" pathways for cellular apoptosis. As of this writing, a search of PubMed, selenium and apoptosis, lists nearly 400 publications, many describing selenium-induced apoptosis, along with several excellent and recent reviews on the subject (Rikiishi, 2007;Sanmartin, Plano and Palop, 2008; Zeng, 2009).

The very first citation whose focus is selenium chemistry demonstrating apoptosis is the study by Thompson *et al*. (1994) published in Carcinogenesis, "Comparison of the Effects of an Organic and an Inorganic Form of Selenium on a Mammary Carcinoma Cell Line". The organic selenium compound studied was *bis*(methylene) selenocyanate (p-XSC), and the inorganic selenium compound was selenite. Both compounds are now known to redox cycle (Table 3) and both compounds inhibit cell growth in a concentration-dependent manner. The 1994 abstract from the paper concludes, "The induction of apoptosis by selenium compounds may partially account for their chemopreventive activity". That selenium apoptosis is induced by either the intrinsic or extrinsic pathways is now widely accepted. The weight of the evidence suggests redox cycling, oxidation of varied intracellular thiols with accompanying oxidative stress, affects mitochondria and the intrinsic apoptotic pathway or other proteins and/or inhibitor and enzymes of the extrinsic apoptotic pathway. Sarafian and Bredesen (1994) were invited to write a commentary on the subject; "Is Apoptosis Mediated by Reactive Oxygen Species?" Their conclusions were that ROS are central mediators of apoptosis and that generators of ROS are effector apoptotic signalling molecules, "leading to transcription changes of apoptosis via redox-sensitive transcription factors" such as AP-1 and NFκB.

Selenium has the potential capacity to reduce carcinogenesis; such effects were mostly observed at high doses in experimental animals (El-Bayoumy and Sinha, 2004). Selenium-induced apoptosis of cancer cells has been suggested to be an important mechanism for cancer prevention. If this mechanism is indeed critical, the risk of selenium toxicity appears to be unavoidable, unless the preferential selection of killing cancer cells is firmly established for selenium compounds. Some studies have reported that selenium compounds preferentially inhibit growth and induce apoptosis in cancer cells as compared with corresponding normal cells (Watrach *et al*., 1984; Ghose *et al*., 2001). In contrast, it was surprising to find that the cytotoxic effects of both inorganic and organic selenium compounds were more potent in normal hepatocytes as compared with hepatic carcinoma cells (Weiller *et al*., 2004). Furthermore, it was reported that non-tumourigenic prostate cells are highly sensitive to selenium toxicity compared with prostate cancer cells at physiologically relevant concentrations (Rebsch, Penna and Copeland, 2006). As selenium-induced apoptosis may not overcome the risk of toxicity to normal tissues, the mechanism of phase 2 enzyme activation induced by high-dose selenium seems to be a reasonable strategy to identify optimal selenium forms for cancer prevention. Accordingly, a selenium form with lower toxicity but possessing equal activity of inducing phase 2 enzymes compared with sodium selenite, selenomethionine and Se-methylselenocysteine would be more appropriate for cancer prevention.

5 NANO-SELENIUM PARTICLES

As mentioned above, the element selenium was discovered by Jons Jacob Berzelius as a red deposit. The red precipitate, that is, elemental selenium of zero valence state, can be generated by reacting together sodium selenite and glutathione. There has existed a long-held dogma that elemental selenium is biologically inert. Indeed, purchasable black elemental selenium has no bioactivity, and the bioavailability of the red elemental selenium formed in some bacteria or prepared via reducing sodium selenite by using a reductant is only 2–4% of sodium selenite (Combs *et al*., 1996). Zhang*et al*. (2001) found that the addition of bovine serum albumin to the reaction system of sodium selenite and glutathione could control the aggregation of neonatal elemental selenium atoms in the form of nano-selenium particles (Nano-Se) as shown in Figure 1. Bovine serum albumin concentration in

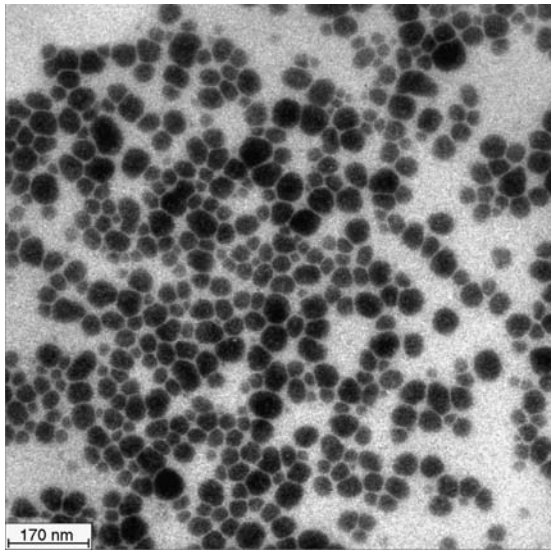

Figure 1. High-resolution transmission electron microscopy image of Nano-Se.

the reaction system was negatively correlated with particle size (Huang *et al*., 2003). As expected, a size-dependent effect of directly scavenging an array of free radical species was observed, with smaller sized Nano-Se being more effective (Huang *et al*., 2003). Consistent with this finding, the redox activities of Nano-Se particles prepared from selenourea dispersed by using bovine serum albumin or sodium dodecyl sulfate varied linearly with the surface area of the particles, thus exhibiting size-dependent redox activity (Mishra *et al*., 2005). Unexpectedly, there was no size effect of 5–200 nm Nano-Se upon increasing selenoenzyme activities including glutathione peroxidase and thioredoxin reductase in both selenium-deficient cells and mice (Zhang *et al*., 2004). Under conditions of selenium deficiency, the avidity of selenium absorption may be increased to maintain the biosynthesis of fundamental selenoenzymes for redox homeostasis. Such intrinsic avidity may override extrinsic size advantage of small-sized Nano-Se on selenoenzymes (Peng *et al*., 2007). Based on this hypothesis, it is anticipated that the size effect of Nano-Se on the biomarkers sensitive to supranutritional levels of selenium can then reappear once selenoenzymes have been saturated (Peng *et al*., 2007). Indeed, the size-dependent effects of Nano-Se on increasing selenium accumulation and inducing glutathione *S*-transferase, a phase 2 detoxifying enzyme, were observed when mice were administered with supranutritional levels of Nano-Se of different sizes (Peng *et al*., 2007). These results together suggest that the biological activity of Nano-Se is a function of their size. A particular example is the photochemically generated eight-atom elemental selenium at subnano size with either serum albumin or lipoproteins acting as the dispersant and/or conjugating agent. Selenium 8 molecules would be expected to fit into the 10-Å hydrophobic pocket near CySH-34 of albumin to form Se(0)-protein conjugates (Sieber *et al*., 2005). Although proteinated elemental selenium at 36 nm and polysaccharide-fabricated 59 nm Nano-Se are cytotoxic (Zhang *et al*., 2001; Chen *et al*., 2008), such colloidal selenium preparations may not have been able to match the potency of photochemically generated elemental selenium which in fact is even more toxic than selenium dioxide, sodium selenite, selenomethionine, and selenocystine (Sieber *et al*., 2005).

5.1 Impact of Nano-Se and Selenocompounds on Selenoenzymes and Glutathione *S*-transferase

The human body metabolizes various selenium forms into selenide. Hydrogen selenide then provides selenium for the synthesis of a number of selenoenzymes including glutathione peroxidase and thioredoxin reductase (Ohta and Suzuki, 2008). Glutathione peroxidases catalyse the reduction of hydrogen and organic peroxides. Thioredoxin reductases provide reducing power for thioredoxin, which regulates multiple important biochemical processes and defends against oxidative stress. A direct deleterious consequence of selenium deficiency is compromised selenoenzymes. Consequently, severe selenium deficiency can result in diseases, such as Keshan disease and Kashin–Beck disease in humans (Yang *et al*., 1984; Moreno-Reyes *et al*., 1998).

To evaluate the impact of Nano-Se on selenoenzymes, 20–60 nm Nano-Se with average size being 36 nm was used. In selenium-deficient cells, sodium selenite at the concentrations of 10, 20 and 50 nM dose-dependently and significantly increased glutathione peroxidase and phospholipid hydroperoxide glutathione peroxidase activities (Zhang *et al*., 2001). However, there were no significant differences between sodium selenite and Nano-Se at

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat243
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

the same doses by ANOVA analysis. In selenium-deficient rats, supplementation with sodium selenite at 0.1 ppm selenium in diet for 8 weeks significantly increased liver selenium and liver glutathione peroxidase activity. Whereas supplementation with Nano-Se at the same dose and duration generated similar effects, no significant difference between sodium selenite and Nano-Se were found (Zhang *et al*., 2001). In a study evaluating the effects of sodium selenite and Nano-Se on growth performance and glutathione peroxidase activity of avian broilers, selenium supplementation significantly improved daily weight gain and survival rate, decreased the feed conversion ratio and increased serum and liver glutathione peroxidase activities compared with the controls, with no significant difference between sodium selenite and Nano-Se (Wang, 2009). These *in vitro* and *in vivo* results together demonstrate that the two selenium forms have an equal capacity of increasing the activities of the selenoenzymes. Moreover, when 36 nm Nano-Se was compared with the organic selenium compounds selenomethionine and Se-methylselenocysteine, on oral administration of the three selenium compounds at the doses of 35 and 70 $\mu g\,Se\,kg^{-1}$ for 7 consecutive days to selenium-deficient mice, each selenium compound could significantly increase glutathione peroxidase activity in plasma, liver- and kidney in a dose-dependent fashion. In addition, each selenium form could significantly increase liver and kidney thioredoxin reductase activity. In general, there were no significant differences between Nano-Se and selenomethionine or between Nano-Se and Se-methylselenocysteine in increasing these selenoenzyme activities (Wang, Zhang and Yu, 2007; Zhang *et al*., 2008).

As discussed above, phase 2 enzyme activation induced by high-dose selenium may be an important mechanism for the cancer-preventive effect of selenium. Induction of phase 2 enzymes is an effective and sufficient strategy for achieving protection against the toxic and neoplastic effects of carcinogens (Talalay, 2000). Among the phase 2 enzymes, glutathione *S*-transferase plays a pivotal role in detoxifying carcinogens (Coles and Ketterer, 1990). For many cancer chemopreventive compounds, inducing glutathione *S*-transferase is a common attribute (Talalay, 2000). It has been reported that selenium compounds at supranutritional levels (550–1100 $\mu g\,Se\,kg^{-1}$) administered to mice can enhance liver glutathione *S*-transferase activity (El-Sayed *et al*., 2006). Wang *et al*. showed that Nano-Se and selenomethionine increased liver glutathione *S*-transferase activity by 78 and 22% at a supranutritional dose of 1000 $\mu g\,Se\,kg^{-1}$ in mice, respectively. There was a significant difference ($P < 0.001$) between the two selenium forms (Wang, Zhang and Yu, 2007). Zhang *et al*. demonstrated that Nano-Se and Se-methylselenocysteine equally increased liver glutathione *S*-transferase activity at a supranutritional dose of either 1000 or 1500 $\mu g\,Se\,kg^{-1}$ (Zhang, Wang and Xu, 2008a). Altogether, these results suggest that the biological activities of Nano-Se of increasing phase 2 enzyme and selenoenzyme activities are comparable to those of the other generally used selenium compounds, bringing sharp contrast to the dogma that elemental selenium has no biological activities.

5.2 Toxicity of Nano-Se and Selenocompounds

It is known that toxicity or pro-oxidant activity of sodium selenite is associated with the interaction of selenite with glutathione to form reactive selenotrisulphides, leading to the production of toxic superoxide and hydrogen peroxide (Spallholz, 1994; Seko and Imura, 1997). Zhang *et al*. (2001) found that the ratio of reduced/oxidized glutathione increased in a selenium dose-dependent manner when the glutathione concentration was held constant and the selenium compounds were added. However, sodium selenite was one order of magnitude more catalytic than Nano-Se in oxidizing glutathione, suggesting that sodium selenite has enhanced toxicity compared with Nano-Se. In an acute toxicity experiment using Kunming mice, it was found that the median lethal dose of Nano-Se was 7.2-fold greater than that of sodium selenite based on the selenium dose (Zhang *et al*., 2001b). In a short-term toxicity experiment using C57BL/6 mice, orally administering selenium at 4 mg $Se\,kg^{-1}$ for 4 weeks, body weight of the mice treated with sodium selenite was only 72–76% of the control during the last 2 weeks (all $P < 0.001$ as compared with the control), whereas the body weight of the Nano-Se group remained not significantly different compared with the control mice throughout the experimental period of 4 weeks. In addition, sodium

selenite caused severe liver injury, whereas the liver pathology in the Nano-Se group remained normal (Zhang *et al*., 2008). In a 13-week subchronic toxicity experiment using Sprague–Dawley rats, the no-observed-adverse-effect level of Nano-Se and sodium selenite in male and female rats was determined to be 3 and 2 ppm, respectively (Jia, Li and Chen, 2005). Taken together, these results consistently show that Nano-Se is less toxic than sodium selenite.

Selenomethionine and Se-methylselenocysteine are two major naturally occurring organic selenium compounds recommended for selenium supplementation and cancer prevention. When present in tissue or cells, they are metabolized by methioninase and β-lyases to a common metabolite methylselenol, which can react with glutathione and generate superoxide in a similar fashion as in the case of selenite. There are reports that toxicity of organic selenium compounds is less than that of sodium selenite in mice (Poirier and Milner, 1983) and in larger animals (Kim and Mahan, 2001; Tiwary *et al*., 2006). Although the toxicity of Nano-Se is less than that of sodium selenite, it remains uncertain whether there are differences between Nano-Se and these two organic compounds. Therefore, Zhang *et al*. further compared the toxicity of Nano-Se, selenomethionine and Se-methylselenocysteine in Kunming mice. In an acute toxicity experiment using Kunming mice, it was found that median lethal dose of Nano-Se was 92.1 mg Se kg^{-1}, whereas corresponding values for selenomethionine and Se-methylselenocysteine were 25.6 and 14.6 mg Se kg^{-1}, respectively (Wang, Zhang and Yu, 2007; Zhang *et al*., 2008a). In a single administration experimental model, a bolus of Nano-Se, selenomethionine and Se-methylselenocysteine at a dose of 10 mg Se kg^{-1} was orally administered to mice. As compared with the control mice, serum alanine aminotransferase activity increased 0.9-, 23.8- and 3.2-fold; serum aspartate aminotransferase activity increased 0.7-, 4.7- and 5.2-fold; serum lactate dehydrogenase activity increased/decreased −0.13-, 3.7- and 3.5-fold; and liver malondialdehyde level increased/decreased −0.12-, 1.6- and 3.7-fold in Nano-Se-, selenomethionine- and Se-methylselenocysteine-treated mice, respectively (Wang, Zhang and Yu, 2007; Zhang *et al*., 2008a). In a short-term toxicity experiment, mice were orally administered Nano-Se, selenomethionine and Se-methylselenocysteine at a dose of 5 mg Se kg^{-1} for 7 consecutive days. The three selenium compounds all caused liver injury, with Se-methylselenocysteine and selenomethionine being more toxic than Nano-Se. As compared with normal liver architecture, Se-methylselenocysteine and selenomethionine caused an irreversible and severe pathological change known as pyknosis, whereas Nano-Se caused a reversible and moderate pathological change referred to as hydropic degeneration (Wang, Zhang and Yu, 2007; Zhang *et al*., 2008a). These data suggest that Nano-Se's toxicity is lower among the generally used selenium compounds, including sodium selenite, selenomethionine and Se-methylselenocysteine.

6 CONCLUSIONS

Selenium is a necessary dietary constituent of at least 25 human selenoproteins and enzymes all containing selenocysteine. Replacement of selenium by sulfur in enzymes diminishes or obfuscates catalytic activity. Replacement of selenium by sulfur in selenium analogues dramatically reduces or totally eliminates toxicity. The reverse is also true. Replacement of catalytic sulfur by selenium in sulfur compounds universally increases catalytic activity and/or toxicity. In excessive amounts, all selenium compounds become toxic in a dose-dependent fashion to cells *in vitro* and to the primary target tissue of chronic selenium toxicity, the liver. Nanotechnology is a rapidly developing modern technology branch dealing with materials in the nanometer-size range. With their extremely small size nanomaterials can enter cells and with their huge surface area nanomaterials have the potential to interact with intracellular macromolecules exhibiting toxicity or bioactivity. There exist obvious public safety concerns about nanomaterials. Accordingly, a new research discipline known as nanotoxicology has emerged. However, nanotechnology may also hold promise for pharmacology because nanomaterials normally exhibit novel properties different from those of both molecular and bulk materials. Elemental selenium has long been considered to be biologically inert. With bovine serum albumin or other dispersant agents such as polysaccharides, biologically active Nano-Se aggregates are formed from sodium selenite and glutathione. Different from the biologically inert black elemental selenium with coarse size, Nano-Se

manifests toxicity which conforms to the concern of nanotoxicity. However, compared with selenium compounds such as sodium selenite, selenomethionine and Se-methylselenocysteine, Nano-Se is not compromised in increasing the activities of selenoenzyme and phase 2 enzyme, but exhibits much lower toxicity. Nano-Se is thus a potential selenium nutritional source with a prominent characteristic of lower toxicity for supplementation.

1 INTRODUCTION

The production of nanomaterials and their use in various fields has evolved remarkably in the last decade. Newly manufactured nanomaterials are being used in a large variety of applications in computing and electronics, construction, cosmetics, drug delivery and medical imaging, paints and coatings, food, packaging, textiles, clothing and others. More than 1000 consumer products that contain nano-materials are being produced today (Nanotechnology Consumer Products Inventory, 2010). There is a great number of engineered nanomaterials that are currently produced including metal-based (e.g., gold, silver, quantum dots, metal oxides such as titanium dioxide, zinc oxide, copper, or iron oxide), carbon-based (e.g., nanotubes, nanowires, fullerenes), and those that are biological in nature (e.g., liposomes and viruses designed for gene or drug delivery) (Card *et al*., 2008). Metal oxides or pure metals are present in almost half of consumer products. Products containing nanosilver account for 30%, metal oxide nanomaterials (TiO_2, ZnO, and CeO_2) for almost 20%, silicon-based products for 17% (Nanotechnology Consumer Products Inventory, 2010). These materials have the highest chance to enter the environments thus, it has been proposed that "nanodust" from engineered nanomaterials might be a new source of metals in the atmospheric environment (Grassian, 2009). It is well known that the properties, biological reactivity and toxicity of materials on the nanoscale differ from that of the bulk or micron sized particles (Nel *et al*. 2006; Oberdorster, Oberdorster and Oberdorster, 2005; Sayes and Warheit, 2009). Previous studies found that materials that were considered inert were causing enhanced toxic responses if used at nanosize (Bermudez *et al*., 2004; Ferin, Oberdorster and Penney, 1992; Goodman *et al*., 2004; Kaewamatawong *et al*., 2005). For instance, titanium dioxide, which in micron particle sizes is considered a very inert material and has often been used as a negative control in animal studies, is now considered as a "potential occupational carcinogen", as defined by the Occupational Safety and Health Act or Administration (OSHA) (Baan *et al*., 2006). Not surprisingly, there is growing interest in understanding health implications of nanomaterials (Maynard, 2007; Nel *et al*., 2006). Of equal importance to the toxicity evaluation of nanomaterials in general and nanoparticles (NPs) in particular is the assessment of the risk of human exposures that

might occur in the ambient or occupational environment. Such assessments are still in progress and are challenging since quantities of nanomaterial used in many consumer products are not identified and there is no obligation for specific labeling at this point (Seaton *et al*., 2009). Another factor is distinguishing engineered NPs from incidental particles in the workplace (Peters *et al*., 2009). It is estimated that accidental inhalation of NPs is the most likely route of significant human exposure. However, the health impacts of NPs can cause systemic response or responses in other organs or systems, depending on their translocations (Oberdorster, Oberdorster and Oberdorster, 2005). Nanomaterials alone may be cause of toxicity; however, they can also induce risk through adsorption and therefore as carriers of impurities (e.g., toxins in the environment), generation of toxic substances by their dissolution or degradation, or by crossing physiological barriers such as the blood-brain (Oberdorster *et al*., 2004), fetoplacental (Saunders, 2007), or cell and nuclear membranes. Given some of these complexities, it is clear that an integrated, interdisciplinary approach is necessary to study the hazards of NPs (Grassian *et al*., 2007a; Holsapple *et al*., 2005; Pettibone, Elzey and Grassian, 2008; Powers *et al*., 2006; Seaton *et al*., 2009). Our group exemplifies such an approach in which chemists, environmental engineers, aerosol physicists, and toxicologists are working together in safety assessment of nanomaterials. In this review, we will focus our attention on particle characteristics and biological responses of nanomaterials after inhalation exposures using murine models. These nanomaterials include metal-based NPs such as titanium dioxide, iron, copper, and silver as well as aluminum oxyhydroxide nanowhiskers.

1.1 Nanoparticle Characterization

According to ASTM International, NPs are defined as a sub-classification of ultrafine particles with lengths in two or three dimensions greater than 0.001 (1 nanometer) and smaller than about 0.1 micrometer (100 nanometers) and which may or may not exhibit a size-related intensive property (ASTM E2456-06, 2003). However, this definition is a topic of debate because of the size range and the presence of a size-related property (Auffan *et al*., 2009). Current usage of this definition emphasizes size and not properties. The length scale may be a hydrodynamic diameter or a geometric length appropriate to the intended use of the NPs (ASTM E2456-06, 2003). Ideally, each toxicological assay (***in vitro/in vivo***) should include a detailed characterization of the investigated material, since different particle properties could have biological relevance and differences have been found between specifications provided by the supplier actual properties of the product. We have also found large differences between individual batches of the same product and inconsistencies with manufacturers' specifications and independent characterization (Grassian *et al*., 2007; Park and Grassian, 2010; Pettibone *et al*., 2008). Furthermore, appropriate storage conditions (e.g., exposure to light, temperature) are critical to assure that particles properties are not modified. At a minimum, this characterization should include bulk and surface composition, surface area, primary size, and size of agglomerates. There are many studies that do not provide sufficient information about the investigated materials (Card *et al*., 2008) and; thus, comparing the toxicity of various nanomaterials among studies is more difficult. It is very important to characterize both primary properties (as received from the supplier or as produced) and secondary characteristics (during exposure if it is in the media or in the air in the form of aerosol). Ideally, properties of particles should also be characterized after administration and uptake by cells or the respiratory system (Sayes and Warheit, 2009).

1.1.1 Physicochemical Characteristics

Manufactured nanomaterials have many physicochemical characteristics that include their size and surface area, chemical composition, purity, crystalinity, electronic properties, surface structure, structure composition, surface functionality (e.g., inorganic or organic coatings, etc.), solubility, shape, and aggregation/agglomeration (Elzey *et al*., 2009; Grassian, 2008; Nel *et al*., 2006) which modify their interactions with biological tissues. All these different properties of nanomaterials can affect particle uptake, persistence, can stimulate cellular responses and biological toxicity. Therefore, it is strongly recommended that these physicochemical properties of nanomaterials are an important component of the study design and reported in any risk assessment and health study (Oberdorster *et al*., 2005; Powers *et al*., 2006; Warheit, 2008).

Table 1. Summary of physicochemical characterization data on metal nanoparticles used in *in vivo* inhalation studies.

Property	Titanium	Iron	Copper	Silver	Aluminum
Crystalline or amorphous material	Crystalline	Crystalline	Crystalline	Crystalline	Crystalline
Phases	Anatase	Fe, Fe_3O_4, γ-Fe_2O_3	Cu, Cu_2O, CuO	Ag	$Al(OH)_3$ and γ-AlOOH
Primary particle distribution	3.5 ± 1 nm	25 ± 2 nm	12 ± 1 nm	12 ± 4 nm	2–5 nm × 100–200 nm whiskers
Surface phases	TiO_2	Fe_2O_3	CuO	Ag	$Al(OH)_3$, γ-AlOOH
Surface functionalization	O, O-H and H_2O	O, O-H and H_2O	O, O-H and H_2O	CO_3^{2-}, OH^-, C = O, C-O-C	O, OH O, O-H and H_2O
BET surface area	$219 \pm 3\ m^2\ g^{-1}$	$17 \pm 1\ m^2\ g^{-1}$	$12 \pm 0.2\ m^2\ g^{-1}$	$3 \pm 2\ m^2\ g^{-1}$	$320 \pm 4\ m^2\ g^{-1}$
Aerosol size distribution[a]	128.0 (1.7) nm	199.9 (1.3) nm	190.1 (1.3) nm	79 (1.5) nm	154.1 (1.6) nm
Exposure concentration	$8.88\ mg\ m^{-3}$	$3.55\ mg\ m^{-3}$	$3.68\ mg\ m^{-3}$	$3.32\ mg\ m^{-3}$	$3.31\ mg\ m^{-3}$

[a] GM (GSD) in whole-body exposure chamber during sub-acute exposure.

Table 1 shows a compilation of the physicochemical properties of nanomaterials that were recently measured for *in vivo* inhalation studies (Grassian *et al*., 2007; Pettibone *et al.*, 2008). Additional comments about some of these various properties are given below.

Particle Size and Surface Area

The size of particles is often considered one of the most determining factors that influence deposition and clearance of materials in the respiratory system. The size of nanomaterials studied is often reported from the nominal primary particle size determined by the supplier; however, as it was found in our studies, this size is not always properly recorded or even correct (Park and Grassian, 2010). In some cases batch-to-batch variability is the cause of these differences. For example, average primary size of copper NPs used in our study (Pettibone, *et al.*, 2008) was reported by manufacturer as 25 nm, however the particle sizes were found to be approximately half the reported value (12 ± 1 nm) with a fairly narrow distribution. If the size of the particles changes, other parameters such as surface area can change and, on the nanoscale, optical, electronic, magnetic, and other physical properties can also change (Lucas *et al*., 2001). The effect of NPs size has been studied extensively in instillation and inhalation exposure studies (Cullen *et al*., 2000; Hext, Tomenson and Thompson, 2005; Kaewamatawong *et al*., 2005; Lison *et al*., 1997; Oberdorster, 2001; Oberdorster, Oberdorster and Oberdorster, 2005; Tran *et al*., 2000). Many studies report that surface area of particles is associated with the magnitude of airway inflammation (Cullen *et al*., 2000; Duffin *et al*., 2007; Monteiller *et al*., 2007; Renwick *et al*., 2004; Singh *et al*., 2007; Tran *et al*., 2000). Various instillation studies of different ultrafine particles reported higher toxicity and inflammatory response increases as the surface area of particles increased on a per mass basis (Oberdorster *et al*., 2000; Oberdorster, Oberdorster and Oberdorster, 2005; Stoeger *et al*., 2006). It has been proposed that different NPs can be ranked according to the degree of inflammation per surface area dose (number of neutrophils cm^{-2}) (Duffin *et al*., 2007). However in a recent study of ours using two different sizes of TiO_2 nanoparticles, we determined that the smaller 5 nm TiO_2 particles did not cause a greater inflammatory response than 21 nm TiO_2 particles, as demonstrated in Figure 1. These plots show the number of neutrophils in BAL fluid in controls and animals exposed to 5 or 21 nm TiO_2 nanoparticles by instillation according to particle mass or surface area. In fact, 21 nm TiO_2 particles induced a larger inflammatory response in the mice than the 5 nm particles through inhalation and instillation exposure (Grassian *et al*., 2007). Since 5 nm particles used in this study had much greater surface area, more than five times that of the 21 nm particles, we expected a greater inflammatory response on a per mass basis in this case for smaller particles. Our results showed that BET surface is not, always the best measure of TiO_2 nanoparticle toxicity for the smallest NPs area (BET stands for

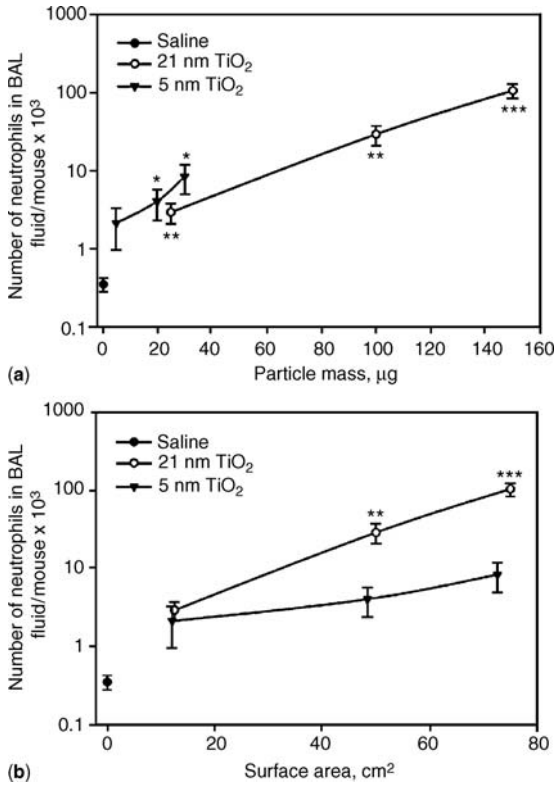

Figure 1. Number of neutrophils in BAL fluid in controls and animals exposed to 5 or 20 nm TiO_2 nanoparticles by instillation, according to (a) particle mass; (b) surface area. Asterisks represent significant increase ($*p < 0.05$, $**p < 0.01$, and $***p < 0.001$) in parameter measured, compared to (a) controls; and to (b) 5 nm TiO_2-exposed groups. (Grassian *et al*., 62). (Reproduced with permission from Taylor & Francis, http://www.informaworld.com.)

Brunauer, Emmett, and Teller three scientists who developed the theory for surface area measurements (Brunauer, Emmett and Teller, 1938)). This is in agreement with Warheit *et al*. (2006) who found that nanoscale particles (nanoscale TiO_2 rods and nanoscale TiO_2 dots) were not more cytotoxic or inflammogenic in the lungs compared to larger sized particles of similar composition after intratracheal instillation. Other studies also suggest that surface area alone is not responsible for nanoparticle toxicity (Sayes *et al*., 2006; Warheit *et al*., 2006; Warheit *et al*., 2005; Warheit *et al*., 2007).

As already noted, there are many properties of nanomaterials that affect their biological responses. Crystaline phases of the particles in our studies were different. The 5 nm particles were pure anatase but the 21 nm particles included both anatase and rutile (Grassian *et al*., 2007). In other study, phase has been shown to matter (*vide infra*), for example a 100-fold increase in the cytotoxicity of the anatase phase compared to rutile phase in particles 10 nm or smaller was observed (Sayes *et al*., 2006). In that same study it was also shown that anatase generated reactive oxygen species (ROS) more effectively because of surface reactivity. Furthermore, in more recent studies of ROS production, Jiang *et al*. (2008) showed that for a series of particles ranging from 4-195 nm the largest amount of ROS was produced by 30 nm particles not the 4 nm particles. Thus, this demonstrates complex size-dependent ROS production for these very small NPs.

Phase, Surface Reactivity and Surface Coatings

When different functional groups or coatings are present on the surface of nanomaterials, the surface reactivity of NPs change and this can have a large effect on toxicity response (Warheit, Reed and Sayes, 2009). Comparing fine rutile TiO_2 particles in inhalation and instillation studies, it was found that only NPs with alumina and amorphous silica surface coating caused adverse pulmonary effects if compared to the base control TiO_2 particles (Warheit *et al*., 2005). Another study evaluating three forms of ultrafine TiO_2 particles (Warheit *et al*., 2007) demonstrated that quartz and anatase/rutile TiO_2 particle exposures produced lasting lung inflammation, cytotoxicity, and histopathology effects in lungs. However exposures to fine TiO_2 particles or ultrafine rutile TiO_2 particles resulted only in transient inflammatory responses without any pathology effects in lung tissues. Evaluation of synthetic 12 nm α-nanoquartz particles and synthetic fine α -quartz particles (~300 nm) and (mined) Min-U-Sil α -quartz particle types (~500 nm) showed that the pulmonary toxicities correlated better with surface reactivity than particle size or surface area (Warheit *et al*., 2007; Warheit, Reed and Sayes, 2009). Furthermore, TiO_2 particles of the same primary particle size with different coatings, one with silane compound and the other uncoated showed a major difference in the pulmonary-inflammatory potency (Oberdorster, 2001). The surface reactivity may be substantially higher for NPs with smaller sizes because of an increase in the thermodynamic surface free energy, even for NPs with the same surface functionality (Zhang *et al*., 1999). Although in

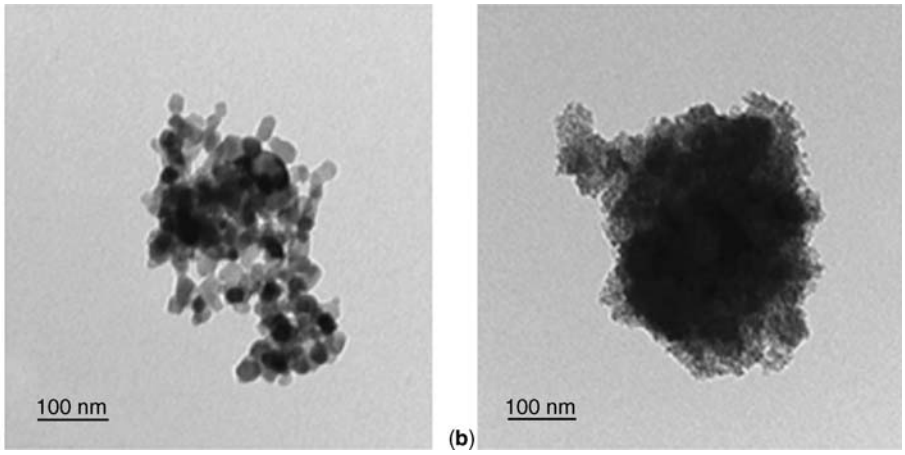

Figure 2. TEM images of the generated aerosol in the whole body exposure chamber: (a) is a representative agglomerate of the 21 nm particles; and (b) is a representative agglomerate of the 5 nm particles. The agglomerates differ in nature as the agglomerate formed from the 21 nm particle appears to have more void space compared to the agglomerate formed from the 5 nm particles. (Grassian *et al.*, 62). (Reproduced with permission from Taylor & Francis, http://www.informaworld.com.)

our study of TiO_2 particles with different sizes (5 and 21 nm), we did not see smaller particles leading to higher toxicity. We proposed that the higher surface reactivity of the smaller NPs may lead to more tightly formed agglomerates (Grassian *et al.*, 2007) and therefore a lower effective surface area for biological interactions.

Agglomeration and Aggregation

Agglomeration/aggregation state of the particles has an impact on particle toxicity and biological response (Sager *et al.*, 2007; Wick *et al.*, 2007). It is very difficult to keep NPs isolated and the ability of NPs to agglomerate and/or aggregate is a well-known characteristic. Thus, it is suggested that the use of aggregated NPs is appropriate in toxicology studies (Lu *et al.*, 2009). According to ASTM (ASTM E2456-06, 2003), "Standard terminology Relating to Nanotechnology", ASTM International) agglomerate and aggregate are defined as follows: **Agglomerate** – is a group of particles held together by relatively weak forces (for example, Van der Waals or capillary), that may break apart into smaller particles upon processing. **Aggregate** – is a discrete group of particles in which the various individual components are not easily broken apart, such as in the case of primary particles that are strongly bonded together (e.g., fused, sintered, or metallically bonded particles). Particle size and propensity of particles to agglomerate affect the uptake of particles by cells, and their clearance in the alveolar region. The size of agglomerates/aggregates determines if particles are deposited in alveolar or interstitial spaces (Ferin, Oberdorster and Penney, 1992; Oberdorster, Cox and Gelein, 1997). After inhalation, fine particles (>100 nm) are quickly phagocytized by alveolar macrophages (Takenaka *et al.*, 2001). The size of agglomerates influences the ability of macrophages to phagocytize them as well as the penetration of cell membranes and translocation through the tissue, lymph, or circulatory system (Nemmar *et al.*, 2001; Renwick, Donaldson and Clouter, 2001). Another factor that may influence the toxicity of nanomaterials is the density of the packing of the nanoparticle building blocks to form the agglomerate as well as the strength of the interaction between the NPs. If a bundle of agglomerated nanoparticles are more tightly packed without void spaces between individual particles, they may yield agglomerates with very small projected surface area (Moss and Wong, 2006) that can potentially reduce toxicity. This was suggested in our study of TiO_2 nanoparticles with particle diameters of 5 and 21 nm. The TEM images of TiO_2 agglomerates collected from the whole body exposure chamber showed that the agglomeration differed in nature between the two sized nanoparticles. The agglomerates from 21 nm particles (Figure 2a) appeared to have more void space compared the agglomerates generated from the 5 nm particles

(Figure 2b) (Grassian *et al*., 2007). A rat instillation study of low-toxicity, low-solubility NPs observed that greater inflammogenicity of NPs was consistent with higher surface area of particles despite aggregation, indicating that aggregation does not influence surface area dose (Duffin *et al*., 2007). Even if NPs occur in the environment as aggregates larger than 100 nm, their toxicity can potentially differ from the toxicity of particles with corresponding particle size (Borm *et al*., 2006). Degree and type of agglomeration can affect *in vitro* cytotoxicity of carbon nanotubes (Wick *et al*., 2007). In Wick *et al.* (2007) nanotubes that differed in the degree of dispersion were investigated. It was shown that agglomerated carbon nanotubes caused more adverse effects relative to more well-dispersed material.

On the other hand, it is also known that if particle are more dispersed they can be incorporated into the interstitium more rapidly and cause different particle deposition and subsequent response. In an *in vivo* study, more dispersed single wall carbon nanotubes (SWCNT) were found to penetrate more into the alveolar interstitium and also caused more extensive interstitial collagen accumulation than the less dispersed SWCNT (Mercer *et al*., 2008). Aggregation is affected by pH, ionic strength, and ionic identity. Ionic strength influences dispersion stability by changing electrical double layer thickness, while pH can change the dispersion state by shifting the zeta potential (surface charge) (Jiang, Oberdorster and Biswas, 2009; Maier *et al*., 2006). In Jiang, Oberdorster and Biswas (2009), it was found that for 15 nm TiO_2 dispersions, the increase of ionic strength from 0.001 to 0.1 M led to a 50-fold increase in the hydrodynamic diameter. Furthermore, it was reported that these particles have a positive surface charge when pH is lower than 6 and a negative surface charge when pH is higher than 6.

Particle Dissolution

Dissolution of metal-based nanomaterials is associated with both changes in nanoparticle size and formation of ions. The augmentation of inflammatory response in transition metals was shown to be proportional to the solubility of the metal in biological media, even though the pathways of inflammatory response were different (Borm *et al*., 2006; Brunner *et al*., 2006; Knaapen *et al*., 2002; Midander, Wallinder and Leygraf, 2007). In our inhalation studies of copper and iron NPs (Pettibone, *et al.*, 2008), we found inflammatory responses in lungs represented by higher number of macrophages as well as high neutrophilia (51%) in bronchoalveolar lavage (BAL) fluid and pathologic changes (perivasculitis and alevolitis) in the lung tissue in mice exposed to copper NPs. With iron NPs, we observed only slight inflammatory response represented by only 4 % neutrophilia in BAL fluid. Overall, our murine studies showed copper NPs to be significantly more toxic than iron NPs. We also observed differences in dissolution between these two nanomaterials. As opposed to iron that did not dissolve in Gamble's solution, a simulated biological fluid, copper NPs were shown to partially dissolve in this solution. Gamble's solution is often used in *in vitro* studies to imitate the interstitial fluid in the lungs, its pH is 7.2–7.4 (Moss 1979). Another artificial fluid used is artificial lysosomal fluid (ALF) that simulates the phagolysosomal composition and pH (4.5–5.0) of alveolar and interstitial macrophages (Midander, Wallinder and Leygraf, 2007; Stopford *et al*., 2003). Both metals studied dissolved in ALF. However, we believe that such a high dissolution was due to the presence of the citric acid in ALF. Our dissolution studies of copper NPs are in an agreement with other studies of copper materials in an artificial and biological media such as saliva, lung fluid, or blood, in which copper had a tendency to dissolve (Chen *et al*., 2006; Midander, Wallinder and Leygraf, 2007). Furthermore, study that reported iron oxide particles having very low solubility, also found that these particles had lower propensity to produce ROS, and did not cause inflammatory responses after intratracheal instillation (Lay *et al*., 1999). Comparing toxicity of ultrafine carbon black particles dispersed in BAL fluid or phosphate-buffered saline administered by intratracheal instillation showed 1.7-fold greater cytotoxicity (release of LDH) and two-fold greater inflammation (number of neutrophils in BAL fluid) in the case where carbon black was dispersed in BAL fluid (Sager *et al*., 2007). Zinc oxide (ZnO) particles were found to induce injury response represented by production of pro-inflammatory cytokines and mitochondrial injury using phagocytic cell line (*RAW 264.7*) and transformed human bronchial epithelial cells (*BEAS-2B*). High solubility of ZnO was considered responsible for toxicity of this nanomaterial (Xia *et al*., 2008). Interestingly, in this study ZnO agglomerates reduced in size from 413 to 36 nm when particles were transferred from water to tissue

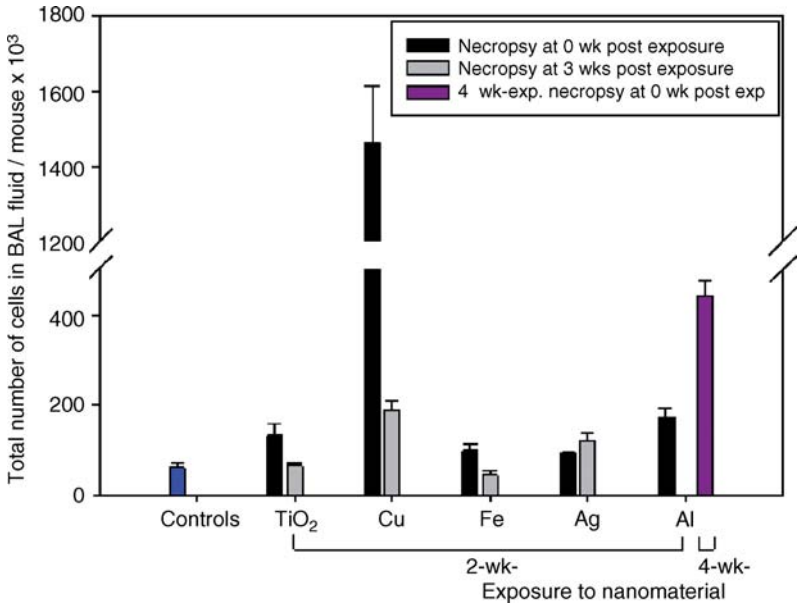

Figure 3. Total number of cells in BAL fluid after sub-acute exposure of mice to selected metal nanoparticles.

culture medium probably due to serum proteins and lipids. Such a size reduction could assist with cellular uptake and intracellular dissolution. Therefore, it is very important to study dissolution properties of nanomaterials, since the amount of soluble ions in solution may increase inflammatory response. Several reports recently have shown that aggregation can impact the solubility of nanoparticles (Liu *et al*., 2009; Rubasinghege *et al*., 2010).

Chemical Composition

Undoubtedly, chemical composition is a fundamental property of any material and has a profound effect on biological responses. Nanomaterials can have very different chemical compositions, from completely inorganic, for example, metals (iron, nickel, zinc, gold, silver), and metal oxides (oxides of titanium, copper, iron, and zinc), to entirely carbon-based materials (fullerenes, carbon nanotubes, nanopolymers). It has also been shown that the chemical purity is very important property of nanomaterial. Some metal impurities such as Fe, Ni, Co can affect the biological response by masking the nanoparticle behavior with their toxicity (Maynard *et al*., 2004; Pulskamp, Diabate and Krug, 2007). In an *in vitro* study of carbon nanotubes (commercial vs. purified) and human A549 cells or rat macrophages, an increase in ROS and a decrease of the mitochondrial membrane was found in both cell types after treatment with commercial but not with purified material. Metal traces found in the commercial nanotubes might have been responsible for these observed responses (Pulskamp, Diabate and Krug, 2007). From metal nanomaterials, Cu- and Zn-based materials appear to be the most toxic (Gordon, Chen and Cohen, 2008; Lanone *et al*., 2009). Ti, Al, Ce, Ag, Ni and Zr-based nanomaterials showed low or moderate toxicity (Lanone *et al*., 2009). *In vitro* comparison of 6 metal oxide particles and carbon nanotubes, showed CuO NPs as most potent concerning cytotoxicity and DNA damage (Karlsson *et al*., 2008). Zinc- and Ni-nanoparticles also demonstrated higher toxicity than Al-, Ag-, or TiO_2 NPs in human alveolar epithelial cells (Park *et al*., 2007). Our studies comparing pulmonary inflammatory response of selected metal nanomaterials after sub-acute inhalation exposure ranked their inflammogenicity (based on higher numbers of total cells and neutrophils in BAL lavage) as follows: Cu > Fe > Ag > Al > TiO_2 (Figures 3 and 4). Certainly, as discussed in this chapter, evaluation of nanomaterial toxicity based only on chemical composition is only the first step in the overall evaluation.

Surface Contamination

Since NPs have such a large surface area attention needs to be paid to possible contamination of their surfaces. The contamination can vary from sporadic surface adsorption, oxidation, and corrosion and can occur in air or liquid environments. Thus, such "contaminated" NPs can transport high levels of various unintentional materials into the organism. The contaminant may modify the aggregation stage or physical properties of nanomaterials. The last concern is that it is hard to distinguish if their toxic potency is from the nanomaterial itself or from the contaminant (Jones and Grainger, 2009). One possible contamination of nanomaterials is endotoxin contamination. Endotoxin, or lipopolysaccharide (LPS) is a glycolipid of gram-negative bacteria. LPS can significantly influence the biological responses and thus confound any effect of studied material (Gorbet and Sefton, 2005; Thorne and Duchaine, 2007). For example conventionally produced gold NPs had a maturing effect on the dendritic cells as a result of LPS contamination. When LPS contamination of these particles was decreased, by alteration of the production process, nearly no effect on phenotypic maturation or cytokine production of dendritic cells was observed (Vallhov *et al.*, 2006). Comparing levels of endotoxin contamination and physical properties of selected engineered NPs no correlation was found (Esch *et al.*, 2010). A study of carbon black NPs administered intratracheally by

instillation showed only slight lung inflammation when delivered alone, however the lung inflammation was intensified when carbon black particles were delivered together with LPS (Inoue *et al*., 2006). There also might be synergistic effects of two inflammation-causing agents, as it was found in study of latex NPs and LPS (Inoue *et al*., 2009). On the other hand, if we want to mimic an exposure to nanomaterials as it would occur in an ambient air or occupational environment, where contamination of materials by environmental endotoxin will certainly occur, one might suggest that studying materials "as is" might be more realistic. Without doubt, a high degree of endotoxin contamination must be avoided and the levels of endotoxin of studied material should always be measured. However, it has been questioned if the widely used assay for endotoxin traditionally used by immunologist (e.g., the *Limulus* amebocyte lysate chromogenic endpoint assay) is able to measure endotoxin bound to a particle surface or is limited only to free endotoxin in solution (Dobrovolskaia, Germolee and Weaver, 2009; Esch *et al*., 2010; Jones and Grainger, 2009). Taking into an account very low contamination by endotoxin, currently it is not known if there is a difference in response in *in vivo* studies, for example, at level of 1 EU mL^{-1} and <0.5 EU mL^{-1} (Jones and Grainger, 2009). Of course considering endotoxin contamination of nanomaterials used in the pharmaceutical industry, biomedical application or *in vitro* studies has higher importance and should definitely be avoided (Dobrovolskaia, Germolee and Weaver, 2009). Efficient removal of LPS can be challenging since this process can also affect the properties of nanomaterials, for example, causing aggregation (Vallhov *et al*., 2006).

1.2 Pulmonary Toxicity Assessment of Nanoparticles

The possible pathogenic mechanisms evoked by exposure to NPs are very complex, depending on the route of exposure, dose, host response, susceptibility, physico-chemical properties of NPs as well as the fate and persistence of the particles in the organism. The nanomaterial toxicity screening working group has defined the building blocks of a screening strategy for toxicity of nanomaterials: evaluation of physicochemical characteristics and dose metrics; acellular assays; *in vitro* assays for lung, skin, and mucosal membranes; and *in vivo* assays (animal experiments) for lung, skin, oral, and injection exposures (Oberdorster *et al*., 2005). Some also deem *ex vivo* models (isolated pulmonary cells or isolated perfuse lung) as a valuable addition to understanding of nanomaterial toxicity (Sakagami, 2006). Each model has advantages and disadvantages that shall be considered. There are no *in silico* models available today that would allow prediction of the activity of untested compounds. Intermediate *ex vivo* models sometimes resolve deficiencies of *in vivo* and *in vitro* models such as kinetic modeling however there are a number of limitations such as short viable periods (only 2–3 h), absence of tracheobronchial circulation as well as no possibility of particle translocation. In addition this model has a very high grade of complexity and is the least utilized (Sakagami, 2006). There is broad interest in the development of standard/reference nanomaterials that can be used for comparison in toxicity evaluation of NPs. This would be valuable however a range of such standards would have to be very wide (Holsapple *et al*., 2005).

1.2.1 Uptake, Transport and Clearance of Nanoparticles

As reviewed by Madl and Pinkerton (2009), recent publications have demonstrated that NPs endure classic mechanisms of uptake, transport, and clearance from the respiratory system, but there are also unique transport pathways specific to the nanosize range (Figure 5). Nanoparticles are cleared by macrophage phagocytosis and transporting through the mucociliary escalator and physicochemical processes (dissolution and physical breakdown). Unique mechanisms for NPs comprise uptake and transport along sensory neurons (nasal olfactory epithelium), direct uptake of particles by epithelial cells in the respiratory tract and subsequent transport to the interstitium, lymphatic system, and blood circulation (Oberdorster *et al*., 2004; Oberdorster *et al*., 2005). Some studies have suggested that clearance of NPs is slower than larger particles since they are taken up by epithelial cells rather than being phagocytized by macrophages (Kreyling, Sommel and Moller, 2004; Oberdorster, Oberdorster and Oberdorster, 2005; Semmler-Behnke *et al*., 2007). As we noted above, physicochemical properties of particles play a crucial role in how NPs are internalized by the pulmonary epithelium.

Use of In Vitro Models

There is a need to develop a fast screening method that would predict the toxicity of manufactured nanomaterials (Ayres *et al*., 2008). Due to the cost and convenience, *in vitro* system should be a way to screen NPs, however, there have been many challenges with *in vitro* systems especially when it comes to mimicking exposure to NPs in the "real world". Most of the cell exposure studies have been done by resuspending particles in media. Many disadvantages are connected with such submerged *in vitro* systems: unrealistic exposure pathway, possible interactions between the cell culture medium and NPs, higher agglomeration of NPs in the medium, and substantial percentage of NPs that remain in the liquid or adhere to the lateral walls of the culture wells (which affects dose of NPs interacting with the cells), and absence of mucus or epithelial airway surface. Particles settle, diffuse, agglomerate and change surface charge and chemistry over time in solution and this can affect their transport to cells (Teeguarden *et al*., 2007). All these factors may impact particle-induced biological responses and impact the predictive value of the *in vitro* model. The cells used in *in vitro* studies may be isolated freshly from lung tissue or broncheoalveolar lavage (primary cultures) or may be obtained from immortalized cell lines (secondary cultures). Furthermore, most *in vitro* studies are typically conducted as mono-culture (one cell type). There is an increasing number of studies that use co-culture of multiple cell types such alveolar macrophages (AMs) along with epithelial cells. *In situ*, these two cell types interact concurrently to effect biologic responses (Hjort *et al*., 2003; Wottrich, Diabate and Krug, 2004). Co-culture of AMs with epithelial cells resulted in augmentation of particle-induced pro-inflammatory cytokine release (Hjort *et al*., 2003; Tao and Kobzik, 2002). The selection of certain cells used in *in vitro* experiment is crucial, since different cells exposed to NPs may show a variety of responses (e.g., inflammatory profiles) (Sayes, Reed and Warheit,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat244

2007; Soto, Garza and Murr, 2007). The human epithelial cell lines exhibited higher sensitivity than the murine and human macrophages probably since lung epithelial cells are the first line of defense against harmful stimuli. However, murine and human macrophage cell lines demonstrated similar responses in various degrees of cytotoxicity (Soto, Garza and Murr, 2007). Recently, novel *in vitro* exposure systems with air-liquid interface have been developed (Brandenberger *et al*., 2010; Grigg *et al*., 2009; Lenz *et al*., 2009; Thorne *et al*., 2010). Such systems overcome major drawbacks of submerged systems. Comparing the transwell system with its air-liquid interface and submerged cell exposure systems using ZnO NPs, differences in expression of IL-8 and oxidative stress marker (HO-1) were found (Lenz *et al*., 2009). Enormous care must be taken in extrapolating data obtained from *in vitro* studies (Donaldson *et al*., 2009). Authors in their study compared quartz, asbestos, and PM_{10} particles and showed that these materials have similar activities in cells *in vitro* (via oxidative stress, activation of NF-κB, pro-inflammatory effects and oxidative adduct formation), however *in vivo* they produced quite different pathological effects. Thus, it appears that *in vitro* systems will have to be further developed, standardized, and validated. Comparisons of *in vivo* and *in vitro* studies using five different NPs displayed low degrees of correlation (Sayes, Reed and Warheit, 2007). Furthermore, differences in oxidative responses of cells such as rat and human alveolar macrophages to various particulates and fibers were found (Rahman, Norwood and Hatch, 1997). This suggests that human alveolar macrophages have a spectrum of responses to the same particles, and they produce more ROS in response to particles than rat alveolar macrophages. Sensitivity of the cells to the NPs studied may be influenced by characteristics of the cell lines used including doubling times, metabolic activity or phagocytic mechanisms (Lanone *et al*., 2009). Silver nanoparticles aggregates were shown to express greater cytotoxicity than asbestos or carbon nanotubes (Soto, Garza and Murr, 2007). However in our murine inhalation study Ag NPs did not induce significant inflammatory or cytotoxic responses. *In vitro* studies are very important however until there is a strong correlation established between *in vivo* and *in vitro* studies there still will be need for animal experiments.

In Vivo Models

In vivo approaches in small rodents continue to be the primary approach for assessment of NP pulmonary toxicity. Rodent studies allow this realistic route of exposure with reproducible NP dosing and lung distribution. Table 2 summarizes traditional endpoints employed in *in vivo* toxicology assessments that are also used in nanotoxicology. Besides the properties of the nanomaterials that affect

Table 2. *In vivo* assessment of pulmonary toxicity.

Possible biological response to inhaled NP	Available pulmonary bioassays
Gross observation	Weight gain, body condition score
Cytotoxicity (cell lysis)	Lactade dehydrogenase (BAL fluid)
Transudation of proteins across alveolar-capillary	Total protein (BAL fluid)
Type II cell damage or increased secretions; transudation of serum proteins	Alkaline phosphatase (BAL fluid)
Inflammation,	Total and differential cell counts (BAL fluid)
Immune response	Cytokine/chemokine production (BAL fluid)
Inflammation and fibrosis	Histhopathology of lungs and other vital organs (liver, spleen, brain, (H&E, Masson Trichrome staining)
	Collagen determination
Host defense	Bacterial infection model of impaired clearance
Oxidative stress	Superoxide dismutase (SOD), glutathione peroxidase (GPx), catalase, glutathione (GSH), oxidized form glutathione disulfide (GSSG) in lung tissue
Changes in pulmonary functions or mechanics	Measurements of lung volumes, resistance, elastance, compliance and impedance
Hematology and chemistry parameters in blood	Complete blood count (including differential counts), levels of electrolytes (Na, K, Cl, CO_2), and renal profile (BUN and creatinine)

toxicity response, there are other variables that need to be taken into the consideration while conducting *in vivo* studies of NPs. The animal species, duration of exposure, as well as different exposure methods (e.g., whole-body, nose-only, intratracheal instillation) may affect degree of inflammatory or toxic response (Bermudez *et al*., 2004; Bermudez *et al*., 2002; Elder *et al*., 2005; Hext, 1994). Observation of behavioral changes, food and water consumption, clinical signs as well as monitoring body weights of animals during a study should be included in toxicity evaluation of any tested material. These observations might be the first indication of a toxic effect of the xenobiotic. The first observation should be for survival and moribundity. Other clinical signs of toxicity monitored should include abnormal level of spontaneous motor activity and body posture, gait, grooming, respiration, and quantity, or quality of fecal output. Body weights should be monitored at least once a week. In chronic studies, animals should be examined for evidence of visible or palpable masses, and quality of coat, body orifices (for excessive or unusual discharges), eyes, and respiratory sounds should be evaluated (Gad, 2007).

Comparison of Species

Small rodents such as mice, rats, and guinea pigs are all suitable for inhalation toxicology assessment of aerosols. It should be noted that rodents have more asymmetric airway branching patterns and only few respiratory bronchioles compared to humans (Thorne, 2000). Airways of guinea pigs are very sensitive and a good model for evaluation of xenobiotics that might cause bronchoconstriction (Thorne and Karol, 1988). For particles with possible fibrogenic effects rat models have traditionally been used (Thorne, 2000). Species differences were found in lung burdens of ultrafine TiO_2 particles. Lung loadings were increased in concentration-dependent manner in rats, mice, and hamsters after 13 weeks of exposure. Particle retention was similar in rats and mice but hamsters cleared particles more efficiently. Furthermore, the magnitude of lung inflammatory response was ranked as rats > mice > hamsters. Pulmonary lesions were found to be most severe in rats (Bermudez *et al*., 2004). Similar results were found after sub-chronic inhalation exposure to carbon black particles. Inflammatory and pathology response in the lungs of animals were more severe and extended in rats than in mice and hamsters. Hamsters in this study showed the most efficient clearance mechanisms and least severe responses of the three species (Elder *et al*., 2005). However, it is well recognized that there is a wide range of responsiveness across the spectrum of mouse-inbred strains. Intratracheal instillation of carbon black cause greater pulmonary toxicity in *ApoE-/-* mice than *C57* mice (Jacobsen *et al*., 2009). Differences in recruitment of neutrophils in 12 inbred strains of mice were found after inhalation exposure to Zn NPs (Gordon, Chen and Cohen, 2008).

Acute, Sub-acute and Chronic Studies

Although not specifically designed for nanomaterials, standard protocols have been adopted by regulatory agencies for both short-term and long-term inhalation exposures. The Organization for Economic Cooperation and Development (OECD) developed guidelines for acute inhalation toxicity studies (Test Guideline [TG] 433), sub-acute inhalation studies lasting 14-28 days (TG 412) and sub-chronic studies lasting 90 days (TG 413) (OECD 2004, 2009). The experimental design for an *in vivo* study performed by the authors is presented in Figure 6. It is sub-acute exposure (lasting 2 weeks) with necropsy immediately (at 0 week) and three weeks post exposure. Animals used in this model were male *C57Bl/6* inbred mice, which are a hardy strain that has been widely used over the past three decades and have unique immunological properties. Many investigators have used *C57Bl/6* mice in pulmonary nanotoxicity studies (Oberdorster *et al*., 2000; Shvedova *et al*., 2008) so their use facilitates comparison of biological responses among different research groups.

It is fundamental to use sentinel and sham-exposed animals in every *in vivo* experiment. Sentinel animals serve as a control for the conditions during transport, housing, and diet. Data obtained from sentinel animals can serve as normal values for particular endpoints. Sham-exposed animals serve as controls for the delivery system and vehicle of the studied material as well as for all the other factors animals are exposed to during study that can have impact on biological response. These include noise, stress and pressure changes during whole-body or nose-only inhalation exposure, possible abrasion, or mechanical injury to the trachea in intratracheal instillation exposures, and possible alteration of feeding and diurnal cycling. Responses

in exposed animals must be evaluated in comparison to responses observed in sham-exposed animals.

Dose Metrics

Dose is a function of exposure and time; however, in the case of nanotoxicity an assessment of dose is not so straightforward. It is crucial to have accurate and complete information concerning conditions during exposure such as concentration, duration of exposure, aerosol size distribution, and other characteristics (Brown, Wilson and Grant, 2005). There is an ongoing debate over an appropriate metric that should be used in toxicity assessment of nanomaterials. Many studies have found that possible health effects from exposure to nanomaterials might be better related with surface area (Duffin *et al*., 2007; Elder *et al*., 2005; Nel *et al*., 2006) and particle number (Wittmaack, 2007) rather than with mass concentration. Intratracheal instillation studies of low soluble and low toxicity materials (TiO_2 and ultrafine and fine carbon black particles) suggested that surface area of particles administered rather than mass burden of particles may be more suitable dose metric for pulmonary toxicity studies (Sager and Castranova, 2009). Earlier toxicity evaluation of inhaled particles also pointed out that various endpoints were correlated with different metrics (Oberdorster, 1996). For example, surface area was recommended as more appropriate metric for inflammatory biomarkers. On the other hand, effects on alveolar macrophages mediated clearance of particles might be the best correlated with the volumetric lung burden of different particle types. Furthermore, various ultrafine particles showed differences in the strength of response that cannot be explained only with distinct surface area. However up to now, the appropriate dose metric still remains an issue, thus, it is recommended that particle number, surface area, and particle mass be measured (Nel *et al*., 2006; Oberdorster, Oberdorster and

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat244
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Oberdorster, 2007; Oberdorster, Oberdorster and Oberdorster, 2005).

Exposure Methods

There are several exposure methods that have been used to study particulate aerosols, such as whole-body, head/nose/mouth-only, intratracheal, or nasal instillation (Brain *et al*., 1976; Muhlfeld *et al*., 2008; Pauluhn and Mohr, 2000; Pauluhn, 2005; Thorne, 2000). One advantage of whole-body or head/nose/mouth-only exposure systems is that they attempt to represent the exposure as it would occur in ambient indoor air or occupational environments and are less stressful for animals than exposure systems that use restraint. Thus, they are often preferred especially for chronic exposures. A disadvantage of whole-body exposure is the possibility of skin exposure and ingestion exposure from grooming. Nose-only inhalation systems are preferred in-situations when exposure from grooming is necessary to avoid, but animal restraiut and the resulting stress, risk of body temperature elevation in exposure tubes and increasing body size in longer term studies are all limitation of this system. However, it is recognized that both instillation and inhalation exposure models have limitations (Brain *et al*., 1976; Driscoll *et al*., 2000; Madl and Pinkerton, 2009; Osier and Oberdorster, 1997; Thorne, 2000). An advantage of instillation studies is more accurate dosimetry; however, distribution of particles in the lung, as it was shown in ours (Grassian *et al*., 2007b) and other studies (Brain *et al*., 1976; Warheit *et al*., 2004) does not follow the normal aerodynamic distribution. Intratracheal instillation or intratracheal insufflation (using a dry powder insufflator) may evoke inflammatory responses due to possible mechanical injury to the trachea as was observed in rats (Brown *et al*., 2001; Dick *et al*., 2003; Hohr *et al*., 2002; Oberdorster *et al*., 2000; Warheit *et al*., 2007a) and mice (Oberdorster *et al*., 2000). The method of pulmonary administration of nanomaterials can affect deposition pattern and biological responses. In a recent study, we compared instillation and inhalation exposure to TiO_2 nanoparticles (5 and 21 nm) in *C57Bl/6* mice (Grassian *et al*., 2007b). Interestingly, we found different types of inflammatory responses in the lungs between two exposure approaches. We observed increased numbers of macrophages with inhalation exposures, while inflammatory responses in instillation exposures were represented by increased number of neutrophils in BAL fluid. We also observed that the instillation solutions themselves contained larger aggregates than those found in the inhalation chamber. Other investigators observed that inflammatory responses in animals exposed by inhalation methods were significantly lower than after instillation exposure (Osier, bags and Oberdorster, 1997; Osier and Oberdorster, 1997; Warheit *et al*., 2005). A murine study of inhaled multiwalled carbon nanotubes (MWCNT) as well as rat inhalation study of single-wall carbon nanotubes (SWCNT) showed a more diffuse pattern of deposition with less severe pathologic lesions than those that were found after intratracheal instillation of a bolus dose (Li *et al*., 2007; Warheit *et al*., 2004). Similarly, rats exposed to MWCNT by intratracheal instillation developed pulmonary inflammation and fibrosis but when MWCNT were delivered by inhalation, no significant pathologic changes in the lung tissues were observed (Muller *et al*., 2005). Studies by Driscoll *et al*. (1991, 1990a, 1990b) in rats report that a longer period is needed for developing pathologic responses after inhalation exposure than after instillation, but still the response remains lower than in instillation studies. It is important to point out, that particles administered by instillation behave differently than particles delivered by inhalation. Instilled particles are deposited predominantly in the basal regions of the lungs and less in passages in the upper respiratory tract that play an important role in biological response (Driscoll *et al*., 2000; Osier, Baggs and Oberdorster, 1997) especially for nanoparticle exposures. In our study (Grassian *et al*., 2007b), a majority of TiO_2 nanoparticles administered by instillation were phagocytized by alveolar macrophages (Figure 7b). This was different in inhalation studies where particles were phagocytized by macrophages but also deposited at alveolar epithelial and interstitial sites as well as endothelial sites (Figure 7d). Similar finding were observed in inhalation studies of carbon nanotubes, where nanotubes were well dispersed in lung tissues and small aggregates or individual nanotubes were present on or beneath the epithelial cell surface in the lungs (Ryman-Rasmussen *et al*., 2009).

Nanoparticle Deposition

The site and extent of deposition of particles in the respiratory system is determined by physical mechanisms (interception, impaction, sedimentation, diffusion, and electrostatic precipitation) and

(Magnification 100 x).

anatomy and physiology of the subject inhaling the particles such as airway geometry, breathing pattern, frequency of breathing, tidal volume, and lung health status. The deposition of NP within the respiratory system happens primarily by diffusion (Heyder, 2004; Kreyling, Semmler and Moller, 2004) and secondarily by thermodiffusion in the first few airways of the lungs during exhalation (Asgharian and Price, 2007). Deposition in the lungs may be altered during respiratory disease (Miller *et al*., 1995). According to a well-known Human Respiratory Tract Model (HRTM) of the International Commission on Radiological Protection (ICRP) (ICRP, 1994) as shown in Figure 5, it is predicted that nanoparticles deposit efficiently in all regions of respiratory tract. Particles less than 10 nm in size deposit most in nasopharyngeal and tracheobronchial areas, whereas particles between 10 and 20 nm in size deposit most in the alveolar region. With increasing size of NPs to 20 to 100 nm, the deposition in alveolar and tracheobronchial regions decreases. For particles above 100 nm, the deposition in the nasopharyngeal area increases. Even though this model was not developed specifically for nanosized particles it is in agreement with a recent mathematical model that focused on deposition of NPs (Asgharian and Price, 2007). This multiple path particle deposition model was developed for all three regions of the respiratory tract by modeling convective flow, axial diffusion, and dispersion. Using this model for prediction of NPs smaller than 10 nm, it was shown that the deposition was high in the tracheobroncheal region and very few particles reached the alveolar region. If particle losses in nasopharyngeal region are taken into consideration, the alveolar deposition of such small particles will be even lower. Particles larger than 10 nm were deposited mainly in the pulmonary region. It was shown that deposition and clearance of particles within the airways is not homogeneous with the highest depositions occurring at the carinal ridge and bifurcational junctions (Balashazy, Hofmann and Heistracher, 2003). The carinal ridge is the point between the right and left main stem bronchus and bifurcational junctions are Y junctions, where bronchus is divided into smaller bronchioles. Even though it was shown that effect of airway geometry on deposition of particles at

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

nano-scale is minor (Zhang, Kleinstreuer and Kim, 2008). Another factor that should not be ignored is the epithelial surface areas in various regions of the respiratory tract. When deposited dose is normalized per unit surface area per cell, deposited dose is higher in the upper generations of the tracheobronchial region than in the pulmonary region (Cohen *et al*., 1988; Oberdorster, Oberdorster and Oberdorster, 2005). The dose at bifurcations may be as much as an order of magnitude higher than in the rest of the airways (Balashazy *et al*., 2003; Cohen *et al*., 1988).

Interaction of Deposited Particles with Lung Surfactant

For correct assessment of nanomaterial toxicity, it is essential to establish not only the deposition site but also the interaction of particles with lung fluids and tissues, including the surfactant film, the airway surface liquid, and the cells (Geiser, Schurch and Gehr, 2003). Lung epithelium is lined with pulmonary surfactant, mainly a mixture of complex lipids, synthesized and secreted by alveolar type II cells. The main functions of surfactant are to prevent alveolar collapse on exhalation (Green *et al*., 2000) and to serve as a primary immune barrier. NPs can directly interact with lung surfactant and can influence physiological characteristics such as metabolism of surfactant, alter particle clearance, lead to biophysical dysfunction of surfactant or modulate particle toxicity (Schleh and Hohlfeld, 2009). Delivered particles in lung fluid may cause disaggregation, which can influence the biological response (Holsapple *et al*., 2005). Using an *in vitro* pulmonary liquid model with dipalmitoyl phosphatidylcholine (DPPC), that is the main component of lung surfactant, dispersed in Dulbecco's phosphate buffered saline (pH 6.5), it was found that the interaction between lung surfactant and TiO_2 did not induce disaggregation of deagglomeration (Maier *et al*., 2006).

1.2.2 Biological Responses to Nanoparticles

The full extent of biological responses to nanomaterials is still not known. However, there are several mechanisms that have been proposed to explain the adverse effects of NPs. These include inflammation, endotoxin effects, stimulation of capsaicin/irritant receptors, autonomic nervous system activity, procoagulant effects, covalent modification of cellular components, and ROS production and the generation of oxidative stress (Nel *et al*., 2006). It has been hypothesized that the mechanism of nanoparticle toxicity for the pulmonary route of exposure acts through two thresholds: (i) a dosimetric threshold, where lung clearance mechanisms cannot remove particles at sufficient rate to prevent particulate accumulation; (ii) a mechanistic threshold where the level of the antioxidant defenses is overwhelmed by production of ROS (Oberdorster, 2002). Inflammation and ROS formation targeting non-inflammatory cells can contribute to the response in both mechanisms. Another hypothesis is that NP exposure causes injury via non-oxidant paradigms (Xia *et al*., 2008). NPs can organize around them a protein corona that depends on particle size, curvature, shape, and surface characteristics such as charge, functionalized groups, and free energy. As a result of this binding, some particles can generate harmful biological responses through protein unfolding, fibrillation, thiol cross-linking, and loss of enzymatic activity. When the thermodynamic properties of the nanomaterial (including surface free energy) allow dissolution of NPs in a biological environment the subsequent release of toxic ions might lead to toxicity of these nanomaterials. This has been studied more in *in vitro* (Brunner *et al*., 2006; Knaapen *et al*., 2002;Midander, Wallinder and Leygraf, 2007) and environmental studies (Wang, Wick and Xing, 2009).

Cell Recruitment to Lung and Inflammation

The clearance and biopersistence of particles in the respiratory system play a crucial role in their toxicity. The persistence of nanomaterials in the respiratory system, dictates particle uptake by airway or alveolar epithelial cells. Particle interactions with the cells is dependent on three primary factors: (i) particle deposition patterns; (ii) penetration of particle through the surfactant and mucus layers; and (iii) clearance or failure to remove particles by inflammatory cells (Churg, 2000). Already in nasopharyngeal areas and trachea, particles promote secretion of mucous (gel phase) that might move either anteriorly through nares or posteriorly into the pharyx. Some particles remain in close association with the epithelium (sol phase) for days or even weeks. Macrophages are present in the whole respiratory system and start to engulf foreign particles as soon as they come into contact with them.

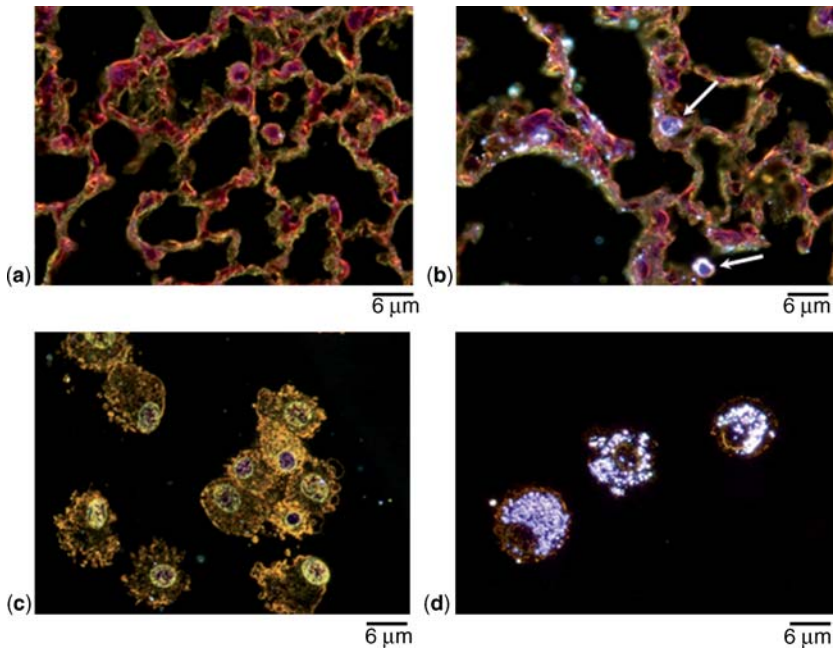

Figure 8. Dark field micrographs of lung tissue with H&E staining (a;b) and alveolar macrophages prepared by cytospinning and H&E staining (c;d). Sentinels (a;c) and animals sub-acutely exposed to TiO_2 nanoparticles with a primary particle size of 2–5 nm and necropsied immediately after the last exposure (b;d). Arrows point to TiO_2 nanoparticle-laden macrophages. (Grassian *et al*., 61). (Reproduced with permission from Grassian et al. (2007a) ©Taylar & Francis Group, plc.)

Phagocytosis is a major function of macrophages and influences the immunologic response of the lungs. Particle-laden macrophages, free particles along with secreted mucus might be carried up the mucociliary escalator to the pharyx where they are swallowed. Some particles are taken up by dendritic cells and transported into the tissue and reach lymph nodes and are presented to the T-lymphocytes. TiO_2-NP-laden macrophages found in bronchoalveolar lavage as well as lung tissue after inhalation exposure are presented in Figure 8. Part of an early lung response after inhalation exposure is not only recruitment of monocytes (macrophages) but also an engagement and activation of other inflammatory cells such as neutrophils. Many studies have scrutinized pro-inflammatory effects of manufactured NPs as a main predictor of their potential hazard (Bermudez *et al*., 2004; Grassian *et al*., 2007; Grassian *et al*., 2007; Pettibone, *et al*., 2008) and many of these studies confirmed that manufactured NPs certainly stimulate inflammatory effects with recruitment of macrophages and neutrophils (Figures 3 and 4). Some studies indicated that the uptake of inhaled ultrafine particles by phagocytosis is limited and that particles entered macrophages or type I epithelial cells by endocytosis (Geiser *et al*., 2008; Geiser *et al*., 2005; Stoeger *et al*., 2006; Takenaka *et al*., 2006).

Cytotoxicity and Oxidative Stress

Nanoparticles can cause toxicity of cells directly or indirectly. They can stimulate cells causing subsequent release of inflammatory mediators. A fast and frequently used assessment method of potential cytotoxicity of nanomaterials is done using *in vitro* studies. However, cytotoxicity is usually higher in *in vitro* studies as compared to *in vivo*, since nanomaterials or degradation products responsible for the toxicity are constantly removed in the case of *in vivo* experiments. The most widely used cytotoxicity assay in *in vivo* studies is the measurement of the cytoplasmic protein lactate dehydrogenase (LDH). This protein is released into the extracellular space either in the case of cell death or cell membrane damage. The enzyme activity of LDH is proportional to the cell injury. The generation of ROS and production of oxidative stress is considered to be the best-developed paradigm of nanoparticle toxicity after inhalation (Ayres *et al*., 2008; Donaldson *et al*., 2001; Nel *et al*., 2006;

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

Oberdorster, Oberdorster and Oberdorster, 2005; Shvedova *et al*., 2005). Membrane damage, cell death, inflammation, or even DNA damage (Schins *et al*., 2002; Trouiller *et al*., 2009) can all be the result of oxidative stress (Nel *et al*., 2006). During an inflammatory response, inflammatory cells like neutrophils, eosinophils, monocytes, and macrophages become activated and produce a respiratory burst when the cells take up oxygen through the activity of an NADPH-oxidase that generates superoxide anion radical (O_2^-) and hydrogen peroxide (H_2O_2) (Doelman and Bast, 1990). These oxygen metabolites give rise to other reactive oxygen species that may also cause damage by destroying surrounding tissue and inducing apoptosis in other immune reactive cells. Thus, redox imbalance, in which ROS or reactive nitrogen species (RNS) production overwhelms the antioxidant defense capacity of the cell, leads to oxidative stress. This condition is a state in which the glutathione (GSH) is depleted while oxidized glutathione (GSSG) accumulates. Many studies use the GSH/GSSG ratio to monitor an ongoing oxidative stress. The GSH/GSSG redox couple serves as the leading homeostatic regulator of cellular redox balance and also functions as a sensor that triggers additional cellular responses that can be protective or injurious. The reactive oxygen species can stimulate bronchoconstriction, increase secretion of mucus, and cause microvascular leakage, which leads to edema formation (Doelman and Bast, 1990).

The hierarchical oxidative stress model described by Nel *et al*., (2006) hypothesizes that minor levels of oxidative stress induce protective effects through antioxidant enzymes that are induced via transcriptional response elements by Nrf-2 (tier 1). However at an intermediate amount of oxidative stress (tier 2), it can lead to more damaging effects. If defensive responses fail to lead to adequate protection, a further increase in ROS production can result in pro-inflammatory and cytotoxic effects. Pro-inflammatory effects are mediated by the redox-sensitive MAP kinase and NF-κB cascades that lead to the expression of cytokines, chemokines and adhesion molecules. At a high level of oxidative stress (tier 3), cytotoxic effects are mediated by mitochondria, which can result in apoptosis or necrosis.

Number of studies (mainly *in vitro*) have demonstrated that nanosized particles can generate ROS and hydroxyl radicals (Brown *et al*., 2001; Carlson *et al*., 2008; Dick *et al*., 2003; Hussain *et al*., 2005). Some studies suggest that ROS production is related to the particle surface functional groups, since it was found that smaller particles were more powerful in production of ROS (Brown *et al*., 2001; Carlson *et al*., 2008; Stone *et al*. 2000). Other particle properties might also be responsible for oxidative stress. Comparison of four different ultrafine particles (carbon black, cobalt, nickel, and TiO_2) administered via instillation in the same protocol, showed distinct levels of inflammation and lung injury. Based on these studies, the authors concluded that the degree of lung damage was associated not with their size or surface area, but with their ability to generate surface free radicals with subsequent oxidant injury (Dick *et al*., 2003). If NPs are metals, or metals are present on the surface of particles, or dissolution of particles causes ion release, they can participate in the Fenton reaction, producing hydroxyl radicals, which are highly reactive and may destroy proteins and initiate the process of lipid peroxidation leading to DNA strand breaks. Destruction of the lipid bilayer by hydrogen peroxide (rapidly converted to hydroxyl radicals in the presence of ferrous ions) causes calcium influx in the cells. These elevated intracellular calcium concentrations are toxic to the cells (Doelman and Bast, 1990). They can lead to mitochondrial perturbation and apoptosis (Xia *et al*., 2006). Carbon black nanoparticles caused calcium influx in primary rat alveolar macrophages (Stone *et al*., 2000). However, as it was shown *in vitro* and *in vivo* (rats) studies of carbon black particles, metals are not necessarily needed for free radical generation after exposure to ultrafine particles (Brown *et al*., 2000).

Finally, it is worth mentioning, that some nanomaterial may generate bioprotective effects against oxidant injury as was found *in vitro* and *in vivo* testing of cerium oxide (CeO_2) nanoparticle and degenerative diseases of the retina (Chen *et al*., 2008) and cerium and yttrium oxide and a nerve cell line (Schubert *et al*., 2006). A cytoprotective effect of CeO_2 to cellular challenge with pro-oxidative organic (DEP) was also found in an diesels exhaust particles *in vitro* study using macrophage and epithelial cells (Xia *et al*., 2008). In the same study, ZnO was found to induce oxidative stress responses using the hierarchical oxidative stress model (production of pro-inflammatory cytokines [Tier 2] and mitochondrial injury [Tier 3], but TiO_2 was shown to be inert. Also, cardioprotective effects of CeO_2 were observed in mice probably through

their autoregenerative antioxidant properties (Niu *et al*., 2007).

Immunological Responses

Cytokines Many cytokines/chemokines are mediators of the tissue reactions following environmental insult such as inflammatory or fibrogenic processes (Shvedova *et al*., 2008; Stone, Johnston and Schins, 2009). Tumor necrosis factor (TNF) plays a role in the pulmonary recruitment of inflammatory cells and subsequent fibrosis formation when overload of lungs with insoluble particles occurs (Driscoll *et al*., 1990a; 1990b). A significant correlation was expressed between TNF release from alveolar macrophages and BAL neutrophil numbers. It has also been suggested that interleukin (IL) participates in granuloma formation in lungs as well as other tissues (Driscoll *et al*., 1990b; Hunninghake, 1984). After sub-acute inhalation exposure to Cu nanoparticles there were selected cytokines/chemokines that were found to be significantly elevated in BAL fluid such as monocyte chemotactic protein (MCP-1), macrophage inflammatory protein (MIP)-1α, IL-12(p40), keratinocyte chemoattractant (KC), eotaxin, TNF-α, regulated upon activation normal T expressed, and secreted (RANTES), granulocyte colony-stimulating factor (G-CSF), gramelocyte/macrophage colony stimulating factor, and IL-6. The largest increase was shown in MCP-1 levels (elevation from 3.4 pg mL^{-1} measured in sentinels to 4398.1 pg mL^{-1} in Cu-exposed group). This elevation was associated with increased number of BAL macrophages (Pettibone, *et al.*, 2008). Higher lung levels of MCP-1 were also found after exposure to carbon NPs (Inoue *et al*., 2005). Similar cytokines/chemokines elevations in BAL fluid were found in case of pharyngeal aspiration with single wall carbon nanotubes (SWCNT) 3 days post exposure (Shvedova *et al*., 2008). Interestingly, even though augmentation of IL-12 (p40) cytokine that is known to be elevated with profibrogenic exposures was observed in Cu-exposed animals, no fibrotic changes in the lung tissues were found in mice necropsied immediately or three weeks post exposure (Pettibone, *et al.*, 2008). Thus, it may require a chronic study to demonstrate fibrosis from Cu NPs.

Immunomodulatory Effects

Ultrafine and fine particulate matter (e.g., DEP or carbon black particles) is known to possess adjuvant properties that can induce exacerbation or modification of immune responses (Th1 versus Th2 response) (Al-Humadi *et al*., 2002; Diaz-Sanchez *et al*., 1999; Granum and Lovik, 2002; Last *et al*., 2004; Nygaard *et al*., 2004). This type of response can possibly induce hypersensitivity or allergic reactions. As shown in animal studies, various particles in combination with an antigen can enhance allergic sensitization expressed by elevation of antigen-specific IgE levels (Al-Humadi *et al*., 2002; Lambert *et al*., 2000; Takano *et al*., 1997; van Zijverden *et al*., 2000). It was also suggested that the exposure of particles with an antigen does not have to occur simultaneously since adjuvant effect from particle exposure may last for several days (Granum and Lovik, 2002). Thus, it is safe to assume that nano-sized particles may also have immunomodulatory potential and they can stimulate (increase the potency of allergens) or suppress the immune system. At this time, it is not clear what properties of NPs are responsible for this adjuvant effect. Is it due to their size, surface area, or chemical composition or other properties? The induction of inflammatory responses after particle exposure is postulated to play a critical role (de Haar *et al*., 2005). Not all studies investigating effect of NPs on allergic airway inflammation studied this effect in relation to different particles properties. Results from a study of residual oil fly ash (ROFA) suggest it was soluble transition metals in RDFA that mediated enhancement of sensitization to allergen (Lambert *et al*., 2000). Based on their animal studies de Haar and colleagues concluded that adjuvant activity of particles might be size-dependent. In this study, particles below 30 nm in diameter (TiO_2 and carbon black particles) induced immune sensitization to co-administered ovalbumen (OVA) that was demonstrated by high levels of cytokines (Th2-skewed immune response), increases in serum OVA-specific antibodies and by allergic airway inflammation. Such a response was not observed for particles over 200 nm (de Haar *et al*., 2006). Inoue *et al*. (2005, 2006) confirmed a size dependent effect (14 nm versus 56 nm carbon black particles) on adjuvant activity for total IgE and allergen-specific production of IgG and IgE, as well as on local expression of certain cytokines and chemokines. Antigen-related airway inflammation and immunoglobulin production were enhanced with smaller particles or larger surface area. One explanation of this response is that particles with

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat244

larger surface area are prone to attach more antigens than particles with smaller surface area. The authors reported that NPs might exacerbate allergic airway inflammation via increased expression of IL-5 and eotaxin and by expression of IL-13, RANTES, MCP-1, and IL-6. It was also suggested that the enhanced oxidative stress was a contributory factor (Inoue *et al*., 2005). Overall, it is proposed that exposure to NPs can be a risk for exacerbation of allergic asthma. This was further confirmed with multiwalled carbon nanotubes (MWCNT) (Inoue *et al*., 2009a). However, latex NPs (15-100 nm in size) did not exacerbate allergic asthma (Inoue *et al*., 2009). This shows that each nanomaterial might have different effects on allergic airway inflammation that depend on their unique properties. Size, shape (e.g., fibrous), chemical elements (e.g., metals) of nanomaterials might play a role in initiation of allergy.

Histopathologic Responses

In many cases lung pathology observed in *in vivo* studies was due to "overload phenomenon" when alveolar macrophages have an impaired ability to remove particles (Bermudez *et al*., 2004; Oberdorster, 1995). Considering this overload phenomenon, any insoluble particle of low toxicity can cause chronic pulmonary inflammation, lung fibrosis, or even tumors at a high enough dose. Species differences need to be considered in histopahological evaluation; rats more than mice or hamsters develop fibroproliferative lesions and lung tumors under pulmonary overload conditions after exposure to poorly soluble particulates such as TiO_2 (Bermudez *et al*., 2004). In our sub-acute studies of TiO_2 nanoparticles at exposure concentration of 8.88 mg m^{-3}, mice (*C57Bl/6*) did not develop remarkable pathological changes in the lung tissue (Grassian *et al*., 2007a).

In sub-acute inhalation studies of iron and copper NPs (particle properties are listed in Table 1) (Pettibone, *et al.*, 2008), iron exposure did not cause any histopathologic changes in the lung tissues; however, in the case of copper exposures, we found perivasculitis and alveolitis in animals nacropsied immediately post exposure (Figure 9a, b). All animals exposed to copper NPs and necropsied at zero-week developed perivasculitis with minimal increase of inflammation and chronic inflammatory cells. Alveolitis with minimal increase of inflammation and acute inflammatory cells were found in 88% of animals. No signs of fibrosis, peribronchiolitis, or interstitial pneumonitis were observed in any animals exposed to Cu NPs. Interestingly, no signs of pathology were found in animals necropsied three weeks after exposure (Figure 9c, d).

In our studies of Fe and Cu NPs sub-acute exposures, lungs were stained with Perls Prussian Blue stain or Rhodanine stain, respectively. In this manner, free iron particles were identified in the alveolar space as well as engulfed in macrophages (Figure 10a) in mice necropsied immediately post exposure. At three weeks post exposure, the majority of iron particles were located inside the macrophages (Figure 10b). In the case of Cu NPs exposure, none of the particles were visualized (Figure 10c, d) probably due to higher dissolution of Cu in biological fluid (Pettibone, *et al.*, 2008).

Histopahological lung evaluation of lung tissues from rats exposed to silver NPs for 90 days showed higher incidence of mixed cell infiltrate perivascular and chronic alveolar inflammation, including alveolitis, granulomatous lesions, and alveolar wall thickening with alveolar macrophage accumulation (Sung *et al*., 2008). In our mouse sub-acute (two weeks) exposure to Ag NPs we did not see pathological changes in the lung tissues, even though we observed macrophages with Ag particles exhibiting a foamy appearance by light microscopy (unpublished data). Similarly, four-week exposure of rats to nanosized Ag particles did not cause pathological changes in the lung tissue except for foamy alveolar macrophages and slight increase in neutral mucine in nasal cavities (Hyun *et al*., 2008). Studying nanosized and microsized SiO_2 it was found that the rats developed milder fibrosis (also demonstrated by lower hydroxyproline content, IL-4 and TGF-β expression in the lungs) with nanosized SiO_2 exposure. The authors postulated that this might be due to diffusion of NPs into the pulmonary interstitium and induction of more scattered inflammation as well as possible translocation of smaller particles to extrapulmonary organs (Chen *et al*., 2004).

Impaired Pulmonary Functions and Altered Lung Mechanics

There are not very many studies investigating pulmonary function or pulmonary mechanics in

animals exposed to nanomaterials. Lung function changes were studied in Sprague-Dawley rats after 90-day-inhalation exposure to silver NPs (Sung *et al.*, 2008). The tidal volume, minute volume, and peak inspiratory flow demonstrated a significant decrease during sub-chronic exposure to silver NPs. This decrease was associated with inflammatory lesions in the lung tissues (infiltrate mixed cell and chronic alveolar inflammation, thickened alveolar walls, and small granulomatous lesions).

Host Defense

The role of alveolar macrophages in protecting the lungs against invading pathogens might be impaired by exposure to environmental contaminants and thus contribute to increased susceptibility to infection by microorganism (Gordon and Read, 2002). Many studies have observed impaired function of alveolar macrophages especially after exposure to ambient air (Antonini *et al.*, 2002; Hatch *et al.*, 1985; Sigaud *et al.*, 2007), ultrafine (Lundborg *et al.*,

2001) and diesel exhaust particles (Yang *et al.*, 2001; Yin *et al.*, 2002). Sequential exposure (pharyngeal aspiration) of mice to single-walled carbon nanotubes (SWCNT) and bacteria (*Listeria monocytogenes*) decreased mouse recovery from bacterial infection (Shvedova *et al.*, 2008). *In vitro* studies showed that SWCNT suppressed chemotaxis of primary human monocyte-derived macrophages even at low concentration that did not cause cytotoxicity (Witasp *et al.*, 2009). In contrast to ultrafine ambient air particles that impact bacterial clearance, many nanomaterials also possess antibacterial activity (Chung *et al.*, 2008; Pal, Tak and Song, 2007; Ruparelia *et al.*, 2008). Thus even though bacterial clearance might be impaired after exposure to nanomaterials, if they also have antibacterial properties it

might depend on the exposure dose or mechanism of NP toxicity what effect is stronger. Further studies in this area are necessary.

Extrapulmonary Nanoparticle Translocation

Inhalation exposure of particulates is considered to be mainly a pulmonary problem; however, translocation of particles to other organs as well as gastrointestinal exposure should be taken into account since a high percentage of particles from the surface of the epithelium are removed by the mucociliary escalator and swallowed (Nemmar *et al*., 2002; Oberdorster *et al*., 2002; Semmler *et al*., 2004). Nanoparticulate translocation has been studied mainly in association with studies of the adverse cardiovascular effects of air pollution (Nemmar *et al*., 2002), however, manufactured/engineered NPs could pose the same risk. There is an ongoing debate if NPs are able to cross the pulmonary blood-air barrier and if this translocation to blood circulation occurs in a significant amount (Nemmar *et al*., 2002; Nemmar *et al*., 2001; Wiebert *et al*., 2006a). There are animal experiments that demonstrated extrapulmonary NPs translocation across the air-blood barrier into the blood (Geiser *et al*., 2005) or secondary target organs (Kreyling *et al*., 2002; Oberdorster *et al*., 2002; Takenaka *et al*., 2001). However, the fractions of translocated particles were very low. Human inhalation studies are controversial – some reported translocation of ultrafine radiolabelled (technetium 99m [^{99m}Tc]) carbon particles (generated with the Technagas Generator^{TM}) into the blood (Nemmar *et al*., 2002) while others observed quantitatively insignificant translocation of 100 or 35 nm Technegas particles to the systemic circulation in healthy lungs (Mills *et al*., 2006; Wiebert *et al*., 2006a; 2006b). Particle properties such as particle size (Mills *et al*., 2006) chemical composition, physical structure of the particle surface (Kreyling *et al*., 2002), *in vivo* solubility, or binding affinity to the cell membrane (Takenaka *et al*., 2006; Takenaka *et al*., 2001) might play a key role influencing systemic translocation of nanosized particles. In our subacute inhalation exposure to Ag nanoparicles with exposure concentration in the whole-body exposure chamber of 3.32 mg m^{-3}, we measured the retained amount of Ag in lungs 20 ± 13.6 mg kg^{-1} lung (dry weight). Silver concentrations in the heart, liver, and brain were found to be below the limit of detection for inductively coupled plasma optical emission Spectrometry (ICP-OES).

Studies of 50 and 200 nm polystyrene particles suggest that only a small portion of ultrafine particles instilled intratrachealy pass into the systemic circulation. However, pulmonary inflammation induced by LPS pretreatment appeared to play an important role in increasing extrapulmonary translocation of particles (Chen *et al*., 2006). The likelihood and mechanism of extrapulmonary translocation has not been established, although Nemmar and colleagues (Nemmar *et al*., 2002) propose that since rapid translocation of ^{99m}Tc-labelled particles takes place, phagocytosis by macrophages and/or endocytosis by epithelial and endothelial cells are not exclusively responsible for particle translocation into the circulatory system.

Genotoxicity

Nanoparticles can impact cellular transcription processes and prompt changes at the molecular level that would subsequently lead to alterations in the nucleus causing genotoxicity and carcinogenicity. To date, most studies evaluating the genotoxic potential of metal NPs were performed using *in vitro* models with pulmonary (Grigg *et al*., 2009) or other types of cells (AshaRani *et al*., 2009; Bhabra *et al*., 2009). Silver NPs were shown to cause DNA damage and chromosomal aberration in human lung fibroblast and the human glioma (AshaRani *et al*., 2009). Another *in vitro* study using an air-liquid interface model demonstrated that iron, gold, and silver NPs induced DNA damage to macrophages (Grigg *et al*., 2009). There are few *in vivo* studies that focus on genotoxicity of NPs. Intratracheal instillation of rats to α-quartz, carbon black, and titanium dioxide particles induced neutrophilic response and mutations in alveolar epithelial cells in a dose- and material- dependent manner (Driscoll *et al*., 1997).

A study examining genotoxicty potential of TiO_2 after exposure via gastrointerstinal tract (Trouiller *et al*., 2009) revealed that TiO_2 NPs induced DNA strand breaks and chromosomal damage in bone marrow and/or peripheral blood of mice. They also found that maternal oral exposure to TiO_2 NPs (500 mg kg^{-1}) during gestation caused DNA deletions in offspring. Authors proposed that this genotoxicity was caused by a secondary genotoxicity mechanism associated with inflammation and/or oxidative stress.

2 SUMMARY AND CONCLUSIONS

Several conclusions can be drawn from studies in the literature that have been focused on the potential of nanomaterials to cause toxic pulmonary responses:

- At this time, there is no reference material that would serve as a standard for comparison of toxicity of various nanomaterials. Many investigators, including our group, rank toxicity of nanomaterials based on various well-known toxicity endpoints. For this reason, a standardized protocol for evaluation of NP toxicity is necessary. However, as can be seen in this review, toxicity comparisons can be quite complex.
- Despite numerous *in vivo* and *in vitro* studies, the mechanism of NP toxicity remains unknown. More studies, especially those focused on long-term exposures to NPs are necessary.
- Full and detailed characterization of nanomaterials used in the toxicity assessment studies is crucial.
- Assessment of actual hazards and risk identification is still warranted so that this knowledge can be applied to safety measures.
- Well-designed epidemiological studies of workers exposed to NPs during manufacturing processes are needed.
- Interdisciplinary teams of scientists that include chemists, aerosol physics and engineers, and toxicologists have many advantages in furthering our understanding of nanomaterial toxicity evaluation.

One last point to make in the toxicity of NPs to humans is that, there is only one study that reports exposure to NPs and clinical toxicity in humans (Song, Li and Du, 2009). The authors reported that lung tissue displayed nonspecific pulmonary inflammation, pulmonary fibrosis and foreign-body granulomas of the pleura in workers exposed to polyacrylate, consisting of NPs. However, this study is a subject of ongoing discussions (Brain, Kreyling and Gehr, 2010; Inoue and Takano, 2010; Song, Li and Du, 2010). A number of scientists have weighed in on this issue and the majority of scientists think that this paper drew conclusions too quickly and that exposure assessment of chemicals and dusts present at this workplace environment were insufficient (Brain, Kreyling and Gehr, 2010). Although the conclusions drawn from this study were rebuked, it is clear that the toxicity of NPs must be taken seriously and there is a need for additional *in vivo* studies, screening of health symptoms of workers and well-designed epidemiological studies of workers exposed to NPs during manufacturing processing.

ACKNOWLEDGMENTS

The research described in this chapter that was performed by our group was supported by the Environmental Protection Agency (EPA RD-83171701-0), NIOSH (R01OH009448) and National Institute of Health (NIH P30 ES 005605). The authors thank Drs. Patrick O'Shaughnessy, John Pettibone, Heaweon Park, Larissa Stebounova, and PhD candidate Mr. Jong Sung Kim for their contributions for many of the studies described in this chapter.

The Role of Oxidative Stress in Nanotoxicology

Christie M. Sayes, Nivedita Banerjee and Amelia A. Romoser

Interdisciplinary Program of Toxicology, Department of Veterinary Physiology and Pharmacology, Texas A&M University, College Station, TX, USA

1 NANOPARTICLE HAZARD AND EXPOSURE

The use of nanoparticles in a myriad of household products (e.g., cosmetics, paints, and food packages) is increasingly wide-spread; therefore, contact with nanoparticles is not only becoming unavoidable, but with many products, exposure is intentional. The current scientific literature tells us that on one hand, nanoparticles have unique properties that enable advantageous phenomena; on the other hand, little is known about the unintentional consequences of man-made materials on the same size scale as normal functioning biological processes. Some have even postulated that exposures to nanoparticles could cause cardiopulmonary disease or extensive hepatocytic damage. Therefore, there is an overwhelming need to evaluate each material in order to protect human health and the environment.

A vast amount of information has been published and generally accepted on the nanoparticle-biological interactions of carbonaceous nanoparticles (Moussa, 1995; Moussa, 1997; Moria, 2006; Gharbi, 2005; Kolosnjaj, Szwarc and Moussa, 2007, 2007). The work focusing on carbon nanotubes leads to the concern that inhalation of nanoparticles will produce pulmonary hazards (Lam, 2004; Shvedova, 2005; Warheit, 2004). Other studies say carbon nanotubes and other fullerenes can induce oxidative stress (Sayes, 2006; Sayes, 2005; Fortner, 2005; Lyon, 2005; Sayes, 2004). Pulmonary disease induced by inhaled needle-like carbon nanofibers, extensive liver damage induced from accumulation of fullerene nanoparticles causing oxidative stress, or autoimmune disorders caused by an overproduction of alveolar macrophages or Kupffer's cells are just a few examples of human health problems due to chronic or sub-chronic exposures to nanoparticles. Poland *et al.* (2008) reported that the toxic effects of carbon nanotubes are "similar to asbestos". While the precise pathway of quantum dot exposures is unclear, prolonged exposures are widely accepted as a potential multi-organ threat.

Clearly, there are differences in the biological response after exposure to nanoparticles; thus the need to investigate why some are toxic and others do not induce a toxicological response. There are, potentially, many different "nano" modes of actions. The toxicological responses observed in many published studies could be measures of oxidative stress. This chapter outlines some of the oxidative stress biomarkers that are cited in the nanotoxicology literature.

2 NANOPARTICLE EXPOSURES FOLLOW PRECISE PATHWAYS TO CAUSE OXIDATIVE STRESS

2.1 Pathway #1: Inflammatory Cascade

Studies have shown that exposure to nanoparticles *in vitro* and *in vivo* systems may cause production

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat245
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

of inflammatory biomarkers (Warheit, 2004; Gurr, 2005; Sayes, 2006; Zhu, Oberdorster and Haasch, 2006). After nanoparticles are internalized by cell, such as phagocytes, the inflammatory cascade may be triggered. Inflammation is the complex biological response of cells and tissues to harmful pathogens and other toxicants. It is both a proactive mechanism to remove these harmful pathogens and to initiate production of repair enzymes. Unchecked inflammation can lead to a host of diseases, such as asthma, atherosclerosis, and rheumatoid arthritis; therefore, it is normally tightly regulated by the body.

2.2 Pathway #2: Necrosis or Apoptosis

Another pathway that may be triggered after nanoparticles are internalized by cells is death by necrosis or apoptosis due to particle uptake and accumulation or internal dissociation of ions, such as leaching of heavy metals. Heavy metal toxicity is well established in the literature (Stohs and Bagchi, 1995; Di Toro, 2001; Kirchner, 2005; Webb and Verschoyle, 1976; Ellender, 1979). It is also a complex biological response of cells and tissues to harmful ions. Usually, there is no cellular recovery after cadmium poisoning, for instance, but other free metal ions, such as selenide or zinc, may induce a slightly different response. Furthermore, if both nanoparticles and free metal ions are present within a cell, two pathways may be triggered.

2.3 Pathway #3: "Naïve" Antibody Repertoire

Even before challenge with a particular pathogen or immunogen, there is a pre-immune repertoire of antibodies circulating in the body. Some of these are innate IgM antibodies (termed "natural"), generally low affinity/highly cross-reactive antibodies to bacterial moieties (Zinkernagel and Hengartner, 2006). In addition to the natural antibodies, there are existing antibodies of other classes patrolling blood, lymph, and mucosa, many having been affinity matured and expanded by previous immune responses. It is possible that these existing antibodies may be capable of binding and neutralizing nanoparticles, without the active induction of a specific clonal B cell response towards the nanoparticle.

2.4 Pathway #4: Nanoparticle Induced Humoral B Cell Response

Although "small" is usually equated to "non-immunogenic" in immunology, it is possible that nanoparticles could activate a specific immunoglobulin on a B cell and cause an adaptive humoral response (Tizard, 1982). This could occur through conjugation with a carrier protein *in vivo*, providing both B cell receptor aggregation and linked recognition of a peptide for T cell help. If antibodies specific for nanoparticles are being produced (as opposed to antibodies cross-reactive with nanoparticles pre-existing as described above), they would not only clear the first nanoparticle introduction but would provide an augmented memory response with faster kinetics.

3 TOXICOLOGICAL RESPONSE DEPENDS ON CELLULAR UPTAKE MECHANISMS

Nanoparticles are novel tools in biological and biomedical applications, which can be used to determine the cellular uptake pathways of other small particles. However, the mechanisms of cellular uptake are unknown and the toxicity of nanoparticles within biological systems is of concern. The nanoparticle size, degree and type of surface coating, and surface charge are factors affecting NP endocytosis. Surface charge is believed to affect the interactions between particles and cell membranes (Zhang, 2009; Harush-Frenkel, 2007). Negatively charged nanoparticle surfaces, such as particles coated with hydrolipic acids, and positively charged nanoparticles, such as particles coated with polymers, are more capable of incorporation into human cells than particles with no surface charge. The surface coating of a nanoparticle influences the uptake by cells, which is accomplished via phagocytosis or pinocytosis. Pinocytosis includes macropinocytosis, clathrin or caveolao-mediated endocytosis, or clathrin/caveolae independent endocytosis.

Another factor that influences nanoparticle cellular uptake and subsequent toxicological response is proteins absorbed and adsorbed onto the surface of the nanoparticles. For example, proteins have been shown to coat particles when placed in cell culture media, serum, and lung fluid (Chen,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat245
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

2006; Chen, 2005; Huang, 2007; Schellenberger, 2008). Under normal circumstances, most protein, and other macromolecule endocytosis depends on clathrin-mediated endocytosis, where adaptor proteins are required for clathrin pit formation. This type of cellular uptake may also apply when proteins are attached on the surface of particles and are internalized via nanoparticle clathrin-mediated endocytosis. However, uptake of nanoparticles without proteins absorbed onto their surface may be clathrin-independent; uptake of particles of this nature may be regulated via caveolae. Lipid raft mediated pathway involvement is rapid: internalization of negatively charged nanoparticles occur after five-minute incubation times (Schroeder, 2007; Partha, 2008; Villanueva, 2009; Qaddoumi, 2003). However, positively charged particles are reported to internalize into cells through the clathrin-mediated pathway (Qaddoumi, 2003; Chung, 2007). Therefore, the exact relationship of nanoparticle surface charge and clathrin versus caveolae mediated pathways is unknown and needs further study. Figure 1 shows some of the cellular uptake mechanisms involved in nanoparticle exposures.

4 OXIDATIVE STRESS INDICATORS

The presence of excessive reactive oxygen species (ROS) can cause cellular oxidative stress (Figure 2), which may lead to subcellular damage such as DNA, RNA, protein, mitochondrial, and membrane or other lipid degradation, as well as perturbations in normal cell function. Additionally, oxidative stress can be used as an indicator for a variety of metabolic and neurologic diseases, as well as some biological conditions, such as obesity, neoplasia, Alzheimer's and Parkinson's diseases.

4.1 Protein Oxidation

Protein oxidation is the process of oxidative damage to polypeptides and amino acids present in cells. Examples of assays that measure oxidative protein damage are Protein Carbonyl Content (PCC) and 3-Nitrotyrosine. Techniques used to evaluate the oxidant-antioxidant biomarkers are enzyme-linked immunosorbant assays (ELISA), ion

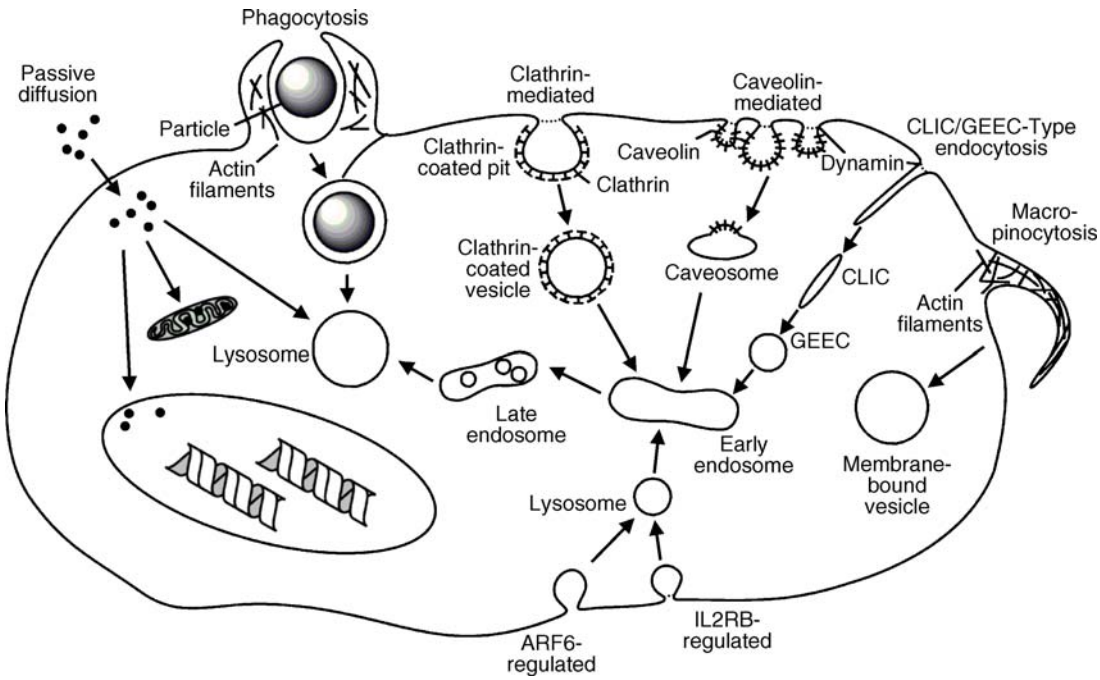

Figure 1. The relationships between nanoparticle surface charge and cellular uptake mechanisms is unknown. Clathrin and caveolae mediated uptake are believed to be involved, but depend on the nanoparticle surface charge (Zhang, 2009; Harush-Frenkel, 2007; Mayor and Pagano, 2007; Gould and Lippincott-Schwartz, 2009; Doherty and McMahon, 2009).

exchange chromatography, immunoblotting, and electron paramagnetic resonance imaging.

4.2 Protein Oxidative Damage

Several mechanisms are known that describe how electophiles and pro-oxidants cause protein damage. Alterations in protein function can occur following one or more of these events: (i) formation of covalent bonds between electrophiles and nucleophilic amino acids (e.g., cysteine thiols, lysine, and histidine amines); (ii) oxidation of nucleophilic amino acids (e.g., oxidation of cysteine thiols to disulfides or methione sulfides to sulfoxides); and (iii) production of reactive nucleophiles (e.g., phosphorylation or acetylation of endogenous protein).

4.3 DNA Oxidation

Among the numerous biomarkers for oxidative stress, some are specific for DNA oxidation. Assays capable of measuring DNA oxidative stress or damage include those that measure levels of 8-hydroxyguanosine (8-OHG) and 8-hydroxydeoxyguanosine (8-OHdG) nucleosides (Cattley and Glover, 1993; Hwang and Kim, 2003). Cells, urine, blood, and other tissues can be tested for DNA oxidation. The Comet Assay, which is gaining in popularity due to its ease of use and

sensitivity, measures general DNA damage via gel electrophoresis of cell lysate, followed by fluorescence signal quantification.

4.4 DNA Oxidative Damage

In nanotoxicology, DNA oxidative stress can be used as an indicator for potential cytotoxicity. Recently, research has shown that different types of DNA damage and repair after oxidative DNA damage can provide insights into mechanisms and modes of action (Cooke, 2003). DNA damage is a result of a break or change in the chemical sequence of DNA in the nucleus of a cell. Each type of DNA lesion has different affects on the cells. For example, some DNA lesions result in mutations and can affect DNA replication and transcription; other types of DNA damage are repairable (Cooke, 2003). DNA oxidation can be detected by measuring the amount of 8-hydroxydeoxyguanosine (8OHdG) found in the cell (Cattley and Glover, 1993; Hwang and Kim, 2003). It is hypothesized that 8-hydroxyguanosine (8-OHG) reacts with ROS produced by the surface of the nanoparticles to produce 8-hydroxydeoxyguanosine (8-OHdG). 8OHdG acts as a mutagenic agent and as a cellular marker.

4.5 Mitochondrial Oxidation

Oxidative stress caused by the accumulation of nanoparticles within the mitochondria, ROS from the nanoparticle surface at the site of the mitochondria, or ROS produced by the mitochondria because of nanoparticle exposure may lead to cell damage or death. In structurally and functionally intact mitochondria, (the primary consumers of cellular oxygen), the production of ROS is balanced by an extensive antioxidant defense system that works to detoxify the oxygen radical generation, resulting in very low net ROS present at any time (Nicholls and Budd, 2000). This protection is provided by glutathione and less abundant antioxidants as well as superoxide dismutase and a host of other enzymes.

4.6 Mitochondrial Oxidative Damage

Nanoparticles of various compositions have been shown to create cellular ROS. ROS production has been found in systems testing diverse materials, such as C_{60} fullerenes, single-walled nanotubes (SWNTs), quantum dots (Qdots), and ultrafine metal oxide particles (UFPs) such as TiO_2. ROS attributed to nanoparticles is most commonly observed when simultaneously exposed to UV light or transition metals (Oberdorster, Oberdorster and Oberdorster, 2005; Li, 2008; Sayes, 2004). Heightened production of ROS occurs when damage to the mitochondria exists; thus, oxidative stress is often detected by measuring mitochondrial function. Additionally, it has been demonstrated that nanoparticles of various size and chemical composition are preferentially transferred to and accumulate in the mitochondria (Li, 2008).

4.7 Lipid Peroxidation and Membrane Oxidative Damage

Lipid peroxidation and membrane damage are used as indicators of oxidative stress and cellular damage. Lipid peroxides are unstable and degrade to molecules such as reactive carbonyl compounds. Polyunsaturated fatty acid peroxides generate malondialdehyde (MDA) and 4-hydroxyalkenals (HAE). MDA and HAE are colorimetric/flourometric indicators for this type of oxidation. Cytoplasmic and other cellular component membranes are easily targeted due to the amount of lipids found within the membrane. Membrane oxidation can disrupt the ion channel flow.

5 REACTIVE OXYGEN SPECIES FLUORESCENCE DYES

Reactive oxygen species (ROS) can lead to cellular oxidative damage if the amount of oxidant present in the cell is greater than the amount of antioxidant in the cell. However, recent research has uncovered novel roles for ROS, such as for biological regulators and messengers in signal transduction systems (Soh, 2006). As a result, the expansion of new, potential roles has necessitated more sophisticated methods to study molecules, which are very difficult to detect due to their evanescent characteristics. Fluorescent probes are a suitable option because they exhibit high sensitivity and microscopic resolution, in addition to being simple to use (Gomes and Fernandes, 2005).

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat245
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

5.1 Families of Dyes

ROS dyes are categorized according to which type of ROS being probed. In general, there are multiple fluorescence probes for the detection of superoxide radical ($O^{2\bullet-}$), hydrogen peroxide (H_2O_2), singlet oxygen ($^1O_2$), hydroxy radical (HO•), or peroxy radical (ROO•), as well as others (Table 46.1). Some of the dyes, such as 2,7-dichlorodihydrofluorescein (DCFH), which was originally thought to only be specific for H_2O_2, are actually oxidized by multiple ROS.

There is a wide range of applications for these dyes within the realm of detecting ROS. For example, some probes are mainly used in an indirect approach to probe for antioxidant capacity, while others probe for oxidation in particular subcellular compartments and membranes (Gomes and Fernandes, 2005). Interestingly, while some probes *produce* a fluorescent compound when induced by a reactant, others, such as scopoletin and dipyridamole, display a *reduction* in fluorescence upon oxidation. Another probe, called C_{11}-BODIPY$^{581/591}$, is known to undergo a red to green transformation when oxidized (Pap, 1999).

Fluorescent probes are used to investigate ROS generated by nanoparticles. Solid data has emerging, which evaluates oxidative damage to cells due to exposure to metal-containing particles (e.g., quantum dots) (Chang, 2009; Park, 2008; Khatchadourian, 2009; Alekseenko, Waseem and Fedorovich, 2008). The ROS are difficult to measure due to their short lifetime, but can be assessed more easily with the aid of a fluorescent probe. The cellular uptake and potential cytotoxicity of mercaptoproprionic acid-coated CdTe QDs with concominant exposure to UV light can be studied using a Dihydroethidium probe that produces a red fluorescent ethidium compound when oxidized by superoxide anion (Chang, 2009; Gomes and Fernandes, 2005). 2,7-dichlorodihydrofluorescein can be used in nanotoxicity studies that investigate ROS production due to TiO_2 exposures in human bronchial epithelial cells (Park, 2008). The diacetate form of the parent 2,7-dichlorodihydrofluorescein compound, traverses the cellular membrane where it is hydrolyzed to 2,7-dichlorodihydrofluorescein by esterases, then oxidized by several possible ROS to DCF, which is fluorescent (ex/em: 498/522) (Gomes and Fernandes, 2005).

Fluorescent probes are also utilized to measure antioxidant capabilities of compounds. BOPIDY-α-tocopherol, a broad-range ROS probe, has been used to measure increases in cellular antioxidant presence

Table 1. Examples of fluorescent ROS dyes.

Fluorescent Probe	ROS Sensitivity	Ex/Em (nm)	Nano-based Applications
DHE (Dihydroethidium)	$O2^{\bullet-}$	520/610	Probe for UV-induced ROS in quantum dot treated pancreatic cells (Chang, 2009)
B-TOH (BOPIDY-α-tocopherol)	ROO•	514/565	Probe for increased antioxidant induced by CdTe nanoparticles on lipid membrane (Khatchadourian, 2009)
	RO•		
	HO•		
DCFDA (2,7-dichlorodihydrofluorescein)	H_2O_2	498/522	Probe for ROS in rat brain synaptosomes caused by Fe3+ nanoparticles (Alekseenko, Waseem and Fedorovich, 2008)
	ROO•	ROS caused by TiO_2 in human bronchial epithelial cells (Park, 2008)	
	HO•		
CM-H2DCFDA (chlormethyl-dihydro derivative of fluorescein)	H_2O_2	485/538	Probe for reduction of ROS due to antioxidant action of soluble fullerene vescicles in human umbilical epithelial cells (Maeda, 2008)
	ROO•		
	HO•		
HPF (Hydroxyphenyl fluorescein)	HO•	485/535	Probe for reduction of ROS due to antioxidant action of soluble fullerene vescicles in human umbilical epithelial cells (Maeda, 2008)

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat245
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

due to nanoparticle exposures (Khatchadourian, 2009). CM-H2DCFDA (a chlormethyl-dihydro derivative of fluorescein) and HPF (hydroxyphenyl fluorescein) have been shown to probe for reduction in ROS after addition of water-soluble fullerene-treated human umbilical epithelial cells (Maeda, 2008).

5.2 Confocal Microscopy as a Tool to Probe Stress

Oxidative stress can potentially lead to cell death; therefore, a viable means of detecting oxidative stress can be of significant importance. Oxidative stress can induce a dose-related decrease in the level of fluorescence, which can be detected and monitored by fluorescence or confocal microscopy. In confocal microscopy, fluorescent probes are used to stain particular cellular structures, which illuminates only the areas of interest. The fluorescent probes dihydrorhodamine 123, dihydroethidium, 2′,7′ dihydro-dichlorofluorescein (H_2DCF), and dihydro-dichlorofluorescen diacetate (H_2DCFDA) are some of the most commonly used detectors of reactive oxygen species (ROS) for use in flow cytometric assays, spectrofluorometric assays, and confocal microscopy (Uggeri, 2004).

One of the advantages of confocal microscopy as a tool for detecting oxidative stress is the ability to image a particular set of cells over a time-lapse. In studies where ROS are induced by H_2O_2 treatment, the increase in ROS can be measured over time. Analysis of the early stages of the apoptotic phase is also possible using confocal microscopy, which in general is a sensitive technique that can detect low concentrations of H_2O_2-induced oxidative stress (Liegibel, 2000). In addition to 2D imaging, 3D images can be taken by scanning sequential sections of the sample to produce a more complete image of the cell or cell structure.

6 NORMAL REDOX AND STEADY STATE IN A 24 H PERIOD

Periodic oscillations in metabolic redox cycle reactions represent fundamental mechanisms linking oxidative processes to cell cycle regulation. Redox status, a term used to describe the relative amounts of an oxidizable and reduceable redox couple (i.e., GSH/GSSG), governs differential transition through the cell cycle by maintaining a balance between normal, cellularly produced ROS and the enzymatic removal of ROS by various antioxidants. Although higher levels of ROS can be toxic to the cell, researchers are beginning to understand the necessary presence of reduced concentration/duration ROS in the cell as biological regulators, the key principle of the "threshold concept" (Menon and Goswami, 2007). Some nanomaterials may be considered redox-active, which simply implies that they efficiently accept or donate electrons, leading to ROS production and oxidative stress (Sayes, 2004; Lovric, 2005). However, the ROS can be produced either exogenously or endogenously, resulting in an imbalance in the cellular redox state (Przybytkowski, 2009).

At no point does thermodynamic equilibrium (absence of net electron flow) exist within a cell until it dies. Many reactions within the cell are maintained at a nonequilibrium steady state, where the ratios of redox couples remain constant for brief periods. In other words, the concentration of products equals the concentration of reactants. However, it must be noted that these reactions may be dramatically altered with changes in pH. During oxidation-reduction exchange reactions, redox couples become redistributed in a quantitative, ratiometric fashion, which provides a convenient endpoint to determine cellular oxidative stress (Figure 3) (Aw, 2003).

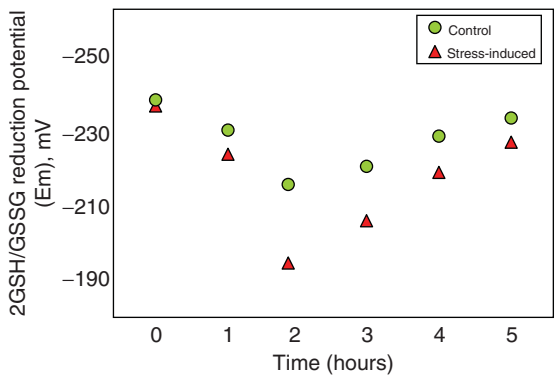

Figure 3. The graph pictured above represents the effects of ROS-induced cells. Oxidative stress-induced cells exhibit a different reduction potential of conjugated glutathione, as compared to unexposed control cells. Glutathione (GSH) is a dynamic, intracellular antioxidant. Over time, the oxidized form of glutathione (GSSG) becomes reduced (or recycled) back to GSH, the functional form responsible for maintaining optimal ROS levels intracellularly.

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat245
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

Estimating the redox environment intracellularly can be accomplished by measuring the ratio of reduced and oxidized glutathione (GSH and GSSG) concentrations using fluorescent or luminescent probes (Østergaard, 2001; Meyer, May and Fricker, 2001; Ridnour, 1999). Many kits are currently available from laboratory suppliers which measure GSH:GSSG levels in cells and/or tissues. These concentrations can then be applied to the Nernst equation to calculate the cellular reduction potential (E_h) (Hancock, 2004).

$$E_h = E_m - \frac{RT}{nF} 2.303 \log \frac{[\mathrm{GSH}]}{[\mathrm{GSSG}]}$$

Where R is the gas constant ($8.314\,\mathrm{J\,K^{-1}\,mol^{-1}}$), T is the temperature in Kelvin, n is the number of electron donors and acceptors, and F is the Faraday constant ($9.6485 \times 104\,\mathrm{Cmol^{-1}}$). E_m is the electrical potential where the concentration of the GSH and GSSG are equal.

7 ANTIOXIDANTS

In mitochondria, reactive oxygen species (ROS) are produced constantly as side products of the electron transport chain. These high-energy radicals would represent a major threat to cellular viability if no mechanisms existed for neutralizing their reactivity. In fact, many biological structures are capable of mediating the destructive capability of ROS. Endogenous to the human body, glutathione, melatonin, and associated enzymes function primarily in the reduction of ROS. Vitamins C and E also fill similar roles in human health (Meister, 1994). However, many antioxidants have been identified in a diversity of living species. Some examples can be found in extracts of green tea (EGCG) and grape seeds (gallic acid).

These natural antioxidants reduce the likelihood of damage by ROS because they are more easily oxidized than cellular structures essential for continued life. This means that electron transfers occur between an oxidant with a high reduction potential and an antioxidant with a much lower reduction potential. For an antioxidant to be useful, its reduction potential must be much lower than that of another present molecule with reducing power. That is, molecules with a smaller reduction potential will react more quickly and favorably with oxidants and effectively discharge their destructive capabilities (Madej and Wardman, 2007).

A fascinating area of the recent literature is the discovery of iron-chelating antioxidants. Through a process called the Fenton reaction, Fe(II) can react with hydrogen peroxide to form the dangerously reactive hydroxyl radical. It is hypothesized that this damaging reaction is at least partially responsible for the deterioration caused in patients with Alzheimer's and Parkinson's diseases (Turnbull, 2003). It has been found that molecules with a hydroxamate functional group can effectively bind free reactive iron. In one study, two such groups were added to a well known neuroprotective peptide called NAP (Blat, 2008). Their results demonstrated that this novel agent was useful in controlling both hydroxyl radical formation and lipid peroxidation.

8 CONCLUSIONS

A systems biology approach in nanotoxicological research is vital to the understanding of nanoparticle-induced modes of action and development of mechanistic models. Using quantitative properties of dynamic systems, such as production of cell-to-cell signaling molecules over time, mathematical models may be able to be developed. Due to the large number of parameters, variables, and constraints in cellular networks, numerical, and computational techniques are often used in biology. The same computational and mathematical concepts can be applied to nanotoxicology. Other tools in systems biology can also be applied to nanotoxicology. These include the integration of information from the literature, the development of online databases and repositories for sharing data and models and using information-extraction and text-mining techniques. Systems biology and nanotoxicology are both fields that study the relationships between components of a biological system (metabolic pathways, organelles, cells, and organisms) and the whole organism in an effort to understand how biological systems function under control versus variable conditions.

Health Effects of Nanoparticles

Armelle Baeza-Squiban, Sonja Boland, Salik Hussain and Francelyne Marano

Functional and Adaptive Biology Group, Laboratory of Molecular and Cellular Responses to Xenobiotics, University of Paris 7 Diderot-Paris, Paris, France

1 INTRODUCTION

Nanomaterials gain diversified utilizations in every field of life but their health and environmental effects still need thorough understanding. Increasing industrial and consumer product utilizations result in the production of enormous quantities of these materials every year. According to Woodrow Wilson Centre's Project on Emerging Technologies (PEN) on line database, as of 25 August 2009, 1015 consumer products containing nanomaterials have been reported. Apart from the environmental, occupational and consumer product exposures, nanomaterials gain increasing utilizations in the nanomedicine. These utilizations range from molecular diagnostics and imaging to drug delivery and gene therapy (Pison *et al*., 2006). For instance, quantum dots are semiconductors promising for computing and the quantum confinement renders these nanoparticles (NPs) highly fluorescent for cellular imaging applications. The super-paramagnetism of iron oxide NPs is useful for magnetic resonance imaging (MRI) or magnetic hypothermia. Local surface plasmon resonance of gold NPs could be used for chemical and biochemical sensing as adsorption of molecules induce a shift in the local index of reflection.

Nanoscale materials exhibit unique surface and quantum phenomena not observed at the microscale. For instance, materials, such as gold or platinum that are chemically inert at normal scales, can serve as potent chemical catalysts at nanoscales. Size reduction is associated with the appearance of specific characteristic properties, such as surface area, surface reactivity, aspect ratio, and surface chemistry (lipophilicity and charge). Such properties makes that nanomaterials are highly susceptible to be reactive toward biological systems. Occupational and environmental medicine has already experienced many situations in which exposure to particles, mainly respirable dusts [asbestos, diesel exhaust particles (DEP), quartz, coal, etc.] are responsible for diseases. Epidemiological studies and experimental studies in animal models have demonstrated the hazardous effects of these particles. With this background, it is well founded to consider that the large and diverse group of engineered NPs represent a hazard that potential health impacts have to be assessed.

A lack of adequate epidemiological and experimental data about the health effects of the nanomaterials has lead to hype both in favor and against these materials. For the moment, the short-term effects after acute dose exposures are the most investigated but still insufficiently characterized effects whereas long-term effects after chronic expositions are still unknown.

Cellular mechanisms behind NP-induced effects have been attributed to abiotic and biotic oxidative stress induction potentials of these materials. In this study, we represent a systemic overview of the current knowledge on the exposure, secondary organ translocation and potential health effects of the NPs. Moreover, potential mechanisms of NP-induced

cellular effects and role of physico-chemical characteristics are elaborated. A growing body of literature reinforces the point of view of rigorous research in the field of nanomaterial-induced health effects.

2 ROUTES OF EXPOSURE TO NANOPARTICLES AND THEIR FATE IN THE BODY

Currently, no data are available on NP concentrations in the environment because of their diversified and unrestricted sources. In occupational settings, such concentrations reach very high levels depending upon the quantity of NP-produced and exposure duration. Major systems of the body that are constantly in contact with the environment (such as the respiratory tract, the gastrointestinal (GI) tract and the skin) are more prone to encounter NPs. In case of NPs, the ability of these systems to provide an efficient protective barrier against exogenous agents seems to be compromised as a result of unique physico-chemical properties of NPs allowing their systemic distribution in the body.

2.1 Major Exposure Scenarios

2.1.1 Inhalation

The respiratory tract is one of the prime targets of NP exposure because it is the route of entry of inhaled particles and it receives entire cardiac output leading to possibilities of exposure to systemically administered NPs.

The respiratory tract is composed of the conducting airways and terminal alveoli. The conducting airways extend from exterior to the bronchia and are involved in the conduction and the clearance of inhaled air till alveoli. The terminal alveoli are involved in the gas exchanges and exhibit a surface area of around 140 m^2. The alveoli are delimited by a very thin epithelium producing a thin layer of surfactant. The air–blood distance is around 2 μm.

After inhalation, particles can be deposited in the different parts of the respiratory tract according to their size. Because of their small size, NPs are submitted to diffusion forces. Predictive models, established from the data of the International Radiological Protection Commission, are used to estimate the deposition of particles (Witschger and Fabries, 2005). 5-nm NPs are uniformly deposited in the three part of the respiratory tract whereas those below 5 nm are mainly deposited in the upper airways and those higher than 5 nm are mainly deposited in the alveoli. In the context of respiratory diseases where air fluxes are modified, it is expected that the pulmonary retention of NPs increased.

Inhaled particles can be cleared from the respiratory tract by two different ways: the mucociliary clearance and the alveolar clearance (Figure 1). The mucociliary clearance is achieved by the mucociliary epithelium covering the upper and lower airways. The ciliary beating allows the displacement of mucus entrapping particles produced by secretory cells. This mucus is either expectorated or ingested. Functional ciliated cells and a good mucus rheology are the two essential conditions for an efficient mucociliary clearance. The alveolar clearance is achieved by alveolar macrophages that are present in the lumen of alveoli and are professional phagocytes. However there are some evidences that their ability to endocytose NPs is less efficient as compared to larger particles (Geiser and Kreyling, 2010). Thus NPs reside longer in the alveoli and can get in contact with type II cells (involved in the production of the surfactant lining the respiratory epithelium) or with type I cells (cells constituting 90% of the alveolar epithelium surface area).

2.1.2 Dermal Contact

Skin can be exposed to NP because of their presence in cosmetics (sunscreens containing TiO_2 and ZnO NP) for better light-reflecting properties as well as in clothes to confer anti-bacterial resistance (use of silver NPs). Human skin has a surface area of nearly 1.5–2 m^2 and is composed of two main layers: the epidermis and the dermis (Figure 1). The epidermis is the most superficial layer of the skin and consequently the first line of contact with environmental injuries. It is a pluristratified epithelium mainly composed of keratinocytes that is constantly renewed from basal cells present in the deeper layer of the epidermis. The outer layer of the skin called the stratum corneum is composed of dead cells having intercellular cement involved in the protection properties of the skin. No blood vessels are present in this layer. The dermis is separated from the epidermis by the basal membrane and is 10- to 40-fold thicker than the epidermis. It is a conjunctive

tissue mainly composed of fibroblasts secreting an abundant extracellular matrix. It contains the skin structures, such as sweat glands, hair follicles, nerve terminations and blood and lymphatic vessels. For a systemic passage, NPs have to cross the epidermis and the basal membrane.

2.1.3 Ingestion

The presence of NPs in food caused by either contamination or intentional introduction in transformed food can lead to an exposure of the GI tract which could also act as an additional portal of entry of NP in the body (Figure 1). The gut with its surface area of nearly 240 m^2 greatly contributes to the total surface of the GI tract. It is covered by a monostratified epithelium composed of secretory cells producing mucus and enterocytes that exhibit at their luminal face numerous microvillosities in order to increase the exchange surface and favor the absorption of nutrients. In addition, lymphoid tissue called Peyer patches (involved in local immunity) is dispersed in the intestinal mucosa. These are composed of M cells that have high phagocytosis capacities.

2.2 Translocation and Biodistribution of Nanoparticles

The respiratory and intestinal epitheliums constitute efficient physical barriers to the penetration of micro-organisms and particles caused by the presence of tight junctions between cells. A paracellular entry (between cells) of NPs is unlikely except in case of either pathological situations or exposure to toxic substances affecting the epithelium permeability. For NPs to cross biological barrier, a transcellular passage involving a mechanism called endocytosis is necessary.

2.2.1 Cellular Uptake of Nanoparticles

There are two modes of endocytosis: the phagocytosis that concerns the uptake of particles of large size and pinocytosis that ensures the uptake of fluids and solutes (Conner and Schmid, 2003). Four different pinocytosis mechanisms can be distinguished: macropinocytosis, clathrin-dependent endocytosis, caveola-dependent endocytosis and clathrin-caveola-independent endocytosis leading to the formation of endosomes of different sizes (0.5–5 μm, 100–150 nm, and 70 nm, respectively).

The phagocytosis is performed by professional phagocytes, such as macrophages, monocytes and polynuclear neutrophiles in order to protect the organism from pathogen invasion. Phagocytic materials are internalized by a process involving actin filaments in large phagosomes (0.1–10 μm) that fuse with lysosomes in order to destroy the pathogen owing to the co-ordinated action of oxidants, proteases and hydrolases in an acidic environment. According to the form or the size of the particle, cell is sometimes unable to engulf totally the particles inducing a frustrated phagocytosis prone to initiate an inflammatory reaction. It has been observed in mice exposed to carbon nanotubes (Poland *et al*., 2008). Numerous studies have also shown that alveolar macrophages are less efficient to endocyte NPs by comparison with larger particles (Geiser *et al*., 2008) leading to the persistence of NPs in the alveoli and their deposition on the alveolar epithelium (Oberdörster, Oberdörster and Oberdörster, 2005).

Several endocytosis pathways involve membrane receptors. The coating of NPs with ligands present in biological fluids could favor their recognition by the membrane receptor and eventual internalization.

Following endocytosis, the internalized material is present in a vesicle separated from the cytosol by a membrane. However NPs have been observed free in the cytosol and even in mitochondria and the nucleus where they could directly interact with macromolecules. Rothen-Rutishauser *et al*. (2007) have observed that after an inhalation exposure of rats to low concentrations of TiO_2, NPs not surrounded by a membrane are found in lung epithelial and endothelial cells, in the conjunctive tissue and even in red cells suggesting that NPs could enter cells by a mechanism different from the classical ones (Rothen-Rutishauser *et al*., 2007). They propose that adhesive interactions could allow the passive diffusion through the plasma membrane caused by the transient formation of pores.

Until now, numerous studies have shown a rapid uptake of diverse NPs in different cell types even not specialized in phagocytosis. However, the involved mechanisms have not been illustrated in detail. In addition, most of these studies have been performed on *in vitro* cell cultures. The major limitation of such systems is the possibilities of interaction between NPs and culture medium leading to adsorption of specific proteins on NPs and thus influencing the receptor-mediated uptake.

2.2.2 *Translocation of Nanoparticles*

There is growing evidence that NPs can cross the epithelial barriers getting access to the blood stream and thus allowing their distribution in the whole body.

Air–Blood Translocation

In the alveoli, distance between air and blood is very thin (2 μm) being a favorable route of entry into the systemic circulation (Figure 1). Numerous studies have been performed on humans as well as on animals to estimate the translocation of inhaled particles through the air–blood barrier. According to studies, the extent of observed translocation differs greatly and could be explained by the differences in NP characteristics and route of administration (inhalation vs. instillation).

When rats were made to inhale for 1 h radiolabeled iridium NPs (15–80 nm), only 1% of the radioactivity is recovered 7 days later in secondary organs, such as liver, spleen, heart and brain (Kreyling *et al*., 2002). NPs are mainly present in feces caused by their lung clearance and ingestion. The follow-up over 6 months revealed that NPs are initially trapped in the interstitium and can come back to the alveolar lumen to be cleared by macrophages (Semmler-Behnke *et al*., 2007). In contrast, a size dependence was observed for intratracheally instilled TiO_2 NPs between 12 and 240 nm NPs (50 and 4% translocation respectively; Oberdörster, Oberdörster and Oberdörster, 2005). Using the same route of administration, Zhu *et al*. (2009) have shown that 22-nm iron oxide NP ($^{59}Fe_2O_3$) are quickly translocated to rat blood (10 nm) and distributed in the liver, spleen, kidney and testis. They estimated a plasma half-life of 22.8 days (Zhu *et al*., 2009). Another study comparing 1.4 and 18 nm gold NPs has revealed a significant translocation of 1.4 nm NPs whereas those of 18 nm are retained by the lung (Semmler-Behnke *et al*., 2008). After intratracheal instillation of colloidal gold (20 nm) in mice, NPs are observed in the interstitium between alveolar cells and endothelial cells as well as over endothelial cells in blood vessels. However, little quantities of NPs were found in the blood stream (Furuyama *et al*., 2009). At the same time, it has also been observed that NP-loaded alveolar macrophages migrate towards the blood circulation and extrapulmonary organs suggesting that the NP translocation could be either direct or indirect via macrophages.

The administration of carbon NPs coupled with Technecium to humans has given contradictory results that are still a matter of debates (Mills *et al*., 2006; Nemmar *et al*., 2002).

In vitro studies performed using alveolar epithelium have highlighted the role of the NP physico-chemical characteristics in their ability to cross the epithelial barrier. The translocation through the alveolar barrier is more important for polystyrene NPs of little diameter (20 vs. 100 nm) as well as for positively charged NPs (Yacobi *et al*., 2008). In addition, it does not occur at 4 °C suggesting that it is an energy-dependent mechanism.

To summarize, these studies revealed that the translocation of NPs through the air–blood barrier is possible but it is more or less significant depending on the physico-chemical characteristics of NPs. However, these studies have been performed after a sole exposure suggesting that a more significant translocation is likely to occur in case of chronic exposure. Pathological situations could also increase the translocation. For example, a more pronounced translocation was observed in rats after intratracheal instillation of polystyrene NPs (56 and 202 nm) when rats were pre-treated with lipopolysaccharide in order to induce an inflammation (Chen *et al*., 2006). Similarly, in rat-perfused lungs, the exposure to iridium NPs results in their translocation in the perfusate only if lungs are simultaneously treated with hydrogen peroxide to mimic the oxidative stress occurring during inflammation or in the presence of histamine that is used to increase the vascular permeability (Meiring *et al*., 2005).

Neuronal Translocation

The monodisperse NPs show an efficient predicted deposition in the nose. The olfactory epithelium present in the nose is a potential route of entry of NPs to the central nervous system (Figure 1) and is investigated as an efficient route for drug delivery (Mistry, Stolnik and Illum, 2009). Translocation of 50 nm gold NPs (in monkey), 35 nm carbon NPs (in rats) and 30 nm manganese oxide NPs (in rats) toward the olfactory bulb through the axon olfactory nerve has been reported (Oberdörster, Oberdörster and Oberdörster, 2005). Particularly, experiments performed with MnO have shown that 11% of the deposited NPs can be recovered in the olfactory bulb and some of them exhibit a more distal location in

the brain (Elder *et al*., 2006). These observations were further associated with inflammatory effects. Another study with TiO_2 (80 and 155 nm) in mice have confirmed the access of these NPs to the brain via the olfactory bulb especially in the hippocampus (Wang *et al*., 2008b).

It has to be kept in mind that these experiments have been performed on rodents that have a well-developed olfactory mucosa (8 cm^2 in rats corresponding to 50% of the nasal mucosa) compared with humans (5 cm^2 corresponding to 5% of the nasal mucosa) and are only nasal breathers. This finding limits the scope of such studies for human extrapolation.

The access of NPs to the central nervous system can also occur from the passage through the blood–brain barrier. This barrier has very efficient junctions between endothelial cells in order to avoid the penetration of particles by the paracellular route. Experiments performed by intravenous or intraperitoneal injections of gold NP (40 nm) have not shown the presence of these NPs in the brain (Sadauskas *et al*., 2007). Currently, active research is underway to establish nanocarriers for drug delivery to brain. It has been observed that binding of serum apolipoproteins to NPs favors their uptake by low-density lipoprotein receptor present on the endothelial cells membrane (Kim *et al*., 2007).

Dermal Translocation

The transcutaneous penetration of NP has been particularly studied for TiO_2 and ZnO as they are components of many sunscreens formulations. Several studies have shown that following repeated exposure of normal human skin to TiO_2, these NPs either stay on the epidermis or are present in the strateum corneum but never penetrate or cross the viable layer of the epidermis. NP can accumulate and persist in hair follicles but until now there is no evidence of a passage towards the dermis by this route.

Quantum dots of different sizes (14–45 nm), forms (spheres, ellipsoid shape) and charges are efficiently adsorbed by normal pig skin maintained in flow-through diffusion cells. But even after 8-h exposure, no translocation of quantum dots is observed in the perfusate suggesting that quantum dots cannot gain access to the blood stream (Ryman-Rasmussen, Riviere and Monteiro-Riviere, 2006). By contrast, using rat skin maintained *in vitro*, it was shown that gold NPs (15, 102, and 198 nm) permeate through the skin in a size-dependent manner (Sonavane *et al*., 2008).

Whereas the healthy skin seems to be an efficient barrier towards NPs, other conditions such as damaged skin (wounds, erythema, eczema, etc.) and flexures sites are more susceptible to NPs translocation. *In vitro* experiments with human skin submitted to mechanical flexions (20 flexions of 45° per min) have shown that in 50% of skin samples flexions favor a low epidermal and dermal absorption of fluorescent NPs (0.5 and 1 μm) after a 60-min exposure whereas particles of larger size (2 and 4 μm) stayed localized on the strateum corneum (Tinkle *et al*., 2003). The abrasion of rat skin allows quantum dots to reach the dermis (Zhang and Monteiro-Riviere, 2008) as well as UV radiation exposure in an *in vivo* mouse model but the penetration is very limited (Mortensen *et al*., 2008).

2.3 Fate of Nanoparticles

NPs present in the blood can be cleared from the body via urine after filtration in the kidney or via feces after their transfer to the bile in the liver.

The filtration through the renal glomerula occurs for particles having a diameter below 5.5 nm. Those between 6 and 8 nm can also be filtered whether there are neutral or positively charged. Those over 8 nm stay in the blood and accumulate in the reticuloendothelial system (RES). The RES is particularly developed in the liver and is represented by Kupffer cells (macrophages with high phagocytosis potential). If they are unable to degrade the engulfed NPs, NPs persist in them. In the liver, hepatocytes are also involved in the endocytosis of particles and their metabolism and clearance by bile. Until now, no studies have considered the metabolism of NPs that is unlikely for metallic NPs but could intervene for functionalized NP.

The fate of NP has been mainly investigated in studies using an intravenous administration. Although it is not a relevant route of exposure considering environmental and occupational exposures, they allow improved knowledge on the behavior and fate of NP in the body.

Several studies have been performed with quantum dots that have shown that according to the size and coatings they are either cleared in urine or taken up by RES and retained in the body (Chen *et al*., 2008a; Yang *et al*., 2007). Another study

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat246
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

has shown that water-soluble, single-walled carbon nanotubes (SWCNT) functionalized with diethylentriaminepentaacetic are cleared from systemic blood circulation through the renal excretion route as intact nanotubes (Singh *et al*., 2006). Still another study with rats demonstrated that TiO_2 NPs accumulate in liver and spleen over 28 days (Fabian *et al*., 2008). According to their size, gold NPs exhibit a different biodistribution in mice and rats. The smallest one (10–15 nm) show a large distribution with an important accumulation in liver followed by the lungs, the kidneys and the spleen and the observation of NP in the brain (Sonavane, Tomoda and Makino, 2008). As the size increase, less organs are concerned but the highest accumulation is still in the liver (De Jong *et al*., 2008).

3 NANOPARTICLE PROPERTIES INVOLVED IN THEIR TOXICITY

A bulk material should have constant physical properties regardless of its size, but nanomaterials have nanostructure-dependent properties that often differ from their bulk counterpart and are used for chemical and medical applications. Indeed, the physical behavior change below 100 nm approaching quantum physics that could lead to new chemical, mechanical, electrical, optical or superparamagnetic properties. Nanomaterials could also be designed to take advantage of these physico-chemical properties to obtain new specific biological activities for medical application in diagnostic and treatment. Size-dependent properties are observed such as quantum confinement in semiconductor particles, local surface plasmon resonance in some metal particles and superparamagnetism in magnetic materials. These are caused by the nanoscale substructure, electronic configuration, size and large surface to volume ratio compared with bulk material. These size-related properties let to the use of NP in various applications.

Much of the fascination about nanotechnology is caused by unique quantum and surface phenomena exhibited at the nanoscale. This also implements, however, that the biological activity of nanomaterials could not directly be predicted by extrapolating the properties of the constituent chemicals and compounds and nanomaterials could have unexpected effects in biological systems. Nanotoxicology is a new field which arose from this need to evaluate the safety of nanomaterials and to develop assays for risk assessment of engineered NPs. The questioning about the toxicity of NPs has originated from knowledge about the health effects of atmospheric particulate matter (PM) which have shown that ultrafine particles (PM $< 0.1\ \mu m$) induce greater biological responses than fine (PM < 2.5) or coarse particles (PM $< 10\ \mu m$) (Ramgolam *et al*., 2009). However, these differences could not solely be attributed to one parameter such as the greater surface area of ultrafine PM but a variety of factors has to be considered.

The biological activities are determined by a large diversity of factors linked to the various physico-chemical characteristics of the nanomaterials: size, surface area (taking into account the porosity and roughness of the particle), shape, bulk chemical composition (including the crystal structure), surface chemistry (including lipophilicity as well as surface charge or coatings) and surface reactivity which is linked to the two latest (surface area and surface chemistry) (Figure 2). Thus, the biological activities induced may differ because of the variety of nanomaterials but some effects may be nanoscale-specific and thus apply to all nanomaterials. Despite the intrinsic characteristics of nanomaterials, the final biological outcome also depends upon their fate inside the body. Indeed, the high energetic adhesive forces at the surface of NP could allow the interaction with other particles leading to agglomeration and aggregation but also with molecules leading to surface modifications influencing the biological response (Figure 2). The biological effects

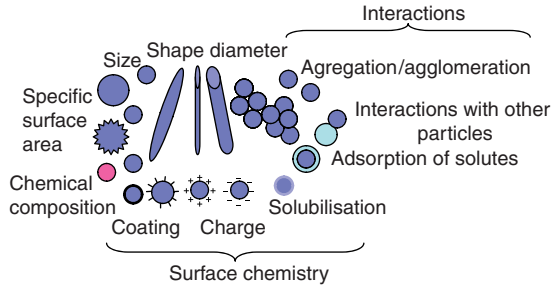

Figure 2. Different physico-chemical characteristics of the nanomaterials involved in their biological activity: size, surface area (taking into account the porosity and roughness of the particle), shape, bulk chemical composition, surface chemistry (including solubility as well as surface charge or coatings) and interactions between particles leading to agglomeration and aggregation as well as with molecules.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

could also be enhanced as a result of biopersistance of the material.

3.1 Size

One of the main differences between NPs and larger-sized particles is their potential to cross biological barriers. The interstitial uptake after *in vivo* inhalation exposure to polystyrene NP is higher than for micrometer-sized particles (Oberdörster, Oberdörster and Oberdörster, 2005). This is caused by higher deposition rates of NPs and their deeper penetration into the lungs. Even for particles within the nanometer range the efficiency of translocation further increases with decreasing size as shown for 18 and 1.4 nm-sized gold NPs (Semmler-Behnke *et al*., 2008). This capacity of NPs to cross biological barriers is actually studied to overcome the challenging problem of brain drug delivery caused by the difficulty to cross the blood–brain barrier (for review Agarwal *et al*., 2009). The size determines not only the uptake of nanomaterials but also the interaction with proteins. Indeed the extent of conformational changes of proteins adsorbed onto NPs depends upon the particle size probably caused by changes in the surface curvature (Lundqvist, Sethson and Jonsson, 2004; Vertegel, Siegel and Dordick, 2004).

3.2 Surface Area

With decreasing particle size, the percentage of surface molecules increases exponentially compared with total molecules of the particle when particles are smaller than 100 nm. This implements higher surface reactivity of the particles and potential chemical as well as biological activities as the number of atoms at the surface is increasing. Higher surface to volume ratios could have desirable effects used in medicine to develop carriers for drug delivery and in industry for catalysts or fillers to reduce weight but also potential toxic outcomes. Comparisons of cellular effects induced by carbon black (CB) or TiO_2 NPs of different specific surface areas have shown that oxidative stress and pro-inflammatory responses are correlated to particle surface areas (Hussain *et al*., 2009). This strong relation of biological response to surface area was also observed for *in vivo* lung inflammation induced by carbonaceous NP (Stoeger *et al*., 2006). It is important to note that the specific surface area [Brunauer Emett Teller (BET) surface] should be considered as it takes into account the porosity and roughness of the particles in contrast to the geometric surface. The role of surface area is also evident considering its importance to allow surface chemistry to take place leading to aging, oxidations or hydrations that could reduce or increase biological responses.

3.3 Shape

The influence of shape on the toxicological outcome of nanomaterials has been put forward by the research on asbestos which led to the three-dimensional model of its carcinogenic risk: dose (total amount inhaled over time), durability (biopersistance in the lung) and dimension (length, width and aspect ratio of the fiber). Indeed, long fibers could not enter the lung and short fibers ($<5\,\mu m$) are cleared effectively by alveolar macrophages whereas intermediate fibers could not be completely taken up by the phagocytes leading to frustrated phagocytosis, biopersistance and inflammation. Some nanomaterials have been shown to induce the same responses than asbestos: exposures of rats to high doses of crocidolite and multi-walled carbon nanotubes (MWCNT) have induced mesothelioma for both types of fibers (Sakamoto *et al*., 2009). However, the high doses used in this study were greatly criticized and whether realistic doses of MWCNT could induce cancer has still to be investigated. Further studies have in addition established the length dependency of asbestos-like pathogenicity of MWCNT (Poland *et al*., 2008) that may explain the absence of a carcinogenic response observed after intraperitoneal injection of shorter ($<1\,\mu m$) MWCNT (Muller *et al*., 2009). The cytotoxicity of MWCNT also depends on their diameter as larger nanotubes have been shown to be more toxic than smaller ones (Wang, Tao and Xing, 2009).

3.4 Chemical Composition

The toxicity of nanomaterials is not merely caused by the nanoscale of the particles but the chemical nature of the material is obviously a key factor determining their toxicity. For instance, the composition of the asbestos fibers, especially the iron content,

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat246
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

is also of crucial importance for their carcinogenic potential. Furthermore, comparing same-sized NPs of CB and TiO_2 it has been shown that these two types of particles have the same toxic potential as they induce apoptosis of bronchial epithelial cells at same concentrations but the cellular mechanisms elicited depend upon the particle type (Hussain *et al*., 2010). Wang, Tao and Xing (2009) have also shown that the toxicity of quantum dots depend upon their composition as CdSe quantum dots are more toxic than CdTe whereas ZnS-$AgInS_2$ quantum dots were much less toxic. This cytotoxicity was attributed to the leakage of highly toxic cadmium ions. Indeed, the solubility of the nanomaterial is a critical feature for their toxicity. The biological effects could either be increased by insolubility leading to biopersistance of the material or in contrast by dissolution as also observed for ZnO and CuO NPs in which toxicity could be attributed to leaching of Zn or Cu ions (Mortimer, Kasemets and Kahru, 2010). However, particle-associated toxicity was also observed in other studies using ZnO NPs (Moos *et al*., 2010). It is important to note that dissolution kinetic is size-dependent and therefore an important factor to be considered for NP toxicity although several other physico-chemical characteristics influence dissolution kinetics: particle surface characteristics, such as roughness or curvature influence the kinetics of dissolution and adsorbed molecules could either slower solubility or serve to catalyze dissolution. The aggregation state of the particles has also to be considered as a hindering factor of solubility (Born *et al*., 2006). It is interesting to note that acidity could favor dissolution and thus preferential uptake of NPs into lysosomes or the less acidic caveolar compartment could thus influence the fate of the particles as shown for ZnO and CeO NPs (Xia *et al*., 2008). Another important factor influencing toxicity of nanomaterials is the crystal structure. It has been shown that rutile TiO_2 NPs were two orders of magnitude less cytotoxic than same-sized anatase TiO_2 NPs that could be due to the higher ability to generate reactive species (Sayes *et al*., 2006b).

3.5 Surface Characteristics

It is the surface of the nanomaterial that interacts with biological systems; however, the surface chemistry could differ from the bulk material. For instance, the effect of DEP mainly depend upon the organic compounds produced by incomplete combustion and that adsorbed on the carbonaceous core (Boland *et al*., 2000; Marano, Boland and Baeza-Squiban (2007)). Interestingly, the higher inflammatory response induced by ultrafine PM compared with fine or coarse PM could not be thoroughly attributed to increased surface area or particle number but the biological effects could be linked to the chemical composition, especially the organic matter that differs between these size fractions (Ramgolam *et al*., 2009). Surface modification of engineered nanomaterials could occur during the production process leading to surface functionalization influencing toxicity. Acidic treatment of MWCNT leading to carboxyl, carbonyl and hydroxyl groups increases their cytotoxicity (Magrez *et al*., 2006), but on the other hand, functionalization increasing water solubility of SWCNT leads to decreased cytotoxicity (Sayes *et al*., 2006a). Chemical aging and photoactivation could further modify surface chemistry. UV illumination has been shown to increase the cytotoxicity of fullerenes (Rancan *et al*., 2002) as well as anatase TiO_2 NPs that was linked to ROS production after photoactivation (Sayes *et al*., 2006b). Aging could also decrease toxicity as shown for ultrafine particles of polytetrafluoroethylene fumes that are no longer toxic when inhaled after several minutes of delay (Johnston *et al*., 2000). Agglomeration of the NP occurring concomitant with aging may however contribute to this decrease in toxicity.

Interaction of nanomaterials with cell membranes will depend upon surface properties, such as charge and hydrophobicity. For instance, hydrophobic poly(lactic-coglycolic)acid (PLGA) NPs are taken up more efficiently by alveolar macrophages than hydrophilic PLGA (Torche *et al*., 2000). It is noteworthy that the size of the particle is an important parameter as a particle could be hydrophobic at small size and hydrophilic at larger sizes (Chiu *et al*., 2009). This behavior arises from a purely geometrical effect caused by the curvature of the particle–water interface. Surface charge also influences the uptake of NPs as, for example, positively charged amine-polystyrene NPs could cross the alveolar barrier 20–40 times faster than same-sized negatively charged carboxy-modified polystyrene NPs (Yacobi *et al*., 2008; des Rieux *et al*., 2005). This is in agreement with the higher toxicity of cationic quantum dots compared with anionic

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat246
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

quantum dots leading to alterations of epithelial barrier function (Yacobi *et al*., 2007). However, the differences in transport may also be attributed to the higher hydrophobicity observed for the cationic NPs (des Rieux *et al*., 2005). In contrast, intravenous injection of carboxyl quantum dots induces a higher prothrombotic effect compared with amine-coated quantum dots (Geys *et al*., 2008). The authors hypothesized that the negatively charged quantum dots trigger coagulation and subsequent fibrin formation and platelet activation.

Moreover, structural defects on the surface of MWCNT are mainly responsible for the pulmonary toxicity observed *in vivo* and *in vitro*. Indeed, annealing structural defects and elimination of metal contaminants by heating reduces the lung responses after intratracheal instillation but further grinding of the material restored their toxic potential (Muller *et al*., 2008). The rigidity of the particles also determines the uptake as macrophages showed a strong preference to engulf rigid objects compared with soft particles of same composition and size (Beningo and Wang, 2002).

3.6 Interactions

Beside these inherent properties of the nanomaterials, the interaction between particles or molecules will also determine their toxicity. First, the agglomeration state not only increases the size of the nanomaterial influencing its lung penetration, deposition and cellular uptake but also increases the solubility of the material (Borm *et al*., 2006). The reduction in the total surface area seems, however, to be limited as the biological effect of agglomerated particles is still correlated to the BET surface area (Hussain *et al*., 2009). The physico-chemical surface properties of the material, such as charge and hydrophobicity, determine the degree of aggregation but the characteristics of the suspending media (pH, viscosity, ionic strength, etc.) also play a role. Thus, coatings of derivative groups as well as dispersants may allow the stabilization of nanomaterials by preventing the formation of aggregates that has an effect on toxicity. For instance, dispersion of SWCNT by the use of surfactant (Wick *et al*., 2007) or by adding functional groups (Sayes *et al*., 2006a) reduces effectively the cytotoxicity.

Interactions between particles of different composition could have unexpected biological consequences as seen for cobalt tungsten carbide particles known to induce hard metal lung disease. It is the contact between the particles which causes the release of ROS involved in the pathogenic response as pure cobalt or carbide particles are inert and soluble cobalt salts in contact with carbide particles have no effect (Lison *et al*., 1995). Recently, the same effect has been observed for co-exposure to CB and Fe_2O_3 NPs leading to oxidative effects whereas exposure to either particle type alone has no effect (Guo *et al*., 2009). This synergistic effect is probably caused by intracellular redox reactions between CB and Fe^{3+} solubilized within the lysosomal compartment leading to Fe^{2+}.

In addition to these interactions between NPs, they could also interact with soluble compounds. Increasing evidence indicates that in biological fluids proteins adsorb onto NPs to form a ≪corona≫. Recent studies have clearly identified a number of proteins that bind to CB, silica, titanium dioxide or acrylamide NPs (Cedervall *et al*., 2007; Deng *et al*., 2009; Val *et al*., 2009;Vertegel, Siegel and Dordick, 2004). Among the proteins identified, several (such as apoliprotein E, granulocyte-macrophage colony-stimulating factor (GM-CSF), or transferrin) are ligands for cellular receptors and may thus contribute to the biological effects of the NPs. However, this interaction could also lead to inactivation of essential proteins, such as metabolizing cytochrome P450 isoenzymes (Fröhlich *et al*., 2010). Furthermore, the coating with proteins or lipids present in blood or epithelial lining fluids could also reduce the surface reactivity of the particles as shown for serum that reduces the biological response of CB and TiO_2 NPs (Val *et al*., 2009).

4 EFFECTS OF NANOPARTICLES

Human health effects of manufactured NPs are relatively unknown because of the fact that these materials gained utilizations in the recent past and adequate risk assessment data are unavailable. Previously acquired data on the deleterious effects of air-borne particulate pollutants and limited experimental data about the effects of manufactured NPs on experimental animals, point toward the possible human health effects of these newly developed materials. Moreover, the major known effects are short-term effects after acute dose exposures and long-term effects after chronic expositions are still unknown.

4.1 Short-Term Effects of NP Exposure

4.1.1 Effects on Respiratory System

Respiratory system is considered as key target for involuntary exposures to NPs. Respiratory effects are mainly produced as a result of solid material deposition in the respiratory tract and indeed, depend upon the physico-chemical characteristics of the deposited material (Hoet *et al*., 2007). They also depend upon extent of penetration in the depth of the respiratory tract and persistence therein because there have been reports of inefficient phagocytosis of NPs.

In humans, there are limited data available about the effects of NPs on the respiratory system. A recent report has put an emphasis on possible induction of pleural effusion, pulmonary fibrosis and granuloma formation in factory workers exposed to polyacrylate NPs (Song, Li and Du, 2009). Although the exact link is unknown and there is also a possibility of involvement of other exacerbating factors, this observation further enforces the need for urgent risk assessment measures for nanomaterials.

Respiratory effects produced by the NPs mainly include inflammation, oxidative stress and functional disturbances. Numerous studies in animals describe inflammatory effects of NPs as transitory responses to NP exposures and assess whether the degree of inflammatory response is related to the exposure dose of NPs. Indeed, various types of nanomaterials have been shown to induce inflammation in lungs after either inhalation (Bermudez *et al*., 2004; Elder *et al*., 2005; Grassian *et al*., 2007) or instillation exposures (Warheit, Webb and Reed, 2006, Warheit *et al*., 2006; Warheit *et al*., 2007b). Such inflammatory responses are measured by local invasion of leukocytes, their numbers in broncho-alveolar lavage fluid (BALF), release of LDH and cytokine production. CNTs (single- and multi-walled) show typical granulomatous reactions in addition to inflammation after pulmonary exposures (Lam *et al*., 2004; Mercer *et al*., 2008; Warheit *et al*., 2004). Various studies with CNTs have demonstrated degree of dispersion plays a significant role in the induction of granulomatous response after CNT exposure.

One of the major factors which need attention in the studies describing inflammatory effects of NPs is the doses used in the studies. Apart from some human volunteer studies on air-borne ultrafine particles, most of the studies describing the health effects of NPs are performed in experimental animals. Indeed, rats are much prone to the overload situations because of anatomy of the respiratory tract as compared with mice and hamster. Under such situations, the clearance mechanisms are impaired and the retention time of the inhaled particles increases leading to chronic inflammation and fibrosis.

Other important consideration is the possible functional disturbances after the NP exposure that include airway hyper-reactivity (AHR) to none specific stimuli and tissue injury leading to disturbance in respiratory functioning (Alessandrini *et al*., 2006; Inoue *et al*., 2007, 2009). These disturbances are mainly studied in the animal models of different pathologies, such as asthma, etc. Indeed, there have been many studies that described the modulatory effects of nanomaterials on the lung functioning and existing pulmonary inflammation (Nygaard *et al*., 2004). However, Huczko *et al*. (2001) tested the effects of fullerenes on pulmonary function but no significant disturbances were observed revealing that beside size another factors contribute to NPs effects.

A detailed review of the literature describing the health effects of the NPs is shown in Table 1.

4.1.2 Effects on Cardiovascular System

Major cardiovascular abnormalities occurring after the NP exposure include thrombosis, arrythmias, coagulation disturbances, blood pressure abnormalities, etc. The mechanisms behind these effects are still unclear. Cardiovascular effects produced by the NPs might be in part caused by the released inflammatory and prothrombotic mediators at the site of deposition (lungs) leading to the activation of blood cells that take part in cardiovascular adverse effects (Simeonova and Erdely, 2009). However, as discussed in the previous part, NPs can translocate from respiratory system to cardiovascular system and may lead to adverse cardiovascular effects.

It has been shown that single oropharyngeal instillation of SWCNT induce dose-dependent cardiovascular pathology through perturbation of mitochondrial dysfunction (Li *et al*., 2007b). Autonomic modulation of the heart and repolarization of the ventricular myocardium are also possible mechanisms at least in susceptible individuals as suggested by exposure of young humans to CB NPs (Zareba *et al*., 2009). Other important contributors to cardiovascular pathology can be platelet activation, platelet aggregation (Radomski *et al*.,

2005) and systemic inflammation (Nemmar *et al*., 2007). Evans *et al*. (2006) have found strong correlations between plasma viscosity (a known marker of cardiovascular disorders) and lung inflammatory markers after instillation of diesel exhaust and silica NPs in a rat model of bleomycin-induced inflammation. Similarly, a study by Chen *et al*. (2008b) has further confirmed the paradigm of the occurrence of susceptible populations by demonstrating age-related differences in pulmonary and cardiovascular responses of rats to SiO_2 NPs after an inhalation exposure.

4.1.3 *Effects on Nervous System*

As discussed in the previous section, different types of NPs translocate to central nervous system after different exposure routes (Kreyling *et al*., 2009). NPs have been shown to cause brain damages comprising of increase in number of segmented neutrophils and lymphocytes, protein carbonyl levels, and interstitial fibrosis, oxidative stress, lipid peroxidation as well as glia activation, that is, activation of innate immune response (Li *et al*., 2009; Oberdorster *et al*., 2004; Wang *et al*., 2008b). For example, TiO_2 after nasal instillation (Wang *et al*., 2008a) or abdominal administration (Ma *et al*., 2010) induces lipid peroxidation, and decreases the total anti-oxidation capacity and activities of antioxidative enzymes, an excessive release of nitric oxide and a down-regulated level of acetylcholinesterase activities. Rats intratracheally exposed to MnO_2 (23 nm diameter) till 9 weeks exhibit Mn in their brain and abnormal motility in an open-field box (Sarkozi *et al*., 2009). Moreover, it has been shown that maternal exposure of mice to TiO_2 NPs affects the expression of genes related to the development and function of the central nervous system (Shimizu *et al*., 2009). However there have been studies that failed to detect same NPs in brain even after high intravenous or subcutaneous doses (Patri *et al*., 2009).

4.1.4 *Miscellaneous Systemic Effects*

NPs are used in huge quantities in cosmetics and abilities of NPs to translocate through the skin are a topic of hot debate. It was shown that subcutaneous administration of carbon nanotubes in rats cause a biphasic response with initial granulation and inflammation and later fibrous tissue formation (Yokoyama *et al*., 2005). Moreover, it has been shown that TiO_2 NPs aggravate atopic dermatitis like lesions in mice presenting skin barrier dysfunction/through predominated Th2 immune responses (Yanagisawa *et al*., 2009).

Fullerene derivative (C60 polyalkylsulfonate) was shown to cause nephropathy and biochemical impairment after intravenous and intraperitoneal applications (Chen *et al*., 1998).

4.2 Long-Term Effect/Carcinogenicity of NPs

Carcinogenicity of engineered nanomaterials is mainly studied on lungs via inhalation or instillation exposures and scarce data exist by other exposure routes. Because of lack of adequate epidemiological data in humans, engineered nanomaterials could not be associated directly with lung cancer risks. Low toxicity, low-solubility dusts (LTSD), such as CB and TiO_2, have been proved to be carcinogenic in experimental animals but there is very limited epidemiological data about the human exposures. These considerations lead to their classification as possible human carcinogens (category 2B of carcinogenic substances) (Roller, 2009). The true mechanisms of NP-induced carcinogenicity are unknown and this could be a primary genotoxic insult or secondary genotoxic response caused by particle-induced inflammation (Schins and Knaapen, 2007).

Another important class of nanomaterials for which carcinogenicity is very important consideration is carbon nanotubes. Takagi *et al*. (2008) reported that MWCNT induces mesothelioma when administered intraperitoneally to p53 heterozygous mice (a mouse strain sensitive to asbestos) and they validated their results by using crocidolite asbestos as positive control. Similar findings were reported by others injecting MWCNT into the scrotum male rats (Sakamoto *et al*., 2009). Similarly, Poland *et al*. (2008) reported asbestos-like pathology (inflammation and granulomas) in the abdominal cavity of mice exposed to MWCNT. Furthermore, they observed that this response was length-dependent. Indeed, there have been serious concerns about the material characterization, doses and model used for the description of these effects. Furthermore, in the presence of other studies that claimed that MWCNT does not possess any carcinogenicity in a 2-year bioassay (Muller *et al*., 2009), care must be taken when interpreting the positive results about the carcinogenicity of MWCNT. Nevertheless, these studies are premier to warrant about the possible health hazard scenarios of CNT exposures.

5 MECHANISMS OF ACTION

5.1 Role of Oxidative Stress in the Cytotoxicity and Inflammatory Responses Induced by Engineered Nanoparticles

An increasing number of papers links the cytotoxicity induced by engineered NPs to the oxidative stress. This stress leads to a cascade of cellular

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat246
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

events and the induction of redox sensitive pathways in the cells. The consequences could be the pro-inflammatory response, the modification of cell cycle and proliferation and, at last, the cell death by apoptosis or necrosis. Oxidative stress paradigm is sustained by many recent reviews on the mechanisms of action of NPs and their comparison with atmospheric fine and ultrafine particles (Hoet, Nemmar and Nemery, 2004; Nel *et al*., 2006; Oberdörster, Oberdörster and Oberdörster, 2005; Xia *et al*., 2006). Oxidative stress is defined to be the consequence of an imbalance between the production of ROS and the antioxidant capacities in the cell that lead to a biological adaptation or adverse effects in relation to the level of oxidative stress. The hierarchical oxidative stress model published by Nel *et al*. (2006) and Xia *et al*. (2006) to explain the biological effect of ambient and manufactured NPs proposes that "minor levels of oxidative stress induce protective effects that may yield to more damaging effects at higher levels of oxidative stress." The adverse effects could be directly induced on the target tissues from the ROS produced by the NPs or indirectly from the inflammatory process associated to NP biological effects. Indeed, the oxidative stress that activates redox-sensitive transcription factors, such as NFκB, AP1 or Nrf2, induces the transcription of a number of pro-inflammatory genes and the increased release of numerous pro-inflammatory factors, such as cytokines.

Initially, the role of oxidative stress in the mechanisms of toxicity of particles was pointed out in the occupational exposures to CB particles, glass fibers, quartz particles and asbestos fibers (Castranova *et al*., 1997; Gilmour, 1995). More recently, it was also demonstrated that DEP as well as atmospheric particles were able to induce an oxidative stress in the lung caused by their chemical compounds and especially metals and organic compounds (Ayres *et al*., 2008). The oxidative power of PM and their ability to produce free radicals are strongly linked to their composition that depends on the sources. When the PM contains a large amount of metals and especially transition metals, such as iron or vanadium, they produce ROS either in the biological fluids in the airways or inside the target cells after phagocytosis. We have also demonstrated in our laboratory that the organic compounds, especially the polycyclic aromatic hydrocarbons, and quinones associated with the $PM_{2.5}$ and PM_1 from traffic or industrial pollution could be associated to an increase of ROS in bronchial cells (Baulig *et al*., 2003; Bonvallot *et al*., 2001) and subsequently the activation of NFκB leading to the transcription of cytokines, such as GM-CSF, interleukin (IL) 6 and IL8, tumor necrosis factor α (TNFα). Interestingly, it also appears that these $PM_{2.5}$ and PM_1 could increase the expression and release of growth factors that are ligands of the epidermal growth factor receptor (EGFR), such as amphiregulin (AR) and this up-regulation is also associated to oxidative stress (Blanchet *et al*., 2004; Rumelhard *et al*., 2007b).

The central role of the transcription factor NFκB is pointed out in numerous *in vitro* studies on the effects of fibers, such as asbestos, PM and NPs (Albrecht, Borm and Unfried, 2004). This cytoplasmic factor constitutes of two sub-units, p50 and p65, associated to an inhibitory protein, IκB. The activation of NFκB occurs when IκB is removed and degraded in the cytoplasm by the proteasome. It induces the migration of NFκB to the nucleus that links a lot of genes promoters, such as cytokine genes (Figure 3). In such mechanisms, ROS produced by the NPs play the role of initiator of the inflammatory response but also, indirectly, the role of amplifier by autocrine or paracrine effects on the target cells. For example, TNFα, the secretion of which is increased by NPs, such as CB NPs on macrophages, could link membrane receptors and

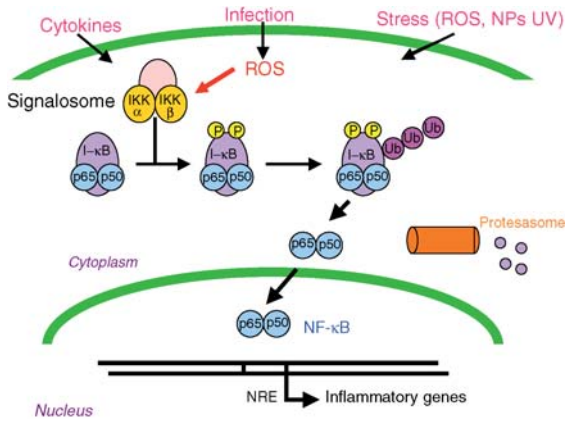

Figure 3. NF-κB activation: different stimuli, such as ROS lead to IκB kinase activation in the signalosome that phosphorylate IκB allowing its ubiquitinylation and subsequent degradation by the proteasome. Consequently, p50 and p65 sub-units of NF-κB can translocate to the nucleus and bind to specific responsive element (NRE, NF-κB-responsive element) to transactivate a great variety of genes such as those involved in the production of cytokines and chemokines.

activate a signaling pathway leading to the release of superoxide-free radical from mitochondria (Brown *et al*., 2004).

The roles of the size of NPs and of their surface reactivity in the ability to induce an oxidative stress were pointed out by several recent studies (Warheit *et al*., 2007b; Xia *et al*., 2006). In our laboratory, the role of physico-chemical characteristics in toxic effects of CB and TiO_2 NPs of different sizes, were evaluated in human bronchial epithelial cell line (16HBE) that represents one of the first line targets encountered by NPs (Hussain *et al*., 2009). Both CB and TiO_2 were taken up in a time- and dose-dependent manner as evaluated and quantified by flow cytometry and transmission electron microscopy analysis. The smallest NPs have higher cytotoxic potentials and induce apoptosis. Exposure to TiO_2 NPs at non-toxic concentrations leads to a stronger pro-inflammatory response characterized by GM-CSF release correlated to the induction of mRNA expression as compared with CB. This GM-CSF induction is higher for TiO_2 and the smallest particles have a greater inflammatory potential. Furthermore, NPs produce ROS under abiotic and/or intracellular conditions depending on their chemical composition and size. The cytotoxic and inflammatory effects of NPs are caused by the oxidative stress produced as use of the antioxidant catalase ameliorated the response (Hussain *et al*., 2009). These results sustain the hypothesis that the surface reactivity of the NPs that increases when the size decreases, in relation with their ability to produce ROS and to associated toxic compounds is an essential factor in their cytotoxic effects (Donaldson *et al*., 2001; Salvi and Holgate, 1999). Park *et al*. (2008) compared CeO_2 and TiO_2 NPs, for their cytotoxic potential with larger particles of same chemical composition and demonstrated a stronger capacity to induce an oxidative stress, to activate apoptotic pathway and to induce a DNA fragmentation leading to apoptosis.

Another important question is to determine whether the effects of NPs depend on the target cells. The skin cells are an important target of NPs, such as TiO_2, ZnO and silver NPs that are largely used in cosmetic industry and consumer health products. Until now, it was not demonstrated a toxicity of TiO_2 and ZnO NPs on healthy skin. However, silver NPs that are used in a lot of cosmetic products and also for the antibacterial treatment of clothes, are cytotoxic on several epidermal cell lines such as HT 1080 and A431. They induce an increase in ROS, lipid peroxidation, and an apoptotic cell death (Arora *et al*., 2008).

Another important target is the lung for inhaled NPs. The cytotoxicity of different kind of engineered NPs (TiO_2, CB, ZnO, CeO_2, etc.) was demonstrated on different cell lines: bronchial human cell lines such as BEAS 2B, 16HBE (Hussain *et al*., 2009; Park *et al*., 2008), macrophages and the alveolar cell line A549 (Hsin *et al*., 2008; Koike and Kobayashi, 2006). As it is likely that the NPs could, even to a low amount, go through the biological barriers, they can target other organs, such as liver, kidney, and brain. The cytotoxicity of engineered NPs was studied on liver cell lines (Hussain *et al*., 2005), renal cell line LLC-PK1 (L'azou *et al*., 2008), and neuronal cell line (Hussain *et al*., 2006). It appears from all these data that, if the cytotoxicity is generally associated to oxidative stress, the sensitivity differs with the cell line, perhaps in relation with the uptake of NPs.

5.2 Nanoparticles and Cellular Signaling Pathways in the Mechanisms Associated to Apoptosis and Inflammatory Responses

The MAP kinases signaling cascades (ERK 1/2, p38, and JNK) have been shown to be involved in the response to different ultra-fine or NPs, such as DEP, TiO_2 as well as amorphous silica (SiO_2) (Kim *et al*., 2009). It could lead to the pro-inflammatory response that generally increases when the size of the NPs decreases (Hussain *et al*., 2009).

There are some evidences that particles may trigger signaling cascade by activating membrane receptors (Figure 4). The role of EGFR and its ligands were underlined in several studies. For instance, bronchial epithelial cells respond to DEP or $PM_{2.5}$ exposure by the over-expression of ligands of EGFR, such as AR and transforming growth factor beta (TGFβ) (Auger *et al*., 2006; Blanchet *et al*., 2004; Rumelhard *et al*., 2007a, 2007b). Particles trigger the activation of EGFR and ERK and JNK MAP kinase pathways leading to EGFR ligands release. The AR release being inhibited by the anti-oxidant *N*-acetyl cysteine but not by a neutralizing anti-EGFR preventing ligands binding to EGFR suggests that a trans-activation of EGFR was triggered by ROS. Moreover, these studies have

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat246
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

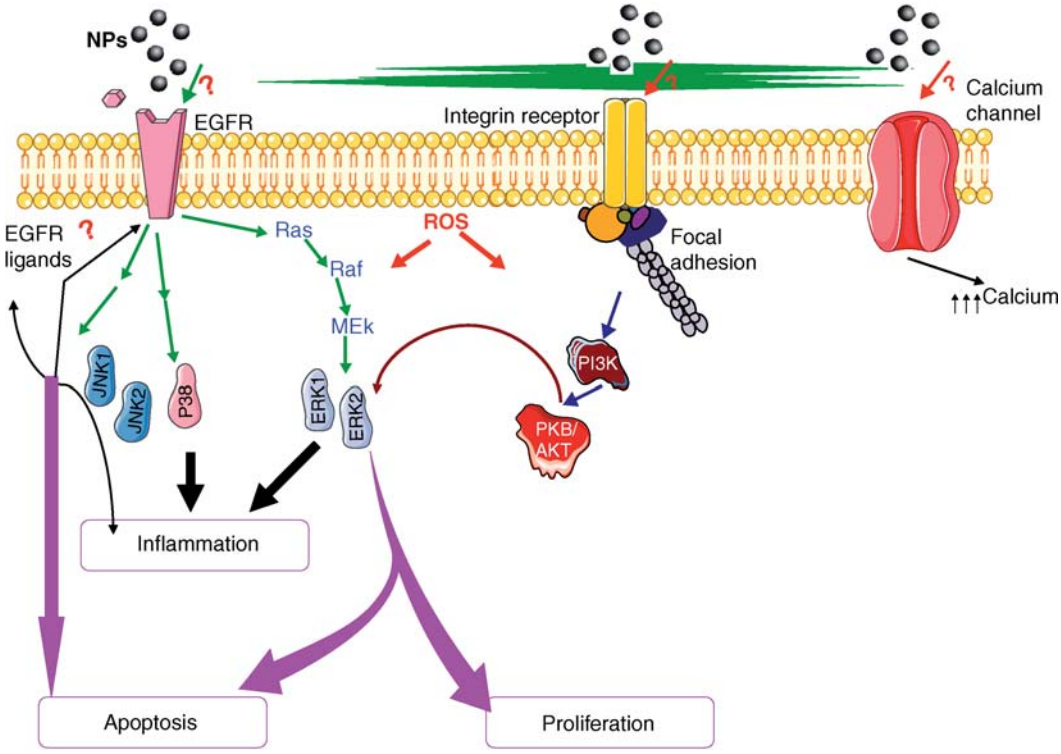

Figure 4. NP trigger signaling pathways by interaction with membrane receptors leading to different cellular outcomes. NP-induced activation of EGF receptor can lead to apoptosis, inflammation or proliferation. In addition activation of integrin receptor and ROS also contribute in proliferation signaling induced by NPs. The role of EGFR ligands such as AR needs to be elaborated.

shown that the particles-induced AR and TGFβ release by bronchial epithelial cells contribute to the release of pro-inflammatory mediators, especially GM-CSF suggesting an autocrine role for EGFR ligands in eliciting and sustaining the proinflammatory response (Rumelhard *et al*., 2007b). These new findings provide additional and valuable information on inflammation following chronic exposure to particles that could contribute to exacerbation of airway remodeling in respiratory-compromised individuals; however, as far as now, it is not demonstrated for engineered NPs.

Other studies have also underlined the role of the EGFR in the mechanism of action of CB NPs. These NPs induce apoptosis and proliferation in rat lung epithelial cells via independent specific signaling pathways but both depending on the activation of EGFR (Sydlik *et al*., 2006). Although the proliferation induced by NPs is solely dependent on the β1 integrins and ERK 1/2 activations, the induction of apoptosis was correlated to c-Jun kinases phosphorylation (Figure 4).

NPs also have the ability to modulate intracellular calcium. Indeed, Möller *et al*. (2005) showed that CB NPs trigger a transient increase of intracellular calcium responsible for impaired phagosome transport and cytoskeletal dysfunctions. This transient increase of Ca^{2+} was not associated with the production of ROS because antioxidants were inefficient in reducing the effects (Möller *et al*., 2005). They postulate that CB NPs could have a direct effect on ion channels that control the calcium homeostasis in the cell.

Altogether these data highlight that transmembrane receptors are implicated in NP-induced cell signaling and could lead to specific biological responses to NPs. However, a thorough understanding of the involved mechanisms is necessary as well as to determine whether they are or not specific to some types of NPs.

NPs are able to induce apoptosis in a variety of *in vitro* systems. (Pan *et al*., 2007, 2009; Sydlik *et al*., 2006; Vamanu *et al*., 2008) This induction of apoptosis triggered by NPs might be implicated in

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat246

different pathologies but, as far as now, it is not demonstrated in humans. NPs might exert apoptotic effects through differential signaling events involving death receptor, mitochondria or lysosomes. However, the signaling pathways and the initial events triggered by NP to induce the executive phase of apoptosis seem to be NP specific and need to be clarified by further researches.

5.3 Genotoxicity of Nanoparticles

Nanogenotoxicology is one of the key areas of research that needs more attention from the people working on the nanomaterials toxicity. Different types of nanomaterials capable of inducing genotoxic responses include CNTs (both SWCNT and MWCNT) (Cui *et al*., 2005; Kisin *et al*., 2007; Monteiro-Riviere *et al*., 2005; Muller *et al*., 2008; Pacurari *et al*., 2008; Zhu *et al*., 2007), TiO_2 NPs (both with and without photoactivation) (Dunford *et al*., 1997; Geiser *et al*., 2005; Kang *et al*., 2008; Rahman *et al*., 2002; Trouiller *et al*., 2009;Wang, Sanderson and Wang, 2007a; Xu *et al*., 2009), aluminium oxide (di virgilio 09), platinum NPs (Asharani *et al*., 2010) and zinc oxide NPs (Dufour *et al*., 2006). Quantum dots have shown DNA-damaging effects both under abiotic conditions and under biotic conditions (Choi *et al*., 2008; Green and Howman, 2005). Although it has been shown that silica NPs induce intranuclear protein aggregation and interfere with cell division, a controversy exists in literature about the genotoxic potentials of silica NPs (Barnes *et al*., 2008; Chen and von, 2005; Wang, Sanderson and Wang, 2007b). Drastic variations in compositions and physico-chemical characteristics of nanomaterials can result in variable genotoxic potentials. It has been proposed that nanomaterials can cause primary as well as secondary genotoxic insult (Schins and Knaapen, 2007). Primary genotoxic response occurs when particles gain entry into the cell nucleus and come in direct contact with the nuclear material and cause damage either by physical interaction with DNA or mitotic spindle or through some indirect mechanisms and essentially these responses occur without any inflammation. Whereas secondary genotoxic response occurs when NP-induced inflammation and oxidative/nitrosative stress causes the DNA damage (e.g., as shown for TiO_2 NPs) (Trouiller *et al*., 2009). This type of DNA damage mostly comprises single- or double-stranded breaks in DNA or by the formation of adducts (e.g., 8-hydroxydeoxy-guanosine adducts). Secondary genotoxic responses are mostly seen in case of LTSD, such as CB and TiO_2 when the exposure doses cause overload in the lungs. Production of ROS occurs either as an intrinsic ability of NPs or through their interaction with cellular components (Hussain *et al*., 2009). An excellent review on the genotoxic potentials of NPs has recently been published by Singh *et al*. (2009). The presence of controversies about the genotoxic potentials emphasizes the need of evaluation of genotoxic potentials by a standardized battery of tests.

6 CONCLUSIONS

Because of the increased unintentional potential exposure to NPs and their specific properties compared with their micro-sized counterparts, the human health effects of NPs have to be carefully considered. There are some experimental evidences that whatever the route of exposure, NPs can enter the blood circulation, reach secondary organ allowing both local and systemic effects. The diversity and complexity of NP characteristics involved in their biological effects makes nanotoxicology a very challenging field. Several parameters could influence to different degrees the final biological response to NPs and it is thus difficult to predict the human health hazard of exposure. It is evident that thorough physico-chemical characterization of the tested nanomaterial prior to *in vitro* or *in vivo* biological evaluation is needed to allow the comparison of data and to draw general or specific conclusions on toxicity of nanomaterials for public health risk assessments. Progress in nanotoxicology will allow to identify the determinants of particle toxicity and to better understand NPs mechanism of action through cellular and molecular interactions. Oxidative stress is one of the already identified mechanisms of NPs toxicity that explains most cellular effects but insufficient for diseases prediction (Donaldson *et al*., 2009).

1 INTRODUCTION

Nanotechnology is the manipulation of matter for use in particular applications through certain chemical or physical processes to create materials with specific properties. Nanotechnology can be applicable to many fields of sciences including Chemistry, Physica, Biology and Medicine. The Internal Standard Organization (ISO) and the Organization for Economic Cooperation and Development (OECD) have defined nanomaterials as having a size ranging between 1 and 100 nm. Nanomaterials include nanoparticles, nanofibers, nanotubes, composite materials and nano-structured surfaces (US Environmental Protection Agency, 2007). Nanotechnology now holds immense societal and environmental benefits with regard to increased economic development, improved materials using less resources and environmental remediation (Roco and Bainbridge, 2005). Commercial applications of nanomaterials have increased since 1990 and include textiles, antimicrobial wound dressings, paints and coatings, fuel catalysts and additives, lubricants, cosmetics and food packaging (Figure 1) (Chaundry *et al.*, 2006).

Although nanomaterials have many prominent advantages compared with classical chemicals/physical agents, there are probably unknown hazards. In addition, the hazards of nanomaterials may be somewhat different. Therefore, new toxicological testing approaches that include traditional testing methods are essential in order to evaluate the hazards of nanomaterials. Generally, nanomaterials can be divided into three types. The first type is unintentionally generated nanomaterials such as diesel soot nanomaterials and welding fumes. The behaviour of airborne particles in the environment differs according to size: nanoparticles smaller than 80 nm in diameter tend to agglomerate rapidly to form larger particles, whereas particles sized from 80 to 2000 nm remain suspended in the air for a long time with a greater chance of being inhaled (Preining, 1998). The second type is industrial nanomaterials that are used to improve the quality of

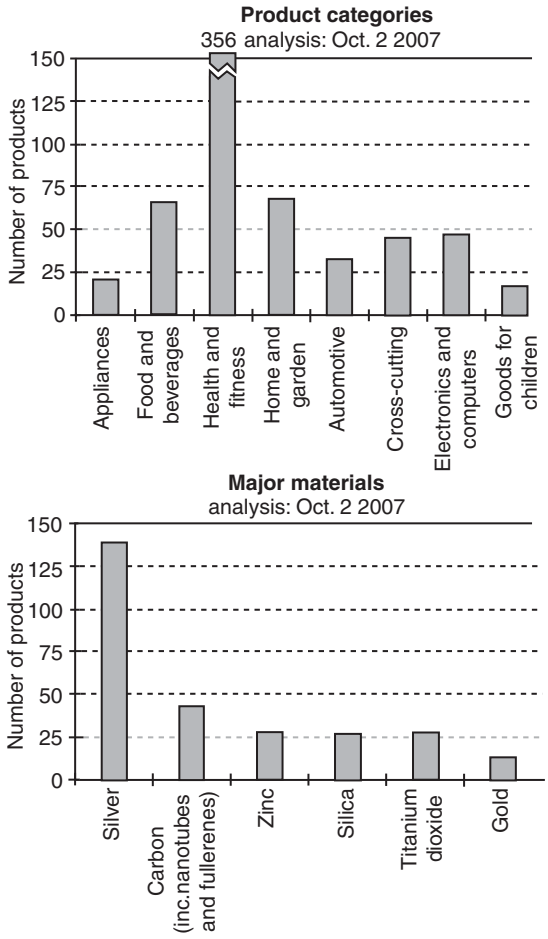

Figure 1. Top chart shows the distribution of 580 products in the inventory according to product category. The products fall into several different categories such as health and fitness, home and garden, electronics and computers, and so on. Bottom chart shows the materials used in the various products in the inventory. The main kinds of materials used are graphite (including carbon nanotubes and fullerenes), silver, silica, TiO_2 and ZnO. Reproduced from Hansen *et al.*, (2008) © Springer).

paints, fuel cells, displays, batteries, fuel additives, catalysts, lubricants, etc. The representative industrial nanomaterials are carbon nanotubes, carbon black, titanium dioxide (TiO_2), cerium dioxide, zinc oxide, copper oxide and nickel oxide (Thomas *et al.*, 2006). The third type is nanomaterials for biomedical applications. Nanomaterials for biomedical applications can be divided into three main uses: (i) diagnosis, (ii) imaging and (iii) therapy. Diagnosis with nanomaterials increases sensitivity and specificity due to their unique properties (Salata, 2004). Through multifunctional application of nanomaterials, these three areas can be applied to one nanomaterial.

Because of the wide spectrum of nanomaterial usage, exposure to nanomaterials, whether intentional or unintentional, may occur via various routes including inhalation, ingestion, skin contact and other parenteral exposure. The safety or potential hazards are also assumed to be different for the same materials on larger scales with respect to the diversity in size, composition and surface properties of nanoscale materials. Conservative methods for the toxicological assessment of each nanomaterial may consume lots of time, laboratory animals, materials and expenditures because of the diversity of structures and compositions and the lack of familiarity with these nanomaterials.

Systems Biology in Toxicology can open a new realm for risk assessment by providing immense but accurate toxicological information while saving laboratory animals and expenditure. Target organs and the modes of action of nanomaterials have begun to be elucidated through systemic toxicological approaches, which provide a general view of the safety, the potential risk on public health and options for risk management of nanomaterials (Walker and Bucher, 2009).

2 MAIN CONSIDERATION OF TOXICITY STUDY

Figure 2 shows the general toxicity mechanisms of nanomaterials. Nanomaterials can release transition metals and ions through several mechanisms including sonication and interaction with biological fluids (McNeilly *et al.*, 2004; Horie *et al.*, 2009). The potential hazardous effects of nanomaterials on human health were evaluated as rather speculative and unfinished. However, increasing numbers of laboratory studies have indicated that exposure to some kinds of nanoparticles can have adverse effects on the lungs and the brain in laboratory animals (Lam *et al.*, 2004; Oberdorster, 2004).

Nanomaterials and their derivatives may generate free radicals (Lu *et al.*, 2009). Nanomaterials can enter cells by simple diffusion or endocytosis. The toxicity induced by nanomaterials can be categorized as direct or indirect damage. The direct damages, including inflammation and DNA

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

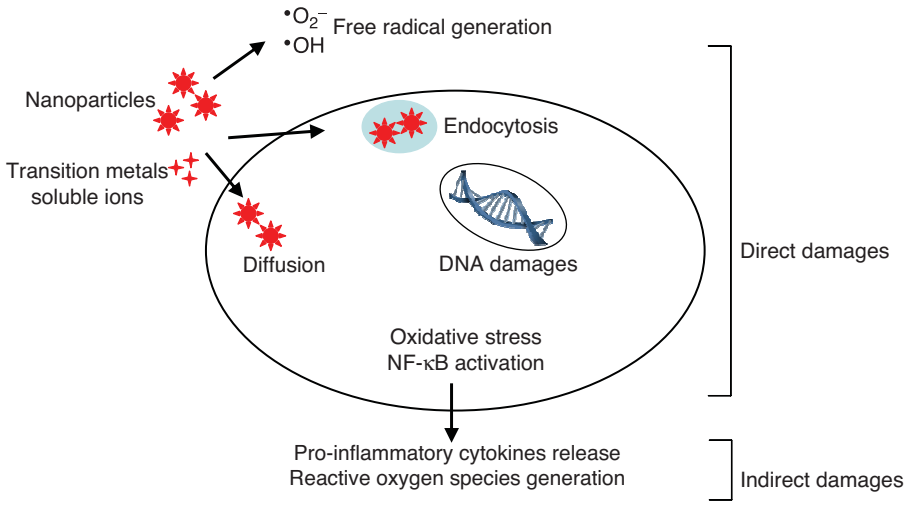

Figure 2. Overview of general mechanisms of nanomaterial toxicity. Toxicity of nanomaterials is divided into direct damage and indirect damage induced by inflammation, oxidative stress and DNA damage.

damage, are induced by reactive oxygen species (ROS) generation, entry into the cells, nuclear factor kappa-B activation and pro-inflammatory mediators. The indirect damage is a secondary reaction induced by released pro-inflammatory cytokines and ROS (Lu *et al.*, 2009).

The unique physicochemical properties of nanomaterials include their small size, purity, crystallinity, electronic properties, surface reactivity, inorganic or organic coatings, solubility, shape and aggregation (Nel *et al.*, 2006). Nanomaterials have completely different toxicity compared with larger particles of the same composition. As particle size decreases, nanoscale materials can cross or penetrate cell membranes that are impenetrable to larger materials (Kim *et al.*, 2006). In addition, nanomaterials can disrupt normal biological functions, including DNA and protein absorption (Horie *et al.*, 2009; Ahamed *et al.*, 2008). As particle size decreases, the surface area increases by geometric progression (Oberdorster,Oberdorster and Oberdorster, 2005). Therefore, nanomaterials have a much greater surface area per unit mass compared with larger materials. The increased surface area contributes to increases in reactivity such as catalytic activity for chemical reactions and the exponentially increased surface molecules. Also, the toxicities vary according to the structures of the nanomaterials. Hansen *et al*. (2007) suggested a new method to categorize nanomaterials into three relevant groups depending on the nanoscale structure in the system: materials that are nanostructured in the bulk, materials that have nanostructure on the surface and materials that contain nanostructured particles. Nanostructured particles are further subcategorized into particles that are surface bound, suspended in liquids or in solids, and airborne. According to these divisions, 19% of nanomaterial products were nanoparticles bound to surfaces, 37% were nanoparticles suspended in liquids whereas 13% used nanoparticles suspended in solids; 1% were powders containing free, potentially airborne, nanoparticles, whereas the rest of the products were not located (Hansen *et al.*, 2008). Toxicological assessment is required separately, after considering particle size and the structure for the applications.

2.1 Size of Nanomaterials

In the industrial workplace, many kinds of nanomaterials are generated including welding fumes, carbon nanotubes and TiO_2. Aerosolization and inhalation of nanomaterials may induce adverse respiratory effects. When nanomaterials enter the lung, they are deposited, internalized and translocated to the systemic circulation depending on size, surface area, surface chemistry, and so on. (Oberdorster, Oberdorster and Oberdorster, 2005). The deposition mechanisms of particles in the lung include inertial impaction, gravitational sedimentation and Brownian diffusion (Yang, Peters and

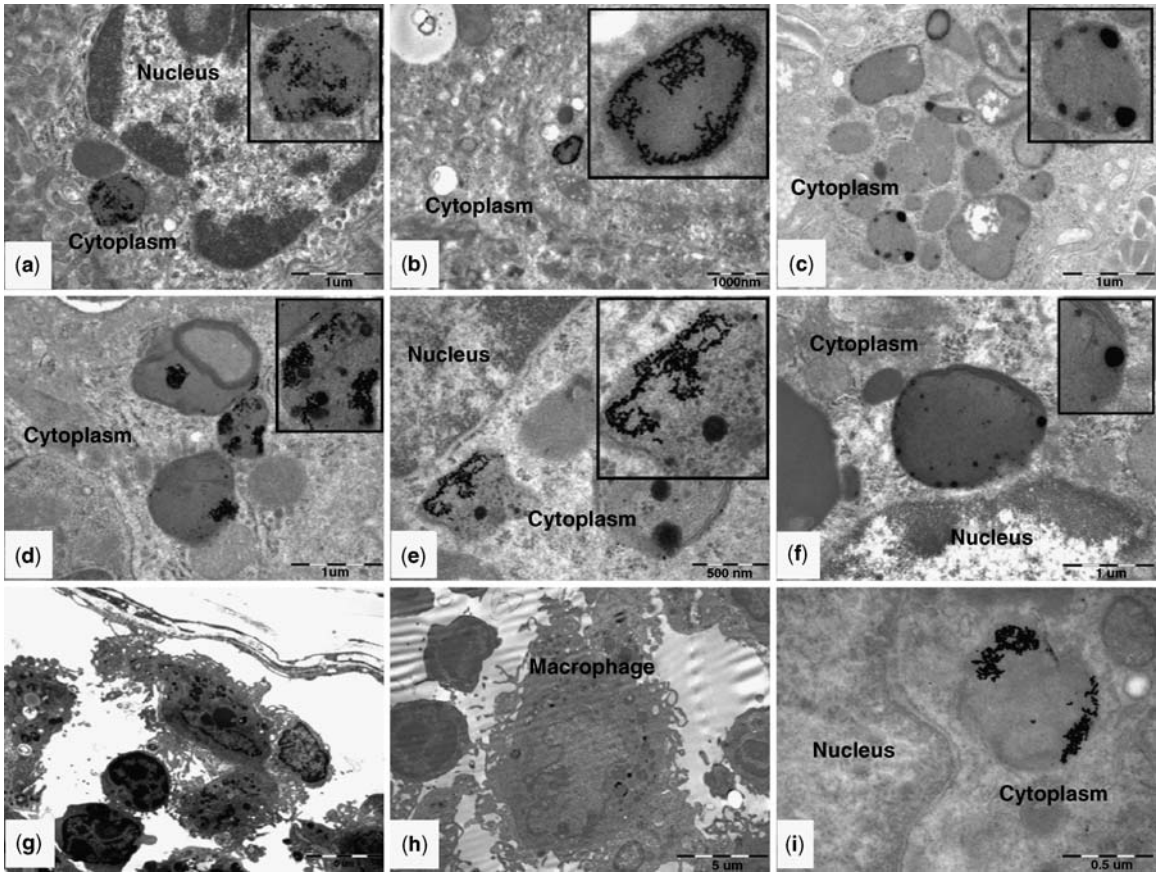

Figure 3. Thin-section TEM images of mouse liver, spleen and lymph node tissues at 7 days after intravenous injection of 4-, 13-, and 100-nm PEG-coated AuNPs. The micrographs show entrapped PEG-coated AuNPs, and their clustering and localization in lysosomes. Kupffer cells at 7 days after injection of (a) 4-nm, (b) 13-nm or (c) 100-nm PEG-coated AuNPs. Spleen macrophages at 7 days after injection of (d) 4-nm, (e) 13-nm or (f) 100-nm PEG-coated AuNPs. (g–i) Macrophages of lymph node at 7 days after 4-nm PEG-coated AuNPs treatment. (g) and (h) clearly show that the particle-engulfing cells are macrophages.

Williams, 2008). Among them, Brownian diffusion is the main mechanism for nanomaterial deposition (Oberdorster, Oberdorster and Oberdorster, 2005). Briefly, particles between 1 and 3 μm in size are the most effectively deposited in the alveolar region. In addition, about 80% of particles less than 1 μm can be exhaled without deposition after inhalation as a result of their low inertia (Patton, 2005).

Nanomaterials have longer retention times and are more translocated than larger particles of the same composition. According to a study of inhalation of ultrafine (∼20 nm) and fine (∼200 nm) TiO_2 nanoparticles, ultrafine particles were cleared more slowly and were more translocated than fine particles (Oberdorster, Ferin and Lehnert, 1994). Intravenous injection of three different sizes of polyethylene glycol (PEG)-coated gold nanoparticles (GNP; 4, 13 and 100 nm) revealed that, as particle size decreased, more nanoparticles were engulfed by macrophages (Figure 3). When three different sizes of rhodamine B isothiocyanate (RITC)-conjugated silica nanoparticles (50, 100 and 200 nm) were injected, tissue distribution and elimination patterns showed size-dependent trends. In the kidney, the fluorescence intensity of all three sizes of silica nanoparticles was strongest throughout the organ at 24 h after administration. Particles were shown in macrophages of the liver and spleen within 24 h. In spleen and liver, residual 200-nm particles were observed more frequently than 50- and 100-nm particles. There were no particles observed

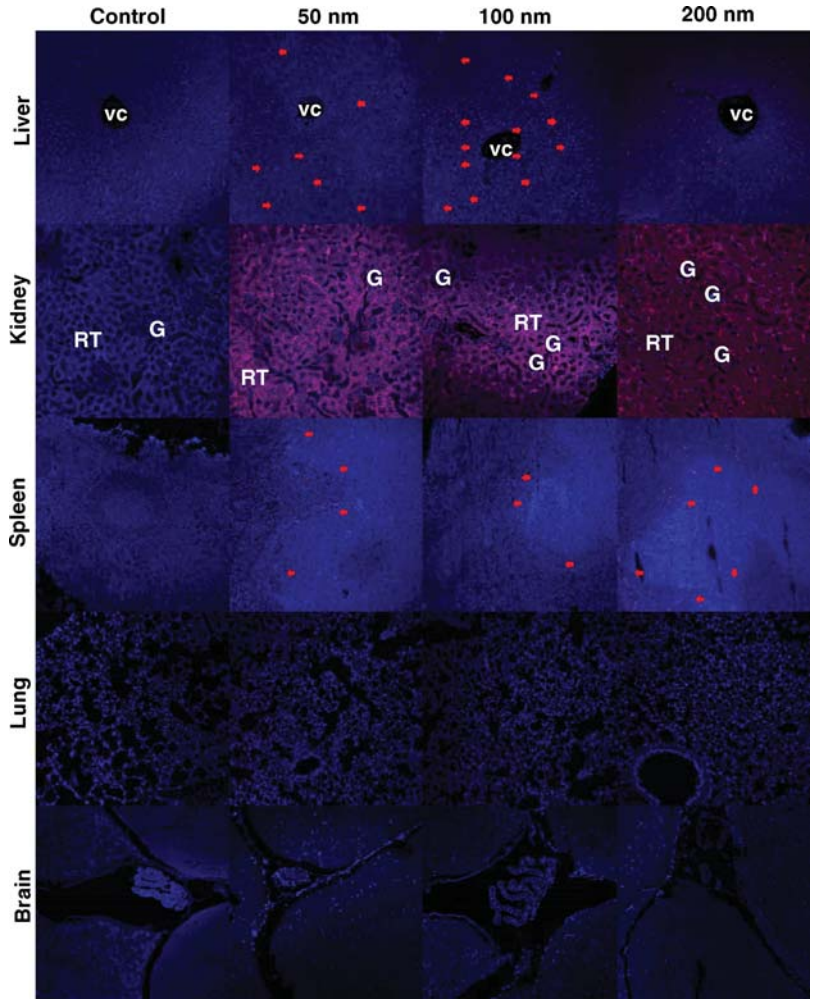

Figure 4. Tissue distribution of silica nanoparticles in various organs of mice at 24 h. Labels on the left side of the images indicate organs. Particle size is indicated above the top horizontal row. Red arrows in the liver and spleen indicate aggregated silica nanoparticles. VC, vein centre in the liver; G, renal glomerulus; RT, renal tubule.

in the brain or lung (Figure 4). All three silica particle sizes remained in the liver and spleen until 4 weeks after a single injection (Figure 5). In addition, all silica particles were eliminated via both urine and bile and the quantity of 50-nm silica nanoparticles in urine and bile was higher than that of 100- or 200-nm particles (Figure 6) (Cho *et al.*, 2009).

2.2 Biologically Effective Dose

The biologically effective dose (BED) is a key concept in understanding the hazards and mechanisms of toxicity of nanomaterials. The traditional mass dose does not reflect the BED of nanomaterials (Table 1). Rather, the BED is a fraction of the total mass dose, and may not necessarily be a mass in the case of particles but could instead be surface area or surface reactivity. When ultrafine (20 nm) and fine (250 nm) TiO_2 particles were instilled intratracheally into rodents, much greater pulmonary-inflammatory neutrophil response was induced by ultrafine TiO_2 than by fine particles when comparing the mass dose, but the response for both ultrafine and fine particles was the same when comparing the particle surface area (Oberdorster, 2000).

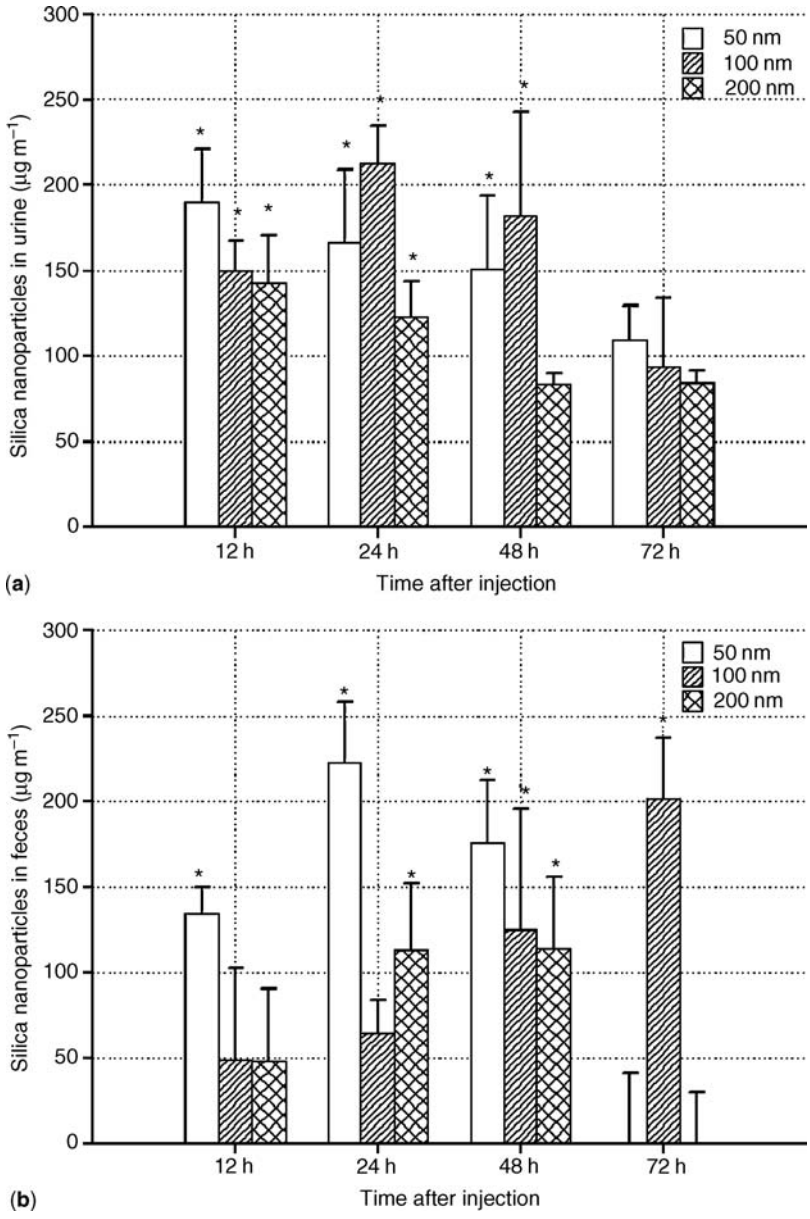

Figure 6. Silica nanoparticle concentration in urine and feces. Silica particles were detected in urine (a) and feces (b). *Significant difference ($P < 0.05$) compared with vehicle control.

To obtain the BED, knowledge about the physico-chemical properties of and the cellular and molecular events involving nanomaterials (including sub-fraction or their variants) is essential. Generally, the BED relates to the ability of nanomaterials to generate free radicals and produce ROS in target cells (Lu *et al.*, 2009; Nel *et al.*, 2006). In addition, inflammation is a key response for the BED of nanomaterials (Oberdorster,Oberdorster and Oberdorster, 2005). The BED is different for each nanomaterial. Therefore, categorization of BED will be very helpful in understanding the biological effects and evaluating the risks of nanomaterials.

2.3 Surface Chemistry and Interactions With Biological Membrane

Nanomaterials tend to naturally aggregate due to increased specific surface/volume ratios or electrostatic interactions. Therefore, nanomaterials for biomedical application are often coated with non-toxic and stable materials to prevent aggregation and toxicity. In addition, surface modification can make nanomaterials soluble for specific applications. Surface chemistry is also a very important factor in the toxicity of nanomaterials. Indeed, toxic nanomaterials can be changed into non-toxic ones through simple surface modification. Silica, polymer and proteins are used most often as coating materials. Intraperitoneal injection of silica-coated magnetic nanomaterials resulted in distribution to various organs without apparent toxicity and penetration of the blood–brain barrier and without disturbing its function (Kim *et al.*, 2006). Polymers can be divided into synthetic and natural polymers. The representative synthetic polymers are polyethylene glycol, polyvinylpyrrolidone (PVP) and polyvinyl alcohol (PVA). Natural polymers include dextran, chitosan and gelatine. Polymer coating technology enables nanomaterials to be well dispersed in aqueous solution and also allows biocompatibility with low toxicity (Gupta and Gupta, 2005). Proteins are also widely used as coating materials for biocompatibility and specific/selective targeting. Albumin protein, which is a major serum protein, makes nanomaterials disperse well in aqueous solution and can bind to various lipophilic compounds effectively (Baker, 1998). In addition, TAT-peptide is used as a coating material to increase membrane permeability (Lewin *et al.*, 2000). GNP conjugated with TAT-peptide can penetrate even the nuclear membrane with high efficacy (Berry *et al.*, 2007; de la Fuente and Berry, 2005). Folic acid is also widely used as a coating material for nanoparticles. Conjugation of folic acid allows nanomaterials to target cancer cells specifically with less immune response (Zhang, Kohler and Zhang, 2002). PEG-coated 13-nm GNP accumulated in the liver and spleen with a long blood half-life after intravenous injection (Figure 7).

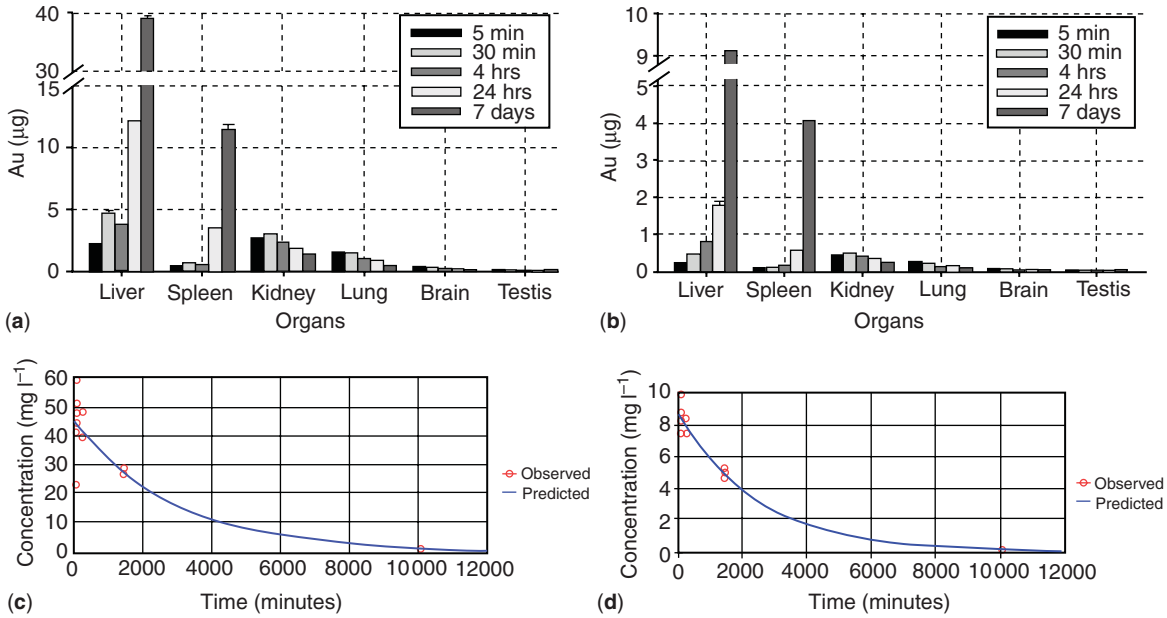

Figure 7. Tissue distribution and pharmacokinetic analysis of PEG-coated AuNPs in major organs at several different times. Tissue distributions of PEG-coated AuNPs were measured by inductively coupled plasma-mass spectrometry (ICP-MS). Mice in the (a) 4.26 mg/kg and (b) 0.85 mg/kg groups showed similar distribution and excretion patterns of PEG-coated AuNPs ($n = 3$ per group). Each group contained three animals and results are shown as mean values with SDs. Predicted and observed plasma concentration-time profiles of PEG-coated AuNPs after a single intravenous administration of PEG-coated AuNPs at (c) 4.26 mg/kg and (d) 0.85 mg/kg ($n = 3$ per group).

Surface charge also influences the toxicity of nanomaterials. The surface charge of nanomaterials can depend on the nature of the nanomaterials and the dispersion media. The charge of nanomaterials can influence host responses (e.g., phagocytosis, inflammation and genotoxicity) and kinetics (e.g., absorption, distribution and elimination) *in vivo* and *in vitro*. For example, carboxyl-terminated quantum dots are more toxic than amine-terminated quantum dots, possibly due to platelet aggregation and vascular thrombosis (Geys *et al.*, 2008). Carboxyl-terminated quantum dots also have a shorter blood half-life than amine-terminated quantum dots (Geys *et al.*, 2008). In addition, carboxyl-terminated quantum dots are more easily taken up by macrophages with little impact on cell viability compared with amine-terminated and pegylated quantum dots (Clift *et al.*, 2008). However, little is known about the impact of surface charge of nanomaterials; thus, further extensive studies are needed.

2.4 Dispersion Media

Nanomaterials can aggregate in both solution and powder form. Industrial nanomaterials (e.g., zinc oxide, TiO_2 and cerium oxide) and environmental nanomaterials (e.g., diesel soot nanoparticles and carbon black) especially tend to aggregate. Aggregated nanomaterials differ from well-dispersed nanomaterials in their size, surface charge, and so on. (Bihari *et al.*, 2008). In addition, aggregated micro-sized particles have been shown to exert different *in vivo* and *in vitro* toxicity compared with well-dispersed nanomaterials (Buford, Hamilton RF and Holian, 2007; Foucaud *et al.*, 2007). Therefore, toxicity data from these aggregated particles are not appropriate and cannot represent the real toxic effects of nanomaterials. Well-dispersed single-walled carbon nanotubes are more prone to enter the alveolar walls and to be fibrogenic without granuloma formation compared with aggregated nanotubes (Mercer *et al.*, 2008). In addition, well-dispersed carbon nanotubes are less cytotoxic than aggregated nanotubes (Wick *et al.*, 2007). Generally, nanomaterials are sensitive to extreme pH conditions and physiological salt concentration. To generate well-dispersed nanomaterials in physiological solution, several dispersion stabilizers, such as pulmonary surfactant, Tween, bronchoalveolar lavage (BAL) fluid, dipalmitoyl phosphatidyl choline (DPPC), albumin or serum, have been suggested (Bihari *et al.*, 2008; Foucaud *et al.*, 2007; Murdock *et al.*, 2008).

3 SYSTEMS TOXICOLOGICAL APPROACH FOR RISK ASSESSMENT OF NANOMATERIALS

Systems biology is a new area of integrative study of biological systems at the molecular level. The comprehensive qualitative and quantitative data of mRNA, protein or other molecular components of the system coupled with a mathematical approach are the driving forces of systems biology (Edwards and Preston, 2008). Systems toxicology requires integrative data through toxico-genomics, toxico-proteomics and relative bioinformatics to analyse and predict the toxic effects of chemicals in biochemical processes (Figure 8)

Although the potential commercial application of nanomaterials is highly expected, concerns have been raised due to the uncertainty of toxicological interactions with living organisms including humans. The unique and various characteristics of nanomaterials in size, surface properties and surface area require a new and/or different approach beyond traditional methodology for evaluating the

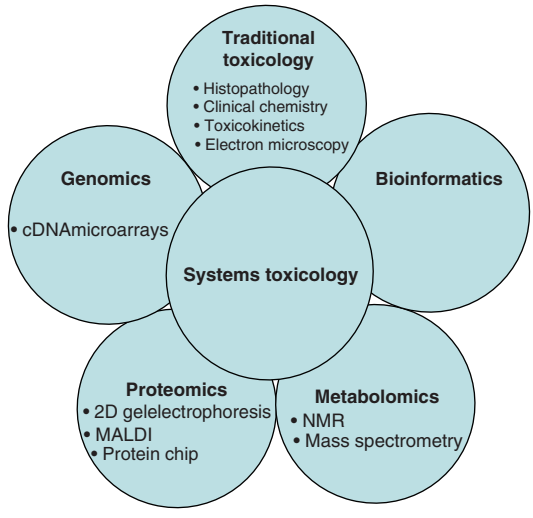

Figure 8. A scheme for systems toxicology. "Omics"technologies including genomics, proteomics and metabolomics, and bioinformatics and traditional toxicologies will lead to better understanding of systems toxicology.

hazardous effects of nanomaterials on human health (Walker and Bucher, 2009). The conventional approach takes a long time for one-by-one toxicity testing on each nanomaterial and would probably hamper our enjoying the benefits of nanomaterials. Potential exposure routes for nanomaterials are gastrointestinal tract (GIT), skin, lung and vasculature. The nanomaterials have the ability to distribute throughout the body via interactions with cells, body fluids and proteins. Because of the systemic distribution of nanomaterials in the body, it is important to assess systemic responses. High-throughput results from toxico-genomics, toxico-proteomics and toxico-metabolomics would provide systemic and integrative information on the biological effects of nanomaterials, which should lead to efficient methods for risk assessment.

3.1 Toxicogenomics of Nanomaterials

Toxicogenomics is the study of the genome involvement in response to toxic substances and includes transcriptomics, proteomics and metabolomics. The major factors that determine the utility of nanomaterials in commercial or medical applications are biocompatibility, toxicity and the ability to penetrate cells (Poma and Giorgio, 2008). Nanomaterials may interact with intracellular proteins, DNA, RNA and other critical cellular molecules, and these interactions can enhance the toxicity. A bundle of single-walled carbon nanotubes (SWCNTs) was found to penetrate into cells and was detected in the nuclei of human macrophages (Porter *et al.*, 2007). SWCNTs also induced lipid peroxidation and oxidative stress through fusion with the plasma membrane (Manna and Ramesh, 2005; Cui *et al.*, 2005). Nanomaterials have ROS-generating capability and pro-inflammatory effects in the lung in a direct relationship with the surface area (Oberdorster,Oberdorster and Oberdorster, 2005; Donaldson *et al.*, 2006). Many studies have shown that ROS generation and oxidative stress are the mechanism of toxicity of inhaled nanoparticles. The oxidative stress results in airway inflammation and interstitial fibrosis. Antioxidant response elements activate the NF-E2-related factor (Nrf)-2 signalling pathway to promote phase II genes as a protective response. However, at higher levels of oxidative stress, this protective response is overwhelmed by inflammation and cytotoxicity or apoptosis. Inflammation is initiated by the activation of pro-inflammatory signalling cascades, such as mitogen-activated protein kinase (MAPK) and nuclear factor κB (NF-κB) cascades, whereas programmed cell death results from mitochondrial perturbation and the release of pro-apoptotic factors (Nel *et al.*, 2006). In addition to the toxicity through oxidative stress and inflammation, some nanomaterials may cause protein denaturation, membrane damage, DNA damage, immune reactivity and granuloma formation (Nel *et al.*, 2006).

The genomic approach may provide information about the critical mechanisms of action of nanomaterials at the molecular level and is valuable for hazard identification and characterization in the risk assessment process by identifying global changes of gene expression by nanomaterials (Gatzidou, Zira and Theocharis, 2007).

The most common nanomaterials are fullerenes, SWCNTs or multi-walled carbon nanotubes (MWCNTs), metal and metal oxide particles, polymer nanoparticles and quantum dots (Poma and Giorgio, 2008). A fullerene is any molecule composed entirely of carbon, in the form of a hollow sphere, ellipsoid or tube. Spherical fullerenes are also called buckyballs (C60) and cylindrical fullerenes are called carbon nanotubes or buckytubes. Many water-soluble fullerenes have been developed as anti-HIV and anticancer agents (Schinazi *et al.*, 1993; Toniolo *et al.*, 1994; Rajagopalan *et al.*, 1996; Chiang, Lu and Lin, 1995; Miyata and Yamakoshi, 1997). Fullerenes have many potential applications because of their unique free radical chemistry and antioxidant properties. Surface chemistry has an important influence on the toxicity of C60. It is known that water-soluble, monodisperse or colloidal fullerene aggregates induce ROS, lipid peroxidation and cytotoxicity (Nel *et al.*, 2006). However, attachment of malonyl groups to the C60 surface makes it a useful antioxidant (Oberdorster, Oberdorster and Oberdorster, 2005). The median lethal dose 50 (LD_{50}) for a water-soluble fullerene is 600 mg/kg BW when it is administered intraperitoneally into rats (Chen *et al.*, 1998). Fullerenes are negative in mutagenic and *in vitro* cytogenetic assays, but their oxidative damage has been identified (Henry *et al.*, 2007). Oberdorster (2004) found significant evidence of oxidative stress, that is, lipid peroxidation, in the brains and glutathione

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat247

depletion in gills of juvenile largemouth bass exposed for 48 h to water containing uncoated fullerenes at 0.5 ppm. An increase in the numbers of BAL-recovered neutrophils, the lipid peroxidation values and the level of glutathione were observed after 1 week of intratracheal instillation of 1.5 and 3 mg/kg BW C60 in rats (Sayes *et al.*, 2007). Lai, Chen and Chiang (2000) also observed a significant increase in lipid peroxidation products but a decrease in the GSH level in intestine after intravenous administration of 1 mg/kg BW C60 in male dogs. A toxicogenomics study using larval zebrafish revealed that administration of C60 in water (C60-water) or suspension of C60 in tetrahydrofuran (THF) followed by evaporation, resuspension in water and nitrogen gas sparging (THF-C60) induced significant up-regulation of genes involved in oxidative damage with higher toxicity in the THF-C60 group than in the C60-water group (Henry *et al.*, 2007). These studies indicate that C60 induces toxic effects through oxidative stress and that the toxic potency depends on the dispersion media or manufacturing process.

Carbon nanotubes are long carbon-based tubes that are either single- or multi-walled and act as biopersistent fibers because of their insoluble and non-degradable properties in biological systems. The diameters of the tubes range from 0.7 to 1.5 nm for SWCNTs and 2 to 50 nm for MWCNTs. SWCNTs are more toxic than MWCNTs, multi-walled carbon nanoonions, C60, carbon black and graphite because of their geometry, fibrous structure and surface electrical properties (Rajagopalan *et al.*, 1996; Chiang, Lu and Lin, 1995; Lam *et al.*, 2004; Jia *et al.*, 2005), and underivatized SWCNT was more cytotoxic than SWCNT functionalized with phenyl-SO_3H, phenyl-$(COOH)_2$ and phenyl-SO_3Na (Sayes *et al.*, 2006). Several *in vitro* studies have shown oxidative damage and inflammatory changes by carbon nanotubes. ROS generation, lipid peroxidation, oxidative stress, mitochondrial dysfunction and changes in cell morphology were found in keratinocytes and bronchial epithelial cells following high doses of SWCNT (Shvedova *et al.*, 2003). Pro-inflammatory changes were observed in keratinocytes in response to MWCNT (Monteiro-Riviere *et al.*, 2005). Also, rodent studies involving intratracheal instillation of high doses of nanotubes demonstrated chronic lung inflammation, including foreign-body granuloma formation and interstitial fibrosis (Lam *et al.*, 2004; Shvedova *et al.*, 2005; Warheit *et al.*, 2004). One or 5 mg/kg BW SWCNT administered into the upper lung of rats induced acute lung toxicity and transient inflammation (Warheit *et al.*, 2004). Carbon nanotube-treated mice (0.04, 0.1 or 0.5 mg per mouse) developed progressive fibrosis and granulomas in lungs. Many *in vitro* and *in vivo* studies reported the toxic effects of carbon nanotubes, including anti-proliferative effects, decreased cell adhesion, necrosis, apoptosis and oxidative stress (Cui *et al.*, 2005; Lam *et al.*, 2004; Jia *et al.*, 2005; Shvedova *et al.*, 2003; Shvedova *et al.*, 2005; Muller *et al.*, 2005). AP-1 and NF-κB were activated in SWCNT-treated macrophage cells, indicating that the uptake of SWCNTs into the macrophages activated T cells, oxidative stress and release of proinflammatory cytokines and ultimately led to chronic pulmonary inflammation, fibrosis and granuloma formation (Chou *et al.*, 2008; Moss and Wong, 2006). In another study, SWCNTs suppressed inflammatory mediators, such as interleukin (IL)-8, IL-6, TNF-a and macrophage chemoattractant protein-1 (MCP-1), as well as the IL-8 promoter and IL-8 gene in human lung epithelial cells (A549 cells) and normal human primary bronchial epithelial cells (NHBE cell) (Herzog *et al.*, 2009). MWCNTs also suppressed systemic immune function via activation of cyclo-oxygenase enzymes in the spleen; that is, spleen cells exposed to MWCNTs partially recovered immune function by ibuprofen, a blocker of cyclo-oxygenase, and cyclo-oxygenase knock-out mice were not affected by MWCNTs (Mitchell *et al.*, 2009). Immune suppression and oxidative stress were also observed in toxicogenomics studies. MWCNTs induced significant over-expression of IL-10 and NAD(P)H quinine oxidoreductase 1 (NQO1) mRNA in murine spleen, but not in the lungs, upon 14-day exposure (Mitchell *et al.*, 2009). IL-10 is a suppressor cytokine of T-cell proliferation and cytokine responses and plays a key regulatory role in tolerance to exogenous antigens (Akdis and Blaser, 2001; Toniolo *et al.*, 1994). The pathway of oxidative stress represents inflammation, apoptosis or necrosis. When oxidative stress is at lower levels, cells usually induce antioxidant and detoxification enzymes controlled by the Nrf-2 signalling pathway, but at higher levels of oxidative stress, inflammation is initiated through the activation of pro-inflammatory signalling cascades such as MAPK and NF-κB cascades. Apoptosis is also the consequence of a high level of oxidative

stress (Kabanov, 2006). NF-κB induction caused by SWCNT with high production of ROS was found in HaCaT cells (Foucaud *et al.*, 2007). In human embryonic kidney cells (HEK293 cells), SWCNTs up-regulated the expression of cell cycle-associated genes, such as p16, Bax, p57, Hrk, Cdc42 and Cdc37, but down-regulated other cell cycle genes, such as Cdk2, Cdk4, Cdk6 and cyclin D3, and reduced signal transduction-associated genes such as Mad2, Jak1, Ttk, Pcdha9 and Erk, implying that SWCNT-stimulated signals result in the reduction of cell adhesion, cell cycle arrest and apoptosis (Cui *et al.*, 2005). Oxidative stress responsive genes such as Hmox1, Hmox2, Cyp 1B1, Ccnc, Dnajb4 and Gadd45a were also highly induced by SWCNT in human BJ foreskin cells (Sarkar *et al.*, 2007).

There is growing evidence that synthetic polymers, when combined with the biological agents, can alter cellular responses via interactions with cellular plasma membranes (Omidi *et al.*, 2003; Kabanov *et al.*, 2005; Regnstrom and Burgess, 2005; Akhtar, 2006). Polypropyleneimine dendrimers (PPI-dendrimers), which were developed as non-viral cationic vectors for nucleic acids and as drug delivery system, induced apoptosis in human carcinoma cells (Kabanov *et al.*, 2006). A toxicogenomics study of PPI-DNA-transfected human epidermoid cells and human lung epithelial cells showed alterations of genes related to apoptosis and cytokine signalling (Omidi *et al.*, 2003). Lipofectin and oligofectamine, common transfection agents, also caused marked changes in gene expression in epithelial cells (Omidi *et al.*, 2003). Rpa1, bcl2a1, casp8, hsp70 and hspd1, which are involved in apoptosis, were over-expressed by formulations of lipofectin or oligofectamine. Down-regulation of anxa2, rxra and s100a8, ednrb and rp16 genes was also observed (Omidi *et al.*, 2003). The functional consequences of this transfection formula-induced gene expression were all related with increased early apoptosis. Conjugation of doxorubicin with poly[*N*-(2-hydroxypropyl) methacrylamide] (PHPMA) resulted in the induction of additional caspase-dependent apoptosis in human ovarian carcinoma cell lines compared to the drug only (Minko, Kopeckova and Kopecek, 2001). In fact, the polymer–drug conjugate induced apoptosis by up-regulating caspases 3, 6, 7, 8 and 9, whereas the free drug induced only caspases 3, 7 and 9. Inflammation was also reportedly induced by polymer formulations. Copolymer of acrylic acid with *N*-vinylpyrrolidone significantly increased the immune response to the conjugated low-molecular-mass trinitrophenyl group, which is not immunogenic by itself (Petrov *et al.*, 1977). Also, individual bacterial or viral antigens, which are not sufficiently immunogenic alone, induced specific immune responses when chemically conjugated to polyoxidonium (Petrov *et al.*, 1983; Petrov *et al.*, 1985). Many polymer excipients are generally regarded as safe (GRAS). However, polymer excipients cannot simply be considered inert when used in combination with biologically active agents. Overall, apoptosis and inflammation are induced by various polymer components in drug delivery formulations by changing the magnitude and directions of the responses, even though the polymer materials are safe alone. To date, it is not fully understood why polymers exhibit significant changes in the cellular responses to the delivered drugs.

Various pulmonary diseases including silicosis, tuberculosis, chronic bronchitis, chronic obstructive pulmonary disease, lung cancer and activation of inflammatory responses were reported to be induced by silica (Rimal, Greenberg and Rom, 2005; Cho *et al.*, 2007). The International Agency for Research on Cancer (IARC) has classified crystalline silica as a Group 1 human carcinogen (IARC, 1997). Inflammation-related genes such as IL-1B, IL-8, IL-6, TNF-a, MCP-1 and MIP-2 are up-regulated by ultrafine amorphous silica particles (UFASs) and then rapidly recovered based on the disappearance of inflammatory lesions in mice (Cho *et al.*, 2007; Le and Vilcek, 1987). Ultrafine TiO_2 causes inflammation, fibrosis, pulmonary damage and DNA damage with much stronger potency because of its size (Afaq *et al.*, 1998; Rahman *et al.*, 2002). TiO_2 has no impact on neurons but stimulates microglia, a macrophage-like phagocytic cell, to release ROS and consequently damages ROS-sensitive neurons in cultures of brain striatum (Long *et al.*, 2007).

Cobalt nanoparticles alter the expression of genes such as interferon-activated gene 203, RAB GTPase and degenerative spermatocyte homolog 1 and thus modulate the cellular pathways of inflammatory response in mouse fibroblast cells (Papis *et al.*, 2007). In the case of GNP, neither significant cytotoxicity nor any significant changes of gene expression were found in human breast cancer cell line (HeLa cells) (Khan *et al.*, 2007). However, silver nanoparticles (AgNPs) up-regulated the oxidative stress-related genes such as superoxide

dismutase-3 (sod-3) and dauer formation protein (daf-12) with reproductive failure in *Caenorhabditis elegans* (Roh *et al.*, 2009).

As a whole, toxicogenomics studies provide a large amount of information about the mechanisms of action of nanomaterials. In many cases, oxidative stress, apoptosis and altered immune function are the main modes of toxicity of nanomaterials. The brain and the immune system are assumed to be the target organs of nanomaterials because these organs are vulnerable to oxidative stress.

3.2 Toxico-Proteomics and Toxico-Metabolomics of Nanomaterials

Toxico-proteomics and toxico-metabolomics have been useful approaches in the identification of key biochemical pathways, mechanisms and biomarkers for the assessment of exposure and toxicity, and may lessen the uncertainties in the process of human health risk assessment (Ge, Preston and Owen, 2007). The goal of toxico-proteomics in nanomaterials is the elucidation of the extent and nature of nanomaterial–protein and protein–protein interactions. In particular, proteomics and metabolomics provide direct information on the final integrated phenotype of an organism because proteins and metabolites are the final downstream products of gene and enzyme regulation (Waters and Fostel, 2004).

When HEK293 cells were exposed to SWCNTs, adhesion-associated proteins, such as laminin, fibronectin, cadherin, FAK and collagen IV, were down-regulated, which led to the inhibition of cell adhesion and decreased cell proliferation (Cui *et al.*, 2005). Those findings indicate that cells make active, self-protective responses via isolation of the cells attacked by SWCNTs from the remaining cell mass.

Fowler, Conner and Yamauchi (2005, 2008) demonstrated marked differences in protein expression patterns in renal tubule cells of male rodents in response to particles of the binary semiconductor compounds [III–V semiconductors gallium arsenide (GaAs) or indium arsenide (InAs)]. They also observed compound- and time-specific proteinuria patterns with sex-dependent differences such that there were greater responses in female rats than in males. In other studies, GaAs or InAs also altered the patterns of proteins involved in the heme biosynthetic pathways; that is, there were higher levels of the heme precursors, delta-amino levulinic acid (ALA) and porphyrins in the urine of rats administered GaAs intratracheally or of Syrian golden hamsters injected with InAS subcutaneously (Goering, Maronpot and Fowler, 1988; Conner *et al.*, 1993; Conner, Yamauchi and Fowler, 1995). The proteomics data of GaAs and InAs suggest a possible integral suppression effect on heme biosynthesis, but further studies are required to elucidate the molecular mechanism and its consequences of anaemia or neurological diseases. Abnormal heme metabolism is known to cause systemic disorders including decreased heme biosynthesis, neurological disturbances, hepatic injury and skin fragility (Akagi *et al.*, 2004). In addition, free heme, largely liberated from hemeproteins under oxidative conditions, is known to stimulate generation of ROS that induce neural death (Dwyer *et al.*, 2006).

4 RISK ASSESSMENT

Toxicogenomics data, including toxico-proteomics and toxico-metabolomics, are valuable in the identification of biological pathways when the toxic mechanism is not clear. It is true that toxicogenomics studies are not currently sufficient to replace existing testing regimens in risk assessment and regulatory toxicology. However, toxicogenomic technology can be applied to the risk assessment by providing insights into the toxic mechanism of action (Pennie, Pettit and Lord, 2004; Boverhof and Zacharewski, 2006), because risk assessment considers the hazard with the dose–response relationship, as well as the estimated exposure amount and the comparison between no-observed-adverse-effect-level (NOAEL) and estimated exposure amount, to determine the margin of safety for exposure to the substance. Inhalation of nanomaterials is considered a major route into the body. However, nanomaterials can be ingested directly via food, water, cosmetics or drugs. Most nanoparticles are rapidly eliminated via feces, although some nanoparticles in food are infrequently taken up into gut lymphatics and distributed to other organs (Kreyling *et al.*, 2002). When in contact with skin, nanomaterials smaller than 50 nm tend to penetrate the skin more easily and are sometimes localized in lymph nodes (Oberdorster,Oberdorster and Oberdorster, 2005). Therefore, it is difficult to perform risk assessment of nanomaterials because there are

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat247
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

too many factors that influence biological effects. Immune dysfunction and inflammation caused or triggered by oxidative stress have been identified as possible mechanisms underlying the aetiology of nanoparticle-associated toxicities (Dick *et al.*, 2003; Xiao *et al.*, 2003) and are supported by numerous toxicogenomics results. Also, disorder of the heme biosynthesis pathway, as suggested from toxico-proteomics and toxico-metabonomics studies, is another candidate mechanism of toxicity of semiconductors. However, there are several debates on the inflammation and oxidative stress paradigms that provide a starting point for toxicological investigation of nanomaterials. In the case of cationic dendrimers, they appear to be related not with oxidative stress, but with disruption of cell membrane integrity through interaction of the positively charged dendrimer terminal groups and the anionic lipids composing the cell membrane (Mecke *et al.*, 2004). Another debate is that the toxicities do not come from the nanomaterial itself, but rather from contaminants that adsorb to the surface during manufacturing or transport (Xiao *et al.*, 2003; Li *et al.*, 2003). Non-purified, iron-rich CNTs are more potent inducers of oxidative stress in macrophages than purified CNTs with low iron content (Kagan *et al.*, 2006). In addition, coating materials of nanomaterials are important factors for toxicity; for instance, polyethylene glycol-coated quantum dots are non-toxic, whereas amine surfaces are cytotoxic and carboxyl surfaces are both cytotoxic and inflammatory (Warheit *et al.*, 2007a, 2007b). Thus, during risk assessment of nanomaterials for human health, various factors must be considered, such as surface properties, impurities, manufacturing process, etc.

There are several acute toxicity studies of nanomaterials. The oral LD_{50} of nanomaterials including fullerene, multi-walled CNT, Fe_3O_4, WN, Cu or TiO_2 ranged from >0.005 to >5 g/kg BW, with no evidence of toxicity in rats and mice (Carrero-Sanchez *et al.*, 2006; Chen *et al.*, 2006; Mori *et al.*, 2006; Xia *et al.*, 2005; Wang *et al.*, 2006, 2007). Intraperitoneal administration of nanomaterials yielded LD_{50} values ranging from 0.040 to >2.5 g/kg BW, with no evidence of toxicity or damage in liver or kidney (Carrero-Sanchez *et al.*, 2006; Chen *et al.*, 2006; Xia *et al.*, 2005; Moussa *et al.*, 1996). Most of the acute toxicity data did not represent the exact toxic potency because no deaths were observed up to the maximum dose administered. A single oral dose of Fe_3O_4, Cu and TiO_2 resulted in kidney damage such as tubular dilation, casts, glomerular swelling and proximal tubule necrosis, liver lesions with hydropic degeneration and steanosis, and spleen atrophy (Chen *et al.*, 2006; Wang *et al.*, 2006, 2007). Nanomaterials are commonly taken up by the reticuloendothelial system (RES), which explains why liver and spleen are target organs for nanomaterials. The kidney is also a common target organ of toxicity for nanomaterials as this organ is the primary clearance route for many nanomaterials, including CNTs, water-soluble polyalkyl-sulfonate fullerenes and low-generation dendrimers (Chen *et al.*, 2006; Wang *et al.*, 2004). Many inhalation studies presented with inflammation and fibrosis and, in some cases, lung tumours. The pulmonary toxicity of nanoparticles is mainly explained by lung overload that overwhelms pulmonary clearance mechanisms (ILSI, 2000; Stern and McNeil, 2008). Nanopaticles easily cause lung overload at lower doses due to their larger surface area that correlates with decreased alveolar macrophage clearance capacity (Moss and Wong, 2006). In the case of CNTs, the formation of pulmonary granulomatous lesions is highly related to agglomerated CNTs (Lam *et al.*, 2004). Positive mutagenic potential, mediated by lipid peroxides, is reported for irradiated fullerene, but *in vivo* tumour studies showed no evidence of carcinogenesis (Sera, Tokiwa and Miyata, 1996).

An important route of exposure to nanomaterials is inhalation. The transfer of particles from the lung to the circulation and secondary organs is of concern because inhaled nanoparticles directly induce systemic disease, such as cardiovascular disease involving platelet aggregation or thrombosis (Radomski *et al.*, 2005). Inhaled nanoparticles translocating from the nasal epithelium to neurons in the olfactory bulb were observed in several studies (Elder and Oberdörster, 2006; Oberdörster *et al.*, 2004). However, CNS uptake of inhaled nanoparticles has not yet been seen in humans. Although in many cases of dermal or oral exposure, nanoparticles showed limited dermal penetration or GI absorption, the adsorption is dependent on the size, shape and surface properties of the nanoparticles (Nohynek *et al.*, 2007). However, the interactions with subcellular structures need to be investigated in studies of the biologic and toxicologic effects of nanomaterials (Oberdorster,Oberdorster and Oberdorster, 2005).

Furthermore, there are limitations of the analytical methods for the quantitation or tracing of nanomaterials in environmental sources and foods that make for added difficulties in exposure assessment for nanomaterials. Nanotoxicology relies on many analytical methods for the characterization of nanomaterials as well as their impacts on *in vitro* and *in vivo* function. Recently, transmission electron microscopy (TEM) electron-dispersive X-ray analysis (EDS) was used to confirm the presence of silver nanoparticles within cells, and electron energy loss spectroscopy (EELS) was used in conjunction with TEM for elemental confirmation of carbon nanotube uptake. Inductively coupled plasma-atomic emission spectroscopy (ICP-AES) was introduced as a powerful technique for the quantification of internalized nanoparticles and had sub-ppb detection limits, high precision and a dynamic range of five orders of magnitude or more (Marquis *et al.*, 2009). Development of assay techniques for the quantitative determination of various kinds of nanomaterials is required for risk assessment.

Further toxicological studies are required for quantitative risk assessment of the human health impact of nanomaterials. Risk assessments of nanomaterials also need to be performed separately for each functional or structural group because the toxicities may vary according to the properties of the nanomaterials such as size, shape, agglomeration state, solubility and surface charge.

5 CONCLUSIONS

Production of ROS and inflammation caused by oxidative stress are key toxicity mechanisms of nanomaterials. Many toxicogenomic and toxicoproteomic studies support this toxic mode of action of nanomaterials. Even though many toxicological studies have been performed for multiple nanomaterials, further confirmation is required before a hazard can be identified and characterized. It is currently impossible to systematically link the properties of nanomaterials to the biological effects. In addition, the most relevant toxicological endpoints, threshold levels that do not have any toxicological concerns, are still unclear, although some studies have presented dose–response relationships. Exposure assessment is also hampered by difficulties in monitoring exposure patterns and levels of various nanomaterials in the workplace and the environment. Considering the present level of knowledge, it is not possible to establish threshold levels for each nanomaterial due to limited toxicological and exposure data. Further studies are required for systemic risk assessment of human health impact considering various properties of nanomaterials. To obtain more integrated and systemic data, genomics and proteomics approaches may provide important information by combining hypothesis-forming and hypothesis-driven research for the risk assessment.

Implementing Systems Toxicology in Drug Development for Regulatory Decision Making

Joseph F. Sina and Frank D. Sistare

Safety Assessment, Merck Research Laboratories, West Point, PA, USA

1 PROMISE

The development of 'omics technologies and completion of the human genome project in the past decade have set an expectation for an exponential positive impact on human health. The FDA's Critical Path report (FDA, 2004), in fact, called for a focus on these applications as ways to enhance drug development and improve the safety and efficacy of drugs. Expanded measurement platforms and improved biological understanding should lead to more and better biomarkers, which would ultimately be able to predict and demonstrate efficacy while minimizing adverse effects of new therapeutics. Overall, drug safety would be further enhanced by targeting treatment to that patient population most likely to benefit. The problem with expectations is that often the reality does not live up to the promise within the hoped for timeframe. In this case, as discussed below, the delay in achieving expectations is driven by (i) the complexity of the biological systems we are attempting to monitor, (ii) the realization that the level of understanding needed to qualify new endpoints will take far more investment in generating new knowledge, and (iii) the high evidentiary standard needed prior to effective implementation in a regulated drug-development setting. These hurdles each require significant time and effort to surmount.

This does not mean that progress has not been made, or that expectations will not be eventually realized. In this chapter, we will explore the progress toward improved risk assessment in drug development through the application of newer tools and technologies within the umbrella concept of systems toxicology and fit-for-purpose standards. We will discuss the path that runs from the development of biomarkers on a whole animal basis, reflecting an integrated understanding of pharmacological and toxicological processes, rather than on an individual pathway by pathway, or gene by gene, basis and the application of these markers to inform a range of needs, from in-house screening to investigations into mechanisms of action to monitoring for toxicity in a clinical population. The process is a continuum, from the standpoint of both the science and the increasing "burden of proof" as one gets closer to making decisions concerning human health. We find that there are layers of interacting and overlapping biological processes whose details need to be elucidated before we can more accurately predict responder and non-responder populations, human or animal. And herein lies the issue for regulatory acceptance of systems toxicology – what level of confidence needs to be reached for a given purpose? What is the bar above which a set of data not only supports a hypothesis, but can be related with

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat248

confidence to have clinical meaning? How much supporting data and how wide acceptance in the scientific community is necessary to be confident of what a marker is reporting? And, finally, how solid is "solid enough" for regulatory application, given that we never expect to achieve 100% understanding and accuracy.

For purposes of this chapter, we need to define two specific concepts – systems toxicology and biomarkers. Although there are various descriptions in the literature, the concept of systems toxicology is generally accepted to refer to a broad understanding of all the component biological processes that interact to result in a given phenotype in an animal, with information at the gene and protein level complementing end-points measured in the whole animal (Kitano, 2002; Edwards and Preston, 2008). To achieve this requires an integration of knowledge from scientific dogma, laboratory experience, and various end-point measurements. Conceptually, the process is actually an enhancement of the way risk is currently evaluated in drug development. Multiple studies, and the measurement of multiple parameters within each, builds up to a more and more complete picture of a compound's on- and off-target activities. The future state revolves around the kinds of additional value-added measurements we can make based on evolving tools and technologies, and how well we are able to mine and integrate *all* relevant information to produce a better system-wide assessment of contributing biological events that lead to an adverse phenotype.

Biomarkers can be thought of as end-point measurements, whether a single assay or an algorithm based on multiple, independent measurements, that provide a readout of a phenotypic manifestation. The official NIH definition of a biomarker (Biomarkers Definitions Working Group, 2001) is: "a characteristic that is objectively measured and evaluated as an indicator of normal biologic processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention". Certainly, there are well-established biomarkers currently used in medical practice. Every medical test ordered by a physician can be considered a biomarker which has been "validated" by years of experience and an understanding of its correlation with a given disease phenotype. And again, running multiple tests serves to provide a broader picture of an individual's health, allowing the sorting of various possible diagnoses more accurately. In the context of a system toxicology approach, however, the question often posed is whether correlation is always enough. To realize the promises of systems toxicology and 'omics tools, we must move beyond just correlation, to a more coherent, evidence-based and integrated biological understanding, which presents a much higher bar for acceptance and future reliance.

2 PROCESS OF SYSTEMS TOXICOLOGY

It is sometimes helpful to define the desired future state, then work backwards to outline a high-level roadmap to achieve this goal. In this section, we will explore what such a roadmap might look like. It is generally acknowledged that "The labor required to deliver a new generation of biomarkers to clinical practice will be long and hard" (Woodcock, 2009). Two recent articles have looked at the systems toxicology landscape (Edwards and Preston, 2008; MacDonald and Robertson, 2009) and present excellent overviews of some of the issues that need to be addressed. For the pharmaceutical industry and regulatory bodies alike, the ultimate goal is to assess the potential risk of a therapeutic drug, in the context of its benefit to people, and to be able to easily monitor adverse effects with non-invasive end-points which are manifested prior to the occurrence of irreversible adverse effects.

In discussions of the future state, the concept of fit-for-purpose is a major driver. The FDA guidance on pharmacogenomic data submissions discusses the need to describe the context in which data are to be assessed. In FAQs clarifying this document (http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083893.htm), the agency specifically refers to this as "fit-for-purpose". Likewise, European Medicines Agency (EMA), in its Guidance on Genomic Biomarkers (ICH Topic E16; http://www.ema.europa.eu/pdfs/human/ich/38063609endraft.pdf), discusses the need to define the "context" of use. Essentially, these documents build from earlier established concepts which recognize that, rather than considering a marker either valid or invalid, there is value in examining the specific purpose for which a marker is proposed, and having that specific goal inform the type and amount of data needed to support the claim (Wagner, Williams and Webster, 2007; Woodcock, 2009). The technical aspects of an assay validation strategy have been more fully explored

by Lee *et al*. (2006) who considers various stages in biomarker qualification, including pre-validation of methods, exploratory and in-study validation (i.e. robustness and reproducibility of the method), and "advanced" validation (a broadening of experience with biomarker performance). And, in fact, the technical roadmap toward providing an evidentiary standard has already been in effect in the Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) process for evaluation of proposed assays as alternatives to animal testing. The NICEATM/ICCVAM website (iccvam.niehs.nih.gov/) provides both high-level information on evaluating the usefulness and limitations of test methods proposed for use in a regulatory environment, and a specific roadmap to technical requirements for sponsors to show that tests are "scientifically valid for their intended purpose" (ICCVAM Biennial Report – http://iccvam.niehs.nih.gov/docs/annrpt/BiennialRpt2007-508.pdf).

Looking earlier in the drug-development timeline, the question that must be answered even before application in regulated phases of drug development and regulatory decision-making is whether the biomarker(s) have been rigorously enough qualified even for internal decision-making. Stated more pointedly, what is our level of trust and confidence in the biomarker at a stage where time, resources, and financial gain are at risk, but not human clinical trial safety? Would we depend on the readout for critical decisions pre-clinically? If so, the question is what body of evidence do we need that provides that level of confidence? The answer to this question may reflect, in large part, the strategy toward regulatory acceptance. Given confidence at that level, the step to clinical translation should be more straightforward. With this information in hand, we can define the technical strategies for reducing biomarkers to practice.

Hartung (2009) has articulated a number of considerations in this portion of the roadmap, the steps critical for implementation. The purpose at this stage is to evaluate a biomarker(s) to understand strengths and limitations, gaps that need to be filled, intermediate uses, etc. To achieve this, Hartung proposes a "stairway" approach focusing on quality assurance of the assay to be used to measure the marker, followed by establishment of an evaluation/validation strategy. In our experience, the test set of samples becomes critical at this point. Beyond samples to establish specificity and sensitivity of a marker, as well as to enable comparison with literature or database information, it is necessary to establish the "truth". In standard toxicology studies, not only are multiple parameters assessed, but the incidence and severity of each end-point is taken into account. A judgment is then made with respect to the risk of toxicity at a dose level and/or time for a test material. For individual samples, however, the outcome may be somewhat more ambiguous, or may represent only part of response, complicating the anchoring process. Take, for instance, a case in which five of 10 animals show hepatocellular necrosis histologically at a given dose/time-point. In assessing a liver injury biomarker, does one consider five animals positive for the histology anchor and five negative? It is conceivable that some among the five "negative" animals are indeed affected, but perhaps no histopathology was observed in the sample of liver obtained. They may also be quite likely to show at least a graded response, if not a full positive response, indicating that some level of toxicity has occurred, even though it has not yet been manifested as histology. A statistical approach referred to as the receiver operating characteristic exclusion analysis has been deployed in consideration of such instances, so that new high-performance biomarkers are not inappropriately penalized (Sistare *et al*., 2010).

The question as to the purpose for which the marker is being developed comes into play at this point as well. The relevant question during the initial phases of biomarker development for pre-clinical or clinical application is whether the purpose is to define diagnostic, prodromal, or predictive markers. A working definition of a diagnostic marker would be one that is used to establish the presence of a "gold standard" condition. For instance, the appearance of Kim-1 in urine indicates nephrotoxicity has occurred, and can report, in most cases, a histopathological diagnosis (Bonventre, 2009). Early in the drug-development process, the need is for a rapid, compound-sparing approach to reliably triage a number of active compounds to enable an internal decision as to which have the highest probability of becoming safe and effective drugs. The initial readout can be essentially digital – higher probability of being toxic versus lower probability of toxicity at a given exposure – because subsequent testing will verify the safety of the compound. As greater predictivity is required, the biomarker would need to report more of a continuum of toxic

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat248

response, from low to high. Many clinical and preclinical markers in use today diagnose that a disease or other adverse condition exists at a stage when a certain amount of damage is already present, that is, enough to trigger the biomarker.

In a clinical scenario, there is much value in diagnostic markers that are early and sensitive enough to report minimal, reversible damage, and with which risk can be monitored and managed. Even better would be prodromal and predictive markers. Prodromal and predictive biomarkers can be defined as those that precede a conventionally observed event, raising a warning flag of impending risk. The prodromal marker represents the earliest response and may be involved in one of the causal events or may be one aspect of a multi-factorial response to an insult. But in any case, it defines a point where the whole animal has initiated a process, but may still adapt and recover, rather than already being committed to presenting with a full adverse response. Development of this type of biomarker demands an ability to monitor multiple events within the context of the whole organism, and also to understand their collective significance. A predictive biomarker would also precede in time and foretell the appearance of a conventionally observed future event, but may not be a component of the adverse response set into motion. Prodromal and predictive biomarkers are far more challenging to experimentally qualify.

This line of thinking leads to another critical question: "Where does a relevant effect start?" (Hartung, 2009). And this is where a systems toxicology perspective becomes a critical consideration. To continue the discussion begun above, although five of 10 animals do not show histopathology, and may or may not show a response to a specific biomarker, are there other indications that the animals are indeed affected by the test material? From another perspective, if the tested biomarker reports out changes within a given pathway, what about other pathways? An example is the case of tumorigenesis. It is well established that tumor formation may require changes in proliferation, apoptosis, DNA damage/repair, and/or angiogenesis pathways, among others. Which are necessary, which are just sufficient, what is the critical interaction or tipping point? The answers depend upon a systems' wide understanding. Similarly, when markers of oxidative stress are being seen in response to a test compound, what is happening with pathways recognized as relevant to protection from oxidative stress? Will they be overwhelmed leading to manifestation of toxicity in the whole animal, or will the animal compensate for the insult with minimal adverse reaction? The systems-wide view becomes critical to an in-depth understanding of processes *contributing to* underlying toxicity risk, in contrast to measuring a marker that *correlates* with risk.

To follow the roadmap to its initiation, we need to evaluate the source of novel biomarkers. The "ideal" properties of a biomarker may differ somewhat with the question being addressed or the context of use (see, e.g. the discussion of Zhang *et al*. 2009 on the characteristics and strategy for developing a biomarker for post-traumatic stress disorder where the diagnosis is complex and multifactorial versus Johann *et al*. 2010 who describe a more defined proteomic evaluation of tissue from a patient with renal cell carcinoma.) But in general, one should be able to demonstrate organ-specific derivation, sensitivity in the sense of the marker appearing prior to irreversible organ damage, and predictivity of severity and reversibility. Additionally, an ideal biomarker would be easily distinguished from biological noise, should be non-invasive, and should bridge pre-clinical and clinical applications (i.e. it is desirable that a marker useful in pre-clinical species should be applicable in humans, and that human markers should bridge back to pre-clinical species as well). Although it is relatively straightforward to design the ideal toxicity biomarker, the process from discovery to evaluation through qualification represents a continuum, with different purposes, and therefore different levels of "proof". Many times, suggestions for novel markers are generated based on the academic literature, although in most cases these are based on limited observations. Often, the number of compounds tested by individual laboratories is too small to speak to sensitivity, specificity, or how generalizable a proposed biomarker might be. Consortia among industries (ILSI/HESI), between academia or government laboratories and industry (fNIH), or between industry and regulatory agencies (PSTC) have a larger pool of resources to devise and execute on a strategy to evaluate the most promising biomarkers. This is time-consuming, and by nature focuses on a relatively narrow goal, rather than the broadest understanding in the context of systems toxicology, but is a necessary step. The bottom line is that the field has found the task of moving potential biomarkers through to regulatory consideration and acceptance to be a lot more complicated and

resource intensive than simply applying the new technologies along with accepted ante-mortem and post-mortem evaluations.

3 PROGRESS

At the crux of the issue is the complexity of the biology we seek to understand (Schrattenholz and Soskic, 2008). Any number of end-points (using 'omics technologies, biochemistry, histology, clinical chemistry, etc.) can be measured and evaluated for correlation with phenotypic anchoring. However, although this provides a large body of information, the data need to be integrated, classified as to relevance, and ultimately understood in the context of the question being addressed. Given multiple measurements from *in vivo* and/or *in vitro* systems, we can begin to build toward an understanding of what to expect in pre-clinical species. Some data will be confirmatory of other observations, and some will need to be set aside as potential "red herrings". Experience will eventually determine the meaning, or lack thereof, for these "outlier" measurements. Taking this system-wide view allows us to begin to overcome the complexity, but still does not necessarily allow yes/no answers unless far more investment is made in independent and rigorous conformational studies.

In point of fact, the label "systems toxicology" could be applied to the process used in drug development today. A regulatory package consists of ante-mortem and post-mortem data from multiple pre-clinical species, as well as data from pharmacology, drug metabolism, and other disciplines. The sum total of the data produces a broad picture of the whole animal response to the drug that is extrapolated to humans, taking into account risk/benefit, exposure margins, knowledge of species differences, etc. Early on, the integrated information informs the safety of phase I studies, although there are gaps in our understanding. With additional animal and clinical information, a more complete, integrated picture emerges, although experience suggests that there will still be some ambiguous information around which an informed, but subjective, assessment as to relevance needs to be made. Ultimately, it is the sum total of these data in pre-clinical and small, human studies, which provides a broad picture of the risk/benefit of the drug, and serves as the basis for ultimate approval or disapproval of permission to pursue clinical development, and ultimately for marketing a compound for a given therapeutic purpose. Even at this point, after having applied the best available science, experience shows that inter-individual differences in response in terms of both efficacy and toxicity may surface once the exposed human population is expanded (Harrill and Rusyn, 2008).

Drawing a parallel for biomarkers, the question is how do we arrive at an understanding of the appropriate interpretation of multiple measurements from models novel to our current drug development experience (e.g. the range of *in vitro* models currently available)? And how can we use these data to complement, rather than confuse, the standard pre-clinical assessments, to increase our understanding of the biological response in people, thus positively impacting our ability to accurately predict risk? Ultimately, will this additional information allow the prediction of the inter-individual responses that currently are difficult to account for within a population? We submit that progress is being made toward these goals.

For example, Woods *et al.* (2009) have recently published a study on the Nrf2-mediated adaptive response in mouse that might serve as an example of a desired future state. Given that alteration of the Nrf2 pathway is associated with oxidative stress, one could simply monitor for effects upon xenobiotic exposure by measuring a rate-limiting step or end product in the pathway. What these authors demonstrated, however, was the dose-dependent "evolution" of pathways perturbed by exposure to hypochlorous acid. At low doses, alterations in Nrf2 response, inflammatory pathways and protein ubiquitination were predominant. At these concentrations, genes associated with cell-cycle regulation and gene transcription were suppressed. At higher, but still non-cytotoxic concentrations of HOCl, Nrf-2 gene responses decreased and secondary stress responses, such as damage-inducible genes, were increased. At still higher and cytotoxic concentrations, pathways associated with protein and DNA damage, such as Gadd45, were increased. Looking at this holistic view, one not only has a biomarker of toxicity measured at a "snapshot in time", but also more of an understanding of the biology changing prior to and in concert with the Nrf2-regulated antioxidant defense program. This is the type of biological understanding that, expanded and augmented by other data, presents us with the

General, Applied and Systems Toxicology, Online © 2011 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat248
This article was first published in print in the *Handbook of Systems Toxicology* ISBN: 978-0-470-68401-6 © 2011 John Wiley & Sons, Ltd.

opportunity to identify earlier, perhaps more sensitive indications of toxicity. These could ultimately be used in: (i) clinical studies to monitor and intervene in a patient prior to an irreversible injury, or (ii) pre-clinical animal studies to shorten the duration of studies needed in order to make go/no go decisions.

A second approach is proposed by Andersen and Krewski (2009), who, in defining a novel vision for toxicity testing in the twenty-first century, see the application of *in vitro* tests and computational models around the concept of identifying and avoiding "significant perturbations" of pathways associated with ultimate development of a toxicologic phenotype. The idea of using high-throughput screening in well-defined model systems is an attractive one, and has been used extensively in industry early in the drug-development process. It is also the basis of the EPA's ToxCast project (Dix *et al*., 2007) which seeks to categorize risk based on *in vitro* testing in order to triage chemicals that are most likely to be of risk to people, and therefore should be subjected to more testing on a priority basis. A number of tests are currently undergoing a qualification process within this project (http://www.epa.gov/ncct/toxcast/), to define those most highly correlated with toxicity pathways for specific chemical classes, with pharmaceuticals targeted for assessment in the near future. Given successful qualification/understanding of the models, one can envision making decisions as to potential risk using an integrated assessment of toxicity and compensatory pathways in *in vitro* and *in vivo* models. Comparison of the data with compounds for which we have relevant human information, and considering issues such as margins of exposure, expected metabolism, etc., could further our confidence that we are truly moving forward those compounds with the lowest probability of risk.

Yet, a third concept is proposed by Wills and Mitchell (2009) around the combination of cell culture, in silico modeling, and mapping of data to human outcomes. They argue that using current toxicogenomics practices of pattern recognition and bioinformatics approaches can be limiting as resources usually do not permit as broad an experimental approach as desired. However, if modes of toxicity relevant to human can be recapitulated in *in vitro* systems and brought together, the resulting data set would more fully support modeling of the expected toxicological response in the whole organism. The *in vitro* systems would be particularly amenable to performing dose–toxicity and dose–time experiments which can be difficult and expensive *in vivo*. The caveat, of course, is that one needs to understand the strengths and limitations of each *in vitro* model to be employed to generate relevant data.

4 CHALLENGE

To bring the roadmap full circle, we come back to the types of information, models, etc. that should be considered in forming an integrated picture of human risk, given that this is ultimately the goal of systems toxicology applied in the regulatory environment. We could sum up by saying that system-wide integration of data equals more knowledge and therefore more confidence that we have met a high bar of rigorous science. But although this is ideal, the question is whether it is achievable in a reasonable timeframe. The key word in the statement above is "knowledge". The amount of data (information) available in the literature around well-researched pathways is growing exponentially. In reality, both public and internal data represent observations that are snapshots in time and dependent upon dose, species, time of exposure, ADME, and a host of other factors. Informatic assessments attempt to consolidate the results and draw patterns, but these do not truly represent knowledge. Rather these efforts usually lead to testable hypotheses which have a higher probability of moving us one step closer to system-wide knowledge. It is evident that we are flooded with information, not only in toxicology but in essentially every aspect of our current world. The issue is how to strip away the extraneous, until one is left with true insight.

Clearly, as discussed above, we need to take advantage of every potential *in vivo* and *in vitro* tool to try to put together the pieces of the systems toxicology puzzle based on rigorous science. The challenge for moving systems toxicology into the regulatory arena, then, becomes one of how much do we need to understand ahead of time, what is the extent of a priori proof, before one can apply a new approach. Do we need to completely characterize the biology around biomarkers and have prospective data in-hand before beginning to apply them? Or can we integrate newer scientific approaches in smaller steps? Clearly, the question not only for regulatory authorities and industry, but also for the

public sector, is how much risk we are collectively willing to take.

For instance, we all understand that correlations are not equivalent to real understanding. Yet in clinical practice, diagnoses are made and treatments prescribed based on correlations confirmed by experience. We "know" from years of observation that elevated serum transaminases, such as ALT, generally mean damage to the liver. We also know that there are cases in which such transaminases are transient and do not appear to lead to compromised liver function, or arise as a result of other factors or disease states (Korones, Brown and Palis, 2001; de Denus *et al.*, 2004). The current state of knowledge arises from both a basic understanding of the biology surrounding serum transaminases and experiential information gained from proven diagnostic ability in the clinic. This could provide the paradigm for use of novel biomarkers. As no single biomarker or clinical (or pre-clinical, for that matter) test is considered definitive, a battery of test results is always available for assessment of risk, so there is little risk as novel markers are assessed. Based on the experience with these new markers, judgments can be made with respect to whether and when to move novel biomarkers into regulatory practice as reliable on their own.

The EPA's ToxCast program (Dix *et al.*, 2007) is an example of a practical, stepwise approach. The initial question is straightforward – given a set of test compounds, does any existing *in vitro* assay correlate well enough to identify chemicals with the highest risk of toxicity for further testing. Similarly, the ICCVAM validation processes around alternatives to the Draize rabbit eye test ultimately asked not whether any proposed assay could replace the *in vivo* test completely, but rather whether any of them could separate severe eye irritants from the rest. This could perhaps be viewed as a tacit acknowledgement that there was a "gray zone" of compounds and/or applications where the review panels did not have sufficient data to support broader claims. However, in both cases, a first step was taken toward incorporating alternatives to *in vivo* models into decision-making. It is reasonable to expect that as we gain experience with these assays and end-points, both in use and with further laboratory work, we will be able to expand their use with greater confidence.

A recent report by Thomas *et al.* (2009) exemplifies some of the realities. The authors simplify the experimental question – can gene expression profiling be used to predict compounds likely to cause an increased incidence of lung tumors in mice. Starting with compounds already known to increase incidence of lung tumors in a 2-year bioassay, they exposed mice to a battery of 26 compounds (approximately half lung tumorigens) and performed microarray analyses. Although they did conclude that the derived signature could help triage potential lung tumorigens, one major question is whether the results can be extended to other tumor sites and types. They estimate, based on their data, that a battery of approximately 25 chemicals could give a robust predictive model. The experiments and subsequent analyses required "several years" work, according to the authors. So part of the reality is that gene expression profiling can be used to categorize compounds for potential liabilities, but not only are the timelines fairly long, but also we only scratch the surface of the deeper confidence we seek in predictive biomarkers.

Bradford Hill (1965) proposed criteria by which we could increase our confidence in the relationship between a factor (e.g. a biomarker) and disease. His statement that "None of my nine viewpoints can bring indisputable evidence for or against the cause-and-effect hypothesis. . ." sums up the major challenge. To what extent do such factors as strength, consistency, and specificity of association, along with experimental evidence of consistency between a biomarker and our understanding of the biology need to be proven before consideration of a new approach in the regulatory arena? The answer to this question will speak directly to issues brought up by the Critical Path report (FDA, 2004) – how effectively and on what timeline can we use novel technologies to improve the safety and efficacy of drugs?

5 PULLING IT ALL TOGETHER

The ideal path forward would be to integrate what is known about key toxicological pathways and the end-point measurements that inform these, and then ask whether we have confidence enough to use the knowledge as the basis for internal, pre-clinical decisions. For those areas where the understanding is robust enough, formal qualification for a specific purpose should be initiated. Muller and Dieterle (2009) have published an excellent review, not only

of this process, but also of the status of various target organ biomarkers.

However, it is easier to define the ideal path than it is to bring the vision to fruition. What we see as barriers are (i) the time and resources to perform rigorous science, and (ii) the current low tolerance for risk which sets the bar for acceptance very high. The two are inextricably linked. If the expectation is that after moving a potential or promising observation through the stages of confirming its strengths, weaknesses, utility with respect to gaps in our current abilities, data need to be collected prospectively in the clinical setting for qualification, we face a long road to gain enough understanding to be confident in biomarker usage. What is needed is a paradigm under which a qualified biomarker becomes part of a weight of evidence approach. We cannot wait for the full understanding of integrated toxicology in a whole organism before beginning to apply biomarkers. Laboratory investigations and pre-clinical and clinical experience need to go hand-in-hand to achieve results in a reasonable timeframe.
