Carcinogenesis and Carcinogens that are also Genotoxic

Douglas McGregor

CONTENTS

1 INTRODUCTION

Cancer as a cause of death is not negligible at any age, but it is primarily a terminal illness in aged populations; therefore, because population age-structure is commonly shifting towards the elderly, the prevalence of cancers will increase even if there is no change in the age-standardized incidences. Carcinogenesis is the process by which these ultimately malignant tumours develop, and oncogenesis refers to the changes involved in the development of any kind of tumour, including benign tumours. A carcinogen, therefore, is a risk factor causally related to an increase in cancer incidence or prevalence. Cancer epidemiologists study the factors that lead people either to develop clinically diagnosed cancer or to die of cancer. In the latter case, the event is entered into mortality statistics; but in both cases, cancer epidemiology is almost always the study of malignancies. Other neoplasms may have been present within the individual that were not recorded because either they were never recognized (e.g. histology was limited to major lesions observed at autopsy) or they did not contribute to the cause of death. To an experimental oncologist, who will make detailed examination of a large number of organs and tissues from all of the animals in his experiment, a carcinogen is not necessarily an agent causing a pathological phenomenon resulting in death. A carcinogen in this experimental context is an agent which increases the incidence of any neoplasm irrespective of whether it is lethal, potentially lethal or benign. In extreme circumstances, a carcinogen may be defined also as an agent that increases the incidence of certain types of preneoplastic change and may even include certain types of hyperplasia. This degeneration in definition has been justified on the basis that had animals lived longer, or could have tolerated a higher dose, then progression to neoplasia malignancy would have occurred (Interagency Regulatory Liaison Group, Work Group on Risk Assessment, 1980). On the other hand, although a morphological

continuum may be evident from the histological evaluation of preneoplastic and neoplastic lesions, it is not axiomatic that all preneoplastic or benign lesions progress to malignancy. Hyperplastic lesions may not progress to neoplasia and may be reversible (Eustis, 1989). Furthermore, certain types of tumour in laboratory animals, for example Leydig cell tumours in rats, are almost never malignant and are extremely rarely a cause of death. In this particular example, the difference between hyperplasia and adenoma is based exclusively on size and an arbitrary decision rule.

The information upon which evaluations of carcinogenic potential are made comes from epidemiology and laboratory animal experiments. Frequently, the animal experiments conducted with high-volume production chemicals, or chemicals which are important for some other reasons, give the first indications that special care may be necessary in handling the chemical because it is carcinogenic, but this is not always so. On other occasions, the primary information may come from observations upon human disease patterns. This chapter is a description of some of the problems associated with carcinogenicity experiments and a discussion of what the results might mean, particularly for those substances that are so-called genotoxic carcinogens. 'So-called' because the term is misleading: its use is based on the tacit assumption that if a chemical possesses both genotoxic and carcinogenic properties then genotoxicity is its mode of carcinogenic action. This is not necessarily so and is a topic that will be discussed below; however, carcinogens that clearly act through some mode of action not involving an inherent genotoxic property are discussed in **Nongenotoxic or Epigenetic Carcinogenesis**.

2 CARCINOGENESIS

The multistep, multifactorial process by which normal cells are thought to develop into cancerous cells involves the loss of genomic stability and the sequential acquisition of genetic alterations (Loeb and Loeb, 2000; Gray and Collins, 2000; Eyfjord and Bodvarsdottir, 2005). The somatic mutations found in cancers are either 'drivers' or 'passengers' (Greenman *et al*., 2007). Driver mutations are those which are causally involved in the neoplastic process and are selected for during tumourigenesis. Passenger mutations are neutral and nonlethal; therefore they are retained by chance during cell population expansion. Proto-oncogenes and tumour suppressor genes have been identified as the main mutational targets (Bishop, 1991; Weinberg, 1991), and carcinogen-specific mutational patterns have been observed in these genes in tumours of laboratory animals (Balmain and Brown, 1988) as well as in human cancers (Harris, 1992; Semenza and Weasel, 1997). This association suggests a mechanistic link between carcinogen exposure, genetic alterations and cancer (Hussain and Harris, 1999). The highly increased tumour incidence in subjects with defects in nucleotide excision repair supports the key role of DNA alterations in the process of cancer development (Stary and Sarasin, 2002). Moreover, organ and cell-type specific differences in DNA repair capacity have been demonstrated to correlate with site of tumour formation under a variety of experimental situations (Goth and Rajewski, 1974; Kleihues and Margison, 1974; Swenberg *et al*., 1984).

3 GENETIC FACTORS IN CARCINOGENESIS

An association of abnormal mitotic metaphase chromosomes with cancer cells has been known for more than a century, but chromosomal aberrations seemed to exhibit no specific pattern with particularly neoplastic diseases and it was far from clear whether the aberrations were causative or secondary events arising during tumour development. The first documentation of a nonrandom chromosomal aberration with a neoplastic disease was the reciprocal translocation between chromosomes 9 and 22 (t(9,22)), giving the Philadelphia syndrome, seen in chronic myeloid leukaemia (Nowell and Hungerford, 1960). Since then, it has been shown that specific reciprocal translocations are prevalent in leukaemias and lymphomas and they also occur in 3% of all neoplasms (reported by Solomon *et al*., 1991). More than 100 recurrent translocations have been described (Mitelman *et al*., 1990). In addition, progression towards increased malignancy appears to be characterized by increased genetic instability, manifest as translocations, deletions, chromosomal breaks, ploidy changes and nondisjunctions.

The genetic instability of tumour cells is well documented, but the mechanisms involved are not yet defined. They may involve mutations in DNA repair and synthesis genes. Evidence for this mechanism in man comes from instability genes in association with inherited chromosomal fragility syndromes, such as xeroderma pigmentosum and ataxia telangiectasia. Comparison of point mutation rates in tumorigenic and nontumorigenic cells does not reveal any marked difference, whereas the rate of gene amplification is clearly higher in tumorigenic cells. This was demonstrated about 20 years ago in the amplification of base sequences encoding the CAD protein (a multifunctional enzyme: carbamoyl phosphate synthase, aspartate transcarbamylase and dihydroorotase). Amplification of this gene cannot be demonstrated in normal cells from man, hamster or rat (frequency $<10^{-9}$), whereas amplification occurs in tumorigenic cells from each of these species at a frequency of about 10^{-4} (Tisty *et al*., 1989; Tisty, 1990).

3.1 Dominant Oncogenes

The finding that the avian retroviral *src* gene had evolved from a captured cellular gene (Stehelin *et al*., 1976) was to guide much future research and the development of the concept of oncogenes. These are dominantly acting mutant forms of normal cellular genes (proto-oncogenes) which play a physiological growth-regulating role (reviewed by Bishop, 1987), many of them having protein kinase activity, particularly for the phosphorylation of tyrosine residues.

When mouse NIH 3 T3 fibroblasts are transfected with DNA from human tumours, the result is malignant transformation of the fibroblasts. Oncogenes were isolated from these cells (Shih *et al*., 1981) and were found to be homologues of retroviral transforming genes (Der *et al*., 1982). Over 100 oncogenes have been discovered since the early 1980s by use of these transfection assays. However, only a few of the oncogenes have a demonstrated involvement in human carcinogenesis, although, in an altered form, they function as oncogenes in laboratory animals and *in vitro* experimental systems. Apart from a few viruses, such as human papilloma virus (HPV) and hepatitis B virus (HBV), which may introduce foreign DNA, genetic alterations in human neoplasia entirely result from changes in structure and/or function of the cell's own genome. The proto-oncogenes are known or suspected to code for proteins acting as growth factors, growth factor receptors, secondary messengers that transduce signals through the cytoplasm, and transcription factors that regulate gene expression within the nucleus. In addition, the bcl-2 gene product appears to be localized on mitochondrial membranes and functions, not by stimulating growth, but by preventing the programmed cell death (apoptosis) of B lymphocytes.

The c-*myc* family and c-*ras* of proto-oncogenes are clearly important in human carcinogenicity, whereas, at present, no major role in human cancer has been found for *fos, myb, scr* or *jun*, which are central to normal mammalian cell growth and differentiation (Nowell, 1991). Nevertheless, oncogenes have been reported in 10–30% of human cancers (Slamon *et al*., 1984), and some less prominent oncogenes could act in collaboration with those that are more manifest. Exposure to some tumour promoters may cause transient increases in *fos, jun, sis* and *myc* expression; and in the case of c-*fos*, this transient expression in NIH 3 T3 cells gives a protein that activates or induces the synthesis of functions that accelerate mutation frequency (van den Berg *et al*., 1991). Oncogenes are capable of cell immortalization and transformation *in vitro,* and normally control a wide variety of cellular functions, such as proliferation, differentiation, morphology, intercellular communication and motility (Barbacid, 1987; Bishop, 1987). Their functions are affected by the cytogenetic processes mentioned earlier. For example, the t(9,22) translocation of chronic myeloid leukaemia results in the activation of the c-*abl* proto-oncogene, while t(8,14), t(2,8) and t(8,22) translocations in Burkitt's lymphoma all result in deregulated c-*myc* expression. There are many examples of proto-oncogenes located close to chromosomal breakage points in leukaemia and other neoplasms.

The prevalence of oncogenes in particular human tumours has its counterpart in chemically induced animal tumours. Some of these animal oncogenes show specific genetic changes involving growth factor receptors (*neu*), signal transducing systems (*ras*) or nuclear DNA-binding proteins (*myc*). The *ras* proto-oncogene mutations are particularly important and result in gene activation or amplification. The mutations are often consistently carcinogen specific (e.g. GT→TA transitions at the second base of codon 12 in H-*ras*, induced by methylating agents such as NMU (*N*-nitroso-*N*-methylurea (*N*-methyl-*N*-nitrosourea)) and MNNG (*N*-methyl-*N′*-nitro-*N*-nitrosoguanidine); AT→TA transversions at the second base of codon 61 in H-*ras*, induced by DMBA (dimethylbenz[*a*]anthracene)), but several polycyclic aromatic hydrocarbons other than DMBA do not induce consistent changes in the *ras* oncogene expressed in the induced tumour (Balmain and Brown, 1988).

Mutations in *ras* are, in some cases, very early events in carcinogenesis, but proto-oncogene activation may also occur late. In a transgenic mouse carrying *pim*-1, a single dose of ENU (*N*-ethyl-*N*- nitrosourea (*N*-nitroso-*N*-ethylurea)) induced lymphomas, most of which expressed K-*ras* or N-*ras*. However, the data suggested that at least some of the *ras* mutations were late events and therefore not induced by the NMU treatment (Breuer *et al*., 1991). Both NMU and ENU also induce gliomas and schwannomas in which *neu* is activated by specific TA → AT transversions within the transmembranal domain. However, adducts formed by NMU or ENU which might lead to this type of transversion have not been identified, so either the adduct is very minor but biologically important, or the activation of *neu* occurs late in tumour development (Balmain and Brown, 1988). Currently, this type of observation is sparse, but they could be important for the interpretation of data in which oncogene expression is found in advanced neoplasms.

3.2 Tumour Suppressor Genes

Malignant transformation cannot be described in terms of proto-oncogene activation. Familial studies have shown that mutations associated with loss of function are important in neoplasia and these are strongly supported by experimental work. Fusion of mouse fibroblasts with carcinoma cells, or fusion of two varieties of sarcoma, resulted in cells which were initially nontumorigenic (Harris *et al*., 1969). As the hybrid clones were cultured

in vitro, there was reversion to the malignant phenotype, which was always associated with loss of specific chromosomes. In mouse, the re-emergence of malignancy was strongly associated with the loss of chromosome 4 (Evans *et al*., 1982). In human/rodent cell hybrids, the reappearance of malignancy was also associated with the loss of certain human chromosomes, particularly chromosome 11 (Klinger and Shows, 1983). Powerful evidence for the insufficiency of oncogene activity for the malignant phenotype is the finding that the hybrid of normal fibroblasts fused with EJ bladder carcinoma cells, which contain an activated H-*ras* gene, are nontumorigenic, even though H-*ras* gene expression continued at high levels (Noda *et al*., 1983). Similarly, the tumorigenicity of K-*ras*-transformed mouse cells is suppressed when they are fused with nontumorigenic mouse cells, although the K-*ras* gene continues to be expressed at high levels (Craig and Sager, 1985). It also emerged from this kind of experiment that fusion of a transformed bladder epithelium cell line with differentiated normal bladder epithelial cells resulted in suppression of tumorigenicity, whereas fusion with undifferentiated fibroblasts did not (Summerhayes and Franks, 1979; Cowell, 1980; Cowell and Franks, 1984). Thus, factors were present in normal, differentiated cells which suppressed malignancy. The concept arose that these factors were coded for in antioncogenes, or tumour suppressor genes. A number of these genes have been reported for a variety of human tumours. Tumour suppressor genes are probably more interesting than oncogenes, since loss of genetic material occurs far more frequently than does activation of a gene function.

The *TP53* suppressor gene (tumour suppressor gene located on the short arm of human chromosome 17 and coding for the phosphoprotein p53) may be the most frequently involved gene in human carcinogenesis, and it is certainly one of the more frequently studied. Indeed, a TP53-specific database is available at the International Agency for Research on Cancer (IARC) (*http://www-p53.iarc.fr/index.html*). TP53 is contained within 16–20 kb of DNA in the short arm of human chromosome 17 at position 17p13.1. This gene codes for a nuclear phosphoprotein that plays a critical role in safeguarding the integrity of the genome. It is mutated or part of its regulatory circuit is functionally inactivated in a proportion of almost all human cancers (**Figure 1**). TP53 protein is a sequence-specific DNA-binding transcription factor that is normally at low levels in cells. Stress signals, such as DNA damage, can stabilize and activate TP53. The critical event leading to the activation of TP53 is the phosphorylation of its N-terminal domain. The N-terminal transcriptional activation domain contains a large number of phosphorylation sites and can be considered as the primary target for protein kinases transducing stress signals. This activation and stabilization results in a large increase in the half-life of the protein, which therefore accumulates in cells. Upon activation, TP53 binds to the enhancer or promoter elements of downstream target genes and regulates their transcription. Four cellular elements are involved in a regulatory circuitry: TP53, murine double minute-2 (Mdm2), $P14^{ARF}$ and E2F-1. These are organized in two interactive feedback loops. In the loop formed of TP53 and Mdm2, TP53 activates Mdm2 transcription, and Mdm2 negatively regulates TP53 by promoting TP53 ubiquitination and degradation. In the other loop, E2F-1 activates ARF (acute renal failure protein) transcription, and $P14^{ARF}$ facilitates the proteolytic degradation of E2F-1. The two loops interact in two ways. $P14^{ARF}$ interacts with Mdm2, thereby inhibiting Mdm2-mediated ubiquitination and degradation of TP53 and this, in turn, results in the stabilization of TP53 (reviewed in Jin and Levine, 2001).

The majority of *TP53* mutations in human tumours occur in the evolutionarily highly conserved domains in exons 5–8. The missense mutations are predominantly GT → TA transitions and > 95% code amino acids that are entirely conserved in mouse, rat, monkey and man (Hollstein *et al*., 1991). In squamous-cell carcinoma of the skin, however, UV-specific CC → TT double-base and dipyrimidine C → T substitutions are also found which apparently do not occur in *TP53* of internal organs (Brash *et al*., 1991). All mutations of this gene so far examined have lost the ability to suppress transformation. Some of these may be dominant negative mutations that inhibit the function of normal TP53 by complex formation, while others not only have lost suppressor activity, but also can act, with the p21 product of *ras*, as dominant, cooperating oncogenes. Interaction between the products of oncogenes and tumour suppressor genes has been described. In the case of wild-type TP53 protein, inactivation can presumably result from binding with the oncoproteins derived from several tumour viruses, for example, SV40 (simian virus 40) large T antigen, adenovirus E1B protein and papilloma virus E6 protein, as well as specific cellular gene products, for example Mdm2. Similar inactivation can occur with retinoblastoma gene product, $p105^{RB}$, which may play a role in transcriptional regulation (Mitchell, 1991) and is a binding target of the protein from transforming gene *E1A* of adenovirus-12 (Whyte *et al*., 1988; 1989), of SV40 large T antigen (DeCaprio *et al*., 1988) and of HPV-16 E7 protein (Dyson *et al*., 1989). These DNA tumour virus oncoproteins may, therefore, mediate transformation by inactivating the *RB* gene by forming a complex with $p105^{RB}$.

3.3 Genomics

There has been an enormous amount of study of individual tumour suppressor genes and oncogenes, but even that effort is fast becoming over-shadowed by what is now possible following the sequencing of the human

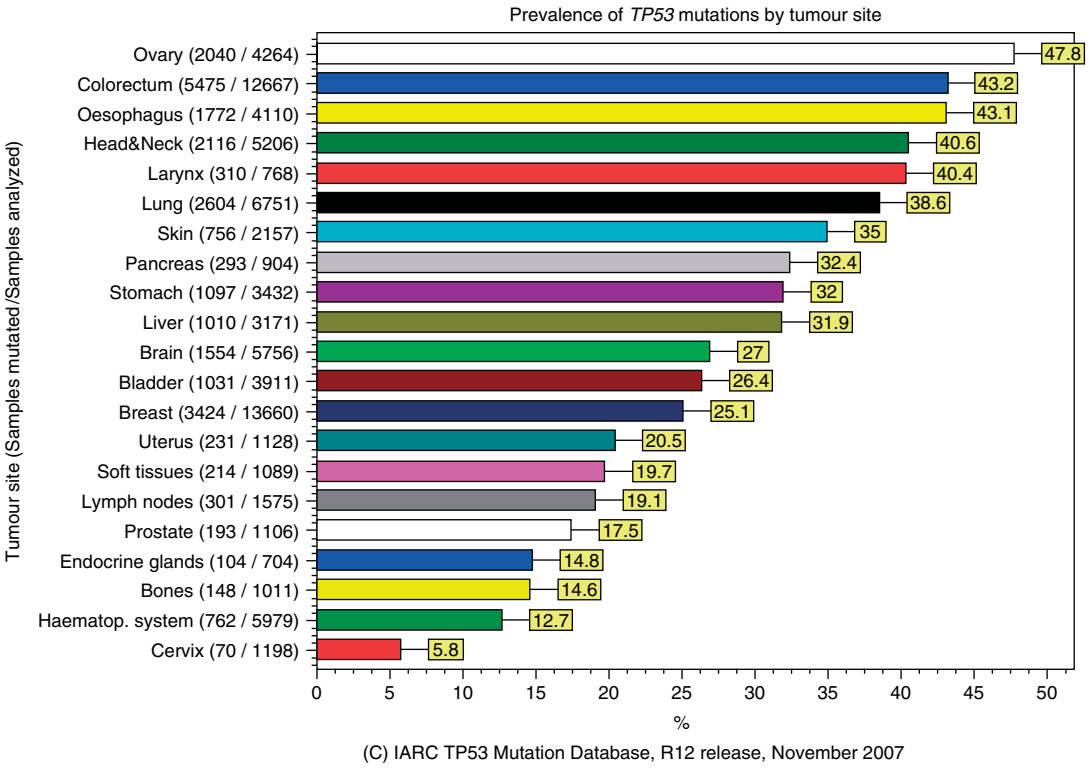

Figure 1 Prevalence of *TP53* mutations in human cancers. (Reproduced with permission from IARC.)

genome. Recently developed technologies have permitted the investigation and analysis of large fractions of the genomes of cancer cells to levels of detail that would have been unthinkable a decade ago. In spite of these advances that have made the identification of genetic alterations in cancers a goal that is attainable, it remains much more difficult to understand the precise role of these changes in the carcinogenic process. Previously, emphasis was placed on studying the very commonly occurring mutant genes of tumours (e.g. *TP53, APC* and *KRAS* in particular), but the data accumulated using the new technology show that the vast majority of mutations in cancers do not involve these genes. The data support the view (Beerenwinkel *et al*., 2007) that a large number of mutations, each associated with a small fitness advantage, drive tumour progression. Also, pathways, rather than individual genes, appear to govern the course of tumourigenesis (Vogelstein and Kinzler, 2004). The particular genes that seem to contain the driver mutations are quite different in different tumours, most mutated genes occurring in <5% of tumours. These differences in pattern across the genome may be responsible for the differences in characteristics observed in the individual tumours.

Analysis of exons representing 20 857 transcripts from 18 191 genes in DNA isolated from 11 breast and 11 colorectal tumours showed that the genomic landscapes of breast and colorectal cancers were composed of a handful of high-frequency mutated genes. In colorectal cancer these were *TP53, APC, KRAS* and, to a lesser extent, *Pik3CA* and *FBXW7*, while in breast cancer these were *TP53* and *Pik3CA*. In both organ cancers there was a much larger number of genes that were mutated at low frequency (Wood *et al*., 2007). However, most of the circa 80 DNA mutations that alter amino acids in typical cancers occur at very low frequency, and most of these changes may be harmless. There are <15 mutations likely to be responsible for tumour initiation, progression and maintenance (Wood *et al*., 2007).

It is generally assumed that, although these genetic changes are being observed in malignancies, they arise at all stages of the carcinogenic process, and it appears reasonable to assume that agents acting through genotoxic mechanisms are responsible for these changes. For carcinogens operating through a nongenotoxic mechanism it is assumed that there is a dose threshold below which an administered compound may not give a carcinogenic response, thus leading to a nonlinear dose–response relationship. Although for genotoxic carcinogens there may be a dose-threshold response due to a number of different protective mechanisms acting at different levels, it remains the default position that nonthreshold dose–response relationships exist for genotoxic carcinogens.

By analogy with the 'single hit' model of action of ionizing radiations (Lea, 1946), it has been proposed that, no matter how little it may be, any interaction of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

direct-acting genotoxic chemicals with the genetic material poses a finite probability of generating a response (McMichael and Wooward, 1999). Studies on covalent binding of substances that are both genotoxic and carcinogenic to DNA show a linear dose–response relationship in the low-dose range, with no indication of a threshold (Neumann, 1980; Dunn, 1983; Lutz, 1987; Beland *et al*., 1988). This might be thought to suggest a linear decrease of genotoxicity, and eventually of cancer risk, at low doses, and implies that exposure to even a single molecule of a genotoxic substance could produce DNA damage and thereby some degree of risk. However, a DNA adduct does not in itself have genetic consequences, but it needs to be fixed into a mutation through DNA replication. The probability that a DNA adduct becomes fixed is dependent on the rates of DNA repair and cell proliferation, both of which may be influenced by dose; consequently, there are likely to be deviations from linearity (Lutz, 1990). It is to be noted that a relatively high level of DNA damage is normally produced by physiological processes (Beckman and Ames, 1997). This suggests that the contribution of very low doses of substances that are both genotoxic and carcinogenic to background damage may be negligible. The saturation or overload of repair capacity at high doses (Pegg and Dolan, 1987) may result in increased mutation incidences and tumour yields. Moreover, chemicals which stimulate the rate of cell division or reduce cell cycle delay (which is required for DNA repair) enhance the fixation of mutations from primary DNA lesions. As an example, the stimulation of cell proliferation is believed to be responsible for the nonlinearity of bladder tumour induction in mice treated with 2-acetylaminofluorene (2-AAF) (Cohen and Ellwein, 1990), and liver tumours in rats treated with *N*-nitrosodiethylamine (Peto *et al*., 1984). As the high doses applied in carcinogenicity bioassays usually elicit significant toxicity with regenerative cell proliferation in target organs, simple linear extrapolation from experimental data to effects at low doses may lead to a considerable overestimation of the true incidence. Moreover, cancer is acknowledged to be a multistep process, where sequential steps consist of different genetic alterations driving towards the progressive transformation of normal cells into malignant derivatives (Hanahan and Weinberg, 2000). Because cancer is the result of multiple, independent genetic alterations, the incidence of cancer is theoretically expected to rise as a polynomial function reflecting the number of independent events required. This expectation also applies when the acquisition of increased mutability speeds up the entire process (Lengauer *et al*., 1998). This may result in a 'practical' threshold for carcinogenesis induced by genotoxic chemicals, similarly to other toxic effects arising from multiple molecular interactions (Kirsch-Volders *et al*., 2000). The possibility that DNA repair may cope successfully with low levels of DNA damage has been advocated as a putative mechanism for a biological threshold for genotoxic effects (Purchase and Auton, 1995). According to Preston and Williams (2005), most, if not all, chemicals that are DNA reactive in rodent species are DNA reactive in humans, although there may be quantitative differences. In addition, it is reasonable to assume, also as a qualitative conclusion, that the form of the dose–response curve for DNA-reactive chemicals is similar across species. This conclusion encompasses the important point that linearity is not the rule for DNA-reactive chemicals, but rather the default: nonlinear forms are observed and predicted (US Environmental Protection Agency, 2005).

4 THE GENOTOXICITY OF CARCINOGENS

Chemicals which increase carcinogenic risks have been categorized as 'genotoxic' and 'nongenotoxic', a process which can have effects upon the manner in which the chemicals are handled in the regulatory arena. Butterworth (1990) has defined a genotoxic agent as one for which a *primary biological activity* of the chemical or a metabolite is alteration of the information encoded in the DNA. Chemicals exhibiting such activity can usually be identified by assays that measure reactivity with DNA, induction of mutations, induction of DNA repair or cytogenetic effects (see **Mutagenesis**; **Cytogenetics**). Many of these assays have been considered to be predictive of carcinogenicity. Many human cancers are associated with exposure to such genotoxic chemicals and the formation of DNA adducts is an important early step in their mode of action. The key events that follow (Preston and Williams, 2005) are shown in **Table 1**.

Nongenotoxic chemicals are those that lack genotoxicity as a primary biological activity. While these agents may yield genotoxic events as a secondary result of other induced toxicity, such as forced cellular growth, their primary action does not involve reactivity with the DNA (see **Nongenotoxic or Epigenetic Carcinogenesis**).

Two assumptions are made in formulating this distinction: that genotoxic carcinogens are biologically active at all doses, and that nongenotoxic carcinogens have biologically significant effects only above a particular threshold dose. This division arises because genotoxic chemicals interact directly with nuclear DNA, of which there is basically a single copy within each cell (although there may be multiple copies of particular genes), while nongenotoxic chemicals react with non-DNA molecules, of which there are many copies. Thus, damage to non-DNA molecules will have biologically important consequences only when a sufficiently large proportion is inactivated so that first-order kinetics and their reactions are no longer followed. The validity of this division is questionable.

A chemical that interacts with DNA will also react with other nucleophiles, and these latter reactions are quantita-

Table 1 Key events for tumour development: DNA-reactive modes of action

1.	Exposure of target cells (e.g. stem cells) to ultimate DNA-reactive and mutagenic species—in some cases this requires metabolism.
2.	Reaction with DNA in target cells to produce DNA damage.
3.	Misreplication on damaged DNA template or misrepair of DNA damage.
4.	Mutations in critical genes in replicating target cell.
5.	These mutations result in initiation of new DNA/cell replication.
6.	New cell replication leads to clonal expansion of mutant cells.
7.	DNA replication can lead to further mutations in critical genes.
8.	Imbalanced and uncontrolled clonal growth of mutant cells may lead to preneoplastic lesions.
9.	Progression of preneoplastic cells results in emergence of overt neoplasms, solid tumours (which require neoangiogenesis) or leukaemia.
10.	Additional mutations in critical genes as a result of uncontrolled cell division results in malignant behaviour.

Reproduced from Preston and Williams, 2005. © Taylor and Francis Group.

tively dominant and could be as important in the carcinogenic process as the reactions with DNA. For no chemical is its mode of carcinogenic action fully understood; assumptions are always made that have greater or lesser validity. Consequently, the term used by the European Food Safety Authority (EFSA) (2005)—chemicals that are both genotoxic and carcinogenic—is less presumptive (although more clumsy) than the common term 'genotoxic carcinogens', which assumes a genotoxic chemical is a carcinogen *because* it interacts with DNA. The carcinogenic response might directly involve DNA damage, but this is seldom—if ever—sufficient to explain the response. Genotoxicity in general terms does not, by itself, prove that the carcinogen is acting through a genotoxic mechanism. It does not even provide evidence for this mechanism, although it does strongly suggest its plausibility. Also, genotoxicity can sometimes be found in the apparent absence of carcinogenicity.

A small number of agents (eight chemicals and one physical-chemical entity) have been evaluated by the IARC for which there is *evidence suggesting a lack of carcinogenicity in experimental animals* (italics as used by IARC). They are all listed in **Table 2**. Note that, of these, only caprolactam was classified in IARC Group 4; all others were classified in IARC Group 3. Indeed, since there were no epidemiological data available at the time of the evaluation, it could be argued that this classification of caprolactam was a demonstration of optimism rather than based on evidence from exposed people as well as laboratory animal experiments. Even though there have been no significant results from genotoxicity tests *in vivo* with caprolactam, significant results were obtained repeatedly in tests for chromosomal aberration and aneuploidy induction *in vitro* with human lymphocytes (Howard *et al*., 1985; Norppa and Jarventaus, 1989; Sheldon, 1989). However, for four of these nine agents, there were available reports of genotoxicity, not only *in vitro*, but *in vivo*.

In addition, styrene can induce lung tumours in mice following inhalation, gavage or intrauterine exposure. Mouse lung tumour incidence is increased following inhalation of 20 ppm styrene atmospheres, whereas the inhalation of even 1000 ppm styrene atmospheres is not carcinogenic to rats. Styrene is metabolized to styrene oxide and can form DNA adducts in mouse lung Clara and non-Clara cells; however, no O^6-guanine adducts were found in the lungs of mice exposed to 160 ppm or of rats exposed to 500 ppm, whereas O^6-guanine adducts were found in the liver of rats exposed to 1000 ppm styrene ($40/10^8$ nucleotides) (Otteneder *et al*., 1999). Hydroquinone is an example of a chemical that has clear genotoxic properties and is carcinogenic to the kidneys of male rats, but genotoxicity appears to play no role in the neoplastic response (reviewed in McGregor, 2007).

Nevertheless, genotoxicity is at least evidence that a chemical interacts with biological molecules to induce an adverse response. The demonstration of genotoxicity *in vivo* indicates that the responsible chemical is bioavailable and that it has the potential to interfere with biological processes, the disruption of which may play multiple roles in neoplasia, including initiation. Biological elements in this process could include, for example, some cell population death with subsequent proliferation of a fraction of the survivors, or loss of communication and homoeostatic control between cells within a tissue.

From another point of view, some carcinogens that are nongenotoxic may be involved in reactions which generate radicals and other charged species. The metabolism of xenobiotics usually involves the cytochrome P450 system, in which electron transfer to the xenobiotic substrate occurs with varying efficiency. Active oxygen species are inevitable products of this inefficiency, so, while neither the xenobiotic nor any of its metabolites might be involved in reactions with DNA, the potential for DNA damage always exists.

Many of the schemes of epigenetic modes of action that have been developed from observations on rodents and man involve disturbance of hormonal regulating networks, while others involve enzyme induction or enzyme inhibition and other expressions of toxicity. It is also clear that a property common to the proposed

mechanisms of action is the persistent stimulation of cell populations to divide, as a hyperplastic response either to toxicity or to mitogenesis; inhibition of apoptosis may also play a role. In many examples, the mode of action has been reasonably well established, up to the point where there is a cell population increase. Why hyperplasia should ever result in neoplasia is not well established, but the assumed mechanism until now has been that a shortened cell cycle time reduces the time for repair of 'background' damage to DNA and increases the probability of mutation. Thus, evidence of genetic toxicity can be important, even when an epigenetic scheme is reasonably supported by sound experimental evidence. For this reason, the IARC has consistently required that there should be no genetic toxicity associated with a substance if an epigenetic mechanism of carcinogenesis is to be accepted.

While intermitotic DNA damage and inefficient repair may be parts of the process, it is known that relatively short cell cycle times are also characteristic of several normal cell populations; for example, dermis, intestinal epithelium, haematopoietic tissues and, not least, throughout the development of embryos and early foetuses. Recognition of another possible process has been emerging from studies in molecular biology and protein chemistry. If a chemical reacts with DNA, then it is highly probable that it also reacts with various amino acids in proteins and peptides that, together with DNA and many other types of molecules, constitute chromatin. These proteins, including histones, are often involved in normal gene regulatory function. It has even been proposed that there is a 'histone code', based upon patterns of acetylation, methylation, phosphorylation and ubiquitination of basic amino acid histone tails protruding from the nucleosomes, that enables other proteins to recognize specific regions of the genome (Strahl and Allis, 2000). This may explain the link between the covalent chemical modification of histone proteins and the epigenetic regulation of gene activity. These patterns, probably coordinating with the methylation patterns that are a feature of CpG islands commonly associated with promoter regions (Antequera and Bird, 1993), determine whether particular genes are expressed or not. Interference with the activity or function of the methyl transferases, acetylases and deacetylases, and so on, may cause inappropriate phenotypic changes, which could include the silencing of repair genes or of tumour suppressor genes. Very important consequences of inappropriate methylation result when certain DNA repair enzymes are silenced, particularly *MLH1* (Nakagawa *et al*., 2001),

which leads to an increased microsatellite instability, and *MGMT*, which seems to precede mutations by occurring in premalignant polyps that do not yet harbour gene mutations (Estelier, 2000; 2001). Post-translational modifications of histones are involved in regulation of chromatin structure and gene activity. These modifications include the core histones H2A, H2B, H3 and H4, which have been extensively studied, and more recently H1, the linker histone, which is not only phosphorylated, but is now recognized as containing a range of phosphorylation, acetylation and methylation sites, as well as sites of ubiquitination and of lysine formylation residues (Wisniewski *et al*., 2007). This recent change in our knowledge of linker histone variations has been brought about by the use of functional proteomic techniques, principally mass spectrometry, to characterize these modifications, although the functionality of many of these sites remains to be determined (Godde and Ura, 2008). A proper understanding of their significance has still to emerge. For some investigators, the tendency for histone modifications to co-occur in groups has suggested that they are not creating an intricate code at all, although an alternative function of these modifications has not been suggested (Rando, 2007). For other investigators, the existence of combinations of structural modifications in histones has suggested that they are associated with distinct gene readouts, for example the methylated histone H3, H3K4me2, coincides with elevated expression levels only in combination with acetylation, while H3ac association with expression is reduced if there are other modifications to the histone (Fischer *et al*., 2008). Where these new avenues of research will lead is unknown, but it is becoming increasingly clear that the informational changes in normal cells that result in neoplastic transformation may be just as subtle as the changes that occur in normal differentiation and development, that is, far more subtle than would be expected from a blunt instrument like direct DNA damage and repair. It is incontrovertible that mutations are involved in neoplasia, but the way in which these occur may not be as obvious as hitherto assumed.

5 THRESHOLDS OF EFFECTS

For most toxic processes, excluding genotoxicity, it is generally assumed that there is a threshold of exposure below which no biologically significant effect will be induced (Dybing *et al*., 2002).

For genotoxic carcinogens where there is no dose threshold, a range of extrapolation models have been developed to estimate carcinogenic potency from animal data. The models include the One Hit, the Linearized Multistage Linearized Multistage model, the Weibull model, Logit model and Probit models. The simplest model is the 'One Hit' model, which leads to linear extrapolation and assumes the carcinogenic mechanism of action is a single event. The more complex models use the assumption of multiple events and interactions leading to a carcinogenic event. These models are described widely in the literature (Edler *et al*., 2002; European Food Safety Authority (EFSA), 2005; Committee on Carcinogenicity of Chemicals in Food, Consumer Products and the Environment (COC), 2004).

The demonstration of a threshold is normally not possible, even when nongenotoxic mechanisms are involved. Attempts to do so have fallen short of their objective because, although there might indeed be a threshold, statistical analysis of the data is also consistent with the absence of a threshold. As an example, Wanibuchi *et al*. (2006) considered that the dose response for GST-P (glutathione-*S*-transferase placental form) foci in the liver of rats administered very low doses of 2-amino-3,8-dimethylimidazol[4,5-*f*] quinoxaline (MeIQx) was consistent with such a threshold. Unfortunately, the graphical representations presented were not optimal (**Figure 2**). Later analysis showed that the 95% confidence interval associated with the curve included zero and so a threshold cannot be demonstrated (Slob, 2007). Erroneous graphical representations have occurred on a number of occasions (e.g. Waddell, 2002; 2003a; 2003b; Waddell *et al*., 2006) in this area of thought, always leading to the unjustified conclusion that a threshold has been demonstrated. If a legitimate graphical representation is used for cancer data, for example log-log scales, then it can be readily appreciated that it is impossible to demonstrate a zero response. This has been done in **Figure 3**, where cancer data from two very large experiments, one with *N*-nitrosodiethylamine (Peto *et al*., 1991a; 1991b), the other with 2-AAF (Farmer *et al*., 1980), are presented in which responses in the very narrow experimental ranges are shown on a log scale, as are the doses, presented as numbers of molecules of each carcinogen per kilogram body weight per day. A linear model was used and the 95% confidence limits are also drawn for extrapolations down to an incidence of one-in-a-million. It is interesting that there would appear to be several thousand molecules of carcinogen per kilogram body weight per day, even at this low extrapolated response. This dose expression can be further manipulated to give approximate numbers of molecules per cell. While one can feel justifiably uncomfortable with such a presentation, these graphs at least give some substance to the threshold discussion that would otherwise give free reign to the default assumption that as little as one molecule of carcinogen per DNA molecule is sufficient to initiate the carcinogenic process. Furthermore, the possible intervention of repair and other protective processes have not been taken into account. Since the possible threshold is in an area of the dose–response curve that is not experimentally

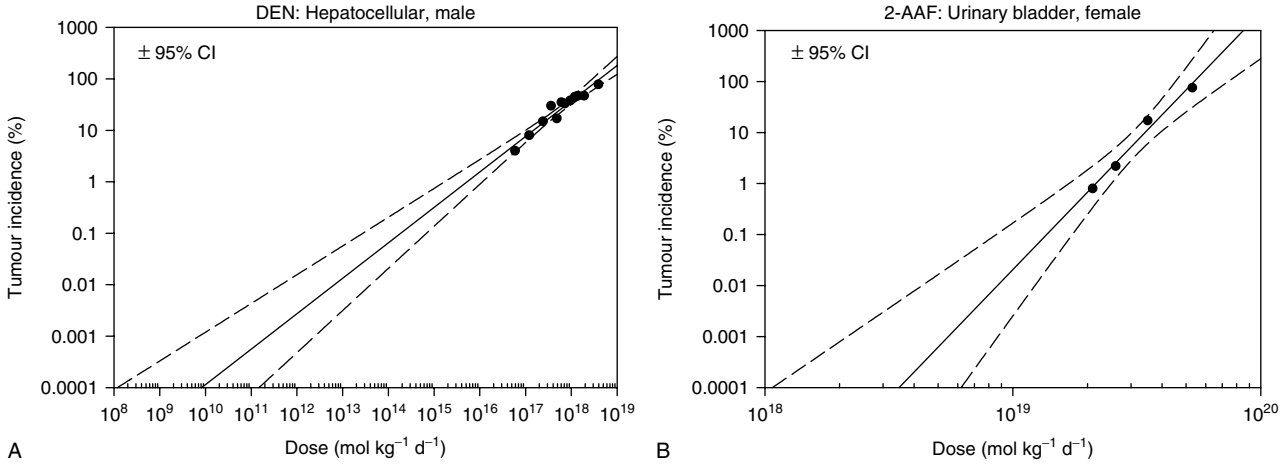

Figure 3 Extrapolations of tumour incidences to unobservable levels (1 in a million) following treatment of male rats with *N*-nitrosodiethylamine (DEN) (A) and female mice with 2-acetylaminofluorene (2-AAF) (B). (Data from Peto *et al*., 1991a; 1991b (A) and Farmer *et al*., 1980 (B).)

observable, it must be conceded that a threshold, or a practical threshold, might exist even if it cannot be demonstrated.

Even though the existence of a threshold cannot be proved or disproved experimentally, the presence of homoeostatic and cytoprotective mechanisms, and the abundance of cellular targets, mean that a minimum degree of interaction of the substance with the critical sites or their occupancy must be reached in order to elicit a toxicologically relevant effect (Dybing *et al*., 2002). Below this critical (threshold) level of interaction, homoeostatic mechanisms would be able to counteract any perturbation produced by xenobiotic exposure, and no structural or functional changes would be observed. In this context, some properties of Mdm2, an important component of the TP53 circuitry (see Section 3.2), following treatment with genotoxic substances are interesting. Phosphorylation of TP53 at Ser15 and Ser20 inhibits the interaction of TP53 and Mdm2, thereby resulting in an accumulation of TP53 (Meulmeester *et al*., 2005). Some early Mdm2 phosphorylations can also lead to TP53 stabilization (Shinozaki *et al*., 2003). DNA damage is one stimulus that results in such stabilization of TP53 and it has been found that nanomolar concentrations of benzo[*a*]pyrene, mitomycin C, etoposide and 5-fluorouracil can induce Mdm2 phosphorylation, while phosphorylation of TP53 requires higher concentrations (Malmlöf *et al*., 2008). Particularly interesting was the

discovery that higher concentrations of benzo[*a*]pyrene (7–10 μM), as well as exposure to the more mutagenic dibenzo[*a*,*l*]pyrene induced TP53 Ser15 binding and a histone, γH2AX, but did not induce Mdm2 binding. This outcome demonstrates that the Mdm2 response versus the TP53 and γH2AX responses in chromatin are mutually exclusive. Clearly, Mdm2 is a sensitive biomarker for at least some types of genotoxic activity. In addition, polycyclic aromatic hydrocarbon-induced Mdm2 binding to chromatin reflects repairable damage, whereas chromatin binding of TP53 Ser15 and γH2AX indicates more persistent DNA damage. There is certainly much more work to be done in this area, but there does seem to be a possible means for separating doses of at least some genotoxins into those that induce readily repairable DNA adducts, and doses that overwhelm the capacity for repair. If so, this would surely indicate a practical, if not an absolute, threshold.

Most, if not all, chemicals that are DNA reactive in rodent species are DNA reactive in humans, although there may be quantitative differences. In addition, it is reasonable to assume, also as a qualitative conclusion, that the form of the dose–response curve for DNA-reactive chemicals is similar across species (Preston and Williams, 2005).

6 RODENT CARCINOGENICITY TESTS

6.1 Test Design

The basic issues in chronic toxicity study design have frequently been described (e.g. Sontag *et al*., 1976; International Agency for Research on Cancer (IARC), 1980; 1986; International Life Sciences Institute (ILSI), 1997; Rhomberg *et al*., 2007); therefore, only some particularly troublesome issues will be mentioned here and the reader is directed to the references cited for more detailed discussion.

It is important to bear in mind that two-year studies are very expensive, take far longer than two years from design stage through to even the first steps in interpretation, and for these reasons the identification of carcinogens is usually only one of the objectives. A notable exception is the US National Toxicology Program (NTP) carcinogenicity assays in rats and mice, in which other systemic effects of a compound have been of secondary interest and there has certainly been no attempt to identify doses that are apparently without effects.

The rodent carcinogenicity test is usually designed as a hypothesis-generating experiment. As a generality, these tests should be followed by confirmatory experiments in which the hypothesis is tested. The scientific desirability of independent verification of a result, be it positive or negative, is, however, frequently lacking from these carcinogenicity data, often for reasons which are justifiable in terms of either animal welfare or—at first sight—finance, but not in terms of scientific method. The use of different sexes, strains and species does not form a basis on which data responsibility can be judged. Many 'standard' carcinogenicity assays have been subsequently repeated because the results from the first experiment could not be interpreted confidently. The multiple pairwise comparisons made in such experiments can result in apparent associations between tumour incidence and treatment which are statistically significant. Furthermore, if the investigators choose to analyse only the increases in tumour incidence, then any random nature of such associations is masked and it becomes more difficult to override them with other considerations.

Moderate control tumour incidences (e.g. 15–25%) can allow the statistically significant demonstration of both increases and decreases in tumour incidence. Partly because of prejudice, the presence of a decrease in tumour incidence (which occurs in many experiments) has often been viewed as an interpretative problem, whereas an increase can be more readily attributed to the action of the chemical under test.

If, however, in animals of the control group incidences of site- or tissue-specific tumours are low, then only increases in tumour incidence are likely to reach statistical significance, while if control group incidences are very high, then only significant decreases can be expected. In the latter case, the animal strain would probably be considered as inappropriate for this kind of experiment.

The currently accepted design for carcinogenicity testing is for rats and mice to be exposed for about two years. Rarely is any other species used and there are efforts to find ways of eliminating one of them—most likely mouse. For each species, 50 males plus 50 females per group are dosed with a vehicle or the test agent in that vehicle. Daily observations are made and, if animals become moribund during the experiment, then they are killed so that their tissues are not lost through autolysis. All animals are subjected to autopsy and almost 40 different tissues are taken from each animal for histological examination. All observations are recorded, summarized and analysed.

The objective is to expose a statistically acceptable number of animals to the highest dose that they will tolerate without reducing their lifespan for reasons other than tumour development. A series of preliminary toxicity tests is conducted, beginning by following some form of single-dose protocol. This initial study is followed by a 2-week and then a longer (4- or 13-week) toxicity study, the purpose of which is to identify a minimally toxic dose, as manifested by reduced body weight gain, reduced food intake, altered appearance or altered behaviour patterns and non-neoplastic histology observed at the end of the experiment. This is the so-called maximum tolerated dose (MTD) determination.

6.2 Maximum Tolerated Dose

There seems to be general agreement that this measurement is necessary, but there are differences over its definition or what should be done with it. Twenty-seven different guidelines were described by the International Life Sciences Institute for the selection of doses in chronic toxicity/carcinogenicity studies (International Life Sciences Institute (ILSI), 1984). Among these, the most commonly used definition is that adopted by the US National Cancer Institute (NCI) (Sontag *et al*., 1976) and the US National Toxicity Program. This states: 'The MTD is defined as the highest dose that can be predicted not to alter the animals' normal longevity from effects other than carcinogenicity.' In practical terms, the MTD is the dose which, in the three-month study, 'causes no more than a 10% weight decrement, as compared to the appropriate control groups, and does not produce mortality, clinical signs of toxicity, or pathological lesions (other than those that may be related to a neoplastic response) that would be predicted to shorten an animal's natural life span.' Ideally, this is precisely what should happen in the carcinogenicity test, but in reality the prediction of the MTD made on the evidence of sequential toxicity studies may be incorrect. In the carcinogenicity test, animals may die too early, thereby invalidating the study, or the predicted toxicity may not be realized, which invites the criticism that higher dose levels could have been used.

Other considerations in establishing the MTD value are metabolism and pharmacokinetics. Disproportionate changes in these parameters with increasing dose may signal saturation of metabolic pathways that are dominant at lower—and, therefore, more probably encountered—human dose levels.

It has been proposed, however, that metabolic and pharmacokinetic considerations should not be used to establish the MTD, but only to determine a lower dose level (International Agency for Research on Cancer (IARC), 1980; 1986). The use of inappropriate metabolism as a reason for reducing the importance of a carcinogenic response has been criticized (Haseman, 1985) on the grounds that it is up to the protagonists of this opinion to demonstrate '. . . explicitly how this overload produced carcinogenic effects.' It is indeed necessary to have a sound basis for introducing the argument of inappropriate metabolism and it would be preferable for this inappropriateness to be demonstrated in advance of the carcinogenic experiment; but the mechanism (as opposed to mode of action) leading to a carcinogenic response is not known in advance for any chemical at any dose level. It would seem to be sufficient to demonstrate a plausible metabolic overload mode of action supported by a reasonable amount of data. The evidence should be documented in a formal manner, as proposed in various publications, particularly those supported by the International Programme for Chemical Safety (IPCS) (Sonich-Mullin *et al*., 2001; Boobis *et al*., 2006).

Discussion of the MTD is important because it is clearly needed for the demonstration of a carcinogenic response in many instances. In the US NTP feeding studies (1979–1983), 62% (8/13) of chemicals were judged to be carcinogenic on the basis of effects observed only at the MTD; at 0.5 × MTD, no carcinogenic effects occurred (Haseman, 1985). The basic problem is that the rodent carcinogenicity bioassay as currently conducted is insensitive: in relation to human populations, the numbers of rodents exposed are exceedingly low. Hence, it is readily conceded that some means must be used to compensate for the low statistical power inherent in the assay and that the use of high dose levels may be one device by which this end can be achieved. At the same time, however, the use of such high dose levels does raise legitimate concerns regarding the mechanisms and relevance of carcinogenesis in these experiments.

It appears that the MTD is not required to demonstrate the carcinogenicity in rodent studies of those compounds known to be human carcinogens. Apostolou (1990) listed the appropriate rodent carcinogenicity data and doses for 13 human carcinogens to demonstrate that the lowest observed effective doses range from 0.005 × MTD to 0.5 × MTD. Since, in many cases, the MTD was not known but was assumed to be the highest tested dose, the real MTD fractions may be even lower than these estimated fractions in some cases. A conclusion one may reach from these data is that a carcinogen of potency sufficient to allow its detection at <0.5 × MTD in rodent tests is required before the relatively insensitive epidemiological methods permit detection in human populations. It would be wrong to conclude, however, that a substance showing a carcinogenic effect only at the MTD in the standard bioassay is not a human carcinogen. All that can be said of these compounds is that they may not be recognizable as human carcinogens by epidemiology, and this must remain a moot point unless we can demonstrate that the mechanism of tumour induction in rats or mice is dependent upon the minimally toxic effect.

6.3 Pathology

The primary information for carcinogenicity evaluation is generated by pathologists. These professionals, like any other group of professionals, vary in their training and experience, and these are characteristics which may influence the evaluation in a number of ways. Some of these are listed below.

1. Differences in terminology may be important when considering controversial lesions.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat077
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2. Lack of consistency throughout a study is likely when a pathologist has only recently become involved with rodent carcinogenicity. Training is usually in a clinical situation, where each animal is unique and there is not the same need for consistency as there is in a rodent carcinogenicity study consisting of 500 animals.
3. Unfamiliarity with the observed lesion in that particular species may cause problems in interpretation.

There is often, among nonpathologists, a suspicion that pathology is highly subjective and that pathologists are uncertain of their own discipline, as shown, for example, by a great reluctance on their part to evaluate tissues without prior knowledge of the treatment. Such criticism is unfair and, indeed, demonstrates a lack of understanding of biology in general and pathology in particular. Certainly, there is the possibility that treated animals might be examined more thoroughly than the controls and that knowledge of treatment of the animal might influence the terminology used to diagnose a lesion. But randomized, 'blind' slide reading is not the solution in the initial, routine evaluation of histological slides. If slide reading were 'blind', then there would be a loss of information about the controls, particularly in long-term studies, where many lesions in senile animals will be found. The other, sometimes stated, objection to 'blind' slide reading—that autopsy data are also important in diagnosis—is correct, but can be overcome through suitable coding of the information.

Possible bias introduced by knowledge of treatment can be corrected in several ways, but the use of a two-stage process would seem to be most efficient:

1. An initial evaluation is performed with full knowledge of the animal's history, including treatment.
2. A second evaluation of specific lesions is then carried out. This should be done blind, either by the same pathologist or, preferably, by the same and a second pathologist.

Differences in evaluation between pathologists should always be discussed by them to resolve these differences; they may be due to subtle differences in diagnosis and do not indicate incompetence in one of the pathologists. It is quite unacceptable for a study sponsor to shop around until he finds a pathologist who gives—for whatever reason—the result he is looking for without giving an opportunity for interaction with all of the other evaluators. Sometimes these diagnoses are given years apart, during which time understanding of the pathogenesis of lesions may change or there may be a change in the accepted definition of a particular lesion. In these circumstances even the first pathologist may not arrive at the same conclusion as he did some years ago.

Evaluation of the data is not purely a statistical exercise. A number of important factors should be considered, as follows: (i) dose–effect relationship; (ii) a shift towards more anaplastic tumours in organs where tumours are common; (iii) earlier appearance of tumours; and (iv) presence of preneoplastic lesions.

The language used to describe the carcinogenic response has masked its complexity and presents a stumbling block to its understanding among nonhistopathologists. Benign or malignant neoplasms do not arise without some precursor change within normal tissue. An important concept in carcinogenicity evaluation is that of neoplastic progression, which was derived from studies on skin tumours (Berenblum and Shubik, 1947) and expanded to a number of other tissues (Foulds, 1969; 1975). There is, on many occasions, a far from clear distinction between normal and hyperplastic tissue, between hyperplasia and benign neoplasia, and between benign and malignant neoplasia.

Hyperplasia and benign and malignant neoplasia are convenient medical terms with prognostic significance. Hyperplasia can occur either as a regenerative response to injury, with no neoplastic connotations, or as a sustained response to a carcinogenic agent. It is an increase in the number of normal cells retaining normal intercellular relationships within a tissue. This normality may break down, resulting in altered growth patterns and altered cellular differentiation, a condition which may be described as atypical hyperplasia or presumptively as preneoplastic lesions. There are found as sequelae of hyperplasia: (i) persistence without qualitative change in either structure or behaviour; (ii) permanent regression; (iii) regression, with later reappearance; and (iv) progression to develop new characteristics indicating increased probability of malignancy. The last of these is the least likely to occur in experimental multistage models, such as in mouse skin or rat liver, where large numbers of hyperplastic lesions may occur, but notably fewer carcinomas develop from them.

Benign neoplasms in most rodent tissues apparently arise in hyperplastic foci, for example, squamous-cell papillomas of the skin and forestomach. Furthermore, these papillomas seldom demonstrate autonomous growth and their progression to squamous-cell carcinomas is even rarer (Burns *et al*., 1976; Colburn, 1980). This decisive progression to carcinoma, when it occurs, provides powerful evidence for the multistage theory of carcinogenesis: the new, malignant cells arising as a focus within the papilloma or even in an area of hyperplasia, since the papilloma is not a necessary intermediate stage. In other organs, benign neoplasia is usually characterized by well-differentiated cell morphology, a fairly uniform growth pattern, clear demarcation from surrounding tissues and no evidence of invasion. The progression towards malignancy involves anaplasia (loss of differentiation) and pleomorphism (variety of phenotypic characteristics within the neoplasm). These changes

may be focal in an otherwise benign neoplasm and may vary in degree and extent. Evidence of invasion of the surrounding tissues or of metastasis are not essential characteristics of malignancy, although their presence strengthens the diagnosis.

6.4 Grouping of Tumours for Analysis

The grouping together of certain tumour types can be an asset to statistical analysis, but it must be done carefully, with full appreciation of the biology and whatever is known of the pathogenesis of the lesions. Grouping for analysis of all animals showing neoplasia, irrespective of the tumour type, is inappropriate because the incidence in most treatment control groups can be very high and, in US NTP studies, approaches 100% in rats and 50–70% in mice (**Table 3**).

There may be similar incidences of tumours in ageing people, but the real prevalence of tumours in human populations is uncertain. In the USA, it has been found that when autopsies are conducted, over one-third reveal previously undiagnosed cancers (Silverberg, 1984). A single type of neoplasm, renal adenoma, is present in 15–20% of all adult kidneys (Holm-Nielsen and Olsen, 1988), although it is unclear whether these 2–6 mm foci of proliferating tubular and papillary epithelium represent small carcinomas or benign precursors of renal cell carcinomas. Irrespective of the significance of these lesions in human pathology, the presence of similar foci in a rodent carcinogenicity experiment would trigger the recording of renal tumour-bearing animals and, hence, their consideration in the statistical and pathological evaluation processes.

The independent analysis of every different diagnosis in rodent studies would also mask significant effects in many cases, while enhancing them in others. Benign and malignant neoplasms of a particular histogenesis are often grouped because the one is seen as a progression from the other. However, this grouping may result in a nonsignificant difference from the controls because there has been an acceleration of progression towards malignancy, the incidence of benign neoplasms decreasing while the malignant neoplasms increase. Guidelines are available for 'lumping' or 'splitting' tumour types (McConnell *et al*., 1988), but in using them, the basis for the classification of neoplastic lesions should be clarified, especially when data generated over several or many years are coupled, since diagnostic criteria and ideas regarding tumour histogenesis may have changed. Reliance on tabulated results alone can lead to serious misinterpretation by those not closely connected with a particular study. For this very important reason, the pathology and toxicology narrative should be full and clear. If it is not, then there will always be doubts about future interpretations, even if these doubts are not, in reality, justified.

6.5 Historical Controls

The use of historical control data, to either support or refute an apparent treatment-related response, assumes that there is a greater stability in the accumulated data variation than in the much smaller concurrent control group and that the experiments performed over a period (perhaps several years) were done under identical conditions with animal stocks which did not vary. If these conditions were to be met, then the larger historical control group would provide a basis for increasing the

power of the assay. When a higher incidence of a tumour that is rarely seen in untreated controls (e.g. brain tumours in rats) is found in treated animals, or when an unusually low incidence of a tumour type that normally has a variable and often high incidence is found in controls with respect to treated animals (e.g. mammary tumours in rats), a comparison with historical control data may provide a clearer insight into the possible biological significance of the finding. Various factors can influence the incidence of spontaneous tumours in rodents (van Zweiten *et al*., 1988), but it is clear that flaws in the randomization process are not commonly considered. An unexpected incidence of tumours in a control group might suggest some bias in the distribution of the animals to their groups at the beginning of the experiment. If such bias has been properly eliminated, then the unexpected incidence should also have occurred in the treated groups. The absence from the treated group of an anomalous low incidence indicates a treatment effect. Thus, a high tumour incidence in a treatment group claimed to be within the historical control range and therefore not attributable to treatment only indicates that, in the absence of randomization bias, if the control group tumour incidence had been in the expected range, then the treatment group incidence would have been higher. However, it is probable that, in most situations, it cannot be assumed that conditions have remained constant over years and it cannot be assumed that animal stocks have not changed with time.

Outbred strains, such as Sprague Dawley (SD) and Wistar rats, are genetically variable. The strain characteristics vary both with time and with the colony from which they are derived. MacKenzie and Garner (1973) showed how SD rats from different suppliers differed substantially in their incidence of spontaneous neoplasms. It has also been shown that Wistar rats from four colonies exhibit substantial genetic differences (Yamada *et al*., 1979) and there appears to be considerable overlap in the genetic characteristics of SD and Wistar rat strains, which cannot be reliably distinguished from each other. A further important characteristic of Wistar rats is that the degree of heterozygosity (a measure of inbreeding) varied in the Yamada *et al*. (1979) investigation from 0% (i.e. this supply of 'outbred' Wistar rats was fully inbred) to 38%. Thus, at most, the outbred strain had only one-third of the heterozygosity that was expected of a fully outbred population and the variability in this value would, in most cases, be unknown because it is not normally checked.

The arguments for the use of outbred as opposed to inbred stocks for certain types of study are two-fold (Gill, 1980): (i) they serve as better models for human populations, which are heterogeneous; and (ii) heterogeneity is particularly useful for first-level screening.

Both proffered reasons, however, are similar and refutable by the same argument. An experiment with outbred animals that would truly mimic a human population would require very large numbers. Because only a portion of the exposed animal population might be responsive, the sensitivity of the assay performed could be low unless this factor was incorporated into the design. However, since the heterozygosity of so-called outbred strains is both low and variable, the modelling objective is confounded from the start. While it is not the only outcome, one important result from the use of outbred animals is that a biological unknown factor is introduced which can lead to difficulties in reproducing an effect with the 'same' outbred strain, adding to confusion in the literature, and the total unreliability of carefully accumulated historical control data to which reference can be made with well-recognized statistical methods.

Many of these problems should be overcome, theoretically, by the use of isogenic strains. Where these are used and—an important caveat—the environmental conditions have been constant and well-controlled, historical control data may be useful, particularly in the assessment of rare events, such as the occurrence of uncommon neoplasms. Isogenic strains are the result of brother–sister mating for >20 generations and F_1 hybrids between such strains. No strain can become fully inbred, but for all practical purposes they can be considered as a stock of genetically identical individuals which can be characterized and, within similar environmental conditions, they can be expected to exhibit the same phenotype over time and in different laboratories (Festing, 1990). However, in spite of the expected lower variance in isogenic strains, when tumour incidence is considered the results are disappointing; there are for example, substantial differences in the experiences of laboratories using F344 rats (Tarone *et al*., 1981; **Table 4**).

The reliability of the historical data is increased when variables are minimized by considering experiments in the same laboratory, with the same strain of animals from the same source and kept under the same husbandry conditions, and where the pathology is evaluated by the same pathologist. Peer review can aid pathology evaluation when different pathologists have been involved in the studies. Also, reliability increases when the data are derived from studies temporally close (e.g. three to five years) to the study in question. Even when historical control tumour data are peer-reviewed and re-examined with uniform and currently acceptable criteria applied, differences in the incidences of certain tumours do occur with time (van Zweiten *et al*., 1988). These authors also point out that the incidence of non-neoplastic changes in shorter studies (e.g. 13 weeks) also varies. In general, the best controls are those concurrent with treatment; resorting to historical controls should be done with great caution and only to support an apparent effect, not to refute one.

6.6 Evaluation of High-Dose Effects

Given at a sufficiently high dose level, any chemical will induce biological damage. This is an understanding in toxicology that is beyond dispute. This position was tentatively advanced a step further by several people as a result of the examination of carcinogenicity data from tests conducted at the MTD. It gave rise to the notion that carcinogens might be recognizable by their systemic toxicity, although there is not necessarily a causal connection. The possible tautology of the correlation was discussed in the literature (Bernstein *et al*., 1985; Crouch *et al*., 1987) and the experimental evidence for the hypothesis was restricted to a small number of chemicals. Thus, among 99 chemicals tested for carcinogenicity and site-specific toxicity in long-term rodent studies by the NTP, only seven of the 53 which were shown to be carcinogenic exhibited target organ toxicity that could have been causal to the observed neoplasms (Hoel *et al*., 1988). Nevertheless, correlations as high as 0.79 were calculated for mouse LD_{50} and TD_{50} values (TD_{50} is that chronic dose rate in mg kg^{-1} body weight per day that would give one-half of the animals tumours within some standard experimental time (the 'standard lifespan' for the species)) among the NCI/NTP carcinogens (Zeise *et al*., 1986), although the correlation was reduced to 0.73 when non-NCI/NTP data were included in the analysis (Metzger *et al*., 1989).

The effects upon the physiology of rodents of life-long exposure to doses in the neighbourhood of the MTD may be expected to be so severe that some perturbation of the ageing process incidence is inevitable (Salzburg, 1989). In the case of a pharmaceutical substance given at a dose which inhibits almost all of some particular aspect of biological activity, the animal is driven into altered equilibrium as a consequence of the changed biochemical milieu. The toxicity engendered by such treatment may be a response to the desired, but exaggerated, pharmacology; but drugs seldom—perhaps never—have a single action and there may be substantial biological effects which were not designed into the drug. These effects will be of an unspecified nature characteristic of any chemical, and so concern regarding effects on ageing could be extended to any substance submitted to a lifespan, high-dose animal experiment. Since the development of most neoplasms is age related, tumour incidence would be one of the factors affected, the response being manifest as either an increase or a decrease in tumour yield. Among 170 NCI studies published as of 1980, 97% showed statistically significant dose-related modifications in at least one species or sex and 70% of them showed statistically significant dose-related modifications of tumour patterns that involved one type of tumour increasing with dose, while another type of tumour was decreasing with dose (Salzburg, 1983). The same situation prevails with the more recent NTP data, at least up to 1986 (Salzburg, 1988). Theoretically, high-dose effects on tumour incidence need not be primarily on the organ or tissue in which the change is found, particularly if hormonal control mechanisms are involved.

In an attempt to accommodate these conflicting responses within experiments, Salzburg (1989) used principal component analysis to describe a tumour profile, which is a weighted combination of site-specific tumours; nonparametric techniques are then used to compare these tumour profile scores across groups. However, this combination technique has been criticized by Haseman (1990) for having no biological significance

and for being misapplied to experiments in which the resulting differences in tumour profiles were due to survival differences and data coding errors. Nevertheless, the problem of increases and decreases in the incidence of different tumour types is one which must be faced and not simply brushed aside, although interest in this issue appears to have waned in recent years.

6.7 Identification of Noncarcinogens

Since the proof of a negative statement is philosophically impossible, then the identification of chemicals which can be said to have no carcinogenic potential is also impossible. The most that can be said regarding carcinogenic inactivity is that activity has not been demonstrated within the operational definition that has been selected. This operational definition includes a testing programme restricted to rodents and a statistical power which varies from experiment to experiment according to the number of animals at risk in control and treatment groups from particular tumour types. While rejection of the null hypothesis is always presented in reports, the power of the experiment to demonstrate its rejection is seldom, if ever, presented when no significant treatment effect has been shown. This is not identical with asserting that all chemicals are carcinogens, although this may also be correct, provided that the circumstances in which carcinogenicity becomes recognizable can be defined. This kind of reasoning may lead one to conclude that there is no strict dividing line separating carcinogens from noncarcinogens, and that epidemiological or laboratory studies of a particular power may fail to demonstrate an effect, whereas a higher-power study may do so.

There is a very high prevalence of carcinogens described in the open literature today, in contrast with the situation to be found 20 years ago. Gold *et al*. (1989a) reported a prevalence of 51% among 955 chemicals tested and entered into the Carcinogen Potency Database (CPDB). This included the NCI/NTP data, where the prevalence was 48% among 251 chemicals (currently the prevalence is 54% among 301 chemicals). Yet, in 1969, Innes *et al*. reported their results with 120 chemicals, largely pesticides and industrial chemicals, in which the prevalence of carcinogens was only 9%. It is plausible that the 9% prevalence of carcinogens in the Innes *et al*. (1969) study is partially due to low statistical power, low doses and short observation time.

6.8 Transgenic Animals in Carcinogenicity Testing

Advances in molecular biology have opened up the possibility of approaches to carcinogenicity testing differing from more traditional approaches. Specifically, the transfer of new or altered genes to the germ-line of mammals has produced transgenic animals that can then be used in short-term *in vivo* tests for carcinogenicity, and may be useful for research into the characterization of critical, genotoxic events in carcinogenesis. In looking for alternatives to lifespan studies (that are so expensive and often provide results that are contentious), much consideration has been given to models involving proto-oncogenes and tumour suppressor genes. These classes of genes have been highly conserved in evolution and are therefore likely to be similar in man and inbred strains of rats and mice. Also, they are known to have key roles in the early and late stages of carcinogenesis in both man, where the aetiology is usually unknown, and in rats and mice used in experiments, where there is a high probability that the causative agent is the test substance administered.

A number of transgenic and knockout models are available and the results obtained so far with three—Trp53+/−,Tg.AC (zeta globin-promoted v-Ha-*ras*) and CBF_1-Tg-H*ras*-2 (originally *ras*H2) mice—indicate that the models can be useful if the outcomes are suitably interpreted.

Heterozygous *p53*-deficient mice (with one wild-type and one null allele) on a C57BL/6 genetic background have a low spontaneous tumour incidence up to 12 months of age. Mice that are homozygous for the null allele generally have a high incidence of spontaneous tumours within the first three to six months of life. Thus, induced deletion of the active allele in the heterozygote will lead to an increase in tumour incidence. This model responds to carcinogens that are genotoxic, although responses are not restricted to genotoxins.

Tg.AC mice on an FVB/N genetic background carry multiple copies of a v-Ha-*ras* oncogene fused to the promoter of the mouse zeta globin gene. An important characteristic of the model is that the skin has the characteristics of genetically initiated skin, and untreated skin appears normal in comparison with the skin of the wild-type FVB/N parent strain. The incidence of spontaneous skin papillomas in untreated mice is very low to zero in a standardized protocol of dermal exposure for 20–26 weeks. Skin papilloma is the most commonly reported response, but other target sites are affected by both mutagenic and nonmutagenic carcinogens. Specific activation of the expression of the transgene is the critical event underlying responses in the model. Since induction of transgene expression can be achieved either by treatment with known carcinogens or tumour promoters or by full-thickness wounding of the skin, 'false-positive' responses might be induced by a chemical that induces some epidermal toxicity; such responses have not been observed, but the possibility should be recognized.

Table 5 Performance of transgenic assays for carcinogenicity as judged against the National Toxicology Program (NTP) carcinogenicity test results in rats and mice

Assay	a. Positive for carcinogens	b. Positive for noncarcinogens	c. Negative for carcinogens	d. Negative for noncarcinogens	Sensitivity*	Specificity**
Trp53+/−	7	0	16	12	7/23 30%	12/12 100%
Trp53 (genotoxins)	7	0	4	5	7/11 64%	5/5 100%
Tg.AC	14	2	14	10	14/28 50%	10/12 83%
*ras*H2	15	0	8	9	15/23 65%	9/9 100%

*Sensitivity = a/(a + c).
**Specificity = d/(b + d).

CBF_1-Tg-H*ras*-2 transgenic mice carry five or six copies of a human c-Ha-*ras* proto-oncogene which is expressed in both tumours and normal tissues.

These three transgenic models were originally evaluated in several laboratories, and each model has been used in at least two laboratories to test chemicals for carcinogenicity (Tennant *et al*., 1998). The available data from 26-week tests indicate that these transgenic models with neoplastic end points could be considered appropriate for identifying carcinogens and tumour promoters. Nevertheless, the limited range of chemicals evaluated to date left the uncertainty that agents that act through pathways other than those altered in the transgenes may not be detected, and the possibility that noncarcinogens may be identified as carcinogens. A more recent evaluation (Pritchard *et al*., 2003) has permitted a larger number of chemicals to be tested in these three models, although, by the standards set by *in vitro* predictive models, the numbers remain low. In **Table 5** it can be seen that, when evaluated against the US NTP standard two-species assay for carcinogenicity, the specificities of these assays are high, whereas their sensitivities are low. Thus, a significant response in one of them is indicative that the chemical would have a high probability of also producing a significant response in a two-year assay. Unfortunately, a nonsignificant response would give little assurance of a similar result in our traditional carcinogenicity tests. This outcome is highly reminiscent of some of the genotoxicity tests that were developed as short-term tests predictive of carcinogenicity (McGregor *et al*., 1999).

7 CARCINOGENIC RISK ASSESSMENT AND MANAGEMENT

These concluding paragraphs may appear ludicrously brief, but my intention is not to describe and discuss the various ways in which regulatory authorities treat data from experiments for carcinogenic potential in animals or the rarer, more complex data from human epidemiology. My intention is only to make a very few general statements.

Firstly, if risk assessment is separate from risk management and risk assessment is a purely scientific process while risk management includes not only these conclusions, but also the contemporary wishes and opinions of society, then this difference should be fully recognized. Currently, there is a tendency for risk assessors to step beyond their strict limits of scientific evaluation and include, notably, the 'precautionary principle'. Of course, this should be a part of safe-guarding human health as far as possible, but there is a danger that the principle can be invoked twice: once in risk assessment and again in risk management. The outcome of this double application is not precautionary, but overly protective.

Secondly, and following from the first, risk assessors must state their evaluations and reasons for them very clearly and unambiguously. When a text is read by another person, it will frequently be interpreted in a sense different from that intended by the writer. It is, therefore, necessary to try to reduce this margin for different interpretations as much as possible.

Thirdly, carcinogenesis is a complex and incompletely understood process. It is therefore necessary to keep an open mind in order to stand any chance of reaching an understanding. Dogma has no place in risk assessment—and neither do default assumptions. If these are to be used in the protection of human health, it is the task of the risk managers to implement them, although it remains the duty of the risk assessors to indicate where they could be reasonably considered.

Nongenotoxic or Epigenetic Carcinogenesis

Christopher J. Powell and Sir Colin Berry

CONTENTS

1 INTRODUCTION

For most, if not all, tumours, heritable changes in the genetic material provide *the* fundamental alteration in cellular biology which results in the production of a neoplasm. However, it is clear that there are many mechanisms by which this process may occur and that epigenetic events, either acting alone or in concert with genetically determined events, may produce tumours. This process, of epigenetic carcinogenesis, is best considered in terms of specific examples, as generalizations are difficult in this field, despite the frequency with which they are employed. Nevertheless, it is reasonable to say that in *many* examples of epigenetic carcinogenesis, the affected tissues show a predictable sequence of changes, including hypertrophy, hyperplasia and a loss of uniformity of cellular response, with focal hyperplasia, adenoma and

possible progression to adenocarcinoma as a consistent sequence.

1.1 Definition

The term 'nongenotoxic' is usually applied to chemicals which cannot be shown to interact directly with, or cause damage to, DNA in a number of short-term screening tests, but which none the less are capable of producing tumours in laboratory rodents by the conclusion of a bioassay.

This definition is pragmatic, and is used because it is neither practicable, desirable nor appropriate to subject a chemical to all possible types of genotoxicity test in order to exclude DNA reactivity. Moreover, some types of DNA damage are not detected by present test methods and there are examples of difficulties of interpretation where genotoxicity testing *in vivo* has given different results to those obtained *in vitro* (see **Mutagenesis**; **Cytogenetics**; **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**). Generally, *in vivo* tests are considered more relevant for human-risk assessment because they allow for the complexity of tissue distribution, kinetics and metabolism. Rather unhelpfully, some authors continue to interpret nongenotoxic as meaning 'all chemicals which are not mutagenic in bacterial test systems' (Lee *et al*., 1995), a source of confusion for those unfamiliar with this subject.

1.2 Bioassays and Mechanistic Studies

Normally, an animal carcinogenesis bioassay would not be performed with a chemical that was clearly positive in genotoxicity tests *in vivo* and, in this sense, a carcinogenesis bioassay is a test for nongenotoxic carcinogenicity. Consequently, for a chemical of commercial interest, the potential or actual existence of a nongenotoxic mechanism only comes to light towards the end of a development programme, which in the case of a new drug is after four to five years of intensive research and the expenditure of several tens of millions of pounds, dollars or euros. For commercial reasons it is therefore often worth investigating whether a nongenotoxic mechanism, which operates in a rodent at high exposure levels, is likely to be relevant for humans. This type of mechanistic study has most frequently been performed in the rat rather than the mouse, because of: (i) the greater biological significance attached to positive results in the former species and (ii) the perception that the mouse may be too small to be practicable for mechanistic studies—a view certainly not relevant for molecular studies.

2 GENERAL FEATURES OF NONGENOTOXIC CARCINOGENS

Certain general statements can be made about many nongenotoxic carcinogens. However, with what can be described as a 'mixed bag' end point reached by many routes, there are many exceptions. The general characteristics include:

- They are nonmutagenic
- They show no evidence of other direct chemical reactivity with DNA
- There are no common chemical structural features between chemicals
- Dose-threshold effects are clearly evident
- The effects of a particular compound are usually limited to one organ and/or species
- Carcinogenic potency is lower than that of genotoxic chemicals.

A large number of the chemicals tested for carcinogenicity in rodent bioassays by the National Toxicology Programme (NTP) in the USA have been characterized as nongenotoxic carcinogens, the most common target organ for these chemicals being the liver (**Figure 1**), with a variety of other glandular tissues as less frequent targets.

2.1 Mechanisms

Comparatively few examples of this process have been studied in sufficient detail to justify the claim that a 'nongenotoxic mechanism' is well understood. A number of mechanisms have been identified (**Table 1**), several of which are considered in more detail in the examples hereafter.

3 THYROID CARCINOGENESIS

Hormonal feedback loops, changes in thyroid hormone synthesis, altered cellular receptor activity, variation in rates of hormone release and metabolism, and direct interference with cell function may all operate to produce the sequence of growth leading to neoplasia in the thyroid gland. Thyroid neoplasia may develop following any stimulus which results in prolonged and excessive thyroid stimulating hormone (TSH) secretion.

Bircher (1910) first reported thyroid nodules in the rat due to iodine deficiency, and Axelrod and Leblond (1955) used a low-iodine diet to induce thyroid neoplasia in this species, with the occurrence of pituitary tumours in the test animals, suggesting over-stimulation of that gland.

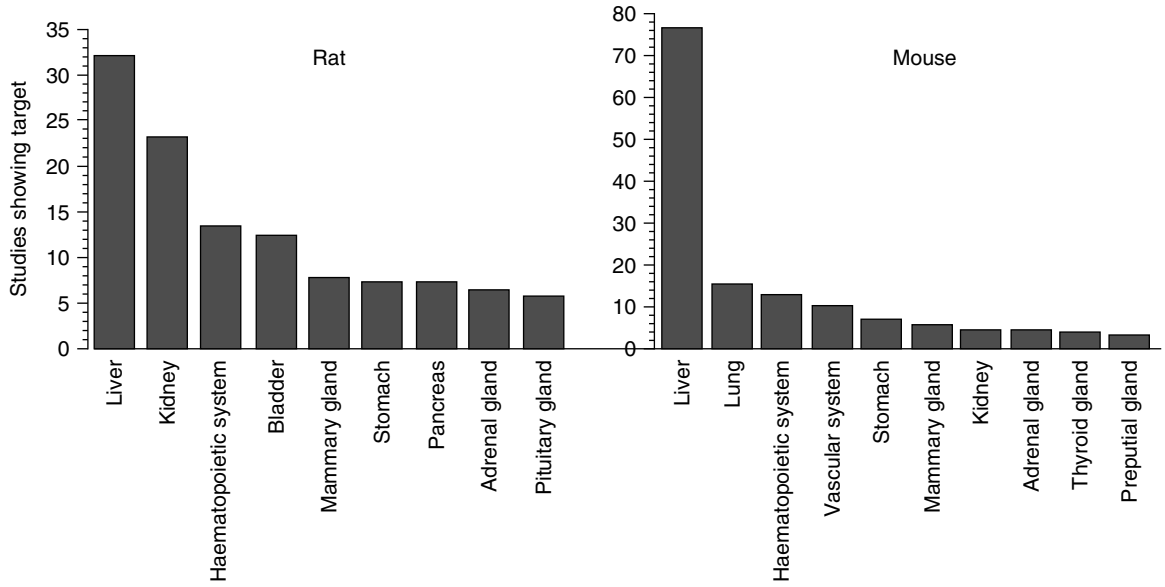

Figure 1 Tissue target sites for nonmutagenic carcinogens. Data from 175 positive NTP carcinogenicity studies. (Reproduced from Gold et al, 1993. © Elsevier.)

Table 1 Proposed mechanisms of nongenotoxic carcinogenesis

Mechanism	Reference
Chronic stimulation of cell proliferation via chronic cytotoxicity or persistent supraphysiological levels of trophic hormones	Melnick *et al*. (1993)
Inhibition of cell death (apoptosis) in DNA-damaged cells	Schulte-Hermann *et al*. (1995)
Impairment of DNA-replication fidelity	Umar and Kunkel (1996)
Inhibition of replication error or unscheduled DNA repair, that is, mutator phenotype	Kaufmann and Kaufman (1993)
Inhibition of gap-junctional intercellular communication	Yamasaki (1995)
Persistent immunosuppression	Cockburn and Krupp (1989)
Altered methylation status of genes controlling cell growth or differentiation	Jones and Gonzalgo (1997)
Dysregulation of karyokinesis, producing aneuploid cells	ECETOC (1997)

Subsequent experiments produced tumours following. TSH administration (Sinha *et al*., 1965). In man, excessive production of TSH occurs in chronic iodine deficiency or following subtotal thyroidectomy, and may be accompanied by neoplasia. The sequence is most clearly evident in dyshormogenetic goitres, where failure of the production of thyroxine leads to pronounced pituitary drive. Increased production of TSH due to inadequate levels of thyroid hormone production may be induced by any of the following failures of the mechanisms of normal thyroid metabolism in dyshormogenesis:

- Failure of iodine trapping
- Peroxidase deficiency, resulting in the failure of intrathyroidal iodine binding
- Failure of iodotyrosine coupling
- Dehalogenase deficiency leading to failure of deiodination of iodotyrosine residues
- Production of abnormal iodoproteins due to defects in thyroglobulin synthesis.

In humans with this type of thyroid disease, the gland may become very large and glands with weights of several hundred grams were not uncommonly found in the past. Nodules are almost invariably present, and microscopically, hyperplasia, often with many cells with pleomorphic nuclei, is inevitable. It is important to note that, rather like some experimental lesions, the progression of these changes to truly malignant behaviour with metastasis is rare (Crooks *et al*., 1963).

In animals, experimental work has shown that the pattern of stimulation of the gland by TSH is also critical, both duration and continuity being important. In general, a period during which the TSH level is allowed to return to normal has a protective effect with regard to tumour production. Goitrogen-induced alterations in the normal pattern of thyroid growth occur in three phases (Stringer *et al*., 1985). There is initially a rapid growth

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

phase (four to eight weeks), followed by a period in which growth is limited, but where the important change of loss of normal response of thyroid follicular cells to normal growth mechanisms occurs (see below). This is followed by the appearance of multiple follicular cell proliferation (tumours).

In the initial rapid growth phase, cell proliferation begins at concentrations within the normal physiological range of TSH levels, but growth responsiveness continues to well above this. In the plateau phase, a growth response can still be obtained to non-TSH stimuli (wounding), but the proliferative response to TSH is lost, although the functional response is preserved. These results were obtained in dissociated cells and were therefore not attributable to locally acting factors dependent on tissue organization. Naturally occurring goitrogens are found in cabbage leaves, Brussels sprouts, turnips and mustard. Goitrin (L-5-vinyl-2-thiooxazolidone), the active goitrogen in turnips, is about as active as propylthiouracil (Haynes and Murad, 1985), and although TSH production may be increased after exposure to naturally occurring goitrogens, a role in thyroid carcinogenesis in man seems unlikely.

3.1 Effects of Drugs

It is simple to identify the steps in thyroid hormone synthesis and release, and to identify the drugs likely to affect the processes involved. However, there is a need for caution, since extrinsic factors may affect target cell sensitivity and the pattern of exposure will affect the outcome dramatically. When the effects of the various factors acting on the demand for, and degradation of, thyroid hormone are added (see **Figure 2A**), a more complex picture generally emerges *in vivo.* It is important to note, however, that the simultaneous administration of goitrogenic drugs (such as thiouracil or thiourea) and thyroid hormone has been shown to prevent the development of follicular cell neoplasia.

Some highly specific effects have been characterized. Aminoglutethimide was widely used as an anticonvulsant until reports of the development of goitre in children on the drug appeared. The drug acts directly on the thyroid cells by reducing the production of thyroxine and diiodotyrosine. The drug does this by inhibiting iodine organification in a concentration-dependent manner, with no effect on I^- uptake by the cells. The related compounds glutethimide, nitroglutethimide and acetylaminoglutethimide had no effect, which suggests that the effect depended on a free amino group in the phenyl ring of the molecule (Brown *et al*., 1986). The increase in thyroid gland size is thus triggered by a very clear metabolic block. Blockage of effective thyroid function may be produced by more than one mechanism. Bromide inhibits the uptake of iodine by the thyroid gland and inhibits the oxidation of iodide to iodine, and thus the incorporation of iodine into tyrosine residues. Bromide also inhibits the coupling of tyrosine residues to thyronine and causes an increase in NADH cytochrome c reductase activity (van Leeuwen *et al*., 1983).

In chronic toxicity studies in rodents, thyroid enlargement and histological changes suggestive of hyperactivity are commonly observed, frequently in association with hepatic hypertrophy and the induction of hepatic xenobiotic-metabolizing enzymes. An increased incidence of thyroid follicular epithelial tumours is often subsequently encountered when animals are continuously exposed to the chemical in lifespan carcinogenicity studies. The underlying mechanism of hormonal dysregulation and adaptation is now well documented (Saito *et al*., 1991; Johnson *et al*., 1993; Wilson *et al*., 1996).

When a xenobiotic is metabolized in the liver via conjugation with glucuronic acid prior to excretion in the bile, the uridine-5′-diphospho-glucuronosyl transferase (UDP-glucuronosyl transferase) responsible is often induced by two- to fivefold, an adaptive response enhancing the rate of biliary clearance of the chemical. Several isoforms of UDP-glucuronosyl transferase exist, but when the type induced is the isoform also responsible for the glucuronidation of thyroxine, there is a simultaneous increase in the rate of excretion of both the xenobiotic and T_4 (Barter and Klaassen, 1994). The resulting drop in circulating T_3 and T_4 levels reduces feedback inhibition on hypothalamic TRH production, in an attempt to restore circulating levels of thyroxine. Release of TSH from the adenohypophysis of the pituitary is thus increased, stimulating both thyroxine secretion from, and cell proliferation in, the follicular epithelium (**Figure 2B**). When elevated levels of TSH are sustained, nodular hyperplasia and, ultimately, neoplasia of the follicular epithelium result. The demonstration of increased rates of biliary thyroxine excretion *and* an increased level of circulating TSH are key to confirming this mechanism of nongenotoxic carcinogenesis. Diurnal variation in TSH levels necessitates careful control of measurement, otherwise biologically significant changes, which may be only 30–50% above basal levels, can be undetectable.

The rat is unusually sensitive to chemicals which enhance hepatic excretion of thyroxine for two reasons. First, the molecular weight threshold for biliary excretion of xenobiotics is lower in the rat than many other species and so more xenobiotic molecules of moderate molecular weight are excreted in the bile than they are in man. Second, plasma protein binding and transport of T_3 and T_4 differ from that of other species, including even the mouse. Rats effectively lack thyroid-binding globulin and, in consequence, rely far more on pre-albumin for transporting T_3 and T_4 (**Table 2**). A significantly larger circulating pool of unbound or free T_3 and T_4 thereby

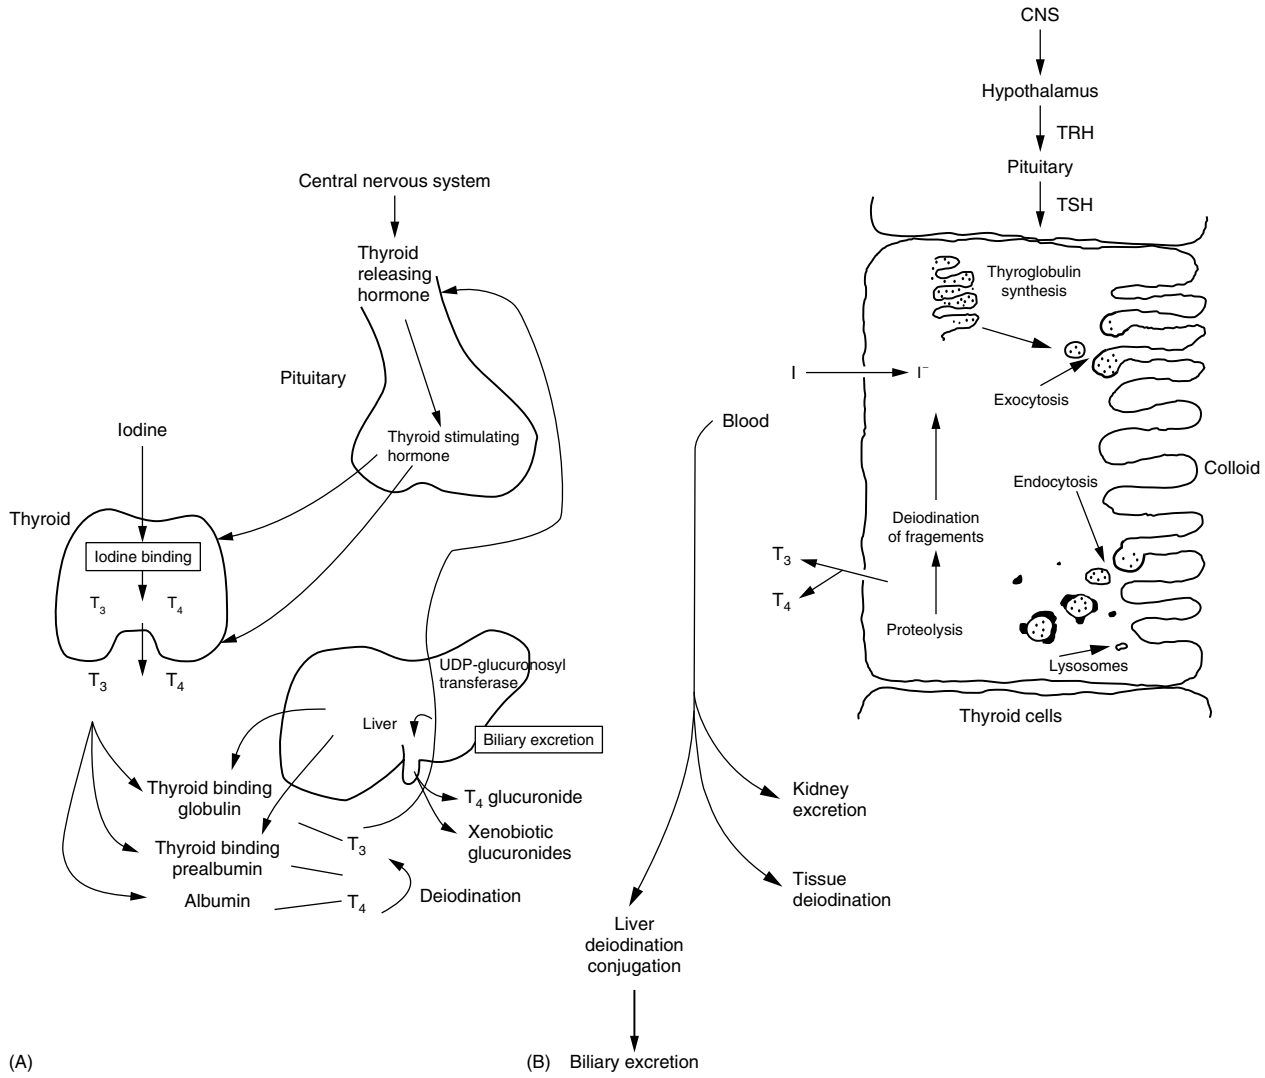

Figure 2 The regulation, transport and excretion of thyroxine. (A) The liver is the site of synthesis of plasma transport proteins and a major route of excretion. (B) Within the follicular epithelium, thyroglobulin is synthesized and secreted into follicles for storage, then reabsorbed, catabolized and excreted as T_3 and T_4.

allows changes in the rate of metabolism or clearance to readily influence plasma levels, that is, there is a smaller reservoir of T_3 and T_4 to buffer changes in circulating levels.

3.2 Support for the Model and Conclusions

In an attempt to predict the oncogenicity of a number of nongenotoxic compounds in a number of organs at early stages in a bioassay (7, 28 and 90 days), Elcombe *et al.* (2002) examined biochemical changes in thyroid-related markers in rodents. They found that TSH levels were increased when T_4 levels were diminished (T_3 was less well correlated) and the thyroid labelling index was closely related to TSH levels. It appears that there is a critical level of T_4 that must be reached before TSH increases. These observations add further weight to the mechanism of action (MOA) described above. In addition, thiazopyr, which was the original case study used to illustrate the 2000 IPCS framework for this mode of carcinogenic action, has been revisited as a case study to illustrate the additional guidance provided in the new 2005 IPCS framework for evaluating the human relevance of animal modes of carcinogenic action (Dellarco *et al.*, 2006).

If human exposure to chemicals of this type is at substantially lower levels than that causing thyroid hyperplasia in the rat, and studies in other species do not suggest effects on thyroid proliferation, epigenetic effects in the rat do not portend a human carcinogenic risk. There is considerable public anxiety about the effects of pesticides in the food chain, and some of these compounds, including the dithiocarbamates (ethylene

Table 2 Species differences in thyroid-hormone-binding plasma proteins (% hormone bound)

		Thyroxine-binding globulin	Albumin	Thyroxine-binding prealbumin	Total protein binding (%)	Unbound (%)
Man	T4	62.5	9.9	27.7	100	0
	T3	62.5	19.9	14.8	97.2	2.8
Rat	T4	1	6	80	87	13
	T3	3	32	42	77	23
Mouse	T4	60	40	0	100	0
	T3	65	25	0	90	10

Note that because the rat effectively lacks thyroid-binding globulin, a far higher proportion of T_3 and T4 circulate unbound and are available for metabolism and excretion. After McClain *et al*. (1989) and McClain (1994).

bis-dithiocarbamates) and triazoles, are goitrogenic and carcinogenic in animals under appropriate conditions of high and continuous dosage (O'Neil and Marshall, 1984; see also **Toxicology of Pesticides**). The food colouring erythrosine (used in maraschino cherries) is also a thyroid carcinogen in this mode of dosing. The clear evidence of threshold effects and the large safety margins emphasize the theoretical nature of the risk in this well-understood example of carcinogenesis.

4 PEROXISOME PROLIFERATION AND NEOPLASIA

Peroxisomes are single-membrane-bound organelles which increase in number dramatically in the rodent liver during exposure to certain lipid-lowering drugs and phthalate-ester plasticizers (Reddy and Lalwani, 1983). The increase in liver size accompanying this change is mediated by binding of the chemical to the peroxisome proliferator-activated receptor (PPAR) and is directly related to increased synthesis of membranes and smooth endoplasmic reticulum (Rao and Reddy, 1996). Total DNA in the liver increases in animals exposed to peroxisome proliferators over a period of days and will persist for weeks (Moody *et al*., 1977). It seems probable that the increase in cell division is in response to the metabolic demands placed on the liver, but the rapidly proliferating liver cells may be more vulnerable to specifically induced (oxidative) damage. The compounds producing peroxisome proliferation are generally not genotoxic and their ability to induce liver tumours in rats and mice after high-dose exposure is of questionable significance for man.

Many enzymes are associated with peroxisomes, including those responsible for the β-oxidation of long-chain fatty acids. Fatty acyl-CoA oxidase is the first and rate-limiting enzyme in the β-oxidation of fatty acids. It uses molecular oxygen and produces hydrogen peroxide. In man, the β-oxidation system has been most studied in the syndrome of sudden infant death, where deficiencies are apparently involved in a small proportion of cases (see Berry, 1989). The induction of hydrogen-peroxide-generating peroxisomal enzymes and the failure of epoxide-metabolizing enzymes (cytosolic epoxide hydrolase, glutathione-S-transferase (GST), microsomal epoxide hydrolase) to increase *pari passu,* was implicated as a key DNA-damaging event, in the initiation of hepatocarcinogenesis (Reddy *et al*., 1986).

This mechanism was questioned because the differential responses of parts of the system which produce and metabolize peroxides, and which prevent activated oxygen-dependent DNA damage, are capable of definitive study only in an intact cellular system with the correct concentration and compartmentalization of the various enzymes and cofactors (Bentley *et al*., 1987; 1988). When DNA damage was sought *in vivo,* excess production of hydrogen peroxide was not associated with oxidative damage, because no strand breaks in hepatic nuclear DNA, unscheduled DNA synthesis in hepatocytes or induction of the formation of micronuclei in the liver were found.

Studies in mice with functional deletion of the gene for fatty acyl-CoA oxidase now fundamentally question the role of peroxisomes in hepatocarcinogenesis. Fatty acyl-CoA oxidase null mice ($AOX^{-/-}$ knockout) develop fatty livers and, subsequently, marked peroxisome proliferation (Fan *et al*., 1998). Even though the peroxisomes of these mice are quite incapable of β-oxidation, the mice still develop high levels of hydrogen peroxide in the liver and hepatocellular carcinoma by 15 months of age. Other sources of oxidizing damage are, therefore, thought to be important, possibly including inflammatory cell-generated hydrogen peroxide.

The significance of the PPAR receptor in hepatocarcinogenesis was revealed in another experiment with genetically engineered mice. PPAR null mice failed to increase hepatic DNA labelling in response to a diet containing 0.1% Wy-14 642 (a potent peroxisome proliferator) and, whereas wild-type mice all developed multiple hepatic tumours within 11 months, none of the PPAR null mice did (Peters *et al*., 1997). Thus, receptor-mediated alteration of gene expression and/or cell proliferation appear necessary for carcinogenesis.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078

While the mechanisms of peroxisome proliferator carcinogenesis in rodents remain uncertain, it is clear that humans express much less PPARα subtype in their liver than rodents and thus, in humans, carcinogenic effects are unlikely to occur at low levels of exposure.

5 THE THIAZOLIDINEDIONES AND VASCULAR NEOPLASMS

Haemangiosarcoma is rare in man and relatively common in domestic and experimental animals. The tumour occurs in about 1% and 5% of control rats and mice, respectively, in NTP studies, and more than 20 agents have been associated with induction of vascular neoplasms (some causing haemangiosarcoma incidences of more than 80%). Since vascular proliferation is an essential part of many continuously running bodily processes, including wound healing and repair, and endometrial cycling, it is clearly a system, like others in the body, where proliferative capacity exists and is closely regulated.

Regulatory concerns have been raised relating to certain thiazolidinediones (antidiabetic and anti-inflammatory drugs) which act via the PPARγ receptor. Troglitazone binds to the PPARγ receptor, resulting in a conformational change that activates the transcriptional regulatory activity of the receptor and correlates with its antidiabetic actions (Berger *et al*., 1996). Troglitazone and several other PPARγ/PPAR dual agonists induce haemangiosarcomas in mice (Herman *et al*., 2002). Muraglitazar, pioglitazone and rosiglitazone also bind and activate PPARγ, but do not produce haemangiosarcoma; therefore, PPARγ binding appears to be necessary, but not sufficient, to produce haemangiosarcoma (Tannehill-Gregg *et al*., 2007; Waites *et al*., 2007).

5.1 Angiogenesis

Angiogenesis is mainly an adaptive response to local hypoxia and is dependent on the local accumulation of hypoxia inducible factors (HIFs) which are composed of α and β subunits of a heterodimeric transcription factor. These are normally continuously degraded by oxygen-dependent processes (the von Hippel–Lindau (vHL) protein (see below) acts by recognition of specific proline residues (Pro 402, Pro 563) in the α subunits, which are hydroxylated and degraded by E3 ubiquitin ligase), but in the absence of adequate oxygen levels the α subunits are stabilized and form heterodimers with HIF β, which is not oxygen sensitive. These transcription factors then activate a number of angiogenic genes, including those for vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), basic fibroblast growth factor (FGFb) and hepatocyte growth factor (HGF) in descending order of importance. VEGF-A, a specific endothelial cell mitogen, acts locally and systemically at tyrosine kinase growth factor receptors (VEGFR-1 and 2) to stimulate endothelial cell mitogenesis and recruit endothelial progenitor cells.

The downstream effects of these growth factors are complex. Connective tissue growth factor (CTGF) is a heparin-binding growth factor produced by fibroblasts after transforming growth factor β (TGFβ) activation and promotes angiogenesis in wound repair, tissue regeneration and skin fibrosis (Igarashi *et al*., 1998). In mesenchymal tumours, CTGF messenger RNA (mRNA) is expressed in fibroblasts of dermatofibromas, some dermatofibrosarcomas, angiolipoma, angiomyeloma and pyogenic granuloma, but not angiosarcoma, suggesting that benign fibroblasts and/or vascular endothelial cells have the capability to express CTGF mRNA when activated, but that expression is lost in malignant tumours. The CD34 antigen (Lanza *et al*., 2001), a glycoprotein involved in cell adhesion, is found to be expressed only in dermatofibrosarcomas (which are locally recurrent tumours) and angiosarcomas. The CD34 antigen is also expressed in multipotent stromal cells (MSCs) from adipose tissue, but not in bone marrow MSCs (Lazennec and Jorgensen, 2008) suggesting that it is a good marker of 'de-differentiation'.

5.1.1 Abnormalities of Angiogenic Regulation

There are a number of clinical syndromes in man in which abnormalities of the vasculature and neoplasia (including vascular and nonvascular tumours) are both significant features. In these syndromes, an inter-relationship between the changes leading to tumour formation in both epithelia and the vasculature are common and are apparently genetically determined. These conditions are informative about the potential role of factors assumed to be significant in an MOA for the production of haemangiosarcoma, in the sense that they exclude a number of what appear to be 'obvious' stimuli. They include syndromes (vHL, Chuvash polycythaemia) associated with mutations in the vHL gene which controls the stability of the HIFs, thus regulating VEGF-mediated angiogenic responses, and the hamartomatous polyposis syndromes, Bannayan-Riley-Ruvalcaba (BRR) syndrome and the Cowden syndrome (Marsh *et al*., 1999; Cho *et al*., 2008). From study of these conditions it is clear that the unrestrained action of HIFs cannot alone produce haemangiosarcoma; in the Chuvash syndrome, the stabilization of the potent angiogen HIFα with its persistent action induces polycythaemia, but not neoplasia (Gordeuk *et al*., 2004). Although these genetic disorders may shed light on vascular proliferation and angiogenesis, the vascular tumours associated with these are benign.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

5.1.1.1 The Target Cells

Recent advances in the understanding of tumour angiogenesis have highlighted the important roles of circulating, bone-marrow-derived progenitor cells, including both endothelial and monocyte/macrophage lineage cells. These findings suggest that haemangiosarcomas may arise, not only from transformation of tissue-resident endothelial cell populations, but also from circulating progenitors or adult stem cells recruited from bone marrow, or possibly also from extramedullary sites of haematopoiesis, such as the liver and spleen. The recent report by Tang *et al*. (2008) suggests that pericytes in fat are possibly the stem cells for some vascular and mesenchymal tumours (they express PPARγ, CD34 and PDGFRβ).

Recruitment, proliferation, localization and differentiation of the different cell types that regulate angiogenic processes is complex and provides ample opportunity to allow species, strain and individual animal variation in angiogenic responses. Research on canine haemangiosarcoma has shown that tumour-restricted expression of proinflammatory and angiogenic genes clusters in the haemangiosarcoma of Golden Retrievers and is distinct from haemangiosarcoma of other dogs, suggesting heritable factors mould phenotypes in sporadic, naturally occurring tumours.

5.2 Mechanisms of Action in the Production of Vascular Tumours

In man, the established causes of malignant vascular tumours—following thorotrast injection (Kojiro *et al*., 1985), after vinyl chloride exposure, in the arms of women with lymphoedema following radical breast surgery (Abbott and Palmieri, 2008) in human herpesvirus 8 (HHV-8) infection and in certain hereditary syndromes—differ widely in pathogenetic mechanisms. As examples, Kaposi's sarcoma (Barillari and Ensoli, 2002), a spindle cell endothelial-cell sarcoma, occurs at a 310-fold higher incidence in the HIV-infected population. It is caused by HHV-8 infection, and is associated with elevated levels of cytokines (IL-1, IL-6, IL-8), HHV-8-encoded vIL-6 and other factors (leukaemia inhibitory factor, oncostatin M and cardiotropin) secreted by a spindle-cell component and acting via gp130 receptors on endothelial cells to induce subsequent proliferation (Amaral *et al*., 1993). Latency-associated nuclear antigen (LANA) is found in the nuclei of this tumour, but not in benign human tumours or angiosarcomas (Schmidt and Zietz, 2005). However, vinyl chloride (see below) acts via a genotoxic mechanism, as does thorotrast, as an α-emitter.

The importance of VEGF signalling pathways in angiogenesis and haemangiosarcoma is highlighted by the finding of mutations in the phosphatase and tensin homologue (PTEN) gene in canine and human haemangiosarcomas. PTEN is a tumour- and angiogenesis-suppressor gene which inhibits angiogenesis due to its lipid phosphatase activity on substrates in the phosphoinositide 3 (PI3) kinase pathway downstream from VEGF receptor signalling (Eng, 2003). PTEN mutations are found in other common tumours, including endometrial and prostatic carcinomas, gliomas and melanoma, and in 80 and 60% of patients with Cowden and BRR syndromes, respectively.

5.3 Regulatory Issues

Haemangiosarcomas in rodents have become an increasingly important issue in evaluating the significance of the results of carcinogenicity studies of a variety of classes of pharmaceutical agents. These tumours, primarily in mice, have been seen with many PPAR dual agonists, some (but not all) calcium-channel blockers, antipsychotics, phosphodiester 5 (PDE-5) inhibitors, dipeptidyl peptidase 4 (DPP-4) inhibitors, antiarrythmics, antisense compounds, nitric oxide releasers, agents causing haemolysis and VEGF inducers. The pharmaceutical agents producing these effects are not genotoxic in standard *in vitro* and *in vivo* genotoxicity assays, and they are not DNA reactive. It is reasonable to assume, therefore, that their mode of action must involve an increase in cell proliferation, but the absence of a, MOA results in significant uncertainty in the assessment of human risk and regulatory decision-making.

Several questions remain regarding haemangiosarcoma induction. Is the target cell that gives rise to the sarcomas the endothelial cell itself or a precursor stem cell arising from the bone marrow or fat? Why are the tumours found in certain tissues in mice (predominantly liver, spleen and bone marrow), but in subcutaneous adipose tissue in humans? Does the inducing chemical act directly on cells that become transformed or do they act on other cell types, producing a biological effect leading to the release of growth factors or other substances which then affect the precursor cells?

5.4 Potential Modes of Action

Haemangiosarcoma clearly arises by a number of mechanisms.

5.4.1 Genotoxicity

Vinyl chloride, an inducer of haemangiosarcomas in both rodents and man, appears to work through genotoxic mechanisms. The mode of action involves the formation of genomic DNA adducts. In rodent studies, molecular dosimetry of DNA adducts in the liver has

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

been examined after vinyl chloride treatment and showed that 7-(2′-oxoethyl)guanine (7OEG) was the major DNA adduct detected (98% of adducts). N^2,3-Ethenoguanine and 3,N^4-etheno-2′-deoxycytidine were also found (1% of adducts). N^6-Etheno-2′-deoxyadenosine was present at even lower concentrations. The persistence of these four adducts showed that while the 7OEG adduct had a half-life of 62 hours, the other three etheno adducts were highly persistent, having half-lives of 30 days or more (see Morinello *et al*., 2002).

5.4.2 Nongenotoxic Mechanisms

There is presently no unifying hypothesis for a nongenotoxic MOA for the many compounds that induce haemangiosarcoma.

2-Butoxyethanol increases haemangiosarcomas following chronic inhalation exposure and, in mice, oncogenesis appears to be related to haemolysis and the induction of oxidative damage in Kupffer cells (iron accumulation and oxidative damage resulting in release of growth factors—Corthals *et al*., 2006). More recent data suggests a possible role for HIF-1α and VEGF in the carcinogenetic process following butoxyethanol exposure.

Carbaryl also induces haemangiosarcomas in the mouse in a dose-related manner. In a mouse two-year carcinogenicity study where 80 CD-1 mice per group were given diets providing 0, 100, 1000 and 8000 ppm carbaryl, there was an increase of liver tumours in females and kidney tumours in males at 8000 ppm (a dose exceeding the maximum tolerated dose) and also an increased incidence of vascular tumours in both sexes at 8000 ppm. An increase of vascular tumours (statistically significant) was still observed in male mice at the mid dose (1000 ppm). At the low dose of 100 ppm, the incidence of vascular tumours in male mice was increased compared to the control, but without statistical significance; no clear dose–effect relationship was obtained (see FAO/WHO, 1997). Carbaryl also failed to induce haemangiosarcomas or other tumours at doses up 4000 ppm in heterozygous p53 knockout mice, suggesting a nongenotoxic mode of action (Bigot-Lasserre *et al*., 2003).

Cohen *et al*. (1990) assessed the human relevance of mouse endothelial cell tumours induced by troglitazone (a low affinity PPARγ agonist developed to treat Type II diabetes) that produced an increased incidence of haemangiosarcomas—mainly in adipose tissue in mice, but not rats. They assessed endothelial cell proliferation using a dual label of Ki-67 (cell proliferation) and CD-31 (an endothelial cell marker) in mice, rats and man. Mice were shown to have a higher basal endothelial cell proliferation rate than rats or humans and have a higher background incidence of vascular tumours. *In vivo*, troglitazone induces endothelial cell proliferation in mice after four weeks of dosing. Using *in vitro* experiments with troglitazone, therapeutic levels were shown to be cytotoxic to human cells, while mitogenic to mouse microvascular endothelial cells. This differential *in vitro* response suggests that troglitazone would not stimulate a mitogenic endothelial response in man (see also Ohnishi *et al*., 2007).

The PPAR nuclear receptor forms a heterodimer with the retinoid receptor (RXR) and retinoids have been shown to induce haemangiosarcomas in mice. 4-Hyroxyphenyl retinamide (4-HPR) (Fenretinide) induces a 100% incidence of haemangiosarcomas at several sites in mice, but like the PPAR agonists, most of the tumours induced are in adipose tissue. Other retinoids, retinyl acetate and etretinate, are also mouse haemangiosarcomagens. They bind to and activate retinoic acid receptors (RARs) on target genes and thus regulate gene transcription. Evidence based on *in vitro* investigations demonstrates that they negatively regulate cell growth and angiogenesis, but it is possible that this might be through RAR-independent pathways.

Several possible factors have also been demonstrated to be involved in the haemangiosarcomas induced in mice by pregabalin, which binds to the $\alpha_2\delta$ subunit of voltage-gated calcium channels. Most of these tumours occurred in the usual tissues involved in this form of mouse neoplasia, namely liver, spleen and bone marrow. The data indicate that the initial event is the induction of hypoxia at high doses, leading to a cascade of events, including the overproduction of megakaryocytes and platelets, with consequent release of various endothelial growth factors, including VEGF and PDGF.

Early events in this process in mice are increases in HCO_3 and blood pH, and corresponding decreases in respiratory rate and minute volume, which are all tightly linked physiological responses. Extensive changes in mouse bone marrow occur, and these are consistent with effects of hypoxia and/or alkalosis and are characterized by erythropoiesis, megakaryopoiesis, increased macrophages, with erythrophages and clusters of haemosiderin-laden macrophages suggestive of macrophage activation. Extramedullary haematopoiesis is also evident in the spleens of pregabalin-treated mice. Peripheral erythrocyte and platelet counts are increased in association with bone-marrow changes, and platelet activation is also increased.

5.4.3 Possible Mechanisms of Action: A Synthesis

A document produced by the Health and Environmental Sciences Institute (HESI) as a result of a Reston (Virginia) meeting cosponsored by HESI and the Society of Toxicology suggests that there are two main contenders for an MOA (SOT, 2008).

Adipocytes are a rich source of growth factors, including those that stimulate angiogenesis, and studies with angiogenesis inhibitors have demonstrated that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

angiogenesis is a necessary requirement for fat-pad growth (Hutley *et al*., 2001; Kershaw and Flier, 2004; Fukumura *et al*., 2003; Tang *et al*., 2008). A key component of a proposed MOA for PPARγ agonist induction of haemangiosarcoma is that adipocytes release angiogenic growth factors, which would stimulate endothelial cell proliferation.

The proposed HESI MOA includes the following major components: (i) PPARγ agonists bind to the PPARγ receptor in adipocytes and stimulate their proliferation, leading to the release of angiogenic growth factors and/or a decrease in antiangiogenic growth factors; (ii) dysregulated angiogenesis occurs due to PPARγ agonists initially inhibiting endothelial cell growth, resulting in local tissue hypoxia which occurs in the presence of a net angiogenic environment, leading to selection of endothelial cells which can proliferate and (iii) a selective growth stimulus leads to clonal endothelial cell expansion and oncogenesis. Accessory cells, such as macrophages, could also contribute to an angiogenic stimulus via interleukins (e.g. IL-1, IL-6).

An alternative hypothesis is that the target organ (i.e. fat pad) provides an angiogenic growth stimulus that recruits circulating endothelial stem cells from the bone marrow and these stems cells seed the target organs, leading to the formation of haemangiosarcoma.

5.5 Conclusions

There is a need for better management and control of Type II diabetes mellitus and the PPARγ-receptor-active compounds appeared likely to make a considerable contribution to this problem, encouraging research into this regulatory issue. However, as so often in toxicology, the resolution of the scientific questions is not only a challenging scientific problem but one that, if it can be resolved, may inform us about many processes in the important phenomenon of angiogenesis.

6 CARCINOID TUMOURS INDUCED BY GASTRIC ANTISECRETORY DRUGS

Carcinoid tumours are tumours of the diffuse neuroendocrine cell populations which are dispersed in many glandular tissues, particularly the gastrointestinal tract (see review by Oberg, 2002). Carcinoid tumours have an extremely low spontaneous incidence in humans and in all commonly used strains of rat and mouse.

6.1 Drugs Responsible

The more potent members of the highly commercially successful group of drugs which inhibit gastric acid secretion (including the histamine H_2 antagonists, loxtidine, tiotidine, oxmetidine, sufotidine. SKF93479, ICI 162, 846, BL-6341 and proton-pump inhibitors such as omeprazole) induce carcinoid tumours in rodent carcinogenesis bioassays (Berlin, 1991; Poynter and Selway, 1991). High doses of these drugs, persistently administered, *first* induce generalized hyperplasia of the gastric glandular mucosa, followed by diffuse and focal hyperplasia of enterochromaffin-like (ECL) cells and, in a significant proportion of cases, invasive carcinoid tumours of ECL cells (**Figure 3**). It is generally accepted that this group of drugs are nongenotoxic (Gatehouse *et al*., 1988).

6.2 Mechanism

The relevance to humans of such rodent carcinoid tumours provoked fierce controversy in the mid 1980s

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

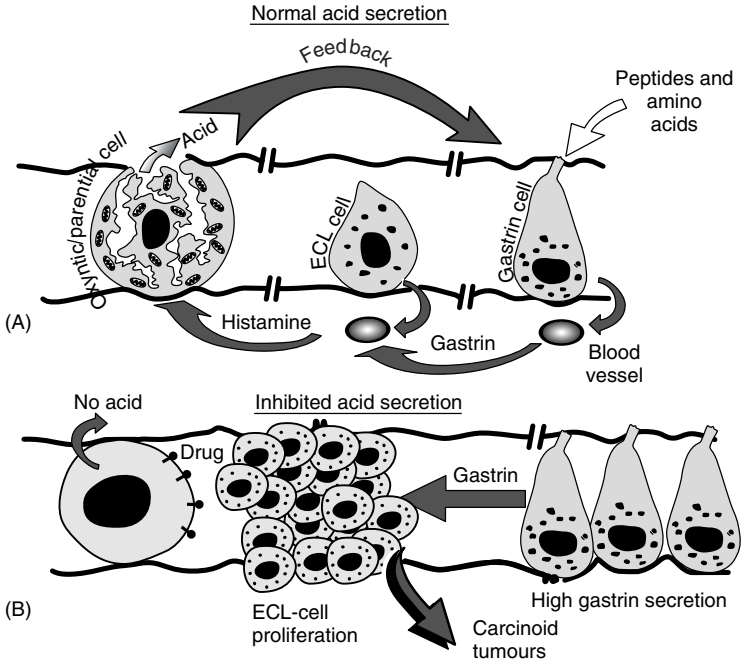

Figure 4 (A) The normal mechanism regulating acid secretion from oxyntic cells in the gastric glandular mucosa. (B) In the presence of antisecretory drugs, the absence of acid feedback inhibition on gastrin secretion causes hypergastrinaemia and sustained proliferation of enterochromaffin-like (ECL) cells.

and remains a matter of some debate. In response, substantial efforts were expended to identify components of a nongenotoxic mechanism, and to determine whether these effects were likely to occur in humans. Normally, acid secretion from parietal cells in gastric glands inhibits gastrin production from G-cells. The inhibition of acid secretion (by antisecretory drugs) removes this feedback inhibition on G-cells, causing hypergastrinaemia and a modest increase in the number of G-cells. Persistent hypergastrinaemia exerts a trophic effect on ECL cells, causing diffuse hyperplasia, areas of nodular hyperplasia and, eventually, carcinoid tumours which invade local lymph nodes and submucosal tissue (**Figure 4**). The initial proliferative response in ECL cells can occur very rapidly and has been observed after as little as two days, in studies with some antisecretory drugs. The degree of hypergastrinaemia which rodents develop is substantially greater than occurs in humans taking clinical doses of these drugs and, when sustained, is proportional to the ultimate incidence of carcinoid tumours (Poynter and Selway, 1991). Marked hypergastrinaemia also characterizes several human conditions in which carcinoid tumours develop: Zollinger–Ellison syndrome, pernicious anaemia and atrophic gastritis (Dayal and Wolfe, 1991).

Carcinoid tumours have also been induced in the rat following long-term administration of the hypolipidaemic fibrate drugs (Spencer *et al*., 1989), which, subsequently, were also shown to have antisecretory activity in this species, but not in the mouse or marmoset. In the rat, surgical resection of the region of the gastric mucosa largely responsible for acid secretion (partial corpectomy) induces hypergastrinaemia and generalized mucosal hypertrophy with ECL-cell hyperplasia. Although not exposed to more than normal diet, 23% of these rats eventually developed carcinoid tumours at two years (Mattsson *et al*., 1991). The gastrin hypothesis may not fully account for the development of carcinoid tumours, as *in vitro* experiments have shown that carcinoid tumours express receptors for a number of growth factors including IGF-1, TGF_Q and EGF (Nilsson *et al*., 1993) and so several mitogens could contribute to ECL cell proliferation.

In terms of human relevance, It is important to remember that the carcinoid tumours that occur in human atrophic gastritis and that are presumably gastrin driven, are small (<1 cm) and slow growing—if they grow at all (Harvey *et al*., 1985).

7 FORESTOMACH TUMOURS IN THE RAT

Spontaneous tumours of the upper gastrointestinal tract are rare in rats, but a large number of compounds of diverse chemical structure will produce hyperplasia in the forestomach with papillary change and the subsequent development of squamous carcinoma. This sequence has been well documented for fatty acids by von Griem (1986), in which class of compounds, the smaller the

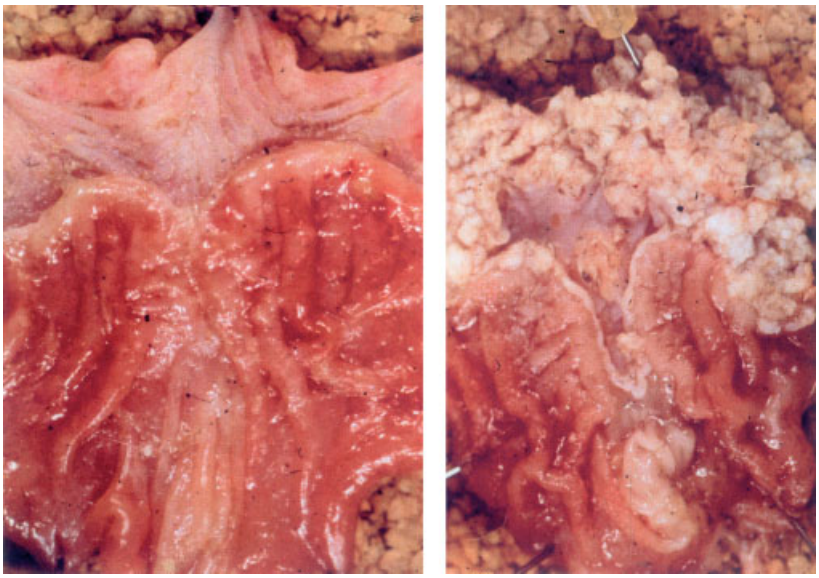

Figure 5 The rat stomach mucosal aspect. (A) In a young untreated rat, showing a clear demarcation between the lower (reddish) mucosal epithelium and the upper (paler) keratinized epithelium of the forestomach. (B) Following two weeks of exposure to 4.8% butyric acid, hyperplasia has caused a diffuse papillomatous thickening of the forestomach.

number of carbon atoms, the greater is the effect: propionic acid (C3) producing hyperplasia, papilloma and carcinoma; butyric acid and valeric acid (C4 and C5), hyperplasia and papillomas only (**Figure 5**) and lauric acid (C12), no significant change. The shorter-chain acids which stimulate epithelial proliferation may be carcinogenic after an appropriate duration of administration; this was not always adequately explored. The antioxidant, butylated hydroxyanisole (BHA), which is widely used as a food additive, produces this sequence in rats, mice and hamsters. Cell proliferation is greatest in the squamous epithelium immediately adjacent to the glandular mucosa (the limiting ridge) and this is also reported to be the site at which most tumours develop.

Although some of the compounds producing this effect produce an initial epithelial necrosis in the forestomach (Lauriault *et al*., 1990), it has been suggested that this change may not be necessary for the later development of hyperplasia (Toledo, 1965). The oesophagus is not usually affected, but cell kinetic studies have shown increased cell proliferation in some species. To illustrate the difference between the effects of genotoxic and nongenotoxic compounds in the same system, aristolochic acid, a phenanthrenecarboxylic acid obtained from the medicinal plant *Aristolochia clematis* L which is genotoxic, produces the sequence of hyperplasia, papillomatosis and squamous carcinoma in the rat (Mengs, 1983) and the mouse (Mengs, 1988), but with this compound adenocarcinoma of the forestomach also develops, together with tumours in other tissues and organs. It is possible in the mouse to achieve 100% tumour incidence. A comparison of the effects of this type of compound in animals with and without a forestomach has been made: the changes observed with BHA in rodents are not seen in dogs (Tobe *et al*., 1986) or monkeys (Iversone *et al*., 1986).

8 LIVER TUMOURS IN THE RAT AND MOUSE

More nongenotoxic mechanisms have been invoked for hepatocarcinogenesis than for most other tissue targets; these include sustained stimulation of cell proliferation, toxin-induced selection for a growth-dysregulated phenotype, down-regulation of gap-junctional intercellular communication, inhibition of apoptosis and altered methylation patterns for genes controlling growth and differentiation.

The significance of a stimulus to cell growth as a major factor in epigenetic carcinogenesis is clearly illustrated by the lesions found in the rodent liver as a result of the adaptive growth induced by xenobiotic compounds. The compounds vary widely in type, phenobarbital, steroid hormones, such as norethisterone, organochlorine pesticides such as dichlorodiphenyltrichloroethane (DDT), hexachlorocyclohexane (HCH) and also Ponceau MX being examples. In general, in the early stages of treatment all these agents produce liver enlargement by a combination of hypertrophy and hyperplasia of cells, with increases in total DNA content, parenchymal DNA synthesis and mitotic activity. In contrast, the antihistamine methapyrilene does not cause marked liver

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

hypertrophy, but provokes a significant and sustained increase in cell proliferation, a regenerative response to chronic cytotoxicity (Powell *et al*., 1994). For many chemicals there has frequently been no evidence of toxic injury to liver cells on conventional morphological examination, and Schulte-Hermann (1979) has suggested that liver tumour formation may be the result of promotion of tumours from pre-existent tumorigenic lesions, as a result of prolonged and excessive stimulation of growth. Newer, more sensitive techniques, such as cumulative cell labelling via implanted miniosmotic pumps, frequently reveal increased hepatocyte turnover in situations where this was not previously detectable.

The apparent similarity of growth response conceals differences in cellular response. A diversity of xenobiotic-metabolizing enzymes can be induced, both microsomal and cytosolic, but no particular pattern of enzymes or magnitude of induction has been related to the neoplastic process. The only safe generalization is that during tumour progression neoplastic hepatocytes tend to acquire a more fetal phenotype, but this is not a distinguishing feature of nongenotoxic carcinogens. Early phenotypic changes are themselves of major significance if they alter the metabolic handling of other xenobiotics. Enzyme induction in the liver is nonuniform and this phenotypic diversity can allow selection pressure to favour the emergence of clusters of hepatocytes (foci) which are less metabolically disadvantaged from continuous exposure to a high level of a xenobiotic. This is consistent with the observation that most, but not all, foci have high levels of protective or defensive metabolizing enzymes such as GST-P or GGT (γ-glutamyl transferase) (**Figure 6A**). At least initially, resistance to toxicity probably confers only a modest or slight degree of growth advantage and is largely reversible. The suggestion that the cells of the altered foci represent an 'initiated' population (Schulte-Hermann, 1987) is speculative and not entirely consistent with the relative abundance of foci in the rat liver compared with most strains of mouse, despite which most mouse strains develop a higher spontaneous incidence of hepatic neoplasia. It may be more appropriate to consider altered foci as cells with a reversible phenotypic change, favouring subsequent selection for genetic changes.

Inhibition of apoptosis has been proposed as a mechanism of nongenotoxic carcinogenesis on the basis that cells with damaged DNA would be prevented from dying and replication could then 'fix' spontaneous mutation or DNA damage, allowing defective cells to accumulate. The observation that apoptosis increases when hypertrophy-inducing hepatocarcinogens (such as phenobarbitone (phenobarbital), nafenopin or butylated hydroxytoluene) are withdrawn, and is suppressed when the chemical is readministered, has prompted the conclusion that these chemicals suppress apoptosis *per se* (Roberts *et al*., 1995; Schulte-Hermann *et al*., 1995).

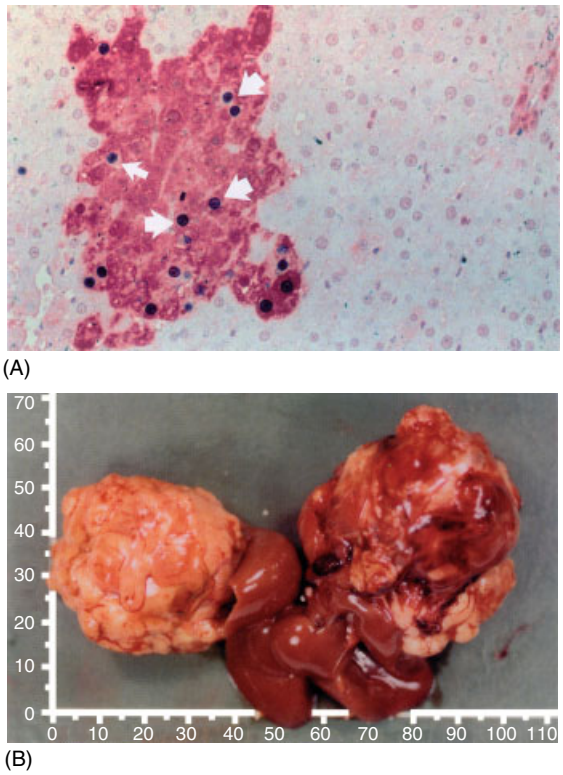

Figure 6 Methapyrilene-induced hepatocarcinogenesis. (A) Preneoplastic focus of altered hepatocytes, after six months of exposure to 400 ppm, identified by immunostaining for placental form of GST (also stains bile ductules, top right). Simultaneous staining for bromodeoxyuridine incorporation shows a higher level of cell proliferation in the focus (arrowed dark nuclei) than the surrounding liver. (B) Two large hepatic tumours induced by a further 12 months of exposure (18 months total) to the same dose of methapyrilene.

This conclusion is flawed by the fact that: (i) involution of liver hypertrophy, consequent to a decreased metabolic demand, cannot be distinguished from the removal of a primary suppression of cell death and (ii) inhibition of apoptosis is not the major cause of liver hypertrophy when these chemicals are first administered. Withdrawal of chemicals which selectively favour growth of preneoplastic foci (i.e. phenobarbital) understandably increase apoptosis in the foci, because the differential growth advantage has been removed. This does not, however, prove that the growth advantage arose from suppression of apoptosis, it merely reflects that growth advantage, from whatever mechanism, has been removed. More convincing support for this hypothesis would result if it could be demonstrated that apoptosis increased on withdrawal of a hepatocarcinogen which did not rapidly induce microsomal enzymes and liver hypertrophy or if lower levels of apoptosis could be convincingly shown during continuous administration of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

nongenotoxic carcinogens. At variance with the suppression of apoptosis hypothesis is the observation that preneoplastic lesions or adenomas induced by nongenotoxic carcinogens often have conspicuously increased levels of apoptosis. The study of Bursch *et al*. (2005) confirmed that apoptosis was not a major cause of strain difference in tumour susceptibility in C3 h/He, B6 C3F1 and C57BL/6 J mice; it is of more significance in the rat.

Examination of the activities of cells from later stages on the neoplastic process, that is liver nodules (adenoma), or carcinomas (**Figure 6B**) has shown them to be altered in metabolic capacity, expression of or responsiveness to growth factors and/or growth inhibitors, levels of cell proliferation or cell death, ploidy or the expression of cellular oncogenes, such as *myc, Jos, raf* and many others. As many malignant neoplasms have gross chromosomal rearrangement or partial deletion and duplication, it is clear that some change during the process of carcinogenesis enhances the likelihood of subsequent genetic change, with the development of a mutator phenotype or genetic instability.

9 SEX HORMONES AND ANTAGONISTS

This group contains an enormous diversity of chemical structures, some of which are potent carcinogens in animals, and includes a number with proven, although low-potency, carcinogenicity in humans, including the oestrogenic hormones used as oral contraceptives and antioestrogenic compounds used prophylactically and therapeutically for hormone-responsive tumours (Grisham, 1996). Many compounds, for example ethinyloestradiol, cyproterone acetate and tamoxifen, reproducibly induce liver tumours in rodents (Greaves *et al*., 1993; Tucker *et al*., 1996), and had for a long time been considered nongenotoxic until more recent studies refuted this. For instance, cyproterone acetate induces unscheduled DNA synthesis in hepatocytes (Demi *et al*., 1993), DNA adducts by ^{32}P postlabelling (Kerdar *et al*., 1995) and sister chromatid exchanges, while tamoxifen produces DNA adducts when studied by ^{32}P postlabelling methods (Carthew *et al*., 1995). Numerous animal studies have shown that oestrogen administration can increase tumour yield if given after a single dose of a genotoxic carcinogen (IARC, 1987). For reasons which are complex, the endocrine tissues of rodents appear to be peculiarly sensitive to chemical carcinogenesis.

In a review of the lesions occurring in the rat pituitary gland, Attia (1985) found that the majority of ageing rats displayed hyperplasia of prolactin-producing (PRL) cells with the morphological criteria of high secretory activity. Somatotrophin-producing (STH) cells showed evidence of similar functional hyperactivity and there was an increased relative proportion and apparent secretory activity of adrenocorticotrophin-producing (ACTH) cells. Around half of the animals in this study had pituitary adenomas which were assigned to cell types on morphological criteria alone; the tumours were not characterized immunocytochemically or electron microscopically. Studies which include the use of current pathological methodology show that many of these tumours are likely to be prolactinomas, probably induced as a result of the changes in oestrogen production which occur in ageing rats (Lu *et al*., 1979). Prolactin has a pronounced proliferative effect on rat mammary epithelial cells *in vivo* and *in vitro* (Nandi *et al*., 1984), and this change probably underlies the increased incidence of mammary tumours in ageing rats. Indeed, it has been known for many years that the administration of prolactin to normal rodents produces an increase in RNA synthesis in the mammary glands, followed by increased DNA synthesis and cellular proliferation (Simpson and Schmidt, 1971).

10 BLADDER CARCINOGENESIS IN THE RAT

In rats, a number of compounds act to produce bladder neoplasia, with a marked difference in incidence in the two sexes, the lesions being almost exclusively seen in males. The silicates which occur in many rat diets are precipitated in the urine under certain conditions and irritate the mucosa, a change apparently more common in males, owing to the large amounts of macromolecules excreted in their urine. Hence there is a background of proliferative change against which other factors may act; urothelial transitional cell hyperplasia occurs and may be defined as an area (focal or diffuse) at least three to four cells thick in an inflated bladder, whereas normal bladders have a cell thickness of one or two flattened cells.

10.1 2-Phenylphenol and its Sodium Salt

An example of a compound which operates in this way is 2-phenylphenol (*o*-phenyl phenol; OPP) and its sodium salt (SOPP). There is an additional point that two different mechanisms appear to act at different doses. Metabolic studies have shown that these compounds are converted into the sulfate and glucuronide conjugates at doses up to around 50 mg kg^{-1}; the conjugates are then excreted in the urine (Nakao *et al*., 1983; Reitz *et al*., 1983). At doses above 200 mg kg^{-1}, hydroxylation occurs, with conversion into 2,5-dihydroxybiphenyl, which is subsequently conjugated. Studies at a very high dose (600 mg kg^{-1} OPP; Reitz *et al*., 1983) showed that quinone compounds were formed via active intermediaries (semiquinones) in the rat. There are large sex

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat078
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

differences in handling these compounds; in males eight times as much 2,5-dihydroxybiphenyl was formed as in females. The pathway via semiquinones has not been identified in dogs, cats or following dermal application in man, but the doses used may well not have revealed it (Savides and Oehme, 1980; Harke and Klein, 1981).

The tumours of the urinary tract which have occurred after exposure to OPP and SOPP have been observed predominantly in male rats. There appears to be a no-effect level of 250 mg kg^{-1} day^{-1}, but a clear dose-related increase in incidence is seen above this level (Hiraga and Fujii, 1981; 1984), which declines above 500 mg kg^{-1} day^{-1} for OPP and less markedly above 1000 mg kg^{-1} day^{-1} for SOPP. Data on the binding of metabolites to macromolecules in the urinary tract (Reitz *et al*., 1984) provide evidence for the suggestion that the 2,5-dihydroxybiphenyl cannot be the oncogenic agent, an argument supported by noting that considerable amounts of the 2,5-compound are formed below doses of 200 mg kg^{-1} and transformed into conjugates; none of these metabolites is therefore likely to be the carcinogen. However, injection of 0.05 or 0.1% 2-phenyl-l,4-benzoquinone resulted in evident hyperplasia of the bladder epithelium within five days. It has been suggested that saturation of the detoxification mechanism resulting in the production of free 2,5-dihydroxybiphenyl and its oxidation product, 2-phenyl-1,4-benzoquinone, allows the excretion of a bladder irritant in significant amounts at high doses in feeding studies. However, there is also evidence of the influence of other factors. Both OPP and SOPP are irritants, and this may be an adequate explanation of bladder mucosal hyperplasia; in addition, there is clearly an effect attributable to changes in pH.

In a study by Fukushima *et al*. (1986), male F344 rats were given OPP or SOPP at 2% in the feed for 24 weeks. Groups of treated animals also received ascorbic acid (AS), sodium ascorbate (SA), acid saccharin (SAC), sodium saccharin (SSAC), hippuric acid (HI) or sodium hippurate (SHI) at 5% in the feed. The urinary sodium concentration was increased in all animals receiving sodium salts in the diet and in SOPP-treated animals. The pH of the urine increased after SOPP, SA and SSAC and the urine osmolarity was decreased by SOPP, SA and SHI. OPP decreased the osmolarity, but did not affect urinary sodium concentrations. Histopathologically, the bladders showed epithelial thickening (4–8 cell epithelial thickness) at 8, 16 and 24 weeks after SOPP, and papillary and nodular changes at 16 and 24 weeks. Treatment with other sodium salts provoked some hyperplasia at 8 and 16 weeks, but no papillary or nodular changes; these changes had regressed by 24 weeks. The authors concluded that a combination of raised urinary pH and sodium acted as a promoting agent for SOPP; SHI raised urinary sodium, but not pH and was without effect.

Fujii *et al*. (1987) performed an essentially similar study on male F344 rats, using $NaHCO_3$ to raise the urinary pH and NH_4Cl to lower it. Both OPP and SOPP were examined (at 1.25 and 2% in the diet, respectively). Changes were seen in all groups and can be summarized as follows: hyperplasia of the bladder epithelium occurred with OPP, OPP and $NaHCO_3$, and SOPP. SOPP with NH_4Cl had no significant effect. Tumours were significantly increased after OPP (12/31), SOPP (22/31) and OPP plus $NaHCO_3$ (20/31). Only three tumours were seen in 31 rats after SOPP and NH_4Cl. The oncogenic effects of OPP were promoted in alkaline urine; those of SOPP were inhibited in acidic urine. The authors' view was that findings that suggested that SOPP was more carcinogenic than OPP related to the greater alkalinity of the former.

These studies have been considered in detail, since they shadow the well-known story of SSAC and bladder neoplasia (see review and comment: Cohen and Ellwein, 1990; IARC, 1999; Weihrauch and Diehl, 2004). This common route of development seen for a number of compounds with a clear dose-, sex- and species-specific effect typifies epigenetic carcinogenesis.

11 IMMUNOSUPPRESSORS

All immunosuppressant drugs, when tested adequately in animal carcinogenicity studies, are likely to increase tumour yield by suppression of normal immunosurveillance, a nongenotoxic mechanism. It is reported that certain immunosuppressors have not tested positive in the rat bioassay, but, when survival is limited by target organ toxicity, such tests can have poor sensitivity. The consensus, nonetheless, is that immunosuppressive drugs are carcinogenic and the International Agency for Research on Cancer has designated ciclosporin (cyclosporine) and azathioprine as human carcinogens (Class 1) (IARC, 1997; 1998). It is likely that all immunosuppressants will prove to be human and animal carcinogens, irrespective of whether they have *in vivo* genotoxic potential. Recent information also suggests that certain immunosuppressants may inhibit DNA damage-repair enzymes, an additional nongenotoxic mechanism.

12 FOREIGN BODY OR INJECTION-SITE CARCINOGENESIS

Extensive experimentation has shown that rats or mice, implanted subcutaneously with foreign bodies, such as plastic films (PVC, polythene, etc.), glass, stainless steel or gold, develop a vigorous fibrosing reaction around the implant and, ultimately, malignant connective tissue tumours. If the same materials are implanted in a powdered form, no tumours result, demonstrating that

Table 3 Examples of nongenotoxic chemicals and their target tissues

Nongenotoxic carcinogen	Target tissue
Oestrogenic hormones	Liver/endometrium
Histamine H2-receptor antagonists and proton-pump inhibitors	Enterochromaffin-like (ECL) cells, stomach
Various chemicals which induce hepatic glucuronosyl transferase	Thyroid follicles
Peroxisome proliferators: phthalates, fibrates and so on	Liver hepatocytes
Immunosuppressants: cyclosporin and so on	Various tissues, particularly lymphoid
Various chemicals inhibiting the catabolism of α_{2-}microglobulin	Kidney
Butylated hydroxyanisole, C_3–C_5 fatty acids and a variety of other chemicals	Squamous epithelium of forestomach
Various chemicals causing liver hypertrophy and persistent compensatory hyperplasia	Liver hepatocytes
Various chemicals causing a persistent increase of cell turnover in the urothelium	Bladder
Subcutaneously implanted inert plastic films and foreign bodies	Connective tissue

carcinogenesis is not due to chemicals leaching from the implant, but to the physical shape of the implanted material (Moizhess and Vasiliev, 1989). This effect has also been termed 'solid-state carcinogenesis'. Larger, more angular implants produce a more vigorous fibrosing reaction and a larger tumour yield than do smaller more regularly shaped objects. Thin films of inert plastic, which induce neoplasia when implanted intact, do not do so when implanted after being repeatedly perforated. A substantial body of experimental evidence shows that foreign body carcinogenesis in rodents is related to the extent of inflammation and fibroplasia (local trauma) at the site of implantation and this is determined by physical features of the implanted object, including surface charge, angularity, surface texture, surface wettability and size (Brand *et al*., 1976). In this type of carcinogenesis, there is no exogenous chemical damage to or interaction with DNA, and so this is a nongenotoxic mechanism. Examples of nongenotoxic chemicals and their target tissues are given in **Table 3**.

A similar mechanism seems to operate when repeated subcutaneous or intraperitoneal injections of irritant materials, such as solutions of low pH or high tonicity, provoke a localized fibrosing reaction. These too can eventually result in malignant connective-tissue tumours (Grasso and Golberg, 1966). Administration of identical, nonirritant solutions (i.e. pH 7.0) has been reported not to cause tumour induction.

Although the subcutaneous tumours induced have been described using varying terminology, most would now be described as mesenchymal tumours, fibrosarcomas or even mixed fibrous histiocytomas. Variants with smooth muscle, osteoid, lipoid or myxoid differentiation illustrate the puripotent nature of mesenchymal cells. No one type of implant has consistently induced tumours of a particular type, and factors such as the strain of animal or diagnostic criteria account for some of the variation. Almost all tumours develop within or adjacent to the fibrous capsule which envelopes the foreign material, but subsequently, tumours invade locally and a proportion metastasize to the liver, lung or other tissue sites.

Humans have not been reported to develop the same persistent fibroplasia around implanted materials and few connective-tissue tumours have been observed at sites of prosthetic implants. Daily subcutaneous administration of peptide hormones in solutions at pH 4.0 or less to rats or mice have produced metastasizing tumours at the injection site, but in regular human use, the same drugs have not provoked injection-site reactions. Almost nothing is known about the reason for species differences in injection-site reactions to foreign bodies. However, the cat can develop mesenchymal tumours at the interscapular site of vaccination (Doddy *et al*., 1996) and, as in rodents, these tumours are preceded by focal and persistent fibroplasia. It is plausible that persistent fibroplasia is sustained by the local release of mitogenic growth factors, such as fibroblast growth factors, and that species differences in the regulation or activity of these peptides could account for the disparity.

12.1 Mesothelioma

On the micro scale, one of the best known and most widely studied examples of foreign body carcinogenesis is asbestos-induced pleural and peritoneal mesothelioma. This distinctive and highly lethal tumour can be induced in experimental animals and man. While asbestos is not mutagenic in bacterial tests, several forms of asbestos fibre give positive results when tested using *in vitro* or *in vivo* tests for genotoxicity (IARC, 1987). Experimental animals exposed to asbestos by inhalation, orally or by intraperitoneal injection develop an increased incidence of tumours at a variety of sites, including abdominal tumours, colonic polyps and mesenteric haemangiomas. The reader is referred to more specialist texts (IARC, 1988) for details of the mechanism of tumour induction

and details of the pathogenesis. Asbestos fibres require particular aerodynamic characteristics to be respirable, but it is their resistance to intracellular biodegradation, which has been related to the localized generation of reactive oxygen species, that are believed to initiate DNA damage and cell transformation.

13 NEW SHORT-TERM TESTS FOR NONGENOTOXIC CARCINOGENS

The substantial cost and time required to perform a rodent bioassay, combined with the frequency with which the results are considered not to be relevant for human safety, has prompted many prototype alternatives. There is considerable enthusiasm, not to say political pressure in some circles, for a six month transgenic or knockout mouse study or a 12 month newborn mouse bioassay to be used in preference to one of the two currently used lifetime carcinogenicity bioassays. A substantial multinational programme to investigate the performance of several such mouse models, Tg.AC, TgHras2 (Yamamoto *et al*., 1997), activated oncogene, $XPA^{-/-}$ (De Vries *et al*., 1997), p53 heterozygote (Harvey *et al*., 1993), inactivated DNA repair or tumour suppressor, and newborn mouse high background of cell proliferation, is underway. Early indications are that certain multitarget, trans-species carcinogens, such as glycidol, are poorly detected. Another limitation is that in some animals the transgene or knockout is not stable (it reverts to normality), and failure to monitor this has compromised some of the recent multilaboratory testing.

On inadequate evidence, the Tg.AC mouse has been suggested, by some, to be a suitable model to detect nongenotoxic carcinogens, whereas the p53 heterozygous or newborn mouse was recommended for testing of mutagenic, nonclastogenic chemicals. In the Tg.AC mouse, four copies of an activated Harvey *ras* oncogene coupled to a zeta-globin promoter and an SV40 viral polyadenylation sequence are located in tandem on chromosome 11 of an FVB/N strain mouse (Hansen *et al*., 1995). The transgene is primarily expressed in skin, the target tissue, with dermal application as the normal route of administration. Only limited data have been published on the performance of the Tg.AC model, but ethyl acrylate, a nongenotoxic carcinogen targeting the squamous forestomach, failed to test positive, whereas two nongenotoxic noncarcinogens (resorcinol and rotenone) did. It has been argued that as the metabolizing capability of skin is limited there may be inadequate exposure to metabolites which are formed on systemic exposure.

Although fascinating experimental tools, the models currently being researched require considerably more fundamental investigation before they could be considered suitable for human-risk assessment. It is unrealistic to anticipate that a uniform protocol of six months duration and 10–20 animals per group will be optimal, or even suitable, for each transgenic or knockout model. The observation that the genetic background onto which a transgene is inserted or a p53 allele is deleted can significantly affect biological response is an obvious cause for concern. It is well understood that humans with Li–Fraumeni syndrome (p53 heterozygotes), or xeroderma pigmentosum, ($XPA^{-/-}$) have a greater probability of developing cancer, and whether results based on such mouse models are better predictors of general human risk than a conventional mouse bioassay is questionable.

14 CONCLUSIONS

As new tests for genotoxic potential are developed, or existing tests are refined and adapted to new target tissues (see **Mutagenesis**), a number of the chemicals currently considered to be nongenotoxic will require reassessment.

One criticism of the most common underlying mechanism in nongenotoxic carcinogenesis is that increased cell proliferation in normally differentiated cells is neither equivalent to nor synonymous with the dysregulated, autonomous proliferation that characterizes neoplasia. Whether exposure of persistently proliferating cells to high levels of a chemical or its metabolites predisposes them to a spontaneous genotoxic event is difficult to confirm. The key question is whether lower exposure levels have a linear relationship with effect, or whether a real biological threshold needs to be surpassed. Except for the case of thyroid tumours which result from administration of exogenous TSH, there are few experimental models in which to examine these relationships. It has been observed that 'increased cell proliferation is neither necessary nor sufficient for chemical carcinogenesis'. While the polemic on mitogenesis vs. mutagenesis continues, it is advisable to consider that there may be a less than distinct boundary between genotoxic and nongenotoxic carcinogenesis, even if this is a little unhelpful in the regulation of chemical safety.

What is the importance of this form of carcinogenesis? Epigenetic neoplasia has a great significance in that the resolution of the mechanisms involved in the instances described above, and in others not considered here, has provided data of considerable significance in our understanding of cell growth and proliferation. In practical terms, the stimulus to resolve some of the issues has come from regulatory toxicology; it is certain that the identification of a mechanism for an adverse effect greatly facilitates risk/benefit

analyses and often permits much lower safety factors to be set—some neoplastic end points may simply not occur in man. Understanding of neoplasia in this work makes both a practical and a theoretical contribution.

Structure–Activity Relationships for Carcinogenic Potential

Raghuraman Venkatapathy, Nina Ching Y. Wang, Todd M. Martin, Paul F. Harten and Douglas Young

CONTENTS

1 INTRODUCTION

The primary objective of testing chemicals for carcinogenicity is to identify the carcinogenic potential in animals, and to extrapolate the relevant risk to humans. The choice of data for use in assessing the potential for carcinogenicity includes (i) experimental human carcinogenicity data, (ii) information from an animal species with biological responses that are most similar to those of humans, and (iii) data from the most sensitive animal species/sex/strain combination when (i) and (ii) are not available. Due to a lack of experimental human carcinogenicity data for many chemicals and because carcinogenicity in mice and rats often predicts carcinogenicity in humans for most chemicals (Ashby and Paton, 1993), carcinogenicity experiments almost always involve using animals, and consist of short- and long-term studies on rats and/or mice. In a typical carcinogenicity assay, one or more groups of rodents of each sex (typically 50 animals of each sex of Fisher rats and/or B6C3F1 mice) is exposed to multiple doses of the test chemical (generally ranging from 0 mg kg body weight^{-1} day^{-1} to the maximum tolerated dose (MTD)) for two years (104 weeks). At the end of the exposure duration, animal tissues are examined histopathologically for the presence of lesions at any of 59 different organ sites. Based on the results of these examinations, the carcinogenicity of the chemical for each sex/species combination is generally classified as Clear Evidence, Some Evidence, No Evidence, Equivocal Evidence or Inadequate Study (NTP, 2009). In addition, the carcinogenic potency of the chemical for each sex/species is also calculated from the experimental dose–response data (see **Dose-Response Analysis in Experimental Toxicology and Risk Assessment**).

1.1 Measures of Carcinogenic Potency

The carcinogenic potency, or the dose at which chemicals cause carcinogenicity in a test animal, is generally measured using the tumorigenic dose rate (TD_{50}) or the oral slope factor (OSF). TD_{50} is defined as that chronic dose-rate in mg of chemical per kg body weight per day, which, at the end of their standard life span, would induce tumours in half the test animals with respect to the control animals (Peto *et al.*, 1984). Other equivalent measures of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

the tumorigenic dose rate include the tumorigenic concentration rate (TC_{50}; used to represent carcinogenic potency due to inhalational exposure) or TD_{05}/TC_{05} (chronic dose/concentration that induces tumours in 5% of an exposed population). The US Environmental Protection Agency (EPA) uses an OSF (inhalational risk unit in the case of inhalational exposure) as a measure of carcinogenicity (US EPA, 2005). Slope factor is defined as an upper bound, approximating a 95% confidence limit, on the increased cancer risk from a lifetime exposure to an agent. This estimate, usually expressed in units of proportion (of a population) affected per $mg\,kg^{-1}\,day^{-1}$, is generally reserved for use in the low-dose region of the dose–response relationship, that is, for exposures corresponding to risks less than 1 in 100 (US EPA, 2005).

Both TD_{50}s and slope factors are widely used as measures of carcinogenic potency, with slope factor generally being the more conservative of the two (NRC, 1993). In general, TD_{50}s do not provide target-organ-specific dose response; they can be determined either for a particular category of neoplastic lesion or for all tumours (Peto *et al*., 1984). Sometimes, the TD_{50} can also be defined even if some of the control animals get tumours. In this aspect, the TD_{50} can be considered to be similar to the dose–response characterization of an acute toxic effect, and, hence, is not reflective of cancers from true environmental exposures. On the other hand, OSFs provide information on cancer at a specific target organ resulting from prolonged exposure to a chemical contaminant. Therefore, TD_{50} is conservative from an acute exposure point of view, while slope factor is conservative from a chronic or lifetime exposure point of view.

1.2 Disadvantages of Animal Testing in Determining the Carcinogenic Potential of Chemicals

In the absence of human carcinogenicity data, long-term animal bioassays for carcinogenicity or short-term mutagenicity tests are regularly used to determine whether chemical agents are capable of inducing cancer in humans (NRC, 1983). In conducting the animal bioassays, it is generally necessary to expose a relatively small group of animals to doses that far exceed potential human exposure levels in order to detect the presence of tumours. Hence, the results of the carcinogenicity bioassays need to be extrapolated from the high dose observed in animals to a lower dose that is more relevant to human exposure. Besides high dose levels, three other important disadvantages of current bioassays are that (i) testing covers a substantial portion of the life span of the test species, (ii) the bioassays are extremely expensive, and (iii) there are ethical and social issues involved with animal testing (Lewis, 1992; Gombar, 1998). In addition, as hundreds of new chemicals are being synthesized every year, innovative approaches are needed to determine the carcinogenicity of new chemicals as well as the existing chemicals that currently lack carcinogenicity data. In the case of predicting carcinogenic potency, these disadvantages can be circumvented by either using mathematical equations that relate the carcinogenic potency of a chemical to other measures of toxicity such as the LD_{50} (lethal dose that produces mortality in 50% of an affected population) and the MTD (highest daily dose of a chemical that does not cause overt toxicity in a 90-day study in laboratory mice or rats), or quantitative structure–activity relationships (QSARs) that relate carcinogenic potency to physicochemical properties of the carcinogens. Similarly, in the case of predicting whether a given chemical is a carcinogen, either the mutagenicity of a chemical or structure–activity relationships (SARs) that relate the carcinogenicity of a chemical to its physicochemical properties and/or chemical structure (in the form of structural alerts (SAs)) may be used.

2 ALTERNATIVE MEASURES FOR PREDICTING CARCINOGENIC POTENCY

Several authors have reported high correlations between the TD_{50} and other measures of toxicity such as the MTD and LD_{50} for chemicals in the Carcinogenic Potency Database (CPDB) (Bernstein *et al*., 1985; Crouch *et al*., 1987; Gaylor and Chen, 1986; Parodi *et al*., 1982; Portier and Hoel, 1987; Rieth and Starr, 1989a; 1989b; Zeise *et al*., 1984; 1985; 1986). The correlation between carcinogenic potency and alternative measures of toxicity such as the LD_{50} and MTD has been shown to take the form

$$\log(1/\mathrm{TD}_{50}) = m\log(1/T) \qquad (1)$$

where T is an alternative measure of toxicity, and the slope, m, is approximately equal to 1.

The above-mentioned equation implies that the potency and the toxicity differ by a factor of 10^{m-1}, and is without a proportionality constant (intercept = 0).

Travis *et al*., (1990a; 1990b; 1991) published three papers pertaining to the correlation of carcinogenic potency with short-term toxicological testing. Their original publication (Travis *et al*., 1990a) showed that short-term batteries of tests (mutagenicity and acute toxicity, $r = 0.83$) are more reliable than test batteries comprised solely of mutagenicity tests ($r = 0.40$) in predicting carcinogenic potency. Subsequently, Travis *et al*. (1990b) combined all the toxicological data (mutation, toxicity, reproduction and subchronic and chronic tumourigenicity) and found a correlation coefficient of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

$r = 0.87$ for 156 mouse carcinogens. Travis *et al*. (1991) studied the prediction of carcinogenic potency of known mouse carcinogens using short-term toxicological data. The ultimate purpose of their work was to determine the classes of toxicological data that either singularly, or in combination, best predict the carcinogenic potency of known mouse carcinogens. The authors concluded that: (i) mutation data alone were poor predictors of carcinogenic potency, and (ii) batteries of different classes of short-term toxicological data were excellent predictors of the carcinogenic potency of known mouse carcinogens. The results of the mutation data alone are not surprising given the failure of the mutagenicity tests to separate known carcinogens from known noncarcinogens by a variety of investigators (Tennant *et al*., 1987; Ashby and Tennant, 1988; Ashby *et al*., 1989).

Goodman and Wilson (1992) developed a series of mathematical equations between the tumour dose (log ($1/TD_{50}$)) and the MTD (log (1/MTD)) for several structurally diverse mutagens and nonmutagens from two different data sources for rats and mice. The first data set, tabulated by Ashby and Tennant (1988), consisted of 222 structurally dissimilar chemicals from the National Cancer Institute/National Toxicological Program (NCI/NTP) database that were mutagenic to *Salmonella*. The second data set consisted of 245 chemicals that had tested positive for mutagenicity in various *Salmonella* strains, and for which quantitative information in terms of the mean number of revertant colonies per plate at each dose level was available in the literature (Haworth *et al*., 1983; Dunkel *et al*., 1985; Zeiger *et al*., 1988). The authors found that for the rat bioassays, the variance of the tumour dose was larger, and the correlation between the TD_{50} and the MTD was weaker for mutagens ($r = 0.74$) than nonmutagens ($r = 0.85$), thereby suggesting that the relationship between the two measures was generally stronger for nonmutagens than for mutagens. In addition, the authors reported no significant differences in the correlation for various statistically significant cut-off values for the tumour dose (probability, $p < 0.01$, <0.025, <0.05 and <0.1) for both mutagens and nonmutagens. Moreover, the authors did not find any significant differences when the level of dose (low, medium and high) as a measure of separating the chemicals in their database was considered ($r = \sim 0.85$ for all levels).

Krewski *et al*. (1993) demonstrated a good correlation ($r = 0.952$ for a multistage model, $N = 191$) between TD_{50} and MTD. Krewski *et al*. (1989) also demonstrated a similar correlation ($r = 0.941$ for a multistage model, $N = 263$) between the OSF, an alternative measure of carcinogenic potency, and MTD.

Part of the correlation between the two measures may be due to a bias that is inherent in a carcinogenicity bioassay. A higher dose is generally more likely than a lower dose to cause cancer in experimental animals. However, a few researchers have suggested that the carcinogenicity observed at the high dose may be due to the toxicity and not due to cancer (Ames *et al*., 1987; Fischer *et al*., 1988). For example, chemicals may be carcinogenic at high doses due to their cytotoxicity via the production of free radicals or increased cell proliferation (Ames, 1989; Fischer *et al*., 1988). For several nongenotoxic chemicals, evidence suggests that carcinogenicity occurs only when the dose is high enough to produce a significant amount of tissue damage at a target site (Goodman and Wilson, 1992). However, toxicity alone may not be a sufficient condition for carcinogenicity since some chemicals tested in rodent bioassays produce site-specific toxic effects following chronic administration at the MTD without showing any evidence of carcinogenicity at any site (Hoel *et al*., 1988). In addition, even if there is a statistical correlation between the carcinogenic potency and alternative measures of toxicity, investigators have concluded that those correlations, and possibly the potency, are in someway determined by the bioassay design or the mathematical and statistical methods used to estimate potency rather than by inherent biological properties of the chemicals (NRC, 1983).

As a case in point, Venkatapathy *et al*. (2009) correlated the TD_{50} of 467 chemicals obtained from the CPDB with alterative measures of toxicity such as the lowest observed adverse effect level (LOAEL), LD_{50} and MTD (due to gavage and feed/water). To preserve consistency, the authors evaluated the alternative measures using TOPKAT®, a commercial QSAR software for toxicity estimation. **Table 1** provides the summary statistics for the correlation between TD_{50} and the alternative measures for the CPDB chemicals. The authors noticed a distinct lack of correlation between carcinogenic potency (for both TD_{50} and OSF) and the alternative measures. The results of the analysis by the authors suggest that alternative measures of toxicity may not be used to estimate the carcinogenic potency of the chemicals in the CPDB. However, the authors noted that a combination of the three alternative measures along with other experimental or easily estimated variables such as mutagenicity and octanol–water partition coefficients may be used to develop classification and regression trees (CART), which may in turn be used to predict the carcinogenic potency of chemicals. Hence, in order to increase the predictive ability, QSAR models with OSF or TD_{50} as the dependent variables and physicochemical properties of the chemicals as independent variables may be necessary to predict the carcinogenic potency of chemicals. These QSAR models have the added advantage in that the carcinogenic potency predictions would depend on the structure of the chemical alone and not on experimental toxicity data of the alternative measures. Hence, the carcinogenic potency can be estimated even for chemicals that lack experimental toxicity data in the literature.

Table 1 Summary statistics of the correlation between carcinogenic potency and alternative measures of toxicity

Alternative measure	Equation	Statistics
LD_{50}	$\log(1/TD_{50}) = 0.922\ (\pm 0.189)\ \log(1/LD_{50}) + 1.96\ (\pm 0.458)$	$N = 423$; $r^2 = 0.179$; adj-$r^2 = 0.177$; $F = 91.5$
MTD-gavage	$\log(1/TD_{50}) = 0.814\ (\pm 0.130)\ \log(1/\text{MTD-gavage}) + 1.41\ (\pm 0.446)$	$N = 372$; $r^2 = 0.290$; adj-$r^2 = 0.288$; $F = 150.9$
MTD-F/W	$\log(1/TD_{50}) = 0.838\ (\pm 0.130)\ \log(1/\text{MTD-F/W}) + 1.06\ (\pm 0.481)$	$N = 369$; $r^2 = 0.306$; adj-$r^2 = 0.304$; $F = 161.8$
LOAEL	$\log(1/TD_{50}) = 0.783\ (\pm 0.147)\ \log(1/\text{LOAEL}) + 1.16\ (\pm 0.558)$	$N = 363$; $r^2 = 0.232$; adj-$r^2 = 0.230$; $F = 109.4$

F/W—feed/water.

3 STRUCTURE–ACTIVITY RELATIONSHIPS FOR CARCINOGENICITY

Predictive toxicological approaches provide the means to estimate the carcinogenic and noncarcinogenic toxicity of a wide variety of chemicals in the absence of experimental toxicity data. Such approaches include (Doull *et al*., 2007): (i) qualitative SAR methods; (ii) QSAR methods; (iii) expert systems; (iv) biologically-based models such as 2D or 3D receptor modelling, comparative molecular field analysis (CoMFA), hologram QSAR (HQSAR), binding, and ligand SAR; and (v) integrative models that incorporate or combine both chemical and biological information. In general, these toxicological approaches describe correlations between various physicochemical properties of a chemical (usually referred to as descriptors of molecular structures of chemicals) and their observed or predicted biological activities. Such relationships assume a common mechanism behind the biological activity of a structurally/functionally related set of chemicals (Basak *et al*., 1995). Hence, differences in the chemical structures that induce the same biological effect, such as carcinogenicity, and their associated descriptors can then be mapped to changes in activity through mathematical equations. The resulting equation can then be used to calculate the carcinogenicity of new chemicals.

3.1 Types of (Q)SAR Models

SARs for predicting the carcinogenicity of chemicals are either qualitative in nature or expert-system based. In the former case, there is a qualitative relationship between the observed biological activity (such as whether a test chemical is a carcinogen or not) and a chemical and/or its substructure (such as its 1- and 2-atom fragments). A substructure associated with the presence of the biological activity may also be referred to as a structural alert. SARs are generally able to qualitatively estimate the toxicity of a given chemical as positive, negative or indeterminate. In the case of expert systems, experts in various toxicological end points review the experimental data on a case-by-case basis and make judgements regarding the toxicity potential for any given chemical. Expert systems may be classified as knowledge based (rules are based on human expert knowledge), induction rule based (based on artificial intelligence, neural networks, machine learning or data mining to automatically derive the rules) or hybrid (rules are initially based on human expert knowledge; machine can 'gain experience' or learn new rules). For example, Ashby (1985) introduced a set of 19 SAs for predicting potential carcinogens and noncarcinogens. These include: alkyl esters of either phosphonic or sulfonic acids; aromatic nitro groups; aromatic azo groups; aromatic rings *N*-oxides; aromatic mono- and di-alkylamino groups; alkyl hydrazines; alkyl aldehydes; *N*-methylol derivatives; monoalkenes; N and S β-haloethyl; *N*-chloroamines; propiolactones and propiosultones; aromatic and aliphatic aziridinyl derivatives; aromatic and aliphatic substituted primary alkyl halides; derivatives of urethane (carbamates); alkyl *N*-nitrosoamines; aromatic amines (including their *N*-hydroxy derivatives and the derived esters); aliphatic and aromatic epoxides; and polycyclic aromatic hydrocarbons.

A QSAR is a mathematical model between a quantifiable biological activity (such as carcinogenic potency) and one or more physicochemical properties of the chemical (also referred to as molecular descriptors) using various statistical methods such as regression analysis, principal component analysis (PCA) or factor analysis. In general, such relationships may be classified as either mechanistic or correlative. Correlative (or statistical) models try to find associations between molecular descriptors (physicochemical properties), toxicological data and a wide variety of chemical structures by statistical means, which are then used to predict the toxicity of a test chemical. Mechanistic models, on the other hand, are developed using human expertise on known mechanisms of action or are limited to a congeneric series of chemicals with the assumption that congeneric chemicals have similar mechanism(s) or mode(s) of action.

DOI: 10.1002/9780470744307.gat079
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Other approaches to predicting the toxicities of chemicals include read-across and chemical-analogues. Read-across is a nonformalized approach in which end-point information for one or more source chemicals is used to make a toxicity prediction for another chemical based on some form of similarity (Worth *et al.*, 2007). Read-across can either be qualitative or quantitative, depending on the whether the data being used to make the prediction are qualitative or quantitative in nature. To estimate the properties of a given substance, read-across can be performed in a one-to-one manner (one analogue is used to make a single prediction) or in a many-to-one manner (two or more analogues are used to make a single prediction).

In rare cases, when existing toxicity data are inadequate for determining a toxicity value for a chemical of interest, a chemical analogue for the test chemical is identified using either known mechanisms of toxicity or using a SAR/QSAR-based approach. The choice of the appropriate analogue is based on similarity between the test chemical and the analogue. The toxicity value of the analogue may then be used as the toxicity value for the test chemical. The similarity of chemicals used in the analogue selection process may be either structural or functional. Structural similarity between chemicals, as the name implies, refers to chemicals that have a similar chemical structure or backbone. Functional similarity, on the other hand, refers to chemicals that have similar functionality or activity. In such a case, the two chemicals may have either similar physicochemical properties, properties that follow the same trend, or they may cause similar health effects and/or have the same mechanism of action. **Table 2** shows examples of the two kinds of similarity.

3.1.1 Advantages/Disadvantages of the Different Types of Models

As with statistical models, there are both advantages and disadvantages with mechanistic and expert-system-based models. The correlative models use unbiased assessment of the data to generate relationships and make toxicity predictions; however, these models provide no insight on the mechanistic nature of chemicals and are capable of generating relationships that have little biological plausibility. In addition, the predictive capability of the model is dependent upon the quality of the data used in model development. For these reasons, correlative models have to be carefully validated prior to use. The advantage of a mechanistic model is that it is based on an understanding of mechanism of action to determine the activity of a given chemical, which is generally done by using human input. However, such systems are restricted to human knowledge and are not capable of providing insight into new relationships or discovering new insights

Table 2 Structural similarity vs. functional similarity

Structurally similar chemicals	Chlorobenzene	Bromobenzene
			Chloromethane	Nitromethane
		Functionally similar chemicals	Coumaphos	Glycine
			Phenobarbital	DDT

and/or novel associations between structure and toxicity. As a result, such models are biased towards current ideas on mechanism of action. The most serious drawback of these systems is that the rules, sometimes in thousands, relate only to 'positivity', and assume that all chemicals that are not governed by any of the rules are 'negative'. This generally leads to a large number of false positive predictions.

3.2 Commercial/Noncommercial Software for Predicting Carcinogenicity

Various commercial and noncommercial (Q)SAR software programs purport to predict the carcinogenicity of noncongeneric series of chemicals (Dearden *et al*., 1997; Lewis *et al*., 1992; 1993; Richard, 1994; 1998; Wang and Milne, 1993). These programs may be broadly classified as expert or knowledge based, or statistically based. Examples of knowledge-based systems include Deductive Estimation of Risk from Existing Knowledge (DEREK, LHASA Ltd., Leeds, UK); HazardExpert (Compudrug Ltd., Budapest, Hungary); OncoLogic (Logichem Inc., Boyertown, PA, USA); and Computer Optimised Molecular Parametric Analysis of Chemical Toxicity (COMPACT, University of Surrey, Guildford, UK). Examples of statistically based systems include Automatic Data Analysis using Pattern Recognition Techniques (ADAPT, Pennsylvania State University, Philadelphia, PA, USA); Discovery Studio TOxicity Prediction by Komputer Assisted Technology (DS TOPKAT, Accelrys Software, Inc., San Diego, CA); Computer-Automated Structure Evaluation (CASE) and Multiple Computer-Automated Structure Evaluation (MultiCASE) (MultiCase Inc., Cleveland, OH, USA); (Q)SAR Application Toolbox (Organisation for Economic Co-operation and Development (OECD)); Laboratory of Mathematical Chemistry (LMC), Bourgas, Bulgaria); Quantitative Structure-Activity Relationships Expert System (QSAR-ES, MultiCase Inc.; US Food and Drug Administration (FDA)); Lazy Structural Activity Relationships (lazar, in silico toxicology, Freiburg, Germany); Prediction Activity Spectra for Substances (PASS, Poroikov and Filimonov, 2005); and COmmon REactivity PAttern (COREPA, Bourgas Prof. Assen Zlatarov University, Bourgas, Bulgaria). Patlewicz *et al*. (2003) and Benigni (2005) provide recent reviews on the ability of the QSAR models referred above to predict the mutagenicity and carcinogenicity of chemicals.

The software programs mentioned above predict the carcinogenicity of chemicals based on their structure alone, and have been used and validated by regulatory agencies including the Danish EPA, US EPA, US FDA, Health Canada, European Chemicals Bureau and the UK Health and Safety Executive (HSE), academia and industry alike because of their ease of use and rapid application. Commonly used software programs to predict the carcinogenicity of chemicals are described in more detail below.

3.2.1 Computer-Automated Structure Evaluation (CASE)/MultiComputer Automated Structure Evaluation (MCASE/MultiCASE)

The CASE and MultiCASE methodology, and the resulting commercial software, including MCASE, MCWeb, MC_NET, MC4PC, CaseTox, ToxLite and METAPC were developed by Klopman *et al*. (Klopman, 1984; 1992; Klopman and Rosenkranz, 1991; MultiCASE Inc., *www.multicase.com/*). These software programs can automatically identify molecular substructures and/or fragments that have a high probability of being responsible for an observed biological activity such as carcinogenicity for a set of tested chemicals, provided the training set that was used to develop the model contains both active and inactive chemicals (i.e. chemicals that are both carcinogens and noncarcinogens in the case of carcinogenicity). New, untested molecules can then be submitted to the program either through a structure-drawing program or as an MDL Molfile (an MDL Molfile is a file format formerly created by MDL, Inc., and currently owned by Symyx Technologies, Inc. (*www.symyx.com*), for holding information about the atoms, bonds, connectivity and coordinates of a molecule) (Dalby *et al*., 1992), and an expert prediction of the potential activity of the new molecule can be obtained. CASE- and MultiCASE-based products provide the user with the capability of adding experimental data.

A modified version of the CASE and MCASE program called MultiComputer-Automated Structure Evaluation-Expert System (MCASE-ES) was developed through a cooperative agreement between the FDA's Centre for Drug Evaluation and Research, and MultiCASE (Matthews and Contrera, 1998). MCASE-ES was built using a larger training set of substances to identify all possible functional groups that may be responsible for the biological activity of the training set, and has a broader range of applicability. In addition, MCASE-ES contains an expanded training set of drug substances, and was specifically designed to filter out single-sex or single-species carcinogens, and thus has the ability to focus on trans-species and transgender carcinogens. Substances that are organometallic or with a molecular weight >5000 Da cannot be evaluated by MultiCASE products, thus limiting its usefulness with regard to polymers and catalysts (Contrera *et al*., 2007).

AGW	FDA male/female mouse (proprietary)	1246

TCDD—tetrachlorodibenzo-*p*-dioxin; PAH—polycyclic aromatic hydrocarbon.

MCASE and CaseTox contain more than 180 modules that cover various areas of toxicology and pharmacology, including acute toxicity in mammals, absorption, distribution, metabolism and excretion (ADME), various adverse effects, antibacterial and pharmacological, carcinogenicity, cytotoxicity, developmental toxicity and teratogenicity, ecotoxicity, biodegradation and bioaccumulation, enzyme inhibition, genetic toxicity, and skin, eye irritations and allergies. There are 36 modules in the carcinogenicity area including CPDB rat and mice carcinogenicity, NTP and FDA rodent carcinogenicity, hepatocarcinogenicity and human carcinogenicity. **Table 3** lists the names of the 36 modules under carcinogenicity, and the number of test chemicals that were used to build the modules.

The CASE and MultiCASE methodology use probability assessment to determine whether structural fragments are associated with carcinogenicity. To achieve this, both carcinogens and noncarcinogens are split into structural fragments up to a certain path length (2–10 atoms). Each of these fragments is associated with a confidence level and a probability of carcinogenicity or noncarcinogenicity that is derived from the distribution of these biophores (a fragment whose functionality is

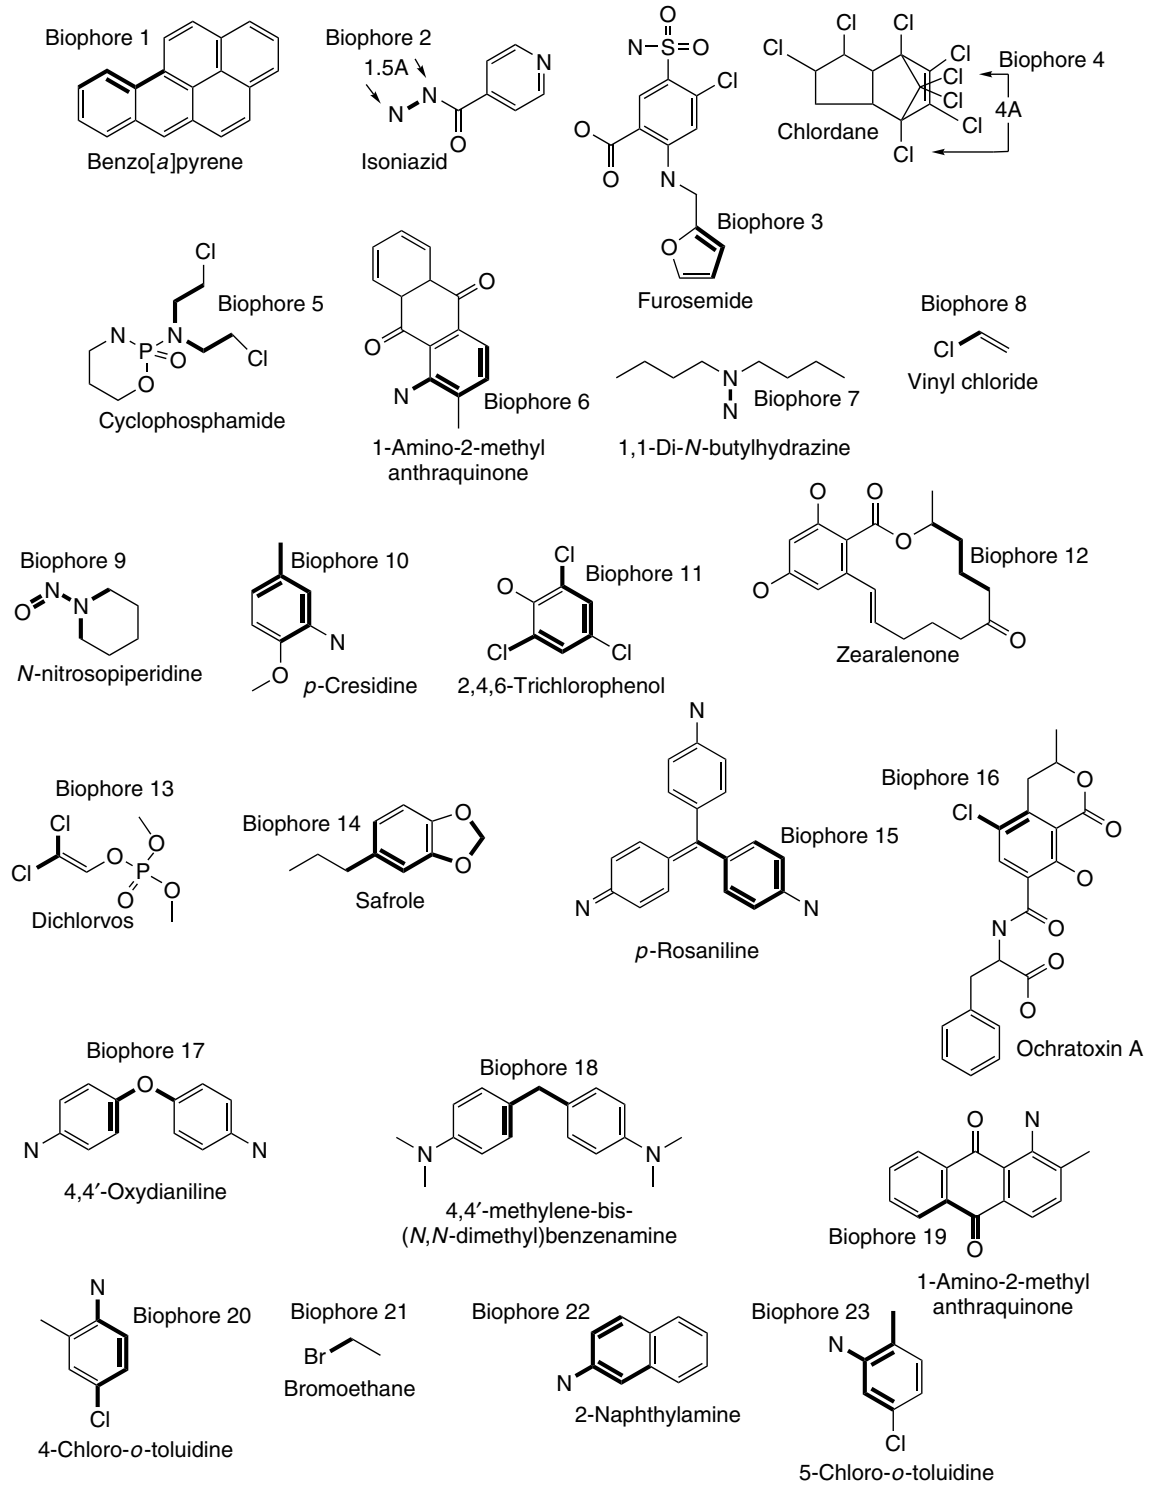

Figure 1 Biophores (bonds that are dark) that predict the carcinogenicity of chemicals in rats. (Reproduced with permission from Cunningham *et al*., 1998. © Elsevier.)

associated with the largest number of carcinogens and the smallest number of noncarcinogens in a training set that contains an equal number of carcinogens and noncarcinogens) and biophobes (the opposite of a biophore). Examples of biophores for predicting carcinogenicity in rats and mice are shown in **Figures 1** and **2**, respectively.

The fragments are then combined to give an equation of the following form (Klopman and Rosenkranz, 1994):

$$\text{CASE units} = a[\text{Fragment 1}] + b[\text{Fragment 2}] + \cdots + \text{Constant} \quad (2)$$

Based upon this relationship, chemicals are designated as carcinogens, marginal or chemicals with weak carcinogenicity, or noncarcinogens.

Cunningham *et al*. (1998a; 1998b) studied the prediction of MultiCASE for carcinogenicity in rats and mice for chemicals in the CPDB. For mice, the authors observed a concordance rate (number of correct predictions divided by the number of total predictions) of 70%, a sensitivity (per cent correct positive predictions) of 63%, and a specificity (per cent correct negative predictions) of 78% using the overall SAR model. The corresponding values for rats were 64, 55 and 73%, respectively. The authors concluded that the poor predictivity of the rat SAR model when compared to the mouse SAR model may be indicative of a more variable response to chemical carcinogens for rats than for mice. The authors also suggest that MultiCASE SAR models for rat and mice were able to make relatively accurate predictions of carcinogenicity for chemicals of unknown activity.

3.2.2 Computer Optimized Molecular Parametric Analysis of Chemical Toxicity (COMPACT)

COMPACT is a methodology developed by Lewis *et al*. (1992). COMPACT can be used to predict the potential of a chemical to act as a substrate for one or more of the cytochromes P450 (P4501, P4502B, P4502E and P4504; Parke *et al*., 1990; Lewis, 1996). COMPACT can also be used to identify chemicals which have the potential to bind to receptors involved in the induction of cytochromes P450 and peroxisome proliferation (Dearden *et al*., 1997), and is based on the hypothesis that the structural characteristics of a molecule determine its ability to fit into the appropriate binding site on an enzyme (molecular shape such as area, depth, etc.) whereas its electronic characteristics (chemical reactivity) determine whether the resulting enzyme–substrate complex can be activated for oxidative metabolism. Thus, a combination of structural and electronic parameters is used to predict whether a particular molecule is likely to act as a P450 substrate. Lewis (1996) and Dearden *et al*. (1997) provide more information on the methodology behind COMPACT.

Lewis *et al*. (1990; 1993) evaluated the rodent carcinogenicity of chemicals tested by the NTP using COMPACT. The authors indicate that the methodology gave a concordance of 72% in a study containing 40 chemicals (Lewis *et al*., 1990) and a degree of correlation of 92% in a study containing 100 chemicals (Lewis *et al*., 1993). Brown *et al*. (1994) evaluated the rodent carcinogenicity of 80 NTP chemicals (56 carcinogens; 24 noncarcinogens) using COMPACT; the authors note that the program predicted both carcinogens (71%) and noncarcinogens (67%) with a similar level of accuracy, leading to an overall concordance of 70%.

3.2.3 Deductive Estimation of Risk from Existing Knowledge (DEREK) for Windows

DEREK is a knowledge- or rule-based expert system that was originally created by Schering Agrochemicals in the UK in 1986, and subsequently developed and marketed by LHASA Ltd. (School of Chemistry, University of Leeds, UK) and Harvard University (Boston, MA, USA) in collaboration with industry, academia and user groups. DEREK is able to predict toxicological end points such as skin sensitization, respiratory sensitization, irritancy, corrosivity, mutagenicity, carcinogenicity, teratogenicity, neurotoxicity, lachrymation, methaemoglobinaemia and anticholinesterase activity, and is based on an analysis of the chemical structure alone. Toxicological predictions for a given end point are generally based on the following criteria (Maslankiewicz *et al*., 2005): SAs, species, toxicity data, toxicity end point and physicochemical properties of chemicals.

To use the system interactively, molecular structures are entered into DEREK either via the built-in chemical editor program or by importing Molfiles or SDfiles (Dalby *et al*., 1992). The program compares structural features in the test chemical with the toxicophores described in its rule base, highlights toxicophores (or biophores), and provides a justification for each prediction in terms of the rules fired, the mechanistic or historical basis for the rule, and any supporting literature used in rule development. In addition, end-point-specific information is also included in the output. For example, in the case of carcinogenicity, additional information may be in the form of organ or species specificity, where sufficient supporting data exist. However, the system reports that no toxicophores have been identified in the structure in the case none of the rules were applied.

DEREK has several rule bases, which generally consist of descriptions of molecular substructures (SAs), which have been associated with toxic end points on the basis of existing knowledge (Dearden *et al*., 1997). An SA in DEREK consists of a toxicophore along with associated references, opinions, comments and examples. The rules are developed and monitored by LHASA Ltd. and its collaborators including industry, academia and user groups, and are based on sets of related chemicals rather than on specific chemicals. In addition, the rules may be based on generic 'use' categories of chemical such as dyes and solvents, or classes of organics such as nitroaromatics and organophosphates. A majority of the rules are derived from mechanistic organic chemistry. New DEREK rules are established using a detailed review of published sources of toxicological, mechanistic and chemical data. Reasoning rules have the following formula (Maslankiewicz *et al*., 2005):

$$\text{If } [\textit{Grounds}] \text{ is } [\textit{Threshold}] \text{ then } [\textit{Proposition}] \text{ is } [\textit{Force}] \quad (3)$$

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

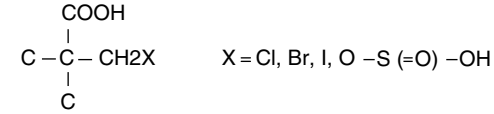
DOI: 10.1002/9780470744307.gat079
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

RULE 27:
RISK Mutagenicity, Carcinogenicity
TOXOPHORE: Alkylating agent
REMARKS:

This rule describes the mutagenicity and carcinogenicity of alkylating agents (alkyl halides, sulphinates and sulphates) according to the following toxicophores:

(I) C-Cl,Br,I (II) C-O-S=O but not C-O-S(=O)-OH

Where C is a primary or secondary alkyl carbon atom, which may only be neopentyl if it is a beta-halo carboxylic acid or its sulphinate, sulphonate or sulphate equivalent of



This is based on the observed mutagenicity, at pH 7.4 of 3-chloropivalic acid, which results from intramolecular cyclisation to a mutagenic beta-lactone.

References: (1) J Ashby, RD Callander and D Gilman, Mut. Res. 140:71 (1984);
(2) EL Tan, PA Brimer, RL Schenley and AW Hsie, J. Tox. Env. Health 11: 373 (1983).

Figure 3 DEREK reference screen for Rule 27 that is triggered for the mutagenicity and carcinogenicity prediction of haloacetic acids. (Reproduced with permission from Richard, 1998. © Elsevier.)

where *[Grounds]* is the evidence to be considered by the reasoning rule, *[Threshold]* is the level above which the grounds must be for the proposition to be assigned the force, *[Proposition]* is the outcome of the reasoning rule, and *[Force]* is the likelihood of the reasoning rule outcome.

For example, **Figure 3** shows a sample reference screen for a DEREK rule supporting the prediction of mutagenicity/carcinogenicity for monohalogenated acetic acid, along with a description of the structural requirements of the rule, mechanistic rationale and supporting references from the literature. The DEREK rule base for carcinogenicity contains more than 49 rules.

Marchant (1996) and the DEREK Collaborative Group (1996) evaluated the ability of DEREK to predict the carcinogenicity of 30 chemicals that were bioassayed as part of the second NTP comparative exercise. The authors report that DEREK had an accuracy of approximately 43%. After the exercise, additional rules were added into the DEREK carcinogenicity knowledge base.

3.2.4 HazardExpert

HazardExpert is a rule-based system developed by Compudrug (Budapest, Hungary) using known toxicophores or biophores collected from the literature or through *in vivo* experiments. The knowledge base in HazardExpert was developed based on the list of toxic fragments reported by more than 20 experts. HazardExpert predicts a range of toxicities including mutagenicity, carcinogenicity, teratogenicity, oncogenicity, irritation, sensitization, immunotoxicity and neurotoxicity. In addition to toxicity, HazardExpert also estimates toxicokinetic effects such as bioaccumulation and bioavailability that are based on predicted physicochemical properties (primarily the octanol–water partition coefficient, log P, and the acid-dissociation constant, pK_a). HazardExpert in combination with its sister product, MetabolExpert (a system for predicting metabolites), can be used to predict the toxicity of both the parent compound and its metabolites.

To use HazardExpert, a user selects a chemical from the HazardExpert database, defines the species, route of administration, dose level and duration of exposure. If the test chemical is missing in the database, the user must enter it into the database using the attached chemical editing interface or by adding the metabolites predicted by MetabolExpert before selecting the chemical. Upon execution, substructures that exert a positive or negative effect with respect to the chosen toxicity are identified based on known toxicophores stored in the toxic fragments knowledge base. HazardExpert provides the user with the means to add and/or modify rules and their related references through the knowledge maintenance module. Toxicity estimation results including the toxicity classification are displayed to the user as histograms.

Dearden *et al*. (1997) evaluated the performance of HazardExpert for its ability to predict human and animal carcinogenicity on 192 chemicals from the International Agency for Research on Cancer (IARC) monographs. The authors report that approximately 55% of the chemicals were predicted by HazardExpert within ±1 of the IARC classification when the 'high' exposure condition was chosen, compared to about 75% when the 'low' exposure condition was chosen. The authors also report the lack of important fragments in the toxic fragments knowledge base, thus leading to incorrect predictions for benzene, vinyl chloride, organophosphates, polyaromatic hydrocarbons, organometallics and isocyanates. In a second study, Brown *et al*. (1994) evaluated the rodent

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat079
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

carcinogenicity of 80 NTP chemicals (56 carcinogens and 24 noncarcinogens) using HazardExpert. The authors report that HazardExpert was found to be good at identifying noncarcinogens (81% specificity), but was poor at identifying carcinogens (36% sensitivity), with an overall concordance of 51%.

3.2.5 OncoLogic

OncoLogic™ is a knowledge-based expert system developed by LogiChem Inc. (Boyertown, PA, USA) in cooperation with the US EPA's Structural Activity Team. The software predicts potential carcinogenicity of chemicals by applying rules of mechanism-based SAR analysis, functional analysis and expert judgement. The rules were developed based on data from a variety of sources including IARC Monographs, NCI/NTP bioassay reports and other publicly available data and information from EPA files (US EPA, 2008).

To make a carcinogenicity prediction, OncoLogic makes use of mechanism-based SAR analysis, which involves comparison with structurally related compounds with known carcinogenic activity, identification of structural moieties or fragments that may contribute to carcinogenic activity through a perceived or postulated mechanism, and evaluation of the modifying role of the remainder of the molecule to which the structural moiety/fragment is attached (OncoLogic, *www.epa.gov/oppt/newchems/tools/oncologic.htm*). Currently, OncoLogic has subsystems that can evaluate fibres, metals, polymers, and 48 classes of organic chemicals. Each subsystem has a fixed, hierarchical, decision-tree structure, consisting of rules of the 'if-then-else' type, and proceeds to a carcinogenicity evaluation based on the structural information entered, and on answers to program queries provided by the user. The organics subsystem is the largest of the four subsystems, and consists of over 40 000 rules derived from the examination of more than 10 000 organic chemicals. If the chemical of interest cannot be placed into one of the chemical classes listed, either the Miscellaneous Class or the Functional Analysis component has to be used to evaluate the chemical.

The carcinogenicity evaluation of a chemical begins when the user chooses one of the predefined chemical classes, and enters the test chemical by either selecting structural templates or by drawing in structures within the constraints of the chosen class. Upon execution, the program makes a prediction of the carcinogenic potential of the chemical (low, marginal, low–moderate, moderate, moderate–high or high) and produces a detailed report which conveys the mechanism-based expert reasoning underlying the evaluation, including the general considerations applicable to the class of chemicals, the rules specific to the test chemical, and rules that apply to the test chemical's reactivity and/or metabolites.

Mayer *et al*. (2008) evaluated the predictive ability of OncoLogic and MCASE for 301 chemicals tested under the NTP. The authors reported that MCASE and OncoLogic had similar concordance values (83 and 88%, respectively), and that OncoLogic had a lower percentage of false negatives. However, the authors also reported that MCASE had broader applicability as it was able to analyse more chemicals in general than OncoLogic. Benigni and Zito (2004) compared the predictive ability of 19 different SAR models for 30 new chemicals tested under the NTP. The authors found that OncoLogic had the best prediction accuracy of 65% among the 19 models.

3.2.6 (Q)SAR Application Toolbox

The OECD (Q)SAR Application Toolbox is open-source software that is currently being developed through a collaborative effort between the Danish EPA, European Chemicals Bureau (ECB), Environment Canada, Ministry of Economy, Trade and Industry of Japan (METI Japan), MultiCASE Inc., LMC, OECD, Syracuse Research Corporation (SRC) and the US EPA. The Toolbox provides several computational methods and information technologies for the application of (Q)SARs, or a category approach for filling data gaps that are necessary for hazard and risk assessment. The toolbox currently contains three tracks—(Q)SAR track, the category track and the flexible track (OECD, 2007).

The (Q)SAR track provides the user with approaches to fill the data gaps using (Q)SAR models. Within this track, the user is able to input target chemical(s), collect available information from databases, and select reliable (Q)SAR models to predict toxicities of chemicals for various health end points. To make a prediction for a particular end point, the user may choose a model from a list of available models and their performance statistics. The category and flexible tracks provide the user with the ability to fill the data gaps by making use of analogues. The Toolbox provides the user with the ability to form a group of chemicals similar to the target chemical using a set of rules based on chemical functionality and structural characteristics. Read-across, trend analysis and (Q)SARs predictions may also be used to assess the missing end points and their reliability for the target chemical. The main difference between the category and flexible tracks is that the user has the ability to jump across functionalities in the flexible track (OECD, 2007).

Currently, depending on the availability of data, the (Q)SAR Application Toolbox is able to make qualitative and quantitative predictions and/or develop (Q)SAR models for various health end points such as aquatic toxicity, carcinogenicity, mutagenicity, eye irritation, skin sensitization, acute toxicity, immunotoxicity, neurotoxicity, biodegradation and bioaccumulation.

The Application Toolbox was created in two phases. A beta version of the Toolbox that emphasised a technological proof-of-concept was released in March 2008. The first phase of the project that developed a more comprehensive Toolbox that fully implemented the capabilities of the beta version while adding functionalities to the built-in databases, and an expansion of the QSAR and SA libraries was launched as (Q)SAR Application Toolbox version 1 in November 2008, which was later updated to version 1.1 in December 2008.

The OECD started the second phase of the project, upgrading the first version to a more comprehensive Toolbox, in November 2008. The long-term goal of the Phase 2 project is to ensure that the 'categories approach' to filling data gaps works uniformly for all discrete organic chemicals and for all regulatory endpoints. Areas of work in Phase 2 include information technology, chassis development and additional functionalities, database compilation, (Q)SAR library, and expert system compilation and training (OECD, 2009). The Phase 2 activities are scheduled over four years (2008–2012). The OECD anticipates that new versions of the Toolbox will be released periodically; version 2.0 is expected to be released in 2010, while version 3.0 is expected to be released in 2012 (OECD, 2009).

3.2.7 TOPKAT

Discovery Studio Toxicity Prediction by Komputer Assisted Technology (DS TOPKAT), originally developed by Health Designs, Inc. (Rochester, NY) and currently marketed by Accelrys Software Inc. (San Diego, CA), is a PC-based modular software for the prediction of a wide variety of health end points. The predictions made by TOPKAT can either be quantitative or qualitative in nature. The qualitative models in TOPKAT provide dichotomous output (yes/no) for NTP rodent carcinogenicity, FDA rodent carcinogenicity, weight of evidence rodent carcinogenicity, Ames mutagenicity, developmental toxicity potential, skin sensitization, skin irritancy, ocular irritation and aerobic biodegradability (Accelrys, 2001). The NTP and FDA rodent carcinogenicity modules are comprised of four models, one each for male rats, male mice, female rats and female mice. The quantitative models provide point estimates for LOAEL, LD_{50}, lethal concentration (LC_{50}), effective concentration (EC_{50}), MTD and octanol–water partition coefficient (V log P) along with 95% confidence limits for each (Accelrys, 2001). Each TOPKAT module consists of a specific database of carefully screened chemicals, and several chemical subclass-specific cross-validated QSAR models for predicting a specific toxicity end point. In order to assess the end-point specific toxicity for any given chemical structure, the software employs appropriate bulk, electronic and transport attributes that are presumed to be responsible for the biological activity of the molecule (Gombar, 1998; Purcell *et al*., 1973).

To make a carcinogenicity prediction, the user has to enter the chemical structure in SMILES (Simplified Molecular Input Line Entry System; Weininger, 1988) format in TOPKAT and select a model as the prediction module. The software first screens the chemical structure against the model substructural library to determine adequate coverage, and automatically chooses the appropriate chemical class-specific QSAR submodel to generate the toxicity prediction. A prediction is considered successful when the results of the substructure analysis satisfy the validation criteria for both the univariate and multivariate procedures that are built into the model, and the descriptor values are within the model domain (Gombar, 1998; Moudgal *et al*., 2003; Gombar and Enslein, 1996).

Prival (2001) used TOPKAT to predict the results of the rodent carcinogenicity bioassays conducted by the NTP (Research Triangle Park, NC, USA). The author found that the positive and negative predictivity and overall concordance figures ranged from 40 to 64%. In addition, Prival (2001) found that TOPKAT predicted a higher proportion of negatives (80%) than were actually found in the NTP studies (52%).

Cotterill *et al*. (2008) compared experimental toxicity of approximately 780 chemicals to those made by TOPKAT for various health end points. Of the 65 chemicals for which carcinogenicity data were available, TOPKAT was able to accurately classify 9 of 11 chemicals as carcinogenic (82%). Of the remaining 54 chemicals that were noncarcinogenic, TOPKAT accurately classified 40 chemicals (74%), while 2 were classified as indeterminate and the remaining 14 chemicals were false negatives.

3.3 SARs and QSARs for Predicting Carcinogenicity and Carcinogenic Potency

In general, QSARs for predicting carcinogenicity have been mostly limited to chemical congeners, that is, chemicals belonging to a certain class such as aromatic amines, in anticipation that these chemicals will have the same mechanism of action (Benigni and Giuliani, 1996; Cronin and Dearden, 1995; Debnath *et al*., 1994; Hansch, 1991; Leo *et al*., 1995; Passerini, 2003). However, a few non-class-specific QSARs for predicting the carcinogenicity of chemicals have also been developed over the past few years. A number of authors have developed QSARs to predict the mutagenicity of aromatic amines (Benigni *et al*., 2003; Chung *et al*., 1997; Colvin *et al*., 1998). Yuta and Jurs (1981) used the ADAPT software to discriminate between carcinogens and noncarcinogens among 157 aromatic amines using topologic and

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

geometric descriptors. The authors found that the total number of rings was the most significant descriptor that differentiated between carcinogens and noncarcinogens.

Dunn and Wold (1981) used the SIMCA (soft independent modelling of class analogy) pattern recognition method to classify the carcinogenicity of 50 *N*-nitroso chemicals that were divided into three classes depending on whether they required metabolic activation (41 chemicals) or not (9 chemicals). The chemicals that required metabolic activation were divided into two classes depending on neutral or electron-donating substituents on the amine nitrogen (27 chemicals) or electron-withdrawing substituents (14 chemicals). The authors reported that the SIMCA procedure correctly classified 44 of the 50 (88%) chemicals.

Ashby and Tennant (1988) analysed 222 chemicals tested by the NTP to determine relationships between chemical structure and carcinogenicity, and mutagenicity. They discovered a 90% concordance between SAs based on DNA-reactivity and *Salmonella* mutagenicity. In a later study on 301 NTP chemicals, Ashby and Tennant (1991) classified each of the compounds as either structurally alerting or nonstructurally alerting. They found that most of the rodent carcinogens (64%) were structurally alerting and that 84% of the structurally alerting carcinogens analysed were mutagenic. However, the authors also observed a low concordance between DNA reactivity and carcinogenicity.

Purdy (1996) developed a hierarchical model consisting of QSARs mainly based on chemical reactivity to predict the rodent carcinogenicity of organic chemicals. The hierarchical model had a classification rate of 96% in a training set of 306 chemicals and 90% in a test set of 301 chemicals. Vračko (1997) studied the carcinogenic potency of 45 benzene analogues using artificial neural networks and three types of descriptors—geometrical structures of molecules described by the three-dimensional coordinates of atoms, geometrical structures in combination with atomic charges and energy of the frontier molecular orbitals. The author reported that while the model was able to describe the training set ($r > 0.9$), the predictive ability was quite poor.

Gini *et al*. (1999) developed an artificial neural network-based QSAR model for predicting the TD_{50} of nitrogen-containing aromatic chemicals. Thirty-four descriptors were calculated and principal components used to reduce the number of descriptors while retaining 85% of the variance in the descriptors. A four-neuron model using all chemicals yielded a cross-validated correlation of 0.69, which increased to 0.82 after removing 12 outliers.

Benigni *et al*. (2000) developed QSAR models for grading the carcinogenic potency of nonheterocyclic aromatic amines for rats and mice. Among the various descriptors in the QSAR model, the authors found that the carcinogenic potency was influenced by increasing hydrophobicity. However, the authors also found that the QSAR models for carcinogenic potency were inadequate in describing the difference between carcinogenic and noncarcinogenic amines. Hence, the authors developed four discriminant models based on electronic and steric parameters for male/female rats/mice to differentiate between carcinogenic and noncarcinogenic aromatic amines (Franke *et al*., 2001). The discriminant functions showed classification rates between 83.3 and 96% for the chemicals considered in their study.

Choo *et al*. (2001) compared the predictive ability of three different three-dimensional QSAR (3D-QSAR) methods (CoMFA, HQSAR and comparative molecular similarity indices analysis (CoMSIA)) for predicting the anticarcinogenic activity of 28 diarylsulfonylureas. The authors reported that all three 3D-QSAR methods had a good predictive ability in terms of external cross-validated correlation coefficient values between 0.63 and 0.74. The authors also indicated that while HQSAR and CoMSIA had slightly lower predictive ability than CoMFA, the two methods process data at a much faster rate than CoMFA as HQSAR does not require the generation of a 3D structure while CoMSIA does not require superposition of the chemical structures.

Contrera *et al*. (2003) used MDL-QSAR software (MDL, San Ramon, CA) to develop SARs to predict the rat carcinogenicity of 86 pharmaceuticals and 22 organic chemicals. The SAR model was developed using a test set of 1275 pharmaceuticals and organic chemicals. The authors report that the model had good coverage (93%), concordance (73%), sensitivity (74%) and specificity (72%) for the 108 chemicals in the validation set. In addition, the model was able to accurately predict 72% of noncarcinogenic compounds and compounds with carcinogenic findings.

Helguera *et al*. (2005) developed a discriminant model that was based on a topological substructural molecular design approach (TOPS-MODE) to predict the carcinogenic and noncarcinogenic activity of 189 chemicals. The authors found that their model classified approximately 76% of the chemicals accurately. The authors suggest that hydrophobicity increased the carcinogenic activity of chemicals while dipole moment had the opposite effect. Helguera *et al*. (2007) also developed a QSAR model using TOPS-MODE and other descriptors calculated using the Dragon software to predict the carcinogenic potency of 35 chemicals that contained a nitroso group. The authors indicate that models developed using TOPS-MODE descriptors was able to account for 83% of the experimental variance while other models developed using Dragon descriptors could account for less than 79% of the experimental variance. The authors suggest that QSARs developed using TOPS-MODE can help in forming a mechanistic basis for the prediction of carcinogenic potency through the identification of SAs.

Valerio *et al*. (2007) evaluated the ability of MDL-QSAR and MDL's rodent carcinogenicity module

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat079
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to predict the carcinogenic potential of 123 naturally occurring chemicals in the human diet. The authors indicate that MDL-QSAR was able to correctly predict 97% of the naturally occurring chemicals with experimental high-risk rodent carcinogenic potential and 53% with experimental low-risk rodent carcinogenic potential. A similar study of 108 pharmaceuticals by Contrera *et al*. (2003) indicated that MDL-QSAR had excellent coverage (93%), good sensitivity (72%) and specificity (72%) for rodent carcinogenicity.

Venkatapathy *et al*. (2007) developed QSARs to predict the rat carcinogenic potency of 448 chemicals from the CPDB (*http://potency.berkeley.edu/cpdb.html*) and the Integrated Risk Information System (IRIS) database (US EPA, 2008). Approximately 4000 descriptors were calculated using CAChe™, AMPAC™/CODESSA™ (Semichem Inc., Kansas City, MO), Dragon (Talete SRL, Milano, Italy) and Molecular Connectivity (Molconn-Z; eduSoft LC, Ashland, VA). Results of the analysis indicated that the harmonic mean of tumour doses in molar units gave the best correlations using fewer descriptors. The authors also found that QSARs based on sex-specific TD_{50}/OSF and mechanism-specific TD_{50}/OSF have slightly higher predictive abilities than nonspecific or global QSAR models. In addition, QSARs developed using a combination of two-dimensional and three-dimensional descriptors gave higher correlations than QSARs developed using only two-dimensional descriptors.

Martin *et al*. (2008a) used a hierarchical clustering (HC) approach to predict the carcinogenicity of several noncongeneric sets of chemicals from the CPDB (Gold, 2009). The HC approach (Martin *et al*., 2008b) used Ward's method (Romesburg, 1984) to divide an experimental toxicity training set into a series of structurally similar clusters (defined in terms of 2D and 3D descriptors) in the hope that the congeners within each cluster possessed the same mode of action. The authors used genetic algorithms to generate several statistically valid QSAR models for each cluster. The toxicity for a given query compound was estimated using the average of the predictions from the cluster models whose chemicals were the most structurally similar to the query compound. Martin *et al*. (2008a) reported that the HC approach achieved cross-validation concordances of 60–65%.

While commercial and noncommercial (Q)SAR models are able to successfully predict the carcinogenic potential and carcinogenic potency of a wide variety of chemicals, there may be a few chemicals (e.g. new chemicals and/or drugs) that may fall outside the prediction domain of currently available models. In such cases, (Q)SAR models may have to be developed to adequately cover the prediction domain of the new chemical.

3.4 Developing (Q)SAR Models to Predict the Carcinogenicity or Carcinogenic Potency of Chemicals

The general procedure for developing a (Q)SAR model for predicting the carcinogenicity or carcinogenic potency of a wide variety of chemicals is outlined in the steps below.

3.4.1 Choosing the Training Set

The values of the dependent variables for the chemicals, such as the carcinogenicity potential or tumour dose, are gathered from public databases. Since a good QSAR model is highly dependent on the quality of the data used in the model construction process, the data should be chosen from a well-documented and vetted source such as the databases from the NTP or the US EPA. In general, the carcinogenicity studies should have followed good laboratory practice (GLP), and have been conducted according to internationally agreed-upon guidelines such as those published by the US EPA (2005) or the OECD (1981). For example, the criteria used by IRIS (US EPA, 2008) to determine the choice of data sets to use in the quantification of carcinogenic potency include (i) the use of human data, (ii) use of animal studies in which the biological responses in animals resemble those in humans if (i) is not available, (iii) use the most sensitive animal species/strain/sex combination if (i) and (ii) are not available, (iv) use the same route of exposure as that of human exposure, (v) estimate overall risk using tumours at sites that have elevated responses, and (vi) combine benign tumours with malignant tumours, unless the benign tumours are not considered to have potential progress to the associated malignancies of the same histogenic origin (McConnell *et al*., 1986). In addition, robust (Q)SAR models are highly dependent on a high degree of similarity between the target chemical and the chemicals in the training set. Hence, in order for the (Q)SAR models to have a broad applicability, the training set should include an adequate number of each diverse set or class of chemicals. **Table 4** illustrates potential sources of experimental toxicity data that may be used to develop (Q)SARs for predicting the carcinogenicity/carcinogenic potency of chemicals.

3.4.2 Calculating Descriptors

Carcinogens may either be genotoxic or nongenotoxic (see **Carcinogenesis and Carcinogens that are also Genotoxic** and **Nongenotoxic or Epigenetic Carcinogenesis**), and have a propensity to be an electrophile, generate electrophilic intermediates (Miller and Miller, 1977) or involve reversible binding onto active sites in the receptors. Hence, descriptors that are commonly chosen for (Q)SAR modelling include

quantum chemical variables such as LUMO (energy of the lowest unoccupied molecular orbital), log P (octanol–water, blood–tissue or a similar partition coefficient), molecular area and volume, molar refractivity index and steric energy. Descriptors for statistical models include the mechanistic descriptors, in addition to those that may or may not have a mechanistic basis such as information indices (Kier and Hall, 1986). In general, the descriptors may be categorized as experimental quantities, spectroscopic data, substituent constants (electronic, hydrophobic, steric), parameters derived from molecular modelling and quantum chemical computations, graph theoretical indices, and variables that describe the presence or absence of certain substructures or fragments.

Descriptors that describe the electronic states responsible for any given end point may be calculated using descriptor-generator programs such as ADAPT, TSAR (Accelrys), Molconn-Z, CODESSA™ GRID (Molecular Discovery, Ponte San Giovanni, Italy), E-Calc, EPIWIN, Dragon and other computational chemistry programs such as CAChe™ and Gaussian. Todeschini and Consonni (2000) provide a comprehensive compilation of molecular descriptors that may be used to develop (Q)SAR models for various health end points.

3.4.3 Developing the (Q)SAR Model(s)

Once a list of potential descriptors is calculated, several statistical methods may be used for generating the final (Q)SAR equation. These may include multiple linear regression, partial least squares (PLS), artificial neural networks, genetic algorithms, logistic regression (for SARs), classification and regression trees, simple linear regression, stepwise multiple linear regression, and principal components analysis.

Various commercial and noncommercial software that provide built-in tools to calculate descriptors as well as develop (Q)SAR models are available. Commonly used software programs are briefly described below.

3.4.3.1 CODESSA™ PRO

CODESSA™ (Comprehensive Descriptors for Structural and Statistical Analysis) PRO (University of Florida, Gainesville, FL) is a comprehensive program for developing QSARs by integrating all necessary mathematical and computational tools to calculate a large variety of molecular descriptors on the basis of the 3D geometrical structure, develop regression equations, carry out cluster analysis of the experimental data and molecular descriptors, interpret the developed models, and predict property values for any chemical compound with known molecular structure.

3.4.3.2 Discovery Studio QSAR

DS QSAR (Accelrys Software, Inc., San Diego, CA) provides easy access to molecular descriptors such as Extended Connectivity Fingerprint (ECFP) descriptors, physicochemical properties and quantum chemical descriptors. The software provides a wide variety of modelling techniques such as Bayesian models, multiple linear regressions, PLS and genetic functional analysis to develop the models.

3.4.3.3 MDL QSAR

MDL QSAR (MDL, San Ramon, CA) is a comprehensive QSAR modelling system that lets scientists establish reliable QSARs, create new calculators for *in silico* screening, and generate new compound libraries based on results—accelerating the discovery of lead compounds in drug and agrochemical research. MDL QSAR provides over 400 built-in 2D and 3D molecular descriptor calculators for rapid processing of thousands of molecules. In addition, MDL QSAR allows users to use third-party calculators through the built-in interface, or import previously calculated descriptor values.

3.4.3.4 Molecular Operating Environment (MOE)

MOE (Chemical Computing Group, Quebec, Canada) provides a suite of applications for manipulating and analysing large collections of chemicals, calculating over 300 molecular descriptors and building QSAR models using linear, probabilistic and decision-tree methodologies.

3.4.3.5 (Q)SAR Application Toolbox

The OECD (Q)SAR Application Toolbox is open-source software that provides several computational methods and information technologies for the application of (Q)SARs, or a category approach for filling data gaps that are necessary for hazard and risk assessment.

3.4.3.6 Scigress Explorer

Scigress Explorer (formerly named CAChe™; Biosciences Group, Newton, MA) is a desktop molecular modelling software package that can draw and manipulate chemical structures, calculate physicochemical properties, and develop QSAR equations using multiple linear regressions.

3.4.3.7 Sybyl QSAR with CoMFA

Sybyl QSAR with CoMFA (Tripos, St. Louis, MO) module builds statistical and graphical models that relate the properties of molecules (including biological activity) to their structures. The software builds the QSAR models by organizing structures and their associated data into Molecular Spreadsheets™, calculating molecular descriptors, and performing sophisticated statistical analyses that reveal patterns in structure–activity data. These models may then be used to predict the properties or activity of novel compounds.

DOI: 10.1002/9780470744307.gat079
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.4.3.8 Tsar

Tsar and Tsar-3D (Accelrys Software, Inc., San Diego, CA) are fully integrated QSAR packages for library design and lead optimization. Tsar's chemical spreadsheet interface may be used to explore 2D or 3D physicochemical properties to analyze for those properties that promote activity, identify chemical analogues and develop predictive models for the activity of interest.

3.4.4 Model Validation

The International Council of Chemical Associations (ICCA) and the European Chemical Industry Council (CEFIC) proposed a set of principles to evaluate the validity of (Q)SAR models (OECD, 2009). According to the established principles, QSARs should:

1. be associated with a defined end point of regulatory importance;
2. take the form of an unambiguous algorithm;
3. have a defined domain of applicability;
4. be associated with appropriate measures of goodness of fit, robustness and predictivity; and
5. have a mechanistic basis, if possible.

The most demanding way to validate the predictive ability of a model is by external validation, which consists of making predictions for an independent set of data not used in the model calibration (Eriksson *et al*., 2003). In the past decade, the NTP conducted two exercises for the prediction of carcinogenicity (Bristol *et al*., 1996). In these exercises, toxicity values were predicted prior to the release of the experimental carcinogenicity data (true external prediction). In the first NTP exercise, the QSAR approaches based solely on information from molecular structure yielded somewhat low prediction accuracies (in the range of 50–65%). One can achieve prediction concordances of 50% simply by randomly selecting compounds to be carcinogenic or not. This was in contrast to the high internal validation statistics reported for these methodologies (Benigni and Zito, 2004). In the second NTP exercise, the best-performing QSAR methodologies achieved prediction accuracies ranging from 60 to 65% (Benigni and Zito, 2004). The NTP prediction exercises illustrate the importance of external validation in establishing the predictive ability of cancer models.

If no external validation set is available, cross-validation may be used instead. Cross-validation is performed by dividing the training set into a number of groups and then developing a number of parallel models from reduced data with one of the groups deleted (Eriksson *et al*., 2003). It should be noted that increasing the number of cross-validation groups to N (the number of compounds in the training set) is not recommended because the Q^2 cross-validation statistic becomes too similar to R^2 (Eriksson *et al*., 2003). There have been several recent studies that have employed cross-validation to evaluate the predictive ability of cancer QSAR methodologies (Contrera *et al*., 2003; Valerio *et al*., 2007).

3.4.5 Applicability Domain

Every QSAR model can formally predict the toxicity (i.e. carcinogenicity) for any compound for which chemical descriptors can be calculated. However, since the models are based on chemicals from a given training set (that cover only a small fraction of the entire chemistry space), an applicability domain for each model should always be defined. This restriction reduces the likelihood of making predictions for compounds that differ substantially from those in the training set (Zhu *et al*., 2008). Generally, there is no universal method of defining the applicability domain. In the carcinogenicity estimation method developed by Contrera *et al*. (2003), a unique cluster (and model) is constructed for each test chemical using the most similar chemicals from the training set. Predictions are only made if there are a minimum number of chemicals in the training set that have a certain degree of similarity with the test compound. Several methods for defining the applicability domain for toxicity models are available in the literature (Eriksson *et al*., 2003; Zhu *et al*., 2008).

3.5 Predictive Ability of Carcinogenicity (Q)SAR Models

In QSAR modelling, it is easy to manipulate data such that an apparently good model can be formulated (i.e. by removal of outliers or by over-fitting the dataset with a large number of descriptors). Such an inappropriate model often arises when one is merely interested in the fit of the model to the underlying data (i.e. in terms of internal validation statistics such as R^2). The problem with internal validation statistics is that they do not provide an indication of the predictive ability of the model. Prediction validation is one way to assess model adequacy for new compounds (Eriksson *et al*., 2003).

Most of the QSAR models for cancer consist of multiple linear regression models containing a small number of molecular descriptors (Passerini, 2003). The descriptors in the models (usually energies of the highest occupied molecular orbital (HOMO) or the lowest unoccupied molecular orbital (LUMO) and the octanol–water partition coefficient) are typically selected manually based on mechanistic considerations. Due to the small size of the training sets, cross-validation is usually not performed. If cross-validation is performed, it must be done carefully. Typically, the model for each cross-validation training set is constructed by recalculating the coefficients for descriptors appearing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat079
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in the overall model (Franke *et al*., 2001). This approach can overestimate the predictive ability of the overall model since the descriptors were selected based on knowledge of the entire dataset instead of the corresponding training sets. A possible solution is to use a genetic algorithm approach to develop new models for each cross-validation training set. The advantage of this approach is that each model is constructed only with the knowledge of its respective training set. The descriptors appearing in the different models might be slightly different, but this approach should provide a conservative estimate for the predictive ability that can be expected from a multilinear regression model fit to the entire dataset (Martin *et al*., 2008a).

4 USE OF 3D-QSAR MODELS TO INCREASE PREDICTIVE ABILITY

In the past, it was typical to characterize toxicity of a chemical without describing and/or understanding the actual target(s) at the molecular level or cellular level. Toxicity is often observed and then recorded at the whole animal level (systemic toxicity) and organ level (end-point toxicity). Even though toxicity at the organ level can provide valuable information (e.g. liver toxicity), SARs/QSARs can be best developed at molecular level with elucidated interactions with macromolecules (e.g. DNA, protein, etc.). Advances in QSAR technology allow researchers to take advantage of these potential chemical–macromolecule interactions as part of QSAR development, namely, 3D-QSAR. Three-dimensional QSAR includes the spatial relationship between a chemical and a potential target. Inclusion of this additional parameter can strengthen the existing (Q)SAR, which relies solely on physicochemical properties of a chemical.

A 3D-QSAR depends on the application of force-field calculations, which requires three-dimensional structures, for example protein crystallography, and molecule superposition (alignment). It is typically used for studying the interactions between a receptor and its ligands. This approach normally uses computed potentials such as the Lennard-Jones potential (Lennard-Jones, 1931), which account for two distinct forces (attractive and repulsive) for a pair of neutral atoms or molecules, rather than experimental constants. Three-dimensional QSAR is different from 2D-QSAR in that it is concerned with the overall molecule rather than a single substituent or fragment. Both the steric and electrostatic fields are taken into consideration for potential target–chemical interactions (Leach, 2001).

Early developers of 3D-QSAR include the Hopfinger group (Potenzone *et al*., 1977) and the Marshall group (Marshall *et al*., 1979), who were the first to investigate the contribution of three-dimensional shape in the analysis of a molecule. Cramer *et al*. (1988) proposed that biological activity could be related to the shape-dependent steric and electrostatic fields of molecules. The authors developed a new method based on PLS and cross-validation, CoMFA, in order to develop models for biological activity predictions instead of a single regression line. CoMFA has since become one of the most popular 3D-QSAR techniques. CoMFA is now widely used to derive quantitative models for protein-binding affinities. Its underlying concept is that a group of congeneric compounds used in a study should act or cause toxicity via the same mechanism and, most likely fit into a common pharmacophore. Even though CoMFA has been applied to drug discovery specifically to eliminate hits with undesirable toxicity, it can also be applied to toxicology if a common target or similar mechanism is known or assumed (Liu *et al*., 2005).

Assuming or knowing chemicals have a common target (e.g. DNA, protein), molecular modellers can use the 3D-QSAR approach for toxicity prediction, or in this case, DNA as a common target for predicting cancer potency. For chemicals that are predicted to be mutagens based on both *in vitro* and *in vivo* assays, one may assume that these chemicals either bind or interact with DNA in either covalent or noncovalent fashion. Docking (*in silico* receptor–ligand binding simulation) may be performed as the initial step to provide the optimal binding orientation (Lengauer and Rarey, 1996). Subsequently, a 3D-QSAR can be generated using either commercial software such as CoMFA in Sybyl (Tripos Inc., MO).

Recently, higher dimensional QSARs such as 4D- (ensemble of conformers), 5D- (induced-fit models) and 6D-QSARs (solvation scenarios) are now possible. These models can provide even more predictive powers (Vedani *et al*., 2006). It would be of great interest to apply these new techniques towards existing 3D-QSAR models, thus making more reliable predictions of carcinogenicity and carcinogenic potency.

The robustness and the predictive ability of (Q)SARs may generally be increased through the use of 3D or higher order QSAR models, which generally requires the modelled chemical as well as the target (protein, DNA, etc.) to have 3D coordinates. One disadvantage of using models that require 3D coordinates is the amount of time required to generate the 3D coordinates as well as the time required to study the interactions between the chemical and the target. One approach to circumvent this problem is to use a grid or distributed computing platform such as the Berkeley Open Infrastructure for Network Computing (BOINC) to perform these computer-intensive calculations.

BOINC (*http://boinc.berkeley.edu/*) is a software program that relies on a network of users who donate the idle time on their computers to run applications that study issues such as climate change, extraterrestrial life, drug discovery and treating cancer. BOINC has several

ongoing projects that study the chemical structures that cause cancer, develop drugs that may help treat cancer or study target sites that are implicated in causing cancer. For example, Rosetta@Home (Schueler-Furman *et al*., 2005) use the BOINC infrastructure to model protein structures and interactions to understand diseases and find cures. In addition, Rosetta@Home are also developing methods for cutting DNA at specific target sites in the genome that are implicated in cancer. After these sites are cut, the DNA could potentially be repaired using an unmutated copy of the gene, thereby eliminating the progression of cancer (Rosetta@Home, *http://boinc.bakerlab.org/rosetta/rah_medical_relevance.php*). Other BOINC projects that study cancer include Folding@Home (*http://folding.stanford.edu/English/FAQ-Diseases*) and World Community Grid (WCG, *www.worldcommunitygrid.org/projects_showcase/hcc1/viewHcc1Main.do*). The predictions made by the BOINC models may then be used to supplement the predictions made by the (Q)SAR models for carcinogenicity and carcinogenic potency.

5 USE OF -OMICS IN (Q)SARs FOR CARCINOGENICITY

Recent technological advances in -omics fields (genomics, proteomics, metabonomics, transcriptonomics, lipomics, etc.) have generated vast amounts of biological data that can be potentially considered as descriptors and subsequently be utilized as part of (Q)SAR model development. In addition to the three common -omics (genomics, proteomics and metabonomics), a new field named toxicogenomics (see **Toxicogenomics and the Evolution of Systems Toxicology**) provides the analysis of a particular toxin or chemical substance on both cellular and tissue level that can be identified and characterized based on a profiling of its known effects on genetic material. This recent technology can serve in a role similar to DNA testing in the forensic identification of individuals. Application to carcinogenicity and/or mutagenicity is therefore possible.

These -omics techniques may also be used as diagnostics to predict adverse effect(s) of chemicals in the environment at low dose. Some suitable measurable markers (biomarkers) that are correlated to the adverse effect(s) in clinical trials and animal studies can be developed as part of mode of action analysis and eventually for SAR analysis. Using both expression profiling and biomarker identification, it is theoretically possible to accumulate enough data for developing a (Q)SAR for a particular chemical class. **Figure 4** summarizes the whole process of integrating -omics data as part of model development. While this approach is not currently implemented, it has great potential.

Traditionally, a descriptor of a chemical is based on physiochemical properties and/or structural properties. With the new -omics data, one can use quantitative expression level (up- or down-regulation) of a particular macromolecule, cluster/family of macromolecules, or assembly of a complex, as an indicator of biological process. These newly generated data can help a QSAR modeller to integrate chemical and biological information into the final QSAR equation, which reflects both the biological and chemical space of chemicals in the training set (**Figure 4**). The final QSAR equation then can be

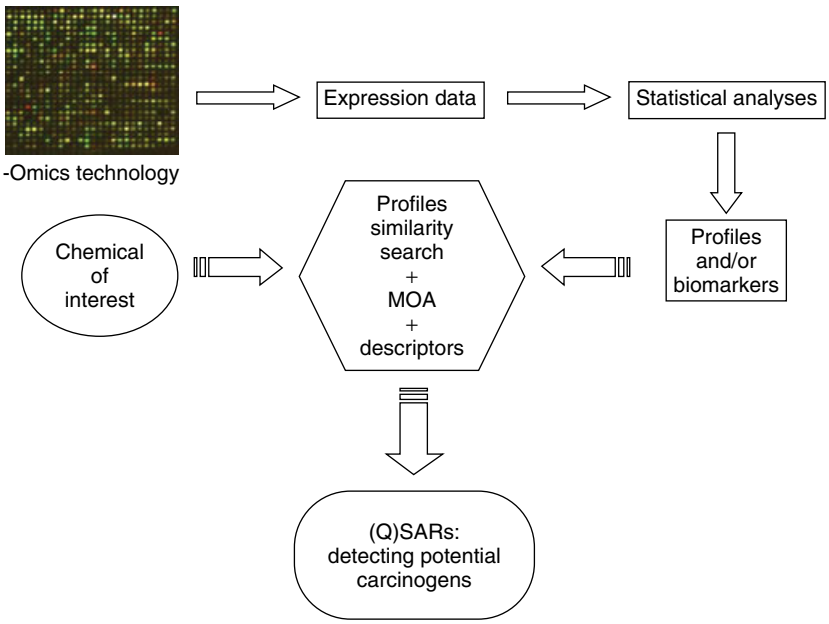

Figure 4 A schematic for developing (Q)SAR models using -omics data.

used for predicting the carcinogenicity of new chemicals of interest that are not part of the original training set, and these chemicals should also be predetermined to be inside the applicability domain of the QSAR model.

Short-term Tests for the Determination of Genotoxic and Carcinogenic Potential of Xenobiotics

Alok Dhawan

CONTENTS

1 INTRODUCTION

Genetic toxicology includes studies of DNA damage (genotoxicity), mutations in DNA (mutagenicity) and cancer formation (carcinogenicity), as well as consequences of DNA damage and repair (see **Mutagenesis**, **Carcinogenesis and Carcinogens that are also Genotoxic**). The main aim of genotoxicity tests is to address gene mutations and chromosome damage. Genetic toxicology has been used for hazard identification, in regulatory toxicology testing since the 1997s and is now being considered for integrated risk assessment (Thybaud *et al*., 2007). It is now an intrinsic component of safety testing for the approval of drugs and animal health products, and also a regulatory tool used by the United States Environmental Protection Agency (USEPA) for environmental exposures.

Genetic toxicology testing started with studies in *Drosophila melanogaster*, demonstrating increased mutation frequency after exposure to X-rays, and later by exposure to chemicals. Similar responses upon exposure to X-rays were observed in mice, leading to the concept that radiation and chemicals could induce mutations in *Drosophila*, as well as mammalian cells (Pitot and Dragan, 2001). Ames (1971) developed a mutation assay in a bacterium—*Salmonella typhimurium*, called the Ames test. This was used to screen large number of chemicals for their mutagenic potential and to label them as potential mutagens and carcinogens. A number of other *in vitro* tests were also developed during the same period. The history of chemical genotoxicity testing has been outlined by Zeiger (2004).

Humans are exposed to a wide range of chemicals—including industrial chemicals, solvents, pesticides and other new chemical entities (NCEs), as well as ionizing radiation, which may lead to DNA damage. About 10^3–10^6 DNA breaks take place per cell per day. However, due to the efficient DNA repair mechanism, most of the DNA damage gets repaired. Damage that is persistent may lead to alterations, like mutations in genes, structural and numerical chromosomal damage, and recombination (see **Cytogenetics**). These changes may cause adverse health effects, including cancer, as well as affect the incidence of heritable mutations in man, and may be transferred to the progeny.

Alterations in DNA that lead to DNA damage/mutations are covalent binding (adduct formation leading to base-pair substitution mutations), crosslinking (intra- or interstrand, producing DNA or chromosomal breaks), intercalations (between the base pairs of DNA

leading to insertion/deletion mutations) or breakage (DNA strand breaks, unrepaired DNA damage causing chromosomal aberrations (CAs)). Indirect genotoxicity is caused by alterations in spindle fibre or kinetochore proteins (leading to incorrect chromosomal segregation) and incorporation of DNA analogues (leading to strand breaks).

It is therefore important to understand the genotoxic potential of chemicals for risk assessment and hazard prediction to safeguard human and environmental health. Hence, adequate test systems that detect alterations in the DNA due to chemicals and/or radiation, have to be developed. Compounds that give positive results in such tests have the potential to be human mutagens/carcinogens.

There are nearly 200 *in vivo* and *in vitro* short-term assays that have been developed to test for genotoxicity in bacteria, plants, insects and mammals. Various strategies have been employed for the identification of a chemical as genotoxic, mutagenic and/or carcinogenic using different test systems (**Figure 1**). Work-groups of the European Union (EU), Organization for Economic Co-operation and Development (OECD) and International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) have defined a standard battery of tests (Kramer, 1998), which need to be conducted for a compound. MacGregor *et al*. (2000) reported the various recommendations from different countries for *in vivo/in vitro* genotoxicity testing. The genotoxicity testing strategies for most regulatory agencies in the USA, Canada, the UK, the EU, Japan and other countries are similar, however, certain variations exist (Cimino, 2006; Jena *et al*., 2002).

A tiered approach is usually employed for the assessment of genotoxicity of chemicals. A standard battery of test includes both *in vitro* as well as *in vivo* tests/assays. The ICH has recommended a bacterial mutagenicity test, an *in vitro* test for chromosomal damage in mammalian cells or mouse lymphoma assay (MLA) (for those compounds that cannot be adequately tested in bacterial systems and are relevant in mammalian cells) and an *in vivo* test for chromosomal damage in rodent haematopoietic cells, for providing information on additional factors such as metabolism and excretion of compounds (International Conference on Harmonization, 1999). The current regulatory scheme of the USEPA (US Environmental Protection Agency, 2005) consists of three levels, where the first level tests consist of a test for gene mutations in bacteria (*Salmonella*), and mammalian cells (MLA) and an *in vivo* test for CA/micronucleus (MN) assay. The second level tests are then conducted *in vivo* in the gonadal (testicular) cells and the third level tests are carried out in the offsprings of the exposed animals (US Environmental Protection Agency, 2005). However, to reduce animal experimentation, the guidelines from the Committee on

Mutagenicity, UK (2000) have added a test for clastogenicity (CA/MN assay) in cultured mammalian cells in the first stage (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000). The second stage includes *in vivo* tests for cytogenetic damage in somatic cells (rodent bone marrow MN or CA assay), while additional tests, such as the Comet assay, unscheduled DNA synthesis (UDS) and ^{32}P-postlabelling may also be conducted, and the third stage consists of *in vivo* tests in germ cells, as well as intergenerational tests (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000).

A positive result in the second tier *in vivo* genotoxicity tests (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000) or data from structure-activity relationship (SAR)/long-term bioassay leads to the chemical being labelled as a potential carcinogen while if *in vivo* genotoxicity data are negative the chemical is evaluated as a potential nongenotoxic carcinogen (Cimino, 2006).

The current genetic toxicology tests being used cannot assess all types of genetic damage that may be relevant for carcinogenicity. Hence, new tests are being developed to characterize the potential carcinogenicity of chemicals. The advances in molecular biology have helped the tests in monitoring at the single gene or chromosome level, as well as evaluating the response of the entire genome. These include the use of microarrays, for example, array CGH (competative genomic hybridization) and electrochemiluminescent arrays (Gant, 2007; Hvastkovs *et al*., 2007; Kim *et al*., 2005), real-time polymerase chain reaction (PCR) (Soberón *et al*., 2007) and *in silico* (Hayashi *et al*., 2005; Mazzatorta *et al*., 2007) tools for prediction of genotoxicity and carcinogenicity of chemicals. These newer tests are cost effective, more sensitive, provide a broad range of responses and permit high throughput for the identification of genotoxicity/carcinogens.

2 TESTS FOR GENOTOXICITY AND CARCINOGENICITY

Well-characterized genetic assays are conducted for evaluation of the genotoxic/carcinogenic potential of chemicals. Depending on the length of time required for the completion of the assay, the tests have been designated as long- (12–24 months), medium- (2–8 months) and short- (several weeks) term assays.

Long-term tests include the chronic two-year rodent bioassay as the 'gold standard' for determining potential carcinogenic activity of a chemical. It has been used to detect human carcinogens by the International Agency for Research in Cancer (IARC; Vainio *et al*., 1991). The bioassay detects complete carcinogens and tumour promoters, as well as cocarcinogens. It requires observation of the test animal for a major portion of its life span for the development of neoplastic lesions, during or after exposure to various doses of a test substance by an appropriate route (Bannasch *et al*., 1986). However, this assay is time-consuming, costly and requires adequate physical facilities and qualified personnel.

Medium-term tests (e.g. newborn mouse model), are used as an alternative to the chronic two-year bioassay, and neoplasia in various tissues in mice, for example, liver, lung and lymphoid organs, are recorded over a period of two to eight months (Fujii, 1991).

Due to advancements in the field of molecular biology and combinatorial chemistry, a large number of chemicals are now being synthesized and are ready for release. However, to keep abreast with this rapid growth of chemicals, and to assess their genotoxic/carcinogenic potential, new and sensitive tests need to be employed, which can provide reliable results in a shorter time. Thus, short-term tests were developed to identify carcinogens by assessing *in vitro* or *in vivo* mutations in DNA (**Table 1**). The short-term tests are also used for mechanistic evaluation and thus help in risk assessment (see **Genetic Toxicology Testing and its Relevance to Human Risk and Safety Evaluation**). These assays may take from one day to a few weeks for completion.

Use of short-term tests is based on the assumptions that: (i) the ultimate cause of cancer is due to some mutational changes in DNA (carcinogens have been shown to induce mutations and impaired DNA repair leads to cancer) and (ii) the similarity of the genetic code and protein synthesis between organisms, allows extrapolation between species (Ramel, 1983). Since none of these tests alone can predict genotoxicity/carcinogenicity of a compound, it has been recommended that a battery of tests needs to be conducted before a compound is labelled as a mutagen and/or carcinogen. These results are then considered equivalent to the predictive value of a long-term animal bioassay.

In vitro short-term tests provide a rapid, inexpensive, highly sensitive, controlled and reproducible tool for the assessment of genetic damage (Kluwe, 1995). They also provide an alternative to the use of animals. However, *in vitro* tests cannot fully mimic the *in vivo* environment, and the exposures given may be higher than those taking place *in vivo*. Hence, an *in vivo* test for genetic damage should be a part of the test battery to provide a test model in which factors like absorption, distribution, metabolism and excretion are included, which may influence the genotoxic activity of a compound (International Conference on Harmonization, 1999). There may also be compounds which are difficult to test in the *in vitro* systems, but can cause genetic alterations *in vivo*, which have been reviewed by Tweats *et al*. (2007).

This chapter reviews the various short-term tests for assessment of the genotoxic and/or carcinogenic potential of chemicals.

3 SHORT-TERM TESTS FOR GENOTOXICITY AND CARCINOGENICITY

In vitro and *in vivo* assays for evaluating genotoxic/carcinogenic potential include tests for gene mutation, cytogenetics and DNA damage, which are discussed in detail below.

3.1 Gene Mutation Assays

These assays rely on the selection of specific traits to detect mutations and are conducted both *in vitro* and *in vivo*. The assays can detect point mutations, frameshift and base-pair substitutions, and small deletions in the genome. They are simple, rapid and inexpensive and thus are prominently used in genetic toxicology.

3.1.1 Mutation Assays in Bacteria

Bacteria have been widely used to study the mechanisms of DNA damage (mutagenicity) as well as for short-term screening tests for potential carcinogens (Venitt *et al*., 1986). They possess elaborate mechanisms for responding to DNA damage. Several methods have been developed which detect reverse or forward mutations.

Bacteria lack the metabolic capabilities of mammalian systems, therefore metabolic activation which converts certain compounds (promutagens) into reactive species (mutagens) is supplied exogenously. The mammalian metabolizing system widely used is the postmitochondrial fraction (S9) from liver homogenate of rats treated with arochlor 1254, benzo[a]pyrene (B[a]P) or a mixture of β-naphthoflavone and phenobarbital.

3.1.1.1 Reverse Mutation Assays

The most widely used reverse mutation assay, known as the Ames test, was developed by Ames (1971) using the *Salmonella typhimurium* bacterium. It is the preferred *in vitro* primary screen for gene mutation and detects most of the human mutagens and carcinogens (Ames *et al*., 1973a; 1973b; 1975; Maron and Ames, 1983). The assay is based on the premise that a substance mutagenic to the bacterium is likely to be a carcinogen in laboratory animals, and hence, presents a risk of cancer in humans.

Bacteria already mutated at an easily detectable locus (e.g. histidine) are tested with compounds that produce a second mutation, nullifying the first mutation; thereby the bacterial strain reverts to normal. Bacterial strains mutated at the histidine locus, do not synthesize histidine and thus die when plated on an agar medium lacking histidine. Different bacterial strains (**Table 2**) are treated with varying concentrations of the test compound in the absence and presence of the exogenous metabolic activation system. When a mutation occurs in these cells that reverts the original *his* mutation, the reverse-mutated cells (revertants) grow on a histidine-deficient agar plate and form a visible colony after 48 hours of incubation (**Figure 2**). A reproducible dose-dependant response in at least one tester strain indicates a positive result, suggesting that the substance is a mutagen and could be a carcinogen as well. If no increase in mutant colonies is seen after testing various strains under different culture conditions, the test chemical is considered to be nonmutagenic. Modifications to the assay for testing gaseous and volatile liquid compounds, as well as solvents and pure compounds, have been discussed (Mortelmans and Zieger, 2000).

The sensitivity of the Ames assay to mutagens and specific classes of chemicals (Josephy *et al*., 1997; McCann *et al*., 1975) has been enhanced through strain engineering. Several specially constructed strains of

Table 2 Bacterial strains used in the Ames test and their characteristics

Bacterial strain	Target DNA sequence	Target allele	Plasmid and other characteristics	Mutation detected	Primary mutations
S. typhimurium TA 97a	CCCCCC GGGGGG	*his*D6610	pKM101 (Ap^r), *rfa, Δuvr B*	Frameshift	C or G deletion
S. typhimurium TA 98	CGCGCGCG GCGCGCGC	*his*D3052	pKM101 (Ap^r), *rfa, Δuvr B*	Frameshift	GC or CG deletions and Complex frameshift
S. typhimurium TA 100	CCC GGG	*his*G46	pKM101 (Ap^r), *rfa, Δuvr B*	Base-pair substitution	GC → AT (ts) AT → GC (ts) TA → GC (tv)
S. typhimurium TA 102	CAAGTAAGAGC GTTCAT TCTCG	*his*G428	pKM101 (Ap^r) and pAQ1 (Tc^r), *rfa*	Base-pair substitution, oxidative and crosslinking mutagens	AT → CG (tv) AT → TA (tv)
S. typhimurium TA 104	TAA GC ATT and CG	*his*G428	pKM101 (Ap^r), *rfa, Δuvr B*	Base-pair substitution oxidative and crosslinking mutagens	GC → AT (ts) GC → TA (tv) AT → GC (ts) AT → CG (tv) AT → TA (tv)
S. typhimurium TA 1535	CC GG	*his*G46	None, *rfa, ΔuvrB*	Base-pair substitution	GC → AT (ts) AT → GC (ts) TA → GC (tv)
S. typhimurium TA 1537	CCCCC GGGGG	*his*C3076	None, *rfa, ΔuvrB*	Frameshift	C or G deletion
E. coli. WP2 *uvr*A	AT TA	*trpE*	None, *uvr A*	Base-pair substitution and crosslinking	GC → AT (ts) GC → TA (tv) AT → GC (ts) AT → CG (tv) AT → TA (tv)
E. coli. WP2 *uvr*A (pKM101)	AT TA	*trpE*	pKM101, *uvr A*	Base-pair substitution and crosslinking	GC → AT (ts) GC → TA (tv) AT → GC (ts) AT → CG (tv) AT → TA (tv)

ts, transition; tv, transversion; *rfa* increases the permeability of cell wall to large molecules; *uvrB* deletes excision repair; plasmid pKM101 encodes *mucAB* gene that participates in SOS repair system; (Ap^r) ampicillin resistance selection of plasmid, (Tc^r) tetracycline resistance selection of plasmid.
Reproduced with permission from Bajpayee *et al*., 2005. © Informa Healthcare.

Salmonella typhimurium, for example, TA1535, TA1537, TA97/TA97a, TA98, and TA100, TA102 and TA104 (Bonneau *et al*., 1991; Levin *et al*., 1982; Ohe *et al*., 1999; Venitt *et al*., 1984; **Table 2**) exist for use in the assay. The strains can detect changes at guanine-cytosine (G-C) or adenine-thymine (A-T) base-pair sites within target histidine genes. Using different strains in the assay helps to assess the specific mutagenic mechanism of the compound. The tester strains have been modified with deep rough (*rfa*) mutation which eliminates the polysaccharide side chain of the lipopolysaccharide on the bacterial surface, making the bacteria more permeable to the test chemicals. Deletion of the excision repair system (Δuvr) confers sensitivity to many mutagens while the plasmid pKM101 carrying the *mucAB* gene confers sensitivity to compounds which act via the SOS system. The TA1535 set (TA1535, TA1536, TA1537, TA1538), is most sensitive to mutagenesis and is recommended for general testing for mutagens and carcinogens *in vitro* (Ames *et al*., 1973b). The compounds suspected to be oxidative mutagens may be detected by strains TA102 and TA104.

Plasmids encoding for mutagenesis and metabolic function (e.g. specific enzymes) provide broad substrate specificity and high mutagenic sensitivity towards chemicals (Carroll *et al*., 2002; Josephy *et al*., 1997; Mortelmans and Zieger, 2000; Suzuki *et al*., 1998). Specific and sensitive detection of the genotoxicity

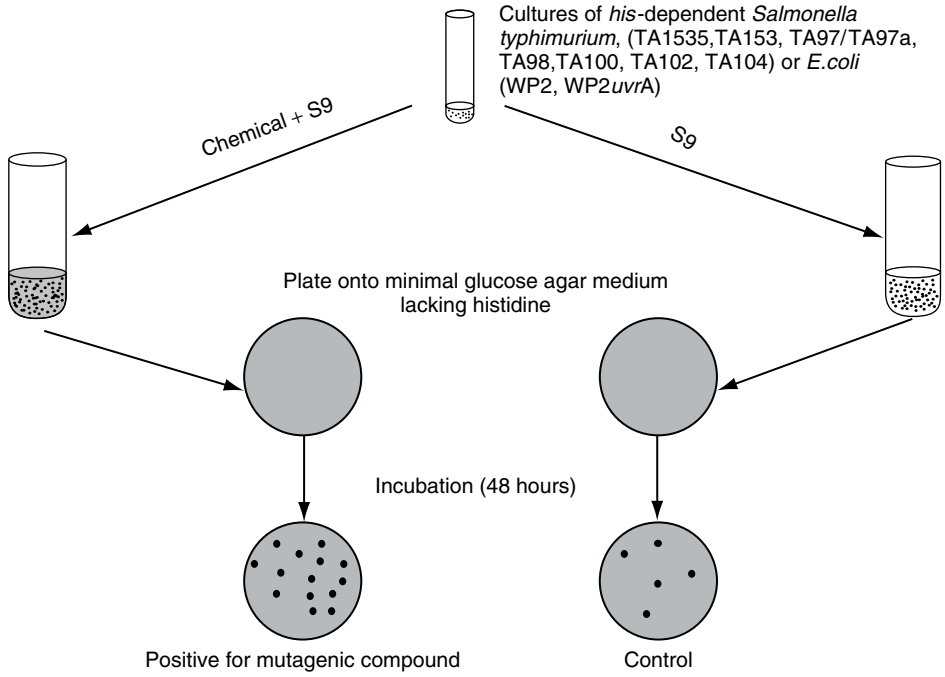

Figure 2 Schematic representation of Ames test.

of B[a]P and other polycyclic aromatic hydrocarbons (PAHs) in complex mixtures with the help of the engineered *S. typhimurium* strain, YG5185, (carrying a plasmid encoding *E. coli* DNA polymerase IV), is several times higher than standard strains (Yamada *et al*., 2006). A new bioluminescent strain of *Salmonella*, developed by Aubrecht *et al*. (2007), employs bioluminescence for identifying histidine-independent revertant cells, and provides an economical, high throughput tool for assessment of mutagenicity.

Along with *Salmonella* strains, the bacterial tryptophan reverse mutation assay with *Escherichia coli* WP2 strains is also recommended (Gatehouse *et al*., 1994; Mortelmans and Riccio, 2000). Inclusion of the DNA-repair-proficient strain, *E. coli* WP2 and WP2 (pKM101), and excision-repair-deficient strains *E. coli* WP2 *uvr*A for detection of crosslinking agents (Barrueco and de la Peña, 1988; Ohta *et al*., 2002; Wilcox *et al*., 1990; **Table 2**) has been accepted by the international guidelines in place of the *Salmonella* strain TA102, because both carry an AT base sequence at the target site which leads to the detection of transitions and transversion (Mortelmans and Riccio, 2000).

A bacterial reverse mutation assay has been designed utilizing the *E. coli lacZ*$^-$ strain. *E. coli* uses lactose as a carbon source, and each strain carries a *lacZ* allele encoding for an inactive β-galactosidase protein, which upon mutation results in *lacZ*$^+$ cells that can grow in a medium lacking lactose. The assay can detect base-pair substitution and frameshift mutations (Josephy, 2000).

It has been established that there is a high predictivity of a positive mutagenic response in the Ames test for rodent carcinogens (McCann *et al*., 1975; Mortelmans and Zieger, 2000). International guidelines have been developed for this assay (e.g. OECD 471; ICH) to ensure uniformity of testing procedures. The extensive database on the assay justifies its inclusion as the initial screening test for detection of mutagens (Seifried, 2008). However, bacterial assays may not provide sufficient information for the assessment of genotoxicity of some compounds. These include compounds that are highly toxic to bacteria (e.g. some antibiotics), those which would interfere with mammalian cell-specific systems (e.g. topoisomerase inhibitors, nucleoside analogues or certain inhibitors of DNA metabolism) or those which may be clastogens and do not produce mutations (heavy metal). Hence, the Ames test should be used with a second test which detects clastogenicity as well as gene mutations and in mammalian cells, for example MLA (Seifried, 2008).

3.1.1.2 Forward Mutation Assays

These assays are less extensively used than the reverse mutation assays. Some mutagenic compounds may not revert the point mutations in the bacterial strains and thus not be detected in the reversion assay. Also, a specific mutagen may have a weak effect on the genome, but cause large number of revertants. These shortcomings led to development of forward mutation assays (Ruiz-Rubio *et al*., 1984). The L-arabinose forward mutation assay in *Salmonella typhimurium* was developed by Ruiz Vazquez *et al*. (1978); mutation at any of at least three different genes (*ara* A, *ara* B or *ara* D) blocks the utilization of arabinose as a carbon source

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat080
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and leads to the accumulation of the toxic intermediate L-ribulose-5-phosphate. Bacterial growth is thus inhibited in the presence of L-arabinose and a carbon source unable to repress the *araBAD* operon. The assay has been used to study the genotoxic potential of river and tap water (Vahl *et al*., 1997; Shen *et al*., 2003). Mutagenicity of nitro-containing compounds can be assessed in a single strain of the *Salmonella typhimurium* BA bacterium that has both the *ara*D531 allele and *his* auxotrophy, allowing for quantitative comparison of induction of forward mutations (to L-arabinose resistance) and reverse mutations (Jurado *et al*., 1994).

Miller *et al*. (2005) have developed a forward mutation assay in *Salmonella* based on resistance to 5-fluorouracil (FU) as a sensitive alternative screen to the Ames assay for detecting a variety of mutagens, including highly toxic compounds that may not be assessed in the standard Ames assay. The assay has been validated with a variety of mutagens and nonmutagens (Vlasakova *et al*., 2005). The mutational target was found to be the uracil phosphoribosyl transferase (*upp*) gene, which, when functional, converted FU to the toxic intermediate 5-fluorouridine monophosphate, thereby inhibiting the wild-type cells. The use of a single strain allows for higher-throughput and reduces the amount of compound required. The highly parallel nature of culture handling/dilution and use of standard microtitre plates also offers the possibility of assay automation (Glaab *et al*., 2005).

3.1.2 Mutation Assays in Mammalian Cells

3.1.2.1 Gene Mutation In Vitro

In vitro cell mutation assays in mammalian cells for possible mammalian mutagens and carcinogens use gene mutations at two loci: thymidine kinase (TK) and hypoxanthine guanine phosphoribosyl-transferase (HGPRT), as end points that confer resistance to toxic chemicals (DeMarini *et al*., 1989). The assays which use these gene mutations are the TK +/− Mouse lymphoma L5178Y assay (Clive *et al*., 1979) and the Chinese hamster ovary (CHO)-HGPRT assay (O'Neill *et al*., 1977; Li *et al*., 1987). Cell lines used in these tests are selected due to the stability of their spontaneous mutation frequency (Aaron *et al*., 1994). CHO and L5178Y mouse lymphoma cells are commonly used since their mutants can be easily isolated. These assays are based on forward mutations and cover a wide range of mutagenic lesions (point mutations involving deletions, base substitutions, frameshift and rearrangement). Mutations at the selected gene result in a loss of phenotype, for example growth in the presence of a toxic compound, and its expression is compared in treated and untreated cells. Forward mutation to drugs like 8-azaguanine, 6-thioguanine, 5-bromo-2-deoxyuridine are widely used as genetic markers. Proliferating cells are exposed to the test substance, both with and without metabolic activation with the mammalian liver postmitochondrial fraction (S9) and concurrent positive and negative (solvent or vehicle) controls are included in each experiment. The phenotypic expression of newly induced mutants in TK requires at least two days and at least six to eight days in the HGPRT assay.

3.1.2.1.1 Mouse Lymphoma Assay (MLA)

This assay, developed by Clive *et al*. (1979), is widely used for detecting mammalian *in vitro* gene mutations and is recommended by regulatory agencies (ICH, USEPA) for genotoxicity testing. L5178Y *tk*+/− 3.7.2 C cells are heterozygous at the TK locus (*Tk1*) on chromosome 11 of mouse (Chen *et al*., 2002). The TK enzyme is used for incorporating pyrimidines in the salvage pathway of DNA synthesis. The functional TK allele thus allows toxic pyrimidine analogues, for example, bromodeoxyuridine (BrdU), fluorodeoxyuridine (FdU) and trifluorothymidine (TFT), to be incorporated into nucleotides, leading to inhibition of cellular metabolism and cytotoxicity in normal cells (**Figure 3**). Forward mutation ($TK^+ \rightarrow TK^-$) in the cells due to a chemical compound inactivates the TK allele conferring resistance to these analogues, and mutants proliferate, forming colonies (Clements, 2000; Moore *et al*., 2000).

There are two versions of the assay—soft agar and micro-well methods (Honma *et al*., 1999a; Moore *et al*., 2003; Oberly *et al*., 1997; Omori *et al*., 2002), and both have been adopted by ICH guidelines (Mitchell *et al*., 1997). Short (3–6 hours) as well as long treatment durations (24 hours) have also been recommended by the International Workgroup on Genotoxicity Testing (IWGT) for conducting an MLA (Moore *et al*., 2007). Short treatments may be insufficient for detecting some clastogens and spindle poisons, which may be cell-cycle dependent. Treatment of cells for more than one cell cycle may be required to see their effect (Honma *et al*., 1999; Moore *et al*., 2002; 2007). A set of 990 compounds reviewed by the workgroup on the MLA, revealed that less than 2% of the compounds were mutagenic at 24 hours treatment time, while the percentage of compounds positive for short-duration exposure was lower (Moore *et al*., 2007). This led to the recommendation and consensus of the workgroup that a long duration of exposure should be applied in cases of compounds which yielded a negative response with 3–4 hours treatment. Mutagenesis in MLA yields small and large colonies, which points to different degrees of genetic damage (Blazak *et al*., 1989) and differential gene expression (Han *et al*., 2006). The small colonies grow slowly and are associated with mutations compatible with viable cells, as compared to gross CA analysis, and thus present a significant risk for human carcinogenicity or mutagenicity (Moore and Doerr, 1990). Molecular analysis and studies with different chemicals, like spindle poisons (colchicine; Honma *et al*., 2001) and alkylating agents (ethylnitrosourea; Chen *et al*., 2002) have shown that

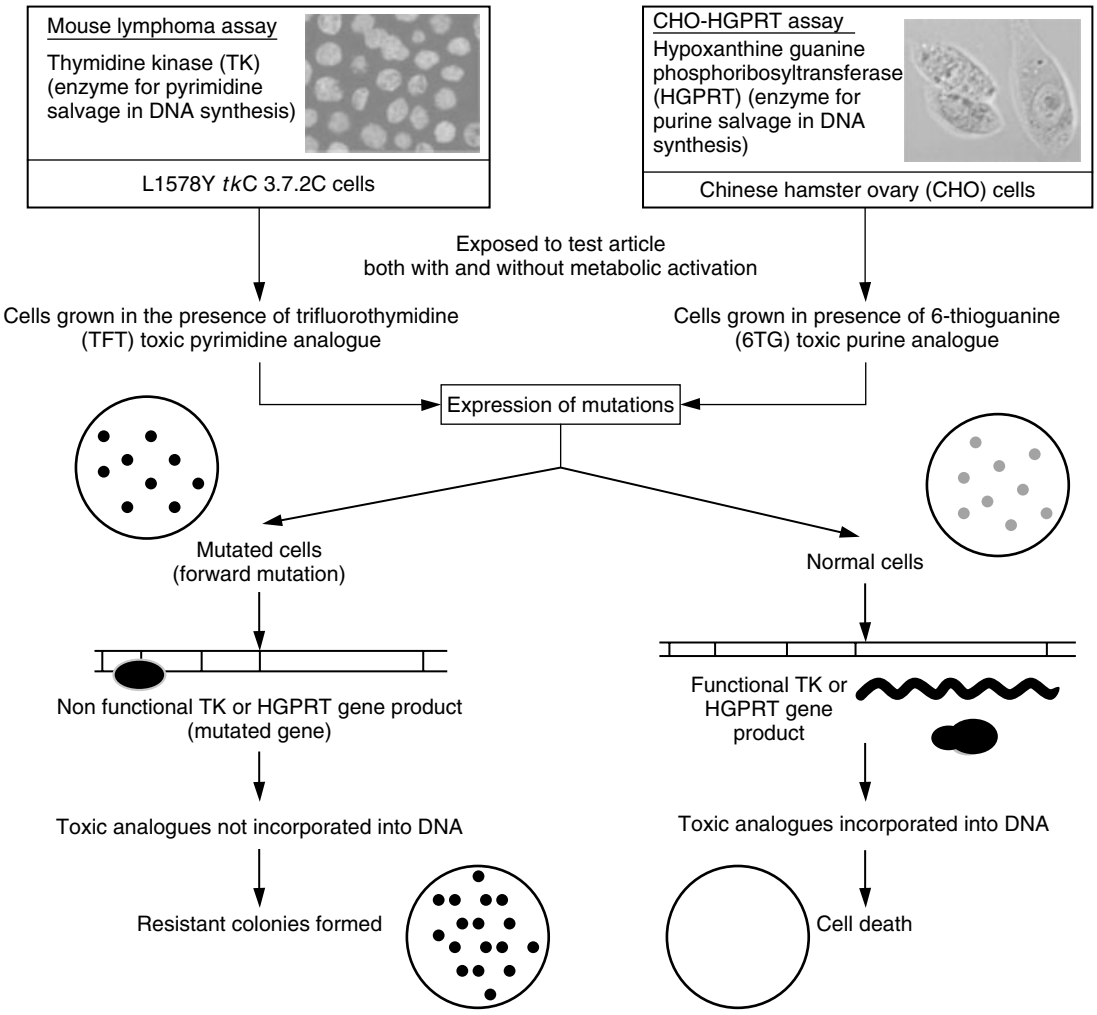

Figure 3 Schematic representation of the *in vitro* mammalian cell mutation assays.

the MLA is suitable for detecting a range of mutagenic events, which has led to its inclusion in regulatory testing.

3.1.2.1.2 Hypoxanthine Guanine Phosphoribosyltransferase (HGPRT) Assay

This assay, widely used for mutagenicity testing, is usually conducted in CHO cells and uses the target gene at the *hgprt* locus on the X chromosome (Li *et al*., 1987). The HGPRT enzyme is important for purine salvaging and will incorporate toxic analogues, for example, 6-thioguanine or 8-azaguanine into DNA, resulting in cell death or inhibition of cell growth. A forward mutation results in cells with an inactive gene product that permits the survival of the cells and formation of colonies in the presence of toxic analogues (**Figure 3**). The use of suspension cultures and soft agar cloning in the CHO assay provides a sensitive test for the identification of mutagens (Oberly *et al*., 1990) and is a viable alternative to the traditional monolayer procedure (O'Neill *et al*., 1977). A modification of this assay permits treatment in suspension and soft agar cloning comparable to the MLA. This methodology eliminates the risk of metabolic cooperation and the trauma of trypsinization. In addition, a larger population of cells can be treated and cloned for mutant selection (Oberly *et al*., 1993).

3.1.2.2 Gene Mutation Assays In Vivo

The analysis of mutations in somatic or germ cells in suitable tissues is carried out after *in vivo* treatment in rodents and also employs cells from humans exposed to chemicals.

3.1.2.2.1 Hypoxanthineguanine Phosphoribosyltransferase (HPRT) Assay in Human and Rodent Cells

The hypoxanthineguanine phosphoribosyltransferase (HPRT) assay employing human peripheral blood lymphocytes has been developed and validated for the understanding of *in vivo* somatic cell mutagenesis (Albertini, 1985). The HPRT enzyme helps salvage purines for DNA synthesis, however, it can also utilize

toxic analogues, rendering them cytotoxic to the normal cells. A mutation in the *hprt* gene leads to the mutated cells growing in the presence of these toxic analogues (e.g. 6-thioguanine (6-TG)). Lymphocytes from blood collected from control and exposed populations are cultured with and without 6-TG, and assayed for positive selection by either autoradiography or cloning, as recommended by the International Programme on Chemical Safety (IPCS) guidelines (Albertini *et al*., 2000). The increased *hprt*-mutated T-lymphocytes in blood of an exposed population demonstrate a genotoxic effect. Peripheral blood T-cells from melanoma patients show increased *hprt* mutant frequencies when compared to controls (Albertini, 2001). The assay is, however, limited in human studies due to confounding factors such as ethics, genetic differences, gender, age and lifestyle (dietary and smoking status), which affect the recovery of 6-thioguanine-resistant clones (Jones *et al*., 1995) and need to be accounted for during the analysis. Also, sampling time has to be considered to obtain and optimally detect mutant T-lymphocytes, since the blood cell population is periodically renewed (Cole and Skopek, 1994).

HPRT is also finding use for *in vivo* mutations in germinal cells (Albertini, 2001). The HPRT assay using rodents has been developed in lymphocytes from spleen, serving as a surrogate model for *in vivo* tissue-specific mutation studies. The assay in humans and rodents is capable of detecting a range of mutations including base-pair substitutions, chromosomal recombinations, inversions and deletions (Albertini *et al*., 1997; 2000; Cole and Skopek, 1994), induced by promutagens as well as direct-acting mutagens (Aidoo *et al*., 1997; Casciano *et al*., 1999; MacGregor *et al*., 2000). However, since only one copy of the *hprt* gene is present, a mutation would result in loss of heterozygosity, and thus large deletions, chromosomal recombination and nondisjunction cannot be detected by the assay (Dobrovolsky *et al*., 1999).

Most carcinogens have been shown to induce *hprt* mutations in lymphocytes of rats. Caloric restriction in ageing rats has been shown to reduce accumulation of spontaneous *hprt* mutation, thereby leading to decreased tumour incidence and retardation in ageing (Aidoo *et al*., 2003).

Though the assay has been widely used in genotoxicity testing, a detailed performance assessment is necessary for it to be used for routine testing.

3.1.2.2.2 Transgenic Animals for *In Vivo* Mutagenesis

In vivo mutation assays developed in transgenic mice, with reporter genes, help in the measurement of spontaneous and chemically induced mutations in different tissues (Mirsalis *et al*., 1995; Lambert *et al*., 2005; Provost *et al*., 1993). These assays allow for rapid screening of frequency of mutants/mutations in DNA from somatic and germ tissues of the animal (Singer *et al*., 2006; Thybaud *et al*., 2003). The assay is accepted by the COM guidelines for the assessment of *in vivo* mutagenesis (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000) and efforts are being made towards formulation of OECD guidelines (Lambert *et al*., 2005). The transgenic mouse mutation assays are lambda phage-based, which employ the bacterial *lacZ* or *lacI* gene as a reporter gene for mutations (Schmezer and Eckert, 1999) and are available as two commercially available transgenic mice named Muta Mouse and Big Blue Mouse (Kohler *et al*., 1990; Nohmi *et al*., 2000), respectively (**Figure 4**). Other systems are also available for testing larger deletions not detected by the *lac* systems, for example, *LacZ* plasmid mouse and *gpt* delta rodents (Lambert *et al*., 2005; Nohmi *et al*., 2000).

In the *lacI* system two transgenic mice (C57BL/6 and B6C3F1) and a rat, (Big Blue transgenic rat system in Fischer rats), have been constructed with each cell containing multiple copies (30–40) of a bacteriophage lambda shuttle vector (λLIZα), at a single locus on chromosome 4 (Dycaico *et al*., 1994). These vectors contain a *lacI* gene as a mutational target. The mice are exposed to the test compound and then DNA is extracted from the tissue of interest (Heddle *et al*., 2003). The shuttle vector is recovered from genomic DNA by *in vitro* packaging and infected into *E. coli* cells, which are then plated onto dishes to form plaques or colonies. The mutated plaques are selected on the basis of their ability to cleave a chromogenic substrate X-Gal. The wild-type phages encode for the *lacI* repressor, which suppresses the action of the enzyme, hence the normal plaques appear colourless. A mutation in the *lacI* gene inactivates the *lac* repressor protein and allows functional expression of β-galactosidase, which cleaves X-Gal, giving a blue colour to the mutant plaques. A significant increase in the mutant frequencies gives a positive response for the test article.

The *lacZ* CD2F1 (BALB/C_DBA2) mouse has the *lacZ* gene in a single EcoRI site of a λgt10 vector (Gossen *et al*., 1989). The principle of recovering the vector and colorimetric detection of mutants is similar to the *lacI* system, however in this system, the β-galactosidase enzyme is active in the wild-type (Heddle *et al*., 2003). Therefore the wild-type cells form a blue plaque and the mutants are colourless. Positive selection of the mutants may also be carried out on *E. coli* host, plated on P-Gal, which is otherwise toxic to cells carrying functional *lacZ* (Vijg *et al*., 1996).

The mutations scored in the *lacI* and *lacZ* transgenic systems consist primarily of base-pair substitution mutations with a few frameshift mutations and small insertion/deletions. A positive response in the assay shows the compound to be genotoxic *in vivo.* Since the sensitivity of the assay is lower as compared to other *in vitro* tests, a positive response is considered more serious,

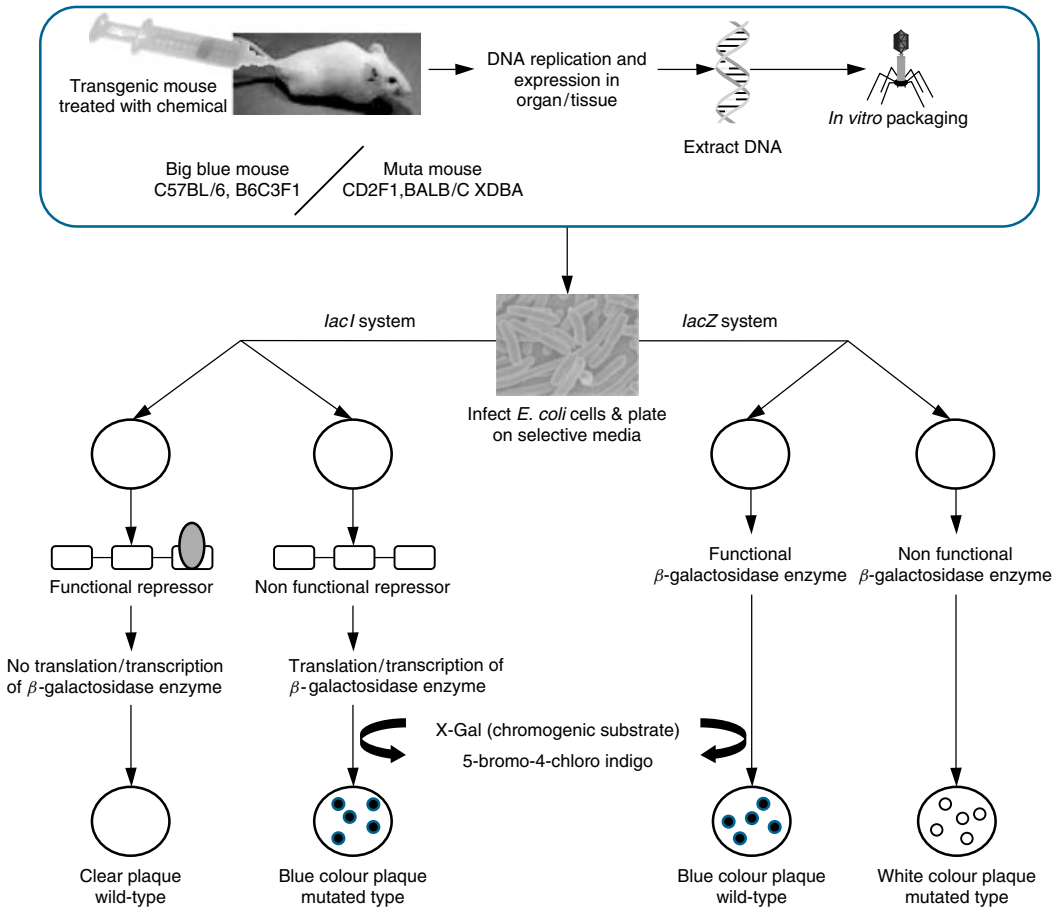

Figure 4 Schematic representation of *in vivo* transgenic rodent assay for mutagenicity.

especially for humans (Nohmi *et al*., 2000). Also mutations induced in the parent germ cells are transmissible to the F1 offsprings (Barnett *et al*., 2002).

The advantages of the transgenic system have been reviewed (Lambert *et al*., 2005). These include flexibility of route of exposure for chemicals, assessment of mutations in any tissue of rodents (due to the neutrality of the transgene) at all stages of development, ease of analysis of the mutations at the molecular level (for deducing the mechanism of mutation induction by different chemicals, and comparison of mutagenesis at different loci), high reproducibility of results in interlaboratory studies and use of the 3Rs of toxicity—reduction (animals can be used for germ/somatic cell mutagenesis, along with other *in vivo* tests like CAs), refinement (in test procedures) and replacement (use of transgenic cell lines). However, constraint in detecting some deletions/insertions, high spontaneous mutation frequency and cost of rodents and consumables are some of its drawbacks (Lambert *et al*., 2005).

Other transgenic models, developed for detecting specific genetic alterations for studying the mechanism of carcinogenesis are promising tools as *in vivo* alternatives to the two-year rodent assay (Storer, 2000; Tennant *et al*., 1995; 1996). Due to their genetic predispositions, these models have increased susceptibility to carcinogens and rapid development of cancer (~24–26 weeks; significantly shorter than the chronic rodent bioassay). These short-term *in vivo* models include the rasH2 transgenic mouse, Tg.AC transgenic mouse and p53 knockout mouse (**Figure 5**). These models have been recommended for cancer testing by the ICH, and the US Food and Drug Administration (US FDA), for new drug applications (Schmidt, 2002). The p53, Tg.AC and rasH2 models are genetically stable (genetic specificity remains in successive generations of breeding), have flexible dosing options and are able to produce a wide spectrum of tumours, depending upon the type of chemical exposure. These assays are hence rapid, reduce the number of animals used in testing and use of an appropriate model gives an accurate human response, aiding in regulatory risk assessment and identification of the mechanism underlying carcinogenesis (Pritchard *et al*., 2003).

The Tg.AC mouse developed by Leder *et al*. (1990), carrys a v-Ha-*ras* oncogene fused to the zeta-globin gene promoter. The v-Ha-*ras* transgene has double point mutations at codons 12 and 59. The altered gene expression (activation) of the transgene shows genetically initiated skin as a target for tumorigenesis (Cannon *et al*.,

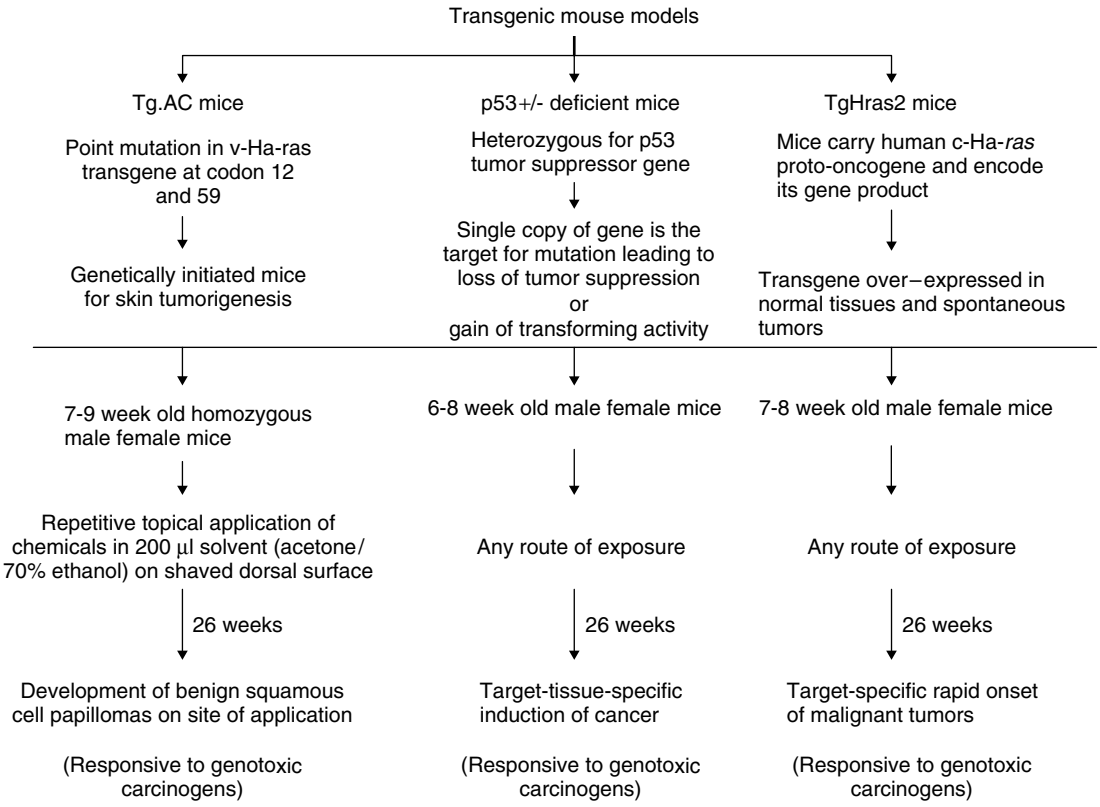

Figure 5 Short-term tests for carcinogenicity in transgenic mouse models. (Reproduced with permission from Bajpayee *et al.*, 2005. © Informa Healthcare.)

1997; Storer, 2000). Repeated application of the skin tumour-promoting agent leads to the development of benign papillomas, which may become malignant. This model has been used for the study and differentiation of initiating agents, tumour-promoting agents and complete carcinogens. Heterozygous p53 +/− deficient mice have a single functional allele and an inactivated null allele of the p53 gene. The mice become nullizygous upon inactivation of the wild-type functional allele due to mutation on carcinogen exposure and develop a high incidence of neoplasia (Tennant *et al.*, 1995). The TgHras2 mice carry a human protooncogene c-H-*ras* and have an endogenous promoter for the c-H-*ras* gene (Yamamoto *et al.*, 1997). The transgene is overexpressed in normal tissues and tumours, for example papillomas and lymphomas, develop in the animal. It has been used to study the effect of carcinogens in Japan (Yamamoto *et al.*, 1998).

The transgenic models are sensitive and specific, providing a better platform for carcinogenicity evaluation *in vivo*.

3.1.2.2.3 Mouse Spot Test

This genetic assay is a rapid and inexpensive test for the detection of somatic cell mutations and has been recommended by the OECD guidelines (OECD 484). Coat colour variation in mice occurs due to mutation in the loci controlling hair colour, resulting in the loss of the heterozygosity. The assay is widely used for the detection of a number of genetic alterations ranging from chromosomal damage to gene mutations (Styles and Penman, 1985). *In utero* treatment of mouse embryos is carried out at a time when pigment precursor cells migrate to the dermis. Mutant clones are recognized by the coloured patches (brown, grey or yellow) of hair at two weeks after birth. Mouse assays detecting genetic instability at endogenous loci predict hazardous effects of an environmental agent and/or genetic predisposition to cancer (Reliene and Schiestl, 2003).

3.1.2.2.4 Mutations in Germ Cells

Genotoxicity tests for monitoring germline mutations induced by chemicals (Russell *et al.*, 1981), which may pose a risk for heritable effects in future generations, are the mouse-specific locus test, mouse heritable translocation assay and dominant lethal assay. These tests are accepted as third-tier tests for gonadal mutations and intergenerational assays (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000), while the latter two are also recommended by the OECD guidelines (OECD 485 and 478, respectively).

The mouse-specific locus test detects single base-pair substitutions to insertions/deletions (Favor, 1999) and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat080
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

intralocus changes to multilocus deletions (Ehling, 1989). Normally heterozygous offsprings with the wild-type phenotype are produced from chemically treated homozygous mice mated with homozygous recessive tester mice. The tester mice are homozygous for seven loci controlling coat colour and the size of external ear. Simple and rapid screening of F1 offsprings with the recessive phenotype due to mutations in the parent is possible (Russell and Russell, 1996).

The mouse heritable translocation test detects reciprocal translocation in chromosomes, which is the mutual exchange of fragments of two nonhomologous chromosomes (Generoso *et al*., 1980). Several protocols can be used to generate mouse mutations with reciprocal translocations, to understand the biological functions of mammalian genes (Stubbs *et al*., 1997).

Genetic alterations, such as clastogenicity or aneuploidy (structural or numerical CAs) in germ cells *in vivo,* are detected by the dominant lethal assay. The test attributes embryonic death to chromosomal breakage in parent germ cells. Induction of a dominant lethal event after exposure to a test substance indicates that the substance has affected germinal tissue of the test species (Ehling *et al*., 1978). Normal female rats mated with chemically treated males are sacrificed at 14–16 days of pregnancy, and the live/dead embryos from the implants counted. The postimplantation loss from the treated and control groups is compared by determining the ratio of dead to total implants. The preimplantation loss by counting the total implants per female in treated and control groups can also be compared (Brewen *et al*., 1975). The post-/preimplantation loss and fertility rate were recommended as the main parameters to be assessed by the Working Group on Mammalian Germ Tests (Adler *et al*., 1994). A schematic method of data presentation was proposed, which enables the most pertinent assay data and parameters to be viewed and considered simultaneously (Ashby and Clapp, 1995).

Most chemicals/compounds that are recognized as *in vivo* somatic cell mutagens are considered to be genotoxic carcinogens and potential germ-cell mutagens (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000). Few compounds are germ-cell-specific mutagens and not somatic mutagens, for example *N*-hydroxymethylacrylamide (NHMA), a mouse carcinogen (Witt *et al*., 2003). The development of transgenic rodent assays and the expanded simple tandem repeat (ESTR) assay, have added value to the detection of germline mutations induced by chemical and radiological agents. The result of these assays is comparable to the specific locus test (Singer *et al*., 2006). The mechanisms of induction of dominant lethal mutations and heritable translocations show that they are dependent on the stage at which the germ cell is treated (Adler, 2000; Generoso *et al*., 1982), with spermatids being most sensitive to induction of dominant lethal mutations (Barnett and Lewis, 2003).

3.2 Assays for Chromosomal Abnormalities

In vivo as well as *in vitro* assays are available for determining the adverse effects of chemicals on the structural and/or numerical makeup of chromosomes. These assays use direct visualization of chromosomal preparations under a microscope. Chemicals/compounds can lead to breakage, translocation insertions/deletions, causing structural changes (clastogenicity) or numerical changes (aneuploidy), which can be studied by analysing CAs in metaphase cells or MN formation (see also **Cytogenetics**). Cultured mammalian cells are most often used for *in vitro* studies, while rodent bone-marrow cells are utilized for *in vivo* studies.

These assays are used as screening tests, along with bacterial mutagenesis assays in the standard battery of tests for determining genotoxicity of chemicals/compounds. The COM guidelines recommend the use of *in vitro* assays for chromosomal alteration in the first stage and the *in vivo* assays in the second stage as follow-up to positive *in vitro* tests. These assays are also recommended for use by other international regulatory agencies like USEPA and ICH (reviewed by Cimino, 2006).

The tests for chromosomal abnormalities include mitotic recombination in yeast, *in vitro* and *in vivo* CA, MN and sister chromatid exchange (SCE) assays.

3.2.1 Mitotic Recombination Assay

The *Saccharomyces cerevisiae* mitotic recombination assay is used to measure gene conversion (unilateral DNA transfer within a gene) or crossing-over (exchange of DNA segments between genes), for assessing the genotoxicity of chemicals (Freedman and Jinks-Robertson, 2002; Zimmermann, 1984). It has been recommended by OECD guidelines (OECD 481). Similar mitotic recombination events in *S. cerevisiae* are induced by double-strand breaks and associated with low and high transcription conditions, showing that transcription promotes DNA breaks (Gonzalez-Barrera *et al*., 2002). A novel sensitive and highly reproducible assay in a diploid construct of *S. cerevisiae* has been developed, to allow efficient detection of mitotic recombination events and forward mutations, as well as chromosome loss or nondisjunction (Schafer *et al*., 2008).

Cells are treated with mutagens in solvents, in the presence or absence of metabolic activation. The colonies are then counted on nonselective or selective media after four to six days. Spell and Jinks-Robertson (2004) have

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

described statistical analyses for calculating the true mean of recombination events, and have discussed their application for the regulation of homologous recombination and to avoid the interference of a spontaneous recombination event in culture.

3.2.2 Chromosomal Aberration

A cytogenetic assay for chromosomal abnormalities using metaphase analysis is one of the currently recommended *in vitro/in vivo* tests for the genotoxic/mutagenic potential of a substance. Chemicals that induce structural changes in the chromosome are known as 'clastogens', while those causing changes in the number of chromosomes are 'aneugens'. These compounds cause alterations in the DNA, which may be processed during replication and/or DNA repair into the various types of aberrations visible in chromosomes at the metaphase stage of cell division.

CAs may be present as the whole chromosome or as single chromatids and include lesions such as breaks (deletion/fragments) or rearrangements (inversion/translocation and exchanges). Chromosome-type aberrations arise from alterations in the unreplicated 'G1' chromosome, while chromatid-type aberrations are formed from lesions arising during or after the 'S' phase. Majority of the chemical clastogens are S-phase dependant and induce aberrations only in cells that pass the S phase after exposure. Clastogens acting in the early S phase, lead to higher number of CAs, probably due to limited error-free repair of primary DNA lesions in the cell. Unbalanced chromatid-type aberrations are frequently lethal because both chromatids are affected, leading to structural chromosome damage in both daughter cells. Cytogenetic alterations include shortening of telomeres, formation of dicentric chromosomes, transfer of telomeric DNA to the homologous chromosomes, inactivation of the centromeres, endoreduplication of chromosomes, and other structural and numerical chromosome abnormalities (Obe *et al*., 2002; Pathak *et al*., 1994). Double-stranded breaks in DNA lead to the formation of chromosome translocations or rearrangements commonly seen in cancer cells. Chromosome breaks and aneuploidy cause a hypermutable state, which may lead to the development of cancer (Fenech, 2002a; 2002b). Most cancer cells show aneuploid states, pointing to the fact that aneuploidy destabilizes the karyotype, leading to preneoplastic and ultimately cancer cells (Fenech, 2002a; 2002b).

The *in vitro* CA is used as a first tier test for screening of compounds for their genotoxicity and is accepted by international regulatory agencies USFDA, USEPA and ICH. The assay is conducted according to the OECD guidelines (OECD 473). Cells with stable, well-defined karyotypes, short cell cycles, low chromosome numbers and clearly visible chromosomes are ideal for cytogenetic analysis. The CHO cells and human peripheral lymphocytes have been used extensively for *in vitro* testing (Evans, 1984; Galloway *et al*., 1994; Preston *et al*., 1987a). Cells are treated during a sensitive period of the cell cycle, for example, the S phase, arrested in the metaphase of the first mitotic cycle using a spindle inhibitor and aberrations scored under a microscope (**Figure 6**). The assay may be affected by artifacts or experimental conditions, such as extreme culture conditions (Scott *et al*., 1991), highly cytotoxic concentrations, extreme pH and genotoxicity of the metabolic activation system (Kirkland *et al*., 1989), leading to false positive results. The study should, therefore, be extended till at least some cytotoxicity is observed (Galloway, 2000).

In vivo CA is conducted in mice and hamsters. Animals are treated with the compound for a specified time and then treated with a metaphase-arresting compound, for example colchicines, two hours before sacrifice (Preston *et al*., 1987b). Cells from bone marrow are then collected for cytogenetic analysis (Tice *et al*., 1994). CAs are counted under a microscope from Giemsa-stained metaphase spreads prepared on slides. The *in vivo* CA test is used in the first tier (US Environmental Protection Agency, 1997; International Conference on Harmonization, 1999) or second tier (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000) of genotoxicity testing to analyse if the chemical is an *in vivo* somatic-cell mutagen, and is conducted according to the OECD guidelines (OECD 475).

CAs have also been employed in human biomonitoring studies (Au *et al*., 2001; Au, 2003; Wolff, 2007) as a biomarker of DNA damage (Albertini, 2000). IPCS guidelines for the planning, performing and conduct of the assay in blood lymphocytes for monitoring human genotoxicity have been reviewed by Albertini *et al*. (2000). An association has long been shown between the level of CAs in human peripheral lymphocytes and the risk of cancer (Bonassi *et al*., 2000; Hagmar *et al*., 2004).

The analysis for aberrations is time-consuming and use of fluorescent *in situ* hybridization (FISH) (Johnson *et al*., 1998) or chromosome painting, to highlight the alterations in the number of copies of selected chromosomes (Natarajan, 2001), has also been made. FISH allows increased resolution of the detection of aberrations and leads to a better understanding of the mechanisms of formation of chromosome aberrations (Natarajan and Boei, 2003). These methods are efficient tools for tumour diagnosis. Specific chromosomal translocations have been shown by FISH painting in mouse plamacytoma (MPC), human Burkitt lymphoma (BL) and other B-cell-derived tumours (Szeles, 2002). Spectral karyotyping and multicoloured or multiplex-fluorescence *in situ* hybridization (m-FISH) allow for visualization of

all chromosomes of a metaphase in a single hybridization step, which enables screening for aberrations and the comprehensive analysis of complex karyotypes (Tchinda *et al*., 2003; Brizard *et al*., 2004; Hande *et al*., 2005).

3.2.3 Micronucleus Assay

Micronucleus is an extranuclear chromatin-containing body formed during mitosis and made of either chromosomal fragments or whole chromosomes (Schmid, 1975). The MN assay can be conducted both *in vitro* (in cell cultures and primary cultures of lymphocytes) and *in vivo* (in bone marrow or blood cells of rodents) for detection of both aneuploidy and clastogenicity (**Figure 7**). MN formation in peripheral blood lymphocytes in human populations occupationally exposed to genotoxic compounds is a valuable cytogenetic biomarker (Bolognesi *et al*., 2004), and widely used in human biomonitoring studies (Albertini *et al*., 2000; Costa *et al*., 2006; Neri *et al*., 2003).

In vivo MN assay is usually conducted in the erythrocytes from bone marrow of rodents according to the OECD guidelines (OECD 474) and the method of Schmid (1975). The animals are treated with the chemical (single or multiple dosing) and bone marrow collected after animal sacrifice. Cell smears are prepared on slides, stained with Giemsa and counted under a microscope (**Figure 8**). A large number of chemicals have been studied using this method for the assessment of genotoxicity of chemicals, including clastogens and spindle poisons (Hayashi *et al*., 1994; Sato and Tomita, 2001). This assay finds its place in the first tier (US Environmental Protection Agency, 2005; International Conference on Harmonization, 1999) or the second tier (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000) of the genotoxicity testing battery. The *in vivo* MN assay has also been conducted using other tissues, for example, liver (Igarashi and Shimada, 1997; Müller-Tegethoff *et al*., 1997). FISH can also be utilized in the *in vivo* MN test to help discriminate MN of clastogenic and aneugenic origins (Attia *et al*., 2003). The use of flow cytometry for analysis of MN has helped in making the assay high throughput (Kissling *et al*., 2007; Hayashi *et al*., 2000). The IWGT *In Vivo* MN Assay Working Group has recently discussed issues related to the performance of the assay (Hayashi *et al*., 2000) and reached a consensus on the use of automated scoring using flow

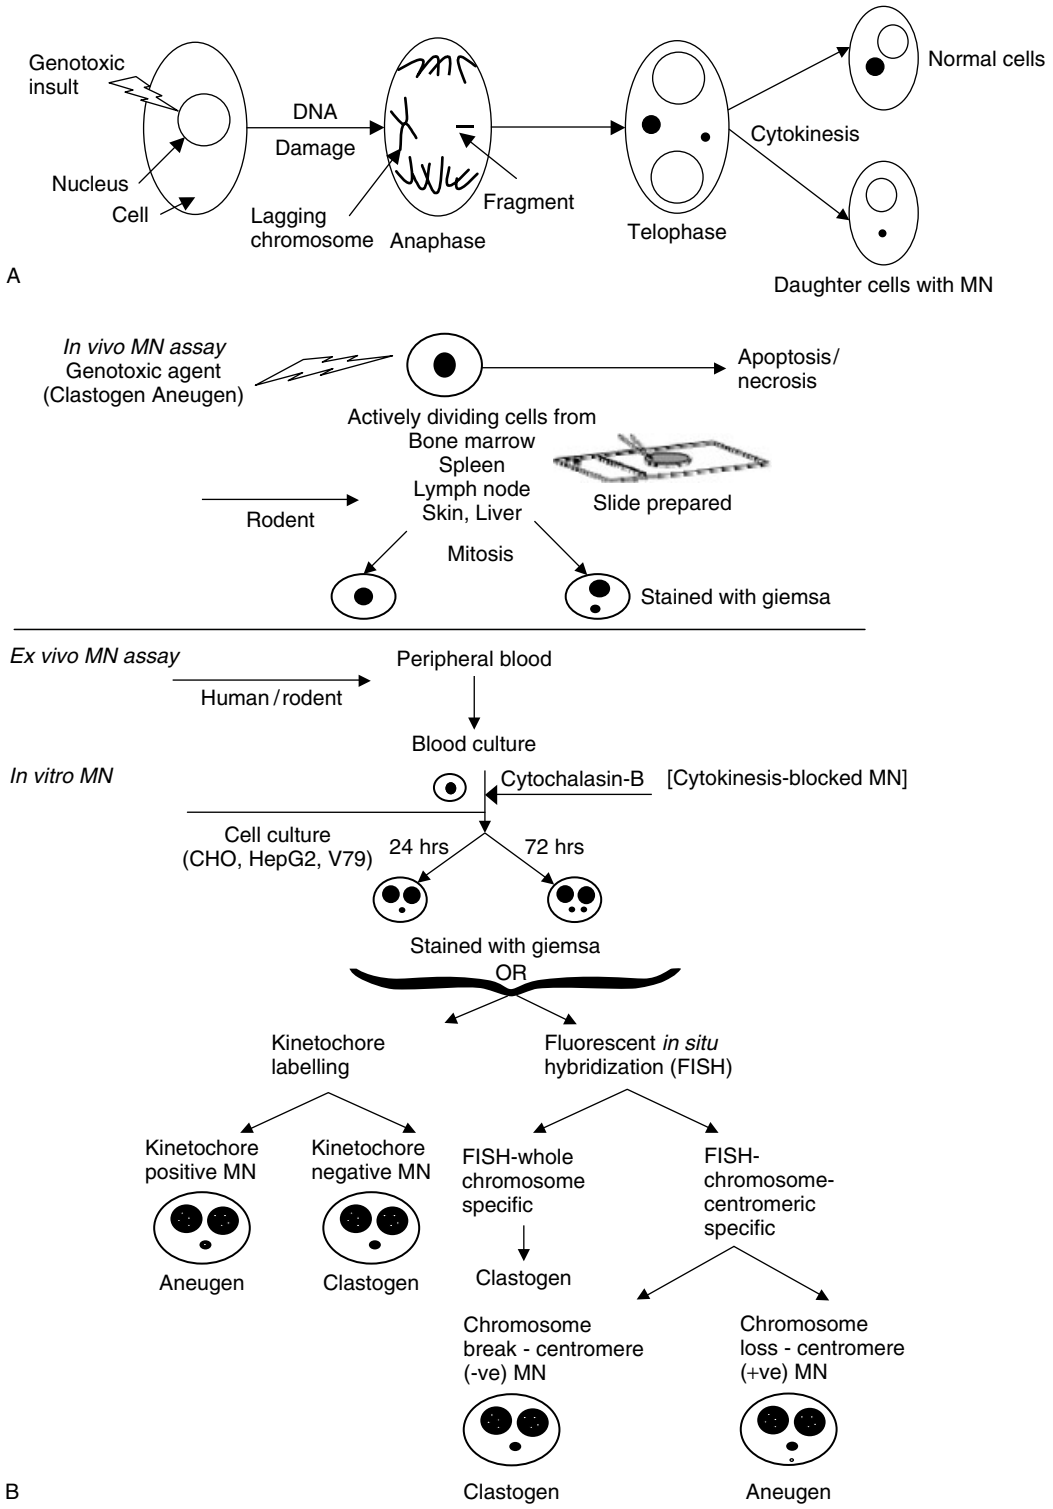

Figure 7 Schematic representation of: (A) micronucleus formation; (B) micronucleus assay.

cytometry (Hayashi *et al*., 2007). The use of blood reticulocytes from young rodents was found to be acceptable for conducting an MN assay, while an MN assay in liver cells from young rodents could be used as a good alternative methodology for genotoxicity assessment (Hayashi *et al*., 2007). The single-dose rat bone marrow MN assay has enhanced sensitivity compared to the subchronic rat dominant lethal assay, thus the rodent bone marrow MN assay can be used as a predictor of possible germ-cell mutagenicity of chemicals (Hayashi *et al*., 2000; Tinwell *et al*., 2001). The IWGT also have reviewed compounds, for example, which are specifically detected in *in vivo*

tests and give a negative response *in vitro*, and have formulated a decision tree for the evaluation of such chemicals (Tweats *et al*., 2007).

The *in vitro* cytokinesis-blocked micronucleus (CBMN) assay is the most widely used assay for genotoxicity assessment (Fenech and Morley, 1985; Kirsch-Volders *et al*., 1997; Rosefort *et al*., 2004) and human biomonitoring (Bonassi *et al*., 2001; 2007; Kirsch-Volders and Fenech, 2001). The MN assay can also be used as a biomarker for cancer (Bonassi *et al*., 2005). The *ex vivo*/*in vitro* CBMN assay for human biomonitoring was validated by the Human MicroNucleus (HUMN) Working Group, which has discussed variations in the experimental and confounding factors influencing the MN frequency (Fenech, 2002a; 2002b; Fenech *et al*., 1999; 2003a; 2003b; Kirsch-Volders *et al*., 2000; 2003). In this assay, cells are treated with the test chemical and cytochalasin-B, an inhibitor of contractile filaments, which prevents the cell cycle at the cytokinesis stage, thus preventing division of the cytoplasm. Hence bi- and multinucleate cells are obtained and the MN are counted in binucleate cells (**Figure 9**). Dicentric and centric-ring chromosomes that arise in the anaphase are visible in CBMN assays as nucleoplasmic bridges (NPBs) due to inhibition of cytokinesis (Thomas *et al*., 2003). Evaluation of NPBs provides a valuable measure of chromosome breakage/rearrangement that would not be available in the MN assay. The analysis of MN can also be carried out with the help of flow cytometry in CHO cells (Wagner *et al*., 2003) and cultured lymphocytes (Nusse and Kramer, 1984).

The nature of any MN formed can be determined with use of FISH, using human pancentromeric DNA probes (Iarmarcovai *et al*., 2006), kinetochore and centromeric staining (Dhawan *et al*., 2003; Lynch and Parry, 1993; Natarajan, 1993; **Figure 10**), which help to categorize the test compound as a clastogen or aneugen (Parry *et al*., 2002; Parry and Parry, 2006), contributing to the sensitivity and specificity of the assay (Mateuca *et al*., 2007). The time of treatment and sampling in relation to the cell cycle influence the formation of MN. Since the majority of clastogens give rise to chromosomal damage during the 'G1' and S phases, leading to formation of micronuclei in subsequent cell cycles, at least one cell cycle is allowed between treatments and harvesting of cells. At shorter sample intervals, MN may escape detection, while longer sampling time may lead to loss/dilution of MN in the cells. Micronuclei induced by dysfunction of spindle or S-phase-independent clastogens can be seen at shorter sampling intervals than S-phase-dependant chemicals.

Discrimination between mutagens inducing DNA breakage (clastogens) or chromosome loss/nondisjunction (aneugens) contributes to the high specificity of the MN assay. COM guidelines (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000) and the IWGT have suggested the inclusion of the *in vitro* MN assay as an alternative test to the *in vitro* CA. Protocols for human primary lymphocytes and cell lines were validated and harmonized (Kirsch-Volders *et al*., 2003) and are now in the final phases of validation by the European Centre for the Validation of Alternative Methods (ECVAM) and of acceptance in the OECD guidelines (Mateuca *et al*., 2007). The MN assay is as sensitive as the CA, having a high concordance with the *in vitro* CA, has good predictivity for cancer, is rapid, less resource intensive, inexpensive, automated and has a higher statistical power (Mateuca *et al*., 2007). The performance of three *in vitro*

tests: MN assay, CA and MLA were also compared for 700 chemicals, where the MN assay gave 84% concordant results with MLA, and had a better predictivity than MLA (Lorge *et al*., 2007; Kirkland *et al*., 2005).

3.2.4 Sister Chromatid Exchange Assay

SCEs represent a symmetrical exchange in chromatid segments within a single chromosome at homologous loci, which involve DNA breakage and reunion during cell division in mammalian cells and are end products of homologous recombination (Helleday, 2003). There is no altered chromosome morphology and differentially stained or labelled sister chromatids are detectable in the SCE assay (Tucker *et al*., 1993), however the mechanisms that mediate SCE are not understood. SCE *per se* is not lethal or cytotoxic, but has been extensively used as an end point in cytogeneticity/mutagenicity testing.

An SCE assay can be performed *in vivo, in vitro* and *ex vivo* (Perry and Evans, 1975) and is conducted according to the OECD guidelines (OECD 479). Lymphocytes from animals or humans can be removed from an exposed population and cultured in presence of BrdU (*in vivo-in vitro* SCE), and cell lines are used for *in vitro* studies (Sayed Aly *et al*., 2002), while *in vivo* SCE is performed on animals implanted with BrdU tablets, or given a continuous infusion of BrdU (OECD 479). Exposure to chemicals is given in the presence or absence of S9 metabolic activation systems in the early S phase and allowed to pass through one cell cycle. The detection of SCE involves pretreatment of cells with agents, that is, BrdU and H^3-thymidine, which are incorporated into the DNA and induce SCE. The removal of SCE-inducing damage is seen by a reduction in SCE frequency with time between exposure and sampling of cells for analysis *in vivo*. Thus these times are important determinants in the final yield of SCE.

A large number of chemicals have been shown to increase SCE frequency in animal/human cells *in vivo* (Rodriguez-Reyes and Morales-Ramirez, 2003) as well as *in vitro* (Mahata *et al*., 2004; Poma *et al*., 2003; Yüzbaşioğlu *et al*., 2008). The observations suggest that SCE inducing damage can be removed before the S phase and that formation of SCE is closely linked to the replication process.

Many SCE-inducing agents are mutagens. The majority of induced SCEs do not represent recombinational/mutational events, but a fraction of exchanges occur at nonhomologous loci and these unequal SCEs could represent mutational events or chromosomal deletion, or be involved in DNA amplification.

3.2.5 Chromosomal Alterations in Germ Cells

Genetic risk due to exposure of chemicals in mammalian germ cells (female and male), may be analysed using cytogenetic end points, such as structural and numerical CA, micronuclei and SCEs. The metaphase analysis is difficult and time consuming, but more feasible in male (spermatogonia, spermatids) than female germ cells (oocytes). The use of FISH has also been made for detection of CAs and MN (Russo, 2000). Germ-cell MN assays in rodent spermatids permits the analysis of chromosomal damage during meiosis. Aneuploidy assays in mouse genetic models have been developed to identify risks of chemical exposures or age in rodent germ cells (Eichenlaub-Ritter, 2005). These models have structural chromosomal rearrangements, which predisposes them for aneuploidy, and thus are a tool for detecting aneugens.

3.3 Tests for Primary DNA Damage

The evaluation of DNA damage and repair due to exposure to chemicals has been used in short-term tests for genotoxicity studies. These tests utilize nonreplicative DNA synthesis and involve the measurement of DNA strand breakage by the alkaline elution method,

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

detection of DNA adducts through ^{32}P-postlabelling and the Comet assay.

3.3.1 Unscheduled DNA Synthesis

DNA repair mechanisms such as excision repair can be used for the detection of chemically induced DNA lesions. The damaged segment of the DNA in mammalian cells is removed by excision enzymes and DNA repair synthesis occurs using the opposite strand as the template. This repair can be detected by autoradiography, after incorporation of H^3-thymidine, as UDS, that is, DNA synthesis outside the S phase of the cell cycle (Madle *et al*., 1994).

In vitro UDS is carried out on primary rat hepatocytes, which are sensitive to the effect of DNA-damaging chemicals, and is conducted as recommended by the OECD guidelines (OECD 482), as well as those of the US Environmental Protection Agency (1998). These cells do not require metabolic activation and are capable of metabolizing procarcinogens to the active carcinogen (McGregor and Anderson, 1999). Since these cells are epithelial in origin, monitoring of genetic damage is relevant to the *in vivo* situation. The autoradiographic method of *in vitro* UDS was found to be sensitive for detecting genotoxic damage by mutagens and pro mutagens in human hepatoma cells HepG2 (Valentin-Severin *et al*., 2004). Many chemicals that are positive for UDS *in vitro* are also positive in the Ames test, but not all are rodent carcinogens. The use of *in vitro* and *in vivo* UDS as supplemental tests in genotoxicity testing of hair dyes has been recommended by the European Scientific Committee on Cosmetics and Non-Food Products (SCCNFP) guidelines and its inclusion in the test battery has been discussed (Kirkland *et al*., 2005).

The rodent liver (*in vivo*) UDS assay is an established test for evaluating the genotoxicity (DNA damage and repair) induced by chemicals in the liver and is appropriate for compounds that require metabolic activation to express genotoxic activity (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000). Use of *in vivo* UDS has been recommended (OECD 486) independent of the results of *in vitro* UDS and as a follow-up to negative results in the standard *in vivo* tests (Kirkland *et al*., 2005).

Ex-vivo UDS assay is designed for the complex patterns of metabolic activation, detoxification uptake distribution and excretion of chemicals (Mirsalis and Butterworth, 1980). The hepatocytes from rats are isolated at two points, that is, 2–4 hours and 12–16 hours after *in vivo* treatment, and cells allowed to undergo *in vitro* UDS. The detailed procedure has been reviewed by Casciano (2000). The positive results from UDS performed *in vivo* or *in vitro* are highly predictive of rodent carcinogenicity. DNA repair capacity and its effect on cancer susceptibility in humans is an important area of investigation (Berwick and Vineis, 2000). UDS in human leucocytes has become a popular tool for estimating an individual's DNA-repair capacity and sensitivity to mutagens (Pero and Ostlund, 1980). Nucleotide excision repair (NER) is differentially expressed in human tissues. A unique culture system in primary cultures of lymphocytes and foreskin fibroblasts to measure NER capacity using the the UDS functional assay has been carried out to study the baseline DNA repair in normal human cells (Kelly and Latimer, 2005; Latimer *et al*., 2003). This helps in evaluation of the effects of 'mutator' genes as aetiological factors in the development of cancer (Latimer *et al*., 2003).

The UDS assay has also been conducted in male germ cells (spermatogonia, meiotic spermatocytes and early spermatid stages) and its correlation with other heritable mutation tests indicates that the *in vivo/in vitro* spermatocyte DNA-repair assay is useful in predicting the mutagenic potential of chemicals in male germ cells (Inoue *et al*., 1993; Sotomayor *et al*., 1996; 1999; Sotomayor and Sega, 2000).

3.3.2 Single Cell Gel Electrophoresis/Comet Assay

Conventional genotoxicity assays, such as CAs and MN, are time-consuming, cumbersome and require pooled cell populations, besides requiring skilful personnel. A simple, rapid, sensitive, reliable, inexpensive and visual microgel electrophoretic technique, to assess quantitatively and qualitatively the DNA damage in single cells, was developed by Ostling and Johanson (1984). This technique has since been modified and improved for the detection of different types of DNA damage (double- and single-strand breaks) and has now become a state-of-the-art technique known as the single-cell gel electrophoresis/Comet assay (Olive *et al*., 1990; Singh *et al*., 1991). The Comet assay has gained wide acceptance and popularity during the last two decades as a short-term test to measure the level of DNA damage and repair *in vitro* and *in vivo*, as well as in human biomonitoring studies. Its ability to evaluate DNA damage in nonproliferating cells makes it a useful tool to work on any eukaryotic cell.

The assay is conducted according to the Comet assay guidelines (Tice *et al*., 2000; Hartmann *et al*., 2003) and is recommended as an *in vivo* test in the second stage of genotoxicity testing (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000), while the IWGT workgroup has recently made recommendations for the assay to be accepted by international agencies (Burlinson *et al*., 2007). The *in vitro* Comet assay has been proposed as an alternative to cytogenetic assays in early genotoxicity/photogenotoxicity screening of drug candidates (Witte *et al*., 2007). Cells of interest are embedded in agarose on a microscope slide and lysed

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat080
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

under high salt conditions. The DNA is subjected to unwinding and electrophoresis under neutral or highly alkaline conditions (pH $\geq$ 13). The migrated DNA after neutralization is stained with an appropriate dye, for example ethidium bromide, propidium iodide, YOYO-1, Hoescht 33258, 4′,6-diamidino-2-phenylindole (DAPI) or acridine orange, and visualized under a fluorescence microscope (**Figure 11**). The DNA damage is then scored using software, or by visual scoring (Kumaravel *et al*., 2009). Several parameters can be monitored by the software, however the most frequently used are tail DNA (%), tail length (μm) and tail moment (arbitrary units).

The assay has been extensively used in evaluating DNA damage in different models, ranging from prokaryotes (bacteria) to human beings (Dhawan *et al*., 2009). The assay is a sensitive biomarker for monitoring ecogenotoxicity using sentinel species such as earthworms (Di Marzio *et al*., 2005), molluscs (Lee and Steinert, 2003) and fish (Dhawan *et al*., 2009; Winter *et al*., 2004). The studies in *Drosophila* have shown it to be a good alternative to animal models for the assessment of *in vivo* genotoxicity of chemicals using the Comet assay (Mukhopadhyay *et al*., 2004; Siddique *et al*., 2005a; 2005b). It is a valuable tool in fundamental DNA damage and repair studies (Speit and Hartmann, 2005; Olive and Banath, 2006), genotoxicity testing (Møller, 2005) and human biomonitoring (Basaran *et al*., 2003; Kassie *et al*., 2000; Møller, 2000, 2006a; Palus *et al*., 2003). The assay has also been used for dietary intervention studies (Glei *et al*., 2005; Møller *et al*., 2004; Wilms *et al*., 2005) and clinical studies (Wynne *et al*., 2007; McKenna *et al*., 2008). White blood cells are the most frequently used cell type for Comet assay in human biomonitoring studies (Angerer *et al*., 2007; Møller, 2006b), however other cells have also been used, for example, buccal (Szeto *et al*., 2005), nasal (Mussali-Galante *et al*., 2005), sperm (Delbes *et al*., 2007; Schmid 2007; Singh *et al*., 2003), epithelial (Graham-Evans *et al*., 2004) and placental cells (Augustowska *et al*., 2007). The Comet assay has also been used for detecting genotoxicity in plant models (Dhawan *et al*., 2009; Gichner *et al*., 2006) with cells from leaves (Gichner and Plewa, 1998), stems and roots (Vajpayee *et al*., 2006). The Comet assay in plants can be incorporated as a test for *in situ* environmental monitoring.

The assay is versatile in the detection of single- and double-strand breaks, DNA crosslinking (Singh, 2000), apoptosis (Singh, 2000) and necrosis (Fairbairn *et al*., 1995). The specificity and sensitivity of the assay is increased by use of lesion-specific enzymes (Collins, 2004), hence, broad classes of oxidative DNA damage, alkylations, and ultraviolet-light-induced photoproducts can be detected as increased amount of DNA in the tail (Giovannelli *et al*., 2003; Møller, 2006a). The Comet assay has also been coupled with FISH (Comet-FISH) for evaluating DNA-specific damage and repair (Glei *et al*., 2009; McKenna *et al*., 2008; Spivak *et al*., 2009).

Although the Comet assay is a useful technique, the variability in results from different laboratories, interpretation of the results and lack of validated studies are some of its disadvantages.

3.4 Cell Transformation Assays

Induction of phenotypic alterations that are indicative of neoplasia in cell cultures is defined as cell

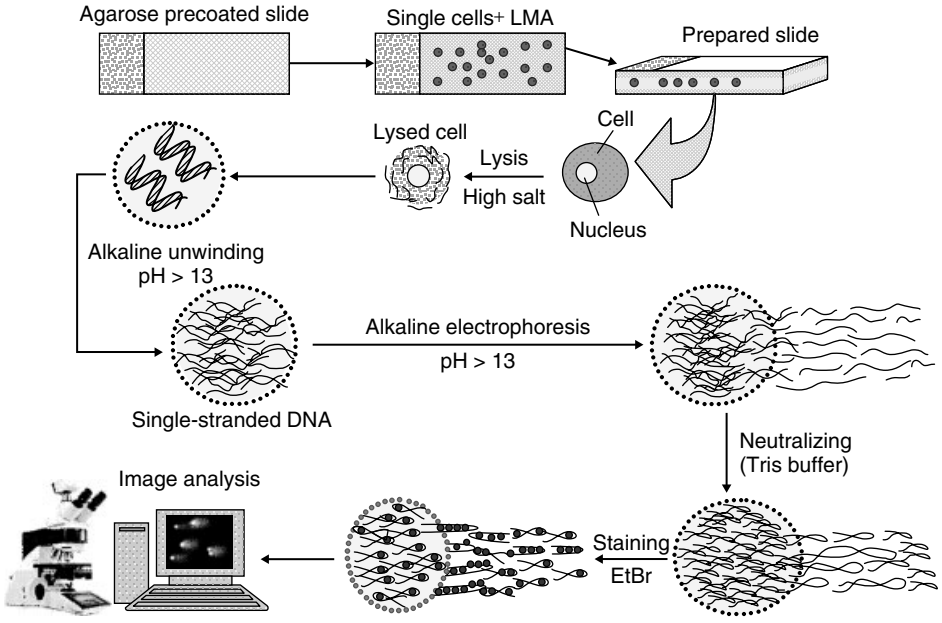

Figure 11 Comet assay protocol.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat080
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

transformation (Barret *et al*., 1986; LeBoeuf *et al*., 1999). The mammalian cell culture (*in vitro*) transformation assay is based on the assumption that neoplastic transformation in the cultured cells occurs by the same mechanism as neoplastic alterations of cells *in vivo*. These assay systems are important short-term tests, used to study the multistage process of neoplastic transformation, and therefore the mechanism of action of genotoxic and nongenotoxic carcinogens (Yamasaki *et al*., 1996).

Morphological transformation of fibroblast cultures shows loss of growth inhibition and cell-to-cell orientation. These cells also have the capacity to produce tumours in immunosuppressed animals. The Syrian hamster embryo (SHE) and Balb/c cell systems are frequently used in this assay.

3.4.1 Syrian Hamster Embryo (SHE) Cell Transformation Assay

This assay was developed by Berwald and Sachs (1965) for detecting the carcinogenic potential of chemical, physical and biological agents (Engelhardt *et al*., 2004; Isfort, 2000; Yamaguchi and Tsutsui, 2003). The assay is conducted in primary cultures of SHE foetal cells (12–14 days of gestation) to test. Alkylating agents, polyaromatic hydrocarbons, nitrosamines and amides, aromatic amines and so on have been tested for their ability to produce morphological transformations in this assay. An OECD guideline has also been drafted for the assay (OECD 965).

The SHE cells are plated onto culture dishes and, after obtaining small colonies, the cells are treated with test chemicals for 24 hours or for the entire period of the study. Colonies are allowed to grow for a week after removal of the test chemical. The resultant colonies formed are fixed with methanol and stained with Giemsa (Barrett *et al*., 1986).

The assay provides the advantage of employing normal diploid cells as target cells, which have a wider range of metabolic capabilities than other cell lines, allowing procarcinogens to convert into the active form, and thus it does not require any exogenous metabolic activation. The assay is also rapid and scoring for transformed cells is possible within 10 days from plating.

The early stages of cells are used for the study, but to reduce culture variations and cell variations from different embryos, cryopreserved SHE cells are preferred. Primary cultures are screened for transformation and highly susceptible batches of the cells are cryopreserved for later use. Normal clones have cells growing in a monolayer in an organized pattern and minimal cell stacking at confluency. Morphologically transformed colonies contain cells in an extensive random-orientation stacked growth with criss-crossing at the periphery and centre. The SHE cell assay has been developed at low pH (6.7) for reducing/eliminating the problems associated with the standard assay (Harvey *et al*., 2005; Kerckaert *et al*., 1996). The pH 6.7 SHE transformation assay allows separation of the cell transformation process into two phases, initiation and promotion, as in *in vivo*. This allows chemicals found to be positive in the traditional SHE cell transformation assay to be further classified as initiators or promoters. Cigarette smoke condensate was found to act at both the initiation as well promotion stages of transformation (Breheny *et al*., 2005).

3.4.2 BALB/c3T3 Mice Cell System

The BALB/c3T3 clone, developed by Aaronson and Todaro (1968), is a spontaneously immortalized cell line derived from a mouse embryo with high sensitivity to chemical transformation, and has been utilized for screening potential carcinogens. The assay is being validated by the ECVAM. Chemicals with short half-lives can be screened on this cell line and a dose–response curve can be obtained with relatively a small number of plates having a large number of cells per plate. The carcinogenic potential of a compound tested is assessed by comparing the number of foci in treated and untreated cells. The interpretation of results is better with statistical analysis by Fisher's exact test rather than the t-test (Ponti *et al*., 2007).

Actively growing cells are treated with chemicals with or without activation and then plated onto dishes at an appropriate cell density and the transformation of cells observed. Positive transformed foci of the BALB/c3T3 cells show basophilia, multilayering of the cells, random orientation and invasion into the monolayer (Fitzgerald *et al*., 1989). The *in vitro* transformation assay of BALB/c3T3 cells has been improved with the use of T medium (modified DME/F-12) supplemented with insulin, transferrin, ethanolamine and sodium selenite (ITES) and 2% foetal calf serum (FCS), causing a five-fold higher transformation frequency and earlier appearance of transformation foci (Kajiwara and Ajimi, 2003; Tsuchiya and Umeda, 1995). This assay is useful as a short-term test for detecting potential carcinogens and shows a concordance of 73.5% with rodent bioassay. The sensitivity and reproducibility of the transformation assay could be enhanced with the use of a low concentration of serum in the growth medium after treatment (Kajiwara *et al*., 1997). In the BALB/c3T3 clone, Bhas 42 cells, transfected with the v-Ha-*ras* gene, are the initiated cells in the two-stage transformation paradigm for detecting tumour promoters, and the end point of the assay is the induction of transformed foci (Ohmori *et al*., 2004). The *Fusarium* mycotoxins, fumonisin B_1 and T-2 toxin, are positive in the Bhas 42 promotion assays, which supports their tumour-promoting activity observed in two-stage carcinogenesis tests in experimental animals (Sakai *et al*., 2007).

The only disadvantage of this cell system is that this subclone BALB/c3T3 has a relatively unstable karyotype

and its properties in culture may also change. Thus, maintenance of cell stock with the original properties is important.

3.5 Assays in *Drosophila melanogaster*

Drosophila melanogaster has been widely used in genetic toxicology as an alternative to animal models for the identification of potential carcinogens, and also for studies of the mechanisms of mutagenesis of chemicals (Vogel *et al*., 1999).

Detection of a variety of genetic damage in germ cells of *Drosophila* is possible because of short generation time (10–12 days) and a broad range of suitable reporter genes. Earlier the sex-linked recessive lethal (SLRL) mutation, an *in vivo* forward mutation assay, was used for detecting both point mutations and small deletions in the germ line of the insect. These mutations, occurring in the X chromosome of *Drosophila*, are phenotypically expressed in the mutant males. Most of the database of chemicals is based on this forward assay. The SLRL assay has been used to study adaptive response of germ cells to alkylating agents, where the response was demonstrated in larvae, but not in adult flies (Savina *et al*., 2003).

The SLRL germ line tests were, however, costly and have been replaced with assays of mitotic recombination, and mutations in somatic tissues (Wurgler *et al*., 1984), allowing for evaluation of a large number of chemicals. The somatic mutations in eye or wing disc cells have been validated, are well established and include the simple and rapid wing-spot test or the wing somatic mutation and recombination test (SMART). Larvae are exposed to the chemical through feeding or inhalation and if loss of heterozygosity occurs in the heterozygous recessive wing markers, (multiple wing hair (*mwh*) and flare (*flr*)), it leads to formation of clones. Various end points such as mitotic recombination, point mutations, deletions, nondisjunction and chromosomal loss can be detected with a single wing-spot phenotype comprising either *mwh* or *flr*. Twin-spot phenotypes, with adjacent *mwh* and flr areas, give direct proof for the recombinogenic property of the test compound (Zimmering *et al*., 1997). This test is highly sensitive and has been validated for distinct types of genotoxic compounds that damage the DNA. The wing-spot test in *Drosophila* is suited to the detection of recombinogenic activity of genotoxic chemicals (Spano *et al*., 2001), and has been used to assess the mutagenic activity of food colourants (Demir *et al*., 2008), airborne particulate matter (Dihl *et al*., 2008), herbicides (Fragiorge *et al*., 2008; Kaya *et al*., 2004), fungicides (Osaba *et al*., 2002) and the genotoxicity of Vitamin A (Klamt *et al*., 2003).

Another test is the white/white$^+$ eye mosaic system for homologous recombination, which is also based on the loss of heterozygosity. In this method, the larvae are exposed to the chemical, and the light spots in the eye of adult females are monitored (Vogel, 1992). Point mutations and deletions which inactivate the white$^+$ allele, CAs and recombination give rise to the expression of white spots in the female genotypes. Parallel detection of these aberrations is possible with eye tissue as the target (Vogel and Nivard, 2000). The assay has been used to detect both mitotic recombination and X chromosome loss, induced by antineoplastic drugs (Rodriguez-Arnaiz *et al*., 2004).

D. melanogaster has also been used as an *in vivo* model for assessment of genotoxicity using the alkaline Comet assay (Bilbao *et al*., 2002; Siddique *et al*., 2005a,b). The mid-gut and brain ganglia cells of larvae have been used in a modified Comet assay for the genotoxicity assessment of a pesticide, cypermethrin (Mukhopadhyay *et al*., 2004).

3.6 Plant Bioassays

Hazardous chemicals (pesticides, industrial waste) may adversely affect the ecosystem, hence *in situ* monitoring of environmental pollutants becomes a necessity. Plants have also been used for the detection of genetic hazards from exposure to genotoxicants in the environment, particularly direct-acting compounds. Short-term plant bioassays utilizing higher plants have the advantage of being rapid, reliable, inexpensive and easy to conduct. These assays detect a wide range of genotoxic end points (CAs, gene mutations) arising in mitotic and meiotic cells from exposure to simple chemicals, as well as complex mixtures (Grant, 1994; Maluszynska and Juchimiuk, 2005). However, promutagens such as nitrosamines, heterocyclic amines and PAHs cannot be detected in these bioassays. Longer life-cycles and major differences in biochemical/pharmacokinetic parameters in plants and mammalian systems are, however, the drawbacks.

The most widely used test systems are conducted in *Allium cepa* (anaphase aberration and MN assays with meristematic root-tip cells), *Vicia faba* (MN and CA assays in root-tip cells) and *Tradescantia paludosa* (MN assay in the meiotic cells and stamen hair mutation tests). Other plants used for the bioassays are *Arabidopsis thaliana*, *Glycine max*, *Hordeum vulgaris* and *Zea mays*. These plant bioassays have been reviewed for their performance in assessing the genotoxicity of chemicals (Ma *et al*., 2005).

Root tips from the *Allium* (onion) bulb and seedlings of *Vicia* are treated with the chemical or environmental sample, fixed and stained, and micronucleated cells counted under the microscope. The CA test in *Vicia*

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

root-tip meristem is a reliable short-term bioassay for studying clastogenicity of chemicals, as well as environmental samples (Kanaya *et al*., 1994). *Vicia* has the advantage of possessing six large chromosomes, which are suitable for cytogenetic analysis and, unlike mammalian cultures, no sterile conditions are required for the assay. These cytogenetic assays have been used for determining the genotoxicity of disinfectants in drinking water (Monarca *et al*., 2005), soil samples (Cotelle *et al*., 1999), radioactive isotopes (Minouflet *et al*., 2005) and industrial effluents (Abdel *et al*., 2007).

The *Tradescantia*-micronucleus (Trad-MCN) bioassay is a rapid, efficient and reliable short-term bioassay for detecting clastogens, used in the International Programme on Plant Bioassays (IPPB) under the auspices of the United Nations Environment Programme (UNEP). It measures chromosome damage as the indicator of the carcinogenic properties of screening carcinogens in gaseous, liquid and solid forms. It is specially qualified for *in situ* monitoring of ambient pollutants. Genotoxicity monitoring of metal contamination in soils (Majer *et al*., 2002), genotoxic compounds in air (Carreras *et al*., 2006; Isidori *et al*., 2003; Klumpp *et al*., 2006), drinking-water disinfectants (Monarca *et al*., 2005), and soil lechates (Lah *et al*., 2008) has been carried out using this bioassay. Young inflorescences are treated with the environmental sample, and flower buds with the early tetrad stage of meiotic pollen cells are selected for scoring of the micronuclei (Ma *et al*., 1994). Test results are obtained within 24–48 hours after the exposure, either on site or in the laboratory.

The *Tradescantia* stamen hair mutation assay is a simple, inexpensive approach for laboratory/*in situ* monitoring of liquid and gaseous mutagens, radiation and radioactive materials (Minouflet *et al*., 2005). It is conducted in mitotic stamen hair cells, which are heterozygous for colour change from blue (dominant) to pink (recessive) (Ma *et al*., 1994). A mutation event would produce a pink cell surrounded by blue cells, which are evaluated for mutagenic frequency.

The *Zea mays* assay is a very good plant bioassay for assessing chromosome damage, both in mitosis and meiosis, and for somatic mutations induced by chemicals and radiations (Grant and Owens, 2006).

Rapid and sensitive detection of DNA damage induced by chemicals/heavy metals in plants has been carried out using single-cell gel electrophoresis/Comet assay (Dhawan *et al*., 2009). Assays have been conducted in fungi (Banerjee *et al*., 2008) and algae (Aoyama *et al*., 2003), as well as higher plants like *Vicia faba* (Menke *et al*., 2000), tobacco (Gichner *et al*., 2007) and *Bacopa monneiri* (Vajpayee *et al*., 2006).

The tests results in plant systems have a positive correlation with mammalian assays and are highly sensitive to predicting carcinogenicity, and hence it has been recommended that plant bioassays be used as alternatives for screening in the first tier of genotoxicity testing.

3.7 Current Status of Short-term Tests

A large number of chemical entities being produced each year have to be evaluated for their genotoxic potential before being released for use by humans. These chemicals are tested using an *in vitro* battery of tests recommended by regulatory agencies like ICH, USEPA and USFDA. The *in vitro* tests being used, that is, the Ames test, MLA, *in vitro* MN and chromosomal assay, are highly sensitive for identifying potential genotoxic carcinogens and mutagens (80–90% of rodent carcinogens are detected). However, 75–90% of rodent noncarcinogens are also reported as positive in one of the standard tests leading to a high level of 'false positives' that are not relevant to humans. Kirkland *et al*. (2005, 2006) have examined data for over 700 chemicals that had genotoxicity and rodent carcinogenicity. The analysis with a larger database covering a wider variety of chemical classes demonstrates that reliable cancer health risk determinations cannot be made on the basis of *in vitro* findings alone (Aardema 2007; Thybaud *et al*., 2007). The *in vitro* and *in vivo* clastogenicity tests have been reviewed by Cimino (2006) and Witte *et al*. (2007). The sensitivity of each assay was high and concordant results were obtained (Ames + MLA + CA = 84.7%). The MLA provides concordant results to the *in vitro* CA, however the MLA is preferred due to its simplicity and sensitivity by most of the regulatory agencies (Cimino, 2006; Honma *et al*., 1999b). The *in vitro* MN assay is suggested to be used as an alternative to the *in vitro* chromosome aberration test or the MLA (Committee on Mutagenicity of Chemicals in Food, Consumer Products and the Environment (COM), 2000; Lorge *et al*., 2007) due to its simplicity, and its ability to analyse aneuploidy along with clastogenicity. A strong agreement of Comet assay and chromosome aberration test (CA test) results was demonstrated, indicating that the Comet assay can be used as a predictive test for the outcome of the CA test, as used for regulatory purposes (Hartmann *et al*., 2003) and it could be used as a alternative to the *in vitro* clastogenicity tests.

However, the predictive value and specificity of *in vitro* mammalian clastogenicity assays was very low for rodent carcinogenicity (Kirkland *et al*., 2005; 2006). The large number of false positives in the *in vitro* assays has raised concern requiring revision of testing methods (Witte *et al*., 2007), as well as follow-up with an *in vivo* assay.

4 RECENT ADVANCEMENTS IN GENETIC TOXICOLOGY STUDIES

Genetic toxicity tests are being improved and modified to meet the challenges of modern-day drug discovery and chemical development. Genomics, proteomics and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat080

high-throughput screening have added to the sensitivity, specificity and reliability of the test systems. The advancements in genotoxicity studies using molecular biology have made it possible to characterize the potential carcinogenicity of chemicals. These tests include flow cytogenetics, application of microarrays (arrayCGH, electrochemiluminescent arrays) for genotoxicity assessment (Gant, 2007; Hvastkovs *et al*., 2007; Kim *et al*., 2005), real-time PCR (Soberón *et al*., 2007), randomly amplified polymorphic DNA (RAPD; Noel and Rath, 2006) and *in silico* tools (Hayashi *et al*., 2005; Mazzatorta *et al*., 2007) for prediction of genotoxicity and carcinogenicity of chemicals. These newer tests are cost effective, sensitive and permit high throughput for the identification of carcinogens.

Flow cytogenetics has immense potential in assessment of genotoxicity of compounds at low concentrations, and has evolved into a rapid, sensitive technique for analysis of DNA content. The technique involves the use of flow cytometry to assess cytogenetic parameters like MN. Flow cytometry has been used for analysis of cellular DNA content, phenotypic expression of markers, drug transport, calcium flux, proliferation and apoptosis.

Flow cytometry is a laser-based technology that is used to measure biochemical and molecular characteristics of single cells and its constituents (nuclei and other organelles) as they flow in a liquid medium past an excitation source (Cram *et al*., 1998; Jaroszeski and Radcliff, 1999). Flow cytogenetics is used in aneuploidy studies by estimating DNA content in cells (Pajor *et al*., 1998), karyotyping of cells in patients with aberrant chromosomes (Fiegler *et al*., 2003), evaluating MN *in vitro* — in CHO cells (Wagner *et al*., 2003) and cultured lymphocytes (Nusse and Kramer, 1984) — and *in vivo* — in reticulocytes in human blood (Abramsson-Zetterberg *et al*., 2000) and mouse erythrocytes (Cammerer *et al*., 2007) — as well as in studying chromosomal abnormalities, DNA fragmentation and *hprt* variants in the human population (Kotova and Grawe, 2002).

The *in silico* approach involves reactivity, structure, mechanism, activity metabolic data and the use of algorithms with activity relationships for prediction of a broad range of toxicological end points, including carcinogenicity, genotoxicity, hepatotoxicity and various other end points for different classes of compounds. Development of statistical and expert systems helps in genotoxicity predictions. Commercially available *in silico* tools, including DEREK, QSAR, MCASE, ADMEWORKS, Meteor (for prediction of the metabolic fate of xenobiotics), Vitic (structure searchable toxicity database) are widely used in the assessment of genotoxicological end points. Some of these *in silico* systems have been applied to a large number of chemicals using *Salmonella*/microsome assay results from CGX and ECJ databases. With the use of these approaches we get high-throughput results with greater sensitivity, specificity and high concordance (Kirkland *et al*., 2005; Hayashi *et al*., 2005). Genetic toxicology data has accumulated during the last few decades from *in vitro* as well as *in vivo* mutagenicity and carcinogenicity tests. This data, along with the knowledge of structure–activity properties of chemicals, has helped in the creation of computational quantitative structural toxicity relationship (QSTR) models (see also **Structure-Activity Relationships for Carcinogenic Potential**). Such QSTR models provide robust statistical analyses, and the development of neural networks help in predicting the genotoxicity of NCEs, thereby screening them rapidly and avoiding animal testing (Snyder and Smith, 2005). The combination of SAR models and inductive databases for the Ames test has also been proposed (Mazzatorta *et al*., 2007). However, the challenge is to predict organ toxicity as well as toxicity in whole organisms. It will also be an appreciable advancement in this field to predict long-term toxicity effects in chronic treatments.

Microarrays, such as arrayCGH, have been developed for genotoxicity assessment, epigenetic assessment in developmental and transgenerational toxicology and micro RNA (miRNA) assessment in all toxicology types, but particularly developmental toxicology (Gant, 2007). Electrochemiluminescent arrays for high-throughput *in vitro* cytochrome P450-activated genotoxicity screening have also been developed (Hvastkovs *et al*., 2007). These arrays help in the estimation of the relative properties of different enzymes to produce genotoxic metabolites. Complementary DNA (cDNA) microarrays have also been developed with mouse cDNA chips, to evaluate similarities and differences in the gene-expression profiles for genotoxic and carcinogenic compounds (Kim *et al*., 2005). The results provide valuable information for the evaluation of potential genotoxicity using gene-expression profiling in mouse lymphoma cells.

With these advancements in the field of genetic toxicity testing, it is likely that fewer potent genotoxicants will get released into the environment, and the validated short-term tests for mutagenicity and carcinogenicity will help to develop better interventional strategies for human cancers.

ACKNOWLEDGEMENTS

I am greatly indebted to Dr. Mahima Bajpayee for her support in compiling this chapter. I also appreciate the help received from my graduate student Mr. Sayan Chatterjee during the preparation of this manuscript.

Epigenetic Mechanisms and their Toxicological Significance

Rebecca E. Watson

CONTENTS

1 INTRODUCTION

With the sequencing of the human genome, a great deal of attention has been paid to various sequence polymorphisms and mutations, and which of these are linked to various toxic outcomes. However, the maintenance of normal patterns of genetic expression is a multidimensional process, and DNA sequence is only one of those dimensions. Another, often overlooked dimension involves epigenetic mechanisms that regulate gene expression without altering the DNA sequence itself. Although it should be recognized that an epigenetic alteration in and of itself does not necessarily lead to a toxicologically significant effect (just as a mutation might or might not have a meaningful impact), the end result of certain epigenetic changes can easily be as, or more, pronounced than one would expect from established mutagens. It stands to reason that an agent that decreases the expression of a gene through epigenetic means would ultimately have a similar impact to a mutation that decreased the expression or function of the gene. Thus, when evaluating possible factors contributing to gene dysregulation, toxicologists should be careful to consider both genotoxic and epigenetic modes of action. Conversely, careful manipulation of epigenetic mechanisms to up- or down-regulate gene expression could aid in the treatment of certain disorders. Current information regarding the major epigenetic mechanisms and their impact on human health is presented herein.

2 DEFINING EPIGENETICS

The definition of epigenetics has changed considerably over the past several decades, and the first major definition of epigenetics was proposed well before what we currently understand as the field of epigenetics was acknowledged. In 1942, C. H. Waddington defined epigenetics as 'the branch of biology which studies the causal interactions between genes and their products which bring the phenotype into being' Waddington (1942). The current definition of epigenetics refers to the study of reversible, heritable genetic mechanisms by which a gene's phenotype is altered without changing

the underlying DNA sequence. Such mechanisms basically behave to amplify or decrease gene expression. As is the case with DNA sequence, epigenetic patterns are inheritable and tend to be maintained from cell to daughter cell in the adult organism. However, unlike most changes to the DNA sequence itself, epigenetic mechanisms are reversible. The overall effect is that epigenetic mechanisms act as a form of malleable 'genetic memory' whereby patterns of gene expression are typically maintained through replication but can be altered in response to certain stimuli. Of interest to toxicologists is determining both what types of stimuli influence epigenetic mechanisms and what the consequences might entail.

3 EPIGENETIC MECHANISMS

This review will focus on DNA methylation, histone acetylation, histone methylation and microRNAs. Additional epigenetic mechanisms such as ATP (adenosine triphosphate)-mediated chromatin remodelling complexes and histone phosphorylation are also biologically important, but less well characterized, and will not be discussed here.

3.1 DNA Methylation

Methylation of the 5′ site of the cytosine base of DNA occurs predominantly (but not exclusively) at the CpG dinucleotide (cytosine–phosphate–guanine) of eutherian mammals, and approximately 4% of cytosines throughout the genome are methylated (Ehrlich *et al*., 1982). In general, DNA methylation serves to silence gene expression by directly blocking access to transcription factors and/or by recruiting CpG-binding proteins that contribute to chromatin condensation, further limiting transcription factor accessibility (Curradi *et al*., 2002). When examining the impact of DNA methylation on transcription of a particular gene, the focus is usually on the methylation status at a CpG island in the promoter region of that gene. CpG islands are defined as stretches of DNA around 200 bp long that are typically unmethylated and contain a greater density of the CpG dinucleotide than found in the rest of the genome (Gardiner-Garden and Frommer, 1987). Approximately 60% of mammalian genes are potentially regulated by a promoter region CpG island (Antequera and Bird, 1993). Although methylation at these sites is of considerable biological significance, it should be noted that the bulk of DNA methylation is not located in CpG islands, but at transposable elements throughout the genome (Walsh and Bestor, 1999; Robertson and Jones, 2000). Overall, about 70% of mammalian CpG sites are methylated, mainly at repetitive sequences (Yoder and Bestor, 1996). Although at first glance, this appears to contradict the above statistic of the percentage of methylated cytosines in the genome, this percentage is consistent, because throughout the genome, the CpG dinucleotide is present at a much lower frequency than would be expected with a random distribution of nucleotides (Sved and Bird, 1990). Methylation of transposable elements and viruses throughout the genome serves a protective function by silencing the expression of DNA which could otherwise compromise genetic integrity (Carnell and Goodman, 2003; Vivekanandan *et al*., 2008).

Deoxyribonucleic acid methyltransferases (DNMTs) catalyse the reaction whereby a methyl group from *S*-adenosylmethionine (SAM), the proximate methyl group donor, is added to the 5′ site of the cytosine residue. The three major methyltransferases are DNMT1, DNMT3a and DNMT3b. DNMT1 binds preferentially to hemimethylated DNA and is the predominant maintenance methylase whereby patterns of DNA methylation are inherited from cell to daughter cell (Okano *et al*., 1999). DNMTs 3a and 3b are predominantly active during development, and function as *de novo* methyltransferases. Levels of SAM are influenced by dietary components that play a role in the one-carbon folic acid pathway as will be discussed in detail in a subsequent section. In general, DNA methylation serves as a relatively stable epigenetic mark and is transferred to daughter cells upon replication; however in some cases demethylation may occur. Demethylation may occur passively through replication without maintenance methylation, or actively via demethylase activity (Cervoni *et al*., 1999).

3.2 Histone Acetylation and Methylation

Histone acetylation and methylation alter the conformation of chromatin around the histones. Acetylation of the lysine residues of amino terminal histone tails by histone acetyltransferases (HATs) reduces the positive charge of lysine, and thereby decreases the affinity of the histone for negatively charged DNA (as reviewed in Clayton *et al*., 2006). The result is a looser chromatin conformation, termed euchromatin. Euchromatin is more easily accessible by RNA polymerase and various transcription factors and is therefore considered relatively transcriptionally active. When histone deacetylases (HDACs) remove the acetyl groups from the chromatin, the positive charge of the lysine residues is unopposed, and thus, the affinity of the chromatin for the DNA is increased (Nakao, 2001). Tightly wound, unacetylated, transcriptionally repressed chromatin is termed heterochromatin. Acetylation of residue 9 on the N-terminus of histone 3 (H3K9) in particular has been well characterized and is

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tightly linked to transcriptional activation (Sinha *et al.*, 2006).

Histone methylation is a process whereby histone methyltransferase (HMT) adds one to three methyl groups to lysine or arginine residues of the histone amino terminal tails. Depending on the histone methylation site, the effect may be to enhance or suppress levels of transcription in the surrounding DNA. For instance, methylation of H3K9 inhibits acetylation of the H4K16 site associated with active chromatin (Nishioka *et al.*, 2002). Methylation at H3K27 is also repressive, and is particularly important during development (Reik, 2007). Conversely, methylation of H3K4 facilitates transcription, and appears to inhibit H3K9 methylation and promote H3 acetylation (Fischle *et al.*, 2003).

3.3 Interactions between DNA Methylation and Histone Modifications

DNA methylation and histone modifications are mutually reinforcing processes, such that the histones of highly methylated DNA are modified in a manner that condenses the chromatin. Hypoacetylated H3 and H4 histones are associated with highly methylated DNA and vice versa (Schübeler *et al.*, 2000). Various proteins can bind to methylated cytosines, and recruit additional proteins which impact histone conformation. These mechanisms work in concert to render the DNA in the region transcriptionally inactive, as illustrated in **Figure 1**. The best characterized example of this is the methylcytosine binding protein 2 (MeCP2) binding to the mSin3A transcriptional repressor and HDACs (Nan *et al.*, 1998). In this model, DNA methylation serves as the first epigenetic mark; however, there is evidence to suggest that histone modifications can impact DNA methylation status. Cervoni and Szyf (2001) showed that administration of a HDAC inhibitor to a human cell line increased histone acetylation and was associated with active DNA demethylase activity.

3.4 Micro RNA

Although microRNA (miRNA) is less often described as an epigenetic mechanism, miRNA molecules are involved in the regulation of various genes and are of considerable interest for their therapeutic potential. MicroRNA expression is controlled by tissue-specific transcription factors and serves to modulate various processes necessary for proper differentiation and development (Negrini *et al.*, 2007). As will be discussed in greater detail, altered levels of miRNAs are frequently reported in human cancers.

MicroRNAs consist of small segments of RNA that inhibit post-transcriptional gene expression (Chuang and Jones, 2007). Their formation and mode of action is illustrated in **Figure 2**. MicroRNA production begins with a 60–70 bp nuclear-derived primary microRNA (pri-miRNA) transcript with a stem–loop structure. The pri-miRNA interacts with a microprocessor complex consisting of Drosha and Pasha proteins to form a shorter

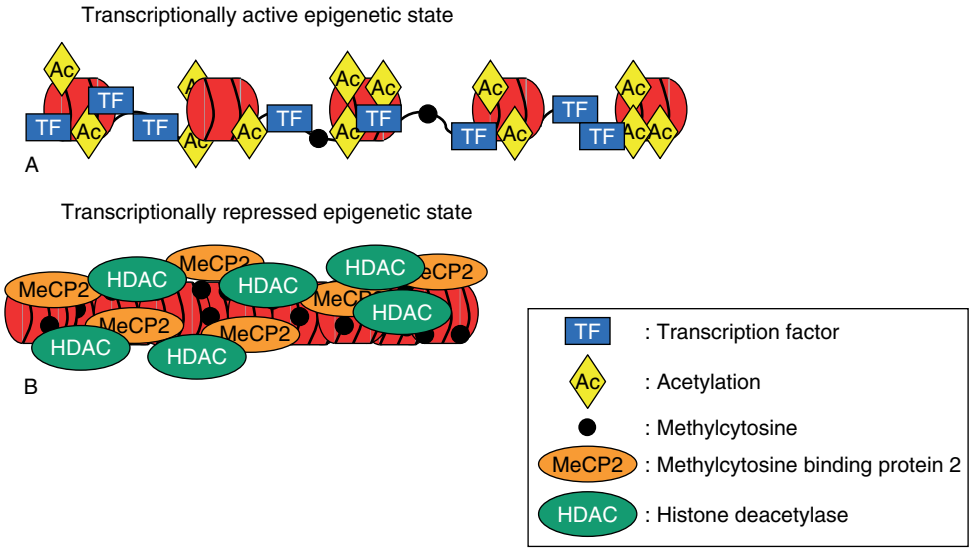

Figure 1 The role of DNA methylation and histone modifications in transcriptional silencing. In (A) the DNA is sparsely methylated and the histones are acetylated, facilitating access to transcription factors. In (B) the DNA is methylated, and methylcytosine binding protein 2 (MeCP2) binds to the methylcytosine bases. MeCP2 recruits histone deacetylases, condensing the chromatin. The overall effect is to silence gene transcription.

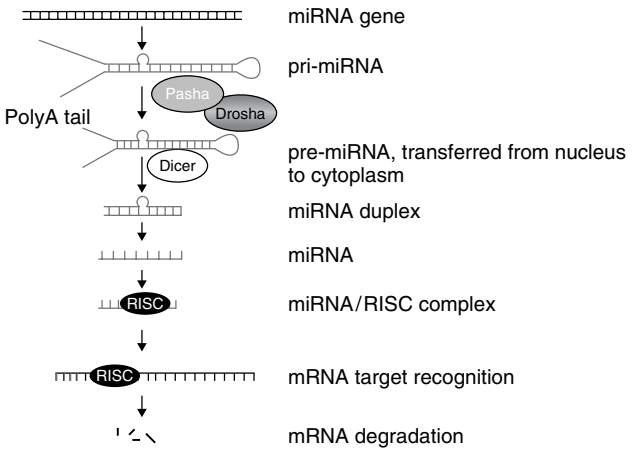

Figure 2 MicroRNA (miRNA)-mediated transcriptional control. In this illustration, a pri-miRNA (~70 bp) with a hairpin loop structure and a polyadenine (PolyA) tail is produced from a miRNA gene in the nucleus. Pasha and Drosha proteins bind to the pri-miRNA, forming a microprocessor complex with nuclease properties. The result of this interaction is a shortened pre-mRNA molecule that is transported into the cytoplasm. The dicer endonuclease protein binds to the pre-miRNA in the cytoplasm, removing the stem–loop structure and producing an miRNA duplex approximately 22 bp long. A single stand of the duplex binds to the RISC (RNA-induced silencing complex), which directs the binding of the miRNA to the mRNA. Binding of this complex to mRNA leads to degradation of the molecule.

pre-miRNA molecule that is transported to the cytoplasm (Denli *et al*., 2004). Once in the cytoplasm, the pre-miRNA is acted upon by the Dicer endonuclease to produce a ~22 bp miRNA duplex molecule (Denli *et al*., 2004). One strand in this duplex then enters a complex with an RNA-induced silencing complex (RISC) and binds to a complimentary mRNA (messenger RNA) target (Tang, 2005). Argonaute proteins within this complex then facilitate the cleavage and degradation of the mRNA target (Diederichs and Haber, 2007).

4 THE EPIGENETICS OF DEVELOPMENT AND REPRODUCTION

Epigenetic processes undergo dynamic changes during early development, and therefore, the epigenome is likely to be particularly sensitive to chemical and/or nutritional factors that affect the epigenome during this time. Epigenetic changes during development are necessary for two major goals: (i) to reprogramme the epigenome for the next generation; and (ii) to orchestrate gene expression patterns necessary for viable, healthy offspring. Epigenetics also regulates reproductive processes. In assisted reproductive technologies, subtle changes in epigenetic mechanisms might underlie an increased incidence of certain diseases, an issue that is of considerable clinical importance given the increased demand for these procedures. Additionally, the role of epigenetics in the normal function of the ovary serves as an excellent example of how hormonal stimuli can influence epigenetic processes in a manner that allows for cyclical, specific functions.

A general illustration of epigenetic changes occurring throughout development is presented in **Figure 3**. Gametes have sex-specific epigenetic patterns, with sperm DNA typically more heavily methylated than in the oocyte (Mertineit *et al*., 1998). The paternal pronucleus is demethylated within the zygote prior to the first cellular division, while the maternal genome is passively demethylated (Mayer *et al*., 2000). This begins the process whereby the epigenome is largely 'reprogrammed' (Brandeis *et al*., 1993). However, epigenetic marks responsible for the proper expression of imprinted genes, as well as intracisternal A particles (IAPs) are likely spared from this wave of demethylation, making transgenerational inheritance of particular epigenetic mechanisms possible (Oswald *et al*., 2000; Reik, 2007). Afterwards, *de novo* DNA methylation, as well as methylation of H3K27, occurs just prior to implantation, silencing expression of various genes. It should be noted that methylation of H3K27 imparts somewhat transient silencing properties, while DNA methylation is thought to silence gene expression in a more stable manner (Reik, 2007). Gene-specific histone acetylation, demethylation of H3K27 and/or methylation of H3K4 then allows for the expression of genes at the appropriate time for normal development (Reik, 2007). In mice, it has been shown that an additional wave of demethylation occurs in the primordial germ cells shortly prior to entering the gonads, erasing much of the epigenome for the subsequent generation (Hajkova *et al*., 2002).

The importance of epigenetic mechanisms during development has been underscored by research demonstrating that the lack of components necessary for these processes reduces viability of the offspring. Normal patterns of methylation and histone conformation are crucial for normal development and the maintenance of a differentiated state (Reik *et al*., 2001; Rideout *et al*., 2001). Murine embryos lacking DNMT1, 3a or 3b die *in utero* or soon afterwards, likely because lack of these proteins results in patterns of gene expression that are incompatible with life (Okano *et al*., 1999). In the oocyte, the methyltransferase DNMT3L appears to be required for maternal-specific methylation patterns required for imprinted genes (Hata *et al*., 2002). MicroRNA's involvement in development is not yet well characterized, but it is known that embryonic stem cells without the Dicer endonuclease needed for miRNA processing fail to differentiate (Bernstein *et al*.,

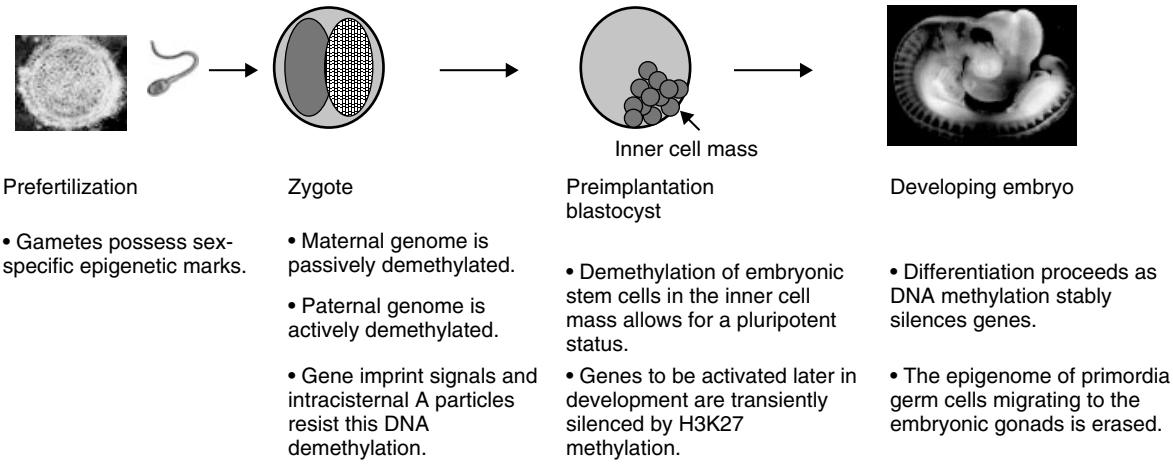

Figure 3 Reprogramming of the epigenome.

2003; Kanellopoulou *et al*., 2005). In addition, specific miRNAs, including miR-196 regulate homeobox genes that encode vital developmental transcription factors (Mansfield *et al*., 2004).

Recent studies have shown that altering natural reproduction occasionally appears to adversely affect developmental outcome, and this might be due to subtle changes in epigenetic processes. Normal patterns of DNA methylation appear to be more reliably established when an animal is naturally conceived with egg and sperm compared to using nuclear transfer techniques. It has been suggested that a lack of normal waves of epigenetic changes during development might contribute to developmental failure of cloned animals, and aberrant methylation patterns have been reported in cloned cows and mice in which aberrant expression of imprinted genes typically regulated by epigenetic processes is commonly observed (Cezar *et al*., 2003; Ohgane *et al*., 2008). Similarly, in humans conceived by assisted reproductive technologies, there is a small, but significant increase in the risk of diseases characterized by aberrant imprinting such as Angelman syndrome (AS) (Cox *et al*., 2002), Beckwith–Wiedemann syndrome (DeBaun *et al*., 2003) and transient neonatal diabetes (Lawrence and Moley, 2008).

The role of histone conformation in regulating ovarian function demonstrates how hormone-induced epigenetic changes allow for the proper timing of gene expression and hormone release needed for a cyclical process. The LH (luteinizing hormone) surge preceding ovulation has been shown to be regulated by an epigenetic-mediated increase in expression of the steroidogenic acute regulatory (STAR) protein (Christenson *et al*., 2001). Stimulation of monkey and murine granulosa cells with hCG (human chorionic gonadotrophin) has been shown to increase the acetylation status of H3K9 and decrease H3K9 methylation in the promoter region of STAR, increasing expression and stimulating ovulation (LaVoie, 2005). In porcine cells, FSH (follicle-stimulating hormone) was found to stimulate H3K9/K14 acetylation, increasing STAR expression. Acetylation was repressed by the STAR transcriptional repressor EGF (epidermal growth factor) (Rusovici *et al*., 2005).

5 IMPRINTING

Epigenetic mechanisms are necessary for genetic imprinting, a non-Mendelian genetic process whereby gene expression occurs in a paternal- or maternal-specific fashion (Li *et al*., 1992). It is estimated that approximately 100–200 genes are imprinted (Murphy and Jirtle, 2003). Imprinting is of interest to toxicologists because a loss of imprinting has been associated with various disease states (Feinberg *et al*., 2002). Furthermore, imprinted genes are likely to be particularly sensitive to toxic insults because the functionally haploid expression of these genes negates the normal protection received from diploid gene expression (Murphy and Jirtle, 2003).

Igf2 (insulin-like growth factor 2) is the classic example of a paternally expressed imprinted gene. DNA methylation at a particular imprint control region (ICR) on the paternal allele blocks the binding of the vertebrate enhancer blocking protein CTCF, which would otherwise inhibit access of an enhancer protein to the Igf2 promoter region (Bell and Felsenfeld, 2000). On the maternal allele, the ICR DNA is unmethylated, permitting CTCF binding, and forming a block between enhancers located distally to the CTCF binding region and the Igf2 promoter region (Bell and Felsenfeld, 2000). The end result is that the paternal Igf2 allele is transcribed, and the maternal allele is silenced. Maintenance of chromatin conformation associated with imprinted genes is likely to be tightly associated with DNA methylation patterns (Murphy and Jirtle, 2003).

6 EPIGENETICS AND DISEASE

In general, epigenetic processes are protective of the genome, directing patterns of gene expression in a manner that is beneficial to the organism. However, when these processes are altered, the result can lead to widespread dysregulation of gene expression patterns, which, in turn, can lead to disease. It is important to recognize that not all epigenetic malfunctions are the underlying cause of a disease; changes in epigenetic mechanisms might occur secondarily to other toxic outcomes, and/or may not, in and of themselves, be associated with an adverse clinical outcome. That said, epigenetic mechanisms have been shown to be probable underlying factors in the development of particular diseases including, but not limited to, cancer and neurological disorders.

6.1 Cancer

Epigenetic mechanisms are almost always altered in some manner during carcinogenesis. Typically, the epigenetic change associated with cancer involves one of the following outcomes (reviewed in Watson and Goodman, 2002a): (i) decreased expression of tumour suppressor genes; (ii) increased expression of transposable elements or oncogenes that compromise genetic integrity; (iii) alterations to normal patterns of gene imprinting; and/or (iv) an increase in cytosine-to-thymine transitions secondary to increased incidence of deamination of 5-methylcytosine to thymine. Neoplastic tissue is typically characterized by an overall reduction in global, or overall, levels of DNA methylation with increased methylation status and decreased histone acetylation in the promoter regions of specific tumour suppressor genes (Robertson and Jones, 2000; Ehrlich *et al*., 2002). The mechanisms underlying the increased methylation at certain regions with a decrease in other regions is poorly understood, but might be due to sequence-specific activity of particular DNMTs and/or histone-modifying enzymes. Tumour suppressor genes shown to be silenced by DNA methylation and/or histone deacetylation include p16, E-cadherin, O^6-methylguanine methyltransferase (Esteller, 2003). DNA hypomethylation and histone acetylation of the promoter regions of oncogenes and subsequent up-regulation of these genes is infrequently described in carcinogenesis, but appears to underlie the increased expression of raf in mouse liver tumours (Ray *et al*., 1994). Finally, the increased prevalence of CT (charge-transfer) transitions in the p53 tumour suppressor is likely due to an increased amount of methylcytosine in the region (Schumutte *et al*., 1996). Differences in the extent of epigenetic alterations observed after administration with a tumour-promoting dose of phenobarbital have been shown to be associated with strain differences in cancer susceptibility. Following treatment, the C57 tumour-resistant mouse strain exhibited a slight decrease in global methylation status and a slight increase in DNA methylation in CpG island regions. In contrast, in the B3H/He tumour-sensitive mouse strain, a pronounced decrease in global methylation status with increased methylation in CpG island regions was observed (Counts *et al*., 1996; Watson and Goodman, 2002b). Thus, susceptibility to carcinogenesis appears to be inversely related to the ability to maintain normal patterns of DNA methylation.

A number of proteins that contribute to histone modifications have also been linked to carcinogenesis, including the Enhancer of Zeste homologue 2 (EZH2), which methylates the K9 and K27 residues on H3, and functions as an oncogene (Kuzmichev *et al*., 2002). Increased levels of EZH2 are associated with poor prognosis in breast cancer and lymphoma (Kleer *et al*., 2003). One of EZH2's particularly notable properties is its links to DNA methylation and miRNA. EZH2 recruits DNMT activity to EZH2-targeted genes (Viré *et al*., 2006). MicroRNA-26a targets and inactivates EZH2 mRNA (Wong and Tellam, 2008). Similar cooperative actions are likely to occur with numerous other specific epigenetic factors.

MicroRNAs are becoming increasingly recognized as being involved in carcinogenesis, as various interactions with tumour suppressors and oncogenes are being revealed (Negrini *et al*., 2007). In human cancer specimens, various miRNAs have been deregulated (Negrini *et al*., 2007). The let-7 family of miRNAs is involved in the down-regulation of the ras oncogene; therefore, when let-7 miRNA is down-regulated, ras expression increases (Johnson *et al*., 2005). Members of the let-7 family of miRNAs have been found to be down-regulated in various cancer types, including 50% of lung cancers (Takamizawa *et al*., 2004). In the same vein, microRNAs 15a and 16-1 regulate the antiapoptotic BCL2 oncoprotein (Negrini *et al*., 2007). Down-regulation of these miRNAs is associated with a reduction in apoptosis and an increased susceptibility to carcinogenesis (Negrini *et al*., 2007). MicroRNA 15a and/or 16-1 have been shown to be down-regulated in over 50% of chronic lymphocytic leukaemia cells (Cimmino *et al*., 2005). MicroRNA can also present a problem if its expression results in activation of a particular oncogene. Translocation of the mir-142 regulatory element has been shown to serve as an activator of the MYC proto-oncogene in B cell leukaemia (Gauwerky *et al*., 1989; Negrini *et al*., 2007).

Overall, epigenetic mechanisms appear to be particularly well suited for the promotion phase of the initiation, promotion and progression model of carcinogenesis (Pitot and Dragan, 1994). In this model, initiation typically involves an irreversible, heritable alteration to a cell such that it has a growth advantage over

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat082
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

surrounding cells in the promotion stage. The promotion stage then provides a favourable environment for the initiated cell to clonally expand, whereby additional alterations confer additional growth advantages to subclones of cells. In the progression stage, malignant conversion occurs. Promoting agents such as tobacco and phenobarbital facilitate the clonal expansion of initiated cells (Schulte-Hermann *et al*., 1990). An important feature of the promotion stage is that it is reversible, and the dose–response relationship for promoters exhibits a threshold (Pitot and Dragan, 1994). Epigenetic mechanisms in particular appear to be prone to act as underlying mechanisms in the promotion stage of carcinogenesis because they provide reversible means by which gene expression can be increased or decreased in a manner that confers a growth advantage in response to various stimuli. In SENCAR (sensitive to mouse carcinogenesis) mice initiated with DMBA (dimethylbenzanthracene) and promoted with several doses of cigarette smoke condensate (CSC) for various amounts of time, increased DNA methylation in CpG-rich regions of skin DNA was observed in a dose and time-dependent manner. Furthermore, when skin was left unpromoted for six weeks prior to harvesting, most of the methylation increases were no longer detected, suggesting that the altered patterns of DNA methylation no longer provided a growth advantage once the promoting agent was withdrawn (Watson *et al*., 2003).

6.2 Neurological Disorders

Specific patterns of DNA methylation and histone acetylation are necessary for normal brain development and function. Conversely, particular abnormal epigenetic patterns have been implicated in the aetiology of various types of neurological/developmental disorders including Rett syndrome, Prader–Willi syndrome (PWS) and AS, as well as Beckwith–Wiedemann syndrome. Errors in the epigenetic mechanisms responsible for maintaining imprinted genes appear to be a particularly common finding with some of these disorders.

With respect to the role of epigenetics in normal brain function, an illustrative example of how epigenetic changes are necessary for crucial neurological function is in the maturation of astrocytes. In this process, DNA methylation is present in the promoter region of the glial fibrillary acidic protein (GFAP) gene on embryonic day (E) 11.5 in the mouse, preventing the binding of the STAT3 transcription factor (Takizawa *et al*., 2001). By E 14.5, methylation at this region is no longer present, allowing for the binding of STAT3, and the transcription of GFAP, a gene necessary for the differentiation of neuroepithelial cells into the astrocytes (Takizawa *et al*., 2001). Histone acetylation has been shown to be necessary for normal patterns of cognition and synaptic cognition, and has been shown to be altered in Huntington's and Parkinson's diseases (Abel and Zukin, 2008).

Neurological disorders associated with errors in epigenetic machinery tend to result in mental deficits coupled with various forms of developmental abnormalities. Rett syndrome, an X-linked form of mental retardation afflicting mostly females, is tightly linked to mutations in the gene for the MeCP2 protein (Nan and Bird, 2001). Some autistic individuals have also been reported to have decreased levels of MeCP2 (Nagarajan *et al*., 2006). Altered patterns of imprinting are clearly implicated in some mental disorders such as PWS and AS, as well as Beckwith–Wiedemann syndrome. Both PWS and AS are characterized by severe mental deficits and developmental abnormalities. The aetiology of these syndromes is linked to alterations in a 2 Mb domain in the 15q11–q13 region of DNA at which a variety of imprinted genes are clustered. PWS results from microdeletions in this region on the paternal allele, and AS results from microdeletions at this site on the maternal allele (Shemer *et al*., 2000). The end result is to disrupt paternal- and maternal-specific imprinted gene expression (Mann and Bartolomei, 1998). Beckwith–Wiedemann syndrome is characterized by developmental growth disorders and an increased prevalence of Wilms' tumour. This condition is typically accompanied by an increase in Igf2 expression, due to alterations to normal patterns of imprinting (Issa and Baylin, 1996).

7 NUTRITIONALLY INFLUENCED EPIGENETIC CHANGE

The impact of nutrition in DNA methylation is much more thoroughly defined than the role of nutrition in either histone conformation or miRNA. It has long been recognized that DNA methylation is dependent upon methyl group donor nutrients and cofactors in the one-carbon metabolic pathway (Poirier, 2002). Several components of this pathway, including choline, methionine, zinc, B_{12}, betaine and folic acid, are predominantly obtained from dietary sources, such as leafy green vegetables, eggs and meats. In addition, soya products appear to impact the epigenome in a manner that encourages healthy patterns of gene expression. The effects of these nutrients on the epigenome and associated heath consequences are presented in **Table 1**.

The one-carbon metabolic pathway is presented in **Figure 4**. DNMTs catalyse the reaction whereby methyl groups from SAM are made available to various methyl group acceptors, including DNA. The end result of this reaction is a methylated acceptor and *S*-adenosylhomocysteine (SAH) (Bottiglieri *et al*.,

Table 1 A selection of nutrients that alter the epigenome

Nutrient	Impact on epigenome	Outcome of epigenetic alterations
Components of the one-carbon metabolic pathway • Folic acid • Methionine • Choline • B_{12} • Betaine	• Groups in this provide necessary components for DNA methylation to occur. • Deficiency of these nutrients reduces DNA methylation status. • Increased levels of methyl group donor nutrients in the maternal diet increase methylation status of a target intracisternal A particle in the offspring in an agouti mouse model (Wolff *et al*., 1998; Waterland and Jirtle, 2003).	• Deficiencies in choline, methionine and folic acid have been linked with various cancer types including hepatocarcinoma, colon cancer (Counts *et al*., 1996; Dela Pena *et al*., 2007; Kim, 2005). • Some studies indicate that excess folic acid could increase breast cancer risk (Kim, 2006; Stolzenberg-Solomon *et al*., 2006; Kotsopoulos *et al*., 2003); some studies do not support a link (Larsson *et al*., 2007; Ericson *et al*., 2007).
Soya products • Genistein • Soya protein isolate • Lunasin	• Aid in maintaining a healthy SAM/SAH ratio (Le Leu *et al*., 1998). • Decrease DNA methylation status promoter regions of tumour suppressor genes and inhibit methyltransferase (Fang *et al*., 2007). • Increase DNA methylation status at intracisternal A particles when administered during gestation (Dolinoy *et al*., 2006). • Lunasin has been shown to selectively disrupt histone acetylation/histone deacetylation dynamics in cells in the process of transformation (De Lumen, 2005).	• Epidemiological and animal studies have demonstrated that dietary soya is associated with a decreased incidence of various types of cancers including breast, colon and prostate (Zhou *et al*., 2007; Oba *et al*., 2007; McCormick *et al*., 2007). Soya's impact on hypomethylating and re-activating tumour suppressor genes might play a role in the chemopreventive effects.

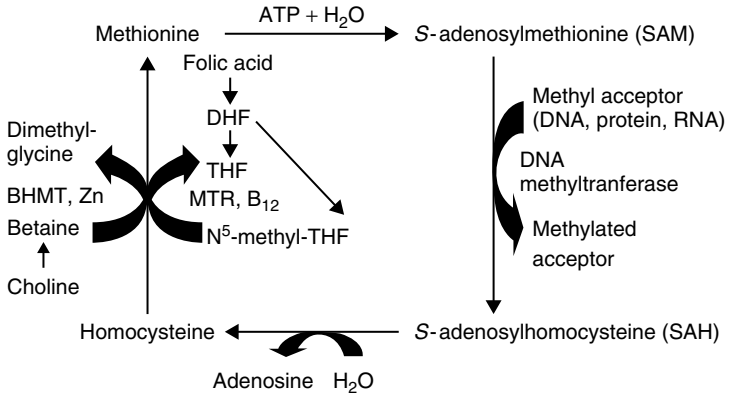

Figure 4 The one-carbon metabolic pathway. DHF—dihydrofolate.

2000). In a reversible reaction, SAH is hydrolysed to homocysteine, a precursor for methionine. There are then two pathways by which a methyl group can be added to homocysteine to synthesize methionine. In one pathway, methionine is produced in a B_{12}-and-folic-acid-dependent reaction catalysed by methionine synthase (MTR), and involving the transfer of a methyl group from N^5-methyl tetrahydrofolate (N^5-methyl-THF) (Van den Veyver, 2002). In the second pathway, a methyl group from betaine can be coupled to homocysteine in a reaction catalysed by betaine homocysteine methyltransferase (BHMT), which requires zinc as a cofactor. BHMT is only available in the mammalian liver and kidney (Finkelstein and Martin, 1986). In this reaction, choline

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat082
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

is a precursor for betaine (Zeisel and Blusztajn, 1994). Following either of the above pathways, methionine is hydrolysed to SAM (Van den Veyver, 2002).

Many studies have indicated that deficiencies in nutrients involved in the one-carbon pathway are harmful. For instance, a choline and/or methionine-deficient diet leads to global hypomethylation of liver DNA, and an increase in spontaneous hepatocarcinoma (Counts *et al*., 1996; Dela Pena *et al*., 2007). Folic-acid deficiency has been linked to an increased risk of colon cancer, neural tube defects and cardiovascular disease (Michie *et al*., 1998; Kim, 2005). Fewer studies have addressed the adverse effects associated with elevated levels of methyl group donor nutrients, but there have been recent conflicting reports of whether excessive folic acid increases the risk of breast cancer. Some epidemiological reports have indicated that women who consume folic acid supplements of $\geq 400\,\mu g\,day^{-1}$ have a 20% or more increase in breast cancer risk compared to unsupplemented women (Kim, 2006; Stolzenberg-Solomon *et al*., 2006). Similarly, in rats, a deficiency in dietary folic acid beginning at weaning was associated with inhibition of *N*-methyl-*N*-nitrosourea-induced breast cancer in Sprague Dawley rats (Kotsopoulos *et al*., 2003). However, a meta-analysis by Larsson *et al*. (2007) indicated that there is no clear link between folic acid intake and breast cancer, and high folate intake was associated with a decrease in breast cancer in postmenopausal women in a study by Ericson *et al*. (2007). An increased amount of methyl group donor nutrients in the maternal diet have been shown to impact the methylation status of an IAP controlling coat colour in the A^{vy} (agouti viable yellow) mouse model, with increased IAP methylation associated with a darker coat colour (Wolff *et al*., 1998; Waterland and Jirtle, 2003).

Soya products have also been shown to alter epigenetic patterns, although details of the underlying mode of action are not yet fully understood. Soya protein has been shown to help maintain normal patterns of DNA methylation and maintain a healthy SAM/SAH ratio (Le Leu *et al*., 1998). Soya and its isoflavone components have been shown to inhibit methyltransferase activity and reduce the DNA methylation status of tumour suppressor genes, reactivating expression (Fang *et al*., 2007; Raynal *et al*., 2008). In addition, administration of genistein to pregnant mice has been shown to increase the DNA methylation status of an IAP in the A^{vy} agouti mouse model (Dolinoy *et al*., 2006). Epidemiological and animal studies have demonstrated that dietary soy is associated with a decreased incidence of various types of cancers including breast, colon and prostate (Zhou *et al*., 2007; Oba *et al*., 2007). Soya protein and/or soya isoflavones in the maternal diet of the rat can reduce the incidence of colon and mammary carcinogenesis in the F1 generation (Xiao *et al*., 2005; Su *et al*., 2007). It is possible that the chemopreventive effects are due, in part, to soya-mediated hypomethylation and reactivation of tumour suppressor genes, particularly in light of the fact that epigenetic changes are plausible underlying factors in transgenerational effects, such as those reported in Xiao *et al*. (2005) and Su *et al*. (2007), as will be discussed in greater detail. The reason for the soya-product-mediated decreased methylation in some areas of the genome and the increase in others might be due to activity on a particular type of methyltransferase that works selectively at promoter region CpG islands. Lastly, certain soya products are also thought to impact histone conformation. For example, lunasin, a cancer-preventive soya-derived peptide, appears to selectively kill cells in the process of being transformed by binding to deacetylated core histones, disrupting the dynamics of histone acetylation–histone deacetylation and contributing to cell death (De Lumen, 2005).

8 EPIGENETIC ALTERATIONS ASSOCIATED WITH XENOBIOTICS

Various xenobiotics have been shown to impact patterns of DNA methylation and histone conformation, and a summary of these is presented in **Table 2**. It should be recognized that with the exception of certain chemotherapy drugs, the role of epigenetics in mediating the toxic outcomes associated with these chemicals is unclear. Further research in this area is needed to determine if epigenetic perturbations underlie the effects of these xenobiotics and/or whether they could serve as useful biomarkers of exposure.

Certain chemotherapeutic drugs alter epigenetic status in a manner that could plausibly underlie the therapeutic and toxicological effects by reversing certain epigenetic marks characteristic of cancer. The cytosine analogue 5-aza-2′-deoxycytidine (dAzaC) irreversibly binds to and inactivates methyltransferases, thus decreasing DNA methylation status (Avramis *et al*., 1989). This drug targets the methylation status of rapidly replicating cells. As is the case with many other chemotherapeutic drugs, administration of dAzaC during pregnancy is teratogenic, perturbing DNA synthesis and contributing to embryonic death or low foetal weight (Rogers *et al*., 1994). Similarly, the antileukaemic adenosine analogues, 2-chloro-2′-deoxyadenosine (cladribine) and 9-arabinosyl-2-fluoroadenine (fludarabine), inhibit DNMTs (Wyczechowska and Fabianowska-Majewska, 2003). Trichostatin A is used as a HDAC inhibitor experimentally, and HDACs are a particularly promising group of therapeutic drugs (Yoshida *et al*., 1990).

Nonchemotherapeutic drugs shown to alter the epigenome include certain metals, CSC, phenobarbital, bisphenol A and high doses of trichloroethylene

Table 2 A selection of xenobiotics that alter the epigenome

Chemical	Impact on epigenome
5-Aza-2′-deoxycytidine (decitabine)	Irreversibly binds to and inhibits methyltransferases (Avramis *et al*., 1989)
2-Chloro-2′-deoxyadenosine (cladribine)	Inhibits DNA methyltransferases (Wyczechowska *et al*., 2000)
9-Arabinosyl-2-fluoroadenine (fludarabine)	
Arsenic	Methyl group acceptor; reduces global methylation (Vahter, 2008)
Bisphenol A	Decreases DNA methylation at intracisternal A particle (Dolinoy *et al*., 2006)
Chromium, nickel	Increase DNA methylation levels, chromatin condensation (Salnikow and Zhitkovich, 2008)
Cigarette smoke condensate	Increases DNA methylation at GC-rich regions (Watson *et al*., 2003)
Phenobarbital	Decreases global DNA methylation status, and increased methylation in GC-rich regions (Counts *et al*., 1996; Watson and Goodman, 2002b)
Trichloroethylene	At high doses, these reduce the DNA methylation status of oncogenes, increasing their expression (Tao *et al*., 2000)
Dichloroacetic acid Trichloroacetic acid	
Trichostatin A	Experimental histone deacetylase inhibitor (Yoshida *et al*., 1990)
Valproic acid	Demethylates DNA and increases histone acetylation (Detich *et al*., 2003)
Vinclozolin	Transient exposure contributes to transgenerational increases in DNA methylation (Anway *et al*., 2005)

(TCE), dichloroethylene (DCE) and trichloroacetic acid (TCA). Nickel and chromium have recently been shown to increase DNA methylation levels and favour a condensed chromatin conformation (Salnikow and Zhitkovich, 2008). Arsenic is a methyl group acceptor, effectively decreasing the amount of methyl groups available for DNA methylation. Some of arsenic's adverse effects (particularly associated with early life exposure) on immune suppression and neurological function are proposed to be at least partially due to hypomethylation (Vahter, 2008). CSC leads to increases in GC (guanine–cytosine)-rich and gene-specific methylation patterns in tumour and nontumour tissue, as well as global hypomethylation in skin papillomas in the SENCAR mouse (Watson *et al*., 2003). Valproic acid, a drug used for epilepsy and mood stabilization, has been found to trigger a decrease in DNA methylation and increase histone acetylation in a replication-dependent manner via recruiting of a methylcytosine-binding protein/demethylase complex, representing a rare example of chemically-induced active demethylation (Detich *et al*., 2003). Phenobarbital is associated with decreased global methylation and increased methylation in CpG rich regions (Counts *et al*., 1996; Watson and Goodman, 2002b). Bisphenol A in the maternal diet was shown to decrease the methylation status of an IAP in the F1 generation (Dolinoy *et al*., 2007). Finally, administration of high doses of TCE, DCE and TCA have been shown to reduce the DNA methylation status of the promoter region of c-jun and c-myc oncogenes, and increase expression of these genes (Tao *et al*., 2000).

9 EPIGENETICS IN THE DEVELOPMENTAL ORIGINS OF ADULT DISEASE

Given the number of confounding factors involved, making a clear link between maternal diet and adult disease is extraordinarily difficult in humans. However, there are suggestions that this does in fact occur, and the means by which this takes place may be epigenetic-mediated. In a study by Lucas (1991), premature babies were fed a standard infant formula, a fortified formula or breast milk for approximately one month. When these individuals were examined fifteen years later, there were major group differences in the leptin/fat mass index and the allergy status. Breast feeding has been associated with lower blood pressure and a reduced incidence of some immune-related diseases (Schack-Nielsen and Michaelsen, 2006). Furthermore, the children of women that were pregnant during the Dutch famine were found to exhibit glucose intolerance, and a more atherogenic lipid profile as adults (Rosebloom *et al*., 2006). Thus, there is precedence for the belief that maternal diet can impact adult human health, and epigenetic mechanisms, by way of serving as a type of genetic memory, can potentially play a key role in this phenomenon.

Although DNA methylation patterns are potentially reversible, patterns developed *in utero* tend serve as relatively stable templates for thousands more daughter cells in a rapidly proliferating cell population (Reik, 2007). Thus, epigenetic mechanisms are likely to be

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat082

particularly sensitive to the availability of methyl group donor nutrients during embryonic development, when the epigenome is first being established. Exposure to carcinogenic substances later in life could then result in selection for cells that have methylation patterns more typical of precancerous and cancerous tissues.

Several animal studies have shown that maternal diet can alter offspring DNA methylation patterns in a long-lasting manner. In studies by Wolff *et al.* (1998) and Waterland and Jirtle (2003), supplementation of the maternal diet with a combination of methyl group donor nutrients increased methylation at an IAP inserted into an agouti gene governing coat colour. In Dolinoy *et al.* (2006), a similar finding was found after the maternal diet was supplemented with genistein. DNA methylation patterns remained static in the adult animals up to at least 100–150 days of age, even though the animals were placed on control diets postweaning (Waterland and Jirtle, 2003; Dolinoy *et al.*, 2006). Feeding rats a protein-restricted diet leads to hypomethylation of PPARα (peroxisome-proliferator-activated receptor alpha) and glucocorticoid receptor (GR) promoters and increased expression of these genes (Lillycrop *et al.*, 2005). Finally, it appears that maternal behaviour can perhaps impact epigenetic mechanisms that in turn impact offspring patterns of gene expression. Pups of rats that demonstrated low levels of nurturing behaviour had an increased stress response correlating with hypermethylation of the glucocorticoid receptor in the hippocampus (Weaver *et al.*, 2004). Furthermore, there is evidence for multigenerational effects of agents that alter epigenetic processes. The F1 and F2 generations of rats fed a protein-restricted diet exhibited hypomethylated GR and PPARα DNA (Burdge *et al.*, 2007a; 2007b). Transient exposure of pregnant rats to vinclozolin or methoxychlor induced a decrease in spermatogenic capacity in the F1–F4 generations (Anway *et al.*, 2005). These changes correlated with altered DNA methylation patterns in the germ line (Anway *et al.*, 2005).

If similar long-lasting and transgenerational effects hold true in humans, this would have a considerable impact on our current understanding of the importance of maternal nutrition and chemical exposure during gestation and early development. A relevant example of this is the current recommendation that pregnant women take a supplemental amount of folic acid. Although this practice clearly reduces the incidence of neural tube defects (Centers for Disease Control and Prevention (CDC), 2008), the effects of this methyl donor nutrient on the epigenome are poorly understood and may have long-lasting effects which may be beneficial or detrimental. This is of particular concern if many pregnant women take a 'more is better' approach towards folic acid supplementation, when the long-term risks associated with this practice are unknown.

10 THERAPEUTIC APPROACHES TARGETING EPIGENETIC MECHANISMS

An enhanced understanding of epigenetic processes as well as the nutrients and chemicals that affect them has resulted in therapeutic approaches that work through actions on the epigenome. In addition, aberrant epigenetic processes can serve as biomarkers of disease development or susceptibility, particularly in cancer.

The ability to hypomethylate DNA underlies the anticarcinogenic activities of dAzaC, cladribine and fludarabine (Wyczechowska *et al.*, 2000). Genistein re-activates tumour suppressor genes in leukaemic cells in mice (Raynal *et al.*, 2008), and in human breast cancer cells (King-Batoon *et al.*, 2008). HDAC inhibitors have also been shown to have considerable promise as chemotherapeutic agents (Zhu and Otterson, 2003), including trichostatin A, sodium butyrate, depsipeptide and valproic acid. A synergistic therapy with HDAC and dAzaC has been shown to be particularly effective in the induction of apoptosis, differentiation and cell growth arrest in a number of cancer cell lines (Zhu and Otterson, 2003). HDAC inhibitors have also been shown to ameliorate some of the adverse effects associated with various neurological disorders, including Huntington's and Parkinson's diseases (Abel and Zukin, 2008).

As previously discussed, it is also possible that nutritional supplementation can counteract the action of agents that cause various effects on the epigenome, with folic acid and genistein shown to counteract the hypomethylating effects of bisphenol A-induced hypomethylation in the F1 generation (Dolinoy *et al.*, 2007). Similarly, methionine administration prevented hypomethylation induced by injection of doses of TCE, DCA (dichloroacetic acid) and TCA (Tao *et al.*, 2000).

The use of microRNAs in therapeutic strategies to alter patterns of gene expression is attractive largely due to the potential of having some degree of control over the specific gene target. MicroRNA has shown some promise for use in chemotherapeutic strategies. Administration of miR-15a and miR-16-1 led to apoptosis induction, and hence a reduction in carcinogenic potential, in a human chronic lymphocytic leukaemia cell line (Cimmino *et al.*, 2005). Conversely, targeting miRNAs that inhibit apoptosis, such as miR-21 can be accomplished by antioligonucleotide constructs (Chan *et al.*, 2005). To date, miRNA has not been used in the clinic, but use of these approaches delivered via viral vectors, liposomes and nanoparticles is currently being investigated (Negrini *et al.*, 2007).

Epigenetic markers can also be used as biomarkers to predict various untoward outcomes, an approach that has shown considerable potential in the early detection of cancer. Hypermethylation of the p16 tumour

suppressor gene in the sputum and/or plasma identified 92% (46/50) of lung patients studied (Liu *et al*., 2003), and methylation of the promoter regions of p16 and MGMT (0^6-methylguanine-DNA methyltransferase) tumour suppressor genes has been detected in the sputum DNA of all patients with squamous cell carcinoma of the lung up to three years prior to clinical diagnosis (Palmisano *et al*., 2000). Furthermore, a blood test for the loss of normal patterns of Igf2 imprinting has shown to be effective in the early detection of colon cancer (Cui *et al*., 2003).

11 FUTURE DIRECTIONS

In the past decade, our knowledge of the impact of epigenetic mechanisms on a plethora of biological processes has been greatly expanded. Just as the DNA sequence has been determined, investigators are now at work on describing the human epigenome. New computational techniques using sequence information to identify imprinted genes in the human genome have been successful (Luedi *et al*., 2007), and characterization of the healthy and cancer methylome using a variety of molecular techniques is underway (Jacinto *et al*., 2008). The goal of these endeavours is to identify additional genes influenced by epigenetic mechanisms in a manner that, if altered, could compromise human health. Such research will continue to increase our awareness of a variety of issues pertinent to public health, including the importance of particular nutrients and chemicals, the labile nature of the epigenome during early development, and the role of epigenetic mechanisms in imparting a long-lasting impact on patterns of gene expression.

Reproductive Toxicology

Norbert Makori, Satoru Oneda, Patricia R. McElhatton, Jennifer M. Ratcliffe and Frank Sullivan

CONTENTS

1 INTRODUCTION

Broadly, reproductive toxicology (or toxicity) is defined as any adverse effect on any aspect of adult male or female sexual function and fertility, or on the conceptus or on lactation, which would interfere with the production or development of normal offspring which could be reared to sexual maturity, capable in turn of reproducing the species. In its more narrow definition, reproductive toxicology is divided into two major classes: (i) adverse effects on reproductive ability or capacity in adult males and females, that is, effects on sexual behaviour and fertility and (ii) adverse effects on maintenance of pregnancy (embryofoetal loss) and developmental outcome of the offspring, that is, developmental toxicity. The former is assessed in both males and females as exposure of a toxicant applies to both, while the latter is assessed in only females and their concepti/offspring (teratogenicity and postnatal evaluations), as exposure only occurs during pregnancy, where the male is used only for mating purposes and is not exposed to the reproductive toxicant.

1.1 Terminology

- Reproductive toxicology: Occurrence of physiologically adverse responses or alterations involving female or male reproductive systems resulting from exposure to chemical or biological agents. The responses or alterations may involve the reproductive organs and related endocrine system, or may affect pregnancy outcomes.
- Fertility: Natural capacity to conceive (females) or induce conception (males).
- Fertile: Capable of breeding or reproducing within or above normal for a given species.
- Infertility: No fertility for a specified period, either temporarily or permanently (sterility).
- Fecundity: The potential reproductive capacity of an organism or population, measured by the number of gametes (e.g. in animals). Producing large litters is regarded as a component of fecundity.
- Teratogen: An agent that alters the normal development of an embryo or foetus that can subsequently result in either embryo/foetal death or a malformation(s) in the newborn.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

- Teratogenicity: The ability of a teratogen to cause gross structural malformations in the developing foetus.
- Behavioural teratogenicity: The ability of a teratogen to affect the foetus in such a way as to result in neurobehavioural disorders in the offspring following prenatal exposure of pregnant females to a teratogen.
- Developmental toxicity (see **Developmental Toxicology**): Occurrence of adverse effects on the developing organism as a result of exposure prior to conception (either parent), during prenatal development, or postnatal, including up to the time of sexual maturity. Common manifestations of developmental toxicity include, but are not limited to: (i) death of the developing organism, (ii) structural (macroscopic or microscopic) abnormality, (iii) delayed or altered growth and (iv) functional deficiency (US EPA, 1998).
- Developmental neurotoxicity (DNT; topic dealt with in detail in **Developmental Neurotoxicity**): Potential, functional and morphological hazards to the nervous system which may arise in the offspring from exposure of the mother during pregnancy and lactation.
- Developmental immunotoxicity (DIT): Development and function of the immune system assessed postnatally, for detection of adverse effects following perinatal immunotoxicant exposure.

2 SCREENING TESTS IN ANIMAL MODELS FOR REPRODUCTIVE TOXICOLOGY

The screening tests will be discussed in four sections, dealing with: (i) drugs (small molecules or biopharmaceuticals), (ii) pesticides, (iii) food additives and (iv) industrial chemicals.

2.1 Drug Testing

The objective of systemic reproductive toxicity testing of drugs (pharmaceuticals) or drug candidates in laboratory animal models is to predict if a drug would adversely affect the ability to achieve and maintain pregnancy and normal development of offspring.

Many drugs that are harmless to the mother can impair development of a human embryo. This led to the recognition of the need for a testing procedure to detect any potential toxicity. A classic example is thalidomide that had beneficial maternal outcomes, but had altered normal embryonic development, resulting in an abnormal offspring. This led to the introduction of legal requirements in many countries for the testing of potential new drugs before release to the general public for use. A major aim was to prevent a repetition of the teratogenic effects of thalidomide and so, not unnaturally, detailed reproductive tests were included as part of the testing battery. In 1966, under the direction of Dr. Lehmann, the United States Food and Drug Administration (US FDA) published guidelines for a three-segment study for drug testing for adverse effects on fertility and pregnancy. This proved to be a classic design, which was used until recently, with only minor modifications, throughout the world (Sullivan, 1988). In 1992, new guidelines for the testing of drugs were agreed internationally (ICH, 1992 and revisions thereafter).

2.1.1 *Three-Segment Reproduction and Teratogenicity Study*

In general for rodents and rabbits, three dose levels plus controls are used in each segment. In nonhuman primates (NHP), a minimum of two dose levels plus control is routinely used, but up to three dose levels is not uncommon.

2.1.1.1 *Fertility Studies (Segment I)*

Fertility and general reproduction performance studies fundamentally test for toxic responses that may be a sequelae of treatment with the test substance before mating takes place, during the mating period, at preimplantation and until completion of implantation (gestation day (GD) 6 in rats and GD9 in NHP) (Dimitriadis *et al*., 2003). It is worth mentioning that the process of embryo implantation itself plays a major role in embryogenesis and the outcome of pregnancy. Parameters evaluated include libido (rats and monkeys), effects on oestrous (rats), effect on menstrual cycle length (monkeys) and implantation (dead and resorbing foetuses in rats).

2.1.1.1.1 Segment I Study Design in Rats

In rats, male animals are treated for 60–80 days to cover the whole period of spermatogenesis. The female rats are pretreated for 14 days to cover three oestrous cycles. The female animals are then mated with the treated males (combined Male and Fertility Study, FDA Segment I and International Conference on Harmonization (ICH) S5), treatment of the males and females continuing during the mating period. In rats, treatment of the females continues either through to GD6 or throughout pregnancy, followed by necropsy and evaluation at GD13 or GD21 (**Figure 1**).

In stand-alone female or male rat fertility studies, the test article is administered only to the females or males, the untreated sex acting only to demonstrate if the treated sex's fertility was impaired.

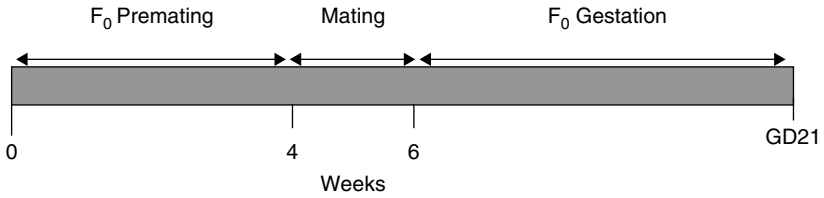

Figure 1 Standard combined study design for investigation of fertility in male and female rats.

2.1.1.1.2 Segment I Study Design in Nonhuman Primates

The use of NHP (specifically the cynomolgus monkey, *Macaca fascicularis*) in reproductive toxicology testing, including fertility (male and female), teratogenicity and peri- and postnatal toxicity, has become increasingly commonplace in recent years because of tremendous growth in biopharmaceuticals being tested for human use. Subsequently, standardized study designs have been established in order to meet international requirements for reproductive toxicity testing using NHP to be in line with ICH Guidelines (ICH, 1994).

In fertility studies using the monkey model (male and female), mating is not normally required (unlike in rodent studies) and as such, fertility or reproductive function assessments are incorporated in a chronic toxicology study design. Animals assigned to such studies must be sexually mature (generally > four years), regularly menstruating females, and males with total testicular volume of at least 20 ml (10 ml per testis) and that can ejaculate on electrostimulation. In males, the ejaculates should have adequate numbers of sperm (mean concentration of $600 \times 10^6\,\mathrm{ml}^{-1}$ (range 150–1012) and mean total count of 131×10^6 per ejaculate (range 50–260)), be of good quality, that is, highly motile and with minimal dysmorphologies. Prestudy screening for hormones is optional (baseline data is obtained during acclimation before animal dosing), and only testosterone levels may be measured. Overall, male reproductive function assessments during the study include testicular volume measurements (using a caliper), semen analysis (preferably automated, CASA (computer assisted semen analysis), e.g. IVOS Hamilton Thorpe Inc.), hormonal analysis (testosterone and luteinizing hormone (LH)) and histopathology of the testis and male reproductive accessory glands (seminal vesicles, prostate gland and the bulbourethral glands). Semen collection methodology is an important consideration for good semen quality (VandeVoort, 2004). Direct penile electrostimulation is the preferred method. This method was first developed by Mastroianni and Manson (1963) using metal foil electrodes and square wave pulses. With the use of EKG gel electrodes, the risk of burn injury is drastically reduced (Sarason *et al*., 1991). Animals are not anaesthetized for this procedure, but rather are trained for chair restraint. This method has become common for semen collection and analysis in chronic toxicology studies. To assure the best collection of semen, the following must be taken into consideration: training and acclimation of animals to the restraint method and the procedure (a minimum of four weeks required), and the operator must be calm. Semen collection should be performed at intervals, not only for animal welfare, but also ejaculate quantity and quality, even though it has been reported that collection can be performed several times in a row without ill effects (Settlage and Hendrickx, 1974). As has been reported by VandeVoort, 2004 and based on author experience, early morning collection time produces the best samples. It is likely that in the late morning the male may have already masturbated to the point of depleting sperm numbers in the ejaculate. In order to accurately determine the important variable related to fertility in males, the total sperm count (number of spermatozoa per ejaculate) rather than sperm concentration (number of spermatozoa per unit volume of semen) is taken into account. Moreover, total sperm count reflects testicular volume (Handelsman *et al*., 1984; Andersen *et al*., 2000), and is therefore a measure of total testicular sperm output (MacLeod and Wang, 1979). This correlation is directly related to the chances of pregnancy after coitus (Cooper *et al*., 2007). For hormone analysis, samples are also collected in the morning and at a consistent time throughout the study period. For LHs, a total of three samples are normally collected at 30 minute intervals (±5 minutes) at each time-point to measure moment-to-moment changes in circulating concentrations of the hormone (Ramaswamy *et al*., 2007).

In females, at least two normal menstrual cycles (mean 28 days (range 25–35 days) must be recorded prior to assigning an animal to a study. Hormonal measurements include progesterone and 17β-oestradiol, at several time-points during one or two menstrual cycles for baseline and each study period (menstruation days (MDs) 2, 9, 13, 16, 19, 23, 27 and 30, and every five days thereafter until the onset of the next menstrual cycle).

2.1.1.2 *Teratology Studies (Segment II)*

Maternally mediated developmental toxicity may occur as a consequence of either direct drug (or metabolite) exposure to the embryo after crossing the placental barrier or toxicant-induced alterations in maternal physiology at dosages not causing overt maternal toxicity, but affecting the conceptus.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Segment II of the study is the 'teratogenicity' or embryotoxicity segment, in females only (males are used for breeding purposes only), and is still essentially included in the new ICH guidelines for rats and rabbits.

2.1.1.2.1 Rats and Rabbits

For most small molecules and industrial chemicals, a teratology study is normally carried out in two species, usually rats and rabbits. Mated animals are treated during the period of organogenesis (days 6–15 in rats, 6–18 in rabbits) and the pups are delivered by Caesarian section (C-section) on day 20 for rats (the day before expected parturition for examination, 21 day gestation period) or on gestation day 28 for rabbits (32 days normal gestation period). The harvest of foetuses before the normal natural delivery dates is necessary in order to prevent loss of deformed foetuses by cannibalism, a normal phenomenon common in these species. The pups are examined for gross, soft tissue and skeletal defects by the use of appropriate dissection and staining techniques.

2.1.1.2.2 Nonhuman Primates

The cynomolgus monkey is the model of choice because of availability of extensive teratology background data. The rhesus monkey may also be used when the test article is crossreactive only in this species. The common marmoset (*Callithrix jacchus*) is rarely used and there is no reproductive background data generated in a regulated (Good Laboratory Practice; GLP) environment. In addition, marmosets have germ-line chimerism (when the sperm and egg cells of an organism are not genetically identical to the adult organism that gave rise to the sperm or egg) and they can carry the reproductive cells of their twin siblings, because of placental fusion during development (Ross *et al*., 2007), thus making this species unsuitable for teratology studies. No guidelines have been established for use of NHP in teratology studies. However, the designs take into consideration ICH S5(R2) (Detection of Toxicity to Reproduction for Medicinal Products and Toxicity to Male Fertility) and ICH 6 (Preclinical Safety Evaluation of Biotechnology-Derived Products, 1997) and are now routinely used. In addition, the embryofoetal developmental timeline is longer than in rodents or rabbits and is comparable to humans (O'Rahilly, 1988), with first trimester between GD0 and 50, second trimester GD50 to 100 and third trimester between GD100 and natural delivery at GD165 (±10 days).

In teratology studies using the monkey model, typically 12–16 animals are assigned to a group and dosed, starting between GD20 and 50 for small molecules or GD20–139 for biopharmaceuticals. Ultrasound monitoring is performed on a regular basis to monitor embryofoetal viability.

At day 100 (typically for small molecules) or day 140 (for biopharmaceuticals), foetuses are collected by C-section and evaluated for external, visceral and skeletal malformations (example details in Martin *et al*., 2007). The diagram below outlines the general scheme for a teratology study in NHP using the traditional small molecule design as an example (**Figure 2**).

The incidence of embryofoetal loss ranges from 0 to 25%, with a mean of 12% (Hendrie *et al*., 1996; Martin *et al*., 2007).

2.1.1.3 Peripostnatal Studies (Segment III)

The study design aims to detect any adverse outcomes developmentally and/or functionally on the offspring. Pregnancy period outcomes may also be detected (e.g. abortions) because the treatment of the female starts at implantation (GD6 for rats, GD20 for NHP), or in rats towards the end of organogenesis (~GD15), to lactation and weaning (postnatal day (PND) 21). Detailed study designs and regulatory requirements for using rats can be found in the ICH Guidelines. Segment III study designs in NHP are not included in any guidelines because the need for testing using this species is recent due to the emergence of biopharmaceuticals. In designing Segment III studies using NHP, the ICH guidelines are taken into consideration. Dosing starts on GD20 up to GD50 for small molecules and up to natural delivery (±165 days) for biopharmaceuticals. Typically, no dosing of

the maternal animals or infants is performed following delivery. The infant is raised naturally by the maternal animal and is evaluated for approximately six months.

In both the Segment II and Segment III studies, detailed embryofoetal monitoring is carried out throughout pregnancy. Parameters monitored by ultrasound at various time-points are shown in the following chart (**Table 1**) (see Tarantal and Hendrickx, 1998 for additional parameters).

Segment III studies in rats are carried out on pregnant animals treated either during the last part of gestation (in rats) or throughout gestation in nonhuman primates, NHP (GD20–165).

2.1.1.3.1 Rats

Dosing continues through parturition until weaning. This is to examine whether the drug has any adverse effects on parturition or lactation which have not been detected in the Segment I study. Higher doses may be used in this segment than in the Segment I study.

2.1.2 International Conference on Harmonization (ICH) Guidelines

Although the US FDA guidelines were widely accepted and used for testing drugs, advances in knowledge and increasing interest in adverse effects of chemical exposure during pregnancy on postnatal development led to a number of changes and additions to the test protocols. In particular, there were small, but significant, differences between US/European guidelines and those recommended in Japan, and the number of postnatal studies required to fulfil all the requirements became unwieldy and led to the recommendation of a new set of guidelines for the testing of new medicinal products under the auspices of the ICH in 1992 (ICH, 1993; 1994; Manson, 1994). The underlying theme of the new guidelines is flexibility; to define the major areas of concern to be investigated with respect to developmental toxicity and to give wide scope for the experimenter to design a series of tests, suitable for the specific drugs investigated. Factors specifically relevant in the design of the actual testing strategy include: (i) anticipated drug use in relation to reproduction, (ii) the form and routes of administration intended for humans and (iii) making use of any existing data toxicity, pharmacodynamics, kinetics and similarities with other compounds in structure/activity.

The specified aim of the studies is to choose a combination of studies, which will allow exposure of male adults and all stages of development from conception to sexual maturity. To allow for detection of immediately delayed effects, it is recommended that exposure should be through the whole of one complete life cycle, that is, conception in one generation through to conception in the following generation. For convenience of testing, the guidelines divided this into six stages:

1. Premating to conception
2. Conception to implantation
3. Implantation to closure of the hard palate
4. Closure of the hard palate to the end of pregnancy
5. Birth to weaning
6. Weaning to sexual maturity.

It is emphasized that whatever study design is chosen by the investigator, all of these stages should be performed without omissions, and that where a number of separate studies are performed, there should be an overlap of at least one day in the exposure periods of related stages. Other guidelines address studies which are designed primarily for the detection of effects, and state that when an effect is detected, then further studies to characterize the nature the response have to be designed on a case-by-case basis.

When positive results are observed in any part of reproduction studies, this will normally lead to further studies being carried out to investigate the mechanism of action. The effects observed may be extensions of

pharmacological actions which might be expected at high doses used in the toxicity tests, but would no longer be expected at the lower doses used clinically. Sometimes the actions may be exerted on rodent-specific aspects of reproductive physiology and would not be a problem to humans. Differences in results between rats and rabbits may be due to metabolites which are produced in one species, but not another. It is then important to know which metabolites are produced in humans and to be sure that these are adequately tested in the animal studies; it may sometimes be necessary to synthesize adequate quantities of human-specific metabolites and for animal tests to be repeated using these.

2.2 Pesticide Testing

The safety evaluation of pesticides for reproductive toxicity has to take into consideration several factors which are not relevant for drug testing. By their nature pesticides are toxic compounds since their use is to kill target species, which may be plants, insects, fungi and so on, although they may have very low toxicity for mammals. First consideration has to be given to the safety of workers handling these chemicals. Depending on their use, the exposure of operators may be considerable and this has to be taken into account in the final risk assessment of safety in use and the need for protective clothing to be worn. For chemicals used for crops there have to be residue data so that exposure of the general public consuming the food can be calculated. For chemicals used on amenity lands such as parks, gardens and playing fields, consideration has to be given to exposure of the public using the facilities. The environmental ecological impact must also be examined so that studies may have to be carried out to look for effects on beneficial species such as earthworms and bees, and also on fishes, birds, predators and so on. Reproduction tests on these latter species are outside the scope of this chapter, but are of great environmental interest.

For tests related to operator exposure, it is common to carry out tests equivalent to the Segment I ad II tests described above for drugs. These cover possible affects on male and female fertility and developmental toxicity. For pesticides leaving significant residues on food, it is usual to carry out a multigeneration study to test for long-term or cumulative effects in adults or effects on young developing animals. In such tests animals are treated continuously with the chemical, usually at three dose levels administered in the diet, though several generations. Several different designs of multigeneration studies have been used for pesticides testing. The original design proposed by the US FDA for testing food additives (Fitzhugh, 1968) which is a three-generation, two-litter test, has been widely used. This involves treating young male and female rats with three dose levels of the test substance, plus a control group, and allowing them to produce two litters, F1a and F1b. Selected pups from the second (F1b) litters are reared to maturity, still under treatment, and in turn are allowed to produce two litters (F2a and F2b). Again, selected pups from the second (F2b) litters are reared to maturity, still under treatment, and allowed to produce two litters (F3a and F3b). The second (F3b) litters are then subjected to full pathological examination to examine for any affects of long-term exposure. An immense amount of information is obtained in such studies, not only on the different aspects of fertility and pregnancy, but also on possible affects on growth and development of the young animals.

In Europe, in an attempt to reduce the numbers of animals involved without significant loss of information, it is common to perform this test using only two generations with two litters in each. The new European legislation covering nonagricultural pesticides (Biocides Directive, 1998; Biocides Directive, Revision of Directive 98/8/EC, 2008) recommends that the tests carried out should be those in Annex V of Directive 67/548/EEC, which are, in practice, identical with the Organization for Economic Cooperation and Development (OECD) test guidelines. There is a new OECD draft guideline for a two-generation reproduction toxicity test (OECD, 1996). In the USA, a modified test using two generations with one litter in each, but with a large number of end points being assessed, is proposed for pesticide testing for the US EPA (US EPA, 1998). Recently, designs have been used where a third litter is produced in one or two of the generations with the dams killed just before delivery for examination of the foetuses so that the test also includes a teratology element.

2.3 Food-Additive Testing

The reproductive toxicity test requirements for the testing of food additives are less well defined in Europe than for the other classes of chemicals considered above (EEC, 1989; DHSS, 1982), but in general the test methods of the OECD are acceptable. In the USA, however, the FDA have published an extensive account of the types of test which may be required depending on the use, amount, frequency and duration of exposure expected (US FDA, 1982), and an extensively revised final version (Redbook II) was published in 2000 (US FDA, 2000). In general, fertility and developmental toxicity are tested using segments modified so that the period of chemical exposure, especially in the teratology test, is extended to include most of gestation. Consideration also has to be given to whether the metabolism of the chemicals may alter on chronic administration, so that more than one dosing regimen may have to be used. For food-additive

chemicals, where there is likely to be prolonged or extensive exposure, multigeneration studies are normally performed using one of the designs discussed above, usually a two-generation, two or three-litter test.

2.4 Industrial Chemicals Testing

In most industrialized countries, there are now testing requirements for industrial chemicals when these are introduced in significant amounts. In Europe, for example, under the requirements of the laws generally known as the 'Dangerous Substances Directive' (EU, 2008) there is a stepwise system which permits regulatory authorities to require sequential testing for fertility, teratogenicity and multigenerational effects, as the tonnage of chemical produced per year, or *in toto*, reaches certain critical values. There has been good international cooperation under the auspices of the OECD to establish mutually acceptable guidelines for conduct of reproductive toxicity studies, which have acceptance worldwide. As these are regularly updated, interested readers should obtain the most recent versions from the OECD.

The US National Toxicology Program has developed a test protocol for the evaluation of the reproductive toxicity of chemicals using a continuous breeding study design (Chapin *et al*., 1997; Lamb, 1985). The protocol was originally developed for mice as a cost-effective alternative to the more conventional regulatory breeding studies, but has also been employed successfully with the rat as the test species. The outline design is that after a one-week pretreatment period, males and females are housed as breeding pairs in individual cages and allowed to mate continuously during a 14 week testing period. Exposure to the test substance (usually in the feed or drinking water) is continued throughout the study, and the litters are removed from the cage immediately after parturition. Usually four to five litters will be produced in such a study. After the cohabitation breeding period, the pair is separated and the last litter is raised to weaning. This study design allows several litters to be examined per generation and adverse effects, which may not be observed in the first mating, may become evident in later mating. Other short-term testing or screening protocols have been published (Harris *et al*., 1992; Linder *et al*., 1992).

3 MECHANISM OF ACTION OF CHEMICALS AFFECTING REPRODUCTION

When any adverse effects are detected in any of the above screening tests, then extrapolation to humans involves analysis of the mechanisms and sites of action of the chemicals causing the effects. Some of the factors which have to be taken into account in analysing effects in males and females are considered in detail below, together with detailed descriptions of the types of toxic effects which can be produced in males and females.

3.1 Effects on the Male Reproductive System

3.1.1 Introduction

Exposure to a toxic agent may affect the male reproductive system at various stages of life: during foetal development of the gonads, due to exposure of the pregnant mother; during the quiescent prepubertal period before active spermatogenesis begins and postpubertal, during the long period of activity of spermatogenesis, which, although a gradual decline in testicular function occurs after middle age, continues into old age in man (Lipshultz and Howards, 1983). The two critical end points of concern in male reproductive toxicology are: (i) the production of sufficient sperm which are capable of fertilizing an egg and (ii) the production of sperm with normal chromosome number and structure, and genetic material. A toxic agent may produce alterations in spermatogenesis via an effect on the hypothalamo-pituitary-testicular axis, or affect accessory sex gland function or sexual function (libido, potency, ejaculation), with the end result that fertilization fails to occur. A toxin may, however, cause genetic or chromosomal damage to the germ cell, so that if a sperm carrying damaged genetic material fertilizes an egg, foetal death or a structural or functional abnormality in the newborn occurs (which may not become apparent until later life or even the subsequent generation).

In Western countries, about 15% of couples are clinically infertile (i.e. have not conceived after one year of unprotected intercourse), although estimates vary widely in different countries (Belsey, 1984). An estimated 30% of clinical infertility in couples has been attributed to the male, with a further 20% due to a combination of male and female factors (Lipshultz and Howards, 1983). A considerable proportion of infertility (perhaps 30%) is idiopathic, that is, cannot be explained by diagnosed genetic, anatomical or organic conditions in either partner. There is increasing concern about the possible role of environmental chemicals that cause endocrine disruption as possible aetiological factors in the decline in sperm counts which have been reported in different populations (Carlsen *et al*., 1992). Some 15–20% of recognized pregnancies end in spontaneous abortion and a further unknown number of conceptions are absorbed before pregnancy is diagnosed; approximately 50% of recognized first trimester abortions and about one-third of all recognized abortions up to 28 weeks are abnormal,

according to Warburton *et al*. (1980); the frequency in early abortions is thought to be considerably higher. Approximately 6% of prenatal deaths and 0.6% of live births are chromosomally abnormal; further, an estimated 1% of infants carry a gene for autosomal dominant disease, of which possibly 20% are new mutations (Wyrobek, 1989). It is not known, however, what proportion of these abnormalities are contributed by the male or could be attributable to toxic exposures. Nevertheless, a number of agents have been identified experimentally as affecting one or more aspects of male reproduction and mechanisms of toxicity elucidated by which they exert their effect; a number of agents have also been studied in humans. Below we first briefly describe the physiology of male reproduction, then outline the main methods by which reproductive toxicity can be studied in animals and man and finally describe mechanisms and site of action of toxic agents, using examples from the experimental, clinical and epidemiological literature.

3.1.2 Physiology of the Male Reproductive System

3.1.2.1 The Hypothalamo-Pituitary-Testicular Axis

In the hypothalamus, neuroendocrine neurons secrete gonadotrophin-releasing hormone (GnRH) into the hypophyseal portal system, where it is carried in the blood to the adenohypophysis or anterior pituitary, where it stimulates the release of the gonadotrophic hormones, LH and follicle-stimulation hormone (FSH). Prolactin is also released from the anterior pituitary under the control of dopamine released from neuron terminals in the median eminence. In contrast to the action of GnRH, the presence of dopamine inhibits the release of prolactin. In turn, the hypothalamic neuroendocrine neurons contain receptors for monoamines (noradrenaline, dopamine, serotonin), and these are affected by the CNS transmitters (and agents which affect these transmitters). The target of action of both LH and FSH is the testis; although the primary actions of each hormone are on different testicular cells (see below), there is increasing evidence that their functions may be more complex and overlapping than previously thought. The functions of prolactin in males is less clear; it appears that prolactin may potentiate the effect of LH in the testis (for general reviews, see, e.g. Hansson *et al*., 1981; Lobl and Hafez, 1985; Cooke and Sharp, 1988; Johnson and Everitt, 1988; Knobil and Neill, 1994).

3.1.2.2 The Testis

The mammalian testis consists of two major compartments: the seminiferous tubules, in which spermatogenesis takes place, and the interstitial compartment. The interstitial space contains Leydig cells, which produce testosterone and other androgens under the influence of LH. These cells are closely associated with blood vessels and lymphatics which facilitate transport into the seminiferous tubules. Most of the circulating testosterone produced by the testis is bound to plasma proteins. Androgens are responsible for controlling spermatogenesis, the growth and secretory activity of accessory sex glands, somatic masculinization, male behaviour and various metabolic functions. *In utero*, androgen secretion by the developing foetal testis, critically in gestational weeks 4–6 in humans, is essential for sexual differentiation of the gonads; androgens control both the regression of the Mullerian duct (which forms female internal genitalia), the development of Wolffian ducts into the epididymis, vas deferens, seminal vesicle and ejaculatory duct and the development of the urethra, penis, scrotum and prostate.

There are two major cell types in the seminiferous tubules: the spermatogonial cells and the Sertoli cells. Sertoli cells have numerous functions, principally: (i) the nutrition of developing cells, (ii) the synthesis of androgen-binding protein, which permit the binding of testosterone within the tubular fluid of the adluminal compartment (note that the Sertoli cells themselves also have androgen receptors on them), (iii) synthesis of inhibin, which is probably involved in feedback regulation of both LH and FSH in the pituitary, (iv) secretion of fluid into the lumen of the tubule and (v) maintenance of the blood–testis barrier (BTB). The BTB, first demonstrated by Setchell *et al*. (1969), consists principally of specialized Sertoli-cell-to-Sertoli-cell junctions within the seminiferous epithelium. The layers of myoid cells surrounding the seminiferous tubule epithelium also appear to retard the passage of molecules. Permeability to compounds appears to be determined primarily by molecular size (Dixon, 1983; 1985; Pereira and Garcia e Costa, 2007; Gallegos-Avila *et al*., 2007; Wong *et al*., 2006). Molecules smaller than about 0.36 nm or MW $\sim$ 150 (e.g. water, urea) are transported easily. The rate-limiting factor for transport across the BTB is lipid solubility (Dixon, 1983). The permeability characteristics appear to be similar to those of the blood–brain barrier, membranes in the gastrointestinal tract, mammary gland and aqueous humour. (For general reviews of testicular function and the BTB, see, e.g. Burger and de Kretser, 1981; D'Agata *et al*., 1983; Schulze, 1984; Guo *et al*., 2007).

3.1.2.3 Spermatogenesis

Spermatogonia undergo several mitotic divisions in the basal compartment of the seminiferous tubule (separated from the adluminal compartment of the Sertoli cells). One population of dividing spermatogonia become stem cells, which will go on to become spermatozoa, while the rest form a replacement population of spermatogonia. The last mitotic divisions of spermatogonia (after a characteristic number of divisions in different species) result in primarily spermatocytes, which push past the tight

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Sertoli cell junctions and enter the adluminal compartment, where they continue to divide meiotically into secondary spermatocytes and finally round spermatids. Thus, meiotically dividing spermatocytes and subsequent stages of spermatozoal development are protected by the BTB provided by the Sertoli cells, whereas the spermatogonia are not. Cohorts are differentiating at varying times; there is a net continuous release of mature spermatids from the tubule. One cycle of the seminiferous epithelium (the time between successive entries into spermatogenesis of any given Type A spermatogonia) is remarkably constant in different species (e.g. 12 days in rats, 16 days in human), as is the total time for spermatogenesis (the spermatogenic cycle), which is about four times the length of the seminiferous cycle. The *rate* of spermatogenesis does not appear to be affected by the action of exogenous agents. This regularity allows the identification of the precise stage of spermatogenesis affected by, for example, experimental administration of a toxin. Agents can selectively cause degeneration of a given population of germ cells and thus eliminate subsequent stages of cells.

Spermiogenesis is the 'packaging' process by which round haploid spermatids become spermatozoa, and this occurs in close association with Sertoli cells. Immature spermatozoa (incapable of movement and fertilization) undergo maturation in the epididymis under androgen stimulation. It usually takes about 20 days from late spermatid stage to ejaculation in man. During passage through the epididymis, the sperm chromosomes are condensed and packed into the sperm head complete with a cap, and the acrosome which contains the digestive enzymes (including hyaluronidase and acrosin) required to facilitate sperm penetration into the ovum. A midpiece containing mitochondria and a tail are developed. In some species, for example, the mouse, sperm morphology is highly characteristic of the species, but in man, depending on the classification used, up to 40% of the sperm may be 'abnormal', without the oval head and usual tail shape (Belsey *et al*., 1980). In most mammalian species, there is a high degree of redundancy in sperm production, that is, some 10 000 to 100 million sperm are ejaculated. According to early work by Cohen (1975; 1977), at least part of this redundancy may be due to errors in crossing over of chromosome material during meiosis, which render the sperm unsatisfactory for fertilization, since he found a correlation between chiasma frequency in different species and sperm numbers in the ejaculate. Clearly, there is also considerable wastage due to structural or functional deficiency in many sperm, which reduces their viability, motility and ability to reach and penetrate the ovum. Sperm have to penetrate the cervical mucous of the female and combat the possible effect of sperm antibodies in the female tract before proceeding to the ovum. They must also reside for some period of time (usually several hours, depending the on species) in the female tract to become 'capacitated' or capable of fertilization (Yanagimachi, 1981).

The seminal fluid consists of epididymal fluid and secretions of the accessory sex glands, principally from the prostate (30% in man) and seminal vesicles (60% in man), but also from the bulbourethral (Cowper's) glands and ampulla. The biochemical composition of the seminal fluid and its volume may affect the viability and motility of the spermatozoa after ejaculation, but in complex ways that are not clearly understood, including presence of mRNA (for reviews, see, e.g. Burger and de Kretser, 1981; Mann and Lutwak-Mann, 1981; Burger *et al*., 1989; Almog *et al*., 2008; Lambard *et al*., 2004).

3.1.2.4 Libido, Potency and Ejaculatory Function

In man, psychological factors are of critical importance in determining libido, but neurological integrity of the nervous system is also important, as centrally acting agents can affect libido in man and mating behaviour in mammals (see below). Potency in man is under parasympathetic nervous control; endocrine factors are less involved. The sympathetic nervous system controls ejaculation. In both cases, psychological factors may be involved in disturbances of these functions (for a review, see, e.g. Benson and McConnell, 1983; Jern *et al*., 2008).

3.1.3 Methods for Assessing the Effect of Toxic Agents on the Male Reproductive System

Studies of toxic agents and their mechanisms of effect on male reproduction can be divided into: (i) experimental (usually using the rat, mouse or rabbit), (ii) clinical (usually infertility clinic patients or patients undergoing specific drug treatments) and (iii) epidemiological (studies of groups of men exposed occupationally or environmentally to some agent of concern). Clearly, a greater number of reproductive end points and mechanisms can be studied in the laboratory than in the clinic or field setting. Examples of the techniques used in the laboratory include gross pathology and histology of the testes and accessory sex glands (US EPA, 1998; OECD, 1996). Sperm analysis may be carried out to measure sperm viability, motility, swimming speed and morphology, and computer-assisted methods are now widely used (Working and Hurtt, 1987; Slott *et al*., 1991; Chapin *et al*., 1992; Sloter *et al*., 2006). The rabbit (Williams, 1993) and NHP are useful animal models for such studies, since repeated semen samples can be obtained for sequential analysis. Very useful overviews of methodology have been published (Chapin and Heindel, 1993; WHO, 1999).

Studies in the mouse indicate that sperm shaping is under genetic control in this species, and that exposure to known mutagens increases the frequency of abnormal sperm shapes (Wyrobek *et al*., 1983a; Narayana *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2002). There is also a correlation between induction of sperm abnormalities and an increase in germ cell mutations, as tested by the dominant lethal, specific locus and heritable translocation tests (see below), suggesting that, in the mouse at least, abnormal morphology may predict for germ-cell mutagenicity (Wyrobek *et al*., 1983a). However, other reviewers have argued that sperm shape does not necessarily predict for chromosomal or DNA damage within the sperm, particularly as damage to Sertoli cells may result in secondary morphological abnormalities (Russell and Shelby, 1985; Working, 1989). Chromosomal analyses of male germ cells have been developed, which have been shown to detect germ-cell mutagens (Working, 1989). Dixon and colleagues have used a method of measuring unscheduled DNA synthesis in sperm (which would not normally occur after the first replications of DNA before mitotic divisions in the spermatogonia) using incorporation of radiolabelled thymidine into sperm DNA following experimental mutagen treatment (Lee and Dixon, 1978). It has been shown to occur in spermatogonia and leptotene, zygotene, pachytene and diplotene stages in spermatocytes and round spermatids, but not in elongated spermatids and spermatozoa, indicating that DNA mutation induced in these stages cannot be repaired (Working, 1989). The swimming ability, capacitation and fertilization capacity of mammalian sperm have also been studied *in vitro* (Katz *et al*., 1989; White *et al*., 1990). Assays of seminal fluid to assess accessory sex gland function (e.g. levels of fructose and zinc) and assays of gonadotrophic hormones in blood and urine may also be conducted.

To determine the effect of a toxic agent on reproductive performance, mating behaviour (e.g. frequency of copulation) may be measured, usually in rodents (Chubb, 1993). To determine the effect of treatment on the various stages of spermatogenesis, serial mating of treated males with untreated females is conducted and the number of implantations, foetal deaths or litter sizes determined; the effect of agents affecting the epididymal spermatozoa will be seen in the first mating and effects on stem-cell spermatogonia in the last matings (Dixon, 1983). One of the most common tests of chromosomal damage in the germ cell in mammals is the dominant lethal mutation test (Bateman and Epstein, 1971; Ehling *et al*., 1986). A dominant lethal mutation is one which results in the death of the early conceptus, and may be due to chromosome breakage or nondisjunction, or irreparable fatal breaks in DNA strands in meiotic or postmeiotic cells. The mutation occurs prior to fertilization and, theoretically, could kill the zygote at any time during its development. However, in mice, for example, death is rarely seen after 10 days (half the gestational age) (Bateman and Epstein, 1971). It is not clear what the period of vulnerability is in humans, although recent studies of karyotyped human abortuses suggest that most lethal mutations are expelled in the first trimester of pregnancy (Warburton *et al*., 1980), often, as in the case of all monosomies except XO, too early to be detected. To determine the heritability of nonlethal chromosomal and genetic defects, heritable translocation and specific locus mutation tests and multigeneration tests in, for example, mice may be conducted (Flamm and Dunkel, 1989). Behavioural and developmental tests of late effects of toxic exposure of the male on viable off-spring have also been utilized.

In the clinical setting, investigations of infertility or the reproductive toxicity of drugs in humans may include a battery of tests on semen quality, including sperm count, viability, motility, velocity and morphology and seminal fluid analyses (Belsey *et al*., 1980; Amann, 1981; Dixon, 1983; Eliasson, 1983; Lipshultz and Howards, 1983; WHO, 1999); FSH, LH and testosterone levels in serum (Swerdloff and de Kretser, 1983); sperm-cervical mucus interaction assays (Kremer and Jager, 1976); *in vitro* fertilization assays using zona pellucida-free hamster eggs (Rogers, 1989; WHO, 1999); physical examination and testicular biopsy; psychological evaluation and measurement of time to conceive in the individual couple (Lipshultz and Howards, 1983).

The epidemiological study of reproductive toxins presents considerable methodological difficulties, principally those of obtaining an adequate sample size, of being able to measure or estimate exposures or effects accurately and of being able to take into account other exposures or risk factors (e.g. age) which could explain an apparent association between exposure to a toxic agent and an affect of reproductive function (Bloom, 1981; Vouk and Sheehan, 1983; Lockey *et al*., 1984). Further, a number of the tests which have been used in the clinical setting to diagnose the infertility of individuals are not suitable for epidemiological studies, for reasons of expense, practicality and/or unknown predictive value of the tests for infertility in populations (e.g. *in vitro* fertilization, sperm-cervical mucous interaction). Relatively few studies of reproductive outcomes (e.g. spontaneous abortions, birth defects) in partners of exposed men have been conducted, partly owing to the large sample sizes required and the difficulty of taking into account maternal factors and exposures. For example, approximately 170 pregnancies in each of an exposed and nonexposed group, representing about 2000 person years of exposure, are needed to detect a twofold increase in foetal deaths due to an exposure. The use of live birth rates to detect changes in fertility in exposed groups of men has been attempted, but is an insensitive measure of subfertility and presents problems of determining a standardized expected live birth rate (adjusted for, e.g. parity, race), particularly if existing vital statistics have to be used.

Wilcox, Baird and Weinberg have developed a more sensitive measure of time to conception (Baird *et al*., 1986), which requires about 55 pregnancies in each of an exposed and nonexposed group to detect a 50% decrease in the probability of conceiving in any one noncontracepting menstrual cycle. This may still mean

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083

that more than 700 person years of exposure per group must be studied (depending on the pregnancy rate) to obtain the required number of pregnancies. Reliance has therefore been placed on studies of semen quality in exposed men. For example, techniques of semen analysis using mobile laboratory equipment have allowed the study of semen characteristics requiring fresh samples (e.g. sperm motility) to be evaluated in the occupational setting (Schrader *et al*., 1987).

The principal problems in the epidemiological study of male reproductive toxicology remain: (i) determining the predictive value of experimental data in laboratory animals for humans; (ii) determining the biological significance of alterations in semen quality in humans to male fertility and subsequent pregnancy outcomes and (iii) improving the methodologies for studying exposure to toxins on semen parameters and reproductive outcomes.

3.1.3.1 *Mechanisms of Sites of Action of Male Reproductive Toxins*

Several types of toxic agents will be considered here, which may be usefully classed into one of the following groups: physical agents (e.g. ionizing radiation); pharmaceutical (therapeutic) agents; recreational and illicit drugs; industrial or environmental chemicals, including agricultural chemical, and biological, naturally occurring toxins. Although the modes of action of some chemicals or classes of agents have been discovered, it must be emphasized that the mechanisms of action of many agents known to affect one or more aspect of male reproduction have not been elucidated, and may involve multiple sites of action and complex activity.

Some general mechanisms of toxicity may be discussed first. A toxic substance may act in one of more of the following ways:

1. An alteration in chromosome number or structure (e.g. translocations, deletions or insertions of parts of chromosomes) or a gene mutation in the germ cell may occur. Although assessment of chromosomal abnormalities and genetic mutations in human sperm has not been possible until very recently, some data suggest that perhaps 2% of human sperm are aneuploid (i.e. have numerical abnormalities) and 6% have structural chromosomal abnormalities (Martin, 1985; Martin, 2008). In a recent study, it was found that microdeletion and sex chromosome aneuploidy (47, XXY) rates in somatic cells are approximately 3.2 and 4.7%, respectively, while sperm aneuploidy rates are approximately 9.22 and 47% (Cinar *et al*., 2008). It is possible that sperm with abnormal chromosomes are somehow selected out in the female tract before arrival at the ovum or they cannot fertilize the egg. If fertilization does take place, most chromosomal abnormalities would be expected to result in early, or occasionally late, foetal death through a dominant lethal effect, for example, virtually all monosomies and most trisomies are fatal. If the foetus survives, it may have a congenital abnormality or a genetic disorder which may be expressed at birth, later in life or in the next generation. Certain chromosomal abnormalities are entirely due to a paternal contribution (e.g. XYY), whereas in others the contribution is less, for example, 30% for Down's syndrome (trisomy 21); about 50% of mutations of small segments of DNA (minisatellite mutations) are thought to be due to the male. The role of toxic exposures in the induction of genetic abnormalities is unknown.
2. Spermatogenesis and normal sperm viability, motility and morphology may be affected by either direct cytotoxic action on spermatogonial cells or later sperm cells (including agents which interfere with normal meiosis, for example, spindle poisons such as benomyl), an effect on Leydig cells or Sertoli cells, or an effect on the hormonal release and feedback of the hypothalamo-pituitary-testicular axis. Effects on accessory sex gland function secretions may also affect normal sperm function after ejaculation and seminal fluid volume. The net result may be impairment of fertility, due to low sperm numbers, their failure to survive in the female tract or to swim up to the ovum, or their failure to fertilize due to a morphological abnormality or a functional deficit, such as failure to capacitate.
3. An effect on sexual behaviour (reduced mating frequency or loss of libido, impotence or ejaculatory function) may occur, mediated by an effect on central nervous system (CNS) or autonomic nervous system function.

Reproductive toxins may act directly because of structural similarity to an endogenous compound (e.g. agonists or antagonists of endogenous hormones), or because of general chemical reactivity (e.g. alkylating agents); these toxins usually have several sites of action (Mattison and Thomford, 1989; Fukushima *et al*., 2005). Other toxins may require metabolic activation before exerting their effects (e.g. cyclophosphomide, 1,2-dibromo-3-chloropropane (DBCP), polycyclic aromatic hydrocarbons (PAHs)). Finally, some toxins act indirectly by inducing or inhibiting enzymes involved in steroid synthesis or clearance or by interfering with neuronal control of hormone levels or sexual function (Mattison and Thomford, 1989).

It is clear that in order to exert a toxic effect at a given site of action, the toxin or its metabolite must reach the site of action in sufficient concentration to overcome the detoxification and repair mechanisms in the cells of the tissue (Lee and Dixon, 1978). Apart

from general aspects of the pharmacokinetics of absorption, distribution, metabolism and excretion of a toxic agent, several specific aspects of the male reproductive system's response to insult affect toxicity. These include: (i) the resistance offered by the BTB to testicular toxins; (ii) local and systemic biotransformation (activation, detoxification) of chemicals and (iii) the capacity of spermatogenic cells to repair cell damage and damage to DNA (Lee and Dixon, 1978; Dixon, 1983).

Both the testis and the liver contain mixed function oxidase systems which can metabolize (activate or detoxify) chemicals, and also enzymes which are capable of conjugating toxic chemicals for elimination (Lee and Dixon, 1978). In general, the elimination of numerous xenobiotic and endobiotic toxic chemicals requires concerted function of Phase I and II enzymes, as well as the membrane-spanning drug transporters (Sonoda *et al*., 2003). Mixed function oxidase activity appears to be found principally in the interstitial tissue of the testis, whereas conjugating enzymes, such as epoxide hydrase and glutathione-S-transferase, are found mainly in the tubules. In general, the levels of these enzymes are considerably lower than in the liver, but may be important in the local biotransformation of xenobiotics that penetrate the BTB. Certain compounds, such as direct-acting alkylating agents can affect cells without activation, but several testicular toxins, such as dibromochloropropane, PAHs, hydrazines and cytoxan, require metabolic activation first (Lee and Dixon, 1978). There may also be differences in the capacity of the testis to metabolize a given toxin at different stages of spermatogenesis, which may be one explanation for differences in sensitivity of different spermatogenic stages (Bateman and Epstein, 1971).

The timing of exposure is also of critical importance in determining toxicity. If exposure occurs *in utero*, normal sexual differentiation may be interrupted, resulting in anatomical abnormalities in the male gonads. Unlike in the female, however, where the complement of ova are developed *in utero*, the male gonad does not start to develop mature germ cells from the seminiferous epithelium until puberty, when spermatogenesis begins, so that prepubertal exposures would be expected to be of significance only if the testicular seminiferous cords of Leydig cells were irreparably damaged. Exposures to exogenous hormones such as sex steroids, if they delayed the onset of puberty and normal spermatogenesis, would be of importance if administered peripubertally. Once spermatogenesis has begun, the timing of exposure may alter the effect observed, depending on the stage(s) of spermatogenesis exposed and the agent involved. For example, in rodents, early spermatids appear to be two to three times more sensitive to the effects of ionizing radiation on mutation induction than epididymal sperm (Bateman and Epstein, 1971), but late spermatids and epididymal sperm are more sensitive to the effects of alkylating agents.

3.1.3.2 Examples of Toxins and Their Mechanisms and Sites of Action

3.1.3.2.1 Toxins Which May Affect Germ Cell Chromosomes, Genes and DNA or RNA Synthesis

Toxins that can interfere with normal meiosis and the accompanying numerical and structural rearrangement of chromosomes, that subsequently cause chromosomal or genetic damage or that interfere with DNA synthesis or replication are likely to be especially toxic to rapidly proliferating cells such as germ cells (Wudl and Sherman, 1983). Some oligopeptide antibiotics, such as netropsin and distamycin A, form stable complexes with DNA and inhibit DNA and RNA synthesis (Kornberg, 1980). Similarly, certain planar polycyclic aromatic compounds, such as acridine and actinomycin D, intercalate with the DNA molecule and disrupt its structure and function. Alkylating agents, among other actions, covalently bind to DNA base molecules or DNA-binding proteins, for example ethylnitrosourea is a potent mutagen, as shown by the specific locus test in the mouse, and induces reversible sterility in this species (Russell *et al*., 1979; Kennedy and O'Bryan, 2006). Other agents shown to be mutagenic in the mouse-specific locus test include cyclophosphomide, methyl, ethyl and propyl methanesulfonate, procarbazine and triethylenemelamine (Russell *et al*., 1981). A number of cancer chemotherapy drugs, such as niridazole, appear to suppress the meiotic division of spermatocytes (Mann and Lutwak-Mann, 1981).

Certain heavy-metal ions, such as mercury, lead and cadmium, can bind to phosphate, sulfhydryl and imidazole groups in proteins and disrupt the activity of a number of enzymes, such as DNA polymerase. These metals are generally cytotoxic, as they also interfere with the action of mixed function oxidases and phosphorylases, and may affect the transport of ions across cell and mitochondrial membranes.

There are a large number of chemicals which have been tested for dominant lethal mutations in rodents. According to a review of the literature by Green (1985), 65 chemicals could be considered positive in this test. Joffe and Soyka (1981) have also reported data showing that certain compounds, such as morphine, methadone, alcohol and lead, increase the frequency of postnatal mortality in rodents; the mechanism of this effect has not been elucidated. Owing to the methodological difficulties discussed above, there are no cytogenetic data on the induction of chromosomal or genetic mutations by these agents in human sperm, however. Several have been shown to affect sperm quality (see below). Only a few agents have been studied in relation to spontaneous abortions, heritable birth defects or later effects in man, mainly due to methodological difficulties, such as the large samples sized required, as discussed above.

Although some effects have been reported in man, none of the studies have provided conclusive evidence

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of a paternally mediated chromosomal or genetic effect on the foetus or offspring. Infante *et al*. (1976) reported an increase in spontaneous abortions among wives of men exposed to vinyl chloride. In another study by Lindbohm *et al*. (1991), specific mutagenic exposures were evaluated, involving paternal exposure to ethylene oxide, rubber chemicals, solvents used in refineries and solvents used in the manufacturing of rubber products. The study found an increased relative risk of spontaneous abortion, with the risk being higher among wives of rubber-products workers than among unexposed men. A number of early studies of lead-exposed men suggest an increased rate of abortion among their wives (Rom, 1976). Anaesthetic gas exposure has also been linked to abortion in wives (Tomlin, 1979), although not in other studies (Knill-Jones *et al*., 1975). There have been very few studies of paternal exposures and birth defects; a number of investigations using malformation registry data have not shown consistent associations (Barlow and Sullivan, 1982). Specific exposures studied include exposure to 2, 3, 7, 8-tetrachlorodibenzodioxin (TCDD) in Agent Orange used in Vietnam, reported by Erickson *et al*. (1984), who found no association with malformations and waste anaesthetic gas exposure among anaesthetists by Knill-Jones *et al*. (1975), who reported a significant increase in minor malformations, but this has not been confirmed in other studies. Gardner *et al*. (1989) reported a significant increase in childhood leukaemia associated with occupational radiation exposure of the fathers; this is the first case where a link between a paternal exposure to radiation and childhood cancer has been demonstrated.

3.1.3.2.2 Toxins Which Affect Spermatogenesis and Sperm Quality

There have been a large number of experimental studies of drugs, narcotics and chemicals on sperm parameters, including sperm count, viability, motility, velocity, morphology and *in vitro* fertilizing capacity (see reviews by Wyrobek *et al*., 1983a; 1983b; Pasqualotto *et al*., 2004). It is well known that different toxins may act selectively on different stages of spermatogenesis, affecting different germ-cell populations (Parvinen *et al*., 1993). It is often not easy to distinguish, however, even in experimental studies, whether observed effects on spermatogenesis are caused by direct effects on germ cells, damage to Leydig or Sertoli cells or effects on endocrine function, or by combinations of these effects. According to Bernstein (1984), there are a number of classes of organic compounds for which structure–activity relationships have been shown to predict for spermatotoxicity, and which have in fact been shown to affect sperm quality in animals (Wyrobek *et al*., 1983a). These include: (i) straight-chain two-and three-carbon compounds containing halogen atoms (e.g. ethylene dibromide, dibromochloropropane, halothane); (ii) organochlorine compounds with a symmetrical chlorinated carbon bridge (e.g. dichlorodiphenyltrichloroethane (DDT), methoxylchlor, heptachlor, chlordane and hexachlorophene pesticides); (iii) nitrobenzenes (e.g. 4-nitrobenzamide, dinoseb); (iv) certain organophosphates (e.g. the pesticides dichlovos, trichlorfon); (v) aminobenzenes containing sulfonic, carboxylic or hydroxyl solubilizing groups (e.g. the drug sulfasalazine, used to treat ulcerative colitis) and (vi) the glycol ether family of solvents, especially the methyl and ethyl forms. In addition, heavy metals and some of their compounds (Barlow and Sullivan, 1982; Davies, 1983); alkylating agents, antibiotics and antimetabolites used as cancer chemotherapeutic agents, such as cyclophosphamide, chlorambucil, adriamycin, cytosine arobinoside, vinblastine (Davies, 1983; Kinsella, 1989); other halogenated PAHs (e.g. polychlorinated and polybrominated biphenyls) and a number of other miscellaneous chemicals and biologically occurring toxins, for example, gossypol, are spermatotoxic (Davies, 1983).

A number of these agents have also been reported to affect semen quality in man, including the range of cancer chemotherapeutic drugs and the drugs prednisone, sulfasalazine (Wyrobek *et al*., 1983b); the recreational drugs alcohol, marijuana and, more equivocally, tobacco (Wyrobek *et al*., 1983a; Pasqualotto *et al*., 2004); the industrial chemicals carbon disulfide (Lancranjan, 1972), lead (Lancranjan *et al*., 1975; Assennato *et al*., 1986); dibromochloropropane (Whorton *et al*., 1977); ethylene dibromide (Ratcliffe *et al*., 1985; 1987); chlorodecone (kepone) (Cannon *et al*., 1978); chloroprene (Sanotskii, 1976) and the glycol ether 2-ethoxyethanol (marginally) (Ratcliffe *et al*., 1989). Physical agents shown to affect spermatogenesis in man include ionizing radiation (Kinsella, 1989). With radiation exposure, spermatogonial cells are the most sensitive, showing morphological and quantitative changes at doses as low as 10 cGy. Spermatocytes are functionally damaged at 200–3000 cGy, when they cannot complete maturation division, and spermatids at approximately 600 cGy; recovery of testicular function is directly related to the dose received, taking up to five years at doses of approximately 600 cGy, in some cases (Kinsella, 1989). Heating of the testis has also been shown to affect sperm count in man and other species reversibly; epididymal sperm seem to be most susceptible to short periods of an increase in temperature of even 2–3°C, such as may occur with repeated hot-tub use. Prolonged heating of the scrotum may affect earlier stages of spermatogenesis (Procope, 1965). Loss of sperm may be partly mediated by a decrease in androgen-binding protein synthesis (Rich and de Kretser, 1977). Environmental chemicals, including endocrine disruptors, have been suggested as factors in the decline in sperm count and the increasing incidences of hypospadias and testicular cancer observed in many countries (Ansell *et al*., 1992; Carlsen *et al*., 1992; Giwercman and Skakkebaek, 1992; Sharpe, 1993).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3.1.3.2.3 Toxins Which Affect Sexual Behaviour

The assessment of libido and potency presents difficulties in humans, particularly when studied epidemiologically, since reliance must be placed largely on self-reported symptoms, and there is no good animal model (other than, e.g. mating frequency or ejaculatory capacity) for this complex area of sexual function. In humans, a number of drugs, which act on the CNS or the autonomic nervous system have been reported to affect libido, erectile potency or ejaculatory function (Woods, 1975). The two largest categories of drugs are antihypertensives and psychoactive drugs (Editorial, 1979). Antihypertensives may affect both erectile potency and ejaculation. Antidepressants may cause impotence via an anticholinergic action (tricyclics) or peripheral ganglionic blockage (monoamine oxidase inhibitors). Certain sedatives and tranquillizers, such as benzodiazepines and phenothiazines, notably thioridazine, may act at several sites, by both decreasing libido at a central level and inhibiting autonomic nerve transmission at a peripheral level to impair ejaculation. It is possible that hypothalamic and pituitary function is also disturbed by phenothiazines, according to Woods (1975). Centrally acting drugs of abuse, including heroin, marijuana, alcohol, lysergic acid diethylamide (LSD) and amphetamines, have all been reported to affect libido and potency in men, particularly after prolonged use. The use of anabolic steroids was reported to decrease libido and potency (together with other spermatotoxic effects in male athletes in one study) (Frasier, 1973). Some industrial chemicals have been reported to affect libido and/or potency, notably carbon disulfide, boric acid, lead and the pesticide kepone (chlordecone) (Barlow and Sullivan, 1982), but findings are not consistent.

3.1.3.2.4 Toxins Which Affect Endocrine Function

Disruption of endocrine secretions, binding, feedback control or target activity can be affected by action at several sites. Often it is not clear, when an alteration in hormone activity is observed, whether this is the result of a primary effect on hormone secretion or a response to testicular damage or some other mechanism. Cimetidine, used in the treatment of peptic ulcers, appears to act by competing with dihydrotestosterone for androgen receptors in the testis and accessory sex glands (Winters *et al*., 1979), resulting in decreases sperm count, gynaecomastia, increased prolactin secretion and decreased prostate and seminal vesicle weight. The persistent DDT metabolite *p*, *p*′-DDE (dichlorordiphenyldichloroethane) has been shown to be a potent androgen receptor antagonist (Kelce *et al*., 1995). LH receptors in Leydig cells have been shown to be depleted in rats exposed to ionizing radiation *in utero* (Rich and de Kretser, 1979). Men working on the production of oral contraceptives were found to have gynaecomastia (Harrington *et al*., 1978); these exogenous steroids are thought to act by suppressing gonadotrophic hormone secretion. Some of the chlorinated PAHs (e.g. polychlorinated biphenyls (PCBs), hexachlorophene) may act by either oestrogen agonism or by inducing mixed function oxidases which increase the clearance of endogenous steroids (Mattison, 1981); this may explain their observed effect on spermatogenesis.

There is one striking example of the effect of exogenous oestrogenic hormone exposure occurring *in utero* and affecting foetal gonadal development. Diethylstilbestrol (DES), a synthetic oestrogenic drug widely prescribed to pregnant women in the 1940s and 1950s to prevent miscarriage, premature delivery and toxaemia, exerted a dramatic effect on male foetal gonadal development by antagonizing the activity of foetal testosterone. The key aspect of the toxicity of DES is its lack of binding to maternal steroid-binding protein or conjugation in foetal liver, processes which protect the developing male genital tract from damage by maternal oestrogens from the placenta and ovaries (Gill, 1989). Numerous structural and functional abnormalities of the reproductive system have been observed in the male offspring, including epididymal (spermatocoele) cysts, testicular hypoplasia, cryptorchidism, hypospadias, abnormal semen parameters and primary infertility (Gill *et al*., 1979; Stenchever *et al*., 1981; Whitehead and Leiter, 1981; review by Gill, 1989). There are conflicting reports of testicular cancer in exposed males, perhaps due to methodological limitations (Gill, 1989).

3.1.3.2.5 Toxins Which Affect Accessory Sex Gland Function

There are relatively few examples of toxins which directly affect these tissues. α-Chlorohydrin and 6-chloro-6-deoxy sugars affect glucose metabolism of epididymal spermatozoa, and at high doses α-chlorohydrin damages the epithelium of the cauda epididymus, causing spermatoceles (Zanefeld and Waller, 1989). Sulfasalizine, probably acting via an active metabolite, affects the fertilizing capability of sperm in rodents and man, apparently by inhibiting the acrosome reaction, either by an effect on epididymal function, so that sperm maturation is impaired, or by a direct effect on the sperm (Zanefeld and Waller, 1989). Hexachlorophene has been found to impair ejaculation in rats by causing fibrosis of the prostate (Gellert *et al*., 1978). Toxins which can impair the motility of spermatozoa *in vitro* could, if found in the secretions of the seminal vesicles or prostate, affect the motility of the sperm after ejaculation. Imidazoles, such as the oral antifungal agent ketoconazole, have been shown to be transported into seminal fluid and to immobilize sperm (Zanefeld and Waller, 1989).

3.2 Effects on the Female Reproductive System

3.2.1 Introduction

Reproduction in the female mammal involves a complex series of inter-related steps under hormonal control via the hypothalamo-pituitary-ovarian axis. These steps involve follicular development, ovulation, ova transfer, fertilization, transport of the conceptus, and its subsequent implantation, and development culminating in parturition. All of these processes are important and are the summation of many systemic, local, cellular and molecular interactions, which still remain poorly understood.

Because of the complexity of the reproductive system and the species differences involved, a description based on the human female will be used with additional information given on other species where appropriate. Basically, female reproduction will be described under the following headings: general physiology of the female reproductive tract, the hypothalamo-pituitary-ovarian axis, the ovary, including ovarian cycles, and the various ways in which these systems can be adversely affected.

3.2.2 General Physiology of the Female Reproductive System

The female reproductive tract consists basically of paired gonads, or ovaries, and a system of hollow ducts, the oviducts, for transport of eggs to the exterior. The oviduct is modified in several ways according to the species and its characteristic mode of reproductions. In humans, the oviducts consist of paired uterine tubes (Fallopian tubes) connected to a single mid-line uterus terminating in a vagina. All of these components are inter-related and are sensitive to hormonal changes, which are controlled by the hypothalamo-pituitary-ovarian axis. This hormonal controlling system is also responsible for the development of secondary sexual characteristics, for example, mammary gland development, fat disposition and, especially in humans, hair distribution and voice changes (Takizawa and Mattison, 1983; Johnson and Everitt, 1988; Knobil and Neill, 1994; Plowchalk *et al*., 1993; Osorio and Windham, 1997).

3.2.2.1 The Hypothalamo-Pituitary-Ovarian Axis

The hypothalamus is a complex structure involved in the control of body temperature, integration of autonomic activity and the release of GnRH. GnRH is carried in the blood via the hypophyseal portal system to the anterior pituitary gland. The anterior lobe of the pituitary contains a variety of cells which release gonadotrophic hormones, FSH, LH, prolactin and other hormones. Prolactin release is under the control of dopamine, released from neurons in the median eminence. Whereas GnRH stimulates the release of FSH and LH, dopamine inhibits the release of prolactin. The target organ for FSH and LH is the ovary. The role of prolactin is less clearly defined and its actions are more species specific. In some rodents, for instance, it has the ability to maintain the corpus luteum (CL) and there is some evidence in humans that it may be involved in luteolysis and in lactation (Lunenfeld and Insler, 1993; Ryan, 1993).

The release of GnRH from the hypothalamus is controlled by a number of feedback loops, principally from the hormones produced by the ovary (Yen, 1991). Although the exact mechanisms and site of action are not fully understood, it is generally thought that tonic release of FSH is involved in follicle growth. As the follicle grows it secretes increasing amounts of sex steroids, predominantly oestrogen, which has negative feedback effect on the hypothalamic pathways resulting in decreased release of FSH from the pituitary (Sadow *et al*., 1980; Feder, 1981a; McCann, 1981; Ben-Menaham and Naor, 1994; Insler and Lunenfeld, 1993).

In some mammals, other factors such as temperature and light intensity, also affect hormone secretion, presumably via other CNS mechanisms (Elliot and Goldman, 1981; Komisaruk *et al*., 1981).

3.2.2.2 The Ovary

The ovary plays a central role in that it controls the production of gametes and sex steroids, which are regulated via the hypothalamic-pituitary pathways. The principal site of action of these ovarian hormones is the uterus, which responds by undergoing cyclical changes which enable conception and foetal development to occur (Ryan, 1993; Paul, 1995).

3.2.2.2.1 Ovarian Development

The ovary develops from the germinal ridge and descends into the pelvis in the early part of foetal life. The germ cells or oocytes, are formed before birth and develop to the primary oocyte stage having undergone the first phase of meiosis (Ross and Schreiber, 1978; Feder, 1981c; Larsen, 1993). They remain in this resting oocyte–follicle complex until they are stimulated by gonadotrophin release at the onset of puberty (Moor and Warnes, 1979) to produce the characteristic mammalian Graafian follicle. Thus, any agents that damage the oocytes will accelerate the depletion of this resting pool and may lead to a reduction in fertility. At maturity, the ovary undergoes cyclical activity of a biphasic nature during which follicles undergo growth, maturation and regression.

In humans it is estimated that in excess of half a million follicles are present at birth; many of these die (atresia) and those that survive are continuously reduced in number. It is estimated that fewer that 500 will be ovulated and fewer still will be fertilized to produce offspring (Sadow *et al*., 1980; Page *et al*., 1981).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

These ovarian cycles are species specific; some of the similarities and differences are described in the next section (Johannisson, 1990; Adashi, 1991).

3.2.2.2.2 Ovarian Cycles

Ovarian cycles, that is, oestrous cycles, and menstrual cycles in the higher primates and humans, vary in their length and frequency of occurrence. Their duration may be a few days, that is, in the mouse, or several weeks, as humans and the horse. The term 'oestrus' refers to the period when the female is most receptive to the male, that is, 'in heat', which usually coincides with high levels of circulating oestrogen and subsequent stimulation of sexual excitement and behaviour patterns (Feder, 1981b). The human female does not exhibit oestrus behaviour as such, even though changes do occur in the reproductive organs, but there is no clear correlation between the secretion of oestrogens and sexual drive or libido.

Mammals having a succession of oestrous cycles, for example, rodents, are called polyoestrous. In others, such as the goat, the cycles are limited to a particular season of the year, that is, the breeding season. The interval between cycles is of relative quiescence and is termed 'anoestrus'. Other mammals, such as cats, dogs and ferrets, are monoestrous. They have one long sustained oestrus during the spring and occasionally another in late summer (Perry, 1971; Elliot and Goldman, 1981). In humans and the high primates such as Old World monkeys and apes, the cycles occur at approximately monthly intervals and are termed menstrual cycles (*mensis* = month). These cycles differ from those of most other mammals in that there is external loss of blood, that is, menstruation at the end of each cycle.

In most mammals, ovulation occurs spontaneously under hormonal control via the hypothalamo-pituitary-ovarian pathways, either during or just after oestrus. However, in some monoestrous animals such as the dog, the additional stimulus of mating is required to trigger ovulation, that is, induced ovulation.

This complex series of events involved in the hormonal control of follicle maturation, ovulation, luteinization and luteolysis will be illustrated by reference to the human menstrual cycle. Significant species differences will be discussed where appropriate (Sadow *et al*., 1980; Feder, 1981a; 1981b; Page *et al*., 1981; Taubert and Kuhl, 1993).

3.2.2.2.3 Menstrual Cycle

The complex process by which a single dominant follicle is selected for ovulation is not well understood (Bahr *et al*., 1977; Takizawa and Mattison, 1983; Greenwald and Terranova, 1988; Espey, 1989). However, it is generally accepted that tonic release of FSH from the pituitary stimulates follicular growth. As the follicle grows, it secretes sex steroids, predominantly oestrogen at this stage. As oestrogen levels increase, they eventually trigger off a reflex discharge of FSH and LH from the anterior pituitary, which results in the release of a preovulatory LH surge. Oestrogen also has a negative feedback on the hypothalamic-pituitary pathways to decrease the amount of FSH released. Following the LH surge, there is an increase in LH concentration in the follicular fluid, which is associated with oocyte maturation, preovulatory progesterone secretion by the granulose cells and the stimulation of prostaglandin (PG) synthesis. Ultimately this results in the rupture of the dominant follicle and the release of the oocyte, that is, ovulation occurs (Chaslow and Pharriss, 1972; Delforge *et al*., 1972; McNatty *et al*., 1975; Gore-Langton and Armstrong, 1988; Lunenfeld and Insler, 1993; Tsafriri and Braw-Tal, 1993). In some mammals there is a slight blood-stained discharge associated with ovulation, which is different from menstruation.

Following ovulation, the remaining follicles become atretic. The dominant follicle collapses and the granulose cells begin to proliferate to form the CL. In humans, the main hormone secreted by the CL for about 8–10 days is progesterone. If fertilization occurs, the conceptus, even prior to implantation, is thought to secrete substances which are recognized by the mother and prevent the breakdown (luteolysis) of the CL (Heap *et al*., 1979). In the cow, PG synthesis is suppressed by embryonically derived pregnancy-specific proteins (Goding, 1974). Similarly in the pig, the blastocyst produces oestrogens which lead to maternal recognition of the conceptus and also inhibit PG synthesis. However, in primates such as monkeys, apes and man, the conceptus secretes human chorionic gonadotrophin (hCG) which supports the CL and maintains a suitable endometrium.

If fertilization does not occur, the CL undergoes luteolysis and its endocrine function ceases. Luteolytic mechanisms tend to be species specific. In rodents, rabbits, cattle, sheep and pigs, PG via the utero-ovarian circulation plays a major role. PG-induced vasoconstriction may also be a contributory factor (Karim, 1972; Cole and Cupps, 1977). In contrast, the primates do not seem to control luteolysis in this way. Although the mechanisms are poorly understood, it seems that alterations in the concentrations and inter-relationships of various hormones, sex steroids, gonadotrophins, prolactin and PG initiate a feedback loop to the hypothalamus and trigger off the release of gonadotrophins, for example, FSH and LH, to initiate the next cycle (Feder, 1981b; Takizawa and Mattison, 1983; Richardson, 1986; Johnson and Everitt, 1988).

3.2.2.3 Oviducts/Fallopian Tubes

The anatomy of the tubes is species specific and related to the way in which ovulation and fertilization occur. The tubes are the site of fertilization and their rich autonomic nerve innervation assists egg retention. The lumen of each tube is bathed with fluid, whose composition and direction of flow are under the control of sex steroids and the autonomic nervous system and varies at different stages of the cycle. In general, egg transport from the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

ovary to the uterus seems to be a cumulative effect of coordinated cilial motility, muscle contractions and subsequent fluid flow. Tubular mobility is controlled by the synergistic effects of oestrogen and progesterone, and in humans during the luteal phase it is towards the uterus (Sadow *et al*., 1980; Page *et al*., 1981; Takizawa and Mattison, 1983; Villalon *et al*., 1991; Verdugo and Villalon, 1993).

3.2.2.4 The Uterus

The anatomy and physiology of the uterus are also species specific. In many species, the uterus acts simply for the transfer of sperm, whereas in others, such as rodents, cows and pigs, it acts as a sperm reservoir.

In humans, the uterus undergoes hormonally dependent alterations in the endometrium during the cycle to prepare the uterus for implantation and subsequent development of the conceptus (Johannisson, 1990). During the preovulatory phase, the follicular-derived oestrogen increases uterine blood flow and stimulates endometrial development. After ovulation, the synergistic actions of oestrogen and progesterone complete this process. The effects of progesterone on the oestrogen-primed endometrium are pleiotropic, causing an increase in protein synthesis and microvilli formation. There is increased vascularity, permeability and discharge of secretory products into the endometrial lumen of the glands which enables the conceptus to implant (Johnson and Everitt, 1988; Dockery *et al*., 1990; Kim-Bjöerklund *et al*., 1991).

The time taken for the conceptus to implant varies with the species and is generally not known. However, it is known that receptivity for implantation has a limited time span in rodents at five to six days and in humans at about seven days (Psychoyos, 1962; Edwards, 1982). The myometrium, on the other hand, remains quiescent for most of pregnancy. However, towards the end of pregnancy, it develops a coordinated pattern of contractions which assist in the expulsion of the foetus at parturition. There are many and varied theories as to the mechanisms controlling this, but on the whole it is accepted that PG synthesis and degradation is one of the key control factors (Porter and Finn, 1977; Yen, 1978; Challis and Lye, 1986; Johnson and Everitt, 1988).

3.2.3 Mechanisms of Action of Reproductive Toxins

As successful reproduction in the female relies on a complex system of hormonally controlled inter-related events, toxic insults at any one stage of this process can have profound effects on both the mother and the foetus. Agents may act directly on germ cells so that conception does not occur, or they may cause severe anomalities resulting in early abortions. Some of the abortuses have been shown to have chromosomal damage. Alterations in sex rates may occur, but interpretation of existing data is difficult. Outcomes involving the prenatal period may involve low birth weights, stillbirths, neonatal deaths, chromosomal damage or gross structural malformations.

Just as there are species-specific differences in the physiology and hormonal control of the reproductive processes, there are also differences in response to toxins. This may in part be explained by the interspecies differences in the pharmacokinetic responses, that is, absorption, distribution, metabolism and excretion of a particular toxin. Other factors, such as gender differences and duration of exposure to the toxin, are also involved.

The principal action of toxins is to alter, in some way, the normal functioning of cells, organs or organisms. Toxins may inhibit ovulation, ova transport, fertilization and implantation by altering the environment within the oviduct. In order for toxins to exert such effects they must have an adequate distribution to the target organ. Alternatively, they may have a much wider range of effects which may be nonspecific and may act at many sites within the organism (Dixon, 1980; Mattison, 1981; Mattison, 1983; Kamrin *et al*., 1994).

3.2.3.1 Mechanisms of Toxicity

Toxins may act directly or indirectly. Toxins may have a direct action because they bear structural similarities to an endogenous substance, for example, hormones, or because of their chemical reactivity, for example, alkylation agents. Others may act indirectly by requiring various metabolic processes prior to exerting their toxic effect or by metabolism to an active metabolite, which may then exert its effect by direct mechanisms. In addition, some indirectly acting toxins exert their effect by altering the controlling mechanisms, for example, inhibition of gonadotrophin release or enzyme-induction inhibition (Forman *et al*., 1996; Daston *et al*., 1997; Gray *et al*., 1997).

Toxins may exert their effect by more than one mechanism of action. The halogenated PAHs, for example, PCBs or PBB (polybrominated biphenyls), behave in such a way, in that they may act indirectly by induction of microsomal mono-oxygenases or transferases or directly because of their steroid hormone agonist properties (Doull, 1980; Neal, 1980; Moses, 1993; Kippen, 1996).

3.2.3.2 Directly Acting Toxins

Toxins which have structural similarities to biologically active molecules are generally agonists or antagonists of endogenous hormones. Oral contraceptives belong to this group in that they act predominantly by suppression of gonadotrophin release (Chasan-Taber *et al*., 1997). Workers who manufacture oral contraceptives are at risk from this type of reproductive-endocrine toxicity (Harrington *et al*., 1978; McDiarmid, 1993). There is also evidence that occupational exposure to antineoplastic drugs is associated with an increased incidence of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

infertility (McDiarmid, 1993; Valanis *et al*., 1997). Exposure to other occupational and environmental substances which have oestrogenic or progestogenic activity may inhibit gonadotrophin release or ovarian function via the hypothalamus and pituitary pathways. Other chemically reactive compounds may be nonspecific in their site of action. This category includes the alkylating agents, the toxic effects of which have been discussed above.

3.2.3.3 Indirectly Acting Toxins

Indirectly acting toxins are substances that may require metabolic activation and the metabolite thus formed may itself be chemically reactive or may mimic an endogenous protein. Oxidation by microsomal mono-oxygenases is one of the mechanisms involved in removing hydrophobic xenobiotics from the body. It has been shown that the ovary has microsomal mono-oxygenases, epoxide hydrases and transferases capable of metabolizing many xenobiotics (Heinrichs and Juchau, 1980). The polar metabolites thus formed may undergo conjugation or be excreted directly. However, some of these metabolites are chemically reactive and are capable of interacting with cellular macromolecules in the same way as exogenously administered substances. Cyclophosphomide (Koyama *et al*., 1977; Lentz *et al*., 1977), DES (Metzler and McLachlan, 1978), ethanol (Ouellette *et al*., 1977; Sullivan and McElhatton, 1986) and the PAHs (Felton *et al*., 1978; Nerbert, 1981) are examples.

Other indirectly acting toxins may affect enzymes, that is, induce or inhibit enzyme systems, which in turn may stimulate or inhibit steroid production or excretion. As the reproductive system is controlled by hormonal feedback loops, substances which alter the steroid balance in any way may have a profound effect on the entire reproductive process. Rodent studies have shown that some of the polyhalogenated hydrocarbons, for example, DDT, PCB, PBB, behave in this way. Some toxins may actually enhance rather than impair fertility. Oral contraceptives, for instance, exert fertility regulation via feedback inhibition of gonadotrophin secretion, and xenobiotics that stimulate clearance of the oestrogenic and/or progestogenic component in the oral contraceptive will cause a decrease in circulating level and consequently may increase the probability of ovulation (reviewed by Mattison, 1983).

3.2.3.4 Interference with Detoxification

Detoxification mechanisms are the methods by which biological organisms respond to toxic insults. Some of these mechanisms have shown to be present in the ovary. They tend to have a relatively broad-based specificity, and may involve conjugation hydrolysis by epoxide hydratase in order to decrease the concentration of the toxin, or metabolism to a less toxic or more easily excreted metabolite and thus limit the activity of the toxin in the body. Impaired detoxification due to the nature of the substrate or enzyme deficiencies within the organism will enhance the toxic effects.

3.2.3.5 Repair

Despite the presence of detoxification pathways within the cell, cellular or organ damage can still occur. In such a situation, attempts are made to repair the damage by various mechanisms. The repair may simply involve alteration in protein synthesis to replace nonfunctioning proteins destroyed by the toxic insult, or more sophisticated repairs may be required if the DNA itself has been damaged, involving excision and subsequent replacement of the damaged DNA region. There is some evidence to suggest that mature oocytes are able to repair damage within the oocyte DNA prior to and after fertilization. However, it is not known whether the oocyte has other types of repair mechanism (Lehmann and Bridges, 1977; Dixon, 1980; Mattison, 1983).

A more detailed account of some of the reproductive toxins and their proposed modes of action is described below.

3.2.4 Sites and Mechanisms of Action of Some Reproductive Toxins

3.2.4.1 The Hypothalamo-Pituitary-Ovarian Axis

Chemicals can act at several levels, on the hypothalamus, pituitary, the endocrine and ovulatory function of the ovary or on the tissues in the reproductive tract, and frequently may act at several sites (Miller and Bellinger, 1993; Paul, 1993; Welch, 1993).

The mode of action of the chemical may give some indication as to whether the toxic effects it produces are reversible or not. Drugs and other chemicals that alter gonadal function directly may well produce infertility via genetic effects, which are irreversible, whereas those producing alterations in the nerve pathways in the hypothalamus, for instance, may cause disruption of fertility, which is reversible.

Ketoconazole, a broad-spectrum antifungal drug, inhibits steroid synthesis by inhibition of cytochrome-P450-dependent enzyme systems, giving rise to a number of endocrine abnormalities (Loose *et al*., 1983). In women, spironolactone acts as an oestrogen antagonist, which may explain the reported menstrual disturbances associated with its use (Levy *et al*., 1980).

Certain CNS drugs such as tranquillizers, barbiturates, narcotics and ‘social’ drugs, such as marijuana, have an inhibitory effect on hypothalamic pituitary function by inhibiting gonadotrophin secretion (McDiarmid, 1993). In animal studies, effects, such as suppression of ovulation, oestrus and fertility, have been reported. Thus, the primary endocrine effect of inhibition of gonadotrophins induces a secondary effect on ovarian steroid synthesis,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

resulting in adverse effects on growth, development and function of the accessory organs.

As the nerve pathways to the hypothalamus are adrenergic and dopaminergic, drugs which alter catecholamine levels, either by inhibiting CNS activity, for example anaesthetics, sedatives, tranquillizers and analgesics, or by stimulating the CNS, for example psychotropic drugs, antidepressants and hallucinogens, can also affect the hypothalamic-pituitary control of gonadotrophin release. Such actions may result in alterations in the secretions of FSH, LH and prolactin, which are important for follicle growth, oocyte maturation, ovulation and maintenance of the CL. However, the CNS and autonomic effects of such drugs are often difficult to distinguish. Similarly, nitrous oxide in high concentrations has been reported to reduce fertility among women employed in dentistry, but the mechanism of action is undetermined (Rowland *et al*., 1992). Drugs of abuse, such as cocaine (crack), ecstasy, cannabis, mescaline and alcohol may also have adverse effects on reproduction, such as decreased fertility, an increase in spontaneous abortions, intrauterine growth retardation (IUGR) and postnatal behavioural problems in the offspring, but these effects are less well documented and their exact mechanisms of action are not known. The study of social drug use and of drugs of abuse in pregnancy is complex because it has been shown, for example, that heavy smokers are often also heavy drinkers and caffeine consumers. Similarly, smoking and alcohol consumption are common in addicts, which, combined with their general lifestyle and poor nutrition, makes identification of the individual contributions of each substance to any one adverse effect difficult.

Some of the drugs which have been studies more extensively are discussed below and have been reviewed by Rosen and Johnson (1982), Abel (1983), Gibson *et al*. (1983), Smith (1983), Armstrong (1986), Boobis and Sullivan (1986), Johnson and Everitt (1988), Clark and Weinstein (1993), Schardein (1993), Ellenhorn *et al*. (1997) and Gilstrap and Little (1998).

3.2.4.2 Major Drugs of Addiction

Adverse reproductive effects, such as a decreased sexual desire, menstrual irregularities, infertility and increased foetal loss have been reported (Wallach *et al*., 1969; Wieland and Yunger, 1970; Finnegan, 1981; Liel *et al*., 1993). The adverse effects on early foetal and postnatal development following intrauterine exposure have been well documented (Ostrea and Chavez, 1979; Sullivan and McElhatton, 1986; Fulroth *et al*., 1989). This has been partly attributed to altered function of the hypothalamo-pituitary axis and partly to altered ovarian functions. Some of the narcotics are reported to cause a significant decrease in LH levels, which may disrupt oocyte maturation and ovulation and interfere with the FSH-LH feedback loops to the hypothalamus.

3.2.4.3 Marijuana

Marijuana is a complex group of drugs derived from the plant *Cannabis sativa*. Recent animal tests and human studies have indicated that chronic, sustained exposure is associated with reproductive dysfunction (Peterson, 1980; Abel, 1983; Hollister, 1986; Ellenhorn *et al*., 1997). A study of marijuana users has reported that these women had shortened menstrual cycles and a higher proportion of these cycles was anovulatory or had shorter luteal phases (Kolodny *et al*., 1979). The psychoactive component is Δ^a-tetrahydrocannabinol (THC) and it is thought that it inhibits the secretion of FSH and LH via a hypothalamic route with secondary effects on the ovary. However, the Kolodny *et al*. study did not confirm these effects as regards gonadotrophins or progesterone, but found a significant decrease in serum prolactin. Experimental studies have shown that the duration of gonadotrophin depression is dose related and persists for up to 24 hours after peak levels of the drug have occurred in the circulation. Furthermore, these effects can be reversed by giving leutinizing hormone releasing hormone (LHRH). THC has also been shown to depress oestrogen production and the LH surge and thus inhibit ovulation in rhesus monkeys. One small double-blind study in 16 women has shown that marijuana smoking significantly depressed LH levels for up to 120 minutes when compared with a placebo (Mendelson *et al*., 1986). Rodent studies have also indicated that there is a decrease in serum prolactin, possibly by THC inhibiting its release from the pituitary. Other studies indicate a decrease or absence of oestrogen and gonadotrophins, but a marked rise in progesterone (Smith *et al*., 1980). It would seem that the data within a species are variable and that there are species-specific differences.

3.2.4.4 Alcohol

The effects of alcohol on female reproduction have been studied in terms of its possible teratogenic effects on the offspring, producing the foetal alcohol syndrome (Jones and Smith, 1975), and also a wide range of other adverse effects, such as increased spontaneous abortions (Harlap and Shiono, 1980), IUGR (Little, 1977), overall failure to thrive postnatally and some mental retardation (Streissguth *et al*., 1978; Mello *et al*., 1989). As alcohol has significant pharmacological effects via the central nervous system in adults, it is probable that the hypothalamic-pituitary pathways and thus reproductive hormone control may also be adversely affected. Whether adverse effects on hormones occur in the developing foetal brain is not known (Root *et al*., 1975). Chronic use of alcohol has been associated with various obstetric and gynaecological problems, such as menstrual disorders, recurrent miscarriages and infertility. However, there is no clearly defined evidence to assess whether alcohol consumption is the cause of such problems (Abel, 1983; Boobis and Sullivan, 1986; Liel *et al*., 1993; Olsen *et al*., 1997).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Studies in which female rats consumed alcohol showed atrophy of the ovaries, Fallopian tubes and uteri, and the ovaries from these rats had fewer well-developed follicles, corpora lutea and secretory granules (Van Thiel *et al*., 1978). It has been shown that infusions of alcohol in female rats cause inhibition of spontaneous LH release, but no inhibition of LH release by LHRH, so that ovulation may be affected by inhibition of LH release (Kieffer and Ketchel, 1970; Blake, 1974).

3.2.4.5 Gonadal Dysfunction Resulting from Cancer Chemotherapy

Alkylating agents (e.g. cyclophosphamide, chlorambucil, busulfan, nitrogen mustard) the vinca alkaloids (e.g. vincristine, vinblastine, vindesine) and radiation produce varying degrees of gonadal dysfunction, which are not only dose related, but also associated with the age at which the exposure occurs. In women, irreversible sterility resulting in premature menopause and sexual dysfunction occurs at higher doses than in males. Lesser degrees of gonadal injury are associated with subfertility, but normal sexual function. Age at the time of exposure is an important factor in that children apparently sustain less gonadal damage for a given dose than do adults (Liel *et al*., 1993; Schardein, 1993).

The ovaries of prepubertal girls are more resistant than those of adults to toxicity induced by cytotoxic chemotherapy, in that the majority who survive the illness go on to have normal menstrual cycles and serum gonadotrophin levels. Furthermore, post-mortem examination of some of the girls whose illness proved fatal showed that their ovaries were normal (Arniel, 1972; Pennisi *et al*., 1975; Lentz *et al*., 1977). In a study of prepubertal, leukaemic children who died, cytotoxic therapy (usually prednisone, vincristine and occasionally methotrexate, 6-mercaptopurine, cytosine arabinoside and l-asparaginase) was shown to inhibit follicle development in the ovaries, as opposed to ova destruction, which is sometimes seen in adults receiving similar therapy (Himelstein-Braw *et al*., 1978).

In mature women, treatment with cytotoxic drugs has variable effects on gonadal function and fertility. Age-dependent factors and also dose and duration of treatment often determine the degree of toxicity observed. However, insufficient data are available to determine critical dose levels for a given age group (Warne *et al*., 1973). Teenagers, for instance, may sustain impaired fertility, whilst serum hormone levels and menstrual cycles remain normal, whereas women in their 20s may develop clinical ovarian dysfunction, the reversibility of which is often dependent on the particular drug regime. Abnormal ovarian function may manifest itself in terms of irregular or anovulatory cycles, alteration in serum gonadotrophins and oestradiol levels, sometimes resulting in premature menopause (hot flushes, insomnia, irritability, depressed libido) and menopausal levels of oestradiol and gonadotrophins. The intensity of such symptoms is often age related in that they tend to be worse in younger women (Chapman, 1983). Although the critical age at which most women undergoing such treatment are likely to develop ovarian failure is not known, multiple drug exposure does seem to increase the risk. For instance, more than 80% of women over the age of 25 years developed complete and irreversible ovarian failure after six cycles with MOPP (mechlorethamine, oncovine (vincristine), procarbazine and prednisone) or MVPP (mustine, vinblastine, procarbazine and prednisolone) (Chapman *et al*., 1979b; Schilsky *et al*., 1981).

Cyclophosphamide alone may produce a reversible form of ovarian dysfunction or complete ovarian failure, in which amenorrhoea, abnormal hormone levels or ova destruction may occur (Kumar *et al*., 1972; Uldall *et al*., 1972; Rose and Davis, 1977). Cyclophosphamide seems to have an affinity for attacking the resting or small oocytes. As these are present throughout the life of the female in the same metabolic state, it cannot account for the age-dependent differences in sensitivity. However, there is evidence that the pathways for detoxification of the reactive metabolites do change with age and this may be a key factor (reviewed by Mattison, 1981).

Busulfan use has also been associated with permanent amenorrhoea, a side effect which also seems to be age related (Belohorsky *et al*., 1960; Schulz *et al*., 1979). Autopsy data from a small number of women treated with busulfan have shown signs of ovarian atrophy (Belohorsky *et al*., 1960; Heller and Jones, 1964).

Neither the vinca alkaloids nor nitrogen mustard alone seem to be associated with ovarian dysfunction. However, there have been occasional case reports of women who developed either reversible or permanent amenorrhoea after vinblastine therapy (Sobrinho *et al*., 1971).

There are many secondary effects, which follow on from ovarian toxicity, leading to early menopause, such as a greater risk of developing osteoporosis, cardiovascular disease and uterine cancer. To some extent these effects can be ameliorated by giving sequential hormone therapy or replacement therapy with oestrogen and progesterone (Gambrell, 1978; Chapman *et al*., 1979a; 1979b; Nordin *et al*., 1980; Paganini-Hill *et al*., 1981; Whitehead *et al*., 1981).

6-Mercatopurine, the active metabolite of azathioprine, has been shown in experimental rodent studies to reduce the fertility of female offspring exposed *in utero* (Gross *et al*., 1977; Reimers *et al*., 1980). It seems to act by causing premature ovarian failure, but whether the mechanism is oocyte destruction *per se* or inhibition of oogenesis is not known. The reproductive toxicity of this group of drugs was reviewed by Schardein (1993).

3.2.4.6 Ovotoxicity

PAHs are ubiquitous environmental pollutants. This group includes substances produced by the combustion of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

fossil fuels contained in car exhaust fumes, smoke stack emissions and cigarette smoke. The PAH group have been implicated as carcinogens, neurotoxins, hepatotoxins and reproductive toxins. They produce their reproductive toxicity by a variety of mechanisms including induction of microsomal monooxygenases, which alter hormone production and clearance, and also metabolism to active intermediates and hormone agonist activity (Mattison *et al*., 1983; Paul, 1993).

PAHs require conversion to reactive intermediates via microsomal cytochrome-P450-dependent mono-oxygenase and epoxide dyrase before they can exert their toxic effects within any biological system. Such converting enzymes are widely distributed throughout the body and are found in high levels in the liver and gonads. It has been demonstrated that in order to cause oocyte destruction, PAHs need to be distributed to the ovary and converted into one or more active intermediate(s) that cause oocyte destruction by either a direct action on the oocyte or by an indirect route via toxicity to the granulose cells that support the oocyte within the follicle (Mattison and Ross, 1983). It is thought that differences in ovarian metabolism may account for strain and species differences in sensitivity to PAH-induced oocyte destruction. Treatment during pregnancy is capable of destroying the oocytes of a female foetus whilst *in utero* (Felton *et al*., 1978).

The susceptibility of NHP and humans to oocyte destruction by PAHs is not known. It has been shown, however, that women who smoke one or more packs of cigarettes per day have a menopause about two years earlier than nonsmokers (Jick *et al*., 1977). The mechanism suggested is that the PAHs in cigarette smoke destroy the oocytes at an earlier age.

3.2.4.7 Oestrogenic Chemicals

Many other halogenated hydrocarbons, including pesticides and fungicides such as DDT, aldrin, 2,4,5-trichlorophenoxyecetic acid (2,4,5-T), PCB, PBB, 2,4-dichlorophenoxyacetic acid (2,4-D), heptachlor, chlordane and hexachlorophene, can interfere with mammalian reproduction in two main ways, namely oestrogen agonist activity and induction of microsomal mono-oxygenase activity responsible for production and clearance of steroid hormones (Mattison, 1981; Barlow and Sullivan, 1982; Bulger and Kupfer, 1983; Safe, 1984; Moses, 1993; Schardein, 1993; Osorio and Windham, 1997).

Treatment of neonatal rats with DDT has led to a dose-dependent premature vaginal opening culminating in an anovulatory syndrome with similarities to the human polycystic ovary disease. These effects, including the inhibition in the rise of gonadotrophins following ovariectomy, are attributed to the oestrogen agonist activity of DDT. The sites of action are thought to be the vagina and the hypothalamus; the neonatal treatment is believed to alter the patterning of the hypothalamus (Welch *et al*., 1969; Bitman and Cecil, 1970; Gorski, 1971). Similar results have been reported for PCB (Gellert *et al*., 1978).

By induction of the mono-oxygenase system, both DDT and PCB can increase the length of the oestrous cycles and decrease the frequency of implantation in the sexually mature mouse. Similar reproductive toxicity has been observed in other species (Ringer *et al*., 1972; Linder *et al*., 1974; Hansen *et al*., 1975; Kihlstrom *et al*., 1975; Spencer, 1982). A direct relationship between enzyme activity and inhibition of uterine weight response to oestrone has also been shown (Welch *et al*., 1971). There is also indirect evidence in primates that the halogenated polycyclics can induce mono-oxygenase activity and thus impair fertility by similar mechanisms (Kolmodin *et al*., 1969; Allen and Lambrecht, 1978).

Methoxychlor (bis-*p*-methoxy-DDT) is much less oestrogenic, less toxic, less persistent and has a shorter half-life than DDT in mammals. The reduced toxicity seems to be related to its rapid metabolism to more polar derivatives (Bulger and Kupfer, 1983; Schardein, 1993).

Kepone (chlordecone), a polychlorinated polycyclic aromatic compound, also has oestrogenic action on the murine uterus (Huber, 1965) and quail oviduct (Eroschenko and Wilson, 1975). There are conflicting data concerning its potential for reproductive toxicity in mice and rats in terms of teratogenicity (Ware and Good, 1967; Chernoff and Rogers, 1976; Khera *et al*., 1976) and postnatal survival and development (Gaines and Kimbrough, 1970; Chu *et al*., 1981). There have been no reports of effects in human pregnancy. However, it has been reported to cause loss of libido and sperm damage amongst manufacturing workers.

3.2.4.8 Genetic Abnormalities and the Effects of Irradiation

During the preimplantation stage, the embryo is susceptible to toxic insults which may cause mutations. If the damage is not repaired or compensated for, it may result in early embryonic death. Radiation and chemical toxins have a wide range of effects on the preimplantation embryo, for example, alterations in membrane permeability, disruption of the mitotic spindle and enzyme activity leading to cell disruption and possibly death. These mutations can be inherited via the germ cells or they can occur in somatic cells during embryogenesis. The nature of these abnormalities varies from specific point mutations in the genome to chromosome derangement, altering both numbers and structural arrangements. The majority of chromosome abnormalities occur during meiosis and gametogenesis, although some do occur during preimplantation development (Dean, 1983; Brent *et al*., 1993; Liel *et al*., 1993).

It has been known for many years that germ cell loss may be due to exposure to either radiation or chemicals. Sensitivity is often species specific and may be dependent on the stage of germ-cell maturation (Oakberg and Clark, 1964) in addition to the age of the animal. There seems to be no general rule to determine radiosensitivity across the species. Oocytes from juvenile mice have the highest sensitivity known for any mammalian cell. There is less information available on the effects of chemical exposure when compared with radiation, but the increasing use of chemotherapy in humans is adding to our knowledge of such effects, as discussed above.

3.2.4.9 *Ionizing Radiation*

High radiosensitivity in the ovarian germ cells has been demonstrated in the mouse, prenatal squirrel monkey and prenatal pig (Dobson *et al*., 1978; Erickson, 1978). Although in the adult pig, germ cells are not particularly sensitive, exposure to continuous gamma radiation at 1 rad day^{-1} throughout gestation results in severe oocyte deficiency in the newborn (Erickson, 1978). Similar studies in dogs (Andersen *et al*., 1961) and cows (Erickson and Reynolds, 1978) have shown that in these species also there are no serious effects on the germ cells of adults. The effects in squirrel monkeys have been reviewed by Dobson and Felton (1983). Prenatal exposures of 0.7 rad day^{-1} can completely kill off the germ cells, but in the adult the same exposure causes a less dramatic germ-cell loss. In other primates, such as the rhesus monkey and Bonnet monkey, the results of experimental studies have been variable, but on the whole, high sensitivity seems lacking (Baker and Beaumont, 1967; Andersen *et al*., 1977). Very little data are available in the human female. However, it would seem that exposures of approximately 400 rad are associated with induction of sterility, with larger doses being required in younger women (Baker, 1971; Baker and Neal, 1977). There have been reports of ovarian failure following abdominal radiotherapy, including treatment for childhood cancer (Shalet *et al*., 1976; Stillman *et al*., 1981), but this has not precluded the occurrence of pregnancies (Gans *et al*., 1963; Vuksanovic, 1966).

There is significant concern about the extrapolation of the animal data, which are species- and strain-specific, to humans. Some studies have shown that the mechanism of action may be different (e.g. the extreme sensitivity of murine oocytes may be due to the vulnerability of the plasma membrane, not adverse effects on DNA)—that is, it is a nongenetic type of effect. Thus, the genetic risks or radiation in humans, especially when it involved exposure of the primordial oocytes, may be overestimated by referring to mouse data unless this is taken into account (reviewed by Dean, 1983; Dobson and Felton, 1983).

3.2.4.10 *Psychosexual Function*

While it is widely accepted that drugs and other chemicals can affect male libido or cause impotence, the possibility that such effects can occur in women has been largely overlooked. In most mammals and subhuman primates, sexual activity is closely linked to ovulation, and thus it is difficult to find an animal model for sexual dysfunction occurring in women. Drug-induced changes in female libido have been associated with the use of oral contraceptives, tranquillizers, monoamine oxidase inhibitors, heroin, methodone, cannabis, cytotoxic drugs and alcohol (Heinrichs and Gadallah, 1983; Griffin, 1986).

Studies by Chapman and her colleagues (Chapman *et al*., 1979a; 1979b) have reported the occurrence of ovarian failure in women treated with cytotoxic drugs, including MVPP for Hodgkin's disease. About 92% (34) of these women reported a decrease in libido; 82% had menstrual irregularities or amenorrhoea and a constellation of other menopausal-type symptoms.

Oral contraceptives have also been associated with decreased libido; however, the mechanism is not established, although some studies associate it with pill-induced depression. It has been shown that oral contraceptives abolish the hormone-controlled mid-cycle peak in female-initiated sexual activity (Adams *et al*., 1978). Cyproterone acetate, which is an antiandrogen used to treat severe acne and hirsutism in women, is also used in some cases as a contraceptive, and this too is associated with loss of libido in women.

Danazol, a drug which is used in the treatment of endometriosis and other menstrual disorders, inhibits pituitary gonadotrophin secretion and is frequently reported to cause loss of libido in women (Westerholm, 1977). The antiobesity drug, fenfluramine, when used in high doses of around 240 mg day^{-1}, produces loss of libido as its main side effect. It is reported that at this dosage 85% of women treated may suffer loss of libido (Connell, 1977).

4 MISCELLANEOUS DRUG AND CHEMICAL EFFECTS

4.1 Oral Contraceptives

The use of oral contraceptives has proved to be one of the most effective forms of reversible fertility control in use today. The composition and actions of these 'pills' have been reviewed recently (Belfield, 1997; Guillebaud, 1997). Currently there are basically two main types: the combined type, containing an oestrogen and a progestogen, with efficacy in the range of 97–99%, and a progestogen-only type, with lower efficacy. In order to eliminate some of the side effects associated with the high oestrogen content of the combined preparations, phased formulations containing a progestogen and variable amounts of oestrogen have been introduced.

DOI: 10.1002/9780470744307.gat083
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are several types of combined pills available, for example, monophasic, biphasic and triphasic. Monophasic pills are the most widely used. They come in packets of 21 identical tablets, which are taken for 21 consecutive days. The pills are then stopped for seven days, during which a withdrawal bleed usually occurs.

The hormone content of the phasic pills varies throughout the cycle. They aim to provide a lower total dose of hormones over each cycle. The different strengths of pill must be taken in the right order for 21 consecutive days as marked on the packet, followed by seven pill-free days.

There are also 'every day' (ED) pills for those who find it easier to take pills every day without a break. Of the 28 pills, seven are inactive. There are also monophasic, biphasic and triphasic varieties of ED pills.

In addition, there is a postcoital pill, containing levonorgestrel 500 µg (UK formulation), which is used in such a way that high dosages of each of the hormones are attained within 12 hours.

4.1.1 Combined Oral Contraceptives

The combined preparation is considered to be the most effective for inhibiting ovulation. The effects of ovarian hormones on gonadotrophin release via the hypothalamic-pituitary axis have already been discussed. The predominant effect of oestrogen is to inhibit the release of FSH, whilst the continued action of progesterone inhibits the release of LH. Thus, ovulation may be inhibited by either inhibiting the ovulatory stimulus or by preventing follicle growth; both of these actions have been observed in experimental studies. However, the orally active progestogens used in the pill cannot be directly equated with progesterone *per se*, because some are inherently oestrogenic or androgenic and some purely progestational, and consequently they may inhibit ovulation in different ways. Measurements of circulating FSH and LH have shown that the oestrogen and progestogen combination inhibits both hormones, resulting in stable plasma FSH and LH and the absence of early follicular FSH and mid-cycle FSH-LH peaks. The combined preparation may also have a direct effect on the genital tract in that they alter the stage of development of the endometrium, thus making it unsuitable for implantation (Briggs, 1976). There are also changes in the viscosity of cervical secretions. At the time of ovulation these secretions are usually copious and watery and provide a good environment for sperm. Under the influence of progesterone, these secretions become thick and mucoid in nature and provide a hostile environment. Although little is known about the coordinated movement of the Fallopian tubes, uterus and cervix in the transport of eggs and sperm, it is generally accepted that the correct hormonal environment is essential for fertilization and implantation to occur.

4.1.2 Progestogen-Only Pills (POPs)

These preparations have lower efficacy than the combined type (pregnancy rates range from 1 to 10%) and have been associated with a higher incidence of menstrual irregularities. Progestogen-only pills (POPs) do not always prevent ovulation and are thought to be effective in only 15–40% of cycles. However, they do provide a suitable alternative for those women in whom high oestrogen levels are to be avoided, and it is a very effective method when taken correctly and consistently.

Low doses of progestogens may cause structural changes in the endometrium and alter the consistency of the cervical mucus without causing menstrual disruption. There are varying degrees of inhibition of FSH and LH and ovulation and this may be associated with the reduced efficacy seen with this type of pill. When a daily administration regime is used, menstruation does occur, but the length of the cycle and the duration of the bleeding period vary considerably. Long-acting progestogens, for example, norethisterone oenanthate and medroxyprogesterone acetate, are often given at two- and three-monthly intervals, respectively, and after an initial period of irregular bleeding give way to amenorrhoea and an atrophic endometrium. The main advantage is that there are no 'user failures' and the efficacy rate is 99–100%.

Although there may be some initial impairment of fertility for some months after oral contraception has stopped, this is of a transitory nature in the majority of women (Vessey *et al*., 1978). However, in a small number of women there is more permanent infertility (Fletcher, 1986).

4.2 Diethylstilbestrol (DES)

DES is of interest in that it is a reproductive toxin with two possible mechanisms of action. It is an oestrogen agonist, which causes changes in both the male and female reproductive tract in rodents (McLachlan and Dixon, 1977; Boylan, 1978; Vorherr *et al*., 1979) and in humans has been reported to cause an increased risk of adenocarcinoma of the vagina in females exposed prenatally (Herbst *et al*., 1971; 1975; O'Brien *et al*., 1979). A few cases have been reported of breast cancer in men treated with DES for metastatic prostatic carcinoma (International Agency for Research on Cancer (IARC), 1979). Some of the women exposed to DES *in utero* have vaginal abnormalities and there is evidence that they have irregular menstrual cycles and dysmenorrhoea and may be less fertile (Barnes *et al*., 1980; Herbst *et al*., 1980). Abnormal development of the uterus with a small hypoplastic T-shaped endometrial cavity has been seen in some of these women (Kaufman *et al*., 1977; Haney, 1987).

4.3 Industrial Chemicals

The potential of industrial chemicals to cause reproductive toxicity has been reviewed by Barlow and Sullivan (1982), John *et al*. (1984), Schardein (1993), Paul (1993), Kippen (1996) and Solomon (1997). There is also growing evidence of reproductive effects associated with occupational and environmental agents, for example, germ-cell damage, embryotoxicity and infertility. The complex relationship between the underlying pathogenic processes and the difficulties of assessing prospective and retrospective data have been carefully reviewed by Joffe (1997).

The major effects reported in female workers are as follows. Menstrual irregularities and other gynaecological disorders have been associated with exposure to aniline, benzene, chloroprene, formaldehyde, glycol ethers, inorganic mercury, PCBs and toluene, but in many instances the lack of data precludes a critical risk evaluation being made (Zielhuis *et al*., 1984; Commission of the European Communities, 1986; Rosenberg *et al*., 1987; Snow, 1994; Osorio and Windham, 1997; Paul, 1997).

Recently, issues have been raised concerning possible reproductive disorders in communities living near hazardous chemical sites (Savitz *et al*., 1997; Scialli *et al*., 1997). Various parameters were measured in women, namely menstrual dysfunction, infertility, pregnancy loss, lactation disorders and pregnancy outcome.

Occupational exposure limits have been set for some dangerous chemicals in the working environment (Hunter *et al*., 1997). However, these are only a tiny fraction of the chemicals to which workers are exposed, but it is encouraging that an ongoing priority work programme is in place to assess other chemicals.

Other substances have been associated with infertility or spontaneous abortions (Paul, 1997). These include anaesthetic gases in both males and females, ethylene oxide, arsenic, lead and some of the substances mentioned above, that is, aniline, formaldehyde and benzene (Figá-Talamanca, 1984; Lemasters *et al*., 1985; Sullivan and Barlow, 1985; Kline, 1986; Winder, 1987; Friedman, 1988; van der Gulden and Zielhuis, 1989; Paul, 1995; Rosenberg *et al*., 1997).

Factors such as decreased foetal growth, low birth weights and poor postnatal survival have been associated with exposures to carbon monoxide, PCBs, vinyl chloride, toluene and formaldehyde (Fletcher, 1986; Tabacova, 1986; Lemasters *et al*., 1989).

Teratogenic effects and transplacental carcinogenesis have been omitted from this section as they are described elsewhere.

4.4 Effects of Exercise

Although there have been reports associating strenuous exercise with adverse effects on the reproductive system, such as delayed menarche, menstrual irregularities or amenorrhoea, a cause–effect relationship is difficult to establish (Terjung, 1979; Cumming and Rebar, 1983). There seems to be a complex interplay of physical, hormonal, nutritional, environmental and psychological factors. One of the underlying concerns is whether or not so-called exercise-induced reproductive dysfunction is truly reversible once vigorous exercise has stopped.

The amenorrhoea associated with exercise is generally thought to be hypothalamic in origin (Speroff, 1981), but data are accumulating to suggest that other circulating hormones may also be involved (Shangold *et al*., 1981). In a review by Cumming and Rebar (1983), it is postulated that exercise-induced amenorrhoea is caused by alterations originating in the periphery as well as from CNS abnormalities. Furthermore, they suggest that the amenorrhoea produced is reversible.

Adverse effects of strenuous exercise once pregnancy has been established have also been reported. These seem to be related to the complex physiological adjustments required in terms of metabolic, endocrine, respiratory and circulatory responses in both the mother and the foetus (Lotgering *et al*., 1985).

Developmental Toxicology

John M. DeSesso and Calvin C. Willhite

CONTENTS

1 BACKGROUND AND MORPHOLOGY

Human embryonic development is a critical period of life and one during which insults can have severe impacts on the quality and length of life. Surprising to many, an embryo's wellbeing may actually be compromised decades *before* conception by insults that occurred during the fourth to sixth weeks of gestation of its parents. At this time in the parents' development, spherical primordial germ cells appear in the yolk sac and migrate to the presumptive gonad region during embryonic folding. During the folding process, the embryo establishes orientation, becomes segmented and develops three-dimensional architecture, as part of the yolk sac is incorporated into the embryo proper. The primordial germ cells then extend protozoan-like cytoplasmic processes (pseudopodia) and migrate along the dorsal mesentery from the hind gut (former yolk sac wall) to the medial aspect of the early urogenital ridge. At gestational week 6, the primordial germ cells (destined to differentiate into the primary oocytes of the genetic female and spermatogonia of the genetic male) become incorporated into the primary sex cords; at this time in gestation the gross morphology of the gonads of both sexes is identical. At birth, the 700 000 to two million primary oocytes of the genetic female have completed the first prophase of their first meiotic division and enter into the dictyotene (resting) stage where they remain in 'suspended animation' for up to 40 years or more. Chromosome damage may accumulate in these cells over time as evidenced by the increased incidence of genetic disease in children (e.g. trisomy 21) born to older (>45 years) mothers (1 : 50 live births) compared to that in younger (<29 years) mothers (1 : 2000). Thus, it is from the time of the appearance of the primordial germ cells during the parents' embryonic development that defines the earliest period sensitive to developmental insult.

Developmental toxicity is manifested in several ways. These include death of the embryo/foetus, structural malformations, retarded growth and functional alterations (that may not be evident until some time after birth). This wide diversity of end points can be induced by an equally broad spectrum of causes or mechanisms. Among these are conditions associated with chromosomal damage (e.g. ovarian dysgenesis in Turner syndrome XO females),

neurological deficits (e.g. ethanol-induced behavioural disorders) and frank physical (structural) malformations (e.g. thalidomide-induced phocomelia). The present chapter will restrict its contents to the origin and pathogenesis of selected structural malformations in humans, including some of the maternal factors that have been shown to contribute to or play a role in their aetiology. Given the vast numbers and diverse types of congenital defects (Wise *et al*., 1997) and the many authoritative texts and reviews, the present chapter is limited to examples that introduce the reader to the discipline.

At the outset, it must be appreciated that some 5% of all live-born infants have one or another defect (including mental retardation) (Behrman and Vaughan, 1987). Unlike many other facets of toxicological sciences, developmental toxicology must be addressed at several levels of biological organization. Furthermore, one must take into account the developmental stage of the embryo and its susceptibility at the time of exposure, in addition to the frequency and magnitude of exposure to the agent. The pathogenesis of congenital malformations begins with descriptions of the ultimate lesion (e.g. agnathia, micrognathia) and works backwards to describe any changes in numbers of cells, movement and fate of embryonic tissues (e.g. reduced migrating cranial neural crest and reduced pharyngeal arch) to changes in the timed intercellular signalling and intracellular regulatory circuits that determine basic embryonic pattern formation (e.g. anteroposterior and dorsoventral directions, segmentation and limb organization) that likely contribute to the ultimate defect. The fundamental patterns followed in human embryogenesis have been conserved over at least 540 million years and these patterns are shared with those used by *Drosophila, Xenopus* and other chordates (including birds) (Gans and Northcutt, 1983; National Research Council, 2000).

1.1 Monsters, Trolls, Mermaids, Villains and Ghosts

There is perhaps no other science save astronomy that predates recorded history more so than teratology (the study of monsters). Records of congenital malformations date from antiquity and they have been described by cultures all over the world. These conditions are not necessarily products of the industrial revolution; they are not necessarily due to modern medicine or consumer products nor do they necessarily result from exposure to obscure, unique or novel synthetic environmental contaminants. For instance, maternal infection with the single-stranded RNA rubella virus responsible for German measles caused more birth defects—including deafness, cataracts and profound mental retardation (not to mention foetal deaths)—in the United States in one year than all of the cases of thalidomide embryopathy (~10 000) recorded during its entire career worldwide (Webster, 1998). Some of the most destructive teratogens (an agent that induces congenital defects in the embryo) were recognized in ancient civilizations and some (e.g. ethanol) remain on pharmacy and grocery shelves to this very day (Willhite *et al*., 1988). Teratology and teratogens are inextricably intertwined into the fabric of contemporary society. The prospect of teratogenesis presents ethical dilemmas in clinical practice, tort claims and medical insurance; sensational stories in the popular press and personal decisions to abort pregnancy often stem from an innate fear of birth defects.

Ample archaeological evidence exists to show that congenital malformations are nothing new (Keenleyside and Mann, 1991; Mann *et al*., 1992; Mann and Owsley, 1989). Ancient people developed explanations for all kinds of natural phenomena ranging from the origin of the planet, to geothermal activity, to the existence of rare and unusual animals and human beings. Clay and marble sculptures, pictographs and woodcuts that date back at least as far as 6500 BC, provide evidence of the birth of ancient malformed humans (Warkany, 1971; 1977). That these depictions are not those of the imagination can be seen from the fact these creations are anatomically correct (Weisman Collection, 1965). Just as in contemporary society, ancient cultures sought reasons why an otherwise normal pregnancy gave rise to such an unusual or gruesome outcome. Today we retain many of these same figures, explanations and depictions in fairy tales, popular literature, in the cinema, in commerce and in legislation, but most people have no idea of their origins or the relations between distant oracles, modern myths and congenital defects.

When a child is born with an anomaly, the parents *always* look for an event or series of events to explain the condition. When explanations are not forthcoming, a reason *will inevitably be devised and applied*—regardless of the evidence. Early cultures practised infanticide, purposely neglected deformed neonates or leaving them to die from exposure (Hrdlicka, 1908; Friedman and Padula, 1988). In some parts of the world today, abnormal infants are sacrificed or abandoned as a result of a belief they arose from the supernatural (Lenz, 1988). In the Western world, and even among the most sophisticated and educated parents and consumers, ignorance, superstition and fear coexist with naturalistic and scientific views of the world. Nowhere is this more evident than a mother's fear of exposure to therapeutic drugs, pesticides, hair dyes, paints, varnishes or solvents, or perhaps trace levels of unidentified, exotic or difficult-to-pronounce industrial or environmental chemicals (Koren *et al*., 1989) that might lead to development of what appears to be an alien being *in utero* (**Figures 1** and **2**).

Pregnant women believe their risk of giving birth to an infant with major malformations is 25%—very

near the risk seen with thalidomide (Koren *et al*., 1989; 1993). Lessons from history show that this belief is reinforced by sensational articles in the popular press. In his text *Wunder, Wundergeburt and Wundergestaldt in Einblattdrucken des funfzehnten dis archtzehnten Jahrunderta* (published in 1543), E. Hollander recounts the story of a Polish child born with 'fiery eyes, Satan's tail and the head of a cat, webbed digits, a trunk and dog heads at the forearms'. This preposterous description appeared in illustrated pamphlets and books, and these were printed and distributed then reprinted and redistributed so many times that the account became accepted as fact (Warkany, 1971; 1977). These stories are really not all that different from today, where 10 popular 'family' and 'science/health' magazines had misleading and sensational accounts that exaggerated the risk of birth defects. More than half of these articles were inaccurate, 46% were intentionally alarmist, 8% were false and only 5% provided even a reasonable account of health risk (Gunderson-Warner *et al*., 1990).

The Babylonians (who lived along the Tigris River about 4000 years ago) were among the first to record unusual humans and the local Babylonian authorities considered these rare individuals evidence of divinity. In a world inhabited by witches, demons, soothsayers, wizards and sorcerers, malformed infants were thought to be evil or the work of the Devil. Babylonian records detail the predictive power of each type or combination of malformations. Belief in that divine power was then followed by the Egyptians, Romans, Greeks and Syrians, and it was adopted by the Europeans, all in the belief that if one could only understand the cause of the condition, this would be key to unlocking the future, divining the hidden and controlling events. Since only a deity possessed true knowledge, the oracle settled for the belief that understanding the reasons behind exceptional animals and humans would predict the future. As a case in point, the Roman, Quintus (Cicero's brother), described the birth of a conjoined (dicephalic) girl and concluded this foretold of 'sedition among the people and adultery in the home'. Further, 'When a woman gives birth to an infant that has the heart open and that has no skin [extrathoracic ectopia cordis], the country will suffer from calamities' and 'When a woman gives birth to an infant whose upper lip overrides the lower, the people of the world will rejoice for the troops'. In some instances, the birth of a monster was taken as a sign the gods were angry at the mother herself or at the whole of society because of a decline in 'family values' (Warkany, 1971; 1977).

1.1.1 Monsters

There are few examples of terata more striking than conjoined twins and the cyclops.

Conjoined dicephalic figurines dating from 500 BC to 800 AD have been recovered from Mexican and Central American graves and from the South Pacific and southern Turkey (Weisman Collection, 1965). Conjoined twins can be craniopagus (cranial union only), pyopagus (joined at the lower spine), thoracopagus (union at the upper half of the thorax), cephalopagus (dicephalics with anterior union at the upper half of the body), parapagus (dicephalics with heads joined side-by-side), ischiopagus (anterior union at the lower body), omphalopagus (anterior union at mid-trunk) (Spencer, 1992) and rachipagus (dorsal union of the entire head and trunk) (Spencer, 2005). Among the more notable, but nowadays unrecognized, conjoined twins are the pair Janus, the two-faced (dicephalic) Roman god of gates and doorways (**Figure 3**). Agni, the Hindu god of fire, is also dicephalic and Brahma (the Creator) has four heads so he can see in all directions at the same time. Dicephalics are not limited to ancient history, for we have drawings and written accounts, from 1790 of the 'Two-Headed Boy of Bengal' (Bondeson and Allen, 1989) to the more

recent accounts of parasitic craniopagus (Lotfy *et al*., 2006).

The physical descriptions of the Brahman Triad (Shiva the Destroyer, his wife Devi and Vishnu the Preserver) are strikingly similar to that of Betty Lou Williams (Albany, Georgia), Jean Libbera (Rome, Italy) and Ernie Defort (Manitoba, Canada) all of whom were born with parasitic twins, a rare (**Figure 4**) but well-documented condition (Gul *et al*., 2004). According to Homer, the carnivorous Scylla lived at the Strait of Messina and she had the face and breasts of a woman but six heads with 12 legs and feet (to assist her in scaling the high Sicilian rocks). Complete duplication of the lower body (dipygus) has been seen in contemporary times, as in the case of Myrtlye Corbin who lived in Lincoln County, Tennessee. Parasitic twins and the *fetus in fetu* (a full or partially developed parasitic twin that is completely enveloped by

the otherwise normal sibling) were also reported in the late twentieth century (including the case of Sanju Bhagat who at 39 years of age underwent surgery to remove his vestigial brother from his abdomen).

By the late 1950s, cinematic techniques advanced with the stop-motion creatures invented by Harryhausen (1958) who used his ball-and-joint armatures (Dynamation) to bring the fantastic Technicolor cyclops in *The 7th Voyage of Sinbad* to life. Unlike his hard-working predecessors, Argos, Steropes and Brontes (the offspring of Uranus and Gaia) or Polyphemus (the son of Poseidon and Thoosa) of Homer's *Odyssey*, the irritated cyclops whom Sinbad had the misfortune to stumble across sprouted a single horn atop his skull, his lower torso took on the furry hindquarters of a goat and he preferred his captives well-done over an open spit. Rather than a malformation (partial or complete fusion) of the eye(s) *per se*, cyclops represent the most extreme manifestation of holoprosencephaly, a condition characterized by failure of the midline neural plate structures to differentiate and separate.

Holoprosencephaly ranges from comparatively mild abnormalities of the midface (flat nose with anosmia due to absent olfactory bulbs or tracts) to a single cerebral ventricle with a single eye and orbit. At least 48 holoprosencephalic variants have been described in human beings, including those presenting with microcephaly, ocular hypotelorism or hypertelorism, unilateral or bilateral cleft lip, coloboma and minimal facial dysmorphia from cebocephaly (hypotelorism with single nostril nose) to ethmocephaly (normal orbits with a single proboscis). Holoprosencephalic features are seen in 1 : 250 pregnancies and at least some facets are seen in 1 : 16 000 newborns (Ming and Muenke, 1998). The severity of the condition is described as lobar, semilobar and alobar (Kokich *et al*., 1982). True cyclopia (alobar holoprosencephaly) presents with either a median orbit and eye, fused eyes (synophthalmia) or absent eyes (anophthalmia). The ethmoid and middle portions of the sphenoid are absent. The absence of the ethmoidal cartilage is responsible for the related structural defects of the face. The cyclops may have no discernible trace of a nose or it may possess a blind-ended proboscis above or below the eye (**Figure 5**). In some cases, derivatives of the cranial neural crest (e.g. mandible) are absent or the cyclops may have a jaw, but only a single central incisor.

Holoprosencephalic conditions are the most common brain anomalies in humans. These occur at rates between 0.56 to 0.63 per 10 000 live births and they are seen in as many as 40 per 10 000 spontaneous abortions (Cohen, 1989). A great many epidemiological studies have been published, including those that focussed on the influence of pregnancy history, maternal disease (e.g. diabetes), tobacco and ethanol consumption, paternal exposure to herbicides, metals and pesticides, prematurity, twinning and birth weight. Of these, only reduced birth weight was associated with the condition and this was due to the fact that most severely malformed infants (regardless of the defect) are often significantly growth retarded. More of the affected infants are females (60%) than males and ~60% are afflicted with other structural malformations (notably polydactyly in 32%, branchial arch defects in 16% and CNS (central nervous system) defects in 16%). Among survivors with serious terata, mental retardation is usually severe.

Figure 5 Foetal rabbit with cyclopia.

The incidence of cyclopia is increased in foetuses with trisomy 13, but, overall, about 50% of the cases have a normal karyotype and 20–50% display one or another chromosomal anomaly. Autosomal recessive inheritance has been seen in the majority of cases with partial trisomy 13 in 70%, deletion at 13q in 10% and the deletion 18p syndrome in 10% of all cases. Foetuses with trisomy 18, dup(3p), del(7)(pter → q32), as well as those with deletions at 1q, 2p, 5q, 5p, 7q, 9p, 11q, 18p and trisomy 20 and 22 or anomalies of the sex chromosomes (e.g. 47,XXX; 47XY, +B, 46 XY/47,XY) are at increased risk. Medical geneticists have also identified an autosomal dominant form of holoprosencephaly with incomplete penetrance and the possibility of X-linked inheritance has been put forward (Cohen, 1989).

From the first anecdotal reports to the epidemics in Idaho, cyclopia among herds of sheep represented a substantial, endemic economic loss experienced by ranchers in the Intermountain West. In the early 1960s, research sponsored by the US Department of Agriculture found that when pregnant ewes ingested a subalpine range plant known as California false hellebor (*Veratrum californicum*) on the 14th day of gestation (corresponding

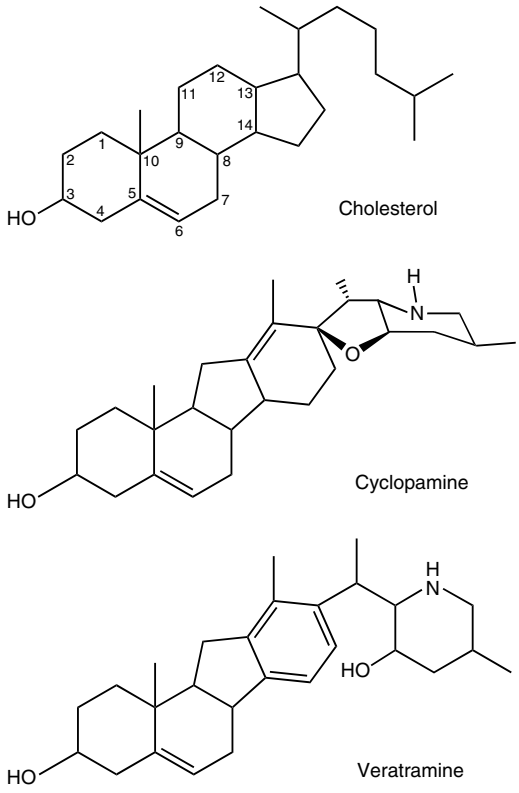

Figure 6 Chemical structures of cholesterol, cyclopamine and veratramine. The C3-OH is shown at the left in all three drawings and the double bond at C5 and C6 is required for activity. When cyclopamine encounters acid in the stomach of rabbits and other monogastric animals, the furan ring is hydrolysed to the –OH of veratramine and the teratogenic activity is destroyed. (Reproduced from Incardona *et al*., 2000. © Elsevier.)

to the neural plate stage), the full range of holoprosencephalic terata could be induced (Binns *et al*., 1963; 1964). Cyclopia and associated terata can also be induced in other ruminants (e.g. cattle, goats) depending upon the quantity of plant consumed and the gestational age at which exposure occurs (Binns *et al*., 1972). This large flowering perennial (commonly known as 'cow cabbage' or 'wild corn') synthesizes and accumulates a number of complex steroidal alkaloids including muldamine, veratramine, corvine, verstrosine, rubijervine, jervine, 11-deoxojervine and cycloposine. These molecules are steroids to which a furanopiperdine ring has been fixed. When 11-deoxojervine (also known as cyclopamine) (**Figure 6**), cycloposine (3O-glucosyl-11-deoxojervine) or jervine were fed to pregnant sheep, malformations identical to those observed after feeding the plant were induced. Structure–activity comparisons revealed that the presence of an intact tetrahydrofurylpiperidine ring was required for teratogenic activity. Oral administration of cyclopamine to pregnant rabbits failed to induce terata because cyclopamine is acid-labile and it is hydrolysed

Figure 7 Anterior view of the common troll.

in the monogastric gut to its inactive congener veratramine (**Figure 6**), in contrast to the ruminant, where the parent compound survives the gut intact. However, when oral cyclopamine was given on day 7 of pregnancy in achlorhydric rabbits after the gastric pH was increased by concomitant administration of sufficient bicarbonate, cyclopia was induced (Keeler, 1970).

1.1.2 Trolls

Scandinavian folklore speaks of the common troll, an ugly and dangerous heathen race of fearsome humanoid goblins. Carnivorous, dim-witted and cowardly, trolls dwell in caves, dark forests or under bridges, as in the Norwegian fairytale *Three Billy Goats Gruff*. Other accounts describe trolls as small, shy, thieving, evil dwarfs that have a nasty habit of carrying away valuables, small children and seducing young maidens (especially princesses) with the same magic found in the lyrical *March of the Trolls Op.54 No. 3* by Edvard Grieg. Today trolls are no longer ugly or shy, but they are whimsical. They wear cute little outfits and they have grown a great mass of long fuzzy hair over their rudimentary skull (**Figure 7**). Trolls have the large eyes (an illusion due to the reduced cranium) and skull of the anencephalic (**Figure 8**).

Anencephalus is part of a constellation of terata known collectively as 'neural tube defects' (NTDs) and these range from complete absence of the head (acephaly) to merely deformed or rudimentary spinal vertebrae covered by skin (occult spina bifida) that may have no clinical consequence (DeSesso *et al*., 1999). While the anencephalic always dies shortly after birth, children with spina bifida (**Figure 9**) are physically disabled with severe neurologic and muscular problems and (often) sphincter paralysis. NTDs arise during the fourth week of development. Damage to the embryonic mesoderm is reflected in the abnormal skeletal elements and interference with elevation and fusion of the neural folds is reflected in the abnormal neurological elements. These defects result from failure of the neural groove to close, a process that begins at day 22 in the central dorsal region and progresses to the caudal and cephalic regions.

Figure 8 Anterior view term human anencephalic. Note the protruding and rudimentary brain, low-set ears, elevated nose and maxilla and the short neck. The short neck is due to malformations of the cervical vertebrae and the protruding maxilla is a consequence of lordosis and deformations of the sphenoid. (Reproduced from Willhite and Mirkes, 2005. © Elsevier.)

Figure 9 Infant with spina bifida. Note the protruding meningocele. (Reproduced with permission from the March of Dimes Foundation.)

Anencephalus and many forms of spina bifida arise from a similar mechanical failure, but differ in the location of initial embryonic damage. The anencephalic face (viscerocranium) and skull (chondrocranium) are rudimentary (**Figure 8**), but all of the bones of this portion of the lower skull are present (Marin-Padilla, 1991). Overall, the incidence of human anencephalus (termed exencephaly in rodents and lagomorphs) can vary by location, by time of year and by social class and race (Elwood and Elwood, 1980). In the United States, historical rates of anencephalus and spina bifida averaged 3.4 and 5.0 per 10 000 live and stillborn deliveries. Rates of anencephalus ranged from 0.8 to 18.4 per 10 000 live and stillborn deliveries in Southern France and Mexico, respectively; areas with high rates of anencephalus also have high rates of spina bifida. Some retrospective epidemiologic studies found seasonal distributions with higher rates among babies born in winter than in summer, but other studies found no such pattern. Families of unskilled manual workers had rates five times those of the professional class, and the incidence was sometimes higher in urban than rural areas, but there was no correlation with urban density. Historical rates in Northern Ireland, South Wales and the Vale of Glamorgan were among the highest in the world (5.2–11.5 per 10 000) and in England there was an apparent decline from west to east, but in Ireland the incidence was higher in the east compared to the west. Rates among those of Irish descent living in Boston were less than those of people who lived in Ireland. Italians and those of African descent had some of the lower NTD rates and Jewish children had very low NTD rates. Offspring of British women living in Quebec had elevated rates of anencephaly, but offspring of French women living in Quebec had elevated rates of spina bifida. Rates were generally higher in a first pregnancy and lower in second pregnancies, but about 95% of affected infants were born to mothers with no such history. NTD rates were high in women less than 20 years of age or greater than 35 years of age compared to ages between those values. The incidence among siblings was up to seven times that in the general population and the risk is increased to as high as 1 in 10 for those born to mothers with two prior NTD pregnancies. Risk of recurrence varies with time and individual risk is related to that for the local population. Studies of same-sex fraternal and identical twins found it rare that both twins were affected, but paternal age had no independent effect (Horowitz and McDonald, 1969).

1.1.3 Mermaids

Half-human, half-fish and always insidiously seductive, mermaids are among the most universal mythical creatures. Their fame increased after publication by Hans Christian Andersen of his 1836 tale *The Little Mermaid*, a book that was translated into many languages and became the subject of a successful animated Disney motion picture. Mermaids appear on Tarot cards, they appear on the corporate logo for the Starbucks chain of coffee houses and they appear on the Warsaw (Poland) coat-of-arms.

There are popular suggestions that the mermaid legend originated in the New World by sailors' observations of the manatee (*Trichechus manatus*), a large aquatic herbivorous mammal of the Order Sirenia that inhabits the

Figure 10 Anterior view of a male siren (sympodia) at 33 weeks showing partial fusion of the lower limbs to the level of the knees. Note the absence of the left ankle and foot, the twisted right foot (talipes equinovarus) with duplicated toes. (Reproduced with permission from Mysorekar *et al*., 2007. © MedKnow Publications.)

coastal waters of Florida (Cooper, 1992). Nonetheless, there are mariner tales dating from as far back as 1000 BC to the second century AD that speak of mermaids as water nymphs and sirens, those innocent and beautiful singing female water fairies prone to enchanting and distracting sailors, causing shipwrecks and dooming the crews. In spite of (or perhaps because of) her six heads, Scylla was the object of romantic desire by the Greek merman Glaucus. Olokun, sea king of the Yoruba (who live in the Midwestern part of Nigeria), is depicted with mudfish legs and the Hindu incarnation Matsya is a four-armed merman.

The incidence of sirenomelia (also known as sympodia or symmelia) (**Figure 10**) varies between 1.5 and 4.2 : 100 000 depending upon whether only live births or aborted foetuses are included in the calculation. The lower limbs are usually fused and may present as a single femur and tibia with the sole of the foot exhibiting fused toes. The foot is often oriented in a ventral position. There are cases where fully developed legs are joined only by cutaneous tissue. Sirenomelic foetuses commonly present with hypoplastic lungs and multiple defects of the heart, spine and abdominal wall, as well as absent genitalia, urinary bladder and anus. In very few cases, sirenomelia was evident along with NTDs (Rodriguez *et al*., 1991; Rodriguez and Palacios, 1992; Kulkarni *et al*., 1994). Sirenomelia is usually lethal due to hypoplastic lungs, cardiac defects and congenital absence of both kidneys, but there are reports of at least three cases with lesser malformations who survived (Murphy *et al*., 1992). Sirenomelia occurs more commonly in males (Sirtori *et al*., 1989) and in twin pregnancies (Temtamy and McKusick, 1978); there are usually no chromosomal abnormalities and there is no increased risk among sibling births (Tang *et al*., 1991).

1.1.4 Villains

Villains have common traits: ignorance, arrogance, greed and the propensity to reappear and repeat their same patterns of dangerous behaviour. There is likely no greater villain in developmental toxicology than methyl mercury (MeHg).

In the early 1900s, Shin Nichitsu (the former Japan Nitrogenous Fertilizer Company known since 1965 as the Chisso Corporation) established an ammonia fertilizer production facility on the shores of Kyushu Island in the Shiranui Sea (about 570 miles southwest of Tokyo). At that time, the residents of Kumamoto made their living primarily as subsistence fishermen and farmers, and they anticipated the economic prosperity they hoped would follow the opening of the plant. By 1932, the plant was successful and Shin Nichitsu expanded their capabilities to manufacture acetaldehyde as a chemical intermediate, a synthetic pathway that required the use of a mercuric ion catalyst (Hagemeyer, 1978). Industrial process water from the plant was discharged to Hyakken Harbour and thence into Minamata Bay. Ionic mercury is transported downward in the water column to sediments (Hurley *et al*., 1991) where it is converted by sulphur-reducing aerobic and anaerobic microorganisms to alkyl mercury (methylated forms) in both salt and freshwater ecosystems (Gilmour and Henry, 1991; Regnell and Tunlid, 1991). MeHg is lipophilic and it concentrates 10 000- to 100 000-fold as it moves up the ecological food chain into fish (particularly large predatory species) and shellfish (International Programme on Chemical Safety (IPCS), 1990).

On May 1, 1956 the first case of an 'unknown disease of the central nervous system' was recorded by the company's hospital staff. By the early 1960s Kumamoto University researchers concluded that the encephalopathy seen in Kumamoto residents was due to ingestion of sea foods containing mercury discharged by Shin Nichitsu (Takeuchi *et al*., 1962; Tsubaki and Irukayama, 1977). Factory discharge was rerouted in 1958 from the harbour to the Minamata river past the village of Hachimon and into the Shiranui Sea where those residents who also consumed local fish subsequently developed identical symptoms. In 1959 Shin Nichitsu began to compensate victims without admitting responsibility or the source of the problem. In 1965, mercury effluent discharged from acetaldehyde production to the Agano River by Showa

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Denko Company also induced MeHg encephalopathy among residents who consumed fish caught in the Niigata Prefecture.

Alkyl-mercury-induced toxic encephalopathy has a prolonged latency (usually several asymptomatic months to possibly years). The initial signs are characterized by slurred speech, numbness of the lips and limbs, loss or constriction of visual fields and muscular weakness that leads to progressive paralysis, blindness, coma and death (International Programme on Chemical Safety (IPCS), 1990). MeHg is readily taken up in the intestine; it crosses the placenta and human milk can contain high levels (Koos and Longo, 1976). Prenatal exposure to sufficiently high concentrations of MeHg (hair Hg $\geq 70\,\mu g\,g^{-1}$) presents a >30% risk for foetal encephalopathy—a condition that resembles cerebral palsy. Often the mothers of affected infants presented with little if any clinical signs of MeHg intoxication. At least 100 victims died and 17 babies were born with MeHg-induced encephalopathy; as of 1974 some 800 victims had been officially recognized. In some cases, the mothers were relatively unaffected, but their offspring were blind and were left mentally and physically debilitated (Matsumoto *et al*., 1965). The pivotal victim was Tomoko Uemara whose black and white photograph with her mother (Smith and Smith, 1975) was published in *Life Magazine*. This intimate and famous portrait titled *Tomoko Uemara in Her Bath* (1972) by W. Eugene Smith is considered one of the most important images ever in the history of photography (Overseas Press Club of America, 1974). Tomoko Uemara died in 1977.

In 1968, Chisso's acetaldehyde production ceased. The company denied all allegations and there were suggestions that the disease was contagious; the provincial government responded by imposing a ban on Minamata seafood in commerce, but permitted continued subsistence fishing in the bay. 'Single shareholder' resistance began with letter writing, nonviolent protests, tent cities and citizens each purchasing one Chisso share in an effort to disrupt the annual shareholders' meeting and corporate governance. In 1972 and apparently at the direction of the company, six Yakuza intimidated and beat Mr. Smith severely (Kaplan and Dubro, 2003). Mr. Smith continued to photograph the civil unrest, the Central Pollution Board meetings and victim presentations before the Environmental Disputes Coordination Commission; for his efforts, he was awarded the Robert Capa Gold Medal for the 'best published photographic reporting from abroad requiring exceptional courage and enterprise' (Overseas Press Club of America, 1974).

In 1973, the Kumamoto District Court ruled the company was negligent: 'We cannot find that the defendant took any of the precautionary procedures called for in this situation whatsoever... We cannot even find one measure taken by the defendant that was either adequate or satisfactory... The presumption that the defendant had been negligent from beginning to end in discharging wastewater from its acetaldehyde plant is amply supported'. As of March 2001, some 3000 people had been certified under Japan's Pollution-Related Health Damage Compensation Law as victims and had received income and funeral compensation, financial and medical assistance totalling ~144 billion yen. In 1975, Kumamoto Prefecture carried out dredging of Minamata Bay at a cost of 48 billion yen and in 1976 the Niigata Prefecture carried out dredging of sediments from Showa Denko's discharge points to the Agano River basin. Total ongoing costs for MeHg pollution control and prevention are 123 million yen per year and total damages amount to 12.6 billion yen per year (Ministry of the Environment, 2002).

Despite the infamous history, disregard for its hazards led to MeHg-induced morbidity in Brazil (Malm *et al*., 1995), French Guiana (Frery *et al*., 2001), the Philippines (Appleton *et al*., 2006), Mexico (Guentzel *et al*., 2007), New Zealand (Kjellstrom *et al*., 1986), Bolivia (Maurice-Bourgoin *et al*., 2000) and Quebec (McKeown-Eyssen *et al*., 1983), in addition to the 400 deaths as a result of MeHg poisoning in Iraq (Amin-Zaki *et al*., 1974). Environmental MeHg remains a threat to the public health to this very day (**Figure 11**).

1.1.5 Ghosts

Parents tell their children 'there are no such things as ghosts'; nonetheless, a scary story frightens young children, in spite of the admonitions of their parents. The same is true of adults, particularly when it comes to their livelihood, their investments in time, labour or life savings and their children. In an atmosphere of scientific ignorance or uncertainty, it is not uncommon that untested ideas, conjectures or hypothetical explanations come forward today—just as in ancient times—to explain the origin and cause of congenital disorders. These stories often appear or sound 'scientific' or have roots in the scientific literature. In the discussion that follows, a modern-day ghost story is recited as an example, but there are similar tales like those of depraved pharmaceuticals (Brent, 1995), demonized spray adhesives (Hook and Healy, 1976), plastics (Goodman *et al*., 2006; Willhite *et al*., 2008) and atmospheric radiation (Trichopoulos *et al*., 1987). Equally frightening (and uninformed or misinformed) exposure scenarios and the consequences of 'chemical rumours' are well known (Koren *et al*., 1989; 1993).

Our ghost story concerns the potato.

Coincident with the Great Depression of the 1930s there was an NTD epidemic in the United States with rates of five cases per 1000 pregnancies in Boston and Providence, but the incidence of the disease mysteriously declined over the next 50 years. In the early 1970s, researchers at the London School of Hygiene and Tropical Medicine noted geographic and temporal correlations between anencephalus and spina bifida and

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

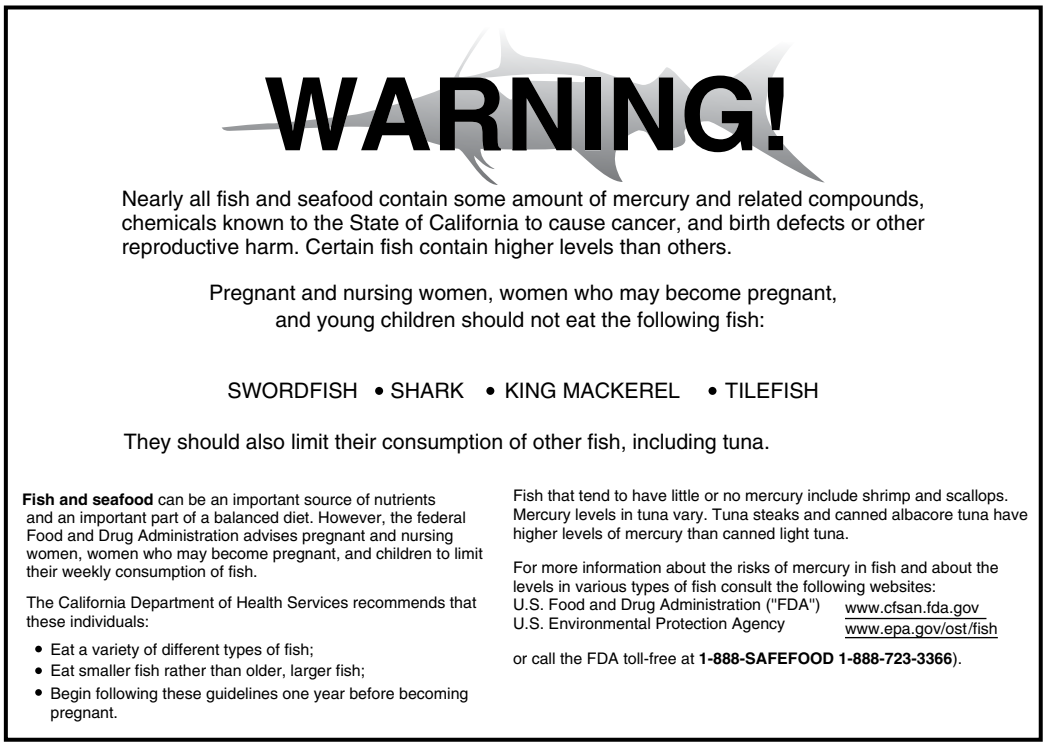

Figure 11 Methyl mercury warning sign posted in restaurants and markets.

found that areas with elevated anencephalus rates also had elevated rates of spina bifida. Year-to-year data indicated a seasonal peak in May and that poor mothers were affected about four times more often than wealthy mothers (Renwick, 1972; 1973; Renwick *et al*., 1974). At that time the epidemiology of anencephalus and spina bifida led Horowitz and McDonald (1969) to state: 'We conclude that all the available evidence indicates that environmental factors are responsible for NTDs but there are few clues to their nature. The tendency of some women to produce children with NTDs appears to be operative throughout the child-bearing period, since multiple cases in sibships appear to be randomly distributed in time. The characteristic must therefore be acquired before maternity, perhaps through nutrition or infection'.

Based on a strength of statistical association (p = 0.005) between the seasonal and geographical observations that fungal infestations of potatoes (blight), (*Phytophthora infestans*) which occurred just before harvest, and the seasonal and geographic rates of NTD, Renwick (1972; 1973) concluded that eating blighted potatoes caused NTDs and that avoidance of potatoes would reduce the incidence of NTDs: 'Most of the evidence for the potato-avoidance hypothesis for the prevention in the UK of 95% of spina bifida and anencephaly does indeed come from blight, that being the best-recorded and most important potato diseases. But the potato, like man, is subject to many diseases perhaps several being capable of eliciting a phytoalexin (antibiotic) response, which in most plants is relatively nonspecific, as it apparently is in the potato'. Renwick (1973) continued, 'Since teratogenesis probably occurs in the first month of pregnancy, the date of peak incidence points to maximal teratogenicity in May. In that month the over-wintered potatoes are at their worst quality'.

That an unassuming, economical dietary staple like the potato could cause birth defects became of immediate distress among potato farmers, processors, trade associations and purveyors who elevated their concerns to government agencies. No one knew whether the effect was due to potato storage conditions, whether one potato variety was more or less toxic than another, whether imported potatoes might be more or less dangerous than those grown locally, whether an unidentified agent was associated with the principal fungus (*Phytophthora infestans*) or to other fungi (e.g. *Erwinia carotovora*, *Alternaria solani*), to an unidentified toxic agent produced by the fungus, secondary infection by other opportunistic organisms or perhaps produced by the potato tuber itself due to fungal infestation, to variations in cooking conditions or inhaled cooking vapours or potato consumption habits—or worse—that unidentified potato and/or fungal toxin(s) accumulated in maternal tissues only to be slowly released into the mother's bloodstream during gestation (Renwick *et al*., 1974). All that was known for certain was that 'culinary pride'—being more or less prevalent in one country or geographical region than another—might lead to 'more frequent

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

discarding of partly blemished potatoes' and those factors might account for differences in national NTD rates.

Governments in the United Kingdom and America responded by sponsoring feeding studies in animals using potatoes rejected by the potato industry or potatoes purposely infected under controlled conditions. Although indications of 'cranial osseous defects' were reported in four of 11 marmoset foetuses (small squirrel-like arboreal primates from Central and South America) whose mothers ate 'blighted' potatoes during gestation (Poswillo *et al*., 1972), there were no reproducible signs of potato blight-induced developmental toxicity in studies with other mammals. Studies in chicken embryos with purified cytochalasins and solanines from green potatoes found NTDs (Mun *et al*., 1975; Jelinek *et al*., 1976), but subsequent retrospective epidemiological evaluations found no differences in potato consumption patterns between mothers with NTD pregnancies and those with healthy pregnancies (Clarke *et al*., 1973). Nevin and Merrett (1975) then conducted a trial in Northern Ireland with 88 mothers matched for age, economic status, religion and parity, all of whom had previously given birth to an NTD child. Interviews at six to eight weeks gestation found 27 who were careful to avoid all potatoes and potato-containing foods and 61 who consumed potatoes. Of 23 pregnancies in the potato-free group that went to full term, there were two anencephalics; of the 56 full-term pregnancies in those who ate potatoes, there were two with spina bifida. There was no significant difference in NTDs between the potato eaters and the potato-free group. With the subsequent publication of anecdotal reports showing NTDs in potato-free pregnancies (Lorber *et al*., 1973), the obituary of the 'potato blight' hypothesis was essentially complete.

But that is not the end of our story. Recall that Horowitz and McDonald (1969) observed 'The characteristic must therefore be acquired before maternity, perhaps through nutrition or infection'. Earlier, Hibbard (1964) and Hibbard and Smithells (1965) examined mothers who had given birth to infants with NTDs and measured their folic acid status at term. These investigators found that mothers of NTD babies were five times more likely to have positive formimoglutamic acid elimination results than matched controls. In 1969, Lanzkowsky *et al*. (1969) and others began to assemble clues that dietary deficiencies, whether due to the dietary composition or due to impaired gastrointestinal absorption or impaired nutrient utilization, might contribute to development of NTDs. In 1976 Smithells *et al*. (1976) reported the results of their prospective study of maternal (N = 900) vitamin status during the first trimester and found six mothers who gave birth to infants with NTDs. In the affected pregnancies, both leucocyte and erythrocyte ascorbate and folate were reduced significantly compared to mothers with uneventful pregnancies. The focus on folic acid was prompted by observations from the 1950s of malformations in offspring of rodents given antibiotics to reduce their intestinal flora that normally synthesize folate (Evans *et al*., 1953; Giroud and Lefebvres-Boisselot, 1951), and by the increased foetal deaths and severe malformations in survivors exposed to the biochemical folate antagonist, aminopterin (Warkany, 1978).

In 1992, Czeizel and Dudas (1992) published one of the more important public health discoveries of the late twentieth century (Oakley, 1993). In a randomized controlled prospective blind trial of 4753 women planning their pregnancy, one group of 2052 received a trace element supplement and 2104 received a vitamin supplement with 0.8 mg folic acid. There were six NTD cases (four anencephalics, two of which also presented with lumbar or thoracic rachischisis, one spina bifida cystica and one lumbosacral spina bifida) in the group given the trace element supplement compared to zero NTD cases in those given the vitamin supplement. In 1992, the Scottish, Welsh and Northern Ireland Departments of Health and Social Services and their US and Australian counterparts responded by advising all adolescent and adult women capable of becoming pregnant to consume at least 400 µg of folic acid each day to prevent having an NTD pregnancy. Follow-up investigations by Werler *et al*. (1993a) and Werler and Mitchell (1993b) found a relative NTD risk of 0.4 among mothers who had consumed folate-containing vitamin supplements, an observation that led Oakley (1993; 2002) to conclude that up to 60% of all NTDs could be prevented by adequate dietary folate and that folate supplementation of diets in Mexico and northern China would reduce their very high NTD rates within one year to levels seen in the United States that required 50 years to achieve. Follow-up studies (Stevenson *et al*., 2000; Persad *et al*., 2002; Williams *et al*., 2005) put the reductions in NTDs at 50% in South Carolina, 54% in Canada and the reductions in spina bifida afforded by adequate dietary folate at 34% in non-Hispanic whites, 36% in Hispanics and 19% in non-Hispanic blacks, respectively. A community-based intervention trial with 400 µg synthetic folic acid per day carried out by Beijing Medical College reported an astounding 85% reduction in NTDs (Berry *et al*., 1999).

So as for the potato ghost, we find that it was not the presence of an unseen and unidentified toxin, or deposition and storage of an exotic or mysterious substance in the body that was the primary aetiologic agent, but that it was the *absence* of an essential nutrient that was responsible for the disease. Folates are present in citrus fruits and vegetables; dark leafy greens (spinach, broccoli, legumes) are particularly rich sources. While the specific dietary composition among mothers giving birth during the Great Depression or among the mothers in Scotland, England and Wales evaluated by Renwick (1973) is not known, it appears that the high financial cost of citrus and other fruits and vegetables—particularly during the winter months—prevented poor urban mothers from

obtaining adequate folate compared to their wealthier or rural neighbours.

2 DEVELOPMENTAL BIOLOGY

To begin objective appreciation of the cause(s) and pathogenesis of any congenital defect, one must possess a basic understanding of normal embryonic development and should be familiar with the establishment of the body's architecture. The earliest steps an embryo takes define the anteroposterior and dorsolateral dimensions and determine body segmentation, steps that are known collectively as 'axis specification'. The fact that fundamental embryonic patterns are conserved from comparatively primitive protochordates to the higher-order chordates suggests vertebrates evolved from ancient notochordal organisms that resembled contemporary cephalochordates (perhaps similar to amphioxus) (Gans and Northcutt, 1983). These patterns have existed for at least one billion years. While the events in vertebrate embryogenesis are more numerous and are more complex than those in simpler animals, the basic chemical signals, pathways, patterns and responses seen at the molecular level are remarkably similar, and these have been conserved over hundreds of millions of years. With the basic organizational patterns remaining intact, one might argue that materials or factors which disrupt embryonic development in lower taxa could also possibly disrupt embryonic development in higher taxa, assuming all other things are equal.

The chordate 'body plan' involves the notochord (primary organizer), a hollow dorsal nerve, segmented muscles, an unsegmented trunk and a perforated pharynx. Humans and other mammals are members of the superclass Gnathostoma, a chordate class that includes reptiles, the cartilaginous and bony fishes, amphibians, mammals and birds. All of these species (along with their agnathous relatives) are members of the subphylum Vertebrata. Amphioxus and the other protochordates (e.g. tunicates) are members of the phylum Chordata, but they have a collagenous or chitin skeleton, their embryonic myotomes are staggered (where vertebrate myotomes are paired) and they lack gills and muscular aortic arches. In vertebrates, the notochord extends all the way to the basicranium, but in protochordates it is restricted to the rostral cephalic region. It is this difference that accounts for the fact vertebrates have a cartilaginous and calcified cranial skeleton; indeed, we should all be thankful for the differentiating cranial neural crest and sclerotomal mesoderm, as without their participation we should all be forever looking for our heads.

The early nervous system influences body shape, but the brain and spinal cord develop in somewhat different manners. To understand its establishment, we need follow it in three dimensions (Campbell *et al*., 1986; Copp *et al*., 1990; DeSesso *et al*., 1999; Gordon, 1985; Hamilton and Mossman, 1972; Morrissey and Mottet, 1980; Moore and Persaud, 2003; Sadler, 2006; Schoenwolf and Smith, 1990; Schoenwolf *et al*., 2008; Sulik and Sadler, 1993).

To follow the shape changes, we begin at fertilization, which, in humans, occurs in the ampulla of the uterine tube. This creates a new diploid organism, the zygote, which undergoes a rapid series of cellular divisions over the next four to five days as it traverses the uterine tube to reach the uterine cavity. By the time the zygote reaches the uterine cavity and begins to implant in the uterine wall, it is a sphere of cells surrounding a small cavity that is referred to as the blastocyst (**Figure 12**). The cells that line the inner cavity of the blastocyst differentiate into hypoblast cells which, in turn, induce the overlying cells to form the epiblast. The epiblast gives rise to the embryo proper. Approximately two weeks after fertilization, the epiblast and hypoblast form the bilaminar germ disc, with the epiblast facing the presumptive amniotic cavity and the hypoblast facing the primitive yolk sac cavity.

At the start of the third week, epiblast and hypoblast rearrange into the three primary germ layers (ectoderm, mesoderm and endoderm) from which the primordia of all tissues and organs arise. This process, termed ingression, begins with the appearance of the primitive streak, a crease in the epiblast of the caudal region (**Figure 13**). Some epiblast cells migrate medially towards the primitive streak and then move beneath the dorsal surface to make up deeper layers. As the epiblast cells migrate through the primitive streak, they acquire information concerning their fate; other epiblast cells subside directly beneath the surface epiblast cells. Most ingressing (or subsiding) cells become the mesoderm (the middle germ layer), but some intercalate with the hypoblast cells to form the endoderm (hypoblast cells *per se* give rise only to the extraembryonic yolk sac endoderm). The epiblast cells that do not ingress or subside become ectoderm.

At the cranial end of the primitive streak, a condensation of tissue (called the primitive node) appears and it surrounds an indentation (called the primitive pit). At days 17–20, ingression of epiblast cells through the primitive pit with subsequent cephalic migration in the midline, results in the formation of a transient tubular structure, the notochordal process (**Figure 14A**). The lumen of the notochordal process remains continuous with the lumen of the primitive pit. Shortly thereafter (days 20–23), the notochordal process becomes associated with the endoderm to form a new structure, the notochordal plate (**Figure 14B**). The notochordal plate subsequently separates from the endoderm (**Figure 14C**) and then segregates into: (i) a deeper rod-shaped epithelial structure (the definitive notochord formed by days 24–25) and (ii) a layer of cells that is incorporated into the floor plate of the neural tube (**Figure 14D**). Similar positional information signals emanate from the notochord and floor plate,

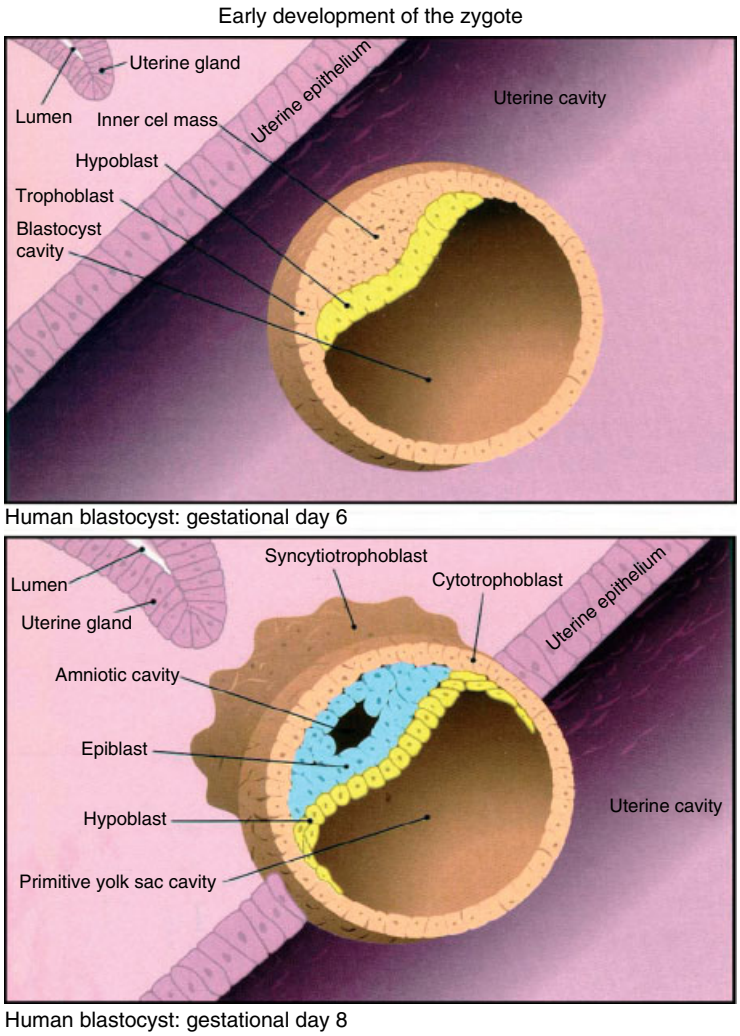

Figure 12 Diagrams that portray the human peri-implantation blastocyst. The upper panel depicts the blastocyst floating freely after hatching in the uterine cavity on gestational day (GD) 6. The major regions of the blastocyst are readily identified by their positions relative to the blastocyst cavity. The single layer of cells that composes the outer shell is the trophoblast, which gives rise to most of the foetal membranes, while the group of cells internal to the shell is the inner cell mass that develops into the embryo proper. The layer of the inner cell mass that is adjacent to the blastocyst cavity is the hypoblast. The lower panel shows the relationships of various parts of the implanting blastocyst on GD8. Note the layer of the inner cell mass above the hypoblast has differentiated into the epiblast. Together, the epiblast and the hypoblast make up the bilaminar embryonic disc. The space within the inner cell mass is the amniotic cavity. The nervous system develops from the epiblast cells shown at the inferior border of the amniotic cavity. providing inductive signals for the ventral portion of the nervous system (Tanabe and Jessell, 1996). The columnar neuroepithelium of the neural plate gives rise to all of the future brain and spinal cord.

Induction of the neural plate by the notochord and floor plate is the first step in neurulation. The notochord/notochordal process induce changes in the overlying ectoderm using cellular signals (morphogenic proteins); the epiblast that constitutes the presumptive ectoderm sends and receives the bone morphogenetic proteins 4 (*BMP-4*). As long as epiblast cells receive the *BMP-4* signal proteins, they will differentiate into ectoderm. If a different signal is present that inactivates *BMP-4*, then those cells will never become ectoderm. Inhibitory signals include *Noggin*, *chordin* (*Chd*) and *follistatin*; all of these proteins are made and released by the notochord and they signal a delimited region of the epiblast to differentiate into the slipper-shaped neural plate. If the cells over the notochord fail to receive the message to become ectoderm (i.e. because *Noggin, Chd* or *follistatin* are present and inhibit *BMP-4*), those cells become the neural plate. If the neural plate receives no other signals, it will develop into the brain. If, in the caudal part of the embryo, the somites (derived from

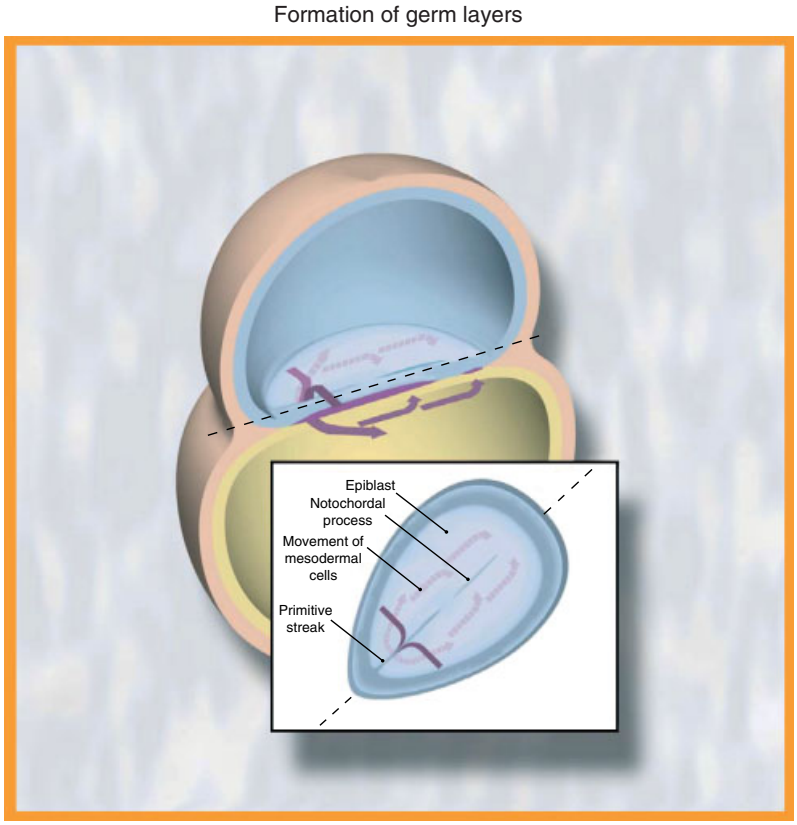

Figure 13 The formation of the human third germ layer (mesoderm) is illustrated. On GD15, a groove (primitive streak) appears in the caudal half of the embryo. Epiblast cells migrate medially to the primitive streak, where they ingress between the epiblast and endoderm and migrate laterally and cephalically to form the mesodermal layer. Epiblast cells that ingress through the cephalic point of the primitive streak migrate directly in the midline to form the notochordal process. The solid arrows demarcate the migration of epiblast cells; the dashed arrows depict the movement of the ingressing mesodermal cells. (Reproduced from DeSesso *et al*., 1999. © John Wiley & Sons, Inc.)

mesodermal cells that contribute to the formation of the vertebrae) secrete fibroblast growth factor (FGF), it specifies that the neural plate in that region shall become the spinal cord.

The neural plate is a cohesive structure whose cells are linked together by junctional complexes. There are structural changes that occur within the neuroepithelial cells that contribute to the formation of the neural groove and then the neural tube. Initially, the notochordal process emits signals that tell the cells of the cuboidal epiblastic ectoderm to change their shape to high columnar; as these cells migrate laterally and away from the central axis, they become truncated pyramids—not unlike building a stone arch. These cells then adopt shapes to create the cylindrical neural tube. As reviewed in Wallingford (2005), the different cell shapes are determined by:

- Actin filaments at the tops of these cells that cinch the crest and force the apex to become narrower than the base.
- Adhesion molecules located at specific apices of the neuroepithelial cells (facing the lumen of the future central nervous system) help these cells retain their new-found shape, while maintaining their positions relative to each other even as their orientation changes from a flat sheet into an arch.
- Microtubular polymerization along the apical–basal axis leads to increased cell height.
- The location of the nucleus within the cell causes the cell to bulge and changing their location changes the height and shape of these cells.

Initially, the neural plate appears as a flat teardrop, broad in the cranial aspect (presumptive brain) and tapering back towards the caudal end (presumptive spinal cord). As the embryo grows, the primitive node moves caudally, with resultant lengthening of the notochord as the latter continues to induce the neural plate. The edges of the neural plate gradually elevate, forming the neural groove; these changes result from continued induction of the caudal neural plate, mitotic divisions in the neuroepithelium, alterations in cell shape (the tall columnar neuroepithelial cells become short cylinders

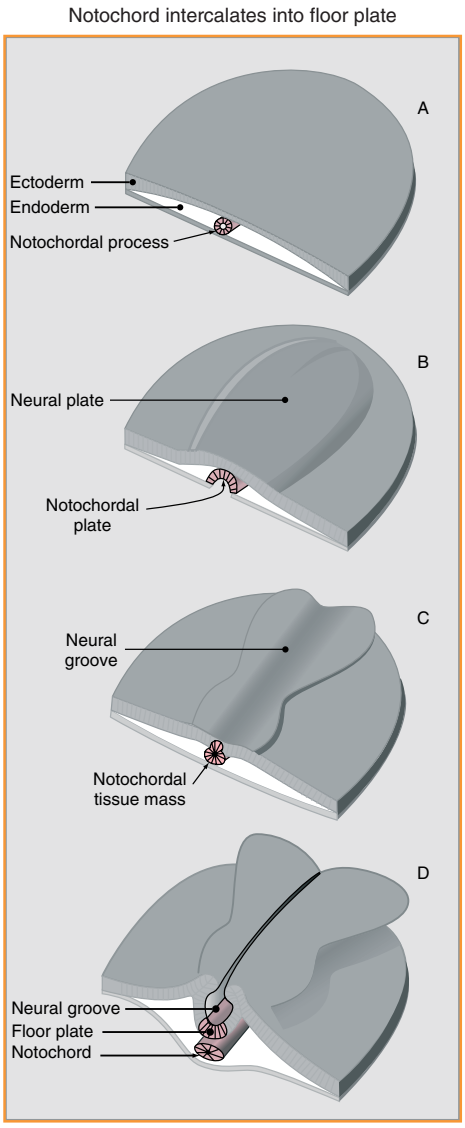

Figure 14 Sequence of diagrams that illustrates the notochordal and neuroepithelial tissues during human neurulation. Early influence of the notochordal process (shown in A) is important in differentiation of the neuroepithelium of the neural plate from the ectodermal epiblast (B). The notochordal process is intercalated into the endoderm as the notochordal plate (B), followed by its separation from the endoderm and reorganization into a tissue mass (C) that gives rise to the definitive notochord and contributes to the floor plate of the neural groove (D). (Reproduced from DeSesso *et al.*, 1999. © John Wiley & Sons, Inc.)

with wide tops) and positional rearrangements of the neuroepithelial cells.

The tall columnar neuroepithelial cells of the neural plate remain firmly attached to each other at the lumen (amniotic) surface and at the basal surface where they face the notochord and mesoderm. During the cell cycle, the nuclei of these cells move in between the mesodermal surface and the dorsal (luminal) surface. During interphase, the nucleus is located near the basal surface, but when the nucleus is ready to divide it is found at the lumenal surface. As the nucleus traverses the cell from basal to luminal surfaces, it causes the cell to bulge. Thus, the shape of the neural plate cells depends on the average location of nuclei among all of the neuroepithelial cells. For any given cell, when the nucleus is in the middle of the cell, the cell assumes a spindle shape with tapered ends; when the nucleus is at either end, the cell assumes a broad or bulbous shape at that end and it tapers towards the other end (**Figure 15**).

The process of rolling up the neural plate into a hollow neural tube is called neurulation. Generally speaking, the neural plate elevates into a 'U' shape, in part because the underlying paraxial mesodermal cells proliferate and push the overlying neuroepithelial cells upwards towards the dorsal aspect. The ridges of the 'U' continue bending towards the midline and fold over to form the neural tube. To understand this important step, a few details of this process follow. Prior to neurulation, the notochordal process is a hollow tube. As the epiblast-derived endoderm replaces the hypoblastic cells (forming the definitive embryonic endoderm), the notochordal process (found at the midline) is attached to the edges of the migrating hypoblast cells and it completes the lining over the yolk-sac cavity. The notochordal process opens up to form an arch (notochordal plate) and then attaches itself to the overlying neuroepithelium. The notochordal plate and the neural plate are connected such that the notochordal plate acts as the neural plate's anchor; differential growth and morphogenesis of the paraxial mesenchyme (which develops into blocks of tissue called somites) contribute to pushing up the two lateral edges of the neural plate while maintaining the anchored connection in the middle. This forms the neural groove (**Figure 15**). Some of the notochrodal cells are incorporated into the bottom of the neural plate and later form the floor of the neural tube. Then, the notochordal plate separates from the neural plate and forms the definitive notochord, a structure that not only generates cell signals, but also provides some rigidity and gives the embryo its axial symmetry.

During the latter part of the third and into the early part of the fourth week, the neural groove deepens with increasing elevation of the neural folds and the folds begin to fuse in the dorsal midline. This fusion process is initiated at several locations along the neural tube and fusion mechanisms vary with location (O'Rahilly and Müller, 1989). In some areas, the initial contact is at the surface ectoderm, with interdigitation of surface cells from the two sides fusing. In other areas, the surface and neural ectoderm from each side make simultaneous contact. Regardless which cells make initial contact, in the dorsal region of the fusing neural folds, the epidermal epithelium and neuroepithelium first delaminate from one

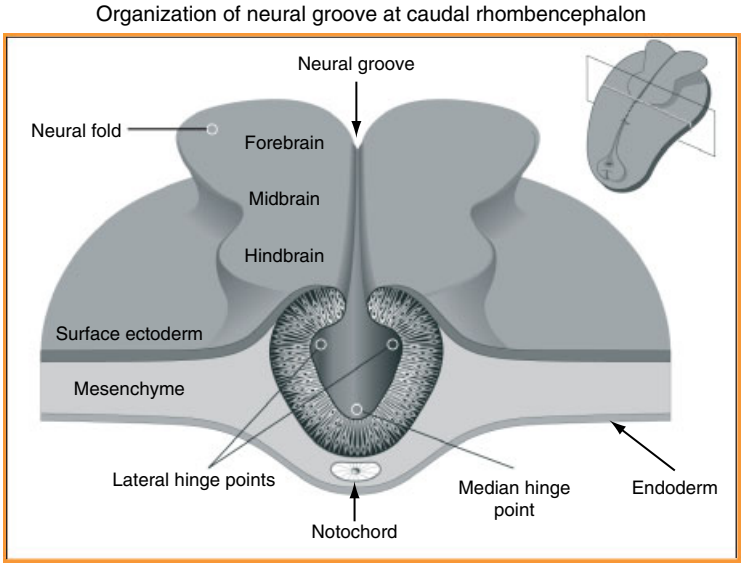

Figure 15 A cross-sectional diagram through the hindbrain of a human embryo during neurulation. There are two lateral hinge points at the region where the neural folds bend and approach each other in the midline and one median hinge in the floor plate that is associated with the notochord. Note the regional differences in position of the neuroepithelial cell nuclei; these help in cell wedging. The neural folds in areas that will form the forebrain, midbrain and hindbrain are of dramatically different sizes. Note the absence of interposing mesenchyme or neural crest cells between the surface ectoderm and the neuroepithelial cells prior to neural fold fusion in the cranial region. (Reproduced from DeSesso *et al*., 1999. © John Wiley & Sons, Inc.)

another providing a pre-existing source of each cell type used in closure (Martins-Green, 1988). The surfaces of the apposing ectodermal and neuroepithelial cells elaborate complex carbohydrates that aid in both recognition and preliminary fusion (Sadler, 1978; McLone and Knepper, 1986). In the rhombencephalon and perhaps at the neuropores, the neural tube is closed by a roof-like membrane that grows over the elevated, but still separated, neural folds (Van Allen *et al*., 1993). The diversity of cellular mechanisms used in this fusion may be one explanation for the different sensitivities of defects in various regions of the embryonic CNS (O'Rahilly and Müller, 1989).

Neural fold closure begins in the cervical region at somite 4 and progresses both rostrally and caudally. The head of the embryo is older than the tail due to the regression of the primitive streak. Because the head and tail are at different stages, the neural tube does not fold evenly along its axis. The right and left sides of the neural plate first make contact then fuse at what will be the nape of the neck (somite 4), and early fusion progresses along the somite regions. At one time, it was thought that from the initial point of contact, the tube 'zipped up' in both directions (i.e. towards the cranial and caudal neuropores), but in fact closure occurs at multiple locations and the large neuropores are only the last of several closure regions. In humans, the anterior neuropore closes 24–26 days after fertilization (20 somite stage) and the posterior neuropore closes at days 25–28 (26 somite stage); the anterior neuropore requires ~5.5 hours to close a gap of 0.3 mm compared with 27 hours to close the same size gap at the posterior neuropore (O'Rahilly and Müller, 1989).

Establishment of hinge points is one of the prominent changes in the neuroepithelium. In the cranial region, there are three such points: one in the midline (where the notochord adheres to the overlying neural plate) and two dorsolateral (**Figure 15**). In the caudal region, there is only one such point. The hinges are formed through alterations in neuroepithelial cell shape, termed wedging (**Figure 16**). The height of the cell in the median hinge decreases simultaneously with an increase in the height of cells lateral to the hinge point. The disparity in cell height accentuates the midline folding of the neural plate and results in a midline furrow. Elevation of the neural folds results in part from the configuration of cells at the hinge points, where they are narrower at their apices than at their base.

Cell wedging depends on the adherence of the neural plate to the notochord and it is related to alterations in cell-cycle length (Schoenwolf and Smith, 1990). The nuclei of the neuroepithelial cells move towards the apex for mitosis and move to the base during interphase; prolongation of the cell cycle with a longer duration of interphase results in a greater amount of time during which the nucleus is at the base and during which the cell is wedge-shaped. The prolonged cell cycle occurs at all three hinge points and in the median hinge, it is associated with juxtaposition of the neural plate and notochord.

The bending forces of cell wedging are supplied by microfilaments at the apices of the neuroepithelial cells.

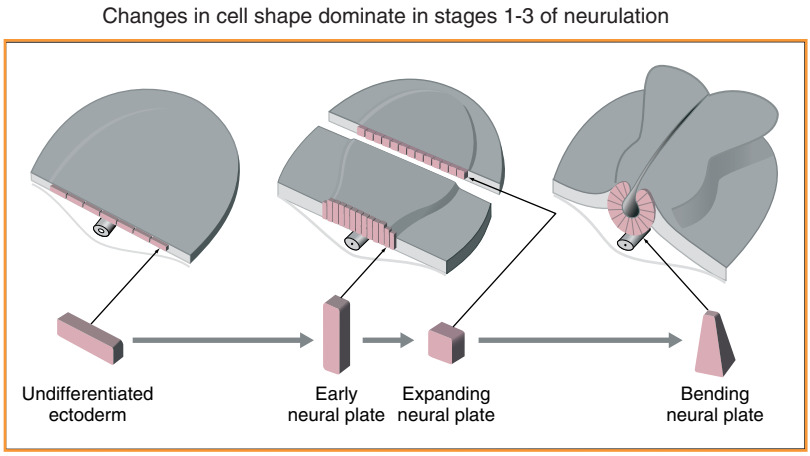

Figure 16 This sequence of diagrams illustrates the changes in shape that occur among neuroepithelial cells as human neurulation proceeds. In the diagram on the left, the undifferentiated epiblast is depicted as squamous cells that are subject to inductive signals with the adjacent notochord and mesenchyme to become the tall columnar cells of the neural plate (shown in the lower portion of the middle diagram). Subsequently, the tall columnar cells shorten themselves, thereby increasing the surface areas of their tops and bottoms and causing the neural plate to expand (upper portion of the middle diagram). With continued growth, the neuroepithelial cells exhibit asymmetric tops and bottoms; the lumenal surfaces become constricted, giving the cells the appearance of a wedge. Cellular wedging is a consequence of differential displacement of the nuclei (**Figure 15**) and it assists in formation of the neural groove (right). (Reproduced from DeSesso *et al*., 1999. © John Wiley & Sons, Inc.)

Synthesis and elaboration of the extracellular matrix, including hyaluronic acid (Schoenwolf and Fisher, 1983) and the cell adhesion molecules E- and N-cadherin (Newgreen *et al*., 1997), are import in expansion. As important as they may be, the forces of cell wedging are not the only drivers of neural fold elevation, as migration and expansion of the surface ectoderm and growth of the mesoderm beneath the neural plate all contribute to normal neural fold elevation (Schoenwolf and Smith, 1990).

The caudal part of the future spinal cord does not participate in the 'rolling up' of the neural plate (primary neurulation). This region is formed from the caudal eminence (in animals with tails this is significant, but less so in humans). Human embryos do have a tail bud that can be seen at the end of the fourth week (DeSesso, 2006) and it forms from the lower part of the pelvis (and in the tails of animals normally having one). Within the tail bud, condensation of undifferentiated mesenchymal tissue (caudal eminence) intercalates with overlying ectodermal cells to form a solid core (blastema). A lumen develops inside the blastema forming a hollow structure that fuses with the caudal end of the primary neural tube (week 6). In humans, the caudal eminence gives rise to a very small part of the neural tube incorporating (at most) spinal cord segments S4 and S5 and the coccygeal elements.

The vertebrate sensory and much of the autonomic system originate with the neural crest and neurogenic placodes. The neural crest is an ectodermal derivative that arises bilaterally along the length of the neural tube to form postganglionic autonomic motor neurons, pigment cells, some endocrine tissues and it contributes to the anterior neurocranium. As the body architecture advances, the neural crest cells migrate away as the neuroectoderm elevates and fuses to form the neural tube.

Vertebrate body organization depends upon development and differentiation of the cephalic epidermal placodes and the hypomere (the unsegmented lateral plate mesoderm found along the ventral aspect). The sensory organs of the head are derived exclusively from the placodes. The epidermal and dorsolateral placodes and the neural crest originate with the ectoderm; the dorsolateral portions of the anterior (cephalic) placodes participate in formation of the sense organs and adenohypophysis, and the ventrolateral portions give rise to the cranial sensory nerves (including the taste buds). Cells from the placodes and neural crest migrate through an extracellular mucopolysaccharide milieu; the data suggest these active organizing centres operate independently and they are derived from an ancestral protochordate. Thus, the principal difference between vertebrate chordates (like hagfish and humans) and the protochordates is the addition of a head. The unsegmented lateral plate mesoderm provides the foundation from which the musculature of the gut and heart derive; in contrast to the neural crest, placodes and special sense organs of the head, comparative data suggest that the hypomere and its skeletal, smooth and cardiac muscle derivatives evolved down an independent pathway from primitive myoepithelial cells (Gans and Northcutt, 1983).

Commensurate with the extensive evolution of vertebrates from primitive metazoic species, numerous and complicated (albeit conserved) cell-to-cell signalling patterns and transcription control pathways came into existence. It is nothing short of remarkable that the basic framework and control systems at the level of the gene are so similar in nematode worms, arthropods and chordates. The increased complexity of higher-order animals comes with common mechanisms that activate and inactivate specific circuits and response profiles (e.g. proliferation, apoptosis, migration) that—under normal circumstances—are subject to strict, orchestrated regulatory controls in both space and time. These complex patterns of gene activation, feedback and repression are not only conserved across phyla, but are repeated over and over in embryonic construction of the more than 300 cell types found in the vertebrate body. The real differences between more primitive and more complex animals rest with the larger numbers of possible combinations, permutations and variations on the basic circuits that are conserved across apparently unrelated (and structurally diverse) animals.

Conserved within the inductive changes in embryonic tissues and spatial contortions that dictate development of a single spherical mass of cells into the segmented cylindrical body are the remarkable intracellular and intercellular regulatory circuits whose expression is repeated over and over as development progresses. These controls are choreographed and the cell signals (of which at least 17 are well described) used and the range of cell responses are common to arthropods, worms and vertebrates. Fourteen of these information-transfer pathways rely on signal activation and transduction, where an agonist combines with its transmembrane receptor, followed by conversion of multiple intermediates from inactive conformations to active conformations and these then activate various protein kinase enzymes that phosphorylate target proteins. Other information transfer pathways involve intracellular receptors (e.g. the retinoic acid family). The common embryonic signalling pathways (e.g. ANT-1, transforming growth factor β (TGFβ), Hedgehog (Hh), Notch-Delta, Cytokine and the Nuclear Receptor) and cell responses to those signals have multiple variants (e.g. the TGFβ family has at least 24 members, including the *Bmp*7, *TGIF*, *TGif2* and *Noggin*). These pathways have been conserved over diverse phyla because they 'were present and already functional in the pre-Cambrian common ancestor of those animals' (National Research Council, 2000).

Embryos use these regulatory circuits sequentially over both small (e.g. physically adjacent cells) and comparatively large (e.g. direction and extent of axon growth) distances to direct organization of whole tissues and organs. Distinct biochemical cascades generate messenger RNA (mRNA) and protein gradients (e.g. high at the anterior and low at the posterior) and these cascades control implementation of the three-dimensional (back-to-front and top-to-bottom) 'body plan'. In turn, these proteins activate positional 'gap' genes whose transcription yields 'gap' proteins that activate 'pair-rule' genes that, when transcribed, activate segment-polarity genes that, when transcribed, activate segmented homeotic or homeobox (*Hox*) genes (e.g. *Ubx* and *Antp*).

Members of the *Hox* gene family (including the Hhs sonic *Shh*, Indian *Ihh* and desert *Dhh*) share ~60 base pairs (termed the homeobox) and are expressed along stripes that correspond to both the anteroposterior body dimensions and their order on the chromosome ('colinearity'); these *Hox* gene anteroposterior patterns (stripes) are seen in *Drosophila*, frog and mouse embryos, but the patterns in mice are more numerous and more complicated than those in arthropods. During anteroposterior patterning in *Drosophila* embryos, gap proteins (also called transcription factors) activate eight pair-rule genes that are arranged in seven stripes arranged in sevenfold repeats. These eight segment-polarity genes are activated by combinations of at least two pair-rule proteins amounting to a total of 14 expression stripes. The 14 segment-polarity genes correspond to the 14 segments of the head, thorax and abdomen. Segment-polarity genes are activated only by pair-rule proteins; *Hox* genes are activated by pair-rule and segment-polarity proteins that correspond to eight domains in the head, thorax and abdomen. Following activation of *Hox* and segment-polarity genes, the pair-rule and gap genes are no longer expressed and their proteins are degraded. Dorsoventral development also employs transcription factors that in *Drosophila* originate with the Pipe protein, a transcription factor that is expressed on the future ventral part of the body and that is involved in mesodermal induction. The Pipe protein activates a series of cascades that ultimately hydrolyse the Spätzle protein to a peptide that binds the Toll transmembrane receptor found on one side of the fertilized egg. The activated transmembrane Toll receptor then activates a series of intracellular reactions that activate the Dorsal protein that, in turn, activates the *Twist* and *Snail* genes (whose transcription products activate gastrulation genes) that inhibit other genes (*Zen* and *Dpp*).

On the other side of the future torso, the inhibitory Dorsal protein is not expressed so that *Zen* and *Dpp* are expressed on the ventral side. On the lateral margins, Dorsal represses *Zen* and *Dpp* expression, yet the expression of Dorsal is not so great as to activate *Twist* and *Snail*. So it comes to be that the early body plan is comprised of three regions (dorsal, lateral and ventral) that arise as a result of expression of *Zen, Dpp* and *Sog*, the last of which encodes for a protein that diffuses into regions controlled by *Zen* and *Dpp* inhibiting their expression in regions giving rise to the future dorsal ectoderm. Interactions between *Hox* gene-expression-patterns control orientation and establishment of the neuroectoderm, neural tube (brain, spinal

cord), somites (vertebrae), cranial neural crest (branchial arch cartilage, sensory ganglia, peripheral nerve Schwann cells, odontoblasts) and limbs in a manner akin to a central dispatching office that is under the control of a complex regulatory network, where independent gene action is discouraged and whose carefully orchestrated transcription products subsequently regulate genes within their individual regions over time and space.

Vertebrate *Shh* arises from the notochord (among the earliest recognizable features of the embryonic midline extending from the prochordal plate to the primitive node) and floorplate. *Shh* expression is required for induction of cells in the ventral neural tube, leading to development of the motor neurons, interneurons of the trigeminal nucleus, neural crest, pituitary gland, oligodendrocytes, the floor plate, the primitive foregut and the developing limb. There is a corresponding *Bmp* gradient that is highest in the dorsal roof and *Bmp* inhibitors arise from the notochord. Dorsal–ventral patterns are determined by the *Bmp* gradient and its activity is reduced by the Tsg (Twisted gastrulation or *Twsg* 1) and *Chd* secreted proteins that bind *Bmp* and prevent its signal; the signal is re-established when a metalloprotease (Tld) hydrolyses *Chd* from its complex with *Bmp* (Larrain *et al*., 2001). Together, the actions of the *Shh* and *Bmp* pathways specify the interneurons and motorneurons, and the *Tsg* and *Bmp* signals control chondrogenesis. Vertebrate *Shh* participates in establishment of the left–right body axis, beginning at the axial mesoderm and it controls CNS dorsal–ventral orientation all along the rostral–caudal plane (Roessler and Muenke, 2003). Among transgenic mice with reduced *Shh* expression, the floor plate fails to develop (Litingtung and Chiang, 2000).

The precursor *Shh* protein is a large peptide that undergoes post-translational autoprocessing to the biologically active form. Autoprocessing involves hydrolysis of the parent protein to a 45 kDa form that yields a 19 kDa amino-terminal and a 26 kDa carboxy-terminal peptide that is esterified with cholesterol molecules at the amino (*Shh*-Np) and carboxy (*Shh*-C) domains. The addition of cholesterol at the C-terminus apparently anchors *Shh* in the cell membrane. Esterification of *Shh* controls its diffusion and confers spatial restriction on the activity associated with the N-terminus. Free *Shh* binds the downstream genes, patched 1 (*Ptch1*), patched 2 (*Ptch2*) and smoothened (*Smo*), and the former inhibit *Shh* signalling in the ventral neural tube. Neural tube *Ptch* expression is upregulated by the *Shh* signal. Relatively high *Shh* and *Ptch* local concentrations are expressed close to the notochord and floorplate and their concentrations decline dorsally as distance from the notochord increases. When the biologically active form of *Shh* binds *Ptch*, the latter is inactivated and *Smo* increases; in the absence of *Shh, Ptch* inhibits *Smo* activity. *Smo* is a seven-pass (serpentine) transmembrane protein that supports *Shh*-directed patterns in the ventral neural tube and *Smo* is important because its actions release *Glis*, transcription factors that mediate *Shh* signal transduction. All three vertebrate *Glis* translocate to the nucleus where their zinc-finger domains bind and activate the promoter consensus sequence TGGGTGGTC in *Shh/Hh* target genes. Cytoplasmic *Glis* are controlled by sequestration with kinase (Fused and Fused suppressor [Su(fu)]) and kinesin-related (Cos-2) proteins to prevent accumulation of *Glis* in the nucleus. The transcriptional activator *Gli1* differs from its siblings in that its amino acid sequence outside the zinc finger is not homologous, and the N-terminal domains of *Gli2* and *Gli3* have repressor functions. The C-terminal domains have activator functions. Functional *Gli* genes are required for neural tube and interneuron development; *Gli2* and *Gli3* are expressed in the neural plate, whereas *Gli1* is found in the ventral neural tube. These genes participate in control of and gradations in *Shh* signalling in neural plate cells and they control *Hox* gene inhibition (Class I) or activation (Class II) along the dorso-ventral axis of the neural tube.

Finally, there is added complexity of the so-called 'cross-talk' between signalling pathways in early embryonic pattern formation and the existence of additional pathways that antagonize the activity of the basic pathways. For instance, the *FRzb*, *Cerberus* and *Sizzled* antagonists modulate the *Wnt* pathway and signals from the *Shh* pathway repress the activity of the Nodal *TGF β* pathways. Mice with defective *TGF β 2* genes are born with cardiac, lung, limb, and craniofacial malformations and NTDs, those with defective *Noggin* genes develop NTDs and mice with defective *Bmp7* genes develop hindlimb polydactyly and renal malformations (Dudley *et al*., 1995); mice missing one copy of *Bmp4* develop holoprosencephaly and craniofacial malformations (Zakin and De Robertis, 2004) and mice with homozygous null *Shh* genes are born with axial skeletal and limb malformations and cyclopia (Chiang *et al*., 1996).

3 PATHOGENESIS OF SELECT CONGENITAL MALFORMATIONS

There are at least 860 specific categories of structural defects (Wise *et al*., 1997) and among those some have multiple variants (Spencer, 1992). Consideration of the immense volume of literature dedicated to each necessitates restriction of the present discussion to the conditions described in the preceding section.

3.1 Conjoined Twins

Human conjoined twins are extremely rare (1 : 50 000 to 1 : 200 000 live births) and there are no reliable animal

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

models for any of the many conjoined variants. There are ample reports of conjoined rodents, cats, rabbits, dogs, cattle, horses and lambs, but all of the specimens are apparently spontaneous and unrelated to any known xenobiotic or physical factor(s) (Willhite *et al*., 1985). Conjoined twins are always joined along the body axis (head-to-head, tail-to-tail, front-to-front, rump-to-rump or side-to-side) sharing the same anterior–posterior orientation. There are no accounts of twins having been joined solely by their limbs or with posterior structures of one joined with the anterior of the second or the dorsal side of one joined with the ventral of the other.

It has long been thought that conjoined twins result from incomplete separation ('fission') of the embryonic inner cell mass (Moore, 1977). More recent descriptions suggest that reunion ('fusion') of two separate embryos may occur, sometimes leaving only vestiges of one (Spencer, 1992). Parallel duplication of the notochord leads to parapagus twins. Parasitic rachipagus (fused double spinal columns) have been attributed to the dorsal union of two identical embryos 'having occupied directly opposite aspects of a single amniotic cavity and the union having occurred in the open neural folds before they united to close the neural tube' (Spencer *et al*., 1996).

3.2 Cyclopia

It is during the third and fourth week of gestation (often before a mother knows she is pregnant) that the human embryo is but a very small flat disc of cells and becomes organized into three layers: the dorsal-most ectoderm, the ventral-most endoderm and the intra-embryonic mesoderm. By this time, cells on the dorsal surface migrate from the early primitive streak towards the future head. By the end of the first month of human pregnancy, the anterior neural folds have completed their elevation and fusion. In short order, this single tube continues to grow and expand and three primary swellings (termed vesicles) appear: the forebrain (prosencephalon), the midbrain (mesencephalon) and hindbrain (rhombencephalon). By five weeks, the prosencephalon grows into two distinct regions: the anterior telencephalon (end brain) with two lateral bulges (primitive cerebral hemispheres) and the diencephalon (destined to give rise to the optic vesicles).

Varying degrees of failure in division of the prosencephalon into proper cerebral hemispheres account for the wide range of conditions known collectively as holoprosencephaly. In its most striking form, there is no recognizable forebrain, a single optic vesicle develops as an outgrowth and the face is severely distorted (**Figure 5**). Holoprosencephalic malformations have been associated with abnormal function of several gene families (e.g. *Six3*, *Zic2*, *TGIF*) (Wallis *et al*., 1999; Brown *et al*., 1998; Muenke and Beachy, 2000), but the most firmly established mode of action concerns interference with the mitogenic, inductive and survival functions of the *Hh* protein family (Belloni *et al*., 1996; Roessler and Muenke, 2003). Of the three *Hh* factors (Sonic, Indian, Desert), prechordal plate *Shh* has been most thoroughly studied and its proper function is required for induction of the ventral brain and spinal cord cells (Nanni *et al*., 1999).

Mutational analyses of 30 families having members with familial or sporadic holoprosencephaly revealed at least five mutations in the *Shh* exon 3 (Roessler *et al*., 1997). In the first multigenerational family, there was a GTG → GAG sequence change in the *Hh* gene that resulted in a single invariant amino acid substitution (Val224 → Glu224). All of the members of this family who displayed signs of holoprosencephaly exhibited this genotype and none of the normal members had this mutation. In the second family, the affected individuals and an unaffected father (who was a carrier of a GCG → ACG mutation) had an Ala226 → Thr226 substitution in the C-terminus of *Hh*. A 21 base-pair deletion was detected in two members of another affected family and this deletion segregated as an autosomal dominant; this deletion resulted in the loss of seven amino acids in an *Hh* processing protein. In yet another family, a GAG → TAG mutation (also linked to chromosome 7q36) resulted in premature termination of *Shh* at position 284 and in still another, there was a GCG → ACG substitution that coded for a Thr → Ala change at position 384. Reduced *Shh* activity in human ventral brain results in failure of *Shh* target gene regulation. Mis-sense mutations in *Shh* result in conformational changes that reduce *in situ* activity to the point that the downstream genes that normally respond to the *Shh* signal are not activated (Schell-Apacik *et al*., 2003). Relative failure to activate the downstream members of the *Shh*-induced cascade disrupts pattern formation in the midline brain and these lead to various degrees of failure of prosencephalon separation into the primitive cerebral hemispheres, leading to failures in pattern formation within the diencephalon. Based on these observations, Roessler *et al*. (1997) predicted that about 23% of familial and 0.005% of sporadic holoprosencephalics were associated with haploinsufficiency for the human *Shh* gene. Follow-up studies found that 37% of families with holoprosencephalic members had *Shh* mutations (Nanni *et al*., 1999), that mutations in *Ptch1* reduced the *Shh* signal (Ming *et al*., 2002) and that deletion of or single nucleotide polymorphisms in the *TGIF* gene (a 272 polypeptide homeodomain transcriptional repressor) that misfold the protein were also seen in human holoprosencephalics (El-Jaick *et al*., 2007).

When the teratogenic activity of cyclopamine and its congeners was discovered, it was hypothesized (due to its structural resemblance to steroid hormones) that these compounds could compete with endogenous steroids and interfere with protein synthesis (Brown and Keeler, 1978). Although cyclopamine shares structural features with cholesterol (**Figure 6**), cyclopamine actions involve neither endogenous steroids, cholesterol metabolism nor intracellular transport (Incardona *et al*., 2000). Cyclopamine interferes with activation of the *Shh* pathway (Cooper *et al*., 1998; Incardona *et al*., 1998) by inhibiting *Shh* signal transduction in a concentration-dependent manner (Incardona *et al*., 1998). It does so not by interference with *Shh* or *Smo* biogenesis or processing (Incardona and Roelink, 2000), but as a result of binding at the *Smo* heptahelical domain to induce a conformation shift in that protein. The conformational shift induced by cyclopamine binding is similar to that induced by *Ptch* that places the membrane protein *Smo* into an inactive state and inhibits *Shh* signal transduction (Chen *et al*., 2002).

Confirmation of the *in vivo* actions of cyclopamine and the temporal nature of *Shh* pathway inhibition come from the studies of Cordero *et al*. (2004) who found that *Hh* blockade prior to *Shh* expression in the prosencephalon produced a single fused telencephalic vesicle in the chick embryo. Blockade of the *Hh* pathway with cyclopamine after *Shh* was expressed in the prosencephalon produced malformations of the face without forebrain defects; thus, Cordero *et al*. (2004) were able to reproduce the full range of variable midline defects of the brain and face that are characteristic of holoprosencephaly and demonstrated that pathogenesis of holoprosencephalic defects depends upon disruption of the *Hh* control pathway at different stages.

3.3 Neural Tube Defects

Although it has been assumed that anencephaly and spina bifida represent failure of closure of the anterior and posterior neuropores, respectively, clinical evaluations suggest that this concept is incorrect (Murakami, 1968; Warkany, 1971; Lemire *et al*., 1978; Golden and Chernoff, 1995). It appears more likely that human NTDs correspond to failure of neural tube closure in larger regions, rather than to only the much smaller neuropores. Extensive failure of closure at the neuropore and down towards somite 4 results in cranioschisis.

Due to the intricate timing and complex tissue interations during neurulation, the process is prone to error. Interruption of any of the aforementioned steps can precipitate faulty development. NTDs are multifactorial in origin and their cause has both genetic and environmental components (Fraser, 1976). Several lines of evidence support this view (DeSesso *et al*., 1999):

- The incidence of NTDs varies greatly among ethnic groups, suggesting genetics plays a role (Copp and Bernfield, 1994).
- The incidence displays a familial pattern among first-, second- and third-degree relatives (Carter, 1974; Copp and Bernfield, 1994).
- Cranial NTDs occur two to three times more frequently among females than males (Carter, 1974; Seller, 1987).
- Increased NTD risk is associated with defects in the gene for 5,10-methylenetetrahydrofolate reductase (*MTHFR*) (van der Put *et al*., 1995; Whitehead *et al*., 1995; Ou *et al*., 1996).

Emery (1986) argued that the human NTD data infer a 60% heritability. Genes other than *MTHFR* implicated as causal factors in human NTDs include those for folate receptor-α (Finnell *et al*., 1998; Trembath *et al*., 1999), *PAX3* (termed *Hup2* in humans) (McLone, 1998; Trembath *et al*., 1999) and others (Fleming *et al*., 1997) that are indispensable for neural tube closure.

Investigations with mutant mice (Copp and Bernfield, 1994; Spörle *et al*., 1996; Smith and Schoenwolf, 1997) led to a catalogue of spontaneous mutations and knockouts that induce NTDs (Harris and Juriloff, 1997). Given the similarities in chordate neurulation, there is optimism that identification of molecular entities that mediate normal and abnormal neurulation in mice (Goulding and Paquette, 1994; Lumsden and Krumlauf, 1996; Tanabe and Jessell, 1996; Fleming *et al*., 1997) will yield information of clinical relevance.

A great many agents (e.g. inorganic arsenic, trypan blue) have been used to study mechanisms responsible for the pathogenesis of NTDs (DeSesso *et al*., 1998; Morrissey and Mottet, 1980). In fact, any material that interferes with one of more of the numerous developmental processes involved in neurulation *if given at an effective delivered dose at the specific time of development when neurulation occurs* will likely elicit an NTD. Thus, the fact that many substances can induce NTDs in laboratory animals should come as no surprise. However, the prevalence of NTDs and their multifactorial nature precludes one from inferring that the mere existence of the defect must be the result of exposure to a particular material or agent.

3.4 Sirens

By the beginning of the fifth week of normal gestation, the two posterior limb buds become evident as a somatic mesodermal core and overlying ectoderm. The initial factors responsible for the siren remain largely unknown, primarily because the condition is so rare and its presentation is so variable. In some cases, there is complete absence of the caudal vertebrae, urinary

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

tract, bladder and hindgut, but others present with a patent large intestine, urinary tract and traces of sacrococcygeal vertebrae. Genetic and xenobiotic manipulations in rodent and chick embryos (e.g. inorganic Pb, amphetamines, trypan blue) can induce caudal defects (e.g. haematoma, regression and dysplasia) in some cases, but until recently there was no reliable animal model of the mammalian siren. From studies at foetal autopsy, at least three explanations for merging, malrotation and defects of the lower limbs have come forward and these have provided some insight into pathogenesis of the siren.

Ordinarily, an early vascular plexus is present around the distal primitive streak and blood channels can be seen even before the somites are evident. Subsequently, the secondary yolk sac supplies embryonic nutrients through the developing embryonic cardiovascular system. These transient vitelline veins are continuous with a web of diffuse blood vessels that surround the yolk sac. Kampmeier (1927) advanced the hypothesis that 'vascular steal' developed and this resulted in a single umbilical artery that arose directly from the abdominal aorta. In this version, merging of the lower limbs follows transfer of blood from the caudal regions of the embryo through a single 'aortic-umbilical artery' (Stevenson *et al*., 1986). This hypothesis holds that reduced vascular perfusion results in reduced angiogenesis leading to disruption of the caudal mesoderm. Alternative hypotheses held that death and complete resorption of one of two monozygotic twins leads to sirenomelia (Kapur *et al*., 1991), that lateral compression of the amniotic folds was responsible or that induction of a localized caudal haematoma between days 13 and 22 was responsible (Barr, 1988). Chandebois and Brunet (1988) observed that a 'factor may stop the migration of the caudal mesodermal cells at the end of the primitive-streak stage'.

Sirens arise from abnormalities induced during establishment of the three germ layers (gastrulation) and prior to the appearance the body form (prior to the end of the third week of human development). Histologic examination of compound mutant $Tsg^{+/-}$; $Bmp7^{-/-}$ mouse embryos destined to become sirens found only a single abnormal umbilical artery arising directly from the dorsal aorta (Zakin *et al*., 2005). At this stage, the lateral plate mesoderm of control embryos was thickened in preparation for growth of the right and left hindlimb buds, but in the mutants, there was only a single ventral mesodermal thickening in the midline and the tailbud mesoderm was sparse. Reductions in the numbers of ventroposterior mesodermal cells due to reduced *Bmp7* signalling results in early fusion of the hindlimb buds and coelomic cavities. Cells of the posterior primitive streak were apparently specified correctly, but cells in the affected ventral posterior mesoderm were 'unable to either proliferate or survive' and the mutant hindlimb buds were fused as early as day 9.5; endodermal *Shh* expression in these mutants was reduced and corresponded to the structural reductions in the hindgut and genitourinary tract (Zakin *et al*., 2005).

4 EVALUATION OF ANIMAL DATA AND HEALTH RISK ASSESSMENT

Developmental toxicity studies ascertain whether a test agent administered to a pregnant mammal adversely affects her offspring. Although data from the mother are collected throughout the study and analysed as part of the assessment, four major end points of developmental toxicity are assessed in the offspring. These end points are: death, structural abnormalities (congenital malformations), altered growth and functional deficits (Harris and DeSesso, 1994). A biologically significant increase in the frequency of any of the four end points indicates the test agent disrupts embryonic development and that sufficiently high exposures may pose a potential developmental hazard for human beings. Standard developmental toxicity tests examine the possibility that a test substance may produce any of the first three manifestations of developmental toxicity. In the past, functional deficits were evaluated infrequently in routine testing, but protocols that include developmental landmarks, motor activity, startle response, a functional observational battery, routine histopathology, *in situ* brain perfusion and brain morphometry are now standard (United States Environmental Protection Agency (US EPA), 1998).

4.1 Testing Procedures

A conventional developmental toxicity assessment begins with a preliminary dose-range-finding or pilot study followed by the definitive toxicity study. The dose-range-finding study determines the exposures to be used in the definitive study. To do this, the range-finding study uses more dose levels with fewer animals per group than the definitive study. A typical range-finding study employs four to six dose groups of 8–10 pregnant animals (usually rats, mice and rabbits) each. A successful range-finding study identifies an exposure that causes minimal maternal toxicity (which will be the highest dose in the definitive study) and an exposure that elicits no adverse effects in the offspring (which will be the lowest dose in the definitive study). In-life maternal data collection requirements in the pilot study are identical to those of the definitive study, but pilot data collected at term are usually limited to gross examination and measures of foetal body weight. The definitive study determines whether or not a test material causes adverse effects in animals and if so, determines a no observable adverse effects level (NOAEL).

4.2 Experimental Design

4.2.1 Route of Exposure

All regulatory agencies recommend that the route of test material administration should be the route by which humans are exposed (Health Canada, 1975; World Health Organization (WHO), 1984; US Environmental Protection Agency (USEPA), 1991a). In these studies, the route of exposure is usually oral (see **Peroral Toxicity**) unless the chemical or physical characteristics (e.g. vapour) (see **Inhalation Toxicity**) indicate a more relevant route of administration.

4.2.2 Dose Selection

The doses in the definitive developmental toxicity study are based on the results of the pilot study. Except when the biological, physical or chemical properties of the test material limit exposure, the highest dose should elicit signs of maternal toxicity (e.g. statistically significant reductions in maternal body weight or body-weight gain). If more than 10% of the treated dams die, the dose is too high. Doses that produce excessive (but nonlethal) maternal toxicity (e.g. convulsions) may also produce increased prenatal death and resorption (rodents) or increased spontaneous abortions (e.g. rabbits). Studies that experience excessive maternal mortality or prenatal loss have limited utility in determining health risk and usually must be repeated. Ideally, the range of doses in these studies should be set such that the highest exposure causes mild signs of maternal toxicity and the lowest dose elicits no adverse effects on the mother or her offspring.

4.2.3 Treatment Groups

The number of treatment groups should be sufficient to establish a dose–response relationship. At a minimum, three groups treated at different dose levels and a concurrent (usually the vehicle in oral studies) control group are required by US and international regulatory agencies. The numbers of animals per group must be large enough to provide sufficient statistical power for meaningful analyses. Most regulatory guidance suggests 20 pregnant rodents and 12–16 pregnant rabbits per group. For changes in body weight to be useful as a valid indicator of potential toxicity, the animals must be assigned randomly to treatment groups in a way that ensures that all dose groups (including the control) start with similar mean maternal body weights and variances. Although regulatory agencies do not often require a reference teratogen ('positive control'), one should be included in the study design for verification of laboratory proficiency.

4.2.4 Exposure Period

Developmental toxicity protocols require time-mating of healthy animals (Kimmel and Price, 1990; Organization for Economic Cooperation and Development (OECD), 1981; 2001; US Environmental Protection Agency (USEPA), 1985; US Food and Drug Administration (USFDA), 1996; 2000). Gestational day (GD) zero (0), the usual reference point for the beginning of gestation, is identified in one of the following ways, depending on the test species and method of breeding. GD 0 is: (i) the day the vaginal plug is observed (rats or mice) or (ii) the day sperm are found in vaginal lavage (rats) or (iii) the day mating was observed (rabbits) or (iv) the day artificial insemination was performed (rabbits). Exposure of the inseminated animals begins after implantation and continues throughout major organogenesis until closure of the hard palate and development of the genitalia (days 6–17 or 18 for rats and mice, 7–19 or 20 for rabbits and 5–14 for hamsters). When the test agent is not incorporated into drinking water or feed and the material is administered by gastric intubation, topical application or inhalation, dosing should be performed at the same time each day with no longer than two hours elapsing between treating of the first and last animals. The timing of exposure is critical because embryological schedules operate during narrow periods of time (DeSesso, 2006). This is especially true in rodents (e.g. hamsters) where gestational stages are compressed.

Current designs incorporate an extended exposure period compared to protocols outlined in historical regulatory guidance. Some designs continue treatment of pregnant animals from the beginning of organogenesis until Cesarean section near term. Such studies can find growth retardation (usually characterized by reduced foetal body weights) that may be missed in studies of short exposure durations. Extended dosing periods allow more thorough evaluation of organs like the heart, brain, lungs and gonads that undergo functional and morphological maturation after the end of major organogenesis. Alternatively, single-exposure studies that target a uniquely sensitive period of development (e.g. early primitive streak) can elicit frank congenital malformations, whereas increased duration of exposure results in higher absorbed doses and increased prenatal death. Thus, the route, frequency and duration of the exposure period may affect the results of a study, and those parameters must be stated carefully when interpreting the study and when comparing different studies.

4.2.5 Study Termination

Pregnant animals should be scheduled for sacrifice and Cesarean section just prior to delivery in order to prevent cannibalization of defective young. Study termination is usually scheduled for GD 21 in rats, GD 18 or 19 in mice and GD 29 in rabbits.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

4.2.6 In-Life Procedures and Data

Humane husbandry practices (National Institutes of Health (NIH), 1985; US Department of Agriculture (USDA), 1970; US Department of Agriculture (USDA), 1990) are required at all times (see **Animal Welfare in the Toxicology Laboratory**). Animals must be observed at least once daily for mortality, morbidity and clinical signs. This is usually accomplished at the same time as body weight is measured. Additional daily observations (shortly after exposures) may be necessary, especially if the test article is acutely toxic to the dam.

4.2.7 Maternal Deaths and Abortions

Pregnant animals can die or abort due to conditions unrelated to the test agent. Such conditions include disease, technical errors during dosing and environmental factors (e.g. hyperthermia). If a pregnant animal dies on test, the necropsy records should be inspected to ascertain the probable cause. For instance, a study wherein the dams were gavaged with an oil vehicle and the deceased exhibited inflamed (red) tracheal lining, pulmonary congestion, nasal discharge and pulmonary oedema, then the most likely cause of death was accidental intratracheal intubation or respiratory disease. Another example is that of a pregnant rabbit whose clinical signs include alopecia, anorexia and diarrhoea; these signs are consistent with a hairball lodged in the stomach (a common occurrence in rabbits). Therefore, any maternal deaths should be investigated, because they may not be associated with the test material, but may be the result of a spontaneous or iatrogenic episode unrelated to the toxicity of the test agent.

Abortions and total litter resorptions may also result from events unrelated to the toxicity of the test material (Chernoff *et al*., 1987; Schardein, 1987). Excessive noise, deviations in the light–dark cycles and rough handling can induce abortions in rabbits. While total litter resorption does not usually occur in rabbits, this can occur in rodents placed under stress.

4.2.8 Maternal Body Weights and Body Weight Gain

In the best designs, the pregnant animals are weighed daily. Alternatively, dams should be weighed according to the following schedule: GD0, GD5, each day of the exposure period; at three to five day intervals during the postdosing period and at study termination. Maternal body-weight gain during specific segments of gestation, especially during the exposure period, is generally a more sensitive indicator of maternal adverse effects than either the mean body weight at study termination or the mean body weight gain over the entire gestational period. The increased sensitivity of incremental body-weight changes is due to their easy detection and the likelihood that those changes will not be masked by a 'rebound' weight gain that can take place after exposure has ceased.

4.2.9 Clinical Signs

Clinical observations are significant qualitative indicators of toxicity. The pilot (range-finding) and other toxicological studies afford an opportunity to confirm clinical signs (e.g. tremors, hunched posture, dyspnoea) induced by exposure to the test agent. Clinical signs and body-weight reductions are the most reliable indicators of maternal toxicity. In many cases, clinical signs are more sensitive indicators of maternal intoxication than changes in maternal body weight.

Documentation of clinical signs includes identity of the observed effect, its time of onset, intensity and duration. Examples of important clinical observations include diarrhoea, excess salivation, discharges from the eyes or nose, hair loss (alopecia), listlessness and convulsions. Likewise, changes in respiratory rate, alertness, mucous membrane colour, urinary frequency and the colour of the urine should be recorded.

Behavioural observations (sometimes described as social interest, passive-avoidance, anxiety, aggression, time spent rearing, feeding or nest building) reported during daily observations are not as objective or quantifiable as clinical signs. These observations are frequently within the range of normal animal behaviour and are not necessarily treatment-related. While changes in behaviour should be recorded, it is not possible to predict whether behavioural changes are early signs of subclinical toxicity that could be manifest as objective clinical signs at higher doses unless a clear dose–response relationship can be demonstrated.

4.2.10 Food and Water Consumption

When the test material is administered in the feed or drinking water, food and water consumption must be measured daily in order to calculate the administered dose. Food and water consumption should also be monitored when the test material is suspected of causing palatability problems due to objectionable taste or odour or causing appetite or excretory effects. Altered food and water consumption after the start of test article exposure are end points that can be used to assess maternal changes, including body weight.

4.2.11 Necropsy Procedures and Data

Detailed descriptions of methodologies for examining offspring are available (Wilson, 1973; Manson and Kang, 1989; Tyl and Marr, 2006). Briefly, the mother is humanely killed and her gravid uterus, with the ovaries intact, is surgically excised and weighed. The corpora lutea on each ovary are counted and recorded for both rats and rabbits; however, in mice, due to the difficulty of differentiating luteal tissue from surrounding ovary, this is not necessary. The uterine contents are examined by incising the uterus along the antimesometrial border

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to open the lumen. The numbers and locations of implantation sites, resorptions, viable and dead foetuses are recorded. Viable foetuses are removed from the uterus, dissected free of their placentae and foetal membranes and weighed. They are then examined to ascertain their sex and evaluated for the presence of external malformations. Pilot studies require no further study of the offspring, but in the definitive study, one half of the viable foetuses are examined for internal (visceral) malformations by either dissection (Manson and Kang, 1989; Staples, 1974; Stuckhardt and Poppe, 1984) or by the freehand razor blade technique (Wilson, 1965). Skeletal structures are visualized in the remainder by clearing then staining with dyes that are specific for bone (alizarin red S; Staples and Schnell, 1968) or bone and cartilage (alizarin red S and alcian blue; Inouye, 1976). An alternative method subjects all foetuses to fresh, visceral dissections of the thorax and abdomen, after which either all foetuses are eviscerated and prepared for skeletal staining or one half are decapitated and the heads fixed in Bouin's solution for examination of the brain and skull by freehand razor sectioning.

4.3 Maternal Data

4.3.1 Confirmation of Pregnancy

When the uterus is examined at study termination, the presence of a conceptus and/or resorption sites is considered evidence of pregnancy. The pregnancy (conception) index for each treatment group can be calculated by dividing the number of confirmed pregnancies in that group by the number of females mated. The pregnancy index is used in the assessment of reproductive performance. Depression of this index relative to that of the control may indicate a possible effect, but *only* if treatment began *prior to mating and implantation*. Since treatment usually begins after implantation is complete, a low pregnancy index suggests maternal health was compromised (perhaps due to poor husbandry) or that the time for initial dosing was miscalculated (i.e. exposure began too early).

Pregnancy indices in timed-pregnant animals (especially mice) that are shipped from commercial suppliers are generally lower than those of animals bred in-house. If there is a significant difference in pregnancy indices among groups, the study may need to be repeated.

4.3.2 Number of Corpora Lutea

Corpora lutea are yellow sites (spots) that remain on the exterior surface of the ovary after the egg cells are expelled during ovulation. Since each corpus luteum contained a single ovum, the number of corpora lutea equals the number of ova that were available for fertilization. The number of implantation sites cannot exceed the number of corpora lutea in a given female. In contrast, when the corpora lutea outnumber the total number of implantations, (i.e. the number of foetuses plus resorption sites), this is evidence the litter experienced pre-implantation loss. Increased pre-implantation loss relative to control values in a standard developmental toxicity study *cannot* be a consequence of treatment because embryonic death occurred *prior* to initial exposure. Thus, the data must be audited to ensure that: (i) dosing did not begin prematurely (i.e. prior to completion of implantation) and (ii) there is no evidence of environmental stress (e.g. hyperthermia) in the animal facility.

4.3.3 Gravid Uterine Weight and Corrected Maternal Body Weight

The pregnant uterus and its contents are removed by transecting the vagina just inferior to the union of the uterine horns and cutting the mesentery that connects the uterine horns to the body wall. The weight of these organs is informative when individual animals bear fewer foetuses per litter than other animals having many foetuses per litter. If a control animal has many more pups than is typically expected in a litter, the foetal body weight within that litter is likely to be less than the usual mean foetal body weight; conversely, in litters with only very few (e.g. two or three) foetuses without a concurrent high number of resorptions, the average foetal body weight is frequently much greater than the norm. While pup weights in the two preceding examples may not be significantly different, often the gravid uterine weights are not. The gravid uterine weight provides a measure of the body weight gain of the pregnant female, regardless of how many foetuses she had in her litter.

Corrected maternal body weight is the terminal body weight of the dam at sacrifice minus the gravid uterine weight. Comparison of this measure among groups allows determination of whether test-compound-induced changes in body weight were caused primarily by toxicity in the dam or in the foetal-placental unit.

4.3.4 Numbers of Implantations, Resorptions, Living and Dead Foetuses

In rodents, prenatal mortality can be identified by resorbed embryos or dead foetuses ('foetal wastage'). Rabbits either resorb or abort their litters. Together, these findings are considered postimplantation loss. Foetal wastage can result from direct toxicity of the test substance, lethal malformations (whether spontaneous or treatment-related), maternal toxicity and/or environmental stress. When there is a positive dose–response relationship, conclusions regarding developmental toxicity have increased confidence. When one type of postimplantation loss predominates, it may be possible to deduce

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the time or gestational stage at which the exposure adversely affected the conceptus.

The number of live foetuses is recorded. This end point, when presented as the percentage of implantations per litter, provides a measure of an agent's ability to kill the embryo or foetus.

4.3.5 Organ Weights and Clinical Chemistry

Current regulatory guidelines do not address maternal organ weights and clinical chemistry data; however, dose-related changes in absolute and relative maternal organ weights (absolute organ weight divided by the corrected maternal body weight) are valuable in assessing potential maternal toxicity. For instance, the maternal liver may show increased weight and this can be a function of enzyme induction, fatty degeneration or hydropic change. Taken in concert with toxicokinetic data, this information can be used to identify the extent to which exposure to the test material adversely influenced maternal well-being and that determination is as important as assessing the potential developmental toxicity of the substance under study.

In some instances, clinical-chemistry parameters (e.g. haematology and enzyme markers) are reported (see **Haematology and Toxicology**). Changes in blood cells or changes in hepatic and other enzymes (see **Clinical Chemistry in Toxicity Testing: Scope and Methods**) can be useful in assessment of maternal health, especially in the absence of changes in gross measures like food consumption or body weight.

4.3.6 Foetal Data

Data must be collected and reported for all pups in the litter; reporting observations for only one, two or three members as representative of a whole litter is deceptive. Foetal body weight is a sensitive end point in developmental toxicity studies. Because the foetal weights vary within the litter, the parameter calculated is the mean foetal body weight expressed on a litter basis. The mean foetal body weight for each litter is determined, then a mean value of the litter means (sometimes called a grand mean) for each treatment group is calculated. This approach helps stabilize the variance and accounts for the impact of the maternal system on her offspring. Significantly reduced mean foetal body weights in treated groups compared to control values provide evidence for growth retardation. When the mean number of foetuses per litter is similar across treated and control groups, dose-related reductions in mean foetal body weight indicate treatment-related toxicity in the offspring. Sometimes, reduced foetal body weight is the only sign of developmental toxicity. When evaluating those data, two points must be considered; first, the mean number of pups per litter should be comparable because foetuses from litters with very few siblings tend to be heavier and second, the similarity of sex distribution within groups must be verified as males can weigh more than females and a disproportionate number of males/females may skew the findings.

The consequences of reduced foetal body weight in common laboratory animals are not known. When reduced foetal body weights are the only observation in a study, the interpretation is not necessarily clear-cut, as modest reductions in neonatal body weights are temporary. In reproduction studies, where the offspring are kept with the dams through weaning, those that were smaller at birth often increase their weight, size and maturation to the point that any appreciable differences between the control and treated groups are abolished. The outcome of differences in foetal body weights cannot be determined from a developmental toxicity study, but must be gleaned from growth and viability data from multigeneration reproduction studies.

Extremely small offspring present a different problem. If the body weight of a given foetus is two or more standard deviations less than the mean control foetal body weight (or 25–30% less than the historical mean control), the foetus is considered a 'runt' or 'stunted' and some laboratories classify these as malformed.

4.3.7 Foetal Examinations

Viable foetuses are examined for external, soft-tissue and skeletal alterations and all morphological differences from the normal configuration should be recorded. These differences are categorized as malformations, anomalies, variations, deviations or retardations (Palmer, 1977; Khera, 1981). Malformations are major anatomical changes that interfere with viability, health, vigour or quality of life. Exencephaly, cleft palate, absence of limbs or digits and cyclopia are examples of malformations (Wise *et al*., 1997). Anomalies include comparatively minor changes like the absence of nails and pliable carpal flexures in rabbits. Anatomical variations are common changes, like asymmetric sternebrae or bifurcated gall bladders in rabbits, that are found in control animals and that have little or no impact on health. Classifying a foetal change as a deviation, retardation or variation depends on the competence of the laboratory and a difference in judgments can lead to disagreements.

At study termination, the gravid uterus and foetuses must be handled with care. Poor laboratory practice can cause subcutaneous haemorrhages that have been mistaken for treatment-related effects. The gravid uterus and foetuses should be removed promptly from the dam and examined, as tissues left unattended become oedematous, foetuses develop carpal flexures and hyperextended or stiff joints, changes that have been mistaken for arthrogryposis. If the umbilical cord is cut carelessly, back flow of blood from the placenta can induce what appears to be a haemorrhage into the liver and abdominal cavity.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Skeletal changes are diverse, even among control foetuses; for example, the presence of 12 or 13 pairs of ribs in rabbits and reduced ossification at sternebrae 5 in both rabbits and rodents are common. Minor alterations in skeletal patterns are called variations and these are due to transient delays in foetal maturation. These include reduced calcium deposition in phalanges and sternebrae, supernumerary ribs and wavy ribs (both of which can resolve during postnatal growth). Supernumerary ribs have been seen in rodents, in foetuses from dams that exhibited nonspecific maternal toxicity (Khera, 1985; 1987), and while these are not considered adverse findings, they can be indicative of maternal stress. To determine whether a significant, dose-related increase in variations relative to the concurrent control is treatment-related, the results are compared to historical control values. As rodent foetuses undergo rapid growth just prior to term, foetuses removed too early (e.g. GD19) show retarded ossification of the skeleton. Thus, mistakes in determination of conception or failures in timing can result in spurious conclusions.

Visceral (soft tissue) changes are not so easily observed as are those of the external body and skeleton. Ventricular septal defects, transposition of the great vessels, hydrocephalus, unilateral or bilateral renal agenesis, polycystic kidney and diaphragmatic hernia are examples of visceral changes that can only be observed upon foetal dissection. Knowledge of normal foetal anatomy is essential; in some instances, the transparent membranous region of the diaphragm has been mistaken as evidence of teratogenicity. The presence of a ventral pancreas or retroesophageal subclavian artery is considered a malformation in rats, but in rabbits these are normal. In rabbits, a bifurcated or duplicated gall bladder is normal because these result from slight shifts in the branching pattern of the hepatic diverticulum. Foetal dissections should be made with care so as not to damage the organs; jagged edges on any organ suggest poor laboratory technique.

4.4 Animal Data Interpretation

4.4.1 Maternal Toxicity

Since the highest dose in the study was designed to elicit mild maternal toxicity, it should be expected that the in-life phase of the definitive study will include signs of maternal toxicity. This requirement has led to several thoughtful papers on the interaction between maternal health and the health of her offspring (Khera, 1981; 1984; DeSesso, 1987; Daston, 1994; Hood and Miller, 2006). Animals in the high-dose group may experience death, increased abortions and/or resorptions, especially in rabbits. When exposures are too high and deaths and litter resorptions too great, there will be too few offspring for evaluation. Ideally, maternal signs will be manifest only at the highest dose, but when the dose–response relationship is steep, the difference between a dose that causes death and that which elicits foetotoxicity can be very small.

In most rodents, maternal body weight and weight gain are end points that can determine the maternal NOAEL. Reduced mean maternal body weights are usually the result of systemic poisoning or reduced food consumption. Rabbits are different in this respect in that they often lose weight during a normal pregnancy. When rodent body weights at the low dose are reduced, but that of the high-dose animals is no different from the concurrent control, this is usually a consequence of excessive maternal mortality at the high dose. Maternal body weight is less useful in determination of a treatment-related effect if a high proportion of the litters are dead.

Another parameter for assessment of maternal well-being is food consumption. In studies where the test material is incorporated into the feed, one must determine whether reduced food consumption is related to palatability or to systemic poisoning. To do this, a feed efficiency index (FEI; grams of food consumed/grams body weight gain) is calculated; if the FEI values for treated and control groups are similar, this suggests systemic toxicity was related to the body-weight reduction. Some rabbits reduce their food consumption just prior to parturition while they nest; abdominal alopecia can arise as they use their hair in nest construction.

4.4.2 Developmental Toxicity

Exposure to a test material is considered a potential developmental hazard when an increase in any of the adverse parameters compared to the spontaneous ('background') incidence can be demonstrated. The background incidence can be estimated from both the concurrent and historical control. When the end point is a frank congenital malformation, the agent can be considered a suspect teratogen.

Interpretation of the data can be confounded, since foetuses within a given litter exhibit similar changes, thereby increasing the apparent response. This tendency is called the 'litter effect' and it is thought to be due to the fact that all foetuses within a litter are exposed to the same maternal environment as their siblings, whereas the maternal environment varies from litter to litter within the same dose group. This leads to an important caveat for the interpretation of the results: due to the large numbers of offspring evaluated and the very large numbers of observations made per foetus, the findings may achieve statistical significance if the foetus is considered the sampling unit. Several statistical procedures (see **Statistics for Toxicology**) have been developed to address this problem (Weil, 1970; Gaylor, 1978; Gad and Weil,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1986). The appropriate experimental unit is the number of treated females (US Environmental Protection Agency (USEPA), 1991a). To address the variation in foetuses per litter and the 'litter effect', these statistical procedures analyse incidence per litter.

Statistical analyses alone are *not* sufficient to judge whether or not an agent should be considered a developmental hazard. When the level of statistical significance is $p \leq 0.05$, one of every 20 comparisons will be significant due to chance alone. Because so many observations (e.g. all skeletal and visceral elements for 300 or more foetuses per dose) are made, one or more observations are likely to achieve statistical significance by chance.

One of the most important considerations is dose–response. A positive dose–response is strong evidence for causality and positive dose-related trends without attainment of statistical significance can be important. To illustrate, a rare malformation like spina bifida may occur at a low (but dose-related) rate, yet still be no different than the control. To understand the observation, the historical control rate for that condition in that species and strain must be consulted (see below).

Another aspect is that the end points may be related to each other such that the presence of one precludes another. For instance, embryonic death precludes finding growth retardation, malformation or functional deficit, and it reduces the numbers of potentially affected offspring. This occurs where malformations are seen at the low doses, but not in the high-dose group because the highest dose killed the offspring; alternatively, when foetotoxicity was not evident at the low- or mid-dose levels, but the highest dose elicits extensive postimplantation loss, the teratogenic potential may be masked. The preceding discussion notwithstanding, the mechanisms that underlie postimplantation loss are *not* always the same as those causing terata (i.e. the agent may increase embryo/foetal deaths, but it may not induce malformations) (Manson and Kang, 1989).

A third consideration is whether or not the dam experienced overt toxicity during organogenesis. Selective developmental toxicants are those that induce reproductive failure in the absence of maternal toxicity. When adverse effects are seen in litters from mothers that experienced notable toxicity, the adverse effects in the conceptus may have been produced indirectly. Maternal toxicity has been associated with production of wavy ribs, retarded ossification and reduced foetal body weight (Khera, 1985; 1987) and occasionally, adverse effects are seen at doses causing only minimal maternal toxicity. In these cases, the findings *cannot* be interpreted to have been caused by maternal toxicity; rather, the data suggest that both the embryo and the mother are susceptible to the exposure. Furthermore, the appearance of maternal toxicity does not guarantee that adverse effects in the conceptus will occur, because some agents elicit profound maternal poisoning, yet exert no apparent adverse effects on the offspring.

Finally, it must be understood that not all malformations are caused by the test agent. Practically every malformation occurs spontaneously (Palmer, 1977) and any particular malformation can be caused by many different chemical or physical agents. Every animal species (and strain) has a background incidence of spontaneous malformations. When rare terata are seen, examination of the laboratory or breeder's historical experience is required.

4.4.3 Historical Control Data

All facilities that follow Good Laboratory Practices maintain control incidence data (usually over the past 5–10 years) and evaluation of rare or unusual terata (e.g. extrathoracic ectopia cordis) or statistical relationships can be facilitated by comparisons of historical to concurrent data. When the incidence of an effect in the treated groups is within the historical range, the finding is likely due to chance. An additional advantage is that over time, historical control data can provide insight into changes caused by genetic drift, changes due to dietary constituents, season or even differences in technical competence.

4.5 Health Risk Assessment

4.5.1 Maternal Toxicity

Since the pregnant female provides her embryo with a physical environment, nutrition and mechanism for waste elimination, it follows that her physiological status affects the health of her offspring (DeSesso, 1987). Indeed, her health and environment may affect her offspring (Chernoff *et al*., 1987; Schardein, 1987). Where there is significant maternal toxicity, it is often difficult to distinguish effects mediated by compromised maternal health and those induced in the embryo itself (Khera, 1985; 1987). Because maternal toxicity can exert nonspecific adverse effects on the developing offspring, it is important to identify an NOAEL (or benchmark dose (BMD)) for developmental toxicity—preferably in the absence of compromised maternal health. Other than agents like ethanol, where the maternal and foetal toxic dose are essentially identical, the greatest regulatory concern rests with substances or physical agents (e.g. radiation) that cause severe effects in the offspring, but elicit few to no adverse effects in the mother. Examples of the latter are methyl mercury and thalidomide.

4.5.2 Predictive Value of Animal Data

Dose–response relationships (see **Dose-Response Analysis in Experimental Toxicology and Risk Assessment**) for the many different end points studied in developmental toxicity assays are often dissimilar because

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the mode of action is not always identical and high doses may preclude manifestations of effects seen at low doses. Unfortunately, the inference of human health risk from animal data is not straightforward (Kalter, 1965). The induction of a particular effect in one species (including humans) does not necessarily predict the outcome in another species. In many situations, humans are exposed to much lower concentrations than those used in laboratory studies and while positive results from adequately designed animal studies suggest the possibility of increased health risk for humans, the animal data cannot *predict* whether or not an exposure to a material or agent will induce reproductive failure in humans. Because laboratory mammals respond to known human teratogens (but not always in the same manner as that in humans), a biologically significant increase in any of the major end points in a developmental toxicity study is of concern and the concern is increased when the response is observed in more than one test species.

4.5.3 Animal Data and Human Teratogenicity

Assessing whether a clinical or environmental agent causes developmental toxicity in humans is neither rote nor trivial. Results from well-designed studies in laboratory mammals can alert one about the potential influence on human reproduction, but because of differences in physiology, systemic bioavailability by different routes of exposure, metabolic handling and disposition, margins of exposure and maternal status, interspecies extrapolation of results in animals to humans with widely divergent exposure conditions cannot be performed with certainty. Consequently, many human developmental toxicants have been discovered by perceptive physicians and astute biomedical scientists who recognized a tentative relation between exposure and adverse outcome. Often, the recognition comes from a case report or series of similar cases. Subsequent epidemiological studies analyse the incidence and trends of adverse pregnancy outcome in relation to exposure to investigate a possible causal relationship. While epidemiology studies examine the species of immediate concern, the most problematic aspect concerns verification of exposure; animal studies have the advantage of precise exposure, but have the troubling aspect that common laboratory species (including nonhuman primates) are only (distant) relatives of the species of concern.

Several criteria are used to examine the likelihood of a causal relationship between human exposure to an agent of interest and its potential developmental toxicity (Brent, 1986):

- Well-designed epidemiology studies consistently find an increased incidence of a particular developmentally toxic effect or set of developmentally toxic effects after exposure.
- When exposures are wide-ranging, secular trend data demonstrate a relationship between the expected developmental toxicity and exposure levels in humans.
- An animal model is (or can be) developed that mimics the human findings at doses that elicit neither maternal toxicity nor reduced food or water consumption.
- The signs and types of adverse developmental outcomes increase as exposures increase.
- The likely underlying mechanism(s) for induction of developmental toxicity are plausible and do not contradict the principles of biology.

While none of the above criteria are sufficient to prove the existence of a human teratogen, the greater the compliance with those criteria, the more compelling the rationale that supports a causal relationship.

5 ENDOCRINE DISRUPTION

'Endocrine disruption' (ED) is a term used to describe the toxicological activity of a wide range of chemicals that display agonist or antagonistic pharmacologic actions of the steroid hormones, substances that influence the biogenesis or metabolism of those hormones and substances that influence their cellular signals and associated gene expression (Phillips and Foster, 2008) (see **Endocrine Disruption in Toxic Responses**).

There is a popular notion that synthetic EDs found in the diet (Tyshenko *et al*., 2008), wastewater (Kumar *et al*., 2008), agricultural and livestock production, pulp and paper mills, mining and textile industries and consumer products (Ashby, 2001) are responsible for reduced sperm counts, altered sex ratios, precocious puberty and increased cancers (Sharpe and Skakkeback, 1993; Sharpe, 2001). These reports have been interpreted by some as due to interference with normal regulation of development by mimicking or otherwise antagonizing the actions of physiological steroids. Human maladies alleged to have been caused by environmental ED range from spontaneous abortions, infertility, mammary, uterine, ovarian and prostate cancer, obesity, diabetes and psychological disorders (reviewed in Phillips and Foster, 2008; Willhite *et al*., 2008) to systemic lupus erythematosus (Yurino *et al*., 2004). However, the results of rodent studies with environmental ED vary substantially and the hypothesis that 'low-dose' (pg to μg kg^{-1}) effects are responsible for these conditions often cannot be reproduced as the 'lack of attention to methodological details makes it difficult to reconcile different ED assay outcomes for the same chemical' (Ashby, 2001). Even the definition of the term ED is debated in that one often cannot differentiate between physiologic alterations and actual adverse health effects due to changes in endocrine status (Foster and Agzarian, 2008).

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat084
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Clinical literature dating from the early 1950s is rich with accounts of ED as a consequence of inadvertent iatrogenic exposures. Ingestion of either androgens (testosterone, methandriol, methyl testosterone, normethandrone) or natural (progesterone) or synthetic (ethisterone, norethindrone) progestins during the first trimester to control nausea and emesis, to maintain pregnancy to term or in pregnancy testing, respectively, have been unequivocally linked to masculinization of the female foetus (pseudohemaphroditism). Feminization of male foetuses due to prenatal progestogen exposure has also been reported (Schardein, 1980).

Overall, the risk of female masculinization associated with prenatal androgen and progestin exposure is <1%. The individual response is related to dose and gestational stage during which exposure occurred. As dose increased, the relative extent of female masculinization increased; exposure during gestational weeks 8–13 produced more complete labioscrotal fusion than at other times because differentiation of the genitalia occurs during that period. Affected infants present with an absent, closed or patent vagina; enlarged labia and clitoris; normal ovaries and Fallopian tubes; and (sometimes rudimentary) uterus. As these girls mature, there is usually total regression of the genital hypertrophy and they are fertile. Iatrogenic female pseudohemaphrodites who experienced transient androgenic hormone exposure *in utero* differ from those with spontaneous congenital adrenal hyperplasia who suffer from progressive virilization. Feminization of the male foetus is limited to hypospadia (Schardein, 1980), but even the tentative association between oral steroids and hypospadias could not be confirmed in follow-up epidemiology studies (Kallen *et al*., 1991).

Prenatal exposures to oral contraceptives (oestrogens with or without progestrogens) have long been suspected of damaging the offspring of women who consumed these drugs during gestation (Janerich *et al*., 1980; Khera, 1984). Overall, the data were conflicting and reports of increased rates of total (Janerich *et al*., 1980; Lammer and Cordero, 1986), skeletal (Kricker *et al*., 1986), cardiac (Hook, 1994; Rothman *et al*., 1979) and urinary tract (Li *et al*., 1995) terata appeared, but other studies (Bracken, 1990; Kallen *et al*., 1991; Oakley *et al*., 1973) found no such associations. Martinez-Frias *et al*. (1998) published a 20 year (1976–1995) case–control study of 20 388 infants with mild to major congenital defects compared to 19 981 normal infants (controls) using 600 different defect categories to investigate possible associations between steroid hormone use and congenital malformations. Exposed infants were those whose mothers consumed sex hormones at any time during the first trimester. Of the hormones used (oral contraceptives, oestrogen combinations, progestogen combinations, oestrogens + progestogens, gonadotropins or other sex hormones), only prenatal exposure to oral contraceptives or oestrogen combinations without progestogens showed significant associations; however, after considering the heterogeneity of the defects and taking into account potential confounding, there was no evidence for increased genital (e.g. hypospadias) or nongenital malformations in any of the exposure categories.

One of the most thoroughly studied EDs is zearalenone, a nonsteroidal oestrogenic mycotoxin found in bread, pie, pizza, corn chips, popcorn, pasta, cake, oatmeal, doughnuts, cow's milk, infant foods and beer, with beer containing some $100\,\mu g\,L^{-1}$ (International Programme on Chemical Safety (IPCS), 2000). The molecule is synthesized by *Fusarium graminearum*, *Fusarium culmorum* and *Fusarium crookwellense*. These fungi colonize corn, wheat, sorghum, rice and barley. Heavy precipitation encourages growth of the fungi; mean concentrations in cereal grains of $17\,\mu g\,kg^{-1}$ with peak levels up to $2000\,\mu g\,kg^{-1}$ have been documented. Dietary zearalenone is hyperoestrogenic, especially in pigs fed $\mu g\ kg^{-1}\ day^{-1}$ doses (Kuiper-Goodman *et al*., 1987). Signs of oestrogenic activity in young female swine include uterine enlargement, precocious mammary development, vaginal prolapse and vulvar swelling; males had reduced testicular size and enlarged mammary and preputial glands. When fed to mature female pigs at similar doses, the animals maintained constant oestrus, as evidenced by morphological changes in the endometrium; ovarian atrophy and pseudopregnancy have also been seen (Berger *et al*., 1981; Etiene and Jemmali, 1982; Kurtz *et al*., 1969). Multigeneration studies with rats fed zearalenone found reduced male and female fertility, reduced numbers of live offspring, increased prenatal death and absent eyelids in the survivors after doses as low as $100\,\mu g\,kg^{-1}\ day^{-1}$ (International Programme on Chemical Safety (IPCS), 2000). Zearalenone binding *in vitro* to oestrogen receptors is 1–10% of that for 17β-oestradiol and its relative potency in cultured cells is 2–5% that of 17β-oestradiol. There are no reports of human ED associated with zearalenone ingestion, perhaps because of the relatively small exposures ($\sim 0.2\,\mu g\,kg^{-1}\ day^{-1}$), efficient hepatic conjugation with α-D-glucose and elimination in urine as the glucuronide. In order to control exposure to zearalenone, a maximum tolerable intake of $0.5\,\mu g\,kg^{-1}\ day^{-1}$ based on the lowest adverse effect level (LOAEL) in pigs has been established (International Programme on Chemical Safety (IPCS), 2000).

Far from restricting the discussion of ED to reproductive hormones, there are few rodent teratogens more effective and reliable than the glucocorticoids (e.g. cortisol, cortisone, hydrocortisone). Long before the appreciation of xenobiotic-induced terata became common knowledge after the thalidomide experience, Fraser and Fainstat (1951) and Fainstat (1954) reported cleft palate in mice and rabbits after maternal cortisone and, like many other rodent teratogens, the dose required to elicit a response is strain-dependent (Diewert and Pratt, 1981; Hackney, 1980; Walker and Patterson, 1978). In general, the doses of corticosteroids required

to induce cleft palate in rodents are equal to or less than those used clinically. Corticosteroids induce irreversible pathology within the basal epithelial cells (evidenced by chromatin clumping and swelling of the mitochondria and rough endoplasmic reticulum) of the vertically developing rodent palatal shelves. Ordinarily, the palatal shelves become horizontal and then fuse with one another over their entire length, but after corticosteroids exposure the shelves fail to fuse as the primary basal cells within the medial edge epithelium have disintegrated (Shah and Travill, 1976).

Given the alterations in the hypothalamic-pituitary-adrenal (HPA) axis seen after deficiency or supraphysiologic corticosteroid levels, their efficacy in treatment of acute and chronic inflammatory disease, allergic reactions, asthma, autoimmune disease and rheumatic disorders (Schimmer and Parker, 1996), in light of their teratogenic activity in animals and the case reports of cleft palate in cortisone-exposed humans (Harris and Ross, 1956; Doig and Coltman, 1956), there was increased concern for possible damage in human embryos after exposure to these compounds. At least 10 prospective cohort (Propert, 1962; Warrell and Taylor, 1968; Schatz *et al*., 1975; Heinonen *et al*., 1977; Mogadam *et al*., 1981; Mintz *et al*., 1986; Fitzsimons *et al*., 1986; Pollard *et al*., 1992; Laskin *et al*., 1997; Park-Wyllie *et al*., 2000; Gur *et al*., 2004) and three retrospective case–control (Czeizel and Rockenbauer, 1997; Rodriguez-Pinilla and Martinez-Frias, 1998; Carmichael and Shaw, 1999) studies of pregnancy outcome after prenatal therapeutic exposure to cortisone, hydrocortisone, prednisone, prednisolone, methylprednisolone, triamcinolone, flucortolone, dexamethasone, flumetasone, mazipredon and betamethasone have been conducted.

To understand the epidemiology of corticosteroids or any other material, it is important to note the baseline ('background') incidence of all malformations in live infants is ~5% (Behrman and Vaughan, 1987). The background rate for cleft palate is 1 : 2500 and that for cleft palate with or without cleft lip is 1 : 500–1000 (Harper, 1998). Although these studies examined large total numbers (e.g. 56 557 to 1 287 345) of liveborn infants (Czeizel and Rockenbauer, 1997; Rodriguez-Pinilla and Martinez-Frias, 1998), there were relatively few infants with maternal prenatal corticosteroid exposure (oral, spray or topical) during the first trimester (0.42–1.88%). As with many epidemiology studies, problems with potential recall bias and adjustments for confounding factors (e.g. maternal tobacco consumption, age, infection, disease, birth order, family history, hyperthermia, maternal use of antiepileptic and other drugs, including sex hormones) were acknowledged. Based on four cases of oral clefts with confirmed exposure during the first trimester (from a total of 1184 total cases of oral clefts), Rodriguez-Pinilla and Martinez-Frias (1998) concluded the risk of cleft lip was increased significantly (p = 0.014) with first trimester corticosteroid exposure. Others (Czeizel and Rockenbauer, 1997; Gur *et al*., 2004) found no increase in absolute risk-adjusted odds ratios and the Fraser and Sajoo (1995) survey of 468 exposed pregnancies concluded that 'treatment with corticosteroids in pregnancy presents little, if any, teratogenic risk to the foetus'. While reduced birth weight was identified as an adverse outcome (Reinisch *et al*., 1978), prenatal corticosteroids during weeks 24–34 represent standard intervention for prevention of spontaneous premature delivery that complicates 7–10% of all pregnancies. Antenatal glucocorticoids reduce infant mortality associated with respiratory failure secondary to inadequate pulmonary surfactant (Anonymous, 1994). The NIH (National Institutes of Health) panel concluded that prenatal corticosteroid therapy does not influence the risk for neurodevelopmental delay or disability (Anonymous, 1994).

6 MALE-MEDIATED DEVELOPMENTAL TOXICITY

Dozens of studies concerning paternal smoking (Wasserman *et al*., 1996), ethanol consumption (Little and Sing, 1987; Savitz *et al*., 1992), occupational 'pesticide' (Garcia *et al*., 1998; 1999; Lacasana *et al*., 2006; Savitz *et al*., 1997), solvents or other anthropogenic exposures (Hooiveld *et al*., 2006; Mageroy *et al*., 2006; Savitz *et al*., 1994) in relation to birth outcome have been published. There is no question that exposure of fertile male rats and male mice to potent mutagens (e.g. 1,3-butadiene, cyclophosphamide) can increase the number of dominant lethal mutations and produce malformations in the offspring of untreated females (Adler *et al*., 1994; Anderson *et al*., 1996; Jenkinson *et al*., 1987; Trasler *et al*., 1985). Male-mediated developmental toxicity in those instances is due to alkylation of germ cell DNA; however, there are no confirmed reports of male-mediated developmental toxicity in human beings after exposure to chlorambucil, cisplatin, bleomycin, 2-bromopropane or other similar genotoxic substances. In those cases, azoospermia, oligospermia, Leydig, Sertoli and germ cell (spermatogonia) toxicity, atrophy of the seminiferous tubules, reduced serum testosterone and elevated lutenizing hormone are seen in both humans and animals and the affected males are infertile. Affected females suffer amenorrhoea, atrophy of their ovarian follicles, arrested follicular development and reduced numbers of primary follicles (Boekelheide *et al*., 2004). Thus, while examples of male-mediated developmental toxicity in rodents can be identified, the findings of male-mediated developmental toxicity are rare, primarily because the outcome at lower doses is most often reduced fertility and/or other systemic complications (e.g. haematopoietic toxicity) (Boekelheide *et al*., 2004).

Other than famine, epidemics and pestilence, perhaps only open and sustained armed conflict has more shaped human history. Since the 1950s, the United States and its allies prosecuted wars in Korea, Vietnam and the Arabian Gulf ('Desert Shield/Storm' and 'Iraqi Freedom'). Subsequent to each conflict, anecdotal accounts of increased birth defects in veterans' offspring appeared only to be followed by increased public and Congressional concern with reproductive toxicity among veterans (Friedman, 1984; National Academy of Sciences, 1997; 2003; Araneta *et al*., 2003; Gamboa, 2003). The more unpopular the war, the greater the level of concern.

There is no more contentious substance in this regard than 'Agent Orange'—a dioxin-containing herbicide sprayed multiple times over 2.6 million acres in Vietnam as part of 'Operation Ranch Hand'. Field and Kerr (1998) concluded 'the evidence from all available studies supports a causal contribution to defects in veterans' children from a paternally mediated genetic effect'—this despite the fact that chlorinated dibenzo-*p*–dioxins (2,3,7,8-tetrachlorodibenzo-*p*-dioxin; TCDD) were neither mutagenic *in vitro* (Randerath *et al*., 1989) nor *in vivo* (Lopreino *et al*., 1982; Lim *et al*., 1987) and dioxins were unable to induce dominant lethality (Khera and Ruddick, 1973). Friedman (1984) reviewed the animal data and found that '2, 4, 5-T is more likely to be teratogenic than TCDD when the level of dioxin contamination of the herbicide is on the order of a few ppm. If the same dose were teratogenic in pregnant women, ingestion of 1.5–2.5 g/day of 2, 4, 5-T or 3–5 ml of Agent Orange would be necessary to produce an effect. In fact, there is no scientific rationale for such extrapolation from rodent to human, and these doses might better be considered those that would be teratogenic in a 110-pound mouse'. The National Academy of Sciences (1997) concluded: 'Laboratory studies of potential male-mediated developmental toxicity of TCDD and herbicides, specifically with regard to birth defects, are too limited to permit conclusions'.

Based upon the Wolfe *et al*. (1995), the Centers for Disease Control (1989) and the Erickson *et al*. (1984) epidemiology studies that identified increased spina bifida and other NTDs among the offspring of Vietnam veterans (five per 1000 and an odds ratio of 1.7, respectively), the National Academy of Sciences (1997) concluded, 'the exposure opportunity index based upon interview data was associated with an increased risk of spina bifida; for the highest exposure opportunity index the odds ratio was 2.7 (confidence interval = 1.2–6.2)'.

Wolfe *et al*. (1995) actually concluded:

"There was an increase in nervous system defects in Ranch Hand children with increased paternal dioxin, but it was based on sparse data. These data provide little or no support for the theory that paternal exposure to Agent Orange and its dioxin contaminant is associated with adverse reproductive outcomes."

Erickson *et al*. (1984) actually concluded:

"Vietnam veterans, in general, did not have an increased risk of fathering babies with defects (all types combined; relative risk estimate 0.97). However, for a few specific types of subgroups of defects the estimated risks were higher for subgroups of Vietnam veterans that may have had a greater likelihood of exposure to Agent Orange. These seemingly higher risks could be chance events, the result of some experience in the Vietnam service of the father or the result of some other unidentified risk factor."

In Australian Vietnam Veterans Validation Study (1999) identified 34 cases of spina bifida to bring the total there to 50 cases (as compared to 33 expected for the cohort). In 2003, the National Academy's Institute of Medicine believed that 'the available scientific literature provides limited/suggestive evidence of an association between exposure to herbicides (2, 4-D, 2, 4, 5-T and its contaminant TCDD, cacodylic acid and picloram) and spina bifida in offspring'.

In September of 1997, President Bill Clinton signed US Public Law 104–204 that provides Veterans Affairs Department (1997a; 1997b) healthcare, vocational rehabilitation and monthly monetary allowances for conditions related to spina bifida. For an affected child to qualify for those benefits, the birth father (or mother) must have served in Vietnam from January 9, 1962 up until May 7, 1975. The US Congress then directed the Department of Veterans Affairs to establish healthcare benefits and compensation 'for children with certain birth defects born to women Vietnam veterans' who entered the Republic of Vietnam between February 28, 1961 and May 7, 1975 (The Children of Women Vietnam Veterans Health Care Program). In December of 2003, the Veterans Benefit Act signed by President George W. Bush granted financial compensation and healthcare benefits to children with spina bifida born to a veteran who served in the Korean demilitarized zone between September 1, 1967 and August 31, 1971 and who was exposed to herbicides.

Examination of reports by 7924 US Army veterans found a clear 'dose–response' for 21 adverse health outcomes and self-reported herbicide exposure; however, other than chloracne and post-traumatic stress disorder, those associations were deemed not plausible because the biologic evidence showed little actual exposure to dioxin-containing materials in Vietnam (Decoufle *et al*., 1992). Subsequent studies with more than 1100 pregnancies with high occupational dioxin exposures 'indicate that TCDD is unlikely to increase the risk of low birth weight or preterm delivery through a paternal mechanism' (Lawson *et al*., 2004). Not one of the Agent Orange epidemiology studies upon which the spina bifida and herbicide conclusions (National Academy of Sciences, 1997;

2003) were based accounted for maternal folate status, an omission common with recent analyses (Ngo *et al*., 2006).

7 SUMMARY AND CONCLUSION

We have seen the monsters, trolls, mermaids, villains and ghosts of developmental toxicology. We have also seen that ghost stories are as dangerous for the human foetus as are villains. To avoid these and other related mistakes, rigorous application of the principles of evidenced-based toxicology (Guzelian *et al*., 2005) guides the investigator into questions of causation and permits one to articulate clearly the limits of our knowledge and experience. There are many historical lessons in developmental toxicology (Warkany, 1971; 1977) and there is no end to contemporary conjecture and xenobiotic speculations that surround reproduction, particularly when the subject sounds as though it has a 'scientific' basis and it is dispensed repeatedly to a willing audience eager to seize upon one or another mysterious cause of impending permanent and debilitating disease (Willhite and Mirkes, 2005). Cardinal sins are committed by those who promote statistical associations as a basis for causal conclusions and by those who transfer animal data, tissue culture and laboratory measurements to human beings without application of the fundamental tenants of hazard identification, dose–response, exposure assessment and risk characterization that are necessary to evaluate and interpret that information (Harris and DeSesso, 1994; Presidential/Congressional Commission on Risk Assessment and Risk Management, 1997).

Those who disseminate rumour and perpetuate fear of intrauterine and neonatal damage prey upon public ignorance of pharmacology and developmental biology. Overwhelming fear of congenital defects and an innate, unshakable desire to identify perpetrators responsible for harming babies amplify the contemporary chemical superstitions that mirror the mysticism of the past. Unsupported conclusions, extrapolations and irrational anxiety surrounding chemical and physical agents in the world of developmental toxicology extract a heavy toll in human misery and suffering (Brent, 1995; Hook and Healy, 1976; Koren *et al*., 1993; Trichopoulos *et al*., 1987). In contrast, effective reductions in foetal and neonatal wastage can be realized by emphasizing public programmes to encourage consumption of folate supplements (Bell and Oakley, 2006)—especially by ethnic minorities (Williams *et al*., 2005)—and providing resources to combat maternal alcoholism, obesity and diabetes (Willhite and Mirkes, 2005).

It is becoming clear that traditional division of toxicology into disciplines like developmental toxicology, cell repair, regeneration and carcinogenesis are more likely a reflection of history than of intrinsic biological differences. For example, it is the deregulation (inappropriate activation or 'escape') of *Hh* genes normally active in partitioning of the prosencephalon and mesodermal differentiation in the gut that is associated with some of the most dangerous and lethal cancers (e.g. chronic pancreatitis and ductal pancreatic carcinoma, prostate carcinoma, small lung carcinoma, medulloblastoma and basal cell carcinoma) in adults (Kayed *et al*., 2006; Nakashima *et al*., 2006; Karhadkar *et al*., 2004; Morton and Lewis, 2007). Mutations in *Smo*, a gene that regulates *Shh*, are found in human basal carcinomas (Xie *et al*., 1998) and transient *Hh* activation is seen during normal epithelial regeneration and turnover in the adult lung and gut (Watkins *et al*., 2003; Beachy *et al*., 2004). It is the untimely expression of genes (like *Shh* that participate with other genes like *Smo* in normal embryonic patterning) that determine progenitor cell transformation and trigger invasive tumour metastasis; the greater the inappropriate *Hh* pathway activity in adult cells, the greater the metastatic response (Scott, 2003). It can be anticipated that advances in understanding genomic regulatory circuits will provide additional parallels between embryonic development and disturbances that give rise to neoplastic disease and other conditions in children and adults (Roessler and Muenke, 2003).

Developmental Neurotoxicity

Susan L. Makris and Kathleen C. Raffaele

CONTENTS

1 INTRODUCTION

Developmental toxicity is defined as including effects that may result from either prenatal or postnatal exposure, may be manifested at any life stage, and may be expressed as functional deficits (OECD, 2008a; US EPA, 1991a). The developmental neurotoxicity (DNT) study is a specialized type of developmental toxicity study designed to screen for adverse effects of pre- and postnatal exposure on the development and function of the nervous system and to provide dose–response characterizations of those outcomes. This chapter focusses on the DNT guideline as a commonly used study design conducted in rodents and used in a regulatory context. While there are many other methods that can be used to assess various aspects of developmental neurotoxic potential, for example, the assessment of neurochemical changes, behavioural studies in nonmammalian species such as zebra fish, and human epidemiological studies, these methodologies are not discussed in this chapter. As well, since the DNT guideline has been primarily developed for the assessment of environmental toxicants, most of the information presented in this chapter is focussed on nonpharmaceutical issues.

2 BACKGROUND AND HISTORY

The field of developmental neurotoxicology evolved from the disciplines of neurotoxicology, experimental and development psychology, and developmental toxicology. It is based upon an extensive history of scientific research and regulatory consideration.

The evolution of a standardized DNT study protocol is rooted in scientific publications that began to appear in the early 1960s, but both the science and the study protocol have continued to develop over the past 40–50 years. A strong foundation for the development, implementation and validation of the DNT guideline is based upon extensive scientific literature. This includes studies evaluating the potential for physical, pharmaceutical and environmental agents to affect the development and function of the nervous system after prenatal and early postnatal exposure and provide dose–response characterization of those outcomes. **Table 1** lists some of the key critical contributions to the development of the DNT guidelines.

In a study conducted according to the standard Environmental Protection Agency (EPA) or Organization for Economic Cooperation and Development (OECD) DNT study guidelines (OPPTS 870.6300 or GL 426,

Table 1 Historical contributions to the Developmental Neurotoxicity Guideline

Date	Event[a]	Summary
1960–1980s	Published research on developmental neurotoxicity and behavioural testing	Evidence that developmental exposure to chemicals and drugs can alter behavioural functioning in young and adult animals
1978–1984	Collaborative Behavioural Teratology Study (CBTS)	Study to examine intra- and interlaboratory reliability and sensitivity of behavioural test methods
1984	Cincinnati Test Protocol	Within-laboratory comparison of CBTS test protocol with the Cincinnati Test Protocol
1982–1985	Collaborative studies of the Japanese Teratology Society	Interlaboratory methods evaluations and assessment of six reference chemicals
1985–1988	European Interlaboratory Collaborative Study	Interlaboratory study to assess sensitivity of behavioural test procedures to detect neurotoxicity of methylmercury
1989	Williamsburg Workshop	Workshop to evaluate the qualitative and quantitative comparability of animal and human data for developmental neurotoxicity
1984–1997	Collaborative studies of the Japanese Teratology Society	Three interlaboratory studies using behavioural teratogens to evaluate a core battery of tests
1995	International Programme on Chemical Safety (IPCS) Collaborative Study	Interlaboratory study using neurotoxic chemicals to evaluate validity, reliability and measurement variability of tests
2000	International Life Sciences Institute Risk Science Institute (ILSI RSI) workshop on developmental neurotoxicity testing	Workshop to review EPA DNT behavioural test methods, pharmacokinetics and neuropathology
2003	Japanese Interlaboratory Study	Interlaboratory study using neurotoxic chemicals to determine sensitivity of behavioural measures
2003 (Sept)	Behavioral Test Methods Workshop	Expert workshop to address design, conduct and analysis of behavioural tests for neurotoxicity evaluation
2004–2008	ILSI RSI Working Group	Working group focussed on variability, statistical analyses, positive controls, identification and interpretation of treatment-related effects and application of developmental neurotoxicity testing to public-health protection

[a]Relevant references for each event are detailed in OECD, 2008b.

respectively), as illustrated in **Figure 1**, pregnant rats are administered the chemical orally from gestation day 6 through to postnatal day (PND) 10 or 21 (US EPA, 1998d; OECD, 2007). The offspring are therefore exposed to the chemical, via the maternal circulation and/or milk, during *in utero* and early postnatal development for approximately 25 to 40 days. Detailed clinical observations are conducted (outside of the home cage) on approximately half of the dams in each group, twice during gestation and twice during lactation, and maternal body weight is recorded at least weekly. The offspring are assessed for evidence of deficits in functional development. Litters are randomly standardized on PND 4 to yield four pups per sex per litter, and the pups are assigned to testing subgroups for neurobehavioural and neuropathological assessment. End points evaluated between birth and PND 60 include measures of physical development, reflex ontogeny, motor activity, motor function, sensory function, and learning and memory. Daily cage-side observations are conducted, and 10 pups per sex per group are examined outside the cage on days 4, 11, 21, 35, 45 and 60. Pups are counted and weighed individually at birth, on PNDs 4, 11, 17, 21 and at regular intervals postweaning. At a minimum, developmental landmarks recorded include the age of vaginal opening or balanopreputial separation. Motor activity is monitored

at early time points and at termination; the EPA guideline specifies the use of an automated activity recording apparatus on PNDs 13, 17, 21 and 60 (±2). Tests of auditory startle habituation (preferably using prepulse inhibition), and associative learning and memory are performed on the offspring around the time of weaning (day 21) and around day 60. At an early time point (PND 11 or 21) and at study termination, the offspring are subjected to extensive neuropathological examination, including simple morphometric analysis. One pup per sex per litter is killed on PND 11 or 21, and of these, 6–10 pups per sex per group are assigned to neuropathological evaluation; their brains are removed and immersed in an aldehyde fixative. At study termination, all remaining offspring are killed; 6–10 rats per sex per group are prepared for neuropathological evaluation with *in situ* transcardial perfusion of appropriate fixatives (paraformaldehyde and gluteraldehyde). Brain weight is recorded at both an early time point (PND 11 or 21) and at study termination (around PND 60). Qualitative neuropathological examination is conducted for the control and high-dose groups, and if a treatment-related finding is evident, the low- and mid-dose groups are also examined. Guidance is provided regarding the regions of the brain to be examined and the types of alterations upon which to focus, particularly emphasizing structural changes indicative of developmental insult. Simple morphometric analysis, performed on offspring killed at the early time point and at termination, is defined as consisting, at a minimum, of a reliable estimate of the thickness of major layers at representative locations within the neocortex, hippocampus and cerebellum.

3 DEVELOPMENT OF THE NERVOUS SYSTEM

3.1 Critical Windows of Nervous System Development

Temporal aspects of nervous system development are critical to assessing insult for use in life-stage-specific risk assessment (Makris *et al*., 2008). The concept of identifying critical windows of development in various organ systems for application to human-health risk assessment was explored in a workshop conducted by the US EPA (Selevan *et al*., 2000). Neurobehavioural outcomes were addressed by Adams *et al*. (2000). It was noted that specific adverse outcomes have been shown to be associated with particular windows of vulnerability for specific agents. The sensitive developmental windows are initiated prior to the formation of the neural plate and end at approximately the age of puberty, when nervous system maturation is predominantly complete. Many neuroactive agents are able to disrupt development at multiple time points during this wide period of potential sensitivity. The end points affected by a particular agent may also vary, dependent on the timing of exposure. Expression of the adverse response may occur during a particular stage of development, at the time of or following exposure and may not be observed except under specific conditions of measurement or following an environmental challenge.

The ontogeny of neurological development is temporally different between humans and the rodents that are typically used in DNT testing. In humans, there is extensive prenatal maturation of the nervous system, while in rodents much of the maturation process (e.g.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

myelination) continues postnatally. These developmental processes include proliferation, migration, differentiation, synaptogenesis, gliogenesis and myelination, and apoptosis (Rice and Barone, 2000). Regional growth rates, timelines of regional neurogenesis and myelination and functional ontogeny exhibit distinct cross-species differences. Thus there is no simple approach to precise correlation of the stage of neurological development in humans vs. test animals. For this reason, the most comprehensive approach to screening for developmental neurotoxic insult in test species has been to include exposures to the test substance during all stages of neurological development (i.e. throughout both prenatal and early postnatal life stages).

Nevertheless, some attempt has been made to compare the achievement of key events in human postnatal central nervous system (CNS) development to those in common laboratory animal species (rats, dogs and nonhuman primates) (Wood *et al*., 2003). The ontogeny of fine motor development and dexterity, sensory and reflex development, cognitive development, communication, social play, fear response and sleep cycles are addressed in the Wood *et al*. paper. Consideration of cross-species differences in the timing of these developmental milestones can be very useful in designing juvenile animal toxicity studies (US FDA, 2006), or in enhancing a standard guideline DNT study in order to address chemical-specific toxicity issues.

3.2 Special Vulnerabilities

Concerns about the vulnerability of the developing nervous system are firmly based in historical tragedies such as the Minamata Bay disaster with methylmercury, the well-documented effects of foetal alcohol syndrome (a very serious public-health problem), the consequences of lead exposure in children and the adverse consequences of *in utero* exposures to some neuroactive pharmaceuticals (e.g. phenobarbital, or antiepileptic agents such as phenytoin and valproic acid) (Weiss, 2000). The importance of screening and testing of pharmaceuticals and environmental toxicants for the potential to affect nervous system development has lead to legislation, such as the FDA Best Pharmaceuticals for Children Act (FDAMA, 2001), which mandates the testing of pharmaceuticals that are intended for paediatric use, and the Food Quality Protection Act (FQPA) (FQPA, 1996), an amendment to the Federal Insecticide Fungicide and Rodenticide Act (FIFRA). The implementation of these laws has resulted in increased testing for DNT. For example, the number of DNT studies that had been submitted to the US EPA Office of Pesticide Programs in support of pesticide registration increased from a total of nine in 1998 (Makris *et al*., 1998) to a current total of at least 73 (Makris *et al*., 2009).

While susceptibility of children can often be attributed to such factors as increased exposure due to child-specific behaviours, or to genetic polymorphisms, there are also a number of vulnerabilities to the developing nervous system that are either unique or enhanced in comparison to development in other systems. Due to the prolonged ontogeny of the nervous system (which continues postnatally for many years in humans), its complexity and the interconnections within the system, there are many opportunities for developmental insult (Bennett and Finnell, 1998). Adverse consequences of agent exposure can, in some cases, be observed as overt structural defects, for example, malformations such as spina bifida or exencephaly, or may be comprised of more subtle changes, for example, disruptions in synaptogenesis, histogenesis or cell–cell communication, leading to functional deficits that may be much more difficult to detect. There are a number of other reasons that effects on neurodevelopment can be difficult to identify. For example, the process of nervous-system development includes constant restructuring of the tissues, through mechanisms such as apoptosis and cell migration. This can provide an opportunity for compensatory development to occur, which might mask the consequences of the primary insult. In some cases, such adverse outcomes may not be observed until the system is challenged (e.g. by a pharmaceutical or toxicant exposure, or by the consequences of ageing) at a later time point. Studies conducted to screen for adverse outcomes in animals or humans may lack the power to detect effects, or they may not include the appropriate tests or parameters.

4 TESTING PARADIGM

4.1 Guideline Study: History of Development

The first regulatory protocol designed to evaluate DNT was developed and implemented by the US EPA in support of hazard evaluation for specific solvents (US EPA, 1986), and a DNT guideline applicable to the evaluation of both industrial chemicals and pesticides was finalized in 1991 (US EPA, 1991b). In 1998, the guideline was revised as part of a broader US effort to harmonize testing guidelines within the US EPA Office of Prevention, Pesticides, and Toxic Substances (OPPTS) and with the OECD (OPPTS 870.6300; US EPA, 1998d). A separate OECD DNT guideline, which includes several improvements to the original testing paradigm, was recently finalized (OECD TG 426; OECD, 2007). Differences between the US EPA and the OECD test guidelines are summarized in **Table 2**.

The process of guideline development, validation and refinement has been an intensive long-term effort over the

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 2 Differences between the US EPA and OECD DNT Test Guidelines

Testing element	US EPA (1998d)	OECD (2007)
Dosing period	Gestation day 6 through postnatal day 11 Note: PND 21 recommended[a]	Gestation day 6 through lactation (PND 21)
Direct dosing to preweaning pups	Not discussed Note: Recommended in some situations[a]	Should be considered for some situations
Minimum group size for pup behavioural assessments	10 per sex per dose for most tests	20 per sex per dose for most tests
Functional observations	Specific days recommended (PND 4, 11, 21, 35, 45 and 60)	Specifies assessment weekly preweaning and biweekly postweaning
Behavioural ontogeny[b]	Not discussed	At least two measures required
Motor and sensory function	Auditory startle habituation specified	Quantitative sampling of sensory modalities and motor functions specified, auditory startle habituation listed as example
Motor activity	Specific days recommended (PND 13, 17, 21 and around 60)	Specifies assessment one to three times preweaning, once during adolescence (around PND 35), and once for young adults (PND 60–70)
Neuropathology—number of animals	Six per sex per dose specified Note: 10 per sex per dose recommended[a]	10/sex/dose
Neuropathology assessment at early timepoint	PND 11, with immersion fixation Note: PND 21 accepted, with perfusion fixation[a]	Between PND 11 and 22, either perfusion or immersion fixation

[a]In general practice, EPA testing recommendations reflect procedural enhancements that have been incorporated into the OECD guideline.
[b]Behavioural ontogeny is not specifically required in the EPA guideline; however, two measures are required in the OECD guideline, one of which can be assessment of preweaning motor activity. Other examples provided in the guideline are righting reflex and negative geotaxis.

past 25 years, involving numerous scientists from various public and private sectors (e.g. government, industry, academia, nongovernment organizations, contract research organizations and public interest groups), with expertise in critical scientific areas (e.g. developmental toxicology, neurotoxicology and risk assessment). A number of pivotal meetings and collaborative studies have been conducted.

The formative history of the DNT guideline includes research on test method development, as well as efforts to characterize and document the sensitivity, reliability and performance of the test methods. Included among these efforts were a number of intralaboratory collaborative studies. A series of studies were conducted in the 1970s in which rats were developmentally exposed to a variety of materials and subsequently tested during postnatal development, using a battery of neurobehavioural tests (Butcher and Vorhees, 1979; Vorhees *et al*., 1979). In other laboratories, behavioural and histological batteries (focussing on sensory and motor function) were used in adult rodents that had been exposed to a wide variety of neurotoxicants (Pryor *et al*., 1983; Tilson *et al*., 1979). An extensive body of research (Gad, 1982; Irwin, 1968; Moser *et al*., 1988) examined the ability of the functional observational battery to detect and characterize the effects of drugs and environmental chemicals in adult and developing animal models. Subsequently, there were broad efforts to characterize the specificity of these test methods and the impact of factors at the level of the organism, as well as experimental factors (e.g. noise, species, strain, gender, test history) (Gerber and O'Shaughnessy, 1986; Levine and Butcher, 1990; MacPhail *et al*., 1989; Spencer *et al*., 1993). Overall, the collective work in this area documents and supports the consensus opinion that proper use and interpretation of the data derived from these test methods provides unique insight into the impact of xenobiotics on the developing and adult nervous system (Cory-Slechta *et al*., 2001; IPCS, 2001; Tyl *et al*., 2008).

Historically, there have also been a number of efforts to characterize the interlaboratory reliability and sensitivity of the neurotoxicology test methods that are included in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the DNT study design. Learning and retention methods were compared among three laboratories by Butcher *et al*. (1979). Subsequently, the Collaborative Behavioral Teratology Study (CBTS) (Buelke-Sam *et al*., 1985; Kimmel and Buelke-Sam, 1985) and the 'Williamsburg Workshop' on qualitative and quantitative comparability of human and animal DNT (Kimmel *et al*., 1990) were conducted. Collectively considered, these efforts addressed various aspects of DNT study design and conduct, demonstrating a sound scientific basis for the test method and its use in hazard evaluation. Since the US EPA DNT guideline was published in 1991, efforts have been conducted to review and update methodologies used for neurotoxicology testing in general and for developmental neurotoxicology testing in particular. These include, for example, the IPCS collaborative study on neurobehavioural screening methodologies (MacPhail *et al*., 1997), an International Life Science Institute (ILSI) Risk Science Institute (RSI) workshop on developmental neurotoxicity and risk assessment (Cory-Slechta *et al*., 2001; Dorman *et al*., 2001; Garman *et al*., 2001; Mileson and Ferenc, 2001), a collaborative study on neurobehavioural screening in 11 Japanese laboratories (Okazaki *et al*., 2003), a behavioral test methods workshop (Slikker *et al*., 2005) and a series of reports from an ILSI/RSI expert working group on neurodevelopmental end points (Crofton *et al*., 2008; Fitzpatrick *et al*., 2008; Holson *et al*., 2008; Raffaele *et al*., 2008; Tyl *et al*., 2008). Descriptions of each of these efforts and their contributions to the scientific basis for DNT testing are summarized by Makris *et al*. (2009).

In the context of toxicological screening and testing to support human-health risk assessment and chemical regulatory activities, the DNT study is a critical tool, because it addresses information that is not covered by other EPA or OECD test protocols. It is the only test guideline that assesses functional, behavioural and anatomical evaluations of the nervous system at multiple time points and in test subjects that were exposed to a test substance during critical pre- and early postnatal periods of nervous-system development. Over the past two decades, this test method has been used extensively to screen a wide variety of chemicals (**Table 3**).

Table 3 Number of chemicals studied using the EPA DNT Guideline or draft OECD 426 Guideline[a]

Chemical class	Number of studies
Pharmaceuticals	3
Miscellaneous agents[b]	4
Solvents	7
Industrial chemicals	8
Positive control chemicals	15
Pesticides	73
Total	110

[a]As cited in OECD, 2008b.
[b]Food additives, cigarette smoke, dietary restriction and maternal separation.

4.2 Validity and Cross-Species Comparability

A recent review of the history and performance of DNT testing was conducted in support of finalizing and implementing the OECD DNT test guideline (TG 426) (Makris *et al*., 2009). As a result of this review, OECD member countries reached a consensus opinion that the DNT guideline was considered to be validated, in accordance with the recommendations of OECD Guidance Document No. 34 (OECD, 2005), which addresses the validation and regulatory acceptance of new or updated test methods for hazard characterization.

In this review, the history of the DNT guideline development (in the US and internationally) was addressed, and the scientific basis supporting the guideline was summarized in detail. This included a number of workshops and collaborative studies, which are highlighted in **Table 1**. The extensive effort that contributed to the development of the DNT guideline development yielded incontrovertible evidence of the sensitivity of the study in detecting effects on neurological development in animal test subjects for a broad array of neurotoxic chemicals and other agents. Research programmes and interlaboratory collaborative studies demonstrated reliability and comparability in test results for the guideline-specified measurements, due in great part to concerted corollary efforts leading to the standardization of testing protocols and methods of data analysis and interpretation.

Another critical issue addressed by Makris *et al*. (2009) was the cross-species comparability of developmental neurotoxic outcomes in animal test models vs. humans. Evidence for such comparability was examined in the 1989 workshop on the Qualitative and Quantitative Comparability of Human and Animal Developmental Neurotoxicity (i.e. the 'Williamsburg Workshop') (Kimmel *et al*., 1990). In this workshop, expert scientists from government, industry, public interest groups and academia reviewed a range of representative chemicals and environmental exposures including: drugs (cannabis, cocaine, methadone and phencyclidine), ethanol, the anticonvulsant phenytoin, methylmercury, lead, polychlorinated biphenyls and ionizing radiation. Based on available human and animal data for these known human developmental neurotoxicants, the workshop participants concluded that DNT methodologies were adequate for detecting DNT. A major conclusion of the workshop was that the DNT protocol would have identified each of the agents considered at the workshop as a potential developmental neurotoxicant (Francis *et al*., 1990), although the critical effects, and the dose at which the effects were observed, might vary across species. This

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

concept has been further discussed by Schardein (1998). The predictive power of DNT guideline studies is largely attributed to the broad scope of neurobehavioural and neuropathological tests included in the study, that can screen neurological functions across multiple neurological domains (i.e. sensory, motivational/arousal, cognitive and motor). The laboratory-animal model serves as an adequate surrogate for humans because many of the biological and behavioural mechanisms underlying these neurological functions are shared between humans and laboratory animals. Wood *et al*. (2003) presents additional discussion of cross-species comparisons of postnatal CNS development, with a focus on functional measurements.

4.3 End Points and Issues

As described above, the current design of the regulatory DNT study assesses a broad spectrum of end points, in an attempt to identify the potential for a chemical to cause changes across many different neural systems. Due to the complexity and organization of the nervous system, it is not possible for changes in a single type of behaviour (or pathology in a single brain region) to adequately reflect dysfunction for the many individual systems of concern. Although one type of assessed behaviour may require intact functioning of multiple parts of the brain (e.g. motor activity involves control of motor systems as well as more cognitive aspects, for example those leading to habituation), each type of assessment also includes functions that may not be required for other types of behaviour (for example, hearing and auditory reflex circuits in auditory startle habituation). Each brain system also has its own normal developmental pattern, and the integration of various neural systems changes as each system matures, leading to differences in behavioural responses over time. For this reason, changes in a single parameter, or at a single assessment period, often reflect an adverse change in neural development even though later assessments of the same behaviour may look normal. It is often not the case that changes in nervous system development will lead to broad disruptions of behaviour on multiple types of end points. The ability to detect adverse effects will depend both on the type of behaviour assessed and on the sensitivity of the procedures used.

It is beyond the scope of this chapter to discuss in detail all aspects of the behavioural testing paradigms employed in evaluating DNT. For more detailed discussion of specific types of behaviour and their evaluation, the reader should refer to the neuropsychological literature (including some of the references cited below) and to the many other works in this area (Annau, 1985; Eckerman and Bushnell, 1992; Harry, 1994; Slikker and Chang, 1998; Weiss and O'Donoghue, 1994). In the discussion below, each type of procedure will be briefly described and some critical aspects of its use in this context will be mentioned.

In addition to behavioural evaluations, alterations in neurochemistry (for example changes in neurotransmitter levels, enzyme levels, ion-channel distribution or receptor levels) may be indicative of DNT. These types of methods have been extensively used for some compounds (Slotkin, 2004); interpretation of the findings in a regulatory context has been difficult, as the consequences of neurochemical changes with respect to functional effects on the whole organism is often not known. Discussion of these methods and their interpretation is beyond the scope of this chapter, however it is likely that their use will become more common as scientific understanding of the functional consequences of these types of changes increases.

In cases where a chemical or class of chemicals is known to cause a specific biological effect, for example, cholinesterase inhibition or thyroid hormone disruption, regulatory studies may also include measurement of these end points. Specific protocols have been developed and recommended by the EPA for these two categories of compounds (Makris, 2006; US EPA, 2005), but they will not be further discussed here. Consideration of these types of evaluations is also discussed in the OECD DNT guideline (OECD, 2007).

4.3.1 Relationship to Maternal/Foetal Paradigm

As a developmental study, the DNT guideline includes exposure to the mother and the foetus, both *in utero* and during lactation. This exposure period is designed to include the periods of most rapid brain development, although some aspects of brain development continue through adolescence, and studies with extended exposure have been conducted (Chapin *et al*., 1997). Because brain development continues after birth, it is important that the exposure to the offspring continue as well; for compounds that are not excreted in milk, it may be necessary to administer the compound directly to offspring after birth to assure continued exposure at levels of concern. It is important to be aware of the possibility that direct effects of the compound on the mother may impact neural development. In most cases, it is not possible to distinguish these effects from direct effects on the offspring. In any case, similar impact of maternal effects on offspring development would be of concern for substances to which humans are exposed, leading to the assumption that any adverse effects detected in the offspring are of concern, regardless of their ultimate cause.

4.3.2 Developmental Landmarks

Several landmarks or milestones of development are assessed in the DNT study. These include measures of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

birth weight and postnatal growth. Pup body weights are recorded by sex several times during the preweaning period and once or twice per month after weaning.

A number of other preweaning developmental landmarks may optionally be assessed. Age at ear pinna unfolding, upper incisor eruption and eye opening have been shown to be reliable measures of development (OECD, 2008a) and are commonly evaluated. Assessments commence just prior to the day that the event is typically expected to occur for the species being tested; this may vary by animal strain. The sample size evaluated (e.g. all pups on study vs. a subset of pups from each litter) and the manner in which the data are compiled and reported (e.g. as mean day of achievement per litter vs. the number of pups achieving the event during several discrete ranges of days assessed) can affect the sensitivity of these assays for identifying treatment-related effects. It is not unusual for preweaning developmental landmarks to be positively correlated with pup body weight.

The DNT guideline includes an assessment of the age of sexual maturity (puberty) in both males (age at balanopreputial separation) and females (age at vaginal patency). Typically, these events occur at approximately PND 40–45 in male rats and PND 30–35 in female rats (OECD, 2008a), although there may be some strain-related differences. It is important to record the body weight of the animals at the time that sexual maturity is achieved, since body mass is associated with age of puberty. Thus the interpretation of these data may be complicated by treatment-related effects on offspring growth.

The method used in calculating the age of the offspring may influence the assessment and interpretation of some developmental landmarks. Pup age may be calculated from the time of birth (i.e. postpartum age) or from the time of conception (i.e. postcoital age). The use of postcoital age has been shown to be a better predictor of the age that preweaning developmental landmarks are achieved than the use of postnatal age (Raimondo and Draghetti, 1990). This is particularly important when the duration of gestation is affected (either increased or decreased) by treatment, since this affects the stage of offspring development at the time of birth.

4.3.3 Functional Observations

The DNT guideline requires functional observations in both dams and offspring, at multiple time points. In the EPA DNT guideline, these assessments are less extensive than those required for the neurotoxicity screening studies in adult rats (US EPA, 1998c), and consist of evaluation in and outside the home cage for autonomic function, abnormal movements (including convulsions and tremors), posture and gait abnormalities, and unusual or abnormal behaviours. In addition, observations in offspring should be age-appropriate.

Presentation of data for these evaluations varies considerably across laboratories. It is important to look for trends across days, as well as differences in treatment groups for any given evaluation. It is also important to note that not all neural systems are fully developed at birth, and expected responses may differ for specific ages of animals. In our experience, this end point is not very sensitive to detecting treatment-related effects in DNT studies because of the limited nature of the observations; however, some chemical classes are known to produce effects on these end points (for example, tremors may be seen with exposure to pyrethroids). In those cases, failure to elicit effects on these end points during the dosing period may raise questions regarding the adequacy of the administered doses.

4.3.4 Auditory Startle

Auditory startle habituation is evaluated twice in offspring: once around the time of weaning and once towards the end of the study (in adult animals). In this paradigm, sound bursts are presented to the animal repeatedly, at regular intervals and whole-body motor response is measured. Over time, the response magnitude will decline, as the animal adapts to the repeated presentations. The neural circuits involved in this behaviour are well understood, and techniques exist that allow identification of the specific neural lesions leading to changes in this response (Adams, 1986; Buelke-Sam *et al*., 1985; Cassella and Davis, 1986; Crofton, 1992; Crofton and Sheets, 1989; Crofton *et al*., 1994; Davis, 1984; Geyer and Swerdlow, 1998; Ison, 1994; Koch, 1999; Marable and Maurissen, 2004; Muijser, 1994). Parameters evaluated in the DNT study include the peak response amplitude, latency to respond and change in response amplitude over repeated trials (habituation). Results are usually presented as mean response for five blocks of 10 trials each. In some studies, prepulse inhibition may also be evaluated; in that procedure, the startle stimulus is preceded by a prepulse of a pure tone, and the magnitude of response with and without the prepulse is compared (Crofton, 1992; Crofton *et al*., 1994). As might be inferred from the title, the use of a prepulse normally attenuates the response to the startle stimulus. Changes in the magnitude of this inhibition can be a sensitive indicator of a change in the function of the neural systems underlying this behaviour.

Auditory startle data should be evaluated by looking at differences in response amplitude among treatment groups, both with respect to mean values for each block of trials and differences in habituation rate, as these end points may respond independently to nervous system toxicity. Baseline response amplitudes can vary considerably among labs, and depend to some extent on initial settings and calibration of the equipment used (this is especially true for accelerometers, where the gain values may be set differently to accommodate the

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

difference in weight of animals as they grow). However, within a laboratory or a study, the baseline values should be comparable between control and treated animals. Although it has been suggested that differences in animal weight (perhaps due to other types of toxicity) may confound interpretation of auditory startle data, in our experience this has not been the case.

In some cases, excessive variability may obscure treatment-related effects (Raffaele *et al*., 2008; Sette *et al*., 2004). Selection of parameters such as interstimulus interval, background noise and stimulus strength (i.e. loudness) can affect responses for this procedure (Crofton, 1992; Geyer and Swerdlow, 1998; Raffaele *et al*., 2008). Selection and control of these variables is very important to obtaining quality data.

4.3.5 Motor Activity

In the DNT guideline study, motor activity is evaluated four times in offspring: three times during lactation (postnatal days 13, 17 and 19), and once in adults. The evaluations are performed in an automated recording chamber, with a sufficient duration to ensure that habituation (a decrease in activity over time) will occur. The three evaluations during lactation allow assessment of the normal development of this behaviour. Both the activity levels (total activity over the duration of the record, usually ranging from 40 to 60 minutes per session) and pattern of activity (the change over time, recorded for consecutive (e.g. 5–10 minute) intervals within the longer session) have been shown to change during development in a reliable way (Ruppert *et al*., 1985), although the exact pattern may depend to some extent on the environment or animal strain. Evaluation of whether or not the measured behaviour is consistent with the expected developmental pattern allows an assessment of whether neural development is proceeding normally in treated offspring. Failure to see expected developmental patterns in control offspring may raise concern regarding the conduct of the testing, and may complicate interpretation of treatment-related changes.

Similarly to auditory startle habituation, motor activity levels and variability in this behaviour can be influenced by many environmental factors, including lighting, extraneous noises and odours, test-device size and configuration, animal handling, and so on. Thus, it is very important that all these factors be well controlled, in order to ensure that data are reliable. In addition, the recording chambers need to be configured so that they accurately record activity in young animals. For example, inappropriate placement of photocells (i.e. height and distance apart) could result in decreased sensitivity (recording of fewer beam breaks) for smaller animals.

Motor activity, like auditory startle habituation data, should be evaluated both with regard to total activity level (for the entire session, as well as for subsessions) and to habituation (the expected decrease in activity with continuing time in the chamber). These parameters can change independently; for example, the data in **Figure 2** show two groups with the same total activity levels, but very different patterns over time. In some types of chambers, females will have higher activity levels than males. In addition, different activity patterns have been seen with different types of devices and different types of measurement systems. Laboratories should be able to demonstrate stable behaviour in control animals over time (Crofton *et al*., 1991; Crofton and MacPhail, 1996; MacPhail *et al*., 1989; Moser *et al*., 1997). Large shifts in baseline within a given laboratory may raise concern about the reliability of the data for this end point.

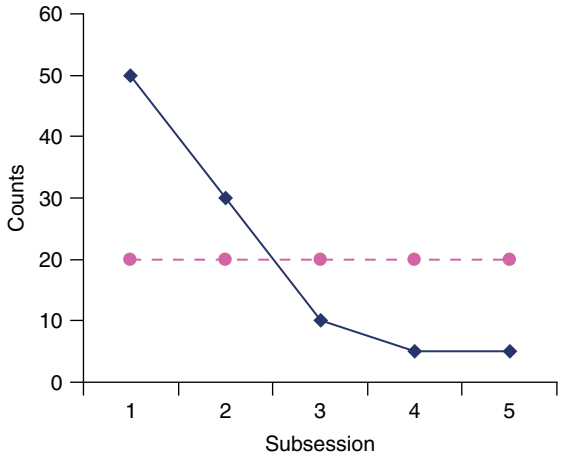

Figure 2 Each line represents activity levels for a group of animals, measured in five equal time intervals. Although the total activity levels for each group are equal (100 counts), the activity patterns are very different. The pattern represented by the diamond shapes shows the type of habituation typical for adult rats in most device types.

Failure of treated animals to demonstrate expected patterns of motor activity, both within a session and with respect to the expected developmental changes in activity patterns is indicative of a treatment-related effect. Treatment-related effects can result in either increases or decreases in activity; and some chemicals may cause both types of changes, depending on the exposure level (i.e. a U-shaped (or inverted-U-shaped) dose–response curve) or age at assessment (see additional discussion below of paradoxical dose–response curves).

4.3.6 Cognitive Testing

The test guideline requires an evaluation of 'learning and memory' at two time points: around the time of weaning and in adult animals (similar to assessments required for auditory startle habituation testing). The guidelines do not specify a particular type of assessment, except to state that both associative learning and retention should be evaluated; broad discretion is left to the testing laboratory regarding the particular procedure to be used.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Recent guidance (OECD, 2008a) has also indicated that either different tests or different animals should be used at the two time points, in order to avoid confounding the results based on retention of previously learned procedures.

To date, studies performed for regulatory purposes have used a fairly limited group of testing procedures, consisting, for the most part, of single choice point position discrimination (T- or Y-) mazes, the Biel water maze, the Morris water maze or a shock-motivated passive avoidance procedure (Bammer, 1982; Brandeis *et al*., 1989; Bushnell, 1982; Crofton *et al*., 1993; D'Hooge and De Deyn, 2001; Green and Stanton, 1989; Lochry and Riley, 1980; Morris, 1984; Peele *et al*., 1990; Vorhees, 1987; 1997; Wier *et al*., 1989). Details of the protocols vary greatly among laboratories, and the sensitivity of some of the procedures has not been well documented (Raffaele *et al*., 2004; 2006).

In interpreting results of these evaluations, it is important to examine both the learning (change in performance across trials) and retention of the task. Learning is usually measured as a decrease in errors or latency to reach a goal, across trials or sessions. These data are easiest to evaluate when plotted in the form of a learning curve. Retention is usually evaluated by comparing the first trial during the retention session with the last trial of the learning session. As an illustration, the time for L6 to R1-1 or R2-1 can be compared in **Figure 3**. The degree of retention will depend on the strength of the initial learning as well as the length of the delay between the final learning trial and the first retention trial; a decline in performance across these two trials would be attributable to a lack of retention. It is very important that both aspects (learning and retention) be assessed, as many substances have been demonstrated to affect one but not the other. In addition, to the extent possible, data for multiple measures for performance (for example errors, latency or path to goal) should be examined, since different measures may reflect different aspects of task performance (cf. **Figure 4**, where the increase in errors with dose is much more apparent than the increase in latency, especially for the low-dose group). Latency data may in some cases be greatly affected by changes in motor behaviour (for example, swim speed may change or the animal may respond abnormally to a shock stimulus). Where available, control procedures (such as latency to traverse a straight channel or otherwise escape from an aversive stimulus) can help to sort out these types of effects. In the absence of appropriate control procedures, the only alternative is to assume the effect is related to treatment, even if the specificity of the deficit to learning or memory function is unclear.

As for other types of behaviour, it is important to assess the performance of control animals. First, it must be determined whether animals in the control group have demonstrated both learning and retention of the task. It is not possible to determine whether treated animals are impaired by comparing them against controls performing at or near chance levels. Conversely, the sensitivity of a particular task may be questionable if controls perform perfectly in every trial but the first. For such a task, a very severe impairment would likely be needed before a performance decrement could be detected. As with other types of tasks, high levels of variability may impede the sensitivity of the task to detect decrements, especially with respect to the power of the statistical analysis. In some cases, increasing the number of subjects may resolve this problem, but in other cases changes in the task parameters may be required.

Any change in task performance should be considered potentially adverse, at either time point. Potential effects of concern are not limited to a failure to learn or remember the task, but also include a change in the rate at which it is learned. Evaluation of a change in the

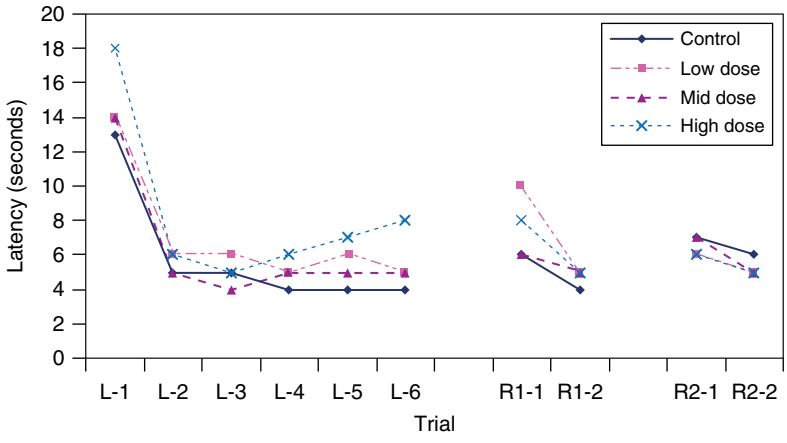

Figure 3 Learning curve for a water maze task, showing latency to goal for six learning trials on one day (L1–L6) and two sets of retention trials (R1 and R2) with a five day delay between each set of trials. Most groups show good retention (i.e. latency for trials R1-1 and R2-1 are similar to those for L-6). The low-dose group shows some decrease in retention for R1, but not for R2.

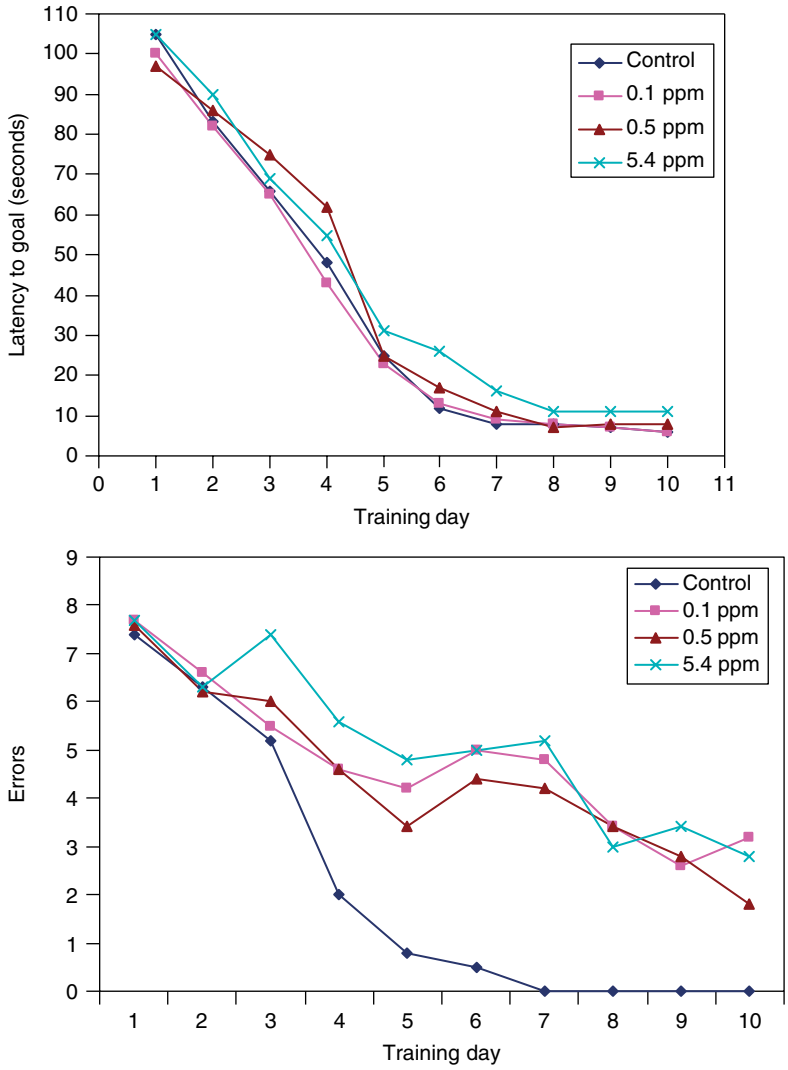

Figure 4 Learning curves for a water labyrinth test in rats, showing the changes in latency (a) and errors (b) over test days. The low-dose group shows no change in latency when compared with controls, but has an increase in errors starting with day 4. This figure also demonstrates the importance of examining the entire learning curve, as the mid- and high-dose groups show increased latency most prominently on day 4, with the mid-dose showing latencies similar to controls by day 5 and the high-dose latencies approaching control levels towards the end of training. Note that errors for all treated groups remain high through the end of training on day 10. (Data extracted from Malek *et al*., 2003b, p. 280.)

rate of learning requires that data be presented for all trials (or blocks of trials) sufficient to allow evaluation of the learning curve. Results reported as differences in errors/trial, averaged over the entire task or a single trials-to-criterion number (without indicating the pattern of errors (i.e. the sequence of 'failed' and correct trials) will not allow adequate assessment of the overall learning process). Although it is sometimes tempting to regard some types of changes (e.g. a decrease in latency to goal) as 'improvements' (and thus not of concern), this is rarely an appropriate interpretation. For example, decreased latency may result from hyperactivity; increased latency (which would result in improved performance in some types of avoidance tasks) could result from impaired motor abilities). As noted above, in many cases sufficient data are not available to determine whether changes in performance in 'learning and memory' tasks are due to specific cognitive deficits or to some other type of performance impairment. Appropriate control procedures (for example, activity levels or speed in a straight alley) may allow improved interpretations of these types of outcomes, but these types of data are often not available for guideline studies.

4.3.7 *Social Behaviours, Attention, Anxiety/Stress*

Changes in social behaviour, attention and anxiety/stress levels are not specifically evaluated in the current recommended guideline test battery, although the OECD

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

guideline does recommend that they be considered in some situations. A number of procedures have been developed that assess anxiety and social behaviours (Branchi *et al*., 2001; Lapiz-Bluhm *et al*., 2008; Malatynska *et al*., 2007), and for the evaluation of different aspects of attention (Bushnell, 1998); some of these paradigms have been used in drug development (Kalueff *et al*., 2005; Malatynska *et al*., 2005).

4.3.8 Postmortem Observations (Brain Weight, Gross Pathology, Neuropathology, Including Morphometry)

The DNT guideline recommends three types of assessments for neuropathology: brain weight, qualitative neuropathology and quantitative neuropathology in the form of linear morphometric measurements of at least three brain regions (neocortex, hippocampus and cerebellum). Assessments are performed at least twice: once in pups (either on postnatal day 11 or 21) and once in adults. Neuropathology assessments performed after PND 11 should use perfused tissue; staining with, at a minimum, haematoxylin and eosin, is recommended. Adult assessments should include tissues from the peripheral nervous system, as well as the brain. Brain weight can be evaluated using either fresh or post-fixed tissue.

For developing animals, special attention should be paid to evaluating structural changes indicative of developmental insult. Examples of these types of changes include death of neuronal precursors, abnormal proliferation or migration, changes in size or shape of brain regions (or evidence of hydrocephalus) or abnormal differentiation. Cellular alterations and tissue changes should be evaluated in both young animals and adults.

Recent evaluation of submitted DNT data has demonstrated that all three types of neuropathologic evaluation provide important information about brain pathology, and that no one measure is reliably predictive of effects on the others (Raffaele *et al*., 2005). This result reinforces the importance of using multiple types of measures to more completely examine the different types of neuropathology that may result from developmental exposures. As might be anticipated, differences in brain weight were more commonly seen in assessments performed at the early time point. Although in some cases brain-weight decreases were seen concomitant with body weight decreases, it is important to note that body-weight decreases were also commonly seen in the absence of brain-weight decreases; a causal relationship between these two measures should not be assumed.

In spite of initial concerns regarding the difficulty of reliably assessing neuropathology, and in particular the conduct of linear morphometric measurements, in the smaller and less robust brain tissue of neonatal animals, experience has shown that these measurements can be reliably performed (Crofton *et al*., 2001) and are sensitive to detection of treatment-related effects (Raffaele *et al*., 2005). Evaluation of data submitted to the EPA indicates that changes in linear morphometric measurements are, in many cases, a more sensitive indicator than changes in brain weight or neuropathology, and that treatment-related changes in this measure are more likely to be seen at both assessment times than are changes in brain weight (Raffaele *et al*., 2005). It is possible that more detailed qualitative neuropathological assessments, using additional tissue-staining techniques and/or evaluation of more brain sections, would result in greater sensitivity than the techniques currently prescribed in the test guidelines. Regardless, it appears that all three types of assessments, and both time points, provide information critical to a thorough neuropathological assessment of the developing nervous system.

4.3.9 Exposure Issues

As noted above, in conducting or evaluating DNT data it is important to include consideration of the actual exposure to the developing organism. The brain and nervous system continue to develop and mature for a considerable period after birth; different neural systems have different maturation periods and patterns, and their sensitivity to developmental insult will vary accordingly (as discussed in more detail above). Exposure limited to the *in utero* period may fail to adequately evaluate potential adverse effects on the development of neural systems that mature after birth. This is especially critical when using data from rats to evaluate potential human DNT, since many systems that mature prenatally in humans mature postnatally in rats.

The optimal DNT study would include exposure during a period equivalent to that expected for the human population of concern. If postnatal exposure is anticipated, it is important to document postnatal exposure in the animal model. For compounds without adequate lactational transfer (i.e. those not excreted in the milk), direct offspring exposure may be needed. Initial concerns about possible adverse effects on the offspring due to direct dosing have not been substantiated (Makris *et al*., 2005; 2006; Moser *et al*., 2005; Zoetis and Walls, 2003). Pharmacokinetic studies evaluating lactational transfer and tissue levels in offspring and maternal animals provide valuable information regarding actual exposure levels that can be used to document offspring exposure and potentially determine the specific exposure levels leading to adverse responses in the offspring. This type of information is particularly useful in a regulatory setting, in determining exposure levels below which adverse effects would not be expected.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

5 EVALUATION AND INTERPRETATION OF DATA

A number of issues regarding interpretation of DNT data, including those related to evaluation of specific end points, have been discussed above. It is important to emphasize here that data need to be interpreted in the context of the developmental exposures and the apical assessments used in the screening battery approach. As discussed previously, development represents a moving target to toxic agents. As the various systems of the nervous system are generated and become mature, each time point presents new opportunities for different types of adverse effects to be caused or different manifestations of an earlier impact to become evident. In the context of a DNT study, this may result in apparently contradictory effects seen during sequential evaluations of the same end point (e.g. an increase in motor activity at one time point, a decrease at another). Given our limited understanding of the mechanisms behind changes in the measured behaviours, it is inappropriate to interpret these apparently contradictory findings as unrelated to treatment.

Related to the likelihood that the impact of exposure to neurodevelopmentally toxic compounds may manifest in different ways at different times, is the likelihood that the impact may vary among different behavioural end points. The DNT study was designed as a test battery with the goal of assessing a wide spectrum of functional consequences. Although there is some overlap in the neural correlates of the various behaviours, many unique systems are involved in different types of behaviour. Thus, adverse effects detected in only one type of test (e.g. motor activity) should be assumed to be related to treatment, even in the absence of effects on other types of test (e.g. auditory startle habituation, neuropathology, learning or memory).

Consistent with other types of toxicity, response to treatment may vary by sex, and an effect seen in only one sex should not be dismissed on that basis. In some cases, appropriate statistical analyses will demonstrate that both sexes have similar responses with statistical significance achieved only in one; in other cases differences in metabolism or hormonal status may be the source of variable responses by sex.

In interpreting the results of specific behavioural assessments, it is important to keep in mind the common occurrence of nonlinear (including U- or inverted U-shaped) dose–response curves for behavioural end points. One example of a compound causing this type of effect might be a stimulant, such as amphetamine, or an intoxicant, such as ethanol: motor activity increases following lower doses, but as the dose continues to increase the activity will start to decrease; ultimately the animal will lose consciousness and motor activity will cease altogether. Depending on which points on the dose–response curve were evaluated, this changing response might also appear to be a plateau (i.e. if doses at opposite points on the increasing and decreasing side of the curve were evaluated), or as an initial increase above normal followed by a decrease below normal (if doses sampled early and late phases of the curve). An example showing this type of response is depicted in **Figure 5**. These complex dose–response curves, when combined with the limited number of doses assessed in a typical DNT study, can make data interpretation difficult. However, it is important to consider the possibility of this type of effect, given the frequent temptation to dismiss effects that fail to show the paradigmatic linear dose–response relationship seen for many standard toxicology end points. Dose–response curves of unusual shape can also complicate attempts to mathematically model these data.

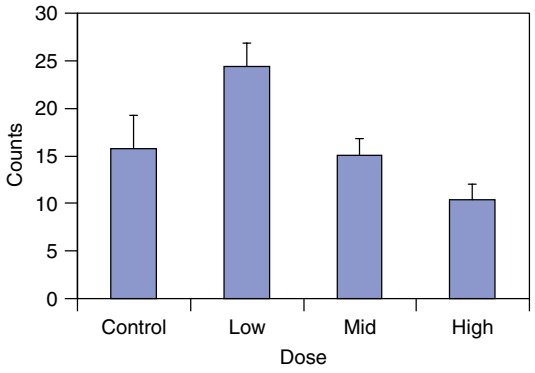

Figure 5 Wall-climbing counts during a three minute open-field motor activity evaluation in rats. These data demonstrate a typical U-shaped dose–response curve, with an increase in counts at the low dose, no change from control at the mid dose, and a decrease in counts at the high dose (changes at both the low and high dose were statistically significantly different from control). (Data extracted from Malek *et al*., 2003a, p. 164.)

Numerous groups have also emphasized the importance of using well-designed procedures and well-trained personnel in order to achieve reliable results in behavioural studies (Crofton *et al*., 2004; 2008; Slikker *et al*., 2005). In the absence of positive control information demonstrating the ability of the procedures to detect treatment-related changes in performance induced by agents known to impact a particular type of behaviour, the failure to detect a treatment-related effect of a test agent cannot be reliably interpreted as a negative result (Crofton *et al*., 2004; 2008). A series of reports evaluating methodologies and results from DNT studies submitted to EPA have found large differences in the stability and variability of control data from different laboratories, for a number of DNT end points (Crofton *et al*., 1991; 2004; Makris *et al*., 2005; 2006; Raffaele *et al*., 2003; 2004; 2005; 2006; Sette *et al*., 2004). These results reinforce the importance of careful evaluation and interpretation of results

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat085
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

from each study with respect to the appropriateness of the procedures used, their sensitivity in detecting the effects of concern and the quality of the resulting data.

It is also important to note that not all types of effects on the nervous system will be detected by the types of behavioural screens included in the guideline DNT study. The lack of specific evaluations of social behaviour, anxiety or attention have already been noted above. In situations where previous information about a chemical (or structurally related chemicals), or knowledge about a mechanism of action, may indicate the potential for adverse effects unlikely to be detected by standard guideline procedures, it may be important to add evaluations, or conduct additional studies, that will specifically address those effects of concern. Two examples where such chemical- or class-specific testing has been used to enhance the evaluation of DNT include the evaluation of neuroreceptors and delayed behavioural outcomes for the pyrethroid pesticides deltamethrin and bioallethrin (Eriksson and Fredriksson, 1991), and the conduct of comparative cholinesterase studies for food-use organophosphorus pesticides, as required by the US EPA Office of Pesticide Programs (Makris, 2006). As another example, potential refinements in staining for neuropathological procedures for DNT testing are discussed in the OECD Guidance on Mammalian Reproductive Toxicity Testing and Assessment (OECD, 2008a). Another approach to DNT screening is to evaluate precursor changes, such as with thyroid-disrupting pesticides, where conduct of a comparative thyroid study (US EPA, 2005) might preclude the need to conduct a standard guideline DNT study.

Several recent efforts have reviewed the current DNT guideline, and have made recommendations for refinement of methodologies (Cory-Slechta *et al*., 2001; Dorman *et al*., 2001; Garman *et al*., 2001; Kaufmann and Gröters, 2006) and improving conduct and interpretation of the studies (Crofton *et al*., 2008; Fenner-Crisp *et al*., 2005; Holson *et al*., 2008; Raffaele *et al*., 2008; Tyl *et al*., 2008). In addition, the historical development and reliability of the DNT methodology has been reviewed (Makris *et al*., 2009). These efforts have generally agreed on the utility of the study and the reliability of the methods, and have provided specific recommendations for future improvement.

6 USE OF DNT IN HAZARD/SAFETY ASSESSMENT AND RISK ASSESSMENT

6.1 Pharmaceuticals and Food Additives

Preclinical screening of pharmaceuticals for adverse developmental outcomes (including DNT) is conducted according to guidelines published by the International Conference on Harmonisation of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH, 2005). This guideline specifies that in a study for effects on prenatal and postnatal development, an assessment of physical development, sensory functions, reflexes and behaviour also be conducted in F1 offspring. While the guidance mentions several developmental landmarks that might be recorded, it does not make any specific recommendations regarding methods for assessing sensory functions, motor activity or learning and memory. A report by Middaugh *et al*. (2003) described a survey that was designed to evaluate the contribution of F1 neurobehavioural testing to hazard identification and characterization in safety-assessment studies. This survey included studies completed since 1990 in industrial laboratories in the US, Europe and Japan. Studies on 179 compounds were included in the analysis, and the majority (81%) of them were pharmaceuticals. Middaugh *et al*. (2003) found that even though the F1 behavioural end points were affected by test compounds less often than general toxicology parameters, these end points (along with other parameters) defined the no observed effect level (NOEL) in 15% (17/113) of the studies, and solely defined the NOEL in 2.6% (3/113) of the studies. Unfortunately, this study did not indicate whether the studies in which the behavioural end points defined the NOEL were for pharmaceuticals or some other type of agent. Nevertheless, Middaugh *et al*. (2003) concluded that the behavioural testing sometimes improved on the standard toxicological measures used in hazard identification, in part because it requires measurement of outcomes not assessed in other preclinical testing.

For preclinical testing of agents that are intended to be marketed as paediatric pharmaceuticals, testing in preweaning animals may be indicated. General guidance for such testing has been published (US FDA, 2006). Studies for known neuroactive agents may be designed to provide a general screen for neurological changes in multiple domains (e.g. as does the US EPA guideline DNT study) or may be designed to address specific parameters or concerns.

For food additives, which are regulated through the FDA Center for Food Safety and Nutrition (CFSAN) in the US, testing guidelines are published in the 'Redbook' (US FDA, 2000a; 2000b). Notably, however, a DNT guideline is not included. The need for DNT testing is considered on a chemical-by-chemical basis. Acrylamide is an example of a food additive for which a DNT study was conducted (Wise *et al*., 1995), although this study did not affect the acceptable daily intake (ADI).

6.2 Agricultural, Industrial and Environmental Chemicals

As previously mentioned, in the context of toxicological screening and testing to support human-health risk assessment and chemical regulatory activities, the DNT study satisfies an information need that is not addressed by other test guidelines. It is quite notably recognized as the only available standardized test guideline that includes functional, behavioural and anatomical evaluations of the nervous system at multiple time points, and in test subjects that were exposed to test substance during critical pre- and early postnatal periods of nervous system development. The DNT study is an important tool in addressing concerns about the potential for increased risk of developmental neurotoxic outcomes following early life exposures to pesticides and other substances and the need for more rigorous assessment (Brent *et al*., 2004; NRC, 2000; Weiss *et al*., 2004).

The basic risk-assessment paradigm is comprised of four components: hazard identification, dose–response assessment, exposure assessment and risk characterization (NRC, 1983). The hazard identification and dose–response assessment includes the overall toxicological evaluation (for epidemiological as well as animal data). It characterizes the sufficiency and strength of the data set, discusses the confidence in the data, and may include some modelling of the toxicological outcomes to better characterize dose–response. Exposure assessment derives estimates of actual or potential human exposure, based upon various scenarios (e.g. environmental, occupational or residential). The risk characterization integrates the toxicology and exposure data and is used along with other factors (e.g. social, economic and engineering) in the process of risk management. The potential use of DNT data in risk assessment has long been recognized and has been described by Kimmel (1998).

Evaluations of the use of the DNT study in human health risk assessment have been conducted by the US EPA Office of Pesticide Programs (OPP). As noted in **Table 3**, the largest number of guideline DNT studies that has been conducted to date has been on pesticides. The reason for this preponderance of pesticide DNT studies is that the US EPA OPP has conducted a concerted effort over the past decade to obtain information on DNT for specific pesticides to satisfy the mandates of the US FQPA (FQPA, 1996). In addition, over the years, the EPA has participated in a continuing analysis of and discourse on the conduct of DNT studies, the interpretation of the data from these studies and their regulatory impact.

The first analysis that was conducted was a retrospective review of 12 DNT studies (Makris *et al*., 1998) that had been submitted to the EPA Office of Pollution Pesticides and Toxic Substance (OPPTS) in support of the registration and/or use of nine pesticides and three solvents. For the nine pesticides examined, the EPA analyses concluded that the NOEL for the DNT study was lower than that of the foetal NOEL from the prenatal developmental toxicity study (OECD, 2001a; US EPA, 1998a) for eight of the nine pesticides tested, and demonstrated an equivalent dose for one. The offspring NOEL for the DNT study was lower than the offspring NOEL for the reproduction study (OECD, 2001b; US EPA, 1998b) for six of the nine pesticides, and equivalent for one. Overall, in two of nine cases, the NOEL for DNT was lower than or equal to that for any adult or offspring end point from the prenatal developmental, reproduction or adult neurotoxicity (OECD, 1997; US EPA, 1998c) studies. Although this review was limited by the small database of DNT studies available in 1998, it clearly indicated that the DNT study, because of its unique end points, which are not examined in any other Test Guideline, enhances the detection of neurobehavioural and neuropathological effects in offspring following exposure during sensitive periods of neurological development. It also supports the conclusion that the DNT study is often identified as a sensitive study in a chemical database, as well as an important source of quantitative and qualitative information for risk assessment.

This analysis was presented to a FIFRA Scientific Advisory Panel (SAP) (US EPA, 1999), which also reviewed the use of the DNT study in risk assessment. The Panel agreed that DNT study results are appropriate for use to support acute and chronic dietary risk assessments and short- and intermediate-term occupational and residential risk assessments for pesticides. As previously noted, the DNT study utilizes exposures of approximately 25–40 days duration, during critical stages of nervous-system development. Even a single toxicant exposure during a critical developmental period has the potential to result in an adverse developmental outcome to the nervous system (Rodier, 1980; 1986; 1994; Rice and Barone, 2000). Therefore, OPP has used the DNT study outcomes in risk calculations for acute (single dose) reference doses (RfDs), and for short-term (1–30 days) and intermediate-term (1–6 months) nonoccupational exposures to pesticides. Although these particular risk calculations are not utilized by all EPA Offices and Programs, they are nevertheless especially applicable to risk assessments for children (Makris *et al*., 2008). Additionally, in accordance with common risk assessment practices used across the EPA (US EPA, 2002a) and in other regulatory programmes world-wide, the results from DNT studies have also been used for chronic risk assessments (i.e. in calculating a chronic RfD for lifetime exposure to a toxicant) when it has been shown to be the most sensitive study in the toxicology database.

To further pursue the issue of how the DNT study is being used in OPP risk assessment, an updated survey was conducted by Rowland *et al*. (2007). In this study, the specific use of the DNT study in the selection of

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

end points and doses for the risk assessment was examined; this was a different approach than was taken by the 1998 retrospective analysis which compared the NOELs of DNT studies with other studies in the various chemical databases. The Rowland *et al*. analysis found that for 58 pesticide chemicals where a DNT study had been considered in the weight-of-evidence review of the toxicology database, the DNT study was utilized to select end points and doses for risk assessments for eight of those chemicals. Four studies were used to establish an acute RfD, four were used for a chronic RfD and six were used for short- or intermediate-term nondietary (e.g. residential) risk assessments. A single study was sometimes used for multiple risk-assessment scenarios. One particularly notable finding of this review was that for four of the eight DNT studies used to select end points and doses for risk assessment, the critical effects either included or were based solely upon offspring behavioural and neuropathological tests that are not evaluated in other guideline studies (i.e. motor activity, auditory startle habituation, learning and memory and morphometric analysis of the brain). Also, based on an examination of the doses and effects identified in the OPP DNT study reviews, in comparison to those used as points of departure in the most recent published OPP risk assessment for the same chemicals, 17 cases were identified where an end point from a DNT study could potentially be selected for use in one or more risk assessment scenarios in future risk assessment actions. The findings of the Rowland *et al*. (2007) review were concordant with the conclusions of the 1998 retrospective analysis by Makris *et al*. Further evidence was provided regarding the sensitivity of the DNT study in identifying adverse effects of chemical exposures during development, and the important role of DNT studies in human-health risk assessments.

In addition to using DNT data for regulatory decisions, some regulatory agencies have also, on a case-by-case basis, incorporated an additional database uncertainty factor into their regulatory decisions because of the absence of DNT data. The use of these uncertainty factors in risk calculations reflect regulator views that DNT data are valuable in establishing permissible exposure levels, and reducing uncertainties about the toxicity of the chemicals (US EPA, 2002a; 2002b).

7 FUTURE DIRECTION AND RESEARCH NEEDS

Diverse groups have advocated increased testing for DNT (Andersen *et al*., 2000; Grandjean and Landrigan, 2006; NRC, 1992; 1993; Nelson, 1986; OTA, 1990; Stein *et al*., 2002; Vorhees, 1986). Although the overall performance of the DNT test method and its ability to detect effects of concern from a regulatory perspective have been well established (Makris *et al*., 2009), there remains an intense focus on this test method. Some critics of the study argue that specific tests (e.g. assessment of cognitive and sensory dysfunction) are insensitive; on the other hand, others believe that the tests included in the DNT study are overly sensitive and have a high rate of false positives (Claudio *et al*., 1999; 2000; Cory-Slechta *et al*., 2001; US EPA, 1995; 2006). Recommendations have been made to include evaluations of end points not currently assessed in the DNT study; examples are social behaviour (Cory-Slechta *et al*., 2001), pharmacokinetics and neurochemistry (Andersen *et al*., 2000; Dorman *et al*., 2001), and latent changes (e.g. during senescence) that are attributable to developmental exposures (Cory-Slechta *et al*., 2001). Criticisms of the study complexity have been accompanied by the suggestion to delete some test components from the protocol (Li, 2005) or to utilize screening approaches that incorporate DNT testing into other protocols (Cooper *et al*., 2006; Ladics *et al*., 2005). Some critics of the DNT study say that for some end points (e.g. motor activity, morphometrics) variability is too high (CMA, 1987; Nolen, 1985; York *et al*., 2004), and others suggest that this *in vivo* test is not necessary to detect DNT (Balls and Combes, 2005). These various and diverse opinions demonstrate a need for ongoing scientifically based evaluation of the test method and the incorporation of appropriate revisions commensurate with advances in scientific knowledge and increased experience with the analysis, interpretation and use of the DNT study.

There are a number of efforts currently underway that are intended to review data from existing DNT studies, identify ways to refine the DNT test and, to the extent possible, reduce the number of animals used in screening for DNT, for example, by applying certain statistical approaches to the behavioural analysis (Chiarotti and Puopolo, 2000; Puopolo, 2004), or through the use of alternative tests (Lein *et al*., 2007). Reviews of historical and positive control data have demonstrated the need for more standardized reporting requirements (Crofton *et al*., 2004; 2008). Further retrospective reviews of control data have identified differences among laboratories in data quality and variability (Crofton *et al*., 1991; 2004; Raffaele *et al*., 2003; 2004; 2008; Sette *et al*., 2004), while another review of various neuropathology assessments conducted in DNT studies identified low variability for measures of brain weight, qualitative histopathology and quantitative (morphometric) evaluations of the brain (Crofton *et al*., 2001), further concluding that no one post-mortem measure is more sensitive than the others, with each providing important data (Raffaele *et al*., 2005). The outcome of these continuing efforts will be to enhance data interpretation, help refine requirements for future testing and guide and promote the development of new methods.

While recognizing the need to refine and enhance the current DNT testing paradigm, there is also a driving need to apply new methodologies and approaches to DNT screening, in the spirit of the recent report on *Toxicity Testing in the 21st Century* (NRC, 2007). At this time, many thousands of chemicals which have a high potential for human exposure (e.g. high-production-volume chemicals, pesticide inert ingredients and antimicrobial pesticides) are lacking in the most basic toxicological screening data (NRC, 1984). Assessing potential neurotoxicological effects will be a major challenge for these chemicals, and new tools and methods are likely to be needed (Dix *et al*., 2007; Kavlock *et al*., 2008; NRC, 2007). As previously discussed, the current DNT guideline generates useful data for risk-assessment purposes. However, conducting this *in vivo* study is expensive and time-consuming. Additionally, it uses a relatively large number of naïve animals when conducted as a stand-alone study. Thus, an alternative approach is needed, that incorporates a validated first tier screening paradigm (e.g. a high-throughput *in vitro* screening battery) designed to rapidly assess large numbers of chemicals and predict their potential to cause DNT (Coecke *et al*., 2007; Lein *et al*., 2007; NRC, 2007; US EPA, 2006). When considered in conjunction with appropriate decision frameworks (Combes *et al*., 2003), data from these high-throughput screens could facilitate prioritization of further *in vivo* testing, for example, for substances identified as potentially hazardous under the European regulation on Registration, Evaluation, Authorisation and Restriction of Chemical Substances (REACH) (EC, 2006). Data generated by the current DNT test method will be important to the validation of high-throughput *in vitro* methodologies, by providing information on their utility and limits, as well as guidance on the potential use of data from these alternative methods in a risk-assessment context (Makris *et al*., 2009).

Drug Toxicity in Neonates, Infants and Young Children

Imti Choonara

CONTENTS

1 INTRODUCTION

It is important to recognize that paediatric patients of all ages are at greater risk of drug toxicity than healthy adults. This is because of several key differences. Firstly, neonates, infants and young children are growing rapidly. Therefore, the organs associated with rapid growth may experience specific toxicities that are not apparent in adults. For example, corticosteroids may result in growth retardation in growing children, whereas this specific drug toxicity is not apparent in fully grown adults. Similarly, substances may have an adverse effect on the developing brain. Corticosteroids used to minimize chronic lung disease in the neonatal period are associated with an increased risk of cerebral palsy.

An additional problem in paediatric patients is that many of the medicines used have not been thoroughly evaluated scientifically before being used widely. Many of the medicines are used in a manner different to that for which they were authorized, that is, they are used in children of a younger age than have been studied previously or used at a different dosage or even administered by a different route to that for which the medicine received a marketing authorization. Such use is termed off-label drug use, and in association with the use of medicines that are unlicensed is a significant problem in children throughout the world (Conroy *et al*., 2000). The risk of drug toxicity in association with unlicensed and off-label drug use in children is greater than that associated with medicines used in the manner for which they were authorized (Turner *et al*., 1999). Unfortunately paediatric health professionals have no other option than to use these medicines in an off-label manner as otherwise children would be deprived of appropriate therapy. It is to be hoped that this situation will improve following European and American legislation which encourages the pharmaceutical industry to perform clinical trials in children (Choonara, 2007).

Another major predisposing factor is the different drug metabolism in paediatric patients of different ages. In general, oxidative processes involving cytochrome P450 enzymes are markedly decreased in neonates. Enzyme activity is dramatically reduced in the premature neonate in particular. Hence, clearance of many drugs is reduced in the neonatal period (de Wildt *et al*., 2003). CYP3A7 activity may compensate slightly for decreased CYP3A4 activity, but overall drug clearance is reduced. This has had major implications in relation to drug toxicity, as documented below.

Phase II metabolizing enzymes such as the UDP-glucuronyltransferases are decreased in neonates

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat087

and infants. For certain medicines (e.g. paracetamol (acetaminophen)) there may be compensatory sulfation. The increased sulfation, however, does not fully compensate for the decreased glucuronidation, and clearance of paracetamol remains reduced in neonates, especially if preterm (Anderson *et al*., 2002). Although the changes in drug metabolism in young children may predispose to drug toxicity, in certain cases it can minimize drug toxicity. In the case of paracetamol, differences in drug metabolism in prepubertal children result in decreased hepatotoxicity following an overdose (Penna and Buchanan, 1991). As well as changes in enzyme activity involved with drug metabolism, there are major changes in relation to volume of distribution, protein binding and renal excretion. These are greatest in the preterm neonate and critically ill neonates and infants.

2 EPIDEMIOLOGY OF DRUG TOXICITY IN PAEDIATRIC PATIENTS

Adverse drug reactions (ADRs) are a significant problem in paediatric patients. A systematic review and meta-analysis of 17 prospective studies suggested that almost 1 in 10 children in hospital experience an ADR, and up to 2% of all paediatric hospital admissions are the consequence of ADRs (Impicciatore *et al*., 2001). More recent studies have shown a similar rate of ADRs occurring in children in hospital and in children admitted to hospital (dos Santos and Coelho, 2006; Fattahi *et al*., 2005). Most of the prospective studies of drug toxicity in paediatric patients have focussed on children. There have been relatively few studies looking at the incidence of ADRs in neonates. The few studies that have occurred have suggested that the incidence of ADRs in neonates on the intensive care unit is considerably higher (10–30%) (Aranda *et al*., 1982; Bonati *et al*., 1990).

Paediatric pharmacovigilance studies carried out in conjunction with regulatory authorities have been successful in identifying less frequent ADRs and, in particular, identifying fatalities (Choonara, 2006). Two studies in particular have reviewed large numbers of fatalities over a longer period of time. One study was performed in the UK and identified 331 fatalities that were suspected ADRs (Clarkson and Choonara, 2002). The group of medicines most likely to be associated with a fatality in this study were antiepileptic drugs. A review of suspected ADRs reported to the Food and Drug Administration in the USA involving infants and children under the age of two years reported over 700 deaths in a period of just over three years (Moore *et al*., 2002). In this study 41% of the deaths involved neonates. Drug toxicity may often not be suspected in a critically ill neonate with multiorgan failure, and hence the actual number of ADRs is likely to be higher.

3 PERCUTANEOUS DRUG TOXICITY

One of the earliest recognized ADRs was the development of methaemoglobinaemia due to aniline dye, which had been used to stamp the name of the institution on nappies (Rayner, 1886). As reported over a century ago, 17 newborn infants developed cyanosis after absorbing the dye percutaneously. Subsequently, there have been other cases of infants developing cyanosis due to percutaneous absorption of aniline dye (Kagan *et al*., 1949). By 1949, a total of seven different reports had identified 63 cases with 5 fatalities (Kagan *et al*., 1949). Many of these infants had a decreased level of consciousness and vomiting. The infants who died all developed pneumonia two to four weeks after developing acute symptoms in association with aniline toxicity.

This ADR illustrates the possibility of enhanced drug toxicity through percutaneous absorption in infants. In general, absorption of compounds is enhanced by issues such as the prolonged contact of a wet nappy with the perineum. Newborn infants have a higher surface-area-to-weight ratio than both children and adults. Therefore medicines that are administered topically result in greater relative exposure in newborn infants. Additionally, a relative increase in the water content of the dermis and a thinner stratum corneum in young infants facilitates transcutaneous diffusion of small molecules. There have been several other examples of percutaneous toxicity occurring both in newborn infants and in children. Antiseptic agents such as hexachlorophene (Powell *et al*., 1973), iodine (Chabrolle and Rossier, 1978) and ethyl alcohol (Püschel, 1981) have been associated with neurotoxicity, hypothyroidism and hypoglycaemia, respectively (**Table 1**).

Hexachlorophene had been used widely as an antiseptic agent in an attempt to reduce staphylococcal infections. Studies in newborn infants showed that, following use as an antiseptic agent on the skin, the compound was detectable in the plasma of newborn infants (Curley *et al*., 1971). Studies in rats had suggested that hexachlorophene may be neurotoxic. Unfortunately this was also shown to be the case in premature, newborn infants. Powell *et al*. (1973) described a spongiform myelinopathy in seven neonates. The infants who developed the spongiform myelinopathy were all premature, weighing less than 1.4 kg, and had been exposed to hexachlorophene washes on more than four occasions (Powell *et al*., 1973). Contamination of a baby powder containing talc with 6.3% hexachlorophene in France resulted in over 200 infants and young children becoming ill (Martin-Bouyer *et al*., 1982; Goutières and Aicardi, 1977). Many of the affected children developed an encephalopathy and 36 died.

Table 1 Examples of percutaneous drug toxicity in paediatric patients

Drug	ADR	References
Aniline dye	Methaemoglobinaemia	Rayner (1886); Kagan *et al*. (1949)
Hexachlorophene	Neurotoxicity	Martin-Bouyer *et al*. (1982); Powell *et al*. (1973)
Iodine	Hypothyroidism	Chabrolle and Rossier (1978)
Ethanol and methanol	Cardiac arrest Hypoglycaemia Metabolic acidosis Respiratory depression Seizures	Giménez *et al*. (1968)
Ethanol	Hypoglycaemia	Püschel (1981)
Nicotine	Agitation Coma Dizziness Vomiting	Davies *et al*. (2001); Woolf *et al*. (1997)

Percutaneous toxicity is not restricted to the neonatal period. In Argentina it has been a widespread practice to apply alcohol-soaked cloths to the abdominal area of sick children. Giménez *et al*. (1968) described 48 children presenting with alcohol toxicity over a period of 14 months (Giménez *et al*., 1968). The mean age of these children was 11 months. Over half the children were exposed to ethanol and a smaller number methanol. There were a total of 14 deaths and the symptoms ranged through hypotonia, coma, respiratory depression, seizures and hypoglycaemia.

Transdermal nicotine is used in adults to help wean them off cigarette smoking. A study in the USA described reports received from Poison Centres in relation to children who had accidentally been exposed to transdermal nicotine patches (Woolf *et al*., 1997). None of the children came to harm and the symptoms were predominantly gastrointestinal weakness, dizziness or localized rashes. In the UK, there has been a case report of an eight-year-old boy who received a traditional topical remedy for eczema (Davies *et al*., 2001). The traditional remedy contained nicotine and the child developed acute nicotine poisoning (agitation, vomiting, fluctuating level of consciousness). He was admitted to hospital and received treatment for suspected acute meningoencephalitis until toxicology demonstrated high levels of nicotine and cotinine in both blood and urine (Davies *et al*., 2001). This case report is a reminder of the problems associated with traditional remedies.

4 ANTIBIOTIC TOXICITY IN NEONATES

4.1 Sulfonamides and Protein Binding

In 1956, neonates who received a combination of penicillin and sulfafurazole were found to have a significantly higher mortality that those who received oxytetracycline (Silverman *et al*., 1956). There was a higher incidence of kernicterus in the neonates who received the penicillin and sulfonamide combination. These infants developed seizures, opisthotonus, spasticity, oculogyric movements and poor feeding. On postmortem examination the pathological diagnosis of kernicterus was made on the basis of yellow staining of the brain. It is important to note that the authors were unable to provide an explanation for the toxicity observed. They were, however, concerned in relation to the increased mortality and were keen that clinicians knew of the dangers associated with this combination of antibiotics.

Subsequent *in vitro* studies showed that sulfonamides have a higher binding affinity than bilirubin for albumin (Odell, 1959). Studies in rats showed that sulfonamides increased the risk of kernicterus (Johnson *et al*., 1959). It was several years later that it was confirmed that sulfonamides increased the free fraction of bilirubin in the plasma in neonates (Dunn, 1964). The free bilirubin in the plasma crossed the blood–brain barrier, and its deposition in the brain resulted in kernicterus. As a result of the studies by Silverman *et al*. (1956), medicines that displace bilirubin, such as salicylates and ceftriaxone, are not used in ill neonates who are at risk of bilirubin encephalopathy.

4.2 Chloramphenicol

A few years after the reported mortality of sulfonamides in sick neonates, the grey baby syndrome was reported with the antibiotic chloramphenicol (Sutherland, 1959). Infants developed abdominal distension, vomiting, cyanosis, cardiovascular collapse, irregular respiration and subsequently died shortly after therapy with chloramphenicol was started. The following year, studies of the pharmacokinetics of chloramphenicol in

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

neonates showed significantly higher plasma concentrations of chloramphenicol in neonates in comparison to levels in older children. The plasma half-life of chloramphenicol in neonates was shown to be 26 hours in comparison with a plasma half-life of 4 hours in children between the ages of four and five years (Weiss *et al*., 1960). The prolonged plasma half-life was due to the reduced conjugation of chloramphenicol to its glucuronide metabolite. Previous studies had shown that newborn infants have decreased conjugation of bilirubin with glucuronic acid, and this is the mechanism for the physiological jaundice that appears in many newborn infants (Brown *et al*., 1958). The high plasma concentrations of chloramphenicol which were responsible for the grey baby syndrome could be avoided by a reduction in the total daily dosage from $100\,mg\,kg^{-1}$ to $50\,mg\,kg^{-1}$.

The drug toxicity in neonates associated with both sulfonamides and chloramphenicol could have been prevented by a greater understanding of the capacity of neonates to handle and metabolize drugs.

5 DEXAMETHASONE THERAPY IN NEONATES, AND DEVELOPMENTAL DELAY

Corticosteroids (usually dexamethasone) have been used for the last 20 years to treat neonates who developed bronchopulmonary dysplasia (Grier and Halliday, 2003). These infants were often ventilator dependent, and dexamethasone was found to be beneficial in weaning the infants off the ventilator and reducing the risk of chronic lung disease (Halliday *et al*., 2003). In 1998 a follow-up study of these infants, at the age of two years, showed a significantly higher incidence of neurotoxicity in the neonates who received dexamethasone (Yeh *et al*., 1998). Over the next two years other investigators confirmed these findings (Kothadia *et al*., 1999; Shinwell *et al*., 2000).

Corticosteroids were known to increase the risk of infection, hyperglycaemia and hypertension, but the adverse neurological effects were unexpected. The neurotoxicity was associated with the early use of dexamethasone (Grier and Halliday, 2003). Subsequent studies have confirmed that dexamethasone used in the first few days of life has an adverse effect on the infant, which results in poorer performance in school-age children (Yeh *et al*., 2004). Dexamethasone use later in the neonatal period, however, does not appear to increase the risk of developmental delay (Halliday, 2003). The neurotoxicity associated with corticosteroids in neonates is a reminder that unexpected drug toxicity may occur with drugs that have been extensively used in children and adults. One therefore needs to be cautious with the use of all drugs especially in the sick, preterm infant.

6 SODIUM VALPROATE AND HEPATOTOXICITY

Sodium valproate is an effective antiepileptic drug that is widely used in adults and children. It was introduced in the USA in 1978 and shortly after its introduction was noted to have a hepatotoxic effect (Sussman and McLain, 1979). Within a few years there had been more than 20 fatalities associated with hepatotoxicity in patients receiving sodium valproate (Zimmerman and Ishak, 1982). A detailed retrospective review of 37 fatalities in the USA identified two main risk factors (Dreifuss *et al*., 1987). Children under the age of three years and patients receiving polypharmacy were at the greatest risk. Subsequent studies by the same group have confirmed that young age and polytherapy are the greatest risk factors and that developmental delay and coexisting metabolic disorders are also risk factors (Dreifuss *et al*., 1989; Bryant and Dreifuss, 1996). The risk of developing hepatotoxicity in children less than two years old on polytherapy in all three of these studies was 1 in 600. In contrast, the risk in an adult on monotherapy is less than 1 in 500 000 (Bryant and Dreifuss, 1996). Polytherapy is the most important risk factor, with adults on polytherapy having a 10-fold greater incidence of sodium valproate-induced hepatotoxicity than adults on monotherapy, that is, one in 50 000 (Bryant and Dreifuss, 1996).

The mechanism of the hepatotoxicity is unknown but is thought to be associated with alterations in fatty acid metabolism by sodium valproate or its metabolites. It is recognized that the metabolism of sodium valproate is different in young children. Additionally, the use of other anticonvulsants alongside the sodium valproate may result in the induction of certain metabolic pathways which predispose to the formation of toxic metabolites (Gopaul *et al*., 2003). One of the metabolites of sodium valproate, in particular, has been suggested as a cause of hepatotoxicity, and this is 4-ene valproate (Bryant and Dreifuss, 1996; Zimmerman and Ishak, 1982).

7 SALICYLATES AND REYE'S SYNDROME

Reye's syndrome was originally described in 1963 (Reyes *et al*., 1963). Children usually had a preceding viral infection and subsequent drowsiness which led to coma, hypoglycaemia, seizures and liver failure. The association between Reye's syndrome and salicylates was raised as a possibility two years later by an observant physician who noted that 15 of the 31 cases reported had received aspirin prior to admission (Giles, 1965).

In 1980, evidence supporting the association between Reye's syndrome and the use of salicylates during a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat087
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

preceding viral infection was published (Starko *et al*., 1980). During an outbreak of influenza A, seven children were admitted to hospital with Reye's syndrome. These seven children were compared with controls from the same class who did not have signs/symptoms compatible with the diagnosis of Reye's syndrome. All the children with Reye's syndrome took salicylates, whereas only 8 of the 16 controls took salicylates. The patients took a larger dose of salicylates as compared to those in the control group and the level of salicylate consumption was associated with the severity of the Reye's syndrome. Subsequent studies confirmed the association between salicylates and the development of Reye's syndrome in children who were experiencing a viral infection (Hurwitz *et al*., 1987; Hall *et al*., 1988).

The restriction of the use of salicylates as an antipyretic and analgesic in children aged 12 and under has led to a dramatic reduction in the incidence of Reye's syndrome (Belay *et al*., 1999). Several cases were subsequently reported of salicylates leading to the development of Reye's syndrome in children between the ages of 12 and 16 (McGovern *et al*., 2001; Clarkson and Choonara, 2002). In 2002 the regulatory agency in the UK issued advice to doctors to avoid the use of aspirin in children under the age of 16 years as an antipyretic (MCA/CSM, 2002). The mechanism of the toxicity is unknown. It is recognized, however, that both the administration of salicylates and a viral infection are required for the development of Reye's syndrome.

8 VIGABATRIN AND VISUAL FIELD DEFECTS

Vigabatrin is an antiepileptic drug which acts as a selective irreversible inhibitor of gamma-aminobutyric acid (GABA) transaminase. Vigabatrin was found to be particularly effective in the management of infantile spasms. In 1997 visual field constrictions were described in three adults receiving vigabatrin (Eke *et al*., 1997). By 1999 there had been several more cases reported and the regulatory authorities in the UK issued advice in relation to restricting the prescribing and also ensuring that regular monitoring was undertaken in patients receiving vigabatrin (MCA/CSM, 1999).

Vigabatrin is known to accumulate in the retina, and retinal degeneration has been reported in rats following therapy with vigabatrin (Sills *et al*., 2001; Butler *et al*., 1987). The pathophysiology in relation to the visual field defects is uncertain. It is, however, thought to be permanent, despite the occasional case report of reversible changes in visual fields (Versino and Veggioti, 1999).

A study in Finland suggested that the prevalence of visual field constriction in children was lower than that in adults (Vanhatalo *et al*., 2002). The Finnish study suggested that just under 20% of children exposed to vigabatrin experienced visual field constrictions. Studies in adults suggest that one in three patients receiving vigabatrin will develop visual field defects (Kalviainen and Nousiainen, 2001). The risk in men is twice that for women (Kalviainen and Nousiainen, 2001). Despite the risk of visual field defects, the benefits of vigabatrin for the management of young children with infantile spasms are considerable and it is still recommended for use in this patient group (BNFC, 2007; Nabbout, 2001).

9 PROPOFOL INFUSION SYNDROME

Propofol is an ultrashort-acting anaesthetic agent that is widely used for the induction and maintenance of anaesthesia in both adults and children. The short elimination half-life and rapid distribution kinetics of propofol allow patients to recover rapidly upon discontinuation of infusion with less toxicity than other parenteral anaesthetic agents (e.g. barbiturates, ketamine). Propofol has also been used as a sedative to facilitate prolonged mechanical ventilation in critically ill children.

To date, there have been reports of 24 children dying following the use of propofol for nonprocedural sedation (Parke *et al*., 1992; Bray, 1998; Wysowski and Pollock, 2006). These children developed severe metabolic acidosis, lipaemia and progressive cardiac dysfunction (hypotension, cardiac failure, arrhythmias). Many of the children subsequently developed multiorgan failure. As well as the 24 children reported in the medical literature, there were 21 deaths reported to the Food and Drug Administration in the USA (Wysowski and Pollock, 2006). These 21 American cases all involved children receiving propofol for nonprocedural sedation. The majority of cases of propofol infusion syndrome have occurred in children who have received propofol at doses above $4\,mg\,kg^{-1}\,h^{-1}$, and for periods of more than 48 hours (Bray, 1998). However, not all children who receive high-dose propofol for more than 48 hours develop the propofol infusion syndrome (Bray, 1999). The propofol infusion syndrome has also been described in adults. It is, however, less common in adults, like many of the other ADRs described in this chapter (**Table 2**).

The mechanism(s) associated with the production of metabolic acidosis by propofol in children without concomitant hypoxaemia is not known. It has been suggested that propofol at high doses disrupts fatty acid oxidation within the mitochondria (Wolf *et al*., 2001). Another case report described a 10-month-old infant who improved with continuous venovenous haemofiltration, and the authors have therefore postulated that a water-soluble metabolite of propofol is involved in the development of propofol infusion syndrome (Cray *et al*.,

Table 2 Examples of adverse drug reactions that are more common in paediatric patients than adults

Drug/compound	Age group	ADR	Mechanism
Aniline dye	Neonates	Methaemoglobinaemia	Percutaneous absorption
Sulfafurazole	Neonates	Kernicterus	Protein-displacing effect on bilirubin
Chloramphenicol	Neonates	Grey baby syndrome	Impaired metabolism
Sodium valproate	Young children (<3 yr)	Hepatic failure	Abnormal metabolism?
Salicylate	Children	Reye's syndrome	Unknown Dose related?
Propofol	Children	Metabolic acidosis	Unknown Dose related?

1998). This group also described reduced cytochrome oxidase activity in muscle tissue.

10 EXCIPIENT TOXICITY

It is important to recognize that all drugs contain excipients. These are other substances that are added to a drug in order to increase its solubility, improve its stability or, in the case of oral medications, often to improve its palatability. Some of the major cases of drug toxicity that have occurred in paediatric patients have been in association with excipient toxicity. Diethylene glycol was used as a solvent to make sulfonamides more soluble in water. It was originally used in the USA in 1937 to prepare a solution of sulfanilamide. Unfortunately diethylene glycol is highly toxic, resulting in both hepatic and renal failure. The sulfonamide/diethylene combination was responsible for the deaths of at least 76 American children and adults (Geiling and Cannon, 1938).

It is disappointing that this historical tragedy has been repeated numerous times, with episodes of diethylene glycol contamination of medicines occurring in Argentina, Bangladesh, Haiti, India, Nigeria, South Africa and Spain (Woolf, 1998; Pandya, 1988). In many of the cases either all or a majority of the victims have been children. Diethylene glycol was used as a solvent for paracetamol and resulted in the death of 47 children in Nigeria (Okuonghae *et al*., 1992), 51 children in Bangladesh (Hanif *et al*., 1995) and 85 children in Haiti (O'Brien *et al*., 1998). In the most recent episode (Haiti), the paracetamol was accidentally contaminated with diethylene glycol. Glycerine was used as an excipient for the paracetamol formulation and it was the glycerine that was contaminated with diethylene glycol. In the cases in Nigeria and Bangladesh, it is unclear whether the diethylene glycol was a contaminant or whether it was used unwittingly by a small unregulated manufacturer. The importance of an adequate quality control of medicines for children in developing countries has been previously highlighted (Choonara, 1992; Woolf, 1998).

There have been several other examples of excipient toxicity, especially in neonates (**Table 3**). Benzyl alcohol is used for its antibacterial properties in ampoules of sodium chloride and water that are intended for intravenous administration. Metabolic acidosis, hepatic and renal failure and cardiovascular collapse have been described among premature newborn infants who were receiving multiple injections of sodium chloride for flushing catheters and bacteriostatic water in association with medicines that have been reconstituted (Brown *et al*., 1982; Gershanik *et al*., 1982). Both solutions contained 0.9% benzyl alcohol, which was postulated as the causative agent in neonates and young infants with a reduced capacity to metabolize and excrete this toxic 'inactive ingredient' in the doses that were unwittingly administered.

It has been suggested that benzyl alcohol may have had a far greater impact on both mortality and morbidity than the 10 deaths reported by Gershanik *et al*. (1982). A group in Oregon reported significant decreases in the mortality rate of preterm infants after the use of solutions containing benzyl alcohol was stopped (Hiller *et al*., 1986). The same group also described a significant decrease in intraventricular haemorrhage and subsequent development of cerebral palsy and developmental delay following discontinuation of benzyl alcohol (Hiller *et al*., 1986; Benda *et al*., 1986). Benzyl alcohol toxicity has also been described in association with its use as a preservative in antibiotic injections such as clindamycin (Hall *et al*., 2004).

In October 1983, intravenous vitamin E was being used in neonatal intensive care units in the USA in order to prevent retinopathy of prematurity. Within a few months, case reports of infants developing hepatic or renal failure in association with acoagulopathy were being described (Bodenstein, 1984; Centers for Disease Control and Prevention, 1984). By April 1984, the intravenous formulation of vitamin E had been withdrawn from the market following the death of 38 neonates

Table 3 Specific examples of excipient toxicity

Error	Drug	Country	Reference
Diethylene glycol used as solvent	Sulfanilamide	USA	Geiling and Cannon (1938)
Contamination of glycerine by diethylene glycol	Paracetamol	Nigeria Bangladesh Haiti	Okuonghae *et al*. (1992) Hanif *et al*. (1995) O'Brien *et al*. (1998)
Contamination with diethylene glycol	Cough expectorant	India	Singh *et al*. (2001)
High concentrations of benzyl alcohol as preservative	Sodium chloride and water	USA	Brown *et al*. (1982) Gershanik *et al*. (1982)
Emulsifiers toxic?	Vitamin E	USA	Bodenstein (1984)

(Phelps, 1984). It was postulated that the emulsifiers used to make the vitamin E water miscible for intravenous use may have been responsible for the deaths (Phelps, 1984).

11 SUMMARY AND CONCLUSIONS

Neonates, infants and young children may experience the same drug toxicity as adults. They may also experience specific drug toxicity that adults do not experience. This may be associated with toxicity related to growth and development, for example the adverse effect of corticosteroids on growth or development of the brain following exposure in the early period of neonatal life. Alternatively they may develop a specific toxicity in relation to a condition that does not occur in adults, for example, Reye's syndrome following exposure to salicylates during the presence of a viral infection.

The altered drug metabolism within paediatric patients is an additional risk factor for drug toxicity. This is most marked in the neonatal period and is illustrated by the impaired metabolism of chloramphenicol which resulted in cardiovascular collapse. Similarly, the altered metabolism of antiepileptic drugs such as sodium valproate in children less than two years of age predisposes this particular age group to hepatotoxicity.

Percutaneous toxicity can occur at any age but is a greater problem in newborn infants who have a higher surface-area-to-weight ratio than older children and adults. Lastly, one needs to recognize that excipient toxicity has been a particular problem in both children and neonates. It is to be hoped that recent legislation within Europe (Choonara, 2007) will result in the pharmaceutical industry spending more money on research into medicines for children. Further, it is to be hoped that this will increase the evidence base for the use of medicines safely and effectively. It is also anticipated that this will improve the availability of formulations created specifically for paediatric patients, which will hopefully prevent major cases of excipient toxicity in the future.

Toxicology of the Placenta

Ramesh C. Gupta

CONTENTS

1 INTRODUCTION

Placental toxicology is a fascinating subject, as it deals with three components: mother, placenta and foetus. It encompasses knowledge of structural and functional changes in the placenta, placentation, implantation, embryotoxicity, foetal death, structural malformation, growth retardation and functional deficits. The late nineteenth and early twentieth century was a golden age for placental research, and Mathias Duval (1844–1907) was one of the pioneers in elucidating intricate details of placentas of different mammalian species, notably rodents (Pijnenborg and Vercruysse, 2006). This subject has received much attention from teratologists, toxicologists, pharmacologists, biologists and regulatory agencies since the disaster of thalidomide in the 1960s. An estimated 8000 babies were born with deformities by the use of thalidomide. Since then, a huge number of chemicals have been shown to produce birth defects. In later studies, the placenta has been found to have many enzymes, receptors and transmitters (Kanevsky *et al*., 1997; Hewitt *et al*., 2006), and thereby it has received enormous attention. By now, most researchers are well convinced that the majority of chemicals reach the foetus from the mother by crossing the placenta. Thus, the placental barrier is not a true full barrier, but prevents access of certain chemicals to the foetal circulation.

The placenta is a rapidly developing complex organ which interfaces two separate genomes: mother and foetus. This organ becomes further complicated by multiple pregnancies, which are common in human gestation and the rule in many species like cats, dogs, pigs and rodents (Benirschke and Masliah, 2001). Undoubtedly, the placenta is an evolutionary organ and unique in the sense, as it plays many roles in the development of the foetus by serving as the lung, gut, kidney and exocrine/endocrine glands. Its role in providing oxygen and nutrients to the developing foetus through maternal circulation is well established. Unfortunately, some of the toxic metals, such as lead (Pb) and cadmium (Cd), are also delivered to the foetus by the same mechanism as that of nutrients.

With regard to chemical toxicity, it is noteworthy that the placenta itself is a target organ for toxicity. In the assessment of placental toxicity of any xenobiotics, there are two major areas of concern: what the placenta does to xenobiotics and what xenobiotics do to the placenta (Myllynen *et al*., 2005; Pelkonen *et al*., 2006). In the former area, the major topics of concern are: the entry and possible storage of substances in placental cells and through the placenta, aided perhaps by various transporters and efflux pumps; the distribution and binding of compounds in placental cells; and biotransformation of substances by intracellular enzymes. Metabolic activation and production of reactive intermediates by placental enzymes link these areas with toxicodynamics of placental toxicants. In the latter area, effects of compounds on placental blood flow and vasculature and the presence of membrane and intracellular receptors, enzymes and other potential targets for xenobiotics are important areas of placental toxicity. Therefore, by having a wide range of activities, the placenta can modify the outcome of foetal toxicity of xenobiotics. In the toxicant-exposed mother, the chemical encounters the placenta before it reaches the foetus. It is likely that chemical-induced damage in the placenta will also appear in the foetus. Obviously, the health of the placenta seems as important as the health of the mother or the foetus.

Recently, with some chemicals such as methylmercury (MeHg), adverse effects on foetal growth or survival have been observed at doses that did not produce any toxicity in the mother. In addition to limited activity of metabolism and elimination, the foetus has a low protein binding capability and incomplete or partial blood–brain barrier (BBB). These few factors, among several others, suggest that risks to the foetus from chemical toxicity are far greater than that to the mother. It is beyond the scope of this chapter to discuss the placental toxicity of every single chemical; instead, this chapter is mainly focussed on drugs of abuse, alcohol, smoke, metals, pesticides, environmental toxicants and mycotoxins.

2 PHYSIOLOGICAL ROLE OF THE PLACENTA: STRUCTURE AND FUNCTION

The primary role of embryonic (foetal) membranes is to provide protection to the embryo and foetus. They also play a significant role in foetal nutrition, respiration and excretion. The placenta is formed from the foetal chorion and maternal endometrium. The umbilical cord, placenta, amnion and chorion are expelled after the birth of the foetus. For many years, the view that the placenta is a rejected tissue and may not be suitable for bioassay or biocomparative assays of drugs and evaluation of the cellular mechanisms of actions of drugs and chemicals has been popular among pharmacologists and toxicologists. Use of pregnant animals is considered the preferred model to assess the toxicological actions of chemicals. However, information obtained with animal models cannot be transferred easily to human situations. A significant progress was made in the 1990s in the use of human placental tissues in pharmacological and toxicological investigations due to several developments (Sastry, 1997): (i) Emphasis on alternative methods to animal use in life sciences. (ii) Relevance of living cells from human sources for screening drugs which are eventually used in humans. (iii) Formation of associations of scientists who use placentas in their investigations, and (iv) an increase in the use of abused drugs by pregnant women. Now several methods are available to use different parts of the placenta in screening drugs and

chemicals and to study the molecular mechanisms for their pharmacological and toxicological effects.

2.1 Placenta Types and Functional Aspects

Mammalian placenta can be classified into four types based on the number of layers between maternal and foetal blood: (i) haemochorial (human, rat, rabbit, guinea pig); (ii) endotheliochorial (cat, dog); (iii) syndesmochorial (sheep, ruminants); and (iv) epitheliochorial (pig, horse). There are anatomical and functional differences among different types of placentas (Syme *et al.*, 2004). Due to practical and technical advantages, animal placentas have been used to study placental function and toxicology. Although qualitative similarities among several types of placenta are present, identity of function and effects of toxicants should not be assumed.

The human placenta is of the haemochorial type, in which the foetal tissue is in direct contact with the maternal blood (**Figure 1**). The membrane separating the maternal and foetal compartments is thin and consists of only three layers: syncytiotrophoblast, connective tissue and vascular foetal endothelium. The intensity of the passage of substances across the placenta is inversely proportional to the thickness of placental membranes. For example, intensity of Na^+ exchange across different types of placentas can be arranged in the following order: haemochorial > endotheliochorial > syndesmochorial > epitheliochorial. In all types of placenta, the intensity of Na^+ exchange increases with gestation, reaching a maximum shortly before term. In the haemochorial placenta, the intensity of exchange decreases at the end of gestation due to deposition of fibrinoid on the exchanging surface. Exchange involves not only physiological constituents, but also substances or elements which represent a pathologic risk for the foetus. Therefore, in assessing placental toxicology of chemicals, all physiological and functional variables should be taken into consideration.

2.1.1 Stages in the Development of Placenta and Dysmorphogenic Agents

The placenta is an important foetal accessory structure which brings maternal and foetal circulations and tissues into close relationship. Morphologically, it is partly of foetal origin (the trophoblast) and partly of maternal origin (from a transformation of the uterine mucosa). In humans, there are two stages for the development of placenta: (i) early embryonic period (of two months), followed by (ii) later foetal period (of seven months). The placenta is differentiated by the third month of pregnancy. During the embryonic period (the first

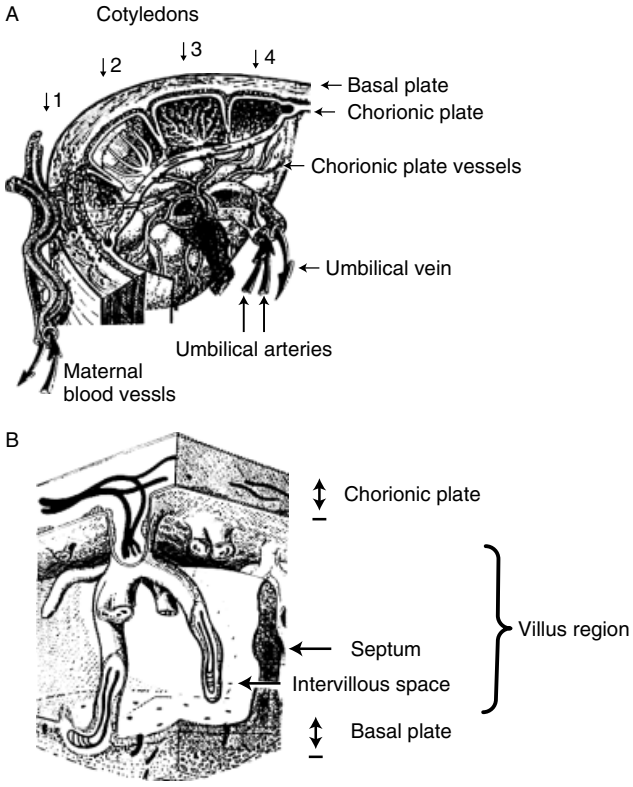

Figure 1 (A) A schematic drawing showing a cross-section of human term placenta. Four distinct cotyledons (1, 2, 3, and 4) are shown. In cotyledon 1, maternal and foetal blood flows are depicted. In cotyledon 2, anchoring villi to basal plate are shown. In cotyledons 3 and 4, all villi and blood flows are shown. (B) Schematic drawing of a single cotyledon, villi and other parts of the placenta. For details of human placental structure, standard books on human embryology should be consulted. (Reproduced from Tuchmann-Duplessis, 1973. © Springer.)

two months) of pregnancy, the embryo acquires definite form (morphogenesis), and the outlines of main organs (organogenesis) are defined (**Table 1**). By the end of the second month, the embryo becomes a foetus. During the foetal period (two to nine months), the organs undergo maturation at the histological (histogenesis) and functional levels. During this period, the foetus grows in size (crown–rump length), volume and weight (**Figure 2**). During the embryonic period, there is no placental barrier. Drugs and environmental chemicals have easy access to the developing embryo and interfere with different stages of morphological differentiation. Chemical- or drug-induced dysmorphogenicity has been recognized in experimental animals for many years. However, the clinical implications of these experimental results have been widely recognized since 1961 due to the discovery of thalidomide-induced phocomelia and other embryopathies. The critical exposure of the embryo occurs *in utero* when the sedative drug thalidomide (100 mg) is ingested by a pregnant woman in the fourth and sixth

weeks of pregnancy. About 8000 victims of this teratogenic substance have been born (Rodin *et al*., 1962; Taussig, 1962).

During the foetal period, the fully formed placenta plays an important role in the maintenance of nutrition to the foetus and in the secretory and regulatory functions that are essential for the maintenance of pregnancy. All 'supplies' to the embryo and foetus—oxygen, water, electrolytes, nutrients, hormones and antibodies—must pass through the placenta (**Table 2**). Several enzymes involved in the four basic processes of drug biotransformation—oxidation, reduction, hydrolysis and conjugation—are present in the placenta. The placenta has a significant role to play in the synthesis of steroid and protein hormones and of several regulatory factors, including acetylcholine (ACh), opioid peptides, tachykinins, platelet activating factor (PAF) and prostaglandins. If the placenta is not functioning properly, it can be the limiting factor not only for foetal nutrition, but also for the maternal–foetal exchange of physiological constituents and foetal–maternal exchange of waste products that may represent a pathologic risk to the foetus. Some of the drugs ingested by the mother may enter the placenta and interfere with placental function and, thereby, foetal development. Some of the compounds may enter the placenta and be metabolized into toxic compounds and enter foetal circulation. Therefore, the human placenta can be a target organ for drug- and chemical-induced injury, especially through abused pharmacologically

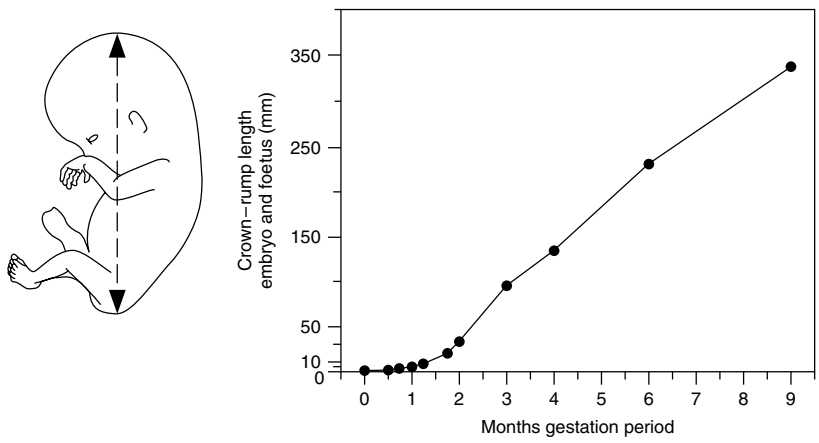

Figure 2 The relationship between gestation period and crown–rump length of human embryo and foetus. In foetal growth retardation both parameters will decrease.

active agents (morphine, cocaine and components of tobacco smoke), which may affect placental function and cause foetal growth retardation and other adverse reproductive effects in humans.

2.2 Structure of Term Human Placenta

The placenta at term looks like a disc of about 20 cm in diameter, 3 cm in thickness, and weighs about 500 g (**Figure 1**). The umbilical vessels are seen through the amnion. The top part of the placenta is termed chorionic plate and contains layers of amnion, connective tissue, parts of cytotrophoblast and syncytiotrophoblast, which faces maternal blood. The umbilical vessels subdivide into chorionic plate arteries and veins and enter the villi. There are 20–30 large villus trunks that correspond to cotyledons, which are distinct lobes seen on the maternal side of the placenta. The lower part of placenta is termed the basal plate, which contains layers of syncytiotrophoblast, parts of cytotrophoblast, compact zone (decidua) and spongy zone. At the time of delivery, the placenta separates from the uterus at the spongy zone. Maternal blood enters the intervillous space through uterine spiral arteries and drains through uterine veins. Maternal blood spreads out in intervillous spaces and circulates between the branches of villus trees. The foetal blood enters villus trunk through umbilical arteries, flows through capillaries in the villi and returns to the foetus through umbilical veins. The exchange of substances from maternal blood to foetal blood takes place through villus membranes which contain three layers: syncytiotrophoblast, collagen or connective tissue layer, and foetal endothelial cells. There are two types of villi: floating villi which hang in maternal blood, and anchoring villi which are attached to basal plate at their tips.

The blood flow in the maternal and foetal circulations of placenta is very high, about 500 ml min^{-1}. This high flow rate favours foetal–maternal exchange. Maternal circulation results from a difference in pressure: high in the artery (70 mm Hg) and low in the intervillous space (10 mm Hg). Foetal circulation is carried out in a closed vascular system where the estimated pressure of 30 mm Hg is higher than that of intervillous space (10 mm Hg). This difference in pressure maintains the position of the villi and prevents their collapse.

2.3 Human Placental Tissues for Pharmacological and Toxicological Evaluation

There are several types of pharmacological preparations from human placenta which have been described by several investigators. These include (i) perfused single placental cotyledon; (ii) villus preparation; (iii) segments of umbilical, chorionic plate, and villus stem arteries and veins; (iv) trophoblast plasma membrane; (v) isolated receptors and transporters; and (vi) stem cells from umbilical blood. Several of these preparations have been described in detail in many papers and reviewed by Sastry (1996).

2.3.1 *Dually Perfused Human Placental Cotyledon*

Several animal models have been used to assess transplacental drug passage, but species differences in placental anatomy and physiology have prevented general acceptance of animal studies as to how well they relate to humans (Hamshaw-Thomas and Reynolds, 1985; Kennedy *et al*., 1986; Carson and Reynolds, 1992; Pelkonen *et al*., 2006; Gupta, 2007). A wide gap exists in our knowledge and understanding of the mechanisms and rates of transport of drugs and chemicals from (i) maternal to foetal and (ii) foetal to maternal circulations.

An isolated, dual-perfusion, human placental model was developed by Schneider *et al*. (1972) and has been revised by Schneider (1995). It has been well validated though studies of the transfer of several different substances. Experiments can be performed using either the closed (recirculating) method or the open (single pass or noncirculating) method. In the closed model, both the maternal and foetal perfusates are recirculated. After a 30 minute equilibration period, the drug (or a chemical) and antipyrine (10 μg ml^{-1}, 53 μM) are added to either the maternal or foetal reservoir and allowed to equilibrate for 3 hours. Samples (1 ml) are taken from the maternal and foetal circuits at 15–30 minute intervals for the duration of the experiment (3 hours), for the measurement of the drug (or chemical), antipyrine, lactate production and glucose consumption.

The recirculation studies are not useful to calculate meaningful clearance data because these data change over time as more drug is transferred and accumulates towards equilibrium between the circuits. Instead, data are expressed in terms of a percent transfer of the drug during the period of greatest transport (i.e. on the steepest aspect of the exponential decline curve of the donor circuit) (Johnson *et al*., 1995).

In open perfusions, after a period of equilibration, a steady state is attained. Maternal to foetal drug clearance (C1) can be calculated by the standard formula. Similarly, foetal to maternal clearances can also be calculated. Integrity and viability of placental tissue are monitored by lack of fluid shifts, partial pressures in both maternal and foetal circuits, lactate output, lactic dehydrogenase release and glucose consumption. Antipyrine is generally used as a freely diffusible marker to evaluate the placental transfer of drugs. These validating methods are standards for this system.

The *in vitro* human placental model has been used to measure placental transfer of certain nutrients (e.g. insulin), vitamins (biotin), local anaesthetics used during pregnancy (e.g. bupivacaine), abused drugs (e.g. cocaine) and several other compounds (**Table 3**). This information is useful to assess the rate of transfer of substances into the foetal circulation after the drugs and other chemical substances are ingested by the mother. The perfusion model is also useful to determine the clearance of the drug and toxic chemicals from the foetal circulation after cessation of maternal exposure to these chemicals.

The *in vitro* human placental model is also useful to assess the effects of endogenous biogenic amines, exogenous amines and other chemical substances on foetal perfusion pressure. For example, the effects of several biogenic amines have been determined on perfusion pressures in human placenta. They may cause vasoconstriction or dilation (**Table 4**). The effects of new chemicals or toxicants on the perfusion pressure changes induced by biogenic amines and other endogenous substances can be studied.

2.3.2 Isolated Placental Blood Vessels

Isolated blood vessel strips from the rat aorta, porcine coronary artery and various other preparations have become useful for evaluating the vascular resistance caused by biogenic amines in pharmacological screening techniques. In recent years, techniques have been developed to use isolated placental blood vessels to evaluate the vascular resistance of biogenic amines. One advantage of placental blood vessels is the availability of human sources. As the placenta is devoid of innervation, direct effects of biogenic amines on their receptors can be evaluated.

As discussed in the previous section, perfusion of isolated human placentas *in vitro* through the umbilical artery has indicated that placental vasculature is sensitive to a variety of compounds with vasoactive properties.

Table 3 Placental transfer of substances using perfused placenta

Hormones and vitamins	Nutrients	Therapeutic agents	Abused agents

This preparation provides useful information on the perfusion flow and overall resistance of the system. However, this preparation does not distinguish the sites of vascular resistance and permit quantification of the actions of drugs. Strips of umbilical arteries and veins have been examined for drug sensitivity, but these studies reflect only the sensitivity of cord vessels *per se* and not of the placental vasculature. Different regions of the placental vasculature tree exhibit different sensitivities to vasoactive peptides. Since the small arteries or arterioles of the placental vasculature are the most probable sites of placental vasculature resistance, it is necessary to compare sensitivities of resistance of vessels to biogenic amines with those of the larger arteries supplying the placenta.

The three regions of human placenta—(i) umbilical cord, (ii) chorionic plate, and (iii) villus stem arteries—are useful for pharmacological evaluation of biogenic amines and drugs. All of these preparations have been reviewed by Sastry (1996).

2.3.3 Trophoblastic Tissue

Several preparations from human trophoblastic tissue have been used to study the effects of drugs on processes in human placental trophoblast. The main parameters frequently used are uptake of amino acids, especially nonmetabolizable amino acids (e.g. L-aminoisobutyric acid), by the trophoblastic tissue, and release of biogenic amines (e.g. ACh) or opioid peptides (e.g. methionine enkephalin). These aspects have been reviewed by Sastry and Janson (1995), Sastry (1993) and Ahmed and Cemerikic (1995). The various types of preparations include (i) placental slices, (ii) dissected syncytiotrophoblastic tissue, (iii) microvillus membrane vesicles, and (iv) subcellular fractions including microsomes. The former three types of preparations are often used in pharmacological assays, while microsomes are used in drug metabolism studies.

2.3.4 Microvillus Plasma Membrane

A preparation has been described by several investigators in which surface microvilli of human term placenta are exfoliated from the syncytiotrophoblast cells (Smith *et al*., 1974; 1977; Fant and Harbison, 1981; Barnwell and Sastry, 1987). The exfoliated microvilli are further purified by differential centrifugation and washing. The microvilli (or membrane vesicles) are essentially plasma membrane. This preparation is enriched in the two marker enzymes of plasma membrane, alkaline phosphatase and 5′-nucleotidase, 24–25-fold when compared to the whole villus homogenate (Barnwell and Sastry, 1987).

The plasma membrane forms microvesicles, which have been used to measure amino acid uptake, to demonstrate the presence of muscarinic receptors by radioligand binding, and to establish the role of phospholipid-*N*-methyltransferase 1 (PMT1) in the uptake of amino acids. PMT1 is enriched about 1.5–2.0-fold in the microvillus plasma membranes when compared to its activity in whole villus homogenate. Inhibition of PMT1 resulted in the depressed uptake of the amino acid AIB (aminoisobutyric acid) by placental villi. This preparation will be useful to study the effects of drugs and toxicants on amino acid transport across the plasma membrane.

2.3.5 Cultured Human Placental Villus Tissue and Cells

There are several types of receptors on human placental cells: muscarinic, nicotinic and opioid receptors. It is difficult to study receptor down-regulation, up-regulation, desensitization and tolerance development against agonists in fresh placenta because the placenta will also be exposed to several other drugs administered to pregnant women. The villus trophoblast which is thoroughly washed free of drugs and maintained in culture for several days is more suitable for studying the different aspects of receptor regulation and the influence of toxic substances in placenta.

The availability of an *in vitro* purified trophoblast system would also facilitate studies on several aspects of trophoblast function, transport of nutrients between maternal and foetal circulation, secretion of steroid and protein hormones, transport of immunoglobulins from mother to foetus, and blockade of the rejection of the foetus by the mother. Isolated cytotrophoblasts and syncytiotrophoblasts facilitate molecular biological studies on placenta. Well-established cell lines from choriocarcinoma are useful in several of the above studies. Some investigations are focussed in developing these techniques: (i) culture of villus trophoblast for long periods (Cemerikic *et al*., 1994; 1995), (ii) isolation of cytotrophoblasts from human term placenta (Kliman *et al*., 1986; 1987; Daniels-McQueen *et al*., 1987; Lobo *et al*., 1987), and (iii) development of cell lines from choriocarcinoma (BeWo, JAr and JEG-3) cells (Loke and Hussa, 1987).

Each culture system has specific advantages and disadvantages. The choice of culture system is based upon the purpose for which it is used (Sastry, 1996). Techniques have also been developed to grow JAr cells as multicellular spheroids (White *et al*., 1988). The similarity of JAr choriocarcinoma cells in monolayer culture to normal human trophoblast cells in terms of morphology and hormone production has enabled investigators to use JAr cells, and other choriocarcinoma cell lines, to study the properties of the trophoblast *in vitro*—for example, the basal and stimulated production of placental protein and steroid hormone. However, hormone production is generally assessed for short periods of time in nearly confluent cultures or on frequently trypsinized cells, where normal functioning may have been impaired.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Further, monolayer cultures are not suitable for the study of higher placental functions, such as implantation, where a three-dimensional arrangement of cells may be appropriate and necessary. These problems have limited the study of certain placental cell functions and have prevented the study of others. JAr cells which are grown as multicellular spheroids are more suitable for studying normal placental cell functions. Of special interest are those functions which may change with time or which may involve three-dimensional cell interactions, such as differentiation and implantation. The potential applicability of the spheroid system for studying higher-level functions of the trophoblast are (i) the long culture period, to study processes over time; (ii) the large size and free-floating status of spheroids; (iii) the three-dimensional nature of the spheroids, which stimulates *in vivo* conditions; and (iv) the large numbers of cells generated in each experimental trial. The spheroid culture system is also useful to study both acute and chronic effects of drugs and toxicants on trophoblast functions.

3 PLACENTAL BARRIER: A REALITY OR FALSE NOTION?

The term 'placental barrier' is a misnomer and a widely held false notion, since the placenta is not a true barrier for the transfer of most xenobiotics from mother to foetus. Instead, the placenta is the entry through which the foetus is exposed to chemicals. The placenta has been characterized as 'a lipid membrane that permits bidirectional transfer of substances between maternal and foetal compartments' rather than as a barrier. In humans, the placental barrier consists of the trophoblastic epithelium covering the villi, the chorionic connective tissue and the foetal capillary endothelium. The average thickness of the barrier at term is 3.5 μm, the average exchange area is approximately 11 m^2, and the placental blood flow rate is approximately 450 ml min^{-1} (Pacifici and Nottoli, 1995).

The placental architecture is composed of cells derived from foetal membranes. Placentation differs among domestic animals (epitheliochorial in pigs, horses and donkeys, and syndesmochorial in sheep, goats and cows), laboratory animals (haemoendothelial in rats, rabbits and guinea pigs), and man and monkeys (haemochorial or haemomonochorial) (Thomas, 1996). Anatomically, the placenta has also been described as zonary in the dog, bidiscoid in the monkey and multicotyledonary in the sheep. The placental thickness depends on the number of foetal and maternal cell layers. For example, the rat and the rabbit have a single layer of cells, primates and humans have three layers of cells and pigs and horses have six layers. It should be noted that the placenta is the first foetal organ to be exposed to exogenous substances.

There appear to be two common factors that are involved in transplacental transfer of toxicants: (i) physicochemical properties of the chemical and (ii) type of placenta. Any chemical with a molecular weight (MW) < 1000 readily crosses the placenta, and most pesticides, metals, mycotoxins, plant alkaloids and other xenobiotics have MW < 1000. Hence these chemicals are not restricted from reaching the foetus. However, the placenta poses a limited permeability barrier to chemicals with MW > 1000 (Morgan, 1997; Syme *et al*., 2004; Gupta, 2007). It is important to mention that metabolic processes in the mother or the placenta can degrade or biotransform high MW into low MW chemicals, thus allowing them to cross the placental barrier. Chemical properties, such as lipophilicity, polarity and degree of ionization, can also affect the placental barrier. Much more research needs to be done to substantiate these facts.

The other factor that predominantly influences the transplacental transfer of chemicals is the type of placenta. From the limited literature available, it appears that the placental barrier is partial and selective to some xenobiotics and is recognized in the simpler choriovitelline type of placenta present in rodents, and also in the chorioallantoic type present in higher mammals (Welsch, 1982; Juchau, 1995). In general, the more complex multilayered placenta of higher animals can make it more difficult for xenobiotics to gain access to the foetus.

So far, diffusion (simple or facilitated) has been the only proven mechanism by which drugs and toxicants cross the human placenta, although several animal studies have suggested a role for active transport or pinocytosis (Mihaly and Morgan, 1984). The rate and extent of transfer differ for various compounds (Welsch, 1982). The rate of diffusion is determined by the maternal–foetal drug gradient, uterine and umbilical blood flow, MW of drug/toxicant, protein binding, lipid solubility and degree of ionization. These factors also determine the time required for maternal/foetal equilibrium.

The evidence for placental transfer of chemicals stems from either direct detection of a chemical residue or its metabolite in the placenta, umbilical cord blood, embryo/foetus or the specific biochemical and morphological changes induced by a chemical toxicant in the placenta/foetus. Placental transfer of various classes of pesticides is described in our previous publications (Gupta, 1995; 2007; Pelkonen *et al*., 2006). Similar information on placental transfer of metals, mycotoxins and drugs has been reported by Eisenmann and Miller (1996), Rogers (1996), Gupta (1998) and Gupta (2007).

Indirect evidence for placental transfer of certain classes of chemicals, for example organophosphates

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(OPs) and carbamate (CM), has been substantiated by measuring the cholinesterase inhibition in foetal tissues (Cambon *et al*., 1979; 1980; Gupta *et al*., 1985; Gupta, 1995; Pelkonen *et al*., 2006). *In vivo* protein synthesis in the placenta, embryo and foetal tissues of rats following *in utero* exposure to parathion-methyl, and polydactylism in the forepaws of cat foetuses exposed to dimethoate are considered strong evidence for indirect placental transfer of OPs (Khera, 1979; Gupta *et al*., 1984).

In essence, the anatomical placental barrier for the majority of toxicants/drugs (including charged molecules such as (+)-tubocurarine, highly ionized salicylates, pesticides, metals, mycotoxins and narcotics) is a widely held false notion, since they cross the placenta and reach the embryo/foetus and, thereby, produce a variety of toxicological and teratogenic effects (Gupta, 1995; 2007; Eisenmann and Miller, 1996).

Recently, the metabolic placental barrier has drawn equal attention from physicians, toxicologists, pharmacologists and others. For example, human term placenta, by having a significant amount of butyrylcholinesterase (BuChE) activity, metabolizes cocaine and thereby serves as a metabolic barrier to protect the conceptus (Simone *et al*., 1994; Sastry, 1995c; Gupta and Sastry, 2000).

4 METABOLISM IN PLACENTA AND FOETUS

Metabolic pathways for both Phase I and Phase II reactions exist in both the placenta and the foetus. Phase I reactions include oxidation, reduction and hydrolysis, and Phase II reactions include conjugation of a chemical with endogenous moiety, such as glucuronic acid or sulfate. The capacity for metabolic processes is expected to vary with species, age and, more importantly, gestational stage. Xenobiotic metabolism in the placenta appears to be similar to that in maternal tissues, but the amount of metabolic activity is usually less. Still, the metabolic activity is adequate enough that the placental-foetal toxicity of chemicals can be significantly modified.

By now, it is well established that the placenta has an abundance of drug/xenobiotic metabolizing enzyme systems, that is, cytochrome P450. Cytochrome P450 exists in multiple forms with distinct, but generally overlapping, substrate specificities, and many of the isoforms are inducible by exposure to exogenous agents (Pasanen and Pelkonen, 1994; Juchau, 1995). The human placental mono-oxygenase system consists of at least one 'constitutive' and one 'inducible' form of cytochrome P450 for xenobiotic transformation. Although several isoforms of cytochrome P450 (P45011A1, P45019, P4501A1, P4503A7 and others) exist in the placenta, isoform P4501A1 appears to have the highest inducibility by xenobiotics. Induction of xenobiotic-metabolizing enzymes mainly takes place in the maternal liver, placenta and foetal liver, but it is not limited to these organs. In the placenta, several steroid hormones are formed and metabolized by cytochrome P450 systems, which may also participate in xenobiotic metabolism (Gonzalez, 1989). It should be mentioned that the human placenta lacks the marker activities for cytochrome P4503A enzymes, which are abundantly present in the liver of the adult human and foetus (Pasanen and Pelkonen, 1994).

The metabolites produced by biotransformation are usually less toxic or inactive, and thereby the xenobiotic-metabolizing enzymes in the placenta protect the foetus from potentially foetotoxic drugs and chemicals. For example, the human term placenta, by having a considerable amount of smooth endoplasmic reticulum and BuChE activity, metabolizes cocaine and thus protects the foetus from maternal cocaine abuse (Simone *et al*., 1994; Sastry, 1995c). It is important to note that the xenobiotic-metabolizing enzymes can also form metabolites which are more toxic than their parent compounds. For example, oxon metabolites of organophosphorus insecticides and epoxides of cyclodiene chlorinated hydrocarbons have a greater potential for foetotoxicity/teratogenicity than their parental forms. In addition, placental metabolism has the capacity to form carcinogenic–DNA adducts.

Xenobiotic metabolism in foetal tissues differs from that in adults, both qualitatively and quantitatively. Some of these differences were described in a review by Slikker and Miller (1994). In brief, (i) general foetal metabolic activity is lower than that in the adult of the same species, (ii) enzymes or isoenzymes (e.g. cytochrome P450) present in the foetus can be replaced by immunologically different isoenzymes in the adult animals, and (iii) enzyme activity generally increases with gestational age; however, the ontogeny of each individual enzyme may be different. With regard to similarities, the liver of the conceptus, and also of the adult, has the greatest xenobiotic-metabolizing activity compared with any other organs (kidney, lung and adrenal gland). Metabolism of the chemical compound may occur in the foetus, and this may lead to a prolonged foetal half-life if the metabolite is a more polar compound. The significance of the placental-foetal metabolism is immense and it is beyond the scope of this chapter to provide complete coverage. Therefore, for further details, readers are referred to some other comprehensive reviews (Pasanen and Pelkonen, 1994; Pelkonen, 1984; Juchau, 1995; Pelkonen *et al*., 2006).

Compared with Phase I, Phase II reactions (conjugation), including sulfation, acetylation and glucuronidation, in the placenta have not been studied in detail. One of the reasons is that the placenta contains low activities of these enzymes (Juchau, 1980), although active involvement of human placental glutathione transferase in detoxification of both endogenous and exogenous alkylating

agents is well established. For further details on Phase I and Phase II reactions in placenta, readers are referred to a recently published review by Syme *et al*. (2004).

5 SUSCEPTIBILITY OF PLACENTA AND FOETUS TO CHEMICAL TOXICITY

The placenta has been described as a dynamic organ that interfaces two separate genomes (mother and developing foetus) during pregnancy (Slikker and Miller, 1994). Structural changes in the placenta evolve as the pregnancy advances and it plays numerous roles, acting as the foetal lung, gut, kidney, exocrine gland and endocrine gland (Juchau, 1995). Since the placenta serves as an exchanger between mother and foetus for nutrients, the health of the foetus seems to be dependent on the health of the mother and the placenta. Unfortunately, toxic chemicals also traverse by similar mechanisms. Eisenmann and Miller (1996) explained the mechanism to support this fact by stating that toxic metals (e.g. Cd or Pb) may enter the placenta and be concentrated there, or may be transferred to the foetus via a mechanism designed to transport nutrients, such as calcium. Further, because foetal demands for nutrients increase with gestation (Haggerty *et al*., 2002), the potential for placental-foetal intoxication with toxic metals may also increase with gestation (Gupta, 2007). It is important to mention that pregnancy is a state of oxidative stress arising from increased placental mitochondrial activity and production of reactive oxygen species (ROS), mainly superoxide anion. The interaction of superoxide with nitric oxide produces peroxynitrite, which exerts nitrosative stress. Placental oxidative/nitrosative stress can be further exacerbated by chemicals (certain metals, pesticides and mycotoxins) that are known to produce oxidative/nitrosative stress.

More than one mechanism exists by which toxicants are concentrated in the placenta and foetal tissues in greater quantities than in maternal tissues. In general, the large placental surface area comes in contact with a relatively large volume of maternal blood (required for normal placental function), and that makes the placenta vulnerable to toxicants (Eisenmann and Miller, 1996). The placenta has certain biomolecules (proteins, carbohydrates, lipids, nucleic acids/nucleotides and enzymes) which can either be the target of toxicity or can play a role in modification of toxicity. Being rich in proteins, the placenta may bioconcentrate chemical residues by means of protein binding and release them into the placental circulation and ultimately into the foetus.

Foetal tissue often accumulates chemical residues because of its inadequate capability for degradation and elimination. Incomplete or partial BBB in the foetus is another reason for its greater sensitivity. As a result, birth/congenital defects occur with the greatest frequency in the central nervous system (CNS) compared with any other organ system, when exposed *in utero* to toxicants such as MeHg, Pb, thalidomide, retinoids, alcohol and others.

In adults, the BBB normally restricts the entry of many solutes and chemicals from blood into the brain and can provide a significant level of protection, especially against neurotoxicants. The foetal BBB develops during pregnancy and, in humans, the BBB is not fully developed until the middle of the first year of life. During this prenatal as well as postnatal period with an incomplete BBB, some toxic agents, like Cd, that are very unlikely to enter the mature brain, may pass into the developing brain. Literature demonstrates that different classes of pesticides are able to change the permeability characteristics of the BBB in rats when administered during susceptible periods of the BBB development, and this effect may persist for varying periods after the cessation of exposure (Gupta *et al*., 1999). Therefore, altered BBB can render the nervous system more vulnerable to other toxicants that would otherwise not be able to pass the BBB.

The placenta and foetus, by having acetylcholinesterase (AChE) and other cholinergic elements, remains highly susceptible to OP and CM toxicity (Koshakji *et al*., 1974; Cambon *et al*., 1979; Gupta *et al*., 1984; 1985; Sastry, 1993; Simone *et al*., 1994; Pelkonen *et al*., 2006; Gupta, 2007). In addition, the placenta has drug-metabolizing enzymes (e.g. mixed function oxidase, cytochrome P450, glutathione transferase), which means that it can transform certain OPs of the 'thioate' group (e.g. parathion) to their 'oxon' analogues (e.g. paraoxon) and transform chlorinated hydrocarbons of the 'cyclodiene' group (e.g. aldrin and hepatochlor) to their 'epoxide' forms (e.g. dieldrin and hepatochlor epoxide). Similar metabolic pathways, although to a lesser extent, exist also in the foetal tissues (Pelkonen, 1984; Gupta, 1995; Harbison *et al*., 1995; Juchau, 1995).

These findings suggest that the placenta and the foetus have the capability of so-called 'lethal synthesis', since the OPs in the form of 'oxon', and cyclodienes in the form of 'epoxides' are much more toxic than their parental compounds. Pesticides with a mechanism(s) of enzyme inhibition, such as AChE-inhibiting OPs and CMs, adenosinetriphosphatase (ATPase)-inhibiting organochlorines and cytochrome P450-inhibiting OPs, make the placenta as susceptible as the mother or the foetus. The placenta has an oxidative mechanism and is, therefore, also predisposed to carcinogenesis by numerous aryl and aromatic hydrocarbons. In essence, the structure and function of the placenta are so unique that its susceptibility to chemical toxicity seems far greater than that of the mother. Also, any damage to the placenta caused by a toxic chemical is likely to be reflected in the embryo and foetus.

6 FACTORS THAT CAN MODULATE PLACENTAL TOXICITY

Whether the toxicants affect only the mother, only the conceptus, only the placenta, or the whole unit of mother–placenta–foetus is not fully understood for any toxicant. Important factors which can modify the overall toxicity of a chemical during pregnancy include (i) maternal toxicity, (ii) placental transfer and (iii) placental-foetal metabolism.

6.1 Maternal Toxicity

Maternal toxicity has been defined as the transitory or permanent state of alteration in maternal physiology or behaviour with a potential to cause adverse effect in the offspring during embryo/foetal or postnatal development (Khera, 1987). In contrast, the term 'maternotoxic' commonly refers to test dosages, agents, signs/symptoms or data relevant to pregnancy without any connotation to its embryo-foetal implications.

Maternal toxicity-related factors, whether intrinsic (such as homeostasis alterations) or extrinsic (such as chemical and physical agents) at maternotoxic levels can produce deleterious consequences in foetal development by either altering maternal physiology or causing maternotoxic effects. Khera (1987) hypothesized that maternal effects caused by chemical agents may be among the factors causing congenital malformations, but found it impossible to test this hypothesis, since data on the maternal health in teratological studies are inadequate.

A strong relationship seems to exist between maternal toxicity and embryo-foetal toxicity/mortality and, therefore, maternal toxicity can be regarded as an aetiological factor for foetal malformation and embryo-foetal death. The common factors related to maternal toxicity include (i) route of drug/chemical exposure, (ii) maternal drug/chemical distribution, (iii) maternal drug/chemical metabolism, (iv) uterine blood flow, and (v) pH of the blood. Although the exact mechanism by which maternal toxicity factors are responsible for foetal toxicity/teratogenesis has remained obscure, alterations in placental function appear to be important. Hence it can be suggested that maternal toxicity plays a major role in adverse foetal outcome by modifying placental function.

6.2 Placental Transfer

Foetal growth directly depends on the nutrients crossing the placenta. Glucose, which is the principle carbohydrate crossing the placenta, is transported by facilitated-diffusion glucose transporters, according to concentration-dependent kinetics (Illsley, 2000), whereas amino acids are transported through energy-dependent processes, via selective amino acid transporters (Battaglia and Regnault, 2001). However, knowledge about placental transport of lipids is still scant. For the details on placental transport of nutrients, readers are referred to the review by Herrera (2002). The role and importance of placental transfer in relation to chemical toxicity have already been discussed in earlier parts of this chapter; some of the factors that are involved in trans-placental transport of chemicals which may alter placental toxicity are discussed here in brief.

The important placental transfer factors include placental blood flow, pH of the blood, placental permeability (passive or active transport system), placental maturity over gestation period (size, surface area and thickness), interspecies variation in placental morphology, lipid–protein content of the membranes, placental metabolism, plasma protein binding, lipid solubility and other physicochemical properties of toxicants (Welsch, 1982; Mihaly and Morgan, 1984; Slikker and Miller, 1994; Andersen *et al*., 2000; Syme *et al*., 2004). The factors related to placental morphology, physiology and metabolism seem to be interrelated, and with continuing change they become more complex as gestation advances.

Plasma protein binding (largely to the albumin fraction) appears to be the important factor that can modify placental toxicity, the reason being that only a chemical in a free form (i.e. unbound) can cross the placenta. It should be mentioned that protein binding is a reversible process and, therefore, the protein-bound chemical can become a free form and cross the placenta. Once the chemical has reached the foetus, either it remains free to produce deleterious effects or, once again, it can bind to proteins of blood and foetal tissue, a phenomenon described as the 'sink effect'. OP and CM insecticides and a toxic metal, Cd, are appropriate examples to substantiate this phenomenon. The protein binding factor has further implications in potentiation of OP or CM toxicity if the mother is pre-exposed to another OP that binds to esterases or proteins (Pelkonen *et al*., 2006; Gupta, 1995; 2007).

6.3 Placental-Foetal Metabolism

Placental-foetal metabolism is one of the major factors that can significantly modulate the placental toxicity of certain chemical toxicants. Metabolism occurs in all maternal, placental and embryonal/foetal tissues, but the capacity differs at all stages of gestation. During pregnancy, metabolism of the drug or toxicant is complicated by two major factors: (i) the pregnancy itself, since the general metabolic activity is low, which may lower the degradation of drugs or toxicants and thereby increase the toxicity; and (ii) pre-exposure or simultaneous exposure

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to other chemicals or environmental pollutants generally results in either reduced or enhanced metabolism and, consequently, altered placental toxicity. For example, previous exposure to drug-metabolizing enzyme inducers, such as enhanced mono-oxygenase activity by polychlorinated biphenyls (PCBs), or other similar environmental pollutants, can potentiate the toxicity of the 'thioate' type of OP insecticides. Cigarette smoking and chronic consumption of alcohol and drugs of abuse (e.g. steroid, cocaine, cannabis) are additional factors that can modify placental-foetal metabolism and placental toxicity (Sastry, 1995c; Gupta and Sastry, 2000; Syme *et al*., 2004).

7 ABUSED DRUGS AND PLACENTAL FUNCTION

There are several drugs which are abused by humans. These include nicotine (through tobacco smoking), morphine, cocaine and alcohol. If pregnant women are exposed to abused drugs or alcohol, their placental functions will be compromised. The common effect of these four drugs is intra-uterine foetal growth retardation (IUGR). All of the causes of IUGR are not well understood. There may be direct effects of drugs on the developing foetus, or indirect effects via influence on placental function. In IUGR, there is a decrease in all dimensions of foetal growth, indicating a common cause for the development of all organs of the foetus (**Figure 2**). One of the requirements for the growth and development of foetal organs is essential amino acids for protein synthesis and tissue formation. Therefore, effects of abused drugs on the placental transport of amino acids are emphasized. There is accumulating evidence that there may be abnormalities in the transplacental transport of amino acids, leading to poor foetal growth. Amino acid supply to the foetus and plasma amino acid concentrations are the strongest regulators of amino acid incorporation into protein and the major factors limiting protein breakdown (Pastrakuljic *et al*., 1999).

7.1 Maternal Smoking, Placental Function and Amino Acid Transport

Currently, tobacco exposure during pregnancy remains a major public health problem. It is well established that human placenta does not pose a metabolic barrier to nicotine transfer to the developing foetus. Maternal smoking in pregnancy is associated with two well-recognized effects—an increase in the frequency of spontaneous abortions, and low birth weight babies (Seller *et al*., 1992; Campbell, 1997; England *et al*., 2001; Zhao and Reece, 2005). The low birth weight may be related to decreased placental functions in smokers. The effects of maternal smoking and nicotine use on placental function have been reviewed (Sastry and Janson, 1995; Shiverick and Salafia, 1999). Maternal smoking alters many biochemical parameters in the maternal compartment (e.g. blood carboxyhaemoglobin), placental compartment (e.g. lowered oxygen consumption) and foetal compartment (e.g. decreased breathing movements). The final result of all these alterations is foetal growth retardation as indicated by the infant birth weight and crown–rump length (**Figure 2**).

Babies of smokers are, on average, 200 g lighter than babies born to comparable nonsmokers (Hasselmeyer *et al*., 1979). The whole weight distribution of babies of smokers is shifted downward compared with the weight distribution of babies of nonsmokers. Smoking-induced foetal growth retardation is not related to the characteristics of the smoker. The more the mother smokes, the greater the reduction in foetal growth. This foetal growth retardation may be related partially to disturbances in amino acid metabolism as indicated by depressed placental transport of amino acids in smokers.

The foetus is dependent on the placental transfer of amino acids from maternal to foetal circulation for its requirement of amino acids. The placental transfer is a two-step process: (i) active uptake of amino acids by placental syncytiotrophoblast cells from the mother's blood; and (ii) passive diffusion of amino acids from placental syncytiotrophoblast cells into umbilical blood. The first step is critical, and its efficiency could be compromised, resulting in depressed uptake into trophoblasts under placental hypoxic conditions induced by maternal smoking. Nicotine and tobacco smoke components (carbon monoxide, cyanides and nitrites) reduced active uptake of amino acids by isolated human placental villi (Rowell and Sastry, 1978; Barnwell and Sastry, 1983; Sastry *et al*., 1983; Sastry, 1984). Exposure of human placental villi to nicotine inhibited the uptake of α-aminoisobutyric acid (α-AIB), and decreased both maximum velocity (V_{max}, 71%) and Michaelis–Menten constant (K_m, 67%) for uptake of α-AIB (Barnwell and Sastry, 1983). Part of the inhibition (16%) is not reversible, which may be of significance in chronic smoking (Sastry, 1991a). Concentrations of several essential amino acids (valine, methionine, isoleucine, leucine, tyrosine, phenylalanine, histidine) and nonessential amino acids (aspartic acid, glutamic acid, glycine, alanine, arginine) in the placental villi of nonsmoking mothers were about 30–50% higher than those of smokers (Sastry *et al*., 1989b). Concentrations of threonine and phenylalanine were about 14–15% higher in the placental villi of nonsmokers than in those of smokers. According to these observations, maternal smoking decreases the uptake of amino acids by the placenta and thus the net transfer of amino acids from

maternal to foetal blood. Further, the placental transfer of all essential amino acids is not affected equally, indicating that the nitrogen balance may be disturbed in the foetus. Therefore, foetal undernutrition for amino acids may provide partial explanation for foetal intra-uterine growth retardation in tobacco smokers.

7.2 Maternal Smoking and the Regulatory Mechanisms for Amino Acid Uptake by the Placental Trophoblast

α-AIB, a nonmetabolizable amino acid, has been used as a model amino acid to study the mechanisms of amino acid uptake by human placenta. Four regulatory mechanisms have been proposed for the cellular uptake of amino acids in the placenta: (i) gammaglutamyl cycle (GC) for the regulation of amino acid transport (Meister and Anderson, 1983; Payne and Payne, 1984); (ii) placental ACh release and amino acid transport coupling (Harbison *et al*., 1975; Rowell and Sastry, 1978; 1981; Sastry *et al*., 1983); (iii) phospholipid *N*-methylation in the plasma membrane (Barnwell and Sastry, 1987); and (iv) oxidative energy sources (Longo *et al*., 1973; Miller and Berndt, 1974).

The GC was postulated for amino acid transport by Meister and Anderson (1983). Gammaglutamyl transpeptidase (GGTP) plays a key role in the GC cycle. It is bound in the outside bilayer of the plasma membrane. Glutathione (gammaglutamylcysteinylglycine) is continuously secreted onto the cell surface, where GGTP transfers a glutamyl group to an incoming molecule of an amino acid. The products, gammaglutamylamino acid and cysteinylglycine, are reabsorbed into the cell. The bulk of the amino acid molecules are absorbed by independent transport systems. The number of these carrier molecules may be inversely related to the degree of absorption of gammaglutamylamino acid. During starvation of the cells for amino acids (or during low levels of extracellular amino acids), more transport carrier molecules are induced and incorporated into the plasma membrane. Thus, gammaglutamylamino acids may serve as transmembrane or environmental signals for the uptake of amino acids by cells (Payne and Payne, 1984). Cells can use the GC cycle for efficient recovery of cysteine. Human trophoblastic microvilli contain high levels of GGTP (Barnwell and Sastry, 1987). Maternal smoking during pregnancy decreases the activity and V_{max} of GGTP of the microvillus plasma membrane (Sastry and Horst, 1988; Horst and Sastry, 1988; Sastry *et al*., 1989a). This decreases the formation and absorption of gammaglutamylamino acids, signalling the cell to induce the synthesis of more amino acid transport carriers and to insert them into the plasma membrane. There is an increase in the uptake of α-AIB, mainly due to an increase in V_{max}, in washed placental villi from smokers. The induction of placental α-AIB transport sites during maternal smoking can be partially explained by depression of the GC cycle. However, in the presence of tobacco-smoke components, the increased carrier systems do not fully compensate for the depression of the GC cycle. The effects of maternal smoking on components of the GC cycle other than GGTP are not known.

Depression of the synthesis of placental ACh by inhibitors of choline acetyltransferase (ChAT) (Rowell and Sastry, 1981; Sastry *et al*., 1983) and inhibition of the conversion of membrane phosphatidylethanolamine to phosphatidylcholine by phospholipid *N*-methyltransferases (PMTs) (Sastry *et al*., 1983; Barnwell and Sastry, 1987) decreases amino acid uptake by placental villi. Therefore, it has been postulated that the placental cholinergic system and phospholipid *N*-methylation regulate amino acid uptake by the placenta. Both ChAT and the PMTs contain active -SH groups. The Cd ions in tobacco smoke inhibit these enzymes (Sastry, 1984; Sastry *et al*., 1985). The PMT activity of the placental plasma membrane is depressed in cigarette smokers (Horst and Sastry, 1989).

Oxygen consumption by placental slices from smoking mothers decreases in proportion to carboxyhaemoglobin (CoHb) concentrations in maternal blood (Tanaka, 1965). The rate of oxygen consumption in placental slices from nonsmoking mothers ($1.9\,\mu l\ mg^{-1}\ h^{-1}$) is about 30% higher than that in placental slices from smoking mothers ($1.3\,\mu l\ mg^{-1}\ h^{-1}$, at an 8% maternal CoHb concentration). These observations indicate that the energy-dependent processes of placental cells may be depressed, and that the formation and concentrations of cellular adenosine 5′-triphosphate (ATP) may be affected by hypoxia. All of the above mechanisms for the regulation of amino acid transport are ATP-dependent. Three ATP molecules are required for operation of the GC cycle and the uptake of one molecule of gammaglutamylamino acid. Another ATP molecule is required to form one molecule of acetyl coenzyme, a substrate for ChAT to form one molecule of ACh. Still another ATP molecule is required to form one molecule of phosphatidylcholine by phospholipid methylation. Therefore, all postulated regulatory mechanisms of amino acid transport in the placenta may be indirectly affected by maternal smoking. Not all babies of smokers are subjected to IUGR. The placentas of some smokers incorporate more amino acid transport systems into trophoblast plasma membranes, and compensate for the effects of smoking. If the placentas of some babies have a genetic defect for this purpose, those babies are subjected to IUGR due to smoking.

In a recent report, Zhao and Reece (2005) reported that the nicotine-induced embryonic malformations are, in part, a result of excessive cell death. Nicotine

increases intracellular [Ca^{2+}] and ROS level, which play a role in nicotine-induced embryonic apoptosis and malformations.

7.3 Morphine Placental Opioid System and its Role in Amino Acid Transport

Different aspects of the human placental opioid system have been reviewed by Sastry (1995a) and Ahmed and Cemerikic (1995). Placental transfer of the three commonly used opioids (fentanyl, alfentanil and sufentanil) was reported by Giroux *et al*. (1997). When ingested by pregnant women, morphine and its analogues are known to retard intra-uterine foetal growth, the extent of which is related to the degree of exposure. This raises questions about the role of the placenta in morphine-induced intra-uterine growth retardation and about the occurrence and role of endogenous opioids. Generally, it is believed that enkephalins and endorphins may serve as neuromodulators and may regulate neurotransmitter or hormone release by positive or negative feedback systems. More specifically, enkephalins may regulate neuronal release of ACh and norepinephrine by negative feedback systems (Sastry, 1991b; 1995b). The occurrence of methionine enkephalin and β-endorphin in human placental villi has been demonstrated using sensitive and specific radioimmunoassays and bioassays. Immunoreactive corticotrophin, lipotrophin and β-endorphin occur in whole placental extracts. Dynorphin (1–8) was also identified in placental extracts by mass spectroscopy. The opioid receptor of the placenta was also purified and identified as the kappa subtype (Ahmed *et al*., 1989). When the floating villi, chorionic plate and basal plate of the same human placenta were extracted and analysed, the methionine enkephalin concentration was lower in the chorionic and basal plates. This suggests that the distribution of methionine enkephalin is similar to that of ACh in human placenta.

ACh occurs in high concentrations in the human placenta. Inhibition of synthesis of ACh in placenta inhibits amino acid uptake. ACh release, activation of a cholinergic receptor, Ca^{2+} influx and amino acid transport are linked to one another in the uptake of amino acids by the human trophoblast (Sastry, 1997). Atropine blocks ACh release and amino acid uptake by placental villi, indicating that ACh stimulates a muscarinic receptor and thereby regulates amino acid uptake by the trophoblast. Amino acid uptake by placental villi is also depressed in a Ca^{2+}-free medium and by morphine (Barnwell and Sastry, 1983). These observations indicate that, in morphine addicts, ACh-facilitated uptake of amino acids by the trophoblast is depressed. Therefore, IUGR in morphine addicts can be partially explained by depressed amino acid transport in the placenta. These studies have yet to be supported by analysis of amino acids in the placentas of morphine addicts and nonaddicts. Some compensatory changes have been reported to occur in the placental opioid systems of mothers who used morphine-like compounds during pregnancy. The number of kappa opiate receptors decreased in the placentas of mothers who used pentazocine or methadone during pregnancy. Morphine did not decrease ACh release from these placentas. These observations indicate that the negative feedback mechanism for the release of ACh is depressed or inactivated due to an inadequate number of kappa receptors in the placentas of opiate addicts. This is a compensatory change to improve ACh-facilitated amino acid uptake by the placentas of opiate-addicted mothers. If there are any other compensatory changes (e.g. a decrease in the synthesis of opioid peptides) in the opioid systems of opiate addicts, they have yet to be investigated.

7.4 Cocaine and Placental Amino Acid Transport

Cocaine abuse has become increasingly prevalent among certain urban populations. Cocaine readily crosses the placental barrier and enters the foetal circulation with the potential to cause adverse effects on the developing foetus. Studies with the perfused human placental cotyledon showed that rapid cocaine transfer exhibits the characteristic of passive transport consistent with its high lipid solubility and low MW (Schenker *et al*., 1993; Simone *et al*., 1994). Cocaine, as a weak base, is only 8–10% protein bound in human plasma, suggesting that the majority of the administered dose is available to equilibrate with the foetal circulation. In addition, most evidence indicates that cocaine decreases uteroplacental blood flow in rats as well as humans. Intra-uterine growth retardation, often associated with cocaine use, is assumed to result from chronic decreases in uteroplacental flow.

The subject of maternal cocaine use and IUGR was reviewed by Sastry (1995c). Investigators have focussed on various complications of pregnancy and malformations in infants, but consistent findings are foetal growth retardation and prematurity. In addition, cocaine may interfere with normal physiological processes in pregnancy, resulting in a higher incidence of spontaneous abortion, placental abruption and premature labour. Cocaine seems to interfere with placental amino acid transport in a similar way to nicotine and morphine. Cocaine acts as a Ca^{2+} antagonist in smooth muscle. It also decreases the release of ACh from placental villi (Sastry *et al*., 1977). This action may arise from the blockade of Ca^{2+} influx into the syncytiotrophoblast. Ca^{2+} is necessary for the release of ACh and the uptake

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of amino acids (Sastry *et al*., 1983). Cocaine depresses the uptake of neutral, acidic and basic amino acids by the human placenta and thus the placental transport of these amino acids (Barnwell and Sastry, 1983). Therefore, cocaine-induced foetal growth retardation also can be partially explained by depression of placental amino acid transport.

7.5 Alcohol and Placental Function

The effect of alcohol on placental functions and foetal toxicity has been reviewed by Henderson and Schenker (1995). Maternal ethanol consumption, either continuously throughout pregnancy or in a 'binge' pattern, may produce adverse and lasting or even fatal outcome. In the human foetus, the most consistent impact is growth retardation, with specific detrimental impacts on the developing CNS. The overall effect of alcohol is described as foetal alcohol syndrome (FAS) which is characterized by (i) growth retardation; (ii) CNS abnormalities (which may include abnormal brain morphology, neurological abnormalities, developmental and intellectual impairment); and (iii) the characteristic pattern of craniofacial abnormalities (Jones *et al*., 1973; Larroque, 1992). These are associated with sustained heavy maternal ethanol consumption (Forrest *et al*., 1992). In addition, several extensive epidemiological studies over the past decade have provided evidence that, even in the absence of growth deficits and developmental delay, subtle but lasting behavioural and intellectual dysfunctions may persist (Committee on Substance Abuse and Committee on Children with Disabilities, 1993). These 'foetal alcohol effects' (FAE) include hyperactivity, attention and fine-motor deficits and a constellation of psychosocial disorders. A question arises about the contribution of the placenta to overall FAS. According to Henderson and Schenker (1995), there is an enormous body of evidence supporting direct impact of ethanol and acetaldehyde, a metabolite of alcohol, on a variety of foetal tissues and their components, and such direct effects may ultimately be proven to be the origin of toxicity of ethanol towards the foetus. In view of the central role of the placenta in maintenance of foetal development and the well-documented effects of ethanol on its three primary functions (transport, metabolic and endocrine), there is ample evidence that alterations of a variety of placental functions may contribute partly to the toxic effects of ethanol on the foetus.

Alcoholism is frequently associated with malnutrition and this, combined with the lack of normal growth and development of FAS children, suggests that impaired nutrition contributes to this syndrome. Thus, several studies have focussed on the hypothesis that maternal ethanol consumption produces a suboptimal supply of nutrients needed for foetal growth. There is some evidence from animal experiments and *in vitro* experiments using human placental tissues that ethanol affects nutrient transport of amino acids, glucose, some vitamins (vitamin B_6, folate, thiamine) and some trace elements (Ca, Zn). During placental transfer a small amount of ethanol is metabolized to acetaldehyde, which is toxic to the embryo and foetus.

Alcohol influences the effects of biogenic amines on human placental vasculature and, therefore, placental blood flow. It also influences membrane fluidity of placental membranes and thereby influences responsiveness of the placental vasculature to biogenic amines.

8 METALS

Metals are ubiquitous in the environment, contaminating soil, water and air and, finally, the human food chain. As a result, metal pollution has been one of numerous environmental problems throughout the world. Some heavy metals, such as copper, iron, zinc, cobalt, manganese and selenium, are nutritional trace elements, whereas others, such as aluminium (Al), arsenic (As), Cd, Pb, mercury (Hg) and nickel (Ni), are metals of greatest toxicological concern. In excessive concentrations, metals from either category are known to exert a wide range of toxic effects. It is well recognized by now that maternal intoxication with certain metals in both man and laboratory animals may adversely affect pregnancy and the development of the conceptus. Placental toxicity of some important metals is discussed here in brief.

8.1 Aluminium

Aluminium is one of the three most abundant metals in the earth's crust. As a result, it contaminates food and water. Al is commonly used in several forms, including the chloride, nitrate, hydroxide (in stomach antacids), chlorhydrate (in deodorants), sulfate (in water treatment) and phosphide (in insecticidal grain fumigants). In addition, Al is also extensively used in cooking utensils, appliances, automotives, aircraft, construction and so on.

Al can be absorbed through oral (po), dermal, inhalation, subcutaneous (sc) and other parenteral routes, and concentrated in the liver, lungs, bone, kidney, spleen, heart, brain and muscles. Al is unequally distributed in these tissues (Yokel and McNamara, 2001). In addition, Al transplacentally traverses and accumulates in the foetal tissues in amounts that adversely influence foetal development (Yokel and McNamara, 1985). Studies using mice and rabbits revealed that the placenta contained four- to five-fold higher Al levels than the foetal or maternal tissues (Yokel and McNamara, 1985; Cranmer *et al*., 1986; Yumoto *et al*., 2000). However, the placenta of

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

the guinea pig does not accumulate Al. Furthermore, placental accumulation of Al in mice and rabbits does not preclude accumulation in the foetal tissues. For the detailed toxicokinetics of Al, the review published by Yokel (1997) and Steinhausen *et al*. (2004) should be consulted.

Al is a nonessential element, as its absence in nutrition does not influence developmental growth. In the last two decades, however, Al has been recognized as an important toxic metal in experimental animals and humans (ATSDR (Agency for Toxic Substances and Disease Registry), 2007a).

Pregnancy in general enhances susceptibility to Al toxicity. Oral administration of Al during pregnancy in laboratory animals is known to cause a developmental syndrome which includes *in utero* death, delayed ossification of skeleton, malformations, growth restriction and developmental delay, at doses that also influence maternal weight gain. The severity of the effects is highly dependent on the form of Al administered.

Following oral administration, only a small fraction of Al is absorbed and, therefore, the degree of severity of developmental toxicity is minimized. Studies using high Al exposures obtained by intravenous (iv) or intraperitoneal (ip) administration report a developmental toxicity syndrome consisting of death and resorptions, skeletal and soft tissue abnormalities, low birth weights and growth retardation in rats, mice and rabbits (Wide, 1984; Yokel, 1997). The high incidence of resorptions was found to be significantly higher in pregnant rats treated with aluminium chloride at dose levels of 75 mg kg^{-1} on gestation days (GDs) 9–13, 100 mg kg^{-1} on GD 14–18 and 200 mg kg^{-1} on GD 9–13 (Benett *et al*., 1975). A high incidence of dead offspring was recovered from mothers treated with aluminium chloride at a dose level of 200 mg kg^{-1} on GD 9–13.

The above studies using rats, mice and rabbits indicate that Al can cause delays in skeletal development in pups. Gross foetal abnormalities include abnormal digits, wavy ribs, missing ribs, absence of xiphoid and poor ossification (particularly in the cranial bones, lower part of the vertebral column and long bones of the limbs). The high incidence of skeletal defects, and also poor ossification in foetuses of mothers treated with aluminium chloride, suggests that Al has an adverse influence on foetal bone formation. This could be due to the binding of Al with phosphate in the tissues, thus reducing the amount of phosphate in the tissues available for bone formation. Depletion of phosphate has also been linked to Al-induced foetal internal haemorrhage by causing failure of the blood clotting mechanism (Wide, 1984).

A number of studies have reported neurotoxicity and neurobehavioural changes in offspring following Al exposure of rabbits, rats and mice at doses of Al that did not produce maternal toxicity (Wide, 1984; Domingo, 1994; Yokel, 1997; Colomina *et al*., 2005). Exposure to aluminium nitrate or aluminium citrate can also produce similar developmental effects. Overall, developing conceptuses or pups are much more sensitive than adults to Al toxicity.

8.2 Arsenic

Arsenic occurs in many forms and, therefore, commonly contaminates the air, food and water. The major sources of human exposure to As include sea food, tobacco and pharmaceutical preparations. Individuals who work in smelters and industries and those involved in the production and use of As-containing pesticides are at especially greater risks. Paint pigments, fly papers and wood preservatives are also potential sources of As.

Both human and animal studies have shown that As crosses the placenta. In pregnant mice, Hood *et al*. (1987; 1988) examined the uptake, distribution and metabolism of sodium arsenite (2.5 µg kg^{-1}, po) and sodium arsenate (40 µg kg^{-1}, po) on GD 18. Maximum concentrations of As in the placenta were noted at 4 and 2 hours after administration of arsenite and arsenate, respectively. Corresponding concentrations in the foetal tissues appeared at 24 and 6 hours. Regardless of the form of As administered, >80% of the As is methylated (mono- and dimethyl-arsenic) in the foetus. In the foetal tissues, inorganic As is converted to the organic form(s) over time. In other words, methylation appears to be the major detoxification mechanism and, therefore, substantially reduces toxicity. Arsenic is completely eliminated from the placenta and foetus within 24 hours of exposure. For some reason, organic As does not seem to cross the placenta; instead, it is stored in the placenta.

Epidemiological investigations conducted in a few countries strongly support the evidence of placental toxicity in humans due to As. In a Swedish study, adverse reproductive outcomes (spontaneous abortions, congenital malformations and low birth weights) were observed in populations working in or residing near the Ronnskär copper smelter. Congenital malformations were higher in the occupationally exposed population. Similar findings were observed in a Hungarian study. In a study conducted in Bulgaria, pregnancy complications and rates of mortality at birth (due to malformations) were high in the smelter area. The average concentration of As in the placentas of exposed populations living near the copper smelter was 26.6 µg kg^{-1}, compared with 7.4 µg kg^{-1} in the placentas of those living in areas with no industrial sources of metal pollution. Reduced glutathione and increased lipid peroxidation in the placenta with As appeared to cause the pregnancy complications. Furthermore, As-induced genetic damage (such as chromosomal aberrations) seems to be the cause of malformations, spontaneous abortions and stillbirths in those who work in smelters or those living nearby (Nordström *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1978). In a case-control study conducted in Boston, no association between As in drinking water and congenital heart defects was found, although an association with coarctation of the aorta was noted. Owing to the small number of cases, this association might be due to random variation. In Bangladesh, As $\geq$0.10 ppm in drinking water was associated with adverse pregnancy outcomes in terms of spontaneous abortion and stillbirth. A study of 202 women from West Bengal, India, reported that exposure to As concentrations of $\geq$0.2 ppm in drinking water (approximately 0.02 mg As kg^{-1} day^{-1}) during pregnancy were associated with a six-fold increased risk of stillbirth (von Ehrenstein *et al*., 2006).

Animal studies (using hamsters, rats and mice) suggest that high doses of ingested As may be foetotoxic and teratogenic. There is evidence that sodium arsenate and sodium arsenite are embryotoxic (Chaineau *et al*., 1990). Common deformities include hypoplasia of the prosencephalon, somite abnormalities, and failure of development of limb buds and sensory placodes. In hamsters, a single iv injection of 20 mg kg^{-1} sodium arsenate, given on GD 8, resulted in 49% malformed and 84% either malformed or resorbed embryos on GD 13 (Holmberg and Ferm, 1969). Common malformations included exencephaly, encephalocele, cleft lip/palate, micro/anophthalmia and ear malformations. In similar studies, other investigators also found developmental defects in the ribs and kidneys. In rats, the spectrum of malformations by As is similar to that described for hamsters.

Placental/developmental toxic effects of As have been more extensively studied in mice than in rats or hamsters. Treatment of female mice with arsenite/arsenate on GD 9 produces the highest incidence of malformed live foetuses, whereas treatment on GD 11 or 12 produces the highest rate of resorption. The common external malformations include exencephaly, micrognathia, exophthalmia, anophthalmia, cleft lip, hydrocephalus, micromelia, ectrodactyly, open eyes, rib defects and vertebral defects. Oral administration of dimethylarsenic acid (100 mg kg^{-1}) in mice produces foetotoxicity (reduced weight, delayed ossification and cleft palate) and maternal toxicity. Mice and rats are much more sensitive than hamster to organoarsenicals, in terms of placental toxicity.

Although the exact mechanism involved in placental toxicity of As has not been explored, increased lipid peroxidation in the human placenta has been linked to As exposure. Increased lipid peroxidation appears to be due to excess production of superoxide and hydroxyl radicals. Arsenic is known to interact with protein sulfhydryl groups, and thereby inactivate target enzymes. Free sulfhydryls are essential for the function of a wide range of enzymes, including glutamic-oxaloacetic acid transaminase, pyruvate oxidase, monoamine oxidase, choline oxidase, glucose oxidase, urease, oxidoreductases and kinases. Arsenic accumulates in the mitochondria and thereby affects a number of enzymes, including those involved in mitochondrial respiration (Rogers, 1996). Arsenic inhibits succinic dehydrogenase activity and uncouples oxidative phosphorylation, which results in ATP decreases. Reduced ATP affects virtually all cellular functions (Na^+/K^+ balance, protein synthesis, etc.). In an *in vitro* study, arsenite proved to be teratogenic at concentrations between 3 and 4 μM, and embryolethal at higher concentrations, whereas arsenate had similar activity, but at concentrations 10 times higher than for arsenite (Chaineau *et al*., 1990). Induction of stress protein or heat shock protein (hsp) synthesis in the embryo has been explained as a common mechanism of teratogenesis by As.

In conclusion, inorganic arsenicals are much more potent toxic agents than organic arsenicals. Trivalent As is developmentally more toxic than pentavalent As. It is believed that compounds containing pentavalent As exert their toxic actions only after their conversion to the trivalent form. Foetotoxicity or teratogenicity due to As is of human concern only at the levels that are maternotoxic. In other words, the foetus is not more susceptible to As toxicity than the mother. For further details on As toxicity in general and placental toxicity in particular, readers are referred to the ATSDR (Agency for Toxic Substances and Disease Registry) (2007b).

8.3 Cadmium

Cd occurs naturally in the earth's crust. Most Cd used in the United States is extracted as a by-product during the production of other metals, such as Zn, Pb and Cu. The major sources of Cd exposure to humans include contaminated food, cigarette smoke and industrial pollution.

Although the biological function of Cd is unknown, its potential for causing developmental toxicity in humans and animals is well established. Correlation between maternal Cd exposure and low foetal birth weight has been established in epidemiological studies conducted in Russia and France. None of these studies has revealed any congenital malformations.

In laboratory animals, Cd has been shown to be a developmental toxicant by the oral, inhalation and parenteral routes. Cd crosses the placenta in both humans and animals with similar kinetic characteristics. High toxic concentrations of Cd accumulate in the human placenta, and then perturb the placental transport of essential elements such as Ca and Zn (Eisenmann and Miller, 1996).

From both humans and animal studies, it is clear that the placenta itself is a target organ for Cd toxicity. In low to moderate doses, Cd is sufficiently sequestered in the placenta, whereas in higher doses, Cd causes

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

placental necrosis and foetal toxicity. Maternal exposure to Cd is known to cause ultrastructural changes in the placenta, especially trophoblast cell layer II (di Saint'Agnese *et al*., 1983). Changes include lysosomal vesiculation, nuclear chromatin clumping, nucleolar alterations and apparent mitochondrial calcification. Cd-induced placental necrosis occurs initially in trophoblast cell layer II and follows rapidly in the remaining trophoblasts.

Subcutaneous administration of cadmium chloride acetate or lactate to pregnant rats at a dosage of 0.04 mmol kg^{-1} between days 17 and 21 of gestation resulted in rapid, progressive placental destruction, especially in the pars foetalis (Parizek, 1964). Necrotic changes could often be seen within 6 hours. Complete destruction of the pars foetalis resulted in resorptions or delivery of dead conceptuses. Similar effects have been observed with other cadmium salts (Rogers, 1996).

In animal models, Cd has been shown to produce a variety of adverse reproductive outcomes. Maternal exposure to Cd during pregnancy can cause maternal toxicity, placental damage, impaired implantation, increased resorptions, reduced litter size, foetal growth retardation, congenital malformations in the foetus and embryonic/foetal death. The developmental toxicity of Cd during mid to late gestation involves both placental toxicity (reduced blood flow and necrosis) and inhibition of nutrient transport across the placenta (Rogers, 1996). Exposure during late gestation results in foetal death in rats, despite low levels of Cd entering the foetus (Levin and Miller, 1980). The increased toxicity of Cd to the pregnant rat may be due to renal failure subsequent to shock from placental haemorrhage.

The teratogenic potential of Cd has been proved in hamsters, rats and mice. Single iv injections of 2 mg kg^{-1} cadmium sulfate were administered to pregnant hamsters on GD 8. In addition to high incidence of resorption, live foetuses showed a high rate of malformations, including facial clefts, exencephaly, anophthalmia, limb defects and rib fusions (Ferm and Carpenter, 1967). Common malformations in the foetuses of rats and mice are club foot, dysplasia of facial bones and rear limbs, cleft palate, micrognathia, sirenomelia/amelia, delayed ossification of the sternum and ribs, microphthalmia/anophthalmia, cryptorchidism, gastroschisis and palatoschisis.

The placenta provides a remarkable barrier to Cd and, therefore, minimized foetal toxicity. This is partly due to the ability of Cd to induce synthesis of metallothionein (MT), a small protein rich in sulphur-containing amino acids; and synthesis in maternal tissues, as well as in the placenta. MTs retain Cd in maternal tissues and the placenta and, thereby, reduce Cd transport to the conceptus. To date, the best understood mechanism for developmental toxicity is the interaction between Cd and Zn, in which Cd substitutes for Zn in metalloenzymes. Cd interferes with Zn transfer across the placenta, possibly via MT induction in the placenta. Because of the high affinity of MT for Zn, MT sequesters Zn in the placenta, impeding transfer to the conceptus. Cd inhibits Zn uptake by human placental microvesicles, suggesting that Cd may also compete directly with Zn for membrane transport (Rogers, 1996).

Reduced uteroplacental blood flow, reduced nutrient transport and placental toxicity by Cd appear to be the major contributing factors for low foetal birth weight, foetal toxicity, malformations and death. Evidence suggests that Cd-induced impaired foetal growth is partly mediated through Zn deprivation, since maternal tissues and the placenta retain Zn. The direct effect of Cd on foetal growth also occurs because of Cd accumulation in the foetus. Mechanistic studies provide strong evidence of embryotoxicity by Cd (Fein *et al*., 1997). The accumulation of only small amounts of Cd could inhibit embryonic DNA and protein synthesis (Holt and Webb, 1987). Results of studies also suggest that Cd exposure significantly compromises the Ca handling ability of trophoblast cells. This effect is probably a consequence of alterations in subcellular cytosolic calcium binding properties.

8.4 Lead

Pb occurs naturally in the environment. The common sources of Pb exposure include Pb-based paint, batteries, gasoline, ceramics, soil/dust, caulking, roofing, ammunition and scientific and medical equipment. As a result, the whole environment (including food, water and air) is contaminated with low levels of Pb. Populations at greatest risk to the adverse health effects of Pb have been identified as pregnant women and their unborn children and preschool-age children.

Pb exposure in the pregnant woman usually occurs through the oral and/or inhalation route. After absorption, Pb is distributed to most of the tissues, but it deposits mainly in the skeleton, kidney and brain (primarily gray matter). Pb is known to cross the placenta in both humans and animals and the maternal/cord blood ratio for the lead ranges from 0.9 to 0.93 (ATSDR (Agency for Toxic Substances and Disease Registry), 2006). Accumulation of Pb occurs in the foetal brain owing to partial or lack of a BBB. In one study, the placenta from a Pb-exposed mother was found to have a greater than three-fold higher Pb level compared with the placenta from an unexposed mother (Loiacono *et al*., 1992). Pb also accumulates in the placenta in times of foetal stress.

In general, cord blood and placenta of exposed women have high Pb levels, which, consequently, are also reflected in the foetus. In fact, prenatal exposure to Pb is generally estimated through maternal and/or cord blood Pb concentrations. Studies suggest that a large maternal–foetal concentration gradient exists and the placenta poses a limited transplacental barrier. Also, a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

number of adverse maternal health conditions can affect the transfer of Pb to the foetus and/or the retention of Pb by the mother or the foetus.

At present, the exact mechanism involved in placental toxicity of Pb remains unknown, although Pb produces intoxication in general by interfering with protein/haemoprotein biosynthesis and by inhibiting membrane and mitochondrial enzymes (Eisenmann and Miller, 1996). Pb is also known to cause deficits in cholinergic, dopaminergic and glutamatergic functions (ATSDR (Agency for Toxic Substances and Disease Registry), 2006).

Following *in utero* exposure, Pb can have a direct effect on the developing conceptus. It is important to mention that the developing nervous system is the most sensitive target of Pb toxicity. Following low levels of Pb exposure in pregnant women, Pb has been associated with increased incidence of preterm births and reduced birth weight (Andrews *et al*., 1994). The other developmental effects include reduced gestational age and neurobehavioural deficits. Exposure to high levels of Pb can cause infertility, neonatal morbidity, miscarriages, spontaneous abortions and stillbirths. It has been shown that Pb can interfere with an early stage of development, such as the invasion of the fertilized ovum into the uterine wall.

Unborn children and young children appear to be particularly sensitive to Pb because of their greater sensitivity during development. At low doses, Pb does not produce congenital malformations. However, at high doses, Pb produces minor anomalies such as haemangiomas, lymphangiomas, cryptorchidism and tags and papillae on the skin. An association seems to exist between drinking water which contains Pb and congenital anomalies of the ear, face, neck and cardiovascular system. In addition, prenatal exposure to Pb can result in neurobehavioural deficits, reduced hearing acuity and endocrine disruption.

Developmental toxic effects of Pb have also been studied in experimental animals, including rats, mice, hamsters and chicks. *In utero* exposure to Pb can cause reduction in fertility and growth retardation. Embryotoxic and foetotoxic effects of Pb seem to be dependent on the exposure period of gestation. For example, when exposure occurs on GD 9, teratogenic effects are observed with few resorptions, compared with exposure on GD 16, with hydrocephalus and CNS haemorrhage (McClain and Becker, 1975). At maternotoxic doses, Pb can cause retarded skeletal development.

In mice, Pb is known to cause postimplantation mortality and skeletal malformations in foetuses. The common skeletal anomaly observed is the fusion of two or more cervical vertebrae (Jacquet and Gerber, 1979). In hamsters, malformations due to Pb exposure occur mainly in the tail, ranging from stunting to complete absence of the tail (Ferm and Carpenter, 1967). In general, common malformations observed in experimental animals are related to brain defects, neural tube defects and urogenital system and tail defects. It should be noted that Pb has a greater potential for neurotoxicity than for placental or developmental toxicity. Further details can be found in previous publications (Eisenmann and Miller, 1996; Rogers, 1996; ATSDR (Agency for Toxic Substances and Disease Registry), 2006; Gupta, 1998; 2007).

8.5 Mercury

Hg is a nonessential metal that occurs naturally in the environment and exists in several forms. Hg is released into the environment in the metallic or elemental form by natural processes. Common sources of Hg include industrial, chemical/mining, medical supplies, adhesives, ink, caulking, fungicides and interior/exterior paint. As a result, Hg is a widespread environmental contaminant that threatens aquatic ecosystems and human health.

The general population is exposed to Hg primarily from food and dental amalgam. In most foodstuffs, Hg is found in the organic form. Fish, marine mammals and some microorganisms convert elemental Hg to organic Hg, which accumulates in the food chain. It is of great interest to note that in humans, organic Hg can be converted to inorganic Hg.

It is now well recognized that Hg (in all forms) is toxic to humans as well as animals. There are numerous incidents in which Hg has been associated with developmental toxicity in humans. The first mass outbreak of MeHg poisoning occurred in Japan in the 1950s and 1960s following the consumption of heavily contaminated fish. The syndrome was referred to as 'foetal Minamata disease'. Over 90% of the total Hg in fish occurs in the form of MeHg. An even larger outbreak of MeHg poisoning took place in Iraq in 1971–1972. Poisoning resulted from consumption of bread loaves prepared from wheat seed grain treated with an MeHg-containing fungicide. These incidents, along with others, indicated that prenatal exposure to MeHg caused severe brain damage in the foetus and infants, whereas mothers were hardly affected. In other words, following *in utero* exposure to MeHg, the target organ is the foetal brain in humans and animals. This is partly due to accumulation of Hg in the foetal brain because of its high requirement for protein synthesis. Also, pregnant women appear to be more sensitive to MeHg toxicity than nonpregnant women.

MeHg is readily absorbed and distributed throughout the body with various concentrations in different tissues. In humans, brain MeHg levels can be as high as six-fold, compared with blood levels. This is in contrast to rats, which have a brain to blood ratio of 0.06, and mice with a ratio of 1.20. There is evidence that the human and rodent

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

placenta, by having a metal- binding protein (metallothionein, a low-MW protein enriched with cysteine), presents some barrier to Hg (Yoshida *et al*., 2002). By using the Gray physiologically based pharmacokinetic (PBPK) model for MeHg, the placenta is modelled as four compartments with separate transfer constants for placental barrier and placental tissue transport. Organic and metallic Hg cross the placenta more readily than inorganic Hg. Consequently, MeHg and metallic Hg accumulate in the foetus, whereas inorganic Hg concentrates in the placenta. Metallic Hg, after crossing the placenta, can be oxidized to Hg^{2+} in foetal tissues. It has been shown that Hg^{2+} accumulates in the placenta and inhibits the foetal uptake of certain essential metabolites or analogues of these metabolites.

It is well evidenced from both human and animal studies that MeHg at a moderate to high level of exposure has a strong potential for neurotoxicity and developmental toxicity. Several studies suggest that prenatal exposure to MeHg can cause a widespread pattern of adverse effects on brain development and organization. Neuropathological findings in the victims of the Japan and Iraq incidents revealed that MeHg significantly altered the normal migration of neurons to the cerebellar and cerebral cortices during brain development. Other changes included diffuse and severe cortical damage with cytoarchitectural anomalies, such as ectopic cell masses and disorganized cell layers, altered oxidative stress, membrane function and signal transduction, decreased protein synthesis and changes in neurotransmission (Gilbert and Grant-Webster, 1995).

Both the Japan and Iraq incidents provided evidence that Hg-exposed pregnant women delivered infants with severe developmental and behavioural deficits, without any obvious symptoms of Hg poisoning in mothers during pregnancy. Common developmental defects due to Hg exposure are reduced birth weight, ataxia, retarded walking and limb deformities. Hg-induced neurobehavioural effects include severe mental retardation, sensory and motor deficits, cerebral palsy, plasticity, seizures, delayed speech, deafness and blindness. At present, human studies with MeHg indicate that maternal hair levels of 10–20 ppm may result in adverse effects on foetal outcome.

Several studies using animal models with high-dose MeHg exposure have described effects similar to those observed in humans. MeHg has been reported to be embryotoxic/foetotoxic and teratogenic in mice, rats, cats, guinea pigs and hamsters. In general, resorptions, dead foetuses and cleft palate are the most common findings. Some other developmental effects include generalized oedema, brain lesions, wavy ribs, asymmetric sternebrae and decreased ossification of parietal and occipital bones (Domingo, 1994).

In summary, both human and animal data suggest that prenatal exposure to sufficient amounts of Hg results in developmental toxicity. In addition, Hg has a strong potential for neurotoxicity and neurobehavioural toxicity. For further details, readers are referred to other publications (Eisenmann and Miller, 1996; ATSDR (Agency for Toxic Substances and Disease Registry), 1999; Gupta, 1998; 2007).

8.6 Nickel

Ni is primarily used in alloys because it imparts the properties of heat resistance, hardness and strength. Its salts are used in alloy steel, stainless steel, cast iron, alkaline batteries, ceramics, electroplating and pigments and as catalysts. The general population is exposed to Ni via food, water, air and tobacco smoke, at very low levels. Data suggest that Ni bioconcentrates in fish and aquatic organisms and, therefore, seafood can be a potential source of Ni exposure. Workers in the industries that produce, process or use Ni are usually exposed to higher levels. As a result, this population group is at greater risk.

Although Ni is an essential element for human and animal health, at higher levels Ni produces deleterious effects, ranging from minor allergic reactions to those as serious as abortions, birth defects and cancer. There is only one published epidemiological report, which provides inconclusive findings on the developmental toxicity of Ni in humans (Chaschschin *et al*., 1994).

Ni has not been studied for placental toxicity in as much detail as other metals. Exposure of pregnant rats to nickel oxide at a dosage of 1.6 mg m^{-3} for 23.6 h day^{-1} throughout gestation resulted in a decrease in foetal body weight, although the weight of the placenta and the number of foetuses remained unchanged (Weischer *et al*., 1980). Treatment of pregnant rats during early gestation with nickel chloride (8–16 mg kg^{-1}, intramuscular) and nickel sulfide (30 mg kg^{-1}, intramuscular) caused embryonic mortality at doses that did not cause maternal deaths, suggesting accumulation of Ni in foetal tissues and greater sensitivity of the foetal tissue to Ni toxicity (Sunderman *et al*., 1978). In another study, pregnant rats treated with 4 mg kg^{-1} ip Ni showed teratogenic malformations (Mas *et al*., 1985). In a multigeneration and multilitter study conducted in rats, Ni has been shown to adversely affect the time of gestation, birth weight and the number of pups surviving through lactation (ATSDR (Agency for Toxic Substances and Disease Registry), 2005).

Ni has also been studied for placental toxicity in mice and hamsters. Nickel chloride given to pregnant mice on GD 7–11 produces embryonic effects such as a higher incidence of resorptions, reduced foetal weight, delayed skeletal ossification and malformations, such as acephalia, ankylosis, club foot and skeletal anomalies. Embryonic tissues retained Ni at levels as much as 800 times higher than controls (Lu *et al*., 1979). With similar findings, Ni has also been proved

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to be embryotoxic and teratogenic in hamsters. Further details can be found in other publications (Domingo, 1994; ATSDR (Agency for Toxic Substances and Disease Registry), 2005).

9 INSECTICIDES

Insecticides of four classes (OPs, CMs, organochlorines and pyrethroids) are known to adversely affect the mother, placenta and conceptus in laboratory animals (Gupta, 1995; 2007; Pelkonen *et al*., 2006). Here, OPs and CMs are discussed together because their effects are similar.

9.1 Organophosphates and Carbamates

Both OPs and CMs, in general, exert overt toxicity of hypercholinergic preponderance by inhibiting the activity of AChE at cholinergic synapses and neuromuscular junctions. Inactivation of AChE occurs owing to phosphorylation by OPs and carbamylation by CMs. It is important to mention that the level of AChE activity is already low during pregnancy. As a result of AChE inhibition by OPs or CMs, accumulation of ACh occurs, which overstimulates the muscarinic and nicotinic ACh receptors. Muscarinic receptor-associated effects include miosis, salivation, lacrimation, urination, diarrhoea and tracheobronchial secretion. Nicotinic receptor-associated effects include tremors, muscle fasciculations and convulsions. In addition, AChE inhibition disrupts cell replication and differentiation, synaptogenesis and axonogenesis (Lauder and Schambra, 1999; Bigbee *et al*., 2000). Evidence also suggests that many of the pharmacological/toxicological actions of OPs and CMs are much more complex and have no direct relationship to AChE inhibition or the accumulation of ACh (Dettbarn *et al*., 2006; Gupta *et al*., 2007). Finally, death supervenes owing to paralysis of the respiratory centre.

Both OPs and CMs readily cross the placenta and act on the cholinergic and noncholinergic components of the developing nervous system and other vital organs (Gupta *et al*., 1984; 1985; Pelkonen *et al*., 2006; Gupta, 2007). Recent studies have shown that, in general, foetuses and young children are more sensitive, because they have lower than adult levels of detoxifying enzymes (paraoxonase or chlorpyriphos-oxonase) that activate OPs (Furlong *et al*., 2006; Holland *et al*., 2006). Furthermore, the developing organism appears to be much more susceptible to the induction of functional neural deficits (Rice and Barone, 2000; Eskenazi *et al*., 2007). Following prenatal exposure to OPs (quinalphos, dicrotophos (Bidrin), parathion-methyl and others), significant inhibition of AChE has been demonstrated in maternal, placental and foetal tissues of rats and mice (Bus and Gibson, 1974; Gupta *et al*., 1985; Srivastava *et al*., 1992). Similar results have been reported for CMs, including carbaryl, carbofuran, aldicarb and pirimicarb (Declume and Derache, 1977; Cambon *et al*., 1979; 1980). These studies revealed AChE inhibition as the major biochemical mechanism of toxicity. Furthermore, subchronic prenatal exposure to parathion-methyl in rats resulted in altered postnatal development of brain AChE and ChAT activities, and selected subtle alteration in behaviour (Gupta *et al*., 1985).

Prenatal exposure to OPs has been shown to affect protein synthesis both *in vivo* (Clouet and Waelsch, 1963; Gupta *et al*., 1984) and *in vitro* (Welsch and Dettbarn, 1971). The inhibitory effect on *in vivo* protein synthesis of parathion-methyl (administered throughout the period of organogenesis) was shown to be dose dependent, greater on day 19 than day 15 of gestation and more pronounced in foetal than in placental or maternal tissues of rats (Gupta *et al*., 1984).

It is important to mention that the mechanisms responsible for OP- or CM-induced embryonic/foetal development and teratogenesis appear to be different from those involved in general toxicity. Alkylation of nicotinamide adenine dinucleotide (NAD^+) coenzymes by OPs appears to be the major mechanism involved in the induction of teratogenesis (Schoental, 1977). Other investigators found altered levels of RNA, glycogen, sulfated mucopolysaccharides and calcium in the developing tibiotarsus (Ho and Gibson, 1972). No such studies have been reported with CMs.

Both OPs and CMs have been demonstrated to have potential for embryotoxicity, embryolethality, foetotoxicity and teratogenesis. In general, these effects vary depending upon the particular OP or CM involved. Embryolethality is encountered so often that the expression of teratogenesis is rarely seen. In humans, babies born to mothers exposed to OPs such as oxydemeton-methyl (Metasystox-R) and mevinphos (Phosdrin) showed cardiac defects (ventricular and atrial septal defects), stenosis of the pulmonary artery and a patent ductus arteriosus, bilateral optic nerve colobomas, microphthalmia of the left eye, cerebral and cerebellar atrophy and facial anomalies (Ogi and Hamada, 1965; Romero *et al*., 1989).

Many placental toxicity studies conducted in rats, mice, rabbits and hamster have failed to demonstrate any teratogenic response to OPs, although, in some studies, growth retardation and embryotoxicity have been noted at maternotoxic doses. However, in some other studies, OPs have been shown to produce developmental alterations in rats, mice, hamsters and rabbits. In an elegant study, Khera (1979) discovered polydactyly in foetuses of cats treated with dimethoate ($12\,mg\ kg^{-1}\ day^{-1}$) during day 14 to 22 of pregnancy (**Figure 3**). A wide species variability

exists in sensitivity to OP-induced placental toxicity. Furthermore, variability exists in gestation period susceptibility.

Abundant recent literature shows that links between exposure to OP pesticides and suboptimal neurodevelopment are found in numerous animal studies (Eskenazi *et al*., 2004). It has been suggested that OP exposure may contribute to poorer neurobehavioural functioning in young animals by producing cellular deficits in their developing brains, particularly rich with cholinergic projections (Campbell *et al*., 1997; Eskenazi *et al*., 2004). Evidence exists that these deficits may result even with lower level exposure if it occurs during critical periods of brain development (Gupta *et al*., 1984; 1985; Eskenazi *et al*., 2004). Recent studies, where chlorpyrifos was administered to neonatal rats further indicated that neonatal exposure produces numerous and persistent deficiencies in cholinergic synaptic function, which can continue into adulthood (Slotkin *et al*., 2001; Slotkin and Seidler, 2007).

Among CMs, carbaryl is the only chemical which has been studied in detail for placental toxicity. Just like OPs, CMs have a greater potential for embryolethality and foetotoxicity, and that precludes an expression of teratogenicity. A study conducted with carbaryl in beagles showed dystocia due to atonic uterine musculature and evidence of terata in 21 of a total of 181 pups. Foetal abnormalities included abdominal-thoracic fissures with varying degrees of intestinal agenesis and displacement, brachygnathia, ecaudate pups, failure of skeletal formation and superfluous phalanges (Smalley *et al*., 1968). Carbaryl exposure during organogenesis produced terata in guinea pigs, but not in hamsters and rabbits (Robens, 1969). Other CMs, such as carbofuran, have proved to be teratogenic (Gupta, 1994).

9.2 Organochlorines

Insecticides of this group are classified into three subgroups: (i) dichlorodiphenylethanes (DDT(dichlorodiphenyltrichloroethane), dicofol, methoxychlor and perthane); (ii) chlorinated cyclodienes (aldrin, dieldrin, endrin, chlordane, endosulfan and heptachlor); and (iii) hexachlorocyclohexanes (BHC (benzene hexachloride), chlordane, lindane, mirex and toxaphene). The acute toxic signs associated with DDT and chlorinated benzene types of insecticides include paresthaesiae of the tongue, lips and face, apprehension, tremors and clonic-tonic convulsions. Stimulation of the CNS is the most prominent effect. The acute signs produced by cyclodienes include dizziness, nausea, vomiting, myoclonic jerking, motor hyperexcitability, convulsive seizures and generalized convulsions. It is important to mention that the epoxide metabolites are much more toxic than their parent cyclodiene compounds (Bondy *et al*., 2003).

The mechanism of action of organochlorine insecticides is not yet fully understood. The DDT-type insecticides alter the transport of sodium and potassium ions across axonal membranes, resulting in an increased negative after-potential and prolonged action potentials. As a result, repetitive firing and a spontaneous train of action potentials occur. Specifically, DDT inhibits the activation of sodium channels and the activation of potassium conductance. The mechanism of cyclodienes involved in hyperexcitation of the CNS and convulsions has been explained based on their structural resemblance to the bicyclic γ-aminobutyric acid (GABA) receptor antagonist picrotoxin. The mammalian GABA receptor is coupled to an intrinsic chloride ion channel and is the primary mediator of neuronal inhibition in the brain. Like picrotoxin, cyclodienes block the inhibitory action of GABA. Similar to other organochlorines, mirex and chlordecone (Kepone) also cause stimulation of the CNS, hepatic injury and induction of the mixed-function oxidase system.

Some of the organochlorine insecticides have the potential to induce placental toxicity. Many organochlorines and their metabolites are known to be found in placentas and to cross the placental barrier (Sala *et al*., 2001). In a recent report, Shen *et al*. (2005) documented the content of many organochlorine pesticides in human placentas. All placentas had measurable levels of some pesticides. The average number of pesticides found per placenta was 18.5 from a total of 27. In

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

animal studies, pregnant Swiss mice exposed to lindane at different stages of pregnancy produced various toxicological effects, including foetotoxicity and reproductive failure (Sircar and Lahiri, 1989). Lindane exposure during early pregnancy (days 1–4) caused total absence of any implantation, during mid-pregnancy (days 6–12) caused total resorption of foetuses, and during late pregnancy (days 14–19) caused the death of all pups within 12 hours to 5 days after parturition. In addition, lindane can cause reproductive failure by causing a deficiency of steroid hormones (oestrogen and progesterone).

The organochlorines (such as methoxychlor, *o*-, *p′*-isomers of DDT, DDE (dichlorodiphenyldichloroethylene), DDD (dichlorodiphenyldichloroethane), dieldrin, toxaphene and endosulfan) have been associated with oestrogen-like effects in the reproductive system of laboratory animals. Exposure of female rats to methoxychlor before and during pregnancy can cause blockade of implantation, suppression of uterine decidualization, lack of corpora lutea and atresia of ovarian follicles (ATSDR (Agency for Toxic Substances and Disease Registry), 2002). Exposure during the preimplantation period of pregnancy blocks implantation, whereas exposure during the postimplantation period causes foetal resorption. Interference in the requisite hormonal milieu seems to be the major effect. Other effects of methoxychlor include oestrogenic influence on uterine preimplantation differentiation, ovum transport rate, luteal regression and postimplantation decidual growth. There are reports that dieldrin produced teratogenic effects, such as supernumerary ribs, with concomitant decrease in ossification centres in foetal hamsters (Chernoff *et al*., 1975; 1979; ATSDR (Agency for Toxic Substances and Disease Registry), 2002).

Exposure of pregnant rats to mirex has been shown to result in perinatal deaths due to persistent cardiovascular problems, such as first- to third-degree foetal heart blockade (Grabowski, 1983). Mirex also causes altered lens growth and cataracts, along with other biochemical, physiological and histological changes (Rogers and Grabowski, 1983).

9.3 Pyrethroids

Recently, the use of synthetic pyrethroids has increased tremendously because they possess such high insecticidal efficacy and low mammalian toxicity. Still, the risks to human and animal health exist from accidental exposure and environmental contamination. These insecticides are of two types. Type I pyrethroids are those which lack α-cyano moiety and give rise to the T-syndrome. This syndrome includes whole body tremors, incoordination, prostration, tonic-clonic seizures and death. Common examples of this type are pyrethrin I, allethrin, tetramethrin, resmethrin and permethrin. Type II pyrethroids are those which contain α-cyano moiety and cause the choreoathetosis/salivation (CS) syndrome. This syndrome is characterized by hyperactive behaviour, hunch backed posture, profuse salivation, tremors and motor incoordination, progressing to sinuous writhing movements. Common examples of this type of pyrethroid include cyphenothrin, cypermethrin, deltamethrin and fenvalerate.

Based on symptomatology, Type II syndrome involves primarily an action in the CNS, whereas with Type I syndrome, peripheral nerves are also involved. Intoxication by pyrethroids results primarily from hyperexcitation of the nervous system. This hyperexcitation is caused by repetitive firing and depolarization in nerve axons and synapses. Pyrethroids act directly through interaction with the sodium channel gating mechanism, thereby interfering with the generation and conduction of nerve impulses and inducing marked repetitive activity in various parts of the brain. Type I pyrethroids affect sodium channels in nerve membranes, causing repetitive neuronal discharge and a prolonged negative after-potential, the effects being similar to those produced by DDT. Type II pyrethroids produce an even longer delay in sodium channel inactivation, leading to a persistent depolarization of the nerve membrane without repetitive discharge, a reduction in the amplitude of the action potential and eventual failure of axonal conduction and a blockade of impulses.

Prenatal or early postnatal exposure of rats to pyrethroids (cypermethrin, fenvalerate and others) has been shown to produce significant neurochemical alterations in neonatal rats (Husain *et al*., 1991; 1992; Malaviya *et al*., 1993). Delayed maturation of the cerebral cortex occurs due to alterations in key enzymes of the neurotransmission process (MAO (monoamine oxidase), AChE and Na^+-K^+-ATPase). Prenatal exposure to these pyrethroids significantly delays differential responses in the levels of brain regional polyamines, and ontogeny of sensory and motor reflexes in offspring. Other biochemical/neurochemical effects of pyrethroids include impairment at the neurotransmitter receptor (dopaminergic, catecholaminergic and cholinergic) level.

The pyrethroids, compared with other groups of insecticides, have been less well studied for placental toxicity because pyrethroids are relatively less toxic. For example, permethrin at concentrations of 2000–4000 ppm showed only a weak to moderate influence on *in utero* foetal development. Female rats dermally exposed to cyhalothrin throughout pregnancy had offspring with delayed fur development, delayed ear and eye opening and delayed descent of the testes, but with no change in the age of vaginal opening. In adulthood, however, the sexual behaviour of both male and female rats exposed to cyhalothrin prenatally is no different from that of control animals (Gomes

et al., 1991a; 1991b). Prenatal exposure of rats to a newer pyrethroid, deltamethrin, has been shown to increase the number of early embryonic deaths and foetuses with retarded growth, hyperplasia of the lungs, dilation of the renal pelvis and increased placental weight (Abdel-Khalik *et al*., 1993). For further details on placental toxicity of pyrethroids, readers are referred to Gupta (2007).

10 DIOXINS AND POLYCHLORINATED BIPHENYLS (PCBs)

10.1 Dioxins

Polychlorinated dibenzo-*p*-dioxins belong to a family of chlorinated aromatic compounds commonly referred to as dioxins. Although there are 75 different dioxin congeners, the term dioxin most often refers to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which is one of the most toxic synthetic chemicals ever known. These compounds are slowly metabolized in the body tissues and, as a result, they persist for a long period of time. It is important to mention that no individual dioxin occurs alone in the environment. In fact, exposure to dioxins usually occurs with a mixture of dioxin congeners along with dibenzofurans, chlorophenols, PCBs and other halogenated aromatic compounds. Hence the toxic effects observed in humans and animals are due to a mixture of chemicals, in which TCDD may be only one ingredient (Safe, 1990; Bursian, 2007). The toxicity of individual congeners varies as much as 1000-fold.

Humans are exposed to dioxins/TCDD by accidental, environmental or occupational means. Contaminated food and water are the major sources of human exposure. So far, there have been only a few studies that described the placental toxicity of dioxins/TCDD in humans. Whether TCDD crosses the human placental barrier is still a matter of conjecture. Human epidemiological studies revealed no clear evidence that TCDD exposure caused birth defects (Mastroiacovo *et al*., 1988; Stockbauer *et al*., 1988). However, high rates for several malformations (in the genitourinary tract, oral cleft, cardiovascular defects and hip dislocation) have been noted in a few studies (Stockbauer *et al*., 1988). A study conducted by the CDC (Centers for Disease Control and Prevention) (Stellman *et al*., 1988) revealed that wives of veterans who had been exposed to Agent Orange had significantly higher risks of having children with birth defects, including spina bifida, cleft lip, cleft palate and a variety of neoplasms. Among a variety of adverse effects, chloracne is the only proven consequence to TCDD exposure.

In animal studies, a variety of toxic effects of TCDD have been reported, which include weight loss, hepatotoxicity, porphyria, dermal toxicity, gastric lesions and haemorrhage, thymus atrophy, immunotoxicity, teratogenicity, reproductive failure, enzyme induction and vitamin A depletion (WHO, 1989; Dickson and Buzik, 1993). These effects vary greatly, depending on dose, species, strain, age and gender.

TCDD is considered one of the most potent embryotoxic and teratogenic chemicals in rats and mice (Safe, 1990; Bursian, 2007). In rats, TCDD is foetotoxic (subcutaneous oedema, intestinal haemorrhage, kidney anomalies, reduced foetal weight and increased foetal death rates) rather than teratogenic (WHO, 1989). In mice, however, teratogenic effects, such as cleft palate and hydronephrosis, have been reported with a single or repeated dose as low as $1-10\,\mu g\ kg^{-1}$ (Skene *et al*., 1989). In rats and mice, the foetotoxic and teratogenic effects are not observed at $0.1\,\mu g\ kg^{-1}\ day^{-1}$. TCDD has also been proved a teratogen in other species, including rabbits, chickens and monkeys (WHO, 1989).

The dioxins and related compounds are proved to be potent developmental toxicants by virtue of their ability to disrupt the actions of hormones and growth factors (Gasiewicz, 1997). Exposure of pregnant animals to dioxins at extremely low levels (doses that do not adversely affect the mother) leads to alterations in the reproductive system of the pups. Ikeda *et al*. (2002) reported that *in utero* TCDD exposure induces demasculinization in male offspring by inhibiting the aromatase activity in the brain during CNS development. Many of the developmental effects are detectable during very early stages, while other effects are not detectable until the offspring reach puberty. Sperm count is decreased in male offspring and their mating behaviour is subtly altered (Gray *et al*., 1997). Ohsako *et al*. (2002) demonstrated that giving pregnant Sprague Dawley rats a single oral dose of TCDD at $1\,\mu g\ kg^{-1}$ body weight on GD 15 resulted in significant decreases in the urogenital complex and ventral prostate weights and urogenital glans penis length of male rat offspring, when sacrificed on postnatal day 70. Testicular and epididymal weights were also lower than control group. Anogenital distance was significantly reduced. The same authors also reported that a single oral administration of TCDD ($12.5-800\,ng\ kg^{-1}$ body weight) to pregnant Holtzman rats on GD 15 caused a decrease in androgen receptor (AR) messenger RNA (mRNA) level in the ventral prostate during the prepubertal period. There are structural abnormalities in the external genitalia of the female offspring and delayed puberty in the male. In the more severely affected pups, fertility is reduced. These effects have been observed in both rats and hamsters. In another study, adult female rhesus monkeys fed a diet containing $0.5\,\mu g\ kg^{-1}\ day^{-1}$ TCDD for six months suffered hair loss, swelling of the eye lids, loss of lashes, irregularities in menstrual cycle, poor conception and abortion (IARC, 1977).

In addition to the effects described above, the developing immune system appears to be particularly susceptible to TCDD (Skene *et al*., 1989). The immunosuppressive effects can be mediated through *in utero* exposure or by postnatal exposure via the mother's milk. Evidence suggests that both prenatal and postnatal exposure to TCDD can substantially reduce the delayed hypersensitivity and lymphoproliferative response for a prolonged period of time.

There is convincing evidence that all known toxic effects of TCDD are mediated via the aryl hydrocarbon (Ah) receptor. The Ah receptor is present in several tissues, including liver, lung, kidney and placenta of man and animals. In rats, the receptor has been detected in the liver, lung, brain, thymus, kidney, skeletal muscle and testes. The Ah receptor has also been detected in human B-lymphocytes and tonsils (Dickson and Buzik, 1993). TCDD binds to the Ah receptor-ligand complex. This complex is speculated to transform the receptor to a form that can translocate the nucleus, bind with higher affinity to specific DNA sequences and stimulate transcription (Landers and Bunce, 1991).

10.2 Polychlorinated Biphenyls (PCBs)

Unlike dioxins, which are unwanted by-products of certain industrial processes and combustion, PCBs are commercially synthesized and used in transformers and capacitors. PCBs represent a complex mixture of 209 unique compounds. Owing to their resistance to thermal degradation and their stability, they persist and bioaccumulate in the environment. Some of these chemicals persist in the environment for tens or hundreds of years, and in the body tissues for many years.

Two major PCB poisoning incidents occurred in the 1970s in which adverse effects were clearly observed in children born to women exposed to high levels of PCBs along with dioxin analogues and polychlorinated dibenzofurans. One incident occurred in Taiwan in 1979, in which many of the babies born had pigmentation abnormalities and problems with teeth and nails. They were small in size and were developmentally delayed, both physically and mentally. Another incident occurred in Seveso, Italy, in 1976, in which a group of humans was exposed to high levels of dioxin after an explosion at a herbicide plant. Children of these exposed women have not yet been examined for subtle developmental deficits, either structurally or functionally. High concentrations of dioxins and PCBs pose serious health problems in pregnant women and their conceptuses in several other parts of the world, such as around the Canadian Great Lakes, South Vietnam, the former Soviet Union and India.

A small number of PCBs are dioxin-like in their biological activity and can produce all of the toxic effects mentioned above for dioxin/TCDD. Some PCBs appear to be neurotoxic, with prenatal exposure to certain PCB mixtures resulting in altered behaviour in the offspring (Tilson *et al*., 1990). Many of the studies, both experimental and epidemiological, suggest that the unborn may represent a population at special risk because PCBs disrupt the endocrine system, which is so critical for rapid growth and development. For details of PCB toxicity, readers are referred to ATSDR (Agency for Toxic Substances and Disease Registry, 2000).

11 MYCOTOXINS

Mycotoxins are secondary metabolites of fungi, some of which are extremely toxic to man and animals. For most mycotoxins, the common substrates are human food and animal feed, especially cereals, resulting in a persistent threat to human/animal health. Several mycotoxins are toxic *in utero*, but only the most important mycotoxins are discussed here. In general, mycotoxins can produce placental toxicity by one or more of three common mechanisms. In brief, mycotoxins can interfere with hormonal activity, which can damage parental gametes, producing infertility or abnormal offspring if successful fertilization occurs. Mycotoxins may cause foetal malformations, especially during organogenesis, by interfering with foetal nucleic acid and protein biosynthesis. This interrupts normal cell differentiation and organogenesis, resulting in malformations. Mycotoxins can also affect the foetus indirectly by affecting vital maternal organs, such as the liver, reducing nutrient transfer to the foetus or increasing transfer of toxicants (Hayes, 1981; Lebepe-Mazur *et al*., 1995). In addition, some mycotoxins, such as fumonisin B_1, cause direct necrosis in the placenta and, consequently, embryolethality/foetotoxicity and abortions (Harrison *et al*., 1990; Floss *et al*., 1994a; 1994b; Gupta, 2007).

11.1 Aflatoxins

Aflatoxins are produced by the moulds, *Aspergillus flavus* and *Aspergillus parasiticus,* which commonly contaminate a variety of food and animal feed. The toxins are usually found as a mixture of aflatoxin B_1 (AFB_1), AFB_2, AFG_1 and AFG_2. Exposure to aflatoxins is typically by ingestion of contaminated foodstuff. Aflatoxins are mutagens, carcinogens and teratogens. Aflatoxin B_1 and G_1, with varying doses administered orally or ip to mice on GD 12 and 13, produced moderate retardation in foetal development, cleft palate and diaphragm changes. Aflatoxin G_1 also produces malformations of the kidneys (Roll *et al*., 1990). Exposure of pregnant rats to aflatoxin B_1 via the oral route has been shown to result

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in significant anti-implantational activity and loss of viability among the litters (Choudhary *et al*., 1992). From the limited studies conducted on laboratory animals, it appears that both aflatoxin B_1 and G_1 have strong potential for embryocidal, foetotoxic and teratogenic effects. Prenatal exposure of rats to aflatoxin B_1 resulted in delay of early response development, impaired locomotor coordination and impaired learning ability in the offspring of rats exposed to this mycotoxin during middle pregnancy, and the early gestational exposure appears to produce more effects than latter exposure (Kihara *et al*., 2000).

11.2 Fumonisins

Fumonisins are a group of mycotoxins (FA_1, FA_2, FB_1, FB_2, FB_3, FB_4 and FC_1) produced by *Fusarium* fungi, principally *F. moniliforme* and *F. proliferatum*. Only the B-series fumonisins have been confirmed as natural products. The A-series consist of *N*-acetyl derivatives, which may be produced during the isolation process. These mycotoxins are found in corn or corn-based food/feed and, therefore, contaminate human food and animal feed worldwide. It is well established that FB_1 and FB_2 are usually the most abundant and appear to be the most potent mycotoxins of this group.

Ingestion of fumonisin-contaminated food/feed has been linked to many organ-specific fatal diseases; for example, oesophageal cancer in man in the Transkei region in South Africa and Linxian county in China, hepatopathy and hepatocarcinoma in laboratory rats, porcine pulmonary oedema (PPE) in swine and equine leukoencephalomalacia (ELEM) or mouldy corn poisoning in equidae. Fumonisins additionally produce mild to fatal toxicity in the liver, kidney and heart of rats and horses. Among all species, the equidae appear to be the most sensitive because fumonisins severely damage the CNS of this species.

Published findings from experimental animal research, and anecdotal findings from field cases, suggest that fumonisins have a strong potential for developmental toxicity and teratogenicity. Purified FB_1 and *F. proliferatum* culture extracts have been shown to be embryotoxic when inoculated into incubated eggs (Javed *et al*., 1993a; 1993b). In addition to mortality, which depended both on the dose and on the time of its administration, day 1 or 10, embryonic changes occurred, including hydrocephalus, enlarged beaks and elongated necks.

Potential detrimental effects of fumonisin B_1 have been discovered in developing hamsters (Floss *et al*., 1994a; 1994b). FB_1 caused increased incidence of prenatal losses, including deaths and resorptions. At a dose of 12 mg kg^{-1}, all litters were affected and 100% of the foetuses were dead and resorbing, without clinicopathological evidence of maternal toxicity. Foetal resorptions were associated with a greater severity of placental necrosis. Placental tissues showed signs of degeneration and involution, focal distortion and necrosis of the trophoblastic layer, especially at the periphery, and recent haemorrhage and necrosis at the base of the placenta. Placentas in dams receiving a 12 mg kg^{-1} dose had extensive necrosis and loss of foetal capillaries in the haemochorial portion, with concomitant collapse of the stroma. Such changes were consistent with the embryolethal effects of FB_1. These data strongly suggest that FB_1 is a developmental toxicant capable of inducing prenatal deaths when administered during organogenesis in hamsters. External malformations, such as hooked or curled tail, ectrodactyly of the front and/or rear limbs, and cleft palate, were also observed. In fact, the incidence of curled tail malformation in foetuses from fumonisin-treated hamsters is dose related.

Developmental toxic effects of aqueous culture extract from *F. moniliforme* in CD1 mice are reported to be due to FB_1 (Gross *et al*., 1994; Reddy *et al*., 1995). These effects include maternal deaths, reduced maternal body weight gain, increased embryonic resorptions, reduced pup weights and foetal malformations, such as cleft palate, hydrocephalus and ossification deficits. FB_1 is also found to be foetotoxic in F344/N rats. Pregnant rats given FB_1 orally at a dose of 30 or 60 mg kg^{-1} from GD 8 to 12 caused significant impairment of ossification of the sternebrae and vertebral bodies in their foetuses (Lebepe-Mazur *et al*., 1995). It appears that FB_1 is foetotoxic to rats by suppressing growth and foetal bone development (**Figure 4**). However, in Sprague Dawley rats, there is very little or no evidence of embryotoxicity or foetotoxicity by FB_1, especially in the absence of maternal toxicity (Ferguson *et al*., 1997). An

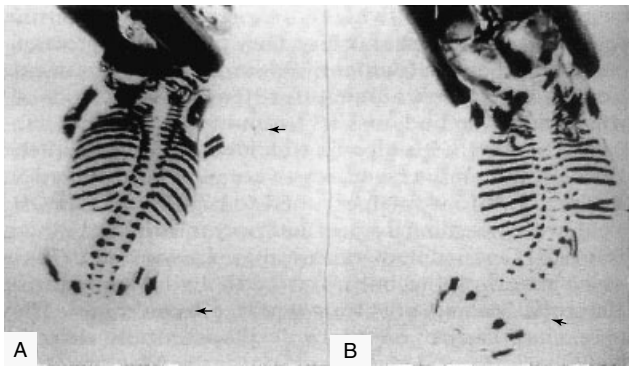

Figure 4 Skeletal development of (A) control and (B) fumonisin-treated rat pup. A = Pup from a control dam, with normally shaped ribs and normal ossification of the phalanges and vertebrae bodies. B = Pup taken from dam treated with 60 mg kg^{-1} fumonisin B_1, having underossification of the vertebral bodies of the cervical and lumbar regions as well as the phalanges. General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

experimental study with FB_1 in pregnant New Zealand white rabbits revealed no evidence of embryotoxicity or teratogenicity, despite the fact that the pregnant rabbits were sensitive to very small doses of FB_1 (LaBorde *et al*., 1997).

Pregnant mares exposed to fumonisins by consuming contaminated corn/corn-based feed showed late term abortions. In some cases, the surviving colts were behaviourally abnormal and slow learners. Suppressed growth, bone development and immune system appeared to be the major contributing factors (Gupta, 2007). Abortions have also been observed in pregnant sows consuming fumonisin-contaminated corn, and may be due to hypoxia resulting from maternal respiratory distress (Harrison *et al*., 1990).

Thus far, the mechanism of toxicity of fumonisins is not completely understood. Fumonisins have been demonstrated to inhibit sphinganine-sphingosine *N*-acetyl transferase (ceramide synthetase) activity and, consequently, increase the concentrations of sphinganine and the ratio of free sphinganine to sphingosine in target organs of many animal species (Wang *et al*., 1992; Riley *et al*., 1993). Accumulations of sphinganine may be responsible for cell death because long-chain bases such as sphinganine and sphingosine are known protein kinase C inhibitors and can be cytotoxic. It is suggested that an abnormal sphinganine/sphingosine ratio in the foetus in the presence of a normal ratio in the dam will attest to the unique sensitivity of the conceptus to fumonisin (Riley *et al*., 1993; Floss *et al*., 1994a; 1994b).

Finally, it is important to mention that human exposure to fumonisins in yellow and white corn meal, measured at 0.75–7.5 mg per 55 kg woman per day (14–140 µg kg^{-1}), suggests that fumonisins might be teratogenic to humans, but do not pose a severe risk. For further details on general toxicity and placental toxicity of fumonisins, readers are referred to Smith (2007) and Gupta (2007).

11.3 Ochratoxin A

Ochratoxin A (OTA) is produced by *Aspergillus* (primarily *A. ochraceus*) and *Penicillium* species (*P. viridecatum* and *P. cylopium*) of fungi. This mycotoxin has been encountered as a contaminant in a variety of feeds and in human food, including cereals and different kinds of beans, such as coffee, cocoa, soya, peanut and corn. OTA has been implicated as the aetiological agent of Balkan endemic nephropathy in humans and acute ochratoxicosis (nephropathy and hepatotoxicosis) in animal species. In addition to other toxic effects, such as carcinogenesis and immunotoxicity, this mycotoxin has been demonstrated to cause teratogenesis in rats (Mayura *et al*., 1982b). The main mode of action of OTA is inhibition of protein synthesis, although the toxin is also known to cause enhancement of lipid peroxidation, partial inhibition of ATP-dependent calcium uptake and inhibition of the cell-mediated immune response. OTA also inhibits the phosphorylase enzyme system, possibly by competing with 3′, 5′-cyclic AMP (adenosine monophosphate) for phosphorylase b kinase activity.

The placental transfer of OTA has been demonstrated in rodents and other species (Galtier, 1991). The relationship of OTA to foetal death in laboratory and domestic animals was established by Still *et al*. (1971). *A. ochraceus* cultures administered on GD 10 to groups of pregnant rats induced a large number of foetal deaths and embryo resorptions. Subsequent work in rats indicated that a high dose of purified OTA administered on GD 10 also caused a large number of foetal deaths and embryo resorptions. Compared with rats, placental transfer of OTA in sheep was found to be in trace amounts, resulting in very little or no evidence of foetal toxicity or teratogenesis. In a recent study, rabbits receiving a combination of OTA and aflatoxin B_1 showed antagonistic interaction, yet revealed a characteristic cardiac anomaly with a valvular defect at the auriculoventricular junction (Wangikar *et al*., 2005). For further details on OT toxicity, see Fung and Clark (2004) and Gupta (2007).

11.4 Rubratoxins

Rubratoxins A and B are mycotoxins produced by *Penicillium rubrum* and *P. purpurogenum*. Rubratoxin B is the principal toxin and it is a hepatotoxic agent. Experimental intoxication has been demonstrated in both laboratory and domestic animals. Typical signs of intoxication are hepatic failure, coagulopathy, haemorrhage of the gut mucosa, bloody faeces and death. Rubratoxin B_1 has been proved to be a potent mutagen and teratogen in mice (Wilson and Harbison, 1973). The teratogenic effects on near-term foetuses are varied and striking, including exophthalmos, missing ears, spina bifida, microphthalmia, anophthalmia, short tail, exencephaly and hydramnion.

11.5 Secalonic Acid D

Secalonic acid D (SAD), a toxic fungal metabolite, is produced by *Penicillium oxalicum*. SAD has been proved to be embryocidal/embryotoxic/foetotoxic and teratogenic in rats and mice. Pregnant CD1 mice treated with SAD at doses of more than 5 mg kg^{-1} ip on GD 7–15 showed a reduction in body weight gain of dams and an increase in resorptions of implanted embryos (Reddy *et al*., 1981). The resorption effect was nearly 100% at 15 or 9 mg kg^{-1} given in sodium bicarbonate, with or without dimethyl sulfoxide, respectively. Multiple

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat088
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

gross, skeletal and visceral anomalies were noted in foetuses born to mothers receiving 10 mg kg^{-1} or more. Major malformations included cleft palate, cleft lip, open eyelids, missing phalangeal ossification centres and shortened mandibles. It is concluded that SAD is embryocidal and foetotoxic, as well as teratogenic, when given to female CD1 mice during pregnancy. In another study conducted on rats, SAD was injected as a single sc dose (25 mg kg^{-1}) on one of GD 6–10, 12 or 14, or 15 mg kg^{-1} SAD on GD 10. Both doses produced teratogenic and foetotoxic effects, although the effects were less marked with the lower dose (Mayura *et al*., 1982a). The highest number of resorptions, greatest depression of foetal body weight and largest number of malformations occurred when SAD was injected on day 10. It is indicated that anophthalmia (days 9 and 10), exencephaly (day 9) and defects in limbs, digits and tail (day 10) were the major gross malformations. Major skeletal defects involved the vertebrae and ribs. The main internal soft tissue defects were hydronephrosis (days 9 and 10), tracheo-oesophageal fistula and renal agenesis (day 10). Hence, it appears that exposure of rats to SAD on day 10 of pregnancy is the most sensitive period for foetotoxicity and teratogenicity.

11.6 Trichothecenes

The commonly encountered mycotoxins of this group include T-2 toxin, diacetoxyscirpenol (DAS) and deoxynivalenol (DON) (vomitoxin). T-2 and DAS are produced by *Fusarium sporotrichioides* and vomitoxin is produced by *F. roseum*. It is important to mention that trichothecenes are heat stable and are not destroyed by normal industrial processing (Creppy, 2002). These mycotoxins are of both human and animal health importance. There is evidence that suggests that trichothecenes cross the placental barrier and can cause both embryonic death and structural malformations when administered to laboratory animals during pregnancy (Francis, 1989). At maternotoxic doses, trichothecenes can produce embryotoxicity or foetal death in both mammals and birds, and only few frank congenital defects are observed in surviving foetuses, though anomalies in the nervous and skeletal systems have been noted. It is noteworthy that trichothecenes in general cause feed refusal in mammalian and avian species and this factor can minimize maternal/foetal toxicity. Trichothecenes can induce toxicity by multiple mechanisms, including inhibition of protein, RNA and DNA synthesis, enhanced lipid peroxidation, inhibition of mitochondrial and electron transport chain function, induction of apoptosis and modulation of immune responses. Only a brief description of trichothecenes' toxicity is given here, while the details can be found in a recent publication by Mostrom and Raisbeck (2007).

11.6.1 T-2 Toxin

One of the most toxic members of the trichothecene family is T-2 toxin, which is mainly responsible for mass poisonings in man (Forgacs and Carll, 1962) and farm animals (Hsu *et al*., 1972). It is well established that T-2 toxin crosses the placenta (Hayes, 1981). The only effect that has been reported in rats exposed prenatally to T-2 toxin is behavioural teratogenesis (Francis, 1989). Mice, compared with rats, have been studied in detail for placental toxicity of trichothecenes. There is a report that indicates that mice receiving a single dose of 3 mg kg^{-1} T-2 toxin on GD 7, 8, 10, 11 or 12, showed maternal toxicity with 17% mortality and whole litter resorptions (Rousseaux *et al*., 1985). Maternal death was typically due to placental haemorrhage, and surviving pups had major, minor and retardation defects of the skeletal system, and also exencephaly, abdominal defects and cleft palate.

In a comprehensive study (Stanford *et al*., 1975), female mice were treated with 0.5, 1 or 1.5 mg kg^{-1} T-2 toxin, ip on GD 7, 9, 10 or 11. Treatment on day 9 reduced the survival rate to 85% at 1 mg kg^{-1} and to 8% at 1.5 mg kg^{-1}, without any evidence of teratogenesis in surviving pups. Among the surviving pups of dams treated at 1 or 1.5 mg kg^{-1} on day 10, 37% were grossly malformed and 42% had skeletal malformations. Commonly observed malformations were exencephaly, congenitally open eyelids and retarded jaws. Treatment on day 11 resulted in greater embryotoxicity (75% deaths at 1 mg kg^{-1} and 100% deaths at 1.5 mg kg^{-1}), but the malformation rate among surviving pups was not greater than 13% at any dosage. In another study, female mice given T-2 toxin in feed at 5 and 10 ppm throughout gestation resulted in whole litter abortions in 67 and 100% of the dams, respectively (Francis, 1989). Delayed ossifications of the coccyx and growth retardation were the prominent effects. Overall, the observed effects were cumulative and dose dependent. In mice, concurrent prenatal exposure to T-2 toxin and rubratoxin B has been shown to result in an increased adverse effect on both foetal weight and mortality of the conceptus in comparison with either mycotoxin given alone (Hood, 1986).

11.6.2 Diacetoxyscirpenol (DAS)

There is one report which describes the placental toxicity of DAS in rats (Mayura *et al*., 1985). DAS at a dose rate of 2, 3 or 6 mg kg^{-1} ip on one of GD 7–11 caused no maternal toxicity. The highest dose caused 100% resorptions. With the lowest dose (2 mg kg^{-1}), the surviving pups showed a variety of malformations, including hydrocephaly and exencephaly.

11.6.3 Deoxynivalenol (DON, Vomitoxin)

Vomitoxin is one of the most common contaminants of cereal grains world wide. In rats, feeding a vomitoxin-contaminated diet at 5 ppm throughout gestation does not adversely affect pregnancy or increase birth defects (Morrissey, 1984). In another study, the same author reported that vomitoxin does not produce teratogenesis even at a 20 ppm dietary level. However, at this dose it can decrease the rate of pregnancy. In a recent study, Collins *et al*. (2006) gavage fed pregnant Sprague Dawley rats daily with vomitoxin at doses of 0, 0.5, 1, 2.5 or 5 mg kg^{-1} body weight on GD 6–19. All females survived to caesarean section. At the highest dose, gravid uterine weights were significantly reduced, 52% of litters were totally resorbed, and average foetal body weight and crown–rump length were significantly decreased. The ossification of foetal sternebrae, centra, dorsal arches, vertebrae, metatarsals and metacarpals was significantly decreased. No adverse developmental effects were observed at the 0.5 or 1 mg kg^{-1} dose. Vomitoxin is considered a teratogen at 5 mg kg^{-1} day^{-1} in Sprague Dawley rats. In mice, intubation on GD 8–11 at doses of 2.5 and 5 mg kg^{-1} vomitoxin produced embryotoxicity, and at doses of 5 mg kg^{-1} or greater produced embryolethality (Khera *et al*., 1982). In mice, vomitoxin at a single dose of 10 mg kg^{-1} caused maternal mortality and 100% foetal mortality (Khera *et al*., 1982). Foetal mortality was 80% at 5 mg kg^{-1} and 72% at 2.5 mg kg^{-1}. With various dosing regimens, there is no evidence of damage to the placenta or teratogenesis by vomitoxin in mice. In essence, the trichothecenes at maternally toxic doses are also embryotoxic. Death of any embryo or foetus is the most common finding. In surviving pups, frank malformations (nervous system anomalies and skeletal malformations) are seen, but rarely. In rabbits, DON given daily on days 0 through 30 of gestation at increasing levels of 0.3–2.0 mg kg^{-1} body weight caused 100% foetal resorption at 1.8 and 2.0 mg kg^{-1} day^{-1} and reduced body weight in rabbit does (Khera *et al*., 1986). Dosages of 0.3 and 0.6 mg kg^{-1} body weight per day of DON did not produce adverse effects in rabbit foetuses at term and these doses were not maternotoxic. The authors concluded that DON did not produce a teratogenic response in rabbits. Minor malformations described as delayed ossification and unwithdrawn yolk sac were reported in chick embryos when hens were fed rations containing DON at 2.5 and 3.1 mg kg^{-1} diet (Bergsjo *et al*., 1993).

12 EPILOGUE

Placental toxicology is an important area of research that has been neglected in the past. The placenta, in addition to maintaining pregnancy, acts as an exchanger interfacing two separate genomes, that is, mother and foetus. It is the main entryway for drugs and toxicants to the unborn from the exposed mother. There is ample evidence that a variety of chemicals (including abused drugs, metals, pesticides and mycotoxins) with MWs of less than 1000 cross the placenta with little or no restriction. This indicates that the placental barrier is not a full barrier, which is a widely held false notion.

It is evident from research findings of the last three decades that the placenta is not a waste or rejected tissue; instead, it plays multiple roles during pregnancy. Compared with toxicology of other target organs, placental toxicology is much more difficult to understand owing to three major factors: (i) it deals with three components—mother, placenta and foetus; (ii) placental structure and functions vary widely among different species; and (iii) continuous changes occur in the structure and function of the placenta throughout the gestation period. Several chemical toxicants concentrate in the placenta, where they produce minor biochemical changes to severe necrosis. Consequently, these changes are also reflected in the conceptus. The placenta, by having an active metabolism, modifies the toxicity of some chemicals, to the placenta and to the foetus. In addition, the placenta has receptors for abused drugs, and therefore, maternal exposure to these substances results in altered placental and foetal functions. The human placenta has a true capacity to compensate for some loss of function due to abused drugs by induction of transport systems to amino acids and down-regulation of placental receptors. This compensation may occur if the pregnant mother abuses one drug at any rime. It is not known if such compensation occurs if the mother abuses several drugs simultaneously. In the years to come, intense efforts of toxicologists will explore novel mechanisms involved in placental toxicity to better understand teratological, neurotoxicological, reproductive and behavioural deficits.

ACKNOWLEDGEMENTS

The author greatly appreciates Mrs. Kristie M. Rohde and Mrs. Robin B. Doss for their assistance in preparation of this chapter.

Air Pollution

Robert L. Maynard

CONTENTS

1 INTRODUCTION

Air pollution science has developed remarkably during the past 20 years: it is not too much to say that the subject has undergone a renaissance. Before discussing air pollutants in detail it will be interesting to consider three advances:

1. Long-term exposure to ambient particles mainly affects the cardiovascular system
2. For none of the common air pollutants can a threshold of effect be defined
3. Whilst particle mass concentration is universally monitored, particle number or surface area might better reflect effects on health.

Not one of these widely accepted propositions would have been accepted 10 years ago. Added to these is the growing realization that very small particles—ultrafine or nanoparticles, may play an important role in causing effects on health. How can these changes in thinking be explained? The answer does not, as yet, lie in toxicology; on the contrary, the advances are due to the application of epidemiological methods on a large scale. Powerful new methods and a willingness to capitalize on 'natural experiments' and on the results of policy initiatives have pushed the field forwards. Epidemiological studies of the effects of air pollutants on health are now numbered in hundreds and meta-analytical techniques have raised confidence in their findings. It is disappointing to record that advances in toxicology—in understanding mechanisms of effects—have not kept pace and, to some, air pollutant toxicology has become a much less important field than it was in the past. Put starkly, toxicology can sometimes explain and support epidemiological findings, but it can seldom refute them. This has led to doubts about the veracity of some epidemiological conclusions. In general, such doubts have been displaced by the sheer weight of evidence. But the challenge to toxicology remains and is being met by innovative work using genetically modified animal models and specially concentrated preparations of ambient pollutants. Dramatic support, for example, for links between exposure to particles and the rapidity of development of atherosclerotic plaques has been produced by studies in rabbits susceptible to atherosclerosis. This work will be discussed later. All this has led to challenges to policy-makers in the air pollution area; at a time when levels of common pollutants are probably lower in developed countries than at any time since the Industrial Revolution, pressure to reduce levels further is at its greatest. In less developed countries a recognition that air pollution has a very significant effect on health is changing the pattern of industrial development. Few areas of toxicology, in its broadest sense, are having more impact on the way we live and work.

2 HISTORICAL BACKGROUND

Air pollution has been a problem since the discovery of fire. Burning fossil fuels inevitably generates pollutants: the blackened civic buildings of the Victorian era testify to this. But for a long period during and following the Industrial Revolution, air pollution was accepted as a cost, undesirable to be sure, of progress. Readers interested in the historical aspects of this subject should consult Brimblecombe's excellent monograph: *The Big Smoke: A History of Air Pollution in London Since Medieval Times* (Brimblecombe, 1987). The possible dangers to health of air pollutants were noted in the thirteenth century and stressed by Evelyn in the seventeenth. Evelyn's book *Fumifugium: or The Inconvenience of the Aer and Smoake of London Dissipated* (Evelyn, 1661) may be taken as the first text on air pollution and, as Lawther has pointed out, can be read with profit today (Lawther, 1961). But little was done and by the nineteenth century coal-smoke-laden fog was a feature of industrial England. Victorian authors like Sir Arthur Conon Doyle used fog as a backdrop for their novels and foggy London is linked in many readers' minds with Sherlock Holmes. Smog (meaning a combination of smoke and fog) was a term coined by Dr. H. A. Des Volux of the Coal Smoke Abatement Society in 1905 and has remained in use ever since. In London the Great Smog of 1952 brought matters to a head: at least 4000 'extra' deaths over a two week period and daily average concentrations of sulphur dioxide (SO_2) and particles of about 4000 $\mu g\ m^{-3}$ (the particle filters of monitoring apparatus were overloaded and results were therefore inaccurate) led to a public outcry and to the Clean Air Act of 1956. Equally importantly, the Medical Research Council (MRC) set up the Air Pollution Unit and research into the effects of air pollutants on health began. Lawther, Waller, Cummins and others undertook seminal studies that form an essential source of reference on the effects of coal-smoke air pollution. Sadly this work stopped in 1979 when it was erroneously believed that the problem of air pollution had all but disappeared. Work in the UK began again in the 1990s.

London was not the only city affected by air pollution, of course. In 1930 a serious episode in the Meuse Valley of Belgium claimed 60 deaths from a population of 6000 and in the United States, in Donora, near Pittsburgh, fog in 1949 killed 20 people and affected 43% of the population.

Reductions in coal-smoke pollution were fairly easily obtained: smoke-free fuel for domestic heating, the increasing use of gas and electricity, and taller chimneys for industrial sources all proved effective. But whilst coal smoke was being mastered, a second source was increasing: the motor vehicle.

Los Angeles in the early 1950s was affected by what was then a new form of 'smog'. No longer smoke and fog, but a mixture of traffic emissions and photochemically produced oxidants such as ozone (O_3) and peroxyacylnitrate produced by sunlight acting on primary pollutants. This 'smog' was strongly irritative to the eyes and lungs and O_3 concentrations of >500 ppm (1000 $\mu g\ m^{-3}$) were recorded. Such levels were sufficient to damage vehicle tyres made of natural rubber. Research in the US and other countries developed rapidly. Progress in research can be followed in the publications of the World Health Organization (WHO; 1987, 2000, 2006). Close reading of these reports reveals the slow move away from accepted thresholds of effect and suggests that a policy of progressive reduction should be adopted. This is not new: in the UK such an approach was advocated by the MRC Air Pollution Unit workers in the 1970s.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

In the early years of air pollution research, emphasis was placed on air pollution episodes. Lawther (1961) argued that much emphasis was misplaced and that more attention should be placed on the effects of long-term exposure. He was correct, though he argued that the key effects were likely to be respiratory. This is no longer believed: the key effects are on the cardiovascular system.

Modern epidemiological studies of air pollutants generate coefficients linking concentrations of pollutants with effects on indices of health. In the UK, a database set up to collate the results of short-term studies now contains about 10,000 coefficients. That air pollution damages health is no longer a subject for dispute: the extent to which it damages health is important, as are the mechanisms by which the effects are produced.

Recent work has focussed on the benefits to health that can be expected as a result of reductions in levels of air pollution. In the UK these have been calculated with some accuracy and form the basis of the Air Quality Strategy for England, Scotland, Wales and Northern Ireland. This has recently been published and runs to three volumes (Defra, 2007a; 2007b). Readers wishing to gain a grasp of modern air pollution control are directed to these volumes. Similar work is underway in other countries and the US Environmental Protection Agency (EPA) has published reviews of unparalleled completeness of effects of air pollutants on health. These are available on the US EPA web site at the following web site address: *http://www.epa.gov*. In the mid 1990s the EPA criteria document on particulate matter ran to three large volumes: these reports are obviously a key source. Fortunately they are available from the US EPA in CD format.

3 SOURCES OF AIR POLLUTION

3.1 Definitions

Air pollutants appear as particles or gases. Particles, including fine droplets of liquid, suspended in air and in a reasonably stable state, form an aerosol. Pollutants may be described as primary if directly emitted from sources, for example, vehicles emit nitric oxide (NO) or secondary if they are formed in the air, as is O_3. Some pollutants, such as particles, comprise both primary and secondary components. Particles range from 1 nm (10^{-9} m) diameter to about 100 µm diameter (1 µm = 10^{-6} m). Primary particles are formed at source: some are given off from a fire, for example. Secondary particles form in the air and begin as very small units (<5 nm diameter), but they soon grow and aggregate and form an important component of the ambient aerosol, with diameters between about 0.1 and 1 µm. Particles larger than about 1 µm are produced by mechanical processes, for example, wind-blown dust and sea spray. The terminology used to describe the ambient aerosol is complicated. Particles are sampled using size-selective (filtration) heads that reject particles above a certain size. This is described as the 'cut size'. If we imagine that all particles of less than 10 µm diameter are selected, collected and weighed, and the result expressed as mass per m^3 air sampled, we will have determined PM_{10}. Of course, the acceptance/rejection profile is not perfect at 10 µm diameter, but the acceptable level of imperfection is specified in the full definition of PM_{10}. In referring to diameter we actually mean aerodynamic diameter: the actual diameter of a sphere of unit density with the same aerodynamic properties as the particle in question (see below in Section 8 on particle toxicology). Similarly, $PM_{2.5}$ or $PM_{1.0}$ may be defined. Particles of diameter less than 2.5 µm are described as fine particles, those larger are described as coarse, those between 2.5 and 10 µm are described as the coarse fraction of PM_{10}. Particles of <100 nm diameter are described as ultrafine. Nanoparticles are described a little more precisely as particles with at least one dimension (width, length) of less than 100 nm. Thus, nanoparticles include rods and tubes, as well as spheroids. The distribution of particles in the air can be expressed in terms of number or mass. Very small particles dominate the former, larger particles dominate the latter. Typical PM_{10} levels for Central London today are 20–25 µg m^{-3}. Note that PM_{10} defines a concentration of size-selected particles, not the particles themselves. Thus, though the term $PM_{10's}$ is widely used, it is in fact a solecism. It will be obvious that PM_{10} includes $PM_{2.5}$, $PM_{1.0}$ and all smaller size fractions.

Gaseous air pollutants such as NO and SO_2 are formed when fossil fuels burn: the latter from sulphur in the fuel, the former largely from the combination of nitrogen and oxygen. NO is oxidized by oxygen (slowly) and O_3 (rapidly), to form nitrogen dioxide (NO_2) and higher nitrogen oxides (N_2O_4, N_4O_8). NO_2 is thus largely a secondary gaseous air pollutant though some (primary NO_2) is directly formed from fuel during combustion. O_3 is entirely a secondary pollutant and forms as a photochemical product in the air. O_3 formation can be represented by the following equations:

$$NO_2 + \text{sunlight} \rightarrow NO + O\cdot \quad (1)$$

$$O\cdot + O_2 \rightarrow O_3 \quad (2)$$

$$NO + RO_2 \rightarrow NO_2 + RO \quad (3)$$

ROO· (or RO_2) represents peroxyradicals provided by volatile organic compounds. In busy streets O_3 is destroyed by the following reaction:

$$NO + O_3 \rightarrow NO_2 + O_2 \quad (4)$$

[a]Direct emissions only (i.e. does not include fugitive dust).
[b]Based on inventory for total suspended particulates.
Modified from World Health Organization (2006). Air Quality Guidelines. Global Update 2005. Particulate Matter, Ozone, Nitrogen dioxide and Sulphur dioxide.

This reaction is failing in some areas, as NO levels decline due to a reduction in emissions caused by the use of catalytic converters, and thus average urban O_3 levels are rising. Peak O_3 levels, on the other hand, are falling in urban locations in the UK.

Pollutants are described as being emitted from:

1. Point sources, for example, a power station
2. Line sources, for example, a motorway
3. Area sources, for example, an urban area.

Sources can also be classified as domestic, industrial, traffic-based, and so on. Inventories of pollution sources are available in developed countries and these form the basis of predictions of reductions of ambient concentrations consequent upon policy initiatives directed at specified sources.

Emissions may be calculated as:

$$\text{annual emissions} = \text{measure of activity} \times \text{emission factor} \quad (5)$$

Emissions may vary by source and by season: domestic heating generates more NO_2 in winter than in the summer. Detailed inventories have been devised for traffic, with vehicle emission factors being defined in terms of vehicle type and age. Inventories can be defined at a large scale (50×50 km grid squares), as used by the European Environment Agency, or smaller, for example, a 1×1 km grid square scale, as in UK urban sites. **Table 1** provides data on transport-based emissions in five countries.

A broader appreciation of sources of air pollutants in the UK is provided by **Table 2**.

Table 2 Sources of air pollutants in the United Kingdom

Source[a]	NO_x	SO_2	NH_3	Nonmethane VOC
Road transport	46.5%	—	—	36%
Domestic	4.5%	—	—	—
Industry	15.2%	31%	—	—
Power generation	22.6%	64%	—	13%
Other (non road) transport	9.1%	4%	—	—
Agriculture	—	—	89%	—
Solvents	—	—	—	18%
Fuel extraction	—	—	—	17%

[a]Only major and well characterized sources are shown. (World Health Organization, 2006).

In developed countries levels of air pollutants are, in general, low in comparison with the past, but this is not the case in rapidly industrializing, developing countries. In very large conurbations, such as Mexico City, a combination of extensive local industry, traffic and sunlight is producing high levels of both photochemical (O_3) pollution and particles. Detailed studies of effects on health in such areas reveal that air pollution remains a major threat. **Figures 1–4** are taken from the recent World Health Organization (2006) publication and provide a snapshot of conditions across the world. (**Figures 1–4** are reproduced by kind permission of the World Health Organization, 2006.)

4 EXPOSURE TO AIR POLLUTANTS

A notable feature of work on the health effects of air pollutants is that we know a good deal about concentration–response, less about exposure–response and still less about dose–response relationships. Ambient concentrations are fairly easy to measure, exposures much less easy and doses very difficult. Epidemiological studies focus on concentration–response relationships and these form the basis for assessing policy initiatives. It is accepted that dose is inevitably correlated with exposure–concentration, though the exact form of the concentration × time product that relates best to response has not been sufficiently explored. For irritant compounds, response is likely to be dependent more upon the concentration of material to which the subject is exposed than to the duration of exposure. In this case the Haber relationship:

$$Ct = K \tag{6}$$

may be modified as:

$$C^n t = k \tag{7}$$

where n = perhaps 3 or 4.

This has been explored at some length by the author elsewhere (Maynard, 2007).

That ambient concentration is related to exposure is also generally assumed, though there is less evidence for this. People spend up to about 90% of their lives indoors and yet we seek to relate outdoor concentrations of pollutants to effects on health. That this has been so successful is in some ways surprising! Indoor concentrations of pollutants generated outdoors tend to be lower than outdoor concentrations. On the other hand, concentrations of NO_2 and carbon monoxide may be greater indoors because of indoor sources. Particle concentrations indoors may be greater than those outdoors, but the composition of the ambient aerosols in the two environments may differ. Indoors, the so-called personal cloud of dust thrown up from furnishings and fittings may make a significant contribution to particle concentrations. Such particles are believed by some to be innocuous, though a firm basis for this belief is lacking. Patterns of indoor to outdoor exposure vary greatly from country to country: in developing countries, people spend less time indoors than is the case in developed countries. But indoor levels of pollution in developing countries can be very high, especially where wood and dried dung are used as fuel. The WHO Air Quality Guidelines (2006) noted that exposure to indoor air pollution associated with solid fuel use might be responsible for nearly 1.6 million excess deaths and about 3% of the global burden of disease. Detailed accounts of indoor air pollution are available (Spengler *et al*., 2001; United States Environmental Protection Agency, 1992; Department of the Environment and Heritage, 2001).

A valuable collation of data on indoor concentrations of particles was published in the WHO Air Quality Guidelines Global Update document (World Health Organization, 2006). This is reproduced with permission as **Table 3**.

It will be seen that indoor concentrations of particles can approach or exceed those of the London Smog of 1952, that is, 5000 $\mu g\ m^{-3}$. Lung cancer, chronic obstructive pulmonary disease (COPD) and airway irritation are associated with exposure to such concentrations.

Total exposure is calculated as the sum of exposures occurring in the series of microenvironments through which people pass each day. These have been studied and high exposures identified, for example, for commuters in busy traffic (van Wijnen *et al*., 1995; Zagury *et al*., 2000; Gómez-Perales *et al*., 2004; Krzyzanowski *et al*., 2005; Han and Naeher, 2006). It should be noted that dose depends on the volume of air inspired and particle or gaseous pollutant concentration in that air: cyclists may increase their dose by vigorous exercise.

Recalling that the majority of a person's time may be spent indoors, the relationship between personal exposure and outdoor concentration may be reduced to (or represented by) the relationship between indoor and outdoor concentrations. This has been studied in detail; the findings are variable (Landis *et al*., 2001; O'Neill *et al*., 2003; Janssen *et al*., 2005; Sarnat *et al*., 2005). In general, it is accepted that average personal exposure correlates well with outdoor concentrations on a day-to-day basis (Özkaynak and Spengler, 1996). Similarly, but on a longer timescale, average exposures in cities over a period of years correlates well with concentrations of pollutants measured in those cities at single site/fixed monitors. We know less about the distribution of individual exposures; this is difficult to measure on a large scale. Living near roads and low socioeconomic status is associated with increased personal exposures (Morello-Frosch *et al*., 2002; Green *et al*., 2004). Much effort has been put into thinking about errors that may be introduced into epidemiological studies by the use of approximations to true exposures. Two types of error have been considered. The first is the so-called 'classical' error that is common in studies where the measured pollution concentration may differ from the true concentration. Such an error is independent of true exposure levels and bias results 'towards the null'. The second type of error is the Berkson error. This occurs when a single value (exposure level) is assigned to many individuals. It is likely that individual exposures will vary around this value. This type of error is considered to introduce little or no bias. But all errors reduce study power and make detection of associations between air pollutants and effects on health more difficult (Steenland and

5 EPIDEMIOLOGICAL APPROACHES

Epidemiological methods have been applied to three main types of problem in the air-pollution area.

5.1 Effects of Short-term Variations in Ambient Concentrations

Though the major sources of air pollutants vary but little from day to day, ambient concentrations vary considerably. This is because meteorological conditions vary markedly from day to day. This variation provides

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089

the temporal heterogeneity of concentration, and thus exposure, that is studied using time-series methods. A number of subgroups of this approach may be identified: classic time-series studies, panel studies and case-crossover studies. Details may be found in handbooks of epidemiological methods (Rothman and Greenland, 1998). The classic time-series study seeks to relate day-to-day variations in concentrations of pollutants to day-to-day variations in indices of ill health. The latter include daily death rates, hospital admissions, primary-care consultations or the consumption of therapeutic preparations. Consider daily death rates. These vary considerably depending on season and on meteorological conditions: in countries like the UK, day-to-day variation in temperature is a, perhaps the, major factor. Temperature is thus a major confounding factor and must be allowed for in the analysis. Day of the week may also be a confounding factor: fewer people are seen by doctors on Sundays than on Mondays. In the early years of time-series analysis a visual approach was taken: daily indices of ill health were plotted against daily levels of pollution and the plot scanned for associations. This approach was used with great success in London in the 1950s (Waller, 1991), but led to an erroneous conclusion that a threshold of effect existed for coal-smoke (particles and SO_2) air pollution. Sophisticated mathematical approaches have been designed in recent years and, despite problems with software (Dominici *et al*., 2002; Ramsay *et al*., 2003), these are now felt to be reliable. Such methods allow identification of very small changes, for example, in risk of death. An increase in PM_{10} of $10\,\mu g\ m^{-3}$ is associated with about a 0.6% increase in daily mortality. This is a very small effect indeed and led some commentators to question the findings. Questions have focussed on the adequacy of allowance for the effects of confounding factors. It has been noted that as methods improved the coefficient (slope of the line linking pollution concentration and daily death rate generated by the mathematical model that takes into account confounding factors and which uses sophisticated nonparametric smoothing functions) has fallen. This has led cynics to observe that with sufficient improvement in modelling, the effect attributed to air pollutants will disappear. This is not true: coefficients from around the world are stabilizing and multicentre studies have increased confidence in the findings. Reanalysis (Dominici *et al*., 2005), has confirmed the validity of the original findings, albeit that adjustments for a long undetected error in software have been necessary.

Time-series studies have a great advantage in that they need not adjust for factors such as socioeconomic conditions, diet and smoking, though these are known to have important effects on health. This is for the simple reason that such factors do not vary from day to day. In recent years the results of time-series studies have been collated (notably in the UK) and meta-analytical techniques applied. This has led to the production of so-called Forest plots; an example is shown in **Figure 5** below.

This figure and the dozens like it that are reproduced in the recent report on cardiovascular disease and air pollution (Department of Health, 2006) bear close study. It will be seen that the central estimates of the coefficient linking PM_{10} and cardiovascular mortality vary widely from study to study. It will also be seen that as the central estimate increases so, in general, do the 95% confidence limits around it. This may be due to publication bias: large coefficients tend to be reported and published even if their confidence limits are wide. Small studies, inevitably, tend to generate wide confidence limits due to their lack of statistical power. The figure shows as an unfilled diamond the meta-analysis-derived summary coefficient. Note that the confidence limits around this are narrow: narrower than those of the great majority of the studies that were included in the meta-analysis. This reflects the great statistical power generated by combining results from many studies. It will also be noted that the vast majority of studies show that PM_{10} is associated with an increase in cardiovascular mortality. The results are remarkably consistent. This consistency has been an important consideration in regarding the association as causal. Further features of the association and the use of tests for publication bias are discussed in the report on cardiovascular disease and air pollution. **Figure 6** below shows a second Forest plot: for cardiovascular mortality and daily NO_2 concentrations.

It will be seen that this closely resembles the plot for PM_{10} shown in **Figure 5**. Why is this? It could be that NO_2 is about as effective as PM_{10} in affecting the daily cardiovascular death rate or (and very importantly) it could be that NO_2 is closely correlated with PM_{10} and the apparent association with NO_2 is simply reflecting the real association with PM_{10} or vice versa. This is a very real problem. The studies used in the meta-analyses deployed single-pollutant models and the effects attributed, for example, to PM_{10} were not adjusted for possible associations with NO_2. If PM_{10} and NO_2 were found to be perfectly and invariably correlated with each other, the approach used in these analyses could not separate their effects. Multipollutant models are needed, but have been used, as yet, to a much lesser extent than single-pollutant models. There are technical reasons for this: incorporation of more variables is said to lead to instability of the models. No doubt this is so, but the toxicologist is left concerned that the epidemiologist may not, despite the power and sophistication of his methods, have identified the causal agent (or agents) linking daily variations in pollutant levels with daily impacts on health. An added complication is provided by effect modification. Studies show that the coefficient linking PM and daily deaths is larger in areas where NO_2 levels are high. NO_2 may be playing a synergistic role in addition to being a confounding factor and, perhaps, playing a role

of its own. We are some distance from unravelling such complexities.

5.2 Intervention Studies

Producing a sudden change in air pollutant levels is seldom possible. Four such events have been studied in some detail: the effect of banning coal sales in Dublin (Clancy *et al*., 2002); the effect of reducing the sulphur content of all oil burnt by power plants and road vehicles in Hong Kong (Hedley *et al*., 2002); the effect of a strike at the Utah Valley steel works (Pope, 1989; Pope *et al*., 1992) and the effect of changing transportation patterns in Atlanta in preparation for the Olympic Games (Friedman *et al*., 2001). In each of these studies a sudden, significant and positive effect on health was observed. In the case of the study in the Utah Valley, toxicological studies have shown that the toxicity of the ambient aerosol fell during the strike (Pope, 1989). Such studies provide excellent evidence to show that reducing levels of air pollutants improves health and conform with Bradford Hill's advice to use the results of natural experiments to assess the likelihood of associations being causal in nature (Hill, 1965).

5.3 Cohort Studies

It is now known that long-term exposure to air pollutants, specifically particulate matter, leads to a reduction in life expectancy. That this was likely may well have been suspected in the days of coal-smoke air pollution, but the question of the magnitude of the effect has recently been put beyond doubt. Studies from the United States and, now, further studies from Europe have shown that long-term average concentrations of fine particles ($PM_{2.5}$) are associated with an increased risk of death at all ages. The key studies were Dockery *et al*. (1993), Pope *et al*. (1995; 2002; 2004), Hoek *et al*. (2002) and Filleul *et al*. (2005). Dockery *et al*. (1993) studied six US cities (the Harvard Six Cities Study): work began in the early 1970s with recruitment of a cohort (8111 people aged 25–74) and the placing of pollution monitors. Thus, the study was truly prospective. In Pope *et al*. (1995; 2002; 2004) advantage was taken of the already extant American Cancer Society (ACS) Cohort (552 138 individuals from 151 US metropolitan areas from which data on $PM_{2.5}$ were available in 50 and on sulfates in all). Confounding factors were carefully considered. Unlike the case of time-series studies, control for individual confounding factors is critical in cohort studies. **Table 4** shows the level of care taken in the Six Cities Study; this was increased in the American Cancer Study.

The results in both studies were modelled using Cox's proportional hazards model and associations between long-term $PM_{2.5}$ levels (or sulfate) and deaths from 'all causes' (save accidents), cardiopulmonary causes and cancer derived. The increase in risk of death (mortality risk ratio) was defined in terms of the difference in long-term pollutant concentrations between the least and most polluted cities or areas in the series. Recent examination of all this work (Department of Health, 2007) has led to the following conclusions:

1. Long-term exposure to a pollutant increment of $10\,\mu g\ m^{-3}$ $PM_{2.5}$ is associated with about a 6% increase in risk of death, at all adult ages, from cardiovascular disease. The effect on deaths from respiratory disease is comparatively trivial.
2. For lung cancer (also per $10\,\mu g\ m^{-3}$ $PM_{2.5}$) the increase risk is about 14%.
3. For other causes of death the effect is zero.

These are simplified conclusions. The US cohort studies have been exposed to unparalleled reanalysis and examination. This was undertaken by a team of experts put together by the US Health Effects Institute (HEI). This report, published in 2000, runs to 421 pages plus appendices. This reanalysis has put doubt to rest: long-term exposure to particulate air pollutants increases the risk of death at all adult ages and shortens life expectancy. Further and equally searching examination of the evidence has been undertaken in the UK (Department of Health, 2006; Department of Health, 2007).

Work by Brunekreef (1997) and Künzli *et al*. (2000) has sought to estimate the extent of life shortening implied by the US cohort studies—in particular by the most recent update of the ACS study (Pope *et al*., 2004). In the UK, a method of life table computation has been developed (Miller *et al*., 1993; Department of Health, 2007). This allows an imaginary cohort (birth cohort or representative population cohort) to be followed for 100 years. The background risk of death at all ages is known from actuarial data and at each age group this is increased according to the results of the ACS analysis. The method is not mathematically complex, but it is arithmetically tedious. If a birth cohort is then considered for long-term exposure to $10\,\mu g\ m^{-3}$ $PM_{2.5}$ the estimated loss of life expectancy (averaged across the cohort) is seven to eight months.

It should be noted that the impact is expressed as an average across the entire population. It is likely that this is not, in fact, the real case: susceptible groups are probably much more affected than suggested by the averaged impact. Unfortunately, we do not know how these susceptible groups are comprised and thus a more refined calculation is impossible. The calculation, as it

No. of deaths	232	156	248	222	281	291
Deaths/1000 person-years	10.73	9.68	12.47	12.45	15.86	16.24
Female sex (%)	52	56	56	54	55	56
Smokers (%)	36	33	40	37	35	35
Former smokers (%)	24	25	25	21	24	23
Average pack years of smoking						
Current smokers	24.0	25.6	25.2	24.5	30.9	28.0
Former smokers	18.0	19.7	21.8	21.1	22.0	25.0
Less than high-school education (%)	25	12	22	35	45	30
Average age (yr)	48.4	48.3	48.5	49.4	51.8	51.6
Average body-mass index	26.3	25.3	25.5	25.1	26.0	26.4
Job exposure to dust of fumes	53	28	38	50	40	48
Total particles ($\mu g\ m^{-3}$)	34.1	56.6	49.2	49.4	72.5	89.9
Inhalable particles ($\mu g\ m^{-3}$)	18.2	26.4	24.2	32.5	31.4	46.5
Fine particles ($\mu g\ m^{-3}$)	11.0	12.5	14.9	20.8	19.0	29.6
Sulfate particles ($\mu g\ m^{-3}$)	5.3	4.8	6.5	8.1	8.1	12.8
Aerosol acidity ($nmol\ m^{-3}$)	10.5	11.6	20.3	36.1	10.3	25.2
Sulphur dioxide (ppb)	4.2	1.6	9.3	4.8	14.1	24.0
Nitrogen dioxide (ppb)	6.1	10.6	18.1	14.1	19.7	21.9
Ozone (ppb)	28.0	27.6	19.7	20.7	20.9	22.3

[a]Air pollution values were measured in the following years: total particles, sulphur dioxide, nitrogen dioxide and ozone, 1977 through 1985; inhalable and fine particles, 1977 through 1985; sulfate particles, 1979 through 1984 and aerosol acidity 1985 through 1988.
World Health Organization, 2006.

stands, forms the basis for calculating benefits to health expected to be delivered by the Air Quality Strategy for England, Scotland, Wales and Northern Ireland. Those wishing to know the details of such calculations are referred to UK official reports published by Defra (2007a; 2007b).

6 SUSCEPTIBILITY TO AIR POLLUTION

It seems self-evident that some individuals are more sensitive or susceptible to the effects of air pollutants than others. Indeed, much of the toxicological thinking is, or was, based on the log-normal dose–response curve

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

described so well by Finney and used by him in his development of probits (Finney, 1971). It is less easy to say why sensitivity is distributed as it seems to be; we fall back on the assertion that it, like other variables (height, for example) is subject to 'normal' variation. One consequence of a normal distribution of sensitivity is that there is unlikely to be a true threshold of effect at a population level. This has come to be accepted in the field of air pollution as a result of epidemiological studies such as those described above. Even at very low ambient concentrations powerful techniques continue to demonstrate adverse effects. In the 1990s this acceptance led experts working on the WHO Air Quality Guidelines to move away from recommending guidelines in the traditional terms of a concentration and an averaging period, and to begin to regard the slope of the line linking concentration and response as the guideline. This was received with some dismay and it was argued that countries which had relied on the WHO Air Quality Guidelines as a basis for (or as) air quality standards were now without practical guidance. Some, including the present author, argued that a new approach to control of air pollutants was needed, indeed required, and that a policy of cost–benefit-tested reductions in concentrations was better than simply 'working down to a standard'. In the 2006 WHO update (World Health Organization, 2006) a compromise was agreed: slopes (coefficients) and numerical guidelines and targets for policy workers were recommended.

Some of the confusion regarding the distribution of sensitivity to air pollutants arises from conflation of thresholds at an individual level and at a population level. If a group of healthy people chosen at random is exposed in a controlled way to decreasing concentrations of SO_2 then a concentration at which nobody in the group shows a measurable increase in airway resistance (reflected as a fall in FEV_1 (forced expiratory volume in 1 s) or PEF (peak expiratory flow)) will be discovered. Unsurprisingly, if subjects with sensitive airways, for example, asthma sufferers, are studied, the threshold will be reached at a lower concentration than in the nonasthmatic subjects. Each person in the group will show a personal threshold and this may be fairly constant, day to day. The same would be true for O_3, NO_2 or SO_2 (Department of Health, 1991; Department of Health, 1992; Department of Health, 1993). The 'no observed effect level' for the group would be likely to be lowered as more and more subjects were studied. In addition the size of the response would be likely to fall as lower concentrations were studied. How large a response should be regarded as adverse? This has puzzled air pollution scientists for years. At one time the view was that if the response, say in terms of reduction in FEV_1, did not exceed that found day to day it should not be regarded as adverse (World Health Organization, 1987). Others have argued that variables such as FEV_1 would need to be reduced by 10% before the change could be regarded as significant in terms of health (American Thoracic Society, 2000). Neither approach now receives much support. It has been pointed out that a 10% reduction in a variable may not mean much to a normal subject, but may be very important in a subject in whom that variable is already depressed by disease. All this brings the epidemiological findings and the human (or animal) toxicological findings into conflict and the debate has become sterile.

So, can anything useful be said about susceptibility? The answer is, yes—the following groups are accepted as likely to be more susceptible (sensitive) than healthy young adults:

1. People with cardiopulmonary disease (Frampton *et al*., 2000; Gold *et al*., 2000; Peters *et al*., 2001)
2. People with asthma or COPD (Foster *et al*., 1993; Weinberger, 1993; Pope, 1991; Thurston *et al*., 1997; Slaughter *et al*., 2003; Chalupa *et al*., 2004)
3. Old people (Devlin *et al*., 2003)
4. Children (Gauderman *et al*., 2004)
5. Unborn babies (Šram *et al*., 2005)
6. Diabetics (Zanobetti and Schwartz, 2002; Zanobetti and Schwartz, 2001)
7. Subjects with GSTM1 (glutathione-S-transferase gene) deficiency (Gilliland *et al*., 2002; Romieu *et al*., 2004)
8. Subjects with the ZZ and null phenotypes for α-1-antitrypsin (Goss *et al*., 2004)
9. Smokers (Torres *et al*., 1997; Daigle *et al*., 2003).

The length of the list reflects its inutility! It might be hoped that if it were possible to identify groups at special risk then these groups could be provided with useful advice as to when episodes of high concentrations of air pollutants are expected as a result of meteorological forecasting. This has proved very difficult and in the UK, advice provided by the Committee on the Medical Effects of Air Pollutants (COMEAP) (web site address: *http://www.advisorybodies.doh.gov.uk/comeap*) has been limited.

Increased susceptibility is also often conflated with increased likelihood of high exposure. Those in urban areas are likely to be exposed to greater concentrations of air pollutants than those in rural areas and thus to be at greater risk of adverse effects. But this does not mean that urban dwellers are *per se* more susceptible to air pollutants than those living in rural areas.

7 INDIVIDUAL AIR POLLUTANTS

Air pollutants may be classified as 'classical' and 'the others'. Classical air pollutants are those that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

have attracted the greatest attention and which have been the subject of regulation. In 2000, the WHO Air Quality Guidelines (Second Edition) (World Health Organization, 2000) listed NO_2, O_3 and other photochemical oxidants, particulate matter and SO_2 as classical air pollutants. Many would add carbon monoxide, lead, benzene, 1,3-butadiene and polycyclic aromatic hydrocarbons (PAH compounds) to this list. Lead and carbon monoxide are considered elsewhere, as are carcinogens including benzene, butadiene and PAH compounds. Here we shall consider only those listed by World Health Organization (2000).

8 PARTICULATE MATTER

It is not possible to present a comprehensive account of all aspects of particulate air pollution in a few pages. For detailed accounts the reader is referred to the WHO Global Update (World Health Organization, 2006) to four UK reports (Department of the Environment, 1995; Department of the Environment, Transport and the Regions, 2001; Department of Health, 1995; 2006) and to the author's monograph (Holgate *et al*., 1999). In addition to these, *Particles in Our Air* edited by Spengler and Wilson (1996) remains a useful source. For a detailed, but accessible, account of aerosols in general, Hinds' book *Aerosol Technology* is unequalled (Hinds, 1999). Lippmann's book *Environmental Toxicants* (Lippmann, 2000) is also an essential source. For details of monitoring methods, the US EPA criteria documents provide excellent accounts and the recent UK publication *Particulate Matter in the United Kingdom* (Department for Environment, Food and Rural Affairs, 2005) presents a comprehensive one-country account in 444 pages. Here we will consider only three aspects of the subject.

8.1 Deposition and Fate of Particles in the Respiratory System

Inhaled particles are deposited on the surfaces of the air passages, from the nares to the alveoli by three major processes. Impaction describes the deposition of particles that, by virtue of their inertia, continue for a short time along their original path when the flow of suspending air changes direction. This causes particles to impinge on the walls of the airways especially at branch points and to be deposited. This form of deposition is dependent on the square of the diameter of the particle. Similarly dependent on the square of diameter is sedimentation: the settling of particles under the influence of gravity. This is important in the slow-moving air in the distal airways. Lastly, particles diffuse as a result of impaction of gas molecules on their surfaces. The diffusivity of a particle is dependent on the square root of the reciprocal of its diameter. Thus, large particles impact and sediment rapidly(d^2) and small particles diffuse rapidly ($\sqrt{1/d}$). If we think of particles between 1 nm and 20 μm in diameter we may define a deposition curve for the entire respiratory tract and another for the alveoli. Deposition is minimal at about 0.5 μm diameter. At this size particles are too small to sediment rapidly and too large to diffuse rapidly. A deposition nadir at 0.5 μm is a constant feature of mechanical filtration systems. The efficiency of respiratory deposition processes for small particles was demonstrated in 1870 by Tyndall who showed that light was not scattered by air emerging from the deep lung (Tyndall, 1870). Small particles are deposited, by diffusion, with great efficiency in the alveolar region. Alveolar deposition declines rapidly as particles of <10 nm are encountered; these particles do not reach the alveoli, they are efficiently deposited, by diffusion, in the upper airways. Particles of diameter greater than about 10 μm deposit in the upper airways and do not enter the thoracic airways. Thus, PM_{10} is based on the so-called thoracic convention and represents particles which might, often do, but need not, deposit in the lung. Particles of more than about 5 μm diameter stand little chance of depositing in the alveolar region. This is reflected by the respirable convention, which is centred at 4 μm diameter. A finer cut is provided by the high risk respirable convention that is centred at 2.5 μm and gives rise to $PM_{2.5}$ as a common measure of particulate air pollution. This latter convention is designed to represent particles likely to be deposited in the alveolar zone of the sick and infirm, and of children (Department of the Environment, 1996). Deposition curves need to be interpreted in terms of number of particles deposited, mass deposited and, perhaps, in terms of the total surface area of the particles deposited. Very small particles dominate in terms of particle number, particles between about 0.05 and 1.0 μm dominate in terms of surface area and mass is contributed by two major size fractions. It will be obvious that though the efficiency of particle deposition is high in the <0.1 μm (<100 nm) diameter region, such deposition will produce a low dose in mass terms. Much will depend on whether dose expressed as mass or dose expressed in terms of particle members is the more important.

Particles of soluble salts (and liquid droplets) dissolve on deposition in the lung and, it is thought, do little harm. Insoluble, or slowly dissolving particles are deposited, but then cleared from the lung. Rapid cilia-dependent clearance is much slower (see **Inhalation Toxicity**). Ambient particles contain both soluble matter (e.g. sodium chloride, nitrate and sulfate, ammonium sulfate), insoluble materials, including elemental carbon, metallic oxides (iron, nickel, vanadium, depending on source)

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

and insoluble silicates from crustal sources. Reactions between acids and metallic oxides may lead to soluble metallic species being formed. This has recently been seen as a means by which material measured as 'sulfate', but which may contain acidic species, may contribute to particle toxicity (Department of Health, 2007).

8.2 Epidemiological Studies Linking Ambient Particles and Effects on Health

8.2.1 Time-Series Studies

The problem in describing the evidence in this area is that it is so extensive that preparing a summary is difficult. Time-series studies are common and the principles have been discussed above. Two major multicity studies, the NMMAPS (National Morbidity, Mortality and Air Pollution Study) in the USA and the APHEA (Air Pollution and Health: A European Approach) study in Europe (World Health Organization, 2006). For effects on mortality the following summary figures may be compared:

Europe: increase of 0.6% (95% CI: 0.4–0.8) per 10 μg m^{-3} PM_{10}

USA: increase of 0.21% per 10 μg m^{-3} PM_{10}.

A collection of the results from Canadian and US studies are shown in **Figure 7**.

It will be seen that the few studies using multipollutant models (1–4) show narrow confidence intervals (CIs): these are large, powerful studies. Note also that there is considerable heterogeneity in the results from different studies and that in some the results are not statistically significant, though in only eight instances does the central estimate suggest a reduction in mortality on exposure to particles. The reader will also see that the estimates regarding $PM_{2.5}$ are similar to, or perhaps a little lower than those for PM_{10}. This observation should put to rest the persistent but ill-informed assertion that measuring PM_{10} fails to provide data indicative of effects on health and that measuring $PM_{2.5}$ would provide such data.

Similar compilations have been prepared regarding effects of short-term exposure to particles on indices of morbidity. Hospital admissions have been studied and results from Canada and the USA are shown in **Figure 8**.

Again, the extraordinary richness of the air pollution database is shown. Clear effects on both cardiovascular and respiratory causes of admission to hospital are seen. For further work on indices of morbidity the reader is referred to the WHO report (World Health Organization, 2006).

8.2.2 Cohort Studies

Nine cohort studies relating to particles had been reported by October 2005: some are follow-ups to earlier work (Dockery *et al*., 1993; Pope *et al*., 1995; 2002; Abbey *et al*., 1999; McDonnell *et al*., 2000; Lipfert *et al*., 2000b; Burnett *et al*., 2000; Hoek *et al*., 2002; Filleul *et al*., 2005). Additional studies have now been reported (Laden *et al*., 2006; Jerrett *et al*., 2005; Enstrom, 2005). In general, the smaller spatial scale studies, some of which follow populations living adjacent to roads, report larger coefficients than the bigger cohort studies. Combining the results of cohort studies using meta-analytical techniques has not yet proved possible, but in the UK a Delphic approach to definition of plausibility intervals around a central estimate coefficient has been developed. This approach is described in the COMEAP report QUARK 2 and the report should be considered for details (Department of Health, 2007). Cohort studies have provided little information on the effects of long-term exposure to particles on indices of morbidity. The startling finding from the cohort studies has been the effect of long-term exposure to fine particles on cardiovascular mortality. Impacts broken down by smoking status are shown in **Table 5**. Note the effects on ischaemic heart disease, but also on dysrhythmias, heart failure and cardiac arrest. These findings have led to intriguing hypotheses of mechanisms of effect discussed below.

8.2.3 Toxicological Studies of Ambient Particles

Until fairly recently the toxicologist was left behind by the epidemiologist; this is now being rectified.

The most relevant toxicological studies undertaken in experimental animals and in human volunteers have involved exposure to concentrated ambient particles (CAPs). These are prepared by taking ambient air and exposing it to high centrifugal forces; a concentration of particles occurs in the outer regions of the rotating air mass and this is drawn off. Thus, for example, ambient concentrations can be raised by a factor of 10. Animals and volunteers have been exposed to these aerosol preparations. In addition, ambient particles can be collected and administered to animals by intratracheal instillation. Sixteen studies in volunteers were reported in the World Health Organization (2006) report. **Table 6** is extracted from a much larger table in that report.

From these and from animal studies the following conclusions have been drawn.

1. PM causes an inflammatory response in the lung

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089

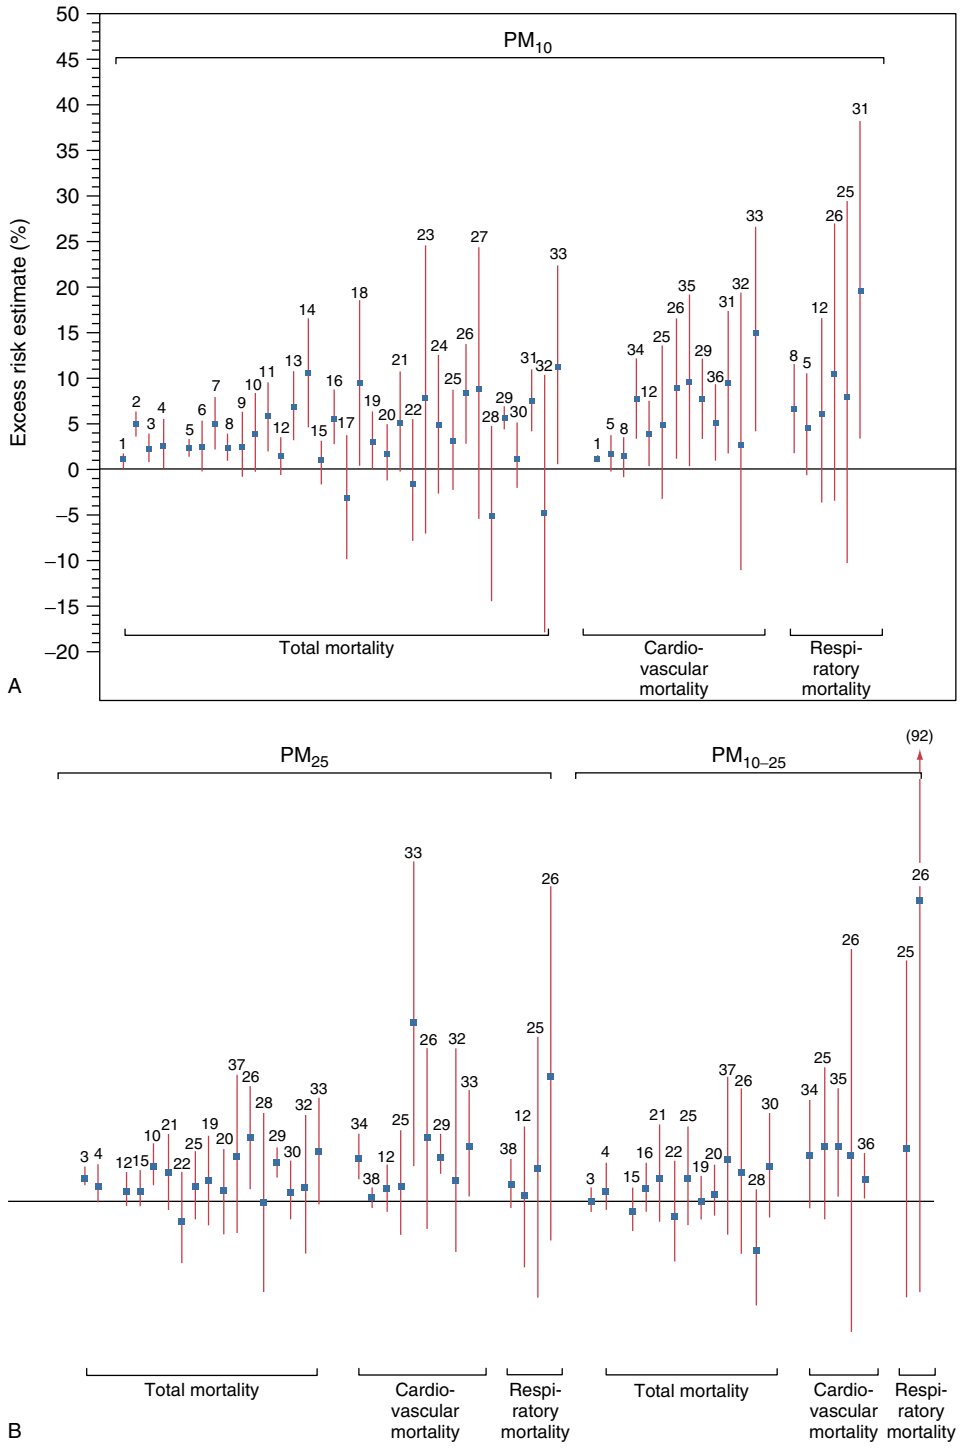

Figure 7 Excess risk estimates for total nonaccidental, cardiovascular and respiratory mortality in multipollutant (1–4) and single-pollutant models for Canadian and United States studies. (Reproduced from the World Health Organization, 2006.)

2. The inflammatory response is likely to be caused by the production of oxidative free radicals
3. Metal species may be involved in free radical formation
4. Transcription factors (e.g. NFκB and AP-1) may be involved, along with changes in cytosolic calcium concentration, in switching on genes controlling production of inflammatory cytokines
5. Changes in clotting factors and in small vessel reactivity may be induced
6. Changes in the autonomic control of the heart may occur.

Table 5 Adjusted RRs and CIs stratified by smoking status for a 10 μg m^{-3} increase in $PM_{2.5}$ (average)

Cause of death	Never smokers	Former smokers	Current smokers
All cardiovascular diseases plus diabetes	1.11 (1.07–1.16)	1.09 (1.04–1.15)	1.16 (1.09–1.23)
Ischaemic heart disease	1.22 (1.14–1.29)	1.15 (1.07–1.23)	1.16 (1.07–1.27)
Dysrhythmias, heart failure, cardiac arrest	1.04 (0.95–1.15)	1.14 (1.00–1.29)	1.31 (1.12–1.52)
Hypertensive disease	0.88 (0.69–1.12)	1.05 (0.76–1.44)	1.57 (1.12–2.19)
Other atherosclerosis and aortic aneurysms	1.18 (0.90–1.55)	0.91 (0.70–1.19)	1.08 (0.84–1.40)
Cerebrovascular disease	1.03 (0.93–1.15)	1.01 (0.88–1.17)	1.01 (0.86–1.20)
Diabetes	1.01 (0.83–1.23)	0.86 (0.66–1.12)	1.26 (0.91–1.74)
All other cardiovascular diseases	0.86 (0.67–1.09)	0.83 (0.61–1.13)	0.83 (0.59–1.15)
Diseases of the respiratory system	1.03 (0.91–1.17)	0.89 (0.80–1.00)	0.85 (0.76–0.96)
COPD and allied conditions	0.96 (0.73–1.24)	0.86 (0.73–1.00)	0.81 (0.70–0.93)
Pneumonia and influenza	1.20 (1.02–1.41)	0.98 (0.80–1.20)	0.90 (0.69–1.18)
All other respiratory diseases	0.74 (0.56–0.97)	0.88 (0.68–1.16)	1.10 (0.76–1.60)

Table modified from Pope *et al*. (2004).

Key studies supporting these findings have been reported by: Batalha *et al*. (2002), Campen *et al*. (2001), Chapman *et al*. (1997), Costa and Dreher (1997), Gardner *et al*. (2000), Godleski *et al*. (2000), Gordon *et al*. (1998), Gurgeria *et al*. (2002), Kodavanti *et al*. (2000), Nemmar *et al*. (2001; 2002a; 2002b; 2003a; 2003b), Salvi *et al*. (1999), Suwa *et al*. (2002) and Vincent *et al*. (2001). All this has led to two key hypotheses. The first suggests that inhaled particles lead to destabilization of, or an increased rate of progression of atherosclerotic plaques in coronary arteries. Suwa and colleagues work (Suwa *et al*., 2002) in animals is key to this, as is the series of papers on APOE−/− mice reported by Lippmann's group (Chen and Hwang, 2005; Chen and Nadziejko, 2005; Gunnison and Chen, 2005; Lippmann *et al*., 2005a; 2005b; 2005c; Maciejczyk and Chen, 2005; Maciejczyk *et al*., 2005; Veronesi *et al*., 2005).

The second relates to changes in heart-rate variability (HRV). HRV refers to the variations in the beat-to-beat interval of the heart. Though the parasympathetic system slows the heart, it actually increases HRV; the sympathetic system has the opposite effect. Decreased HRV is a known indicator of impending heart failure in patients with impaired ventricular function (Department of Health, 2006). Evidence to show that inhaled particles can reduce HRV has been obtained in animals (Godleski *et al*., 2000) and in man (Devlin *et al*., 2003). Links between air pollution and arrhythmias have been reported by Peters *et al*. (1999) and Peters *et al*. (2000). The latter study looked at the frequency of firing of implanted defibrillators and found that, in patients susceptible to frequent arrhythmias, this was linked to ambient concentrations of particles. This is an exceptionally suggestive finding.

8.3 The Ultrafine Hypothesis

Seaton *et al*. (1995) proposed that ultrafine particles might underlie the effects of ambient particles and that the key effects of very low mass concentrations on the cardiovascular systems could thus be explained. A similar hypothesis was advanced by Oberdörster *et al*. (1995). Much of the work outlined above, linking particles with inflammation, with changes in intravascular clotting factors and the evolution of atherosclerotic plaques supports this idea. But epidemiological evidence of effects of ultrafine particles has been slow to accumulate; the question remains open. The ultrafine hypothesis has sparked a great interest in nanotoxicology (see **Nanotoxicology-The Toxicology of Nanomaterials**) and it is not possible to discuss the key evidence in any detail here. The reader is referred to an excellent review by Oberdörster *et al*. (2005).

8.4 Conclusion

Particles are important air pollutants—fine particles ($PM_{2.5}$) appear to be especially important. A vast amount

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

Table 6 Review of studies with concentrated PM

Article title	Study design	Population	Exposure	Findings	Reference
Inhalation of fine particulate air pollution and ozone causes acute arterial vasoconstriction in healthy adults	Randomized crossover trial	25 healthy adults	2 h inhalation of approximately 150 μg m^{-3} fine CAPs plus ozone (120 ppb) vs. response to the inhalation of filtered air	CAPs plus ozone caused a significant brachial artery vasoconstriction compared with filtered air inhalation (−0.09 ± 0.15 mm vs +0.01 ± 0.18 mm, $P = 0.03$). No significant differences in flow-mediated dilatation (+0.29 ± 4.11% vs. −0.03 ± 6.63%, $P = 0.88$), nitroglycerine-mediated dilatation (+3.87 ± 5.43% vs. +3.46 ± 7.92%, $P = 0.83$), or blood pressure responses between exposures	Brook *et al*. (2002)
Exposure to concentrated ambient air particles alters haematological indices in humans	Clinical trial	20 young adults	Mean PM mass of 120.5 ± 14.0 μg m^{-3} for 24 h (n = 15) or filtered air (n = 5)	Exposure of health volunteers to CAPs was associated with decreases in both white blood cell count and lactate hydrogenase and increased concentrations of fibrinogen in the blood	Ghio *et al*. (2003)
Elderly humans exposed to concentrated air pollution particles have decreased heart rate variability	Clinical trial	10 elderly subjects 22 young subjects	Particle concentrations 6–10 times normal Chapel Hill air of $PM_{2.5}$	Elderly people experienced significant decreases in both time and frequency of heart rate variability immediately following exposure. No CAPs-induced changes in heart rate variability were found in young volunteers exposed to CAPs in a previous study	Devlin *et al*. (2003)
Exposures of elderly volunteers with and without chronic obstructive pulmonary disease (COPD) to concentrated ambient fine particulate pollution	Clinical trial	13 elderly volunteers with COPD and six age-matched healthy adults	200 μg m^{-3} CAPs <2.5 μm in diameter and filtered air for 2 h	A significant negative effect of CAPs on arterial oxygenation was more pronounced in healthy subjects. Peripheral blood basophils increased after CAPs in healthy people but not in COPD patients. In both groups, red cell counts increased slightly one day after exposure to filtered air but not to CAPs. Pre-exposure ectopic heartbeats were infrequent in health subjects but increased modestly during/after CAPs exposure relative to filtered air. Ectopic beats were more frequent in COPD patients, but decreased modestly during/after CAPs relative	Gong *et al*. (2004)

Table 6 *(continued)*

Article title	Study design	Population	Exposure	Findings	Reference
				to filtered air. Heart rate variability over periods of several hours was lower after CAPs than after filtered air in healthy elderly subjects but not in COPD patients. Unexpectedly, individuals with COPD appeared less susceptible than healthy elderly individuals	Gong *et al.* (2004)
The role of soluble components in ambient fine particles-induced changes in human lungs and blood	Clinical trial	37 young healthy volunteers	Particle concentrations 6–10 times normal Chapel Hill air of $PM_{2.5}$	Sulfate/iron/selenium factor was associated with increased percentage of neutrophils in bronchoalveolar lavage fluid and a copper/zinc/vanadium factor with increased blood fibrinogen. The concentration of sulfate, iron and selenium correlated highly with PM mass ($R > 0.75$) while the correlations between PM and copper/zinc/vanadium were modest ($R = 0.2–0.6$)	Huang *et al.* (2003)

Modified from World Health Organization, 2006.

of evidence, both epidemiological and toxicological has accumulated to support these conclusions. A series of guidelines have been recommended by WHO. These are shown in **Tables 7** and **8**.

9 NITROGEN DIOXIDE (NO_2)

NO_2 is an irritant gas which, in high concentrations, can cause pulmonary oedema. Concentrations may reach 500 ppb (940 μg m^{-3}), though urban annual averages are much lower: 10–50 ppb (20–90 μg m^{-3}). In 1991, in London, hourly average concentrations exceeded 400 ppb (720 μg m^{-3}) during a cold period in early December and this was considered exceptional. Indoor concentrations often exceed those outdoors: gas cookers (stoves) in kitchens generate NO_2 and levels can exceed 1000 ppb (1880 μg m^{-3}). This has led to concerns about NO_2 as an indoor air pollutant: studies of children have shown that those living in homes using gas for cooking and heating are more liable to respiratory infections than are others (Hasselblad *et al.*, 1992; Chauhan *et al.*, 2003; Sunyer *et al.*, 2004). These studies have led to the view that long-term exposure to NO_2, can be dangerous, and in the early 1990s drove the thinking of experts advising WHO on air quality guidelines for NO_2. Since then a great deal of new data has appeared (Miller *et al.*, 1993).

NO_2 is a gas and 70–90% of inhaled NO_2 is absorbed by the respiratory tract. About 50% of that inhaled may be absorbed in the upper airways (Berglund, 1993; Kommission Reinhaltung der Luft in VDI und DIN, 1985; United States Environmental Protection Agency, 1993). Peak tissue dose along the airways has been modelled: as in the case of O_3, this occurs at the junction of the conducting airways and the gas-exchange zone. Exercise increases the tissue dose in the gas-exchange region of the lung.

9.1 Epidemiological Studies

The great problem in studying the effects of NO_2 is its close association with particulate air pollutants. When effects are found it is difficult to decide which pollutant represents the causal factor. In recent years, enthusiastic work on particles has led to NO_2 being ignored and some authorities argue that NO_2 should be regarded merely as a marker or index for the traffic-related pollution mixture. The position is complicated by the likelihood that if sources of fine particles are controlled, then sources of NO_2 will also be controlled. Seeking areas where NO_2 and PM are not closely correlated is important—but difficult.

Table 7 Air quality guideline and interim targets for PM: annual mean

Annual mean level	PM_{10} ($\mu g/m^3$)	$PM_{2.5}$ ($\mu g/m^3$)	Basis for the selected level
WHO interim target 1 (IT-1)	70	35	These levels are estimated to be associated with about 15% higher long-term mortality than at AQG levels
WHO interim target 2 (IT-2)	50	25	In addition to other health benefits, these levels lower risk of premature mortality by approximately 6% (2–11%) compared to IT-1
WHO interim target 3 (IT-3)	30	15	In addition to other health benefits, these levels lower risk of premature mortality by approximately another 6% (2–11%) compared to IT-2
WHO air quality guidelines (AQG)	20	10	These are the lowest levels at which total cardiopulmonary and lung cancer mortality have been shown to increase with more than 95% confidence in response to $PM_{2.5}$ in the ACS study (Pope *et al*., 1995; 2002). The use of the $PM_{2.5}$ guideline is preferred.

Reproduced from the World Health Organization, 2006.

Table 8 Air quality guideline and interim targets for PM: 24-h mean

24 h mean level[a]	PM_{10} ($\mu g\ m^{-3}$)	$PM_{2.5}$ ($\mu g\ m^{-3}$)	Basis for selected level
WHO interim target 1 (IT-1)	150	75	Based on published risk coefficients from multicentre studies and meta-analyses (about 5% increase in short-term mortality over AQG)
WHO interim target 2 (IT-2)	100	50	Based on published risk coefficients from multicentre studies and meta-analyses (about 2.5% increase in short-term mortality over AQG)
WHO interim target 3 (IT-3)[b]	75	37.5	About 1.2% increase in short-term mortality over AQG
WHO air quality guidelines (AQG)	50	25	Based on relationship between 24-h and annual PM levels

[a]99th percentile (3 d/yr).
[b]For management purposes, based on annual average guideline values, the precise number to be determined on the basis of local frequency distribution of daily means.
Reproduced from the World Health Organization, 2006.

9.2 Time-Series Studies

Many studies have been reported. Stieb *et al*. (2002) have published a meta-analysis of 109 studies: 32 coefficients for NO_2 were included from single pollutant models and 15 from multi-pollutant models. The bottom-line result was for percentage increase in all cause mortality single pollutant models: 2.8% (95% CI: 2.1–3.5) per 24 ppb NO_2; multipollutant models: 0.9% (95% CI: −0.1 to 2.0) per 24 ppb NO_2.

European studies (Katsouyanni *et al*., 1996; 2001; Touloumi *et al*., 1997) have also been reported. These are worth considering: APHEA (1) (Katsouyanni *et al*., 1996): 1.3% increase in all cause deaths per 50 $\mu g\ m^{-3}$ NO_2 (1 hour maximum concentration) when adjusted for particles the coefficient fell to 0.6%.

The US study (NMMAPS) (Samet *et al*., 2000; Dominici *et al*., 2003) also found significant effects. Studies in this area are difficult to compare because:

1. Authors use different measures of NO_2 concentration, for example, 24 hour average or maximum 1 hour concentration in the day
2. Effects on day D may be related to concentrations on day D, day $D-1$, day $D-2$, and so on; this is described in the 'lag structure' of the analysis
3. Adjustment for other pollutants (or some of them) may or may not have been done.

However, it is accepted that daily variations in low concentrations of NO_2 affect daily death rates. Similar effects on indices of respiratory morbidity have been studied: hospital admissions for COPD (Anderson *et al*.,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

1997), asthma admissions (Sunyer *et al*., 1997), all respiratory admissions (Spix *et al*., 1998). COPD admissions were associated, asthma admissions were inconsistently associated and all respiratory admissions were not associated with NO_2. Similarly variable results have been found for cardiovascular admissions. The analysis by Metzger *et al*. (2004) provides a summary of the evidence on these and that of Peel *et al*. (2005) deals with respiratory admissions. It seems that NO_2 is related to hospital admissions for cardiorespiratory disorders. But control for covariate pollutants lowers the estimate of the impact of NO_2 and the coefficient linking NO_2 and effects may lose statistical significance. Of all the impacts, that on asthma admissions is perhaps the most certain. This has been studied in children.

9.3 Time-Series Studies of NO_2 and Asthma Morbidity in Children

Studies in London (Anderson *et al*., 1998; Atkinson *et al*., 1999a, b; Hajat *et al*., 1999), in Canada (Lin *et al*., 2003), in Australia and New Zealand (Barnett *et al*., 2005) and the USA (Peel *et al*., 2005) show that NO_2 is related to emergency admissions to hospital in children suffering from asthma. Associations with PM and O_3 were also found in several studies; NO_2 'survived' adjustment for copollutants better than others, for example, PM and O_3. Studies of panels of asthmatic children have supported these findings and an interaction between exposure to NO_2 and viral infections (a major trigger of asthma attacks in children—especially young children) is now accepted. However, a large European study, the PEACE (Pediatric Asthma Clinical Effectiveness) study (Roemer *et al*., 1998) failed to find associations between particulate air pollutants or NO_2 and indices of asthma morbidity.

9.4 Studies of Effects of Long-term Exposure to Outdoor Concentrations of NO_2

A number of studies have been reported. Here we focus on those that have had a large impact on thinking.

9.4.1 The South California Children Study

This study, reported by Gauderman *et al*. (2000; 2002) and McConnell *et al*. (2003) shows that children growing up in communities with raised levels of NO_2 (and nitrate-rich particulates) suffer a retardation in lung development. Decrements in FEV_1, MMEF (maximum mid expiratory flow) and PEF were recorded and, very importantly, these were shown to resolve in children who moved to less polluted areas. Details may be found in the original papers, but across a range of NO_2 concentrations varying by 35 ppb (difference between communities) FEV_1 decreased by -101 ml (95% CI: -165 to -35). Careful adjustment for other factors affecting indices of lung function was undertaken. These results are supported in adults by European work (Schindler *et al*., 1998). Lung function decrements sustained in childhood are likely to last throughout adult life; these findings are, therefore, potentially important.

9.4.2 Asthma, Respiratory Disorders and Atopy

Here the evidence is less clear cut. Consider a study from the Netherlands: a birth cohort of 3745 children was studied (Brauer *et al*., 2002). NO_2 concentrations at home addresses were modelled. These varied between 12 and 58 $\mu g\ m^{-3}$, annual average. Adjusted odds ratios for a 10 $\mu g\ m^{-3}$ increase in NO_2 were 1.13 (95% CI: 0.99–1.29) for wheeze and 1.18 (95% CI: 0.93–1.51) for asthma. NO_2 was highly correlated with PM. The California Children study referred to above looked at NO_2 and bronchitis and cough. Four year average NO_2 concentrations ranged from 4 to 38 ppb (very low concentrations). The odds ratios for bronchitis symptoms were: per 1 ppb NO_2: 1.02 (95% CI: 1.00–1.03).

These data seem less persuasive, to me, than those on lung function.

In addition to the above, a number of studies have found associations between low birth weight and preterm birth in areas relatively polluted with NO_2 (Wilhelm and Ritz, 2003; Dales *et al*., 2004; Lin *et al*., 2004).

9.5 Toxicological Studies of NO_2

Studies in animal models have not been helpful in explaining the effects seen in man at very low concentrations of NO_2. This section is divided into two parts: studies in animals and studies in man. *In vitro* studies of consumption of antioxidants (Halliwell *et al*., 1992; Kelly and Tetley, 1997) on membrane permeability (Devalia *et al*., 1993) and on the release of inflammatory mediators by culture cells (Ayyagari *et al*., 2004) have been reported. In general, high concentrations of NO_2 were used in these studies.

9.5.1 Animal Studies

Increased lipid peroxidation (a sign of free radical activity) has been reported in rats exposed to 4000 ppb

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

(752 μg m^{-3}) NO_2 for 18 months (Sagai *et al*., 1984; Sagai and Ichinose, 1987). Damage to Type I alveolar cells and ciliated airway cells (Type II alveolar cells and Clara cells appear to be more resistant) has been shown in rats exposed to 340 ppb (640 μg m^{-3}) NO_2 (Department of Health, 1993). Long-term exposure to NO_2 induces emphysema-like changes in several species (Snider *et al*., 1985). Inflammatory responses have been reported, (Ichinose and Sagai, 1982) as has enhanced injury in mice sensitized to and then challenged with ovalbumin after exposure to NO_2 (Hussain *et al*., 2004). Effects on airway defence mechanisms against bacteria have been reported (Ehrlich and Henry, 1968; Ehrlich *et al*., 1977; Gardner *et al*., 1977). These may provide an explanation for the increased respiratory infections experienced by children living in gas-using homes, though the animals were continuously exposed to concentrations similar to those occasionally found in such homes.

9.5.2 Human Studies

Exposure to NO_2 causes changes in indices of lung function, but in normal subjects concentrations of about 1000 ppb (1880 μg m^{-3}) are needed to produce such effects. Asthmatic subjects are more sensitive than others and effects have been recorded on exposure for 2–2.5 hours to 300 ppb (520 μg m^{-3}) NO_2 (Avol *et al*., 1989; Bauer *et al*., 1986; Roger *et al*., 1990). But results amongst studies at this level—and higher levels—are inconsistent (Linn *et al*., 1985; 1986; Linn and Hackney, 1984). Also, the changes in indices of lung function at such levels of exposure are small and of debatable significance. Induction of symptoms in normal subjects and asthmatics requires exposure to much higher concentrations (Linn and Hackney, 1984). Studies involving exposure to NO_2 and subsequent bronchoalveolar lavage have shown that exposure to >1 ppm (1880 μg m^{-3}) can induce a brisk inflammatory response (Jörres *et al*., 1995; Sandström *et al*., 1992). At lower levels of exposure (600 ppb (1130 μg m^{-3}); four separate two hour exposures over six days) no such response was found (Boushey *et al*., 1988). Other studies have shown effects on subsets of lymphocytes but these, too, have used concentrations of NO_2 considerably greater than occur commonly in ambient air. Emphasis has been placed on effects on cytokines (IL-5, IL-10, IL-13 and ICAM-1). These Th2 cytokines might indicate a proallergic effect, but this is unproven (Pathmanathan *et al*., 2003).

9.6 Conclusion

NO_2 is a common air pollutant. Epidemiological studies have shown a range of associations with mortality and morbidity and, most surprisingly, with lung development in children. Indoor exposure is likely to exceed outdoor exposure. Consideration of the evidence led WHO to recommend the following Air Quality Guidelines: annual average concentration: 40 μg m^{-3}; 1 hour average concentration: 200 μg m^{-3}.

10 SULPHUR DIOXIDE (SO_2)

SO_2 is produced when fuel containing sulphur is burnt in air. In the days of coal-smoke smog, SO_2 was treated in combination with particles (often measured as 'black smoke' by a reflectance method), but more recently the effects of SO_2 alone have been considered. SO_2 dissolves rapidly in water and oxidation on the surface of particles—especially if catalytic metals are present—leads to the formation of sulphur trioxide and sulfurous and sulfuric acid. Droplets of sulfuric acid form in the air by primary nucleation—this is an unusual property of sulfuric acid vapour. Sulfuric acid is neutralized by combination with ammonia to produce ammonium bisulfate and sulfate ($NH_4HSO_4(NH_4)_2SO_4$)). Details can be found in the Medical Aspects of Air Pollution Episodes (MAAPE) report on SO_2, acid aerosols and particulates (Department of Health, 1992). SO_2 has been thought to be effectively removed on inhalation by the upper airway. As the concentration of SO_2 in inhaled air falls, so does the percentage absorbed and Amdur (1986) pointed out that upper airway removal of SO_2 might be inefficient at ambient concentrations. Ammonia found in the mouth, produced by bacteria, may be important in neutralizing acid aerosols. The following reactions occur in water:

$$SO_2 + H_2O \rightarrow H_2SO_3 \quad (8)$$

$$H_2SO_3 + H_2O \rightarrow HSO_3^- + H_3O^+ \quad (pK_a = 1.86) \quad (9)$$

$$HSO_3^- + H_2O \rightarrow SO_3^{2-} + H_3O^+ \quad (pK_a = 7.2) \quad (10)$$

Absorbed bisulfite is converted to sulfate:

$$HSO_3^- \rightarrow SO_4^{2-} \text{(catalysed by a molybdenum-dependent oxidase)} \quad (11)$$

Production of sulfate is limited in the lung and much more pronounced in the liver and kidney. HSO_3^- ions react with oxidized glutathione. Note HSO_3^- is a reducing agent: the coal-smoke smog was described as a 'reducing smog'.

SO_2 is a notably irritant gas that causes rapid bronchoconstriction at high concentrations. Asthmatic subjects are more sensitive to SO_2 than are other subjects. It is generally agreed that the lowest concen-

Table 9 Estimated total (nonaccidental) mortality expressed as percentage excess deaths (95% CI in parentheses) per 50 μg m^{-3} increase in sulphur dioxide reported in recent multicity time-series studies and meta-analyses

Study	Estimate	Comment
APHEA 1 (Katsouyanni *et al*., 1997)	Western Europe: 2.9% (2.3–4.6) at the best lag between 0 and 3 d for each city	The effects of sulphur dioxide and PM were 'mutually independent'
12 European cities	Central and eastern Europe: 0.9% (0.2–1.5)	
APHEA 1 (Samoli *et al*., 2001; 2003)	Western Europe: 2.6% (2.1–3.1)	Restricting data range below 150 or 200 μg m^{-3} increased sulphur dioxide risk estimates
12 European cities, using national splines rather than sine/cosine to adjust for temporal trends	Central and eastern Europe: 0.7% (0.0–1.4)	
EMECAM (Ballester *et al*., 2002) (GAM[a] study), 13 Spanish cities	2.5% (0.3–4.9), average of lag 0 and 1 d	—
NMMAPS (Samet *et al*., 2000; Dominici *et al*., 2003) 90 largest US cities	1.1% (0.5, 1.7) at lag 1 d	Adding copollutants reduced the estimate by ~20% and widened confidence bands
Stieb *et al*. (2002; 2003)	Non-GAM[a]	—
Meta-analyses	Single pollutant (29 studies): 1.7% (1.2–2.3) With copollutant(s) (10 studies): 1.6% (0.6–2.5) GAM[a]: Single-pollutant (17 studies): 2.0% (1.3–2.6) With copollutant(s) (11 studies): 1.6% (0.8–2.4)	

[a]GAM stands for generalized additive model: this caused problems in some time-series studies due to a 'glitch' in the software.
Reproduced from the World Health Organization, 2006.

tration of SO_2 likely to cause effects on the airways of asthmatic subjects lies between 100 and 400 ppb (286–1144 μg m^{-3}), with effects towards the lower end of this range being unlikely (Linn *et al*., 1983). Recent work by Tunnicliffe *et al*. (2001) has shown that exposure to 200 ppb (572 μg m^{-3}) SO_2 can produce changes in indices of HRV. Oddly, the changes differed in normal and asthmatic subjects. No lung function changes were observed in either group. Amongst asthmatic subjects the high-frequency component of HRV was reduced—in a clinical setting this would be seen as a deleterious effect—its significance in asthmatic patients is unknown. Whilst considering the effects of SO_2 in man it is important to recall that on exposure to effective concentrations of SO_2 bronchoconstriction appears rapidly—generally within minutes. It does not then increase as exposure is continued. Thus this response is classically a C-dependent response, time (t) is relatively unimportant. Animal studies have contributed little to our knowledge of the effects of exposure to very low concentrations of SO_2. At 300 ppm (858 mg m^{-3}) ciliary slowing has been observed; in explanted human bronchial tissue this effect has been seen at 200 ppb (572 μg m^{-3}). Amdur (1986) showed that the effects of SO_2 were increased by simultaneous exposure of guinea pigs to ultrafine particles. It has been suggested that formation of H_2SO_4 on the surface of the zinc-rich particles may explain this effect.

10.1 Epidemiological Studies

10.1.1 Mortality Studies

Early work focussed on the SO_2–coal smoke mixture; the results of such work are now of limited relevance in developed countries where concentrations of SO_2 are generally low. Time-series studies have been undertaken and the results of a number of large studies and of a meta-analysis are shown in **Table 9**.

More important, perhaps, than the time-series approach has been the intervention study reported from Hong Kong

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat089

Table 10 Summary table based on meta-analysis of time-series studies

Pollutant (24 h average)	N	Outcome measure	Assessment	Random effects (95% CI) (% change per 10 μg m^{-3})
SO_2	67	CV mortality	+	0.8 (0.6, 1.0)
SO_2	7	CV admissions	+	0.6 (0.1, 1.2)
SO_2	18	Cardiac admissions	+	2.4 (1.6, 3.3)
SO_2	10	IHD admissions	+	1.2 (0.5, 1.9)
SO_2	5	Heart failure admissions		0.9 (−0.1, 1.8)
SO_2	7	Cerebrovascular admissions		0.3 (−0.5, 1.1)

Reproduced from the World Health Organization, 2006.

Table 11 Sulphur dioxide air quality guidelines and interim targets to be achieved in improving air quality

	24 h average	10 min average
WHO interim target 1 (IT-1) (2000 guideline level)	125 μg m^{-3}	—
WHO interim target 2 (IT-2)	50 μg m^{-3} Intermediate goal based on controlling either: (i) motor vehicle, (ii) industrial emissions and/or (iii) power production; this would be a reasonable and feasible goal to be achieved within a few years for some developing countries and lead to significant health improvements (such as aiming for the guideline).	—
WHO air quality guidelines	20 μg m^{-3}	500 μg m^{-3}

Reproduced from the World Health Organization, 2006.

by Hedley *et al*. (2002). In this work the concentration of SO_2 fell from 44 to 21 μg m^{-3} but PM_{10} concentrations were unchanged. Now both 44 and 21 μg m^{-3} are low concentrations of SO_2; low in comparison with concentrations used in chamber studies and extremely low in comparison with historical concentrations in, for example, London. But effects were found: the average annual trend in death rate (increasing as the population ages) fell by 2.1% (respiratory deaths: 3.9%; cardiovascular: 2.0%). At the same time as SO_2 levels fell, so did the vanadium content of particles. Whether this was important is unknown, but the point is raised in view of Lippmann's perceptive work regarding the importance of nickel in particles in New York (Lippmann *et al*., 2006).

10.1.2 Morbidity Studies

The intractable problem of surrogacy has bedevilled work on SO_2 as on other air pollutants. Lippmann *et al*. (2006) noted:

> *Interestingly, many of the researchers, in their discussions when sulfur dioxide associations were found, did not often interpret these sulfur dioxide associations with mortality or morbidity as causal but rather as 'artefact', and suggested that sulfur dioxide was acting as a 'surrogate' for a source type. The reasoning offered for the sulfur dioxide levels being 'too low' to be causal was based on prior knowledge. This situation highlights a limitation of the observational studies, the 'surrogate' interpretation, that is, that sulfur dioxide represents a source type (e.g. coal-fired power plant), or a mixture that can affect health through a co-pollutant (e.g. PM), or through pollutants that it is converted into (i.e. sulfuric acid and sulfates). Yet another interpretation is that PM becomes more toxic when sulfur dioxide coexists and gets adsorbed onto PM surfaces.*
>
> *Source: (Reproduced by kind permission of the World Health Organization)*

These problems have stemmed from a lack of confidence in effects of SO_2 at very low concentrations—so low that certainly no effects would be expected in chamber studies using sensitive asthmatic subjects. We shall come back to this point later. Meta-analysis of time-series studies linking SO_2 with effects on the cardiovascular system has shown that clear effects occur. The results of the analysis are shown in **Table 10**.

Perhaps surprisingly Spix *et al*. (1998) failed to find a consistent association between SO_2 concentrations (24 hour averages) and respiratory admissions to hospital. Atkinson *et al*. (2001) did find such an association.

Table 12 Selected studies relating ambient variations of ozone concentrations to short-term mortality

Location	End point	Other pollutants considered	Observed effect	Reference
London	Total mortality, mortality in people >70 years, and cardiovascular and respiratory mortality	Black smoke, sulphur dioxide and nitrogen dioxide	An increase of 8 h ozone from the 10th to the 90th percentile of the seasonal change (14–72 μg m^{-3}) was associated with increases of 3.5, 3.6 and 5.4% in all cause, cardiovascular and respiratory mortality, respectively	Anderson *et al*. (1996)
Rotterdam	All causes (excluding accidents)	Black smoke, sulphur dioxide and carbon monoxide	RR[a] 1.06 for a change of 67 μg m^{-3} ozone. Black smoke also exhibited positive association with mortality	Hoek *et al*. (1997)
Eleven cities in Europe	Respiratory, cardiovascular and digestive (used as control)	Sulphur dioxide, nitrogen dioxide and different indicators of PM	A 50 μg m^{-3} increase in 8 h ozone was associated with cardiovascular (RR 1.02) and respiratory (RR 1.06) mortality. Positive results for black smoke and sulphur dioxide	Zmirou *et al*. (1998)
Meta-analysis of studies conducted in several European cities	All causes (excluding accidents), respiratory disease and cardiovascular disease	—	A 10-μg/m^3 increase in ozone was associated with a RR of 1.003 (1.001–1.004) for all-cause mortality and 1.004 (1.003–1.005) for cardiovascular mortality. The RR for respiratory mortality was 1.000 (0.996–1.005)	Anderson *et al*. (2004)
Fourteen communities in the USA	All causes (excluding accidents), respiratory and cardiovascular disease	PM_{10}	A 20 μg m^{-3} increase in hourly ozone was associated with a 0.23% (CI 0.01–0.44) increase in the risk of death	Schwartz (2005)
Meta-analysis of 144 effect estimates from 39 time-series studies	All causes (excluding accidents), respiratory disease and cardiovascular disease	PM_{10} or $PM_{2.5}$	A 10 μg m^{-3} increase in ozone was associated with a 0.87% (0.55–1.18) increase in total mortality for all seasons and 1.34% increase (−0.45 to 3.17) in the warmer season. For cardiovascular disease, the same increment of ozone was associated with a 1.1% (0.68–1.53) increase during all seasons and a 2.45% increase (0.88–4.1) in the warmer season	Bell *et al*. (2005)

10.2 Long-term Exposure Studies

Reanalysis of the ACS study (see above) by Krewski *et al*. (2000) showed that long-term concentrations of SO_2 were associated with all-cause mortality. Very interestingly, the results were not removed when adjustments for $PM_{2.5}$ and SO_4^{2-} were made. That SO_2, $PM_{2.5}$ and SO_4^{2-} covary in some areas is certain and separation of true causal factors by statistical analysis may be impossible. But the possibility that SO_2 may itself be playing a role remains. Less easy to interpret is the finding from the Adventist Health Study of Smog (AHSMOG) cohort (Abbey *et al*., 1999). In this study SO_2 was found to be related to lung cancer in males and females. That SO_2 is acting as a surrogate for some more obviously carcinogenic component of the ambient air pollution complex seems likely.

10.3 Conclusions

Thinking about SO_2 has changed dramatically during the last 10 or so years. It is now believed that daily variations in already low concentrations affect both deaths and morbidity (cardiovascular and respiratory). In addition, it seems clear from the study in Hong Kong that reducing concentrations of SO_2 is beneficial to health. All this has led WHO to recommend the following Air Quality Guidelines and targets, as shown in **Table 11**.

11 OZONE

We have already noted that O_3 is an outdoor air pollutant, indeed exposure indoors is unlikely because of the rate at which O_3 reacts with furnishings and fittings, and because there are no indoor sources. The last point is true if we except photocopiers and electric motors. O_3 is an unusual air pollutant in that concentrations are rising. In the UK this is due to a slow upward drift of the so-called hemispherical background concentration caused by increased production of volatile organic compounds by developed countries and, in urban areas, by a decline in production of NO by motor vehicles. O_3 concentrations tend to be higher in rural than urban areas, but can be high in suburban areas also. Concentrations in the UK seldom exceed 120 ppb (240 μg m^{-3}), though in Mexico City and São Paulo concentrations can exceed 200 ppb. Concentrations are higher in summer than winter and fall during the night. Peak levels are usual reached in the afternoon. In fact, two peaks can often be seen: the first due to local production and the second due to long-range transport. This is clearly shown by Lippmann (2000). The rather broad afternoon peak in O_3 concentrations and the fact that responses to O_3 are about equally dependent on C (concentration) and on t (duration of exposure) has led to the daily-peak-eight-hour-average concentration being used as a basis for the WHO Air Quality Guideline (World Health Organization, 2006). Personal exposure to O_3 is not closely correlated with outdoor O_3 concentrations and studies linking outdoor concentrations with effects on health are likely to underestimate the 'real' exposure–response relationship. The study of the effects of O_3 on health has been advanced by both studies in volunteers and epidemiological studies. The database is now vast: in the WHO Air Quality Guidelines published in 2006 a separate appendix was needed in which to present a synopsis of the evidence.

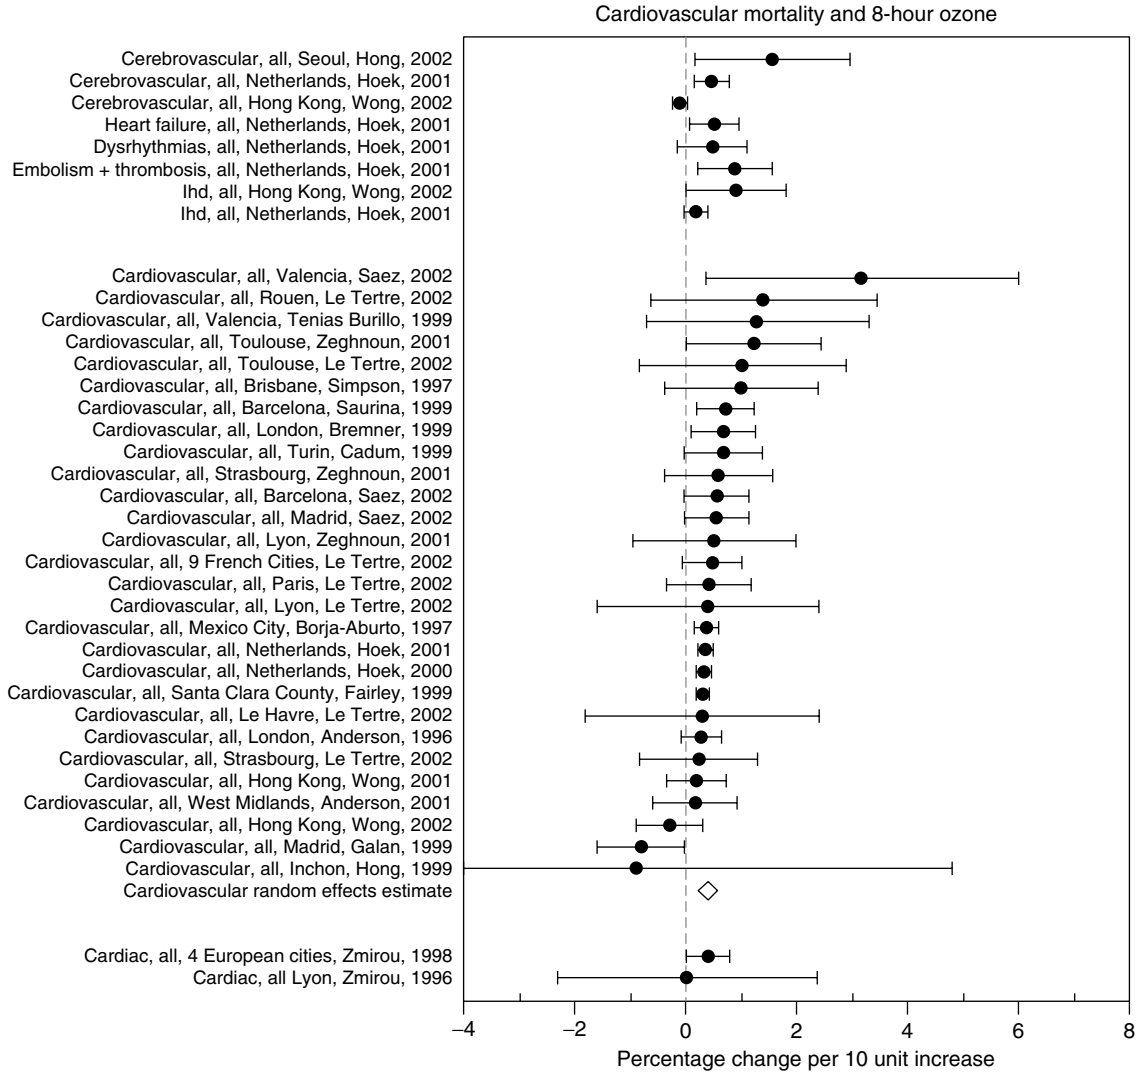

Figure 9 Cardiovascular mortality and eight hour ozone. (Reproduced from the World Health Organisation, 2006.)

11.1 Epidemiological Studies

Time-series studies have linked O_3 with mortality (respiratory rather than cardiovascular) and with indices of morbidity (respiratory and cardiovascular). The World Health Organization (2006) report listed 31 key studies and meta-analyses linking short-term exposure to O_3 and mortality. An abbreviated table is provided here (**Table 12**).

Once again, the weight and consistency of the evidence is impressive. The results of a meta-analysis undertaken from COMEAP in the UK are shown in **Figure 9**.

For morbidity the evidence is more mixed: many studies show no effect. **Figure 10** shows this as regards cardiovascular and one hour peak O_3 concentration.

The pictures for eight and 24 hour average O_3 concentrations are hardly more persuasive (see **Figures 11** and **12** below).

The results of these meta-analyses are summarized in **Table 13**.

Now this is surprising. The association between O_3 and cardiovascular mortality is firm, but associations with indices of cardiovascular morbidity are not. This casts some doubt on the causal nature of the association with cardiovascular mortality: the association is not supported by coherent results regarding other end points. For respiratory effects the picture is clearer: associations with respiratory mortality and indices of respiratory morbidity are firmly established. O_3 has also been shown to be associated with symptoms in asthmatic children (Gent *et al.*, 2003; Mortimer *et al.*, 2002).

11.2 Long-term Exposure to Ozone

Cohort studies are less helpful as regards O_3 than other pollutants. Extension of the ACS cohort study, see above, showed an association between long-term O_3

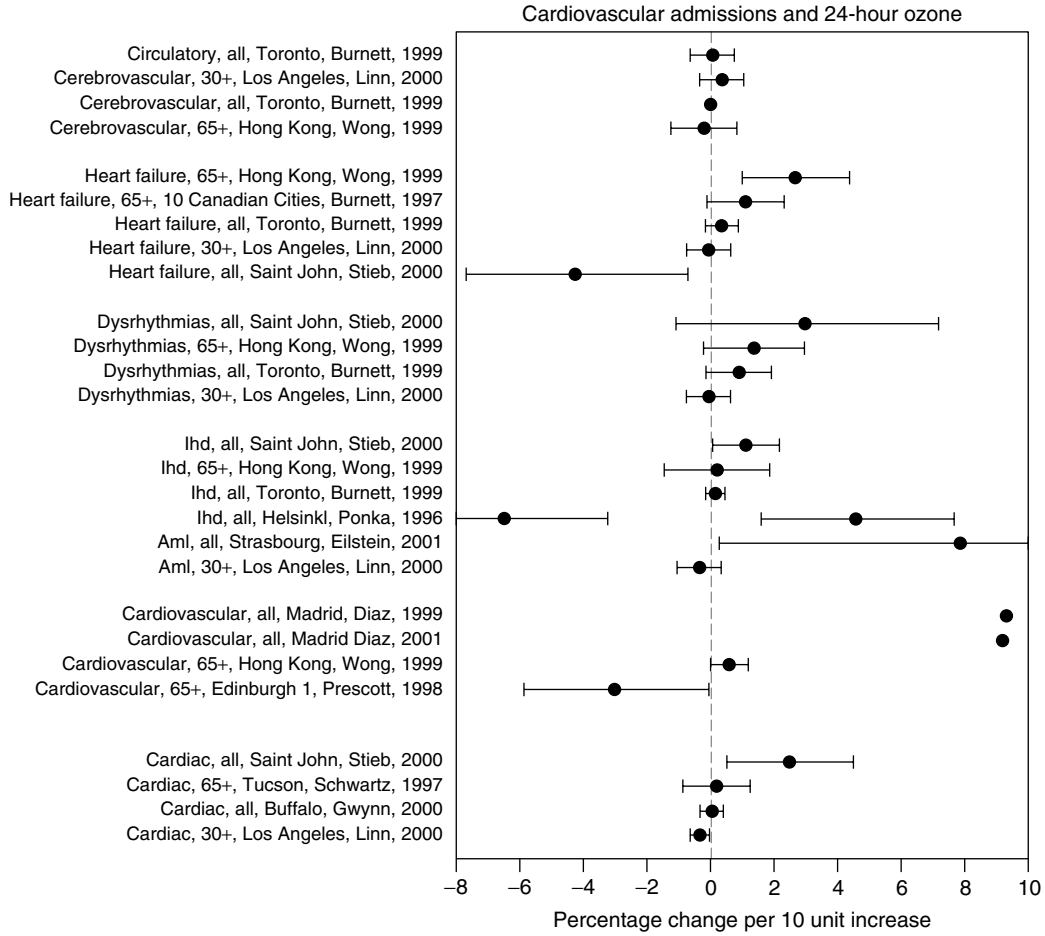

Figure 12 Cardiovascular admissions and 24 hour ozone. (Department of Health, 2006.)

Table 13 Summary table based on meta-analysis of time-series studies

Pollutant (24 h average)	N	Outcome measure	Assessment	Random effects (95% CI) (% change per 10 μg m^{-3})
O_3 8 h average	26	CV mortality	+	0.4 (0.3, 0.5)
O_3 8 h average	8	CV admissions		0.1 (−0.5, 0.4)
O_3 8 h average	6	IHD admissions		−0.1 (−0.7, 0.4)

CV, cardiovascular mortality; IHD, ischaemic heart disease.

concentrations and risk of death from cardiopulmonary disease (Pope *et al*., 2002). But a study of those people in the ACS cohort living in southern California failed to find this effect (Jerrett *et al*., 2005). The AHSMOG cohort study found an association with lung cancer in men (not in women) (Abbey *et al*., 1999). No association with lung cancer has been reported from the ACS cohort study.

Growing up in high O_3 areas seems to retard and reduce development of normal levels of lung function. One study reflects the effect: Galizia and Kinney (1999) studied first year students at Yale and stratified them according to O_3 levels in the areas in which they had grown up. FEF_{25-75} (forced midexpiratory flow) was 8.11% (range: 2.32–13.9%) higher in those growing up in the lowest as compared with the highest O_3 areas. The difference between lowest long-term (mean of daily one hour maximum) concentration was about 300 μg m^{-3} (150 ppb).

11.3 Toxicological Studies in Experimental Animals and Man

O_3 is a reactive oxidant gas, but is rather insoluble in water. Thus it penetrates deep into the lung and peak

Table 14 Ozone air quality guideline and interim target

	Daily maximum 8 h mean	Effects at the selected ozone level
High level	240 μg m^{-3}	Significant health effects; substantial proportion of vulnerable population affected
WHO interim target 1 (IT-1)	160 μg m^{-3}	Important health effects; an intermediate target for populations with ozone concentrations above this level. Does not provide adequate protection of public health ***Rationale*** Lower level of 6.6 h chamber exposures of healthy exercising young adults, which show physiological and inflammatory lung effects. Ambient level at various summer camp studies showing effects on health of children. Estimated 3–5% increase in daily mortality[a] (based on findings of daily time series studies)
WHO air quality guideline	100 μg m^{-3}	This concentration will provide adequate protection of public health, though some health effects may occur below this level. ***Rationale*** Estimated 1–2% increase in daily mortality[a] (based on findings of daily time series studies). Extrapolation from chamber and field studies based on the likelihood that real-life exposure tends to be repetitive and chamber studies do not study highly sensitive or clinically compromised people or children. Likelihood that ambient ozone is a marker for related oxidants.

[a]Deaths attributable to ozone concentrations above an estimated baseline of 70 μg m^{-3} (based on 0.3–0.5% increase in daily mortality for 10 μg m^{-3} 8 h ozone.
Reproduced from the World Health Organization, 2006.

tissue doses (μg μm^{-2} surface) occur at the terminal bronchiole (Miller *et al*., 1993). The oxidative nature of O_3 leads to consumption of antioxidants, including glutathione, ascorbic and uric acids. O_3 also affects pain receptors in the airways and deep inspiration is impaired. Exercise increases the tissue dose of O_3 and thus lowers the concentrations needed to produce specified effects. The database on the toxicology of O_3 is vast (see above) and only the solidly established relationships and mechanisms are listed below. This is derived from the (World Health Organization, 2006) report. For detailed information the reader is referred to Lippmann (2000) and World Health Organization (2006) (Appendix listing studies on O_3) and, for older work, to the report published by the Advisory Group on the MAAPE in 1991 (Department of Health, 1991).

Established effects on lung function and inflammation are:

1. Short-term exposure impairs lung function
2. Chamber studies show that exposure to 80 ppb (160 μg m^{-3}) for 6.6 hours with exercise, causes a reduction in indices of lung function such as FEV_1 and thus reflects an increase in airway resistance
3. Asthmatics are more sensitive to O_3 than are other subjects
4. Inflammatory responses (increase in neutrophils, up-regulation of inflammatory cytokines and adhesion molecules accompany the changes in indices of lung function and may persist for some days following a single exposure
5. Exposure to O_3 increases airway responsiveness to other challenges
6. Studies outdoors show effects at lower levels of O_3 than those used in chamber studies. This may be due to coexposure to other pollutants.

11.4 Conclusions

Exposure to O_3 at ambient concentrations has significant effects on health. These reflect both short-term and long-term exposure. The evidence has led WHO to recommend the following targets and guidelines as shown in **Table 14**.)

Indoor Air Quality

Rikke B. Jørgensen, Sten O. Hanssen, Jan V. Bakke and Ellen K. Jensen

CONTENTS

1 INTRODUCTION

Human physiology is not adapted to the climatic conditions found in temperate and polar latitudes, although parts of these regions have been populated for several 1000 years. The ideal ambient temperature for a naked person at rest is about 29 °C, a climatic condition found in the mountain and savannah regions of Africa, the probable origin of our ancient ancestors (Åstrand and Rodahl, 1986). Without clothing and shelter, man could be regarded as a tropical animal that can only survive in a narrow zone along the equator. When our forefathers migrated north, not only was proper clothing needed, but a protective climatic shield also had to be developed: housing and building technology were adapted to very challenging winter climates. Originally, we were also biologically adapted to continuous supplies of fresh outdoor air for breathing and keeping our bodies cool. The term 'indoor environment' is a consequence of the need for shelter against wild animals and, as mankind moved to more weather-beaten areas, against unfavourable outdoor climates. Indoor air quality, however, depends on a number of factors, including the outdoor air quality, the amount of fresh air provided indoors and the amount of air pollution derived from numerous indoor sources. On average, an adult male with a sedentary occupation will breathe about 15 m^3, or roughly 15 kg of air, drink 1.5 l or 1.5 kg of water, and eat about 0.75 kg of solid food per day. Hence, the weight of breathed air constitutes about 87% of the total mass of human exposure every 24 hours.

Clothing and a building envelope provide two vital levels of shelter between the human organism and its surroundings. Indoor environments are not only vital for our survival, health and wellbeing, but also constitute the greater part of human environmental exposure. The world's first Public Health Act was the British Act in 1848 (UK, 1848), which was a direct result of the *Report on the Sanitary Conditions of the Labouring Population and on its Means of Improvement* (Chadwick, 1842). Basic requirements for healthy built environments had been well established thanks to the health and hygiene movements during the 100 years before 1850. Their implementation over the next 100 years provided the conditions needed for the remarkable improvements

in general health and living standards seen in modern welfare states. These are:

1. Dry building land and dry dwellings
2. Good cleaning and adequate ventilation
3. As much access as possible to sunlight and full daylight (bactericidal effect)
4. Smallest possible risk of accumulation of waste, dust and other pollutants by suitable choice of materials and design of interiors, furniture and furnishings
5. Fast and safe removal of all refuse and garbage by skillfully executed and maintained drains and sewers, rational cleaning methods
6. Abundant access to clean and pure water.

2 HUMAN HEALTH

2.1 Current General Population Exposure Time

People often spend less than 10% of their time outdoors. More than 90% is spent indoors, 65% at home, most of this usually in bedrooms, 20% in other premises outside homes and a further 5% in vehicles (WHO, 1999). The working population typically spends about 20% of its time at work, and an increasing proportion of employees have their work places in nonindustrial environments.

2.2 Vulnerable Groups

In a statement from the World Allergy Organization on World Allergy Day, 8 July, 2005, it was emphasized that allergic diseases affect 22% of the world's population. People with asthma, allergies and other hypersensitivities are particularly vulnerable to inferior indoor environments (Leira *et al*., 2006). Compared to those who are nonallergic, a higher percentage of allergic people suffer from sick building syndrome (SBS) symptoms and complain about perceived annoyances in the indoor environment (Lundin, 1999). Allergic disease is the only group of diseases currently increasing among children in Western and developed societies. Asthma is, at present, the most common chronic disease during childhood, and in most Western countries the commonest cause of admission to hospital among children, representing up to 25% of admissions to paediatric departments in many countries (EEA, 2007). The increase of asthma and allergies in the younger population in Europe will increase the proportion of vulnerable individuals in the future work force. A 2.4-fold increased risk of suffering from asthma among adults born in 1966–1971, compared to those born in 1946–1950, was reported in studies performed in 15 industrialized countries (Sunyer *et al*., 1999). The increase occurred concurrently in most of the countries, in both males and females, and affected the onset of asthma in both childhood and adulthood. Prevalence of chronic obstructive lung diseases (bronchitis, emphysema and asthma) is increasing all over the world (WHO, 2007a), and those affected suffer more in poor indoor conditions. Good environments are particularly important for the health of such people and in preventing early retirement due to disability.

2.3 Health Effects Associated with Indoor Exposures

In recent years, there has been an accumulation of knowledge concerning the effects on health cased by exposure to agents present in indoor air, known as indoor air pollutants (WHO, 1982; 1999). Nonindustrial indoor environments are usually characterized by exposure to a complex mixture of a large number of different agents at very low exposures, mostly far below any known threshold level of biological effect. When assessing risk, it is also important to bear in mind that one effect may be caused by many different exposures, and that one exposure might cause many different effects.

2.3.1 Building-Related Illness (BRI)

Building-related illness (BRI) refers to building-related exposure to indoor contaminants. Infectious and irritative respiratory diseases, respiratory allergies (for example, to house dust mites, animal fur and dander), asthma and mucous membrane irritation are the most prevalent illnesses that have been associated with indoor exposures.

2.3.2 Respiratory Allergies and Hypersensitivity Conditions

Allergic and nonallergic asthma, rhinitis and conjunctivitis can be caused or aggravated by exposures in indoor environments. The conjunctiva of the eyes reacts in the same way as the airways, in terms of the environmental sensitivity and hypersensitivity of the conjunctiva, since symptoms can occur simultaneously in the airways and in the eyes, and can be caused by the same agents.

Respiratory effects of pollutants can, to a certain extent, be predicted by considering where the air pollutants are most likely to be deposited in the airways. Particles $<5\,\mu m$, such as allergens from house dust mites and pets, can be carried down to the peripheral part of the lung, inducing or eliciting asthma. Nanoparticles, typically formed in combustion processes, are efficiently deposited by diffusional mechanisms to all regions of the respiratory tract (Donaldson *et al*., 1998;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat090
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Johnston *et al*., 2000; Oberdörster *et al*., 2005). Coarser particles >10 μm, such as pollen, tend to affect the eyes and upper airways, eliciting allergic rhinoconjunctivitis. Hydrophilic (water soluble) gases, such as sulphur dioxide (SO_2), ammonia (NH_3) and formaldehyde, tend to deposit in and primarily affect upper airways, not reaching the lungs, but producing powerful sensory irritation. Hydrophobic gases, such as nitrogen dioxide (NO_2), can strongly affect the lungs, while only conveying minor warnings with sensory effects to the eyes and upper airways.

2.3.3 Respiratory Infections

Modern epidemiological data on the association between dampness in buildings, indoor moulds and airway infections is limited, although the association was already well-known in the 18th and 19th century. Increased proneness to general respiratory infection is associated with poor indoor climate, particularly in association with dampness in buildings, environmental tobacco smoke (ETS) and exposure to combustion gases, but also to low ventilation rates in combination with crowding, such as in kindergartens, schools and barracks.

Legionellosis is an infection caused by the Gram-negative bacteria *Legionella*, usually by *Legionella pneumophila* (WHO, 2007b). This is a ubiquitous aquatic organism that thrives in warm environments (25–45 °C with an optimum around 37 °C) and causes over 90% of Legionnaires' disease cases. Pontiac fever is a milder respiratory illness without pneumonia caused by the same bacterium. Legionellosis usually occurs as single, isolated cases not associated with any recognized outbreak. When outbreaks do occur, they are usually recognized in the summer and early autumn, but cases may occur at any time of the year.

2.3.4 Other Respiratory Illnesses

Humidifier fever usually develops on a Monday or the first workday of the week, and has mostly been associated with humidifiers in printing offices, but has also been observed in office buildings. The hallmark of the disease is the sudden onset of fever. Other features may include muscle aches and pains and mild shortness of breath. Humidifier fever can be caused by a number of different agents including amoebae, bacteria and fungi living in the moist environment of a humidifier. Humidifier fever typically disappears once the patient is no longer exposed to the causative agent coming from the humidifier.

2.3.5 Cancer

Asbestos and benzene are known carcinogens, but exposure is now practically nonexistent. An increased risk of developing lung cancer has been linked to exposure to ETS, and to radon decay products (WHO, 2000). In areas with high radon exposure, up to 10–15% of all lung cancers occurring in the population may be attributable to indoor radon exposure (WHO, 2000). With regard to ETS, it has been estimated that nonsmokers living with smokers have about 30% increased risk of contracting lung cancer when compared to the nonexposed population. ETS has recently been almost eliminated in the working environment of most Western countries.

2.3.6 Other Illnesses

The effects of indoor air pollutants on reproduction, cardiovascular disease, as well as other systems and organs have not been well documented to date. To a certain extent, this may indicate that no serious effects occur. However, there has been very limited research to document the absence of such effects. A current issue is the use of plastic additives in the indoor environment, including flame retardants and plasticizers to which exposure has increased dramatically since World War II (Bornehag *et al*., 2004a). Animal studies have shown that some phthalates affect male reproductive development. Nanoparticle studies have shown that nanoparticles can cross cell barriers end enter into blood and lymph circulation to reach potentially sensitive target sites such as bone marrow, lymph nodes, the spleen and the heart (Oberdörster *et al*., 2005). Health effects associated with such distribution of nanoparticles are mostly unknown. Recent publications associate exposure to nanoparticles with cardiac disease (Weichenthal *et al*., 2007; Chuang *et al*., 2007), and there is an increasing number of other health-effect studies ongoing (see **Nanotoxicology-The Toxicology of Nanomaterials**).

2.3.7 Sensory Irritation, Sick Building Syndrome (SBS)

SBS consists of a group of general, mucosal and skin symptoms that are related to the time spent in particular buildings (WHO, 1982; Burge, 2004). Building occupants complain of symptoms such as irritation to eye, nose or throat, dry cough, dry or itchy skin; headache and concentration difficulties; dizziness and nausea; fatigue, as well as increased sensitivity to odours. Various factors in the indoor air environment, including dampness, temperature, thermal conditions and particle pollutants, have been suggested as causes of these symptoms. Other factors that may significantly affect the indoor environment include ventilation rates, ETS, combustion products, formaldehyde and volatile organic compounds (VOCs).

SBS is strongly related to mental stress at work (Runeson *et al*., 2004; Marmot *et al*., 2006). Mental stress has even been shown to be more important than the physical environment in explaining prevalence of SBS (Marmot *et al*., 2006). Psychosocial and personal reasons also dominated in mucus-membrane irritation symptoms and general symptoms among teachers in state schools

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat090

when comparing 'moisture-damaged' and 'nondamaged' schools (Ebbehøj *et al*., 2005). Negative psychosocial work factors have been associated with the risk of contracting various illnesses, especially psychosomatic disorders. High demands at work together with low social job control and low job support are combinations of mental factors that may cause various negative effects on health (Theorell and Karasek, 1996).

2.3.8 Multiple Chemical Sensitivity (MCS)

Multiple chemical sensitivity (MCS) is described as a condition in which a person reports sensitivity or intolerance (as distinct from 'allergy') to a number of chemicals and other irritants at very low concentrations. There are different views among medical professionals about the existence, causes, diagnosis and treatment of this condition (EPA (Environmental Protection Agency), 2008). MCS has also been called toxic injury, chemical sensitivity, chemical injury, idiopathic environmental intolerance and toxicant-induced loss of tolerance. The cause and existence of MCS are disputed, and in particular, medical doctors disagree about whether symptoms are physiologically or psychologically generated, or both (Wikipedia, 2008). However, in view of the fact that numerous people all over the world claim that they suffer from a chronic condition characterized by several adverse and variable affects from exposure to very low levels of substances in modern human environments, it is not wise totally to disregard the existence of MCS. MCS is further discussed in **Multiple Chemical Sensitivity: Toxicological Questions and Mechanisms**.

2.4 What are the Most Important Effects Associated with Indoor Environments?

The most important effects on public health are probably allergic respiratory sensitization, aggravation of allergic diseases, increased susceptability to respiratory infection and worsening of chronic obstructive lung diseases. Respiratory diseases, asthma and allergy have mainly been associated with the indoor environment in residential buildings, while a limited number of reports are related to exposure in nonindustrial occupational environments. Reported respiratory illnesses seem mainly to be associated with exposure in damp buildings (Savilahti *et al*., 2000; Rudblad *et al*., 2004; Patovirta *et al*., 2004). Heating and cooking with gas and charcoal, ETS, and cleaning and washing products have also been associated with asthma (Viegi *et al*., 2004). Most effects of indoor environments are results of complicated interactions between several exposures, and combinations of these are difficult to study. Indications of dampness, as well as recently repainted interior surfaces, appeared to be associated with recurrent infant wheezing, with a strengthened effect due to combined indoor exposures (Emenius *et al*., 2004). Family lifestyles, according to preventive guidelines regarding breastfeeding, maternal tobacco smokers and home dampness, were synergistically associated with reductions of recurrent wheezing and asthma at two years of age (Wickman *et al*., 2003).

The most prevalent adverse effects of inferior indoor work environments are thus respiratory infectious diseases, mucosal, respiratory and skin irritation, including aggravation of allergies and other hypersensitivity symptoms, general symptoms, including headache and fatigue, as well as reduced comfort, performance and productivity (Wargocki *et al*., 2000; Wyon, 2004). Interactions and synergies among several exposures are probably important.

3 POLLUTANTS OF IMPORTANCE FOR INDOOR AIR QUALITY

The pollutants in indoor air belong to two different groups, particles and gases. These groups have different characteristics and behaviour, and partly different sources of origin. In the following the two groups of pollutants are described separately. The toxic effects of VOCs (gases and solvents) is further discussed in chapters on organic solvents (**Organic Solvents**) and the nervous system (**Neurotoxicology**).

3.1 Gases

Gases are further divided in two groups, namely the organic gases and the inorganic gases. Gas concentrations can be expressed in mass per volume of air ($\mu g\,m^{-3}$) or parts per volume, ppm (parts per million). The most typical inorganic gases in the indoor air are carbon monoxide (CO), nitrogen dioxide (NO_2), carbon dioxide (CO_2) and ozone (O_3) as shown in **Table 1**. Important organic gases are VOCs, including formaldehyde, phthalates and flame retardants as shown in **Table 2**.

3.1.1 The Combustion Gases, Carbon Monoxide and Nitrogen Dioxide

CO is a colourless, odourless and tasteless gas. $1\,ppm = 1.145\,mg\,m^{-3}$, $1\,mg\,m^{-3} = 0.875\,ppm$. CO is produced from the incomplete combustion of carbon-containing fuel. The amount of CO in the indoor air originates mainly from infiltration of CO from the outdoor air and indoor sources of CO like tobacco smoking, cooking and combustion of fossil fuels. CO is only formed during incomplete combustion, which often take place when the appliances are not well maintained, or when there is not enough fresh air supply (Lebret, 1985).

Table 1 Sources for inorganic gases in indoor air

Chemical	Source	I/O
CO	Incomplete combustion (automobiles, cigarette smoke, heaters)	>1
CO_2	Exhaled air, combustion (cars)	≫1
NO_2	Combustion (automobiles, gas heaters, cigarette smoke)	<1
O_3	Photocopiers, laser printers	<1

I/O is the indoor to outdoor concentration ratio.

Table 2 Sources for organic compounds in indoor air

Chemical	Source	I/O
VOC	Building materials, furniture, paint, surface treatment, microbiologic sources, household and consumer products	>1
Formaldehyde	Chipboard, woodproducts, insulation foam, furniture, paint, cleaning products, cosmetics, clothing, carbonless copy paper, and tobacco smoke	>1
Phthalates	Plasticized products	>1
Flameretardants	Plastics, rubbers and household textiles, computers, TVs and other electronic equipment	>1

I/O is the indoor to outdoor concentration ratio.

NO_2 is a reddish-brown gas with a characteristic sharp, biting odour. $1\,\text{ppm} = 1.88\,\text{mg}\,\text{m}^{-3}$, $1\,\text{mg}\,\text{m}^{-3} = 0.532\,\text{ppm}$. NO_2 is one of several nitrogen oxides. The two most important nitrogen oxides are NO_2 and nitrogen monoxide (NO). These oxides are produced during combustion, especially combustion at high temperatures.

Indoor sources may be gas stoves, cigarette smoke and cooking. Elevated indoor levels of NO_2 have been associated with the use of domestic gas appliances (Dennekamp *et al*., 2001; Melia *et al*., 1990). Willers *et al*. (2006) concluded from comparison with older data that in most new homes, removal of NO_2 formed during gas cooking is more efficient than it was in home studies in the early and mid 1980s.

CO and NO_2 are, together with particles (mentioned in Section 3.3), the most important pollutants released from combustion processes. Increased risk of respiratory diseases associated with improperly vented, poorly ventilated or malfunctioning combustion appliances, occurs widely in developing countries (WHO, 1999; 2002; Viegi *et al*., 2004; Naeher *et al*., 2007). Such appliances even pose a real risk of acute poisoning by CO. Combustion products and pollution from heating systems and cooking using coal, wood, kerosene and gas have also been associated with respiratory health effects in developed countries. Pupils with asthma improved considerably when unflued gas heating was replaced by either flued gas or electric heating in a randomized controlled study (Pilotto *et al*., 2004). Use of gas stoves and wood-burning stoves/fireplaces was associated with aggravation of the disease among adult asthmatics (Ostro *et al*., 1994). Unvented gas space heaters, wood stoves and kerosene heaters were associated with respiratory symptoms among infants and women living in nonsmoking households (Thorn *et al*., 2001; Belanger *et al*., 2003; Naeher *et al*., 2007). Freestanding wood-burning stoves were associated with otitis (inflammation in the ear) among children (Daigler *et al*., 1991). The lowest risk of eczema was found in households with central heating systems and the highest where gas heaters were used (Schäfer *et al*., 1999). All indoor combustion sources must be properly vented to avoid indoor pollution from combustion gases.

Road tunnels, as well as underground and multistorey car parks are special types of indoor environments with a risk of high concentrations of CO. The ice arena is another example of a very special type of indoor environment where combustion engines are used under conditions of insufficient ventilation, with a risk of high CO levels (Hampson, 1996; Paulozzi *et al*., 1993).

Without indoor sources, the level of CO in buildings with mechanical ventilation systems depends of the location of the air intake of the ventilation system. If the air intake is placed directly against highly CO-polluted areas, for example parking places, public transport drop-off areas and locations where vehicles frequently stand at idling speed, there is increased risk of exhaust entering the air intake. Thus, this can lead to increased levels of CO in the indoor air. Another source is infiltration of CO from streets with high traffic intensity outside the building (Li *et al*., 2001).

3.1.2 Carbon dioxide

CO_2 is a colourless and odourless gas. $1\,\text{ppm} = 1.8\,\text{mg}\,\text{m}^{-3}$, $1\,\text{mg}\,\text{m}^{-3} = 0.56\,\text{ppm}$. CO_2 originates mainly indoors by exhalation air from people, but CO_2 is also produced during combustion, for example, wood-burning and smoking.

CO_2 does not affect the way people perceive the indoor air quality at the concentrations that normally occur in indoor air. The CO_2 concentration correlates, however, with emission of bioeffluents (e.g. body odour), and CO_2 measurements can be used in the indoor air context as an hygienic indicator of whether the air supply is sufficient for ventilation with regard to the number of occupants in the room.

3.1.3 Ozone

O_3 is a pale blue gas with a sharp, irritating odour. Conversion factor: $1\,\text{ppm} = 1.963\,\text{mg}\,\text{m}^{-3}$, $1\,\text{mg}\,\text{m}^{-3} = 0.509\,\text{ppm}$. O_3 in indoor air mainly originates from outdoor air.

Several types of office equipment are known to generate O_3, including photocopiers and laser printers (Hansen and Andersen, 1986; Tuomi *et al*., 2000a). Although various photocopying processes produce O_3, most manufacturers incorporate some type of filtration system (e.g. activated carbon filters) to reduce the amount of O_3 emitted to the surrounding air. Electrostatic air filters and electrostatic precipitators can also generate O_3.

Several companies currently offer O_3 generators that claim to remove chemical pollutants from indoor air. Such devices are promoted as being safe for indoor use, which implies O_3 concentrations of 100 ppb or less (Weschler, 2000). In a review Boeniger (1995) examined the use of O_3-generating devices for the purpose of improving indoor air quality. It was concluded that O_3 is not a practicable and effective means of improving indoor air quality, especially in light of the potentially serious risk to health of O_3.

3.1.4 Volatile Organic Compounds (VOCs)

VOCs as a group have been defined as organic compounds with boiling points from about 50 °C to about 260 °C (WHO, 1989). This interval was chosen for reasons of sampling and analytical capabilities rather than from the viewpoint of health effects (Wolkoff *et al*., 1997). **Table 3** lists WHO's definitions of VOCs, more volatile (VVOCs) and less volatile volatile organic compounds (SVOCs), as well as organic matter.

A great number of VOCs occur in the indoor air. In typical indoor environments 50–300 different organic compounds can be detected with today's analytical methods. The actual compounds detected and the concentrations that can be found vary from place to place, and from time to time, dependent of the pollution sources present, and the ventilation efficiency at the actual location. **Table 4** lists VOCs in indoor air measured in European and North American field studies.

The focus on VOC in the context of indoor air quality is mainly caused by speculation about their contribution to SBS, and the general availability of methods for sampling and analysing them. The concentration of each single compound is below the level where health effects have been demonstrated, and far below the threshold limit values (TLVs). Individual VOCs have been added together to comprise an entity called total volatile organic compounds (TVOCs) in order to characterize the pollutant load in terms of VOCs. In the early 2000s a new approach called organic compounds in indoor air (OCIA) was proposed for evaluation of VOCs in the indoor air (Wolkoff and Nielsen, 2001). OCIA included organic compounds as well as organic compounds on particles, in addition to intermediary species (e.g. organic radicals) and ionic species. Compounds of microbiological origin (e.g. glucans, endotoxins) are not part of OCIA. The molecular weights of OCIA were tentatively less than 1000 Da. The idea was to use an approach that included compounds with biological relevance.

During recent years attention has moved towards identification and quantification of the individual VOCs in order to evaluate the toxicological characteristics of each compound, for example, odour thresholds, irritation thresholds, carcinogenic potential, reprotoxic or mutagenic characteristics. The importance of concepts like TVOC and OCIA has consequently decreased. Mølhave stated in 2003 that the TVOC indicator can be used in relation to exposure characterization and source characterization, but for VOCs only, not as an indicator of other pollutants and their health effects (Mølhave, 2003).

The concentration of VOCs is substantially higher indoors than outdoors. This means that the most important sources of VOCs are in the indoor environment. The sources can be divided into stationary sources, like emission from building materials, and variable sources associated with human activities.

3.1.5 Formaldehyde

Formaldehyde is a colourless gas with the formula H_2CO. $1\,\text{ppm} = 1.2\,\text{mg m}^{-3}$, $1\,\text{mg m}^{-3} = 0.833\,\text{ppm}$. Formaldehyde is widely used in indoor materials and products. Chipboard, insulation foam and paint have been major sources, but during the last decade, the emission from such products has been reduced substantially in many countries. Formaldehyde is

Table 3 Classification of organic indoor pollutants

Classification	Abbreviation	Boiling point range		Vapour pressure (kPa)
		from °C	to °C	
Very volatile organic compounds	VVOCs	<0	50–100	>10E-2
Volatile organic compounds	VOCs	50–100	240–260	>10E-2
Semi-volatile organic compounds	SVOCs	240–260	380–400	10E-2–10E-8
Organic compounds associated with particulate (organic matter)	POM	>360	—	—

also found in urea–and phenol–formaldehyde resins, which are commonly used to treat paper products to increase wet strength. Formaldehyde is also used in permanent-press clothing, carpet backings, floor coverings and adhesive binders. Other sources for formaldehyde include furniture, cosmetics, cleaning products, carbonless copy paper and tobacco smoke (Marbury and Krieger, 1991).

In the past, a high formaldehyde concentration was often considered to be the cause of increased SBS symptom prevalence. The use of proper building products (ECA, 1989) and emission control strategies have resulted in lower formaldehyde concentrations in indoor air in most of the developed countries.

3.1.6 Phthalates

Phthalates are less volatile VOCs, so-called SVOCs (WHO, 1989). Phthalates are common contaminants in the indoor environment occurring both in house dust and in indoor air. Di(2-ethylhexyl)phthalate (DEHP) is the dominant component (Fromme *et al*., 2004; Øie *et al*., 1997; Rudel *et al*., 2003).

In a Norwegian study it was shown that the risk of bronchial obstructions among children was related to the presence of polyvinyl chloride (PVC) flooring in homes (Jakkola *et al*., 1999). The plasticizer DEHP is widely used in the production of PVC and vinyl chloride resins, and accumulates to a great extent in interior surfaces of buildings. This led Øie *et al*. (1997) to propose that phthalates may cause lung inflammation through their chemical similarity to prostaglandins, naturally occurring inflammatory agents. Lagercrantz *et al*. (2005) has further shown that controlled inhalation exposures to low levels of phthalates increased levels of exhaled nitric oxide, indicating lower airway inflammation, and Bornehag *et al*. (2004a) found associations between asthma and allergic symptoms in children and phthalates in house dust. Knowledge about the exposure to phthalates and consequent health effects is still insufficient. Seeing that the use of plasticized products and consequently exposure to phthalate esters has increased dramatically since the end of World War II, and that phthalates have been demonstrated in indoor dust, more knowledge about the health risks of this exposure is required.

3.1.7 Flame Retardants

Flame retardants are widely used in plastics, rubbers and textiles to prevent or retard the initial phase of a developing fire. Organic flame retardants consist primarily of brominated compounds, halogenated and nonhalogenated phosphorous compounds, and chloroparaffins. Aluminium trihydroxide, magnesium dihydroxide and antimony trioxide (as synergistic to brominated flame retardants) are applied as inorganic flame retardants. Apart from the positive characteristic of being fire protective, several flame retardants also have negative effects on health and the environment. In 2003, the flame retardants pentabromodiphenylether (penta BDE) and octabromediphenylether (octaBDE) were banned by European Directive 2003/11/EC (European Parliament and Council, 2003).

This has lead to focus on measurements of flame retardants in products, and in the indoor environment. Brominated flame retardants, like penta and tetrabrominated diphenyl ethers, represent a new type of contaminant in indoor air (Rudel *et al*., 2003). Experimental studies have demonstrated the potential for products to emit flame retardants and degradation products (Carlsson *et al*., 1997; 2000; Salthammer *et al*., 2003). Many of these flame retardants and plasticizers have been found in indoor air (Carlsson *et al*., 1997; Rudel *et al*., 2003) and dust (Marklund *et al*., 2003; Rudel *et al*., 2003).

Knowledge about the exposure to flame retardants in indoor air and consequently knowledge of health effects is still insufficient (McDonald, 2002; Siddiqi *et al*., 2003). Seeing that the use of flame retardants has increased dramatically, and that flame retardants are known to have adverse effects on health and the environment, this may be a new area where further work is needed.

3.2 Building Materials and Surface Treatment as Indoor Sources

Building material and furniture are important sources of contamination of the indoor environment. The material, as such, can be a source for emission. However, the surface treatment of the material, as well as wear and tear, maintenance and cleaning procedures, may also contribute to emission of contaminants. The influence of material surfaces on indoor air quality can be divided into three groups: primary emission from materials, the impact of the materials on microbial flora and the ability of the materials to adsorb and desorb organic vapours on material surfaces.

Primary emission from materials can be grouped in two categories of emission sources, based on the emission decay profiles. Paints, adhesive, floor and furniture waxes, and spray products are examples of sources with a fast reduction in the emission rate. These products are used with solvents that are intended to evaporate. Evaporation and consequent drying may take anything from minutes to hours or days. However, such products may continue to release VOCs for extended periods (months or years). The second category is the sources which will emit chemicals for extended periods, for example, carpets, ceiling tiles, chipboard and other solid 'dry' materials. They may have initial emissions during the first few hours, but typically the emission rate remains high for months and even years after installation.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat090
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Emission studies of building materials have formerly focussed on VOCs (Kelly *et al*., 1999; Wolkoff, 1995). Development of low-emitting materials has been of interest as consumers' awareness and demands have increased. Today, there are several labels for tested, low-emitting materials. Some examples are Greenguard (Greenguard, 2008), Blue Angel, the Danish Indoor Climate Labelling Scheme and The Finnish Climate Classifications (Wolkoff, 2003). Newer studies, however, focus on phthalates (Bornehag *et al*., 2005; Kolarik *et al*., 2008) and flame retardants (Carlsson *et al*., 1997; Salthammer *et al*., 2003).

Cleaning must be considered as an additional contamination source, although the intention is the opposite (Nazaroff and Weschler, 2004). Some building materials appear to increase their emission of VOCs through wet cleaning and may thus affect the indoor air quality (Wolkoff *et al*., 1998). Cleaning agents contain evaporative and nonevaporative substances, where the former have VOCs as major constituents of toxicological significance. The use of cleaning agents results in a temporal increase of the overall VOC level. The exposure levels for occupants will depend of the amount of residue, the rate of off-gassing and particle release from surfaces.

Finally, gases and particles in indoor air are able to adhere to surfaces in the indoor environment. Adsorbed organic vapours on interior surfaces can later be re-emitted, and thus lead to elevated concentrations of organic compounds in indoor environments (Jørgensen *et al*., 1999; Tichenor *et al*., 1991).

3.3 Particles

The presence of particles in the indoor air depends on particles entering from the outdoor air, the filtration efficiency of the ventilation system and particles generated within the indoor environment. Particles in the indoor air may be of a biological or nonbiological nature. This subsection will describe nonbiological particles, while biological particles are discussed in Section 3.4

3.3.1 Particle Characterization

The properties and behaviour of particles are important in order to understand their possible influence on human health. In order to characterize the particle, the following characteristics are of interest:

- Size
- Shape
- Mass
- Number
- Surface area
- Chemical composition.

3.3.1.1 Size

The size of the particle decides its fate, whether it will remain airborne or settle on surfaces. Most particles are nonspherical. They can have geometrical shapes such as cubic or cylindrical, and some have irregular shapes. The shape of the particle affects its drag force and settling velocity (Hinds, 1982). In order to describe the particle motion mathematically, the irregular particle is converted to its equivalent sphere. The aerodynamic diameter is the diameter of the unit density ($\rho = 1\ \mathrm{g\,cm^{-3}}$) sphere that has the same settling velocity as the particle. Aerodynamic diameter is the key particle property for characterizing respiratory deposition.

Particles with aerodynamic diameters less than 10 µm are of special interest since they are inhalable. Particles with aerodynamic diameter less than 5 µm are respirable (ISO (1995) use median diameter $4.25\,\mu\mathrm{m} \pm 1.5\,\mu\mathrm{m}$; in publications, both 4.5 and 5.0 µm are frequently used for respirable fraction). These particles are able to penetrate more deeply into the respiratory tree, indeed to the alveoli. In their work, Owen *et al*. (1992) have given an overview of which region of the respiratory tract particles are deposited, as a result of the particles' aerodynamic diameter. Respirable particles can be further classified. Fine particles have aerodynamic diameters less than 2.5 µm, and ultrafine particles have aerodynamic diameters less than 0.1 µm. Nanoparticles have the same size classification as ultrafine particles, at least one dimension of 100 nm or less. Some differentiate between the terms, defining nanoparticles as being engineered, but generally ultrafine particles and nanoparticles describe the same thing (Oberdörster *et al*., 2005; Donaldson *et al*., 2006). Recent publications within toxicology use the term nanoparticles.

Most of the deposited insoluble particles leave the lungs via the bronchiotracheal route by mucociliary action as free particles, or within macrophages (Im Hof and Patrick, 1994). Nanoparticles are efficiently deposited by diffusional mechanisms to all regions of the respiratory tract, and they have a greater potential to cause adverse health effects than larger particles of similar composition (Donaldson *et al*., 1998; Johnston *et al*., 2000; Oberdörster, 2001). The small size facilitates uptake into cells (Geiser *et al*., 2005) and transcytosis across epithelial and endothelial cells into blood and lymph circulation to reach potentially sensitive target sites such as bone marrow, lymph nodes, the spleen and the heart (Oberdörster *et al*., 2005).

3.3.1.2 Shape

The shape of the particle is important regarding deposition in the respiratory system and the function of the cells' defence system. A specific shape of interest is the fibre. WHO defines a fibre as a particle longer than 5 µm with a width less than 3 µm, and with a length : width ratio greater than 3 : 1 (WHO, 1997). Although fibres can be long, their shape and small width enable them

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat090
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

to avoid settlement in the upper part of the respiratory system and to penetrate to the alveoli. Their ability to cause lung disease can be understood on the basis of the length of the fibres and their biopersistence in the lungs. Fibres are cleared by the mucociliary system, by being engulfed by macrophages and by dissolution (Rudd, 2004). These defence mechanisms are insufficient for long and biopersistent fibres, so that fibrosis and cancer may result.

Typical examples of fibres are asbestos and synthetic vitreous fibres (SVFs). SVFs have historically been called man-made mineral fibres (MMMFs), and are a class of inorganic fibrous materials that include glass wool, mineral wool, textile glass fibres and refractory ceramic fibres. Health effects of asbestos are well known, namely a specific fibrosis named asbestosis and cancer in lungs and airways, or in pleura and peritoneum (malignant mesothelioma). SVFs can irritate skin and mucous membrane, and some mineral wool fibres are classified as carcinogenic (Donaldson and Tran, 2004).

The presence of fibres in the indoor air originates from building materials. Lee and Van Orden (2008) have studied airborne asbestos in buildings nationwide in the USA. Their results indicated that as long as asbestos-containing materials were in place, it did not result in elevated airborne asbestos in building atmospheres approaching regulatory levels, and that it did not result in a significantly increased risk to building occupants.

3.3.1.3 Mass

Mass has historically been the main characterization aspect for particles besides size. In TLVs and guidelines, particulate matter for different size fractions has been the key description factor. PM_{10} is defined as the mass of the particles that are collected on a filter after passing a suction device with an interception efficiency of 50% at an aerodynamic diameter of 10 µm (EN, 1999). $PM_{4.5}$ and $PM_{2.5}$ are the similar fractions at aerodynamic diameters of 4.5 µm and 2.5 µm, respectively. PM_{10} has been widely use for particles in outdoor air, $PM_{4.5}$ is a fraction applied in the working environment, while $PM_{2.5}$ is applied for outdoor and indoor particles.

Several studies report good conformity between PM_{10} and respiratory effects and cardiovascular diseases (Harrison *et al*., 1999; Donaldson *et al*., 2001). The relationship between adverse health and particle mass may be the result of particle mass being a substitute for another parameter like particle number or surface area (Harrison *et al*., 1999).

3.3.1.4 Number

In terms of number, the vast majority of airborne particles are in the nanoparticle range (Morawska, 2000). The total mass of these particles is, however, often insignificant compared with the mass of a small number of large particles (Morawska, 2000). Several studies have reported that some health effects are better described by concentration given as particle number rather than by particle mass (Oberdörster *et al*., 1995; Peters *et al*., 1997; Granum *et al*., 2000; Lighty *et al*., 2000). Particle number (or surface area) correlates better than mass fractions with health effects such as inflammatory response (Oberdörster, 2001; Donaldson *et al*., 2002). Although the relevance of particle number has been well described, TLVs and standards for particles only refer to mass.

3.3.1.5 Surface Area

The surface area of the particle is essential for adsorption of chemicals, as well as for determining the potential exchange area between a particle and a body cell. Surface area together with particle number are referred to as key particle characteristics when studying adverse health effects (Tuch *et al*., 1997; Granum *et al*., 2000; Lighty *et al*., 2000). An explanation could be that the large surface area provided by nanoparticles in contact with the lung provides the opportunity for surface chemistry to have a profound effect (Donaldson *et al*., 1998). The large surface area seems to lead to oxidative stress and intracellular calcium changes that could be important in priming and activating cells for an inflammatory response (Donaldson *et al*., 2001).

3.3.1.6 Chemical Composition

Particles can cause physical irritation of the airways due to their physical characteristics (size, morphology) alone. Their chemical composition may cause additional effects due to chemical, toxic or allergic reactions. The particle can have different chemical characteristics:

- Inert particles
- Particles carrying chemical contaminants
- Toxic particles
- Allergens.

Indoor air particles will typically be inert or carry chemical contaminants present in the indoor environment. Toxic particles are more likely found in the working atmosphere. Allergens are described in Section 3.4 on biological particles.

The chemical contaminants adsorbed onto an indoor particle will depend on the chemical sources in the specific indoor environment. VOCs are frequently found adsorbed onto indoor particles (Wolkoff and Wilkins, 1994; Mølhave *et al*., 2000). Use of pesticides inside the house will result in the presence of such contaminants in indoor dust as well (Roinestad *et al*., 1993). Emissions from paint and floor coverings can also be adsorbed onto indoor particles, and thus contribute to their chemical complexity.

When a particle reaches the respiratory system, its chemical composition will influence the interaction with the cells and the mechanisms of defence. Endocytosis and biokinetics are largely dependent on the surface chemistry

(coating) of the particle and *in vivo* surface modifications (Oberdörster *et al*., 2005).

3.3.2 Particle Sources

3.3.2.1 Tobacco Smoking

An important indoor source of particles is tobacco smoking. Tobacco smoke contains more than 4000 chemical compounds and has a significant influence on the indoor particle concentration. Several Western countries have restricted or forbidden indoor smoking in office buildings, which has limited this problem to homes. Wallace (1996) estimated the $PM_{2.5}$ concentration in homes with smokers to be in the range from 25 to 45 $\mu g\,m^{-3}$. A recent study by He *et al*. (2004) measured $PM_{2.5}$ concentration in Australian houses, and found 79 $\mu g\,m^{-3}$, which exceeds the US EPA $PM_{2.5}$ 24 hour standards of 65 $\mu g\,m^{-3}$.

3.3.2.2 Human Activities

Combustion processes are among the main indoor sources of small particles, with the majority of them being in the submicrometer range (Morawska and Zhang, 2002). Examples of significant sources are food preparation (cooking, frying, grilling), heating (kerosene heating, wood burning, electrical convection ovens), burning candles and vacuum cleaning.

In a study of Australian homes by He *et al*. (2004) very high $PM_{2.5}$ concentrations where reported for food preparation, such as cooking pizza, frying and grilling (>700 $\mu g\,m^{-3}$). They also reported that emissions varied from house to house, although they performed the same cooking procedure.

3.3.2.3 Heating

When particles are brought into contact with hot surfaces unstable components can decompose. Examples of common hot surfaces are electrical convection ovens, condensers of refrigerators and lamps. A study by Arashidani *et al*. (1996) indicated that the heating source in the air supply may generate indoor pollutants. They found that the concentration of polycyclic aromatic hydrocarbons (PAHs) increased during use of a kerosene-fuelled heater.

Pedersen *et al*. (2001) reported that the major physical change in indoor particles caused by heating was an increased number of submicron particles emitted. The particle emission started at temperatures as low as 70 °C (Pedersen *et al*., 2003). Emissions and particles can contain a range of compounds which may contribute to odour, as well as irritant effects. VOCs and SVOCs that previously were adsorbed onto particles, can, due to the heating, be desorbed and released to the environment. Hirvonen *et al*. (1994) demonstrated that organic compounds will desorb from household dust, the degree of which depends on temperature. This has been confirmed by Pedersen *et al*. (2003) showing VOC emissions from household dust started at temperatures of 150–200 °C. In a subsequent study, cell cultures where exposed to the same VOC emissions, showing that they inhibit cell proliferation and TNFα (tumour necrosis factor α) release to the growth media (Mathiesen *et al*., 2004).

3.3.2.4 Resuspension of Particles

Ventilation will cause air movement that will affect both airborne and settled particles. In dwellings the ventilation will commonly be of natural origin like opening windows and doors, and mechanic ventilation connected to the kitchen stove. Larger buildings with heating, ventilation and air conditioning (HVAC) systems, which are supposed to have a positive effect on the indoor air quality, can also be its enemy by continuously bringing particles into the breathing zone.

Resuspension caused by sweeping or vacuum cleaning brings particles into the air, which may be breathed, and at this stage the particles can have a more harmful effect than before, because of other compounds attached. Vacuum cleaning leads to extensive resuspension of the settled particles. Most vacuum cleaners do not have efficient filtration systems for small particles (<1 μm), so that these particles will pass through the filtration system and become airborne for a period, depending on their size, while the coarse fraction will to some degree remain in the filter. Appropriate cleaning methods in order to improve the indoor air quality have been studied by Franke *et al*. (1997) and Leese *et al*. (1997). When measuring the total number of particles with a laser particle counter (LPC), Leese and his group found that changing to more effective vacuum cleaners did not affect the total LPC count. This can be explained by the smaller particles remaining suspended, while only larger particles settled on surfaces and were collected by the vacuum cleaner.

3.4 Biological Particles

3.4.1 Pet Allergens

Dander (skin scales) from pets such as cats and dogs are common allergen sources in household dust (Arbes *et al*., 2004). Exposure may be different due to cultural habits, and cockroach and mouse allergens may be more important in inner cities (Matsui *et al*., 2003; Phipatanakul *et al*., 2000). The major cat allergen, Fel d I, is an acidic glycoprotein or group of proteins (Ledford, 1994). The antigen is found on the skin and fur, and is distributed by licking and grooming by the animal. The major dog allergen is Can f 1, and has been detected on the coat of the dog. Both cat and dog allergens have also been found in houses where such animals are not ordinarily kept (Almqvist *et al*., 2001; Kim *et al*., 2007a).

DOI: 10.1002/9780470744307.gat090
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Passive transport on footwear and clothes is thought to bring these allergens into the house.

3.4.2 House Dust Mites

House dust mites have been reported as frequent causes of indoor air allergy and a risk factor for development of asthma in atopic individuals (Platts Mills and Chapman, 1987). The major house dust mite is *Dermatophagoides pteronyssinus* (Der p 1) (Luczynska *et al*., 1998; Voorhorst *et al*., 1967). The main determinants for survival are high humidity, moderate temperature and an adequate food source (amply provided by human skin scales and other detritus of domestic life). Humidity is a critical parameter for establishment and survival of the mite populations. Reduction of household humidity to 45% relative humidity or less is recommended to control the growth of mites, but the most important methods for reduction are frequent cleaning and removal of breeding grounds.

3.4.3 Pollen

The proteinaceous substance in many pollen grains induces an allergic reaction commonly known as hay fever. Pollen grains are generally considered to be a risk factor for pollen allergy outdoors. Birch and grass pollen have been demonstrated in indoor air (Holmquist and Vesterberg, 1999) and settled indoor dust (Yli-Panula and Rantio-Lehtimaki, 1995). Yli-Panula and Rantio-Lehtimaki (1995) found that antigenic activity was detected two months after the peak pollen period, which indicates that indoor dust may cause pollen-allergy symptoms a long time after the season. Pollen and spores are particles too large to remain in the air for prolonged periods (Owen *et al*., 1992). Common cleaning practices such as sweeping, dusting and vacuuming will resuspend a large percentage of the particles.

3.4.4 Microbiology

Micro-organisms are a most important part of daily life, both outdoor and indoor. We breathe in considerable amounts of microbes every day, and on our skin the resident microbial flora help to keep pathogenic micro-organisms away. Exposure to microbes is therefore both a necessity and a challenge for a healthy life. However, micro-organisms are known to be important biopollutants in indoor air, giving rise not only to infections, but even more to noninfectious symptoms such as allergies and toxic syndromes. While viable microbes are a presupposition for infections, both alive, 'resting' and dead microbial cells and their metabolites are of importance for their noninfectious health implications. Among the noninfectious symptoms and clinical signs related to inhalation of microbes are symptoms and signs of allergic alveolitis, febrile reactions (organic dust toxic syndrome), irritation in mucous membranes, allergic asthma and rhinitis. The causal relation between microbes (including their metabolites) and health implications in indoor air environments are not fully understood today. A thorough introduction to the field of health implications from fungi in indoor air environments is available (Flannigan *et al*., 2001). Microbes and their metabolites have also been frequently considered as possible causative agents in connection with respiratory symptoms in indoor environments (Kim *et al*., 2007b; Meklin *et al*., 2002; Nevalainen and Seuri, 2005).

A naturally balanced microbiological flora is often attributed to normal flora. Normal flora will seldom give rise to health implications among individuals exposed on a continuous basis. Strong dominance of one species or total absence of expected groups of microbes are good markers for imbalance in the microbial flora. The microbial flora of indoor air is an important part of the total indoor climate and air quality.

The micro-organism flora will depend on a number of variables like temperature, humidity, light and nutrients. Thus, substantial differences in the flora composition will occur. Nevertheless, there are natural limitations regarding microbial composition in various environments (Dixon and Fromtling, 1995).

Certain bacteria have been specifically discussed in relation to health problems in indoor environments, for example *Legionellae*, *Pseudomonas* and *Thermoactinomycetes*. Although recently identified as a pathogen (1976), *Legionella pneumophilia* is well known as the cause of severe pneumonia-like infections in an outbreak among 200 people attending a meeting of the US American Legion, giving rise to the designation Legionnaires' disease (legionellosis) (Fraser *et al*., 1977). Legionellosis occurs after inhaling water droplets that originated from a water source contaminated with organic matter harbouring active *Legionella* bacteria, often contained in amoebae or protozoa. Potential sources of contaminated water include cooling towers used in industrial cooling water systems, as well as in large central air-conditioning systems, evaporative coolers, hot-water systems, showers, whirlpool spas, architectural fountains, room-air humidifiers, ice-making machines, mist generators and similar disseminators that use public water supplies.

The microbial flora of the indoor environment is usually determined from samples of indoor air or from settled dust samples. Apart from the normal mycoflora of indoor air, which consists mainly of outdoor air genera such as *Penicillium*, *Cladosporium* and *Aspergillus* spp., unusual genera or species may be observed, indeed, the diversity of indoor fungi is remarkable (Miller *et al*., 2000). Identification in indoor air of genera or species that typically grow on moisture-damaged building materials probably reflects the presence of excess moisture.

Certain fungi species within the genera *Aspergillus* and *Penicillium* have been shown to survive in a dried state

for decades, while other species are shown to rapidly lose viability. A possible adaptation to increased temperatures has been reported among fungi in HVAC-treated indoor air compared to the same species in fresh air (Ahlén and Haugen, 1996; Hanssen, 2004).

Microbial toxins are produced both by fungi (Gravesen *et al*., 1994) and bacteria (Andersson *et al*., 1998; Peltola *et al*., 2001). Toxins are regularly detected in mould-contaminated building materials (Engelhart *et al*., 2002; Nielsen *et al*., 1999; Tuomi *et al*., 2000b). Thus, their occurrence may be a common phenomenon in buildings. The substrate, the material on which the organics are growing, may have a critical effect on the production of toxins and other substances with biological activity (Murtoniemi *et al*., 2001; Roponen *et al*., 2002).

Microbial volatile organic compounds (MVOCs), are volatile metabolites from micro-organisms, and are part of TVOCs in indoor air (Mølhave *et al*., 1997). Some compounds have been suggested as being of microbial origin, although few of these compounds are actually specific end products of microbial metabolism (Korpi *et al*., 1998). The toxicological relevance of MVOCs is probably negligible as they occur at very low concentrations (Korpi *et al*., 1999), but these compounds are used more and more frequently for the search for hidden mould growth (Schleibinger *et al*., 2005).

4 SOURCES OF INDOOR AIR CONTAMINATION

The main indoor environment challenges for risk management are the avoidance of dampness in buildings, the choice and maintenance of adequate ventilation rates and the elimination of pollutants from combustion sources, cooking and heating.

4.1 Sources Mainly Found Outdoors

Indoor air originates from outdoor air. Contaminants generated by outdoor sources are, for example, pollen (see Section 3.4), radon and a variety of compounds from traffic and industry.

4.1.1 Radon

Radon-222 (denoted radon) is a noble gas with a half-life of 3.8 days. It is formed from radium-226, which is the fifth decay product of uranium-238. Radon originates mainly from uranium in the earth's crust, and is especially emitted from certain granite and alum shale structures. Radon may penetrate into buildings through cracks and leakage in the base slab or walls. It is mainly a problem in the basement or ground floor in buildings without a basement. The penetration varies with the wind, temperature and pressure differences.

Radon and radon daughter elements occur normally in considerably higher concentrations indoors than outdoors. Radon in building materials normally makes only a small contribution to indoor radon (Khan, 1994), and soil gas is mainly responsible for indoor radon. Radon levels vary considerably between dwellings. Arithmetic mean concentrations in European countries range from about 20 to 100 $Bq\,m^{-3}$, with even higher levels in some regions (WHO, 2000). A North American review found analogous variations, between 25 and 131 $Bq\,m^{-3}$ (Krewski *et al*., 2006).

Radon is among the best studied of environmental carcinogens. In 1999 an extensive study by the US National Research Council estimated that 10–15% of all lung cancers in the USA were caused by radon (National Research Council, 1999). The risk for lung cancer is estimated to increase by 8.4–11% per 100 Bq m^{-3}. The dose–response relationship appeared linear and there is no indication of a threshold (Samet, 2006). In general, WHO recommends that simple remedial measures should be considered for building with radon progeny concentration of more than 100 Bq m^{-3} equilibrium equivalents of radon as an annual average, with a view to reducing such concentrations whenever possible (WHO, 2000).

4.2 The HVAC System as a Contamination Source

Pollutants generated in an HVAC system will also affect the indoor air quality. Today's indoor air, particularly that in offices, schools and similar work environments, is usually processed by HVAC systems. Unfortunately, dust from when the building was constructed often remains in the ventilation system due to lack of cleaning and quality control. Thus, these contaminants can spread to the whole area served by the HVAC system, or deposit in channels and serve as possible nutrients for micro-organisms, provided the right temperature and humidity conditions are present.

Fibreglass duct linings have been used in HVAC systems for thermal and acoustic insulation. Concerns have been expressed as to whether this use may cause glass-fibre emission into the indoor atmosphere. Great care should be taken to keep these materials intact, clean and dry throughout both the construction period and during operation of the HVAC system, otherwise fibres might be released into the air stream (Woods and Goodwin, 1997). In addition, the acoustic and thermal properties might be compromised.

Furthermore, good design and correct location of intake openings are essential for controlling moisture-related problems in HVAC systems. Prevention

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat090
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of microbiological problems depends on limiting dirt and moisture, particularly standing water, which will allow micro-organisms to proliferate. Allied to this is the avoidance of contamination by micro-organisms from outside sources, which then can colonize such systems. Thus, control involves correct design, operation, maintenance and housekeeping (ISIAQ, 1996).

Several investigations focussing on the air intake section in school and office buildings have documented that especially this part of the plant is a place where moisture and contaminants easily meet, and this may lead to microbiological growth that can result in unwanted consequences for the ventilation plant, as well as for the users. In a Norwegian study (Frydenlund *et al*., 2002), the intake sections of 30 ventilating plants were investigated. A total of nine were concluded to be plants of high potential risk because thermotolerant moulds were identified. The investigation also revealed a clear relation between microbiologic and hygienic conditions. If these findings are representative, modern ventilation systems may be potential breeding grounds for micro-organisms, which in turn may represent a health risk for the people living and working in the air-conditioned premises. A thorough introduction to successful system operation, control and prevention of potential problems is available (ECA, 2000).

4.3 Dampness in Buildings

Dampness in buildings is a risk factor for health effects among atopic (hypersensitive) and nonatopic individuals, both in domestic and in public environments (Bornehag *et al*., 2001; 2004b). It may increase the risk of health effects in the airways, such as coughing, wheezing and asthma by 40–120% or even more. Dampness is also associated with other effects such as tiredness, headache and airway infections. Remedial building measures have positive effects on health (Savilahti *et al*., 2000; Patovirta *et al*., 2004; Rudblad *et al*., 2004). The evidence for a causal association between dampness and health effects is strong, but the mechanisms are unknown (Bornehag *et al*., 2001; 2004b). Several definitions of dampness have been used in studies of these associations, and no matter how they have been formulated they all seem to be associated with health problems. The literature is not conclusive with respect to causative agents, for example mites, microbiological agents and organic chemicals from degraded building materials. Even if the mechanisms are unknown, there is sufficient evidence to take preventive measures against dampness, moisture and water damage in buildings.

If building structures are subject to more moisture and dampness than they were intended for, this may cause damage due to chemical or microbiological decomposition of the building materials. Organic dust and filth may provide nutrition for micro-organisms such as bacteria, moulds and amoebae, and insects such as mites, cockroaches and flies. Processes in built environments that are subject to more moisture than intended can therefore cause exposure to:

1. Allergens from house dust mites and other living or dead insects, germs and spores as well as from moulds and bacteria
2. MVOCs, irritating and evil-smelling vapours produced by microbiologic metabolism
3. Mycotoxins from moulds, of which many have strong biological effects; micro-organisms use toxins to suppress other organisms in their fight for survival and growth
4. Endotoxins and glucanes, which are active agents originating from bacteria
5. Chemicals, such as formaldehyde, emitted from building materials; the generation of such substances often increases due to hydrolysis and the decay of materials caused by water damage

It has also been proposed that a more efficient spreading of respiratory infection viruses in damp indoor climate can be a ‘missing link’ between allergen exposure and onset of asthma and allergic disease (Hersoug, 2005). Although many of these potential mechanisms can, theoretically, cause health effects, most exposure levels are usually much too low for health effects to actually occur. One intervention study indicated dose–response relationships between exposure to mould and health effects (Savilahti *et al*., 2000). However, as in other indoor climate cases, the measured levels were still far too low to cause health effects, even when based on current knowledge (Eduard, 2006). The association between dampness and health effects, on the other hand, is strong, although there is no reason to believe that moisture or dampness themselves are the actual causes. Obviously, possible causes must be looked for among the agents that occur due to the effects of increased humidity in buildings and other factors, such as temperature.

Dampness is sometimes associated with mite growth that can induce mite sensitization and allergic disease (Wickman *et al*., 1991). Agents other than mite allergens, which in some studies have been shown to increase the risk for symptoms and medical signs, are airborne moulds and bacteria. However, the literature is not consistent. In conclusion, it is not known which humidity-related agents in indoor air are the main causes of the health effects. Dampness and moisture phenomena in buildings, microbial and chemical exposures, and individual human responses are complex phenomena. While the causative links between exposure agents and health responses are still not well understood, the essential issue is to prevent

DOI: 10.1002/9780470744307.gat090
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

problems by keeping the buildings dry and clean through good design, construction and maintenance.

5 VENTILATION

The achieved indoor air quality depends on the pollution sources in the outdoor air, the infiltration to the building from the ambient environment, the indoor sources with the influence of factors such as dampness, heating, cooling, maintenance, cleaning and finally, ventilation.

The purpose of ventilation is replacement of polluted indoor air with clean outdoor air. Although the HVAC system can be a contamination source for indoor air, it is important to keep in mind that ventilation is part of the solution to improve indoor air quality. Wargocki *et al*. (2002) made a comprehensive review and found that ventilation is strongly associated with comfort (perceived air quality) and health in terms of SBS symptoms, nasal irritative inflammation, infections, asthma, allergy and short-term sick leave. Also, an association between ventilation and productivity (performance of office work) is indicated. By applying current knowledge, indoor air quality can be improved considerably while still maintaining or even reducing ventilation rates and energy use compared to the situation today (Fanger, 2006).

6 CURRENT STATUS

When addressing indoor air quality worldwide, the focus varies between third world countries and the industrialized nations. In third world countries, the major challenges are negative health effects caused by combustion processes. Women and children are emphasized in particular, since they are close to the exposure source. In the more industrialized nations indoor pollution sources like building materials, furniture, electronic equipments, spray boxes, redecoration and so on are still important. However, focus has changed from TVOC emission and SBS only to a broader approach on the specific emission of single compounds like phthalates, flame retardants, carcinogenic compounds and other compounds with specific health effects.

Dampness in buildings is an old risk factor that has become highly important again. The evidence for a causal association between dampness and health effects is strong, but the mechanisms are unknown.

Nanoparticles are a new issue highlighted for both indoor and outdoor air. This is not a new pollution source since it has been present in both nature and in man-made combustion processes. However, engineered nanoparticles introduce new challenges to human health, due to their extremely small size and the expected huge increase in application. The number of ongoing studies related to health effects of nanoparticles and the mechanisms involved is growing rapidly, and publications of the results have just started. This can bring new knowledge into the details of how exposure to, for example, combustion particles affects human health.

It is still a major challenge to unite knowledge and practical application, in order to improve indoor air quality in future buildings. Legislation has the power to require fulfillment of regulations with respect to indoor air quality, and there is considerable potential for improvement of legislation. Most important is the practical implementation of our current knowledge in order to provide healthy indoor environments with sustainable use of energy and other resources.

Multiple Chemical Sensitivity: Toxicological Questions and Mechanisms

Martin L. Pall

CONTENTS

1 INTRODUCTION TO MULTIPLE CHEMICAL SENSITIVITY (MCS)

Multiple chemical sensitivity (MCS) is a complex disorder with cases often apparently initiated by chemical exposure. Following initiation of illness, people with MCS report sensitivity or intolerance to low levels of a wide spectrum of chemicals. The reported symptoms of chemical exposure are diverse and variable from one patient to another, but include pain, especially headache pain, muscle and joint pain, confusion, cognitive dysfunction, asthma-type symptoms, rhinitis, sleep disturbances, fatigue and even such psychiatric symptoms as anxiety and depression and infrequently rage. In the Sorg (1999) review, a total of 41 different symptoms are listed, many of which occur only in a minority of sufferers. Among the more common symptoms following chemical exposure in MCS patients are extreme fatigue, headache, gastrointestinal problems, dizziness, anxiety, depression, upper airways irritation, muscle and joint pain, and memory and concentration difficulties (Sorg, 1999). It should be noted that six out of nine of these symptoms can probably be ascribed to central nervous system (CNS) changes. Changes in brain function have been shown in brain positron emission tomography (PET) scan studies of MCS patients (Heuser and Wu, 2001; Hillert *et al*., 2007), single photon emission computed tomography (SPECT) scan studies (Simon *et al*., 1994; Heuser *et al*., 1994; Fincher *et al*., 1997a; 1997b) and electroencephalography (EEG) studies (Bell *et al*., 1999b; Muttray *et al*., 1995; Ross *et al*., 1999; Schwartz *et al*., 1994; Fernandez *et al*., 1999; Lorig *et al*., 1991; Lorig, 1994). Miller (2001) listed 74 such symptoms that she divided into neuromuscular, head-related, musculoskeletal, gastrointestinal, cardiac, affective, airway, cognitive and other. It is likely, as is discussed below, that the profound variation in symptoms, both qualitative and quantitive among sufferers, may be due to a local mechanism whose tissue distribution may vary among different sufferers.

MCS has been given a number of different names, including chemical sensitivity, multiple chemical sensitivities, chemical intolerance and toxicant-induced loss of tolerance (TILT). The TILT name (Miller, 2001) emphasizes the observation that most cases of MCS follow exposure to one or more chemicals and the basic hypothesis that dominates much of this literature is that chemical exposure initiates cases of illness (Ashford and Miller, 1998). The Cullen case definition requires such an initiating exposure for a case to be considered to be MCS (Cullen, 1987). Furthermore, the spectrum of chemicals reported to initiate cases of MCS is similar or identical to the spectrum of chemicals to which people with MCS appear to be sensitive, suggesting that the mechanism of action of both initiating chemicals and those eliciting sensitivity responses may be similar or identical. Some researchers, mainly those who have advocated some type of psychogenic cause for MCS, have advocated calling it idiopathic environmental intolerance (IEI) and have questioned whether chemicals are in fact initiators of MCS cases.

The phenomenon of MCS has been often ignored in the toxicological literature, largely because up until recently, a series of challenging questions about MCS have been unanswered. From a toxicological perspective, the most relevant such questions include the following:

- How can such diverse chemicals be implicated in initiating cases of MCS and, having initiated sensitivity, subsequently produce responses at very low exposures?
- How can one produce high-level sensitivities to such a broad range of chemicals, with many MCS patients being estimated as being on the order of 1000-fold more sensitive than normal?
- Are there plausible physiological mechanisms that may be expected to produce the above-described pattern of sensitization?
- If so, is there any evidence supporting these mechanisms in MCS?

I will discuss each of these four questions in this review, as well as at least eight other, perhaps equally puzzling, questions about MCS.

2 DIVERSE CHEMICALS ARE REPORTED TO APPARENTLY INITIATE CASES OF MCS

There have been dozens of papers reporting a pattern of chemical exposure preceding development of cases of MCS, typically one high-level exposure or multiple

lower-level exposures (Ashford and Miller, 1998; Sorg, 1999). Pall (2007a, Chapter 13) cited 24 distinct studies reporting chemical exposure preceding development of many cases of MCS and Miller (2000) cited 12 additional such studies and still additional studies are cited below in this section. The types of chemicals most commonly involved are the volatile organic solvents (sometimes described as volatile organic compounds (VOCs)) and pesticides, especially organophosphorus and carbamate pesticides (Ashford and Miller, 1998; Sorg, 1999; Rea, 1992; Ziem and McTamney, 1997). There are a number of additional papers reporting that exposure to organic solvent chemicals that outgas in 'sick building syndrome' situations also appear to initiate cases of MCS (Welch and Sokas, 1992; Davidoff and Keyl, 1996; Miller *et al*., 1999; Hodgson, 2000; Arnold-Llamosas *et al*., 2006; Redlich *et al*., 1997; Ross, 1997). Berglund *et al*. (1984) reported that apparently chemically sensitive individuals reacted to air piped in from such a 'sick building' in blinded fashion, but did not react to uncontaminated air, suggesting that chemicals in the 'sick building' air were causal in generating the reactions. Many of the chronic symptoms of the surviving victims of the Bhopal disaster may be ascribed to MCS (Ross, 2000; Nemery, 1996).

When Miller and Mitzel (1995) wanted to compare cases of MCS apparently initiated by two different classes of chemicals, they chose cases from recently remodelled sick buildings (volatile organic solvent exposure) and compared those with cases apparently initiated by organophosphorus pesticides. In their highly cited paper, Miller and Mitzel (1995) found these two groups of MCS patients were similar, but not identical to each other, with some differences in symptom patterns and some differences in average severity between the two groups. Because MCS cases apparently initiated in these two ways are so common, it was relatively easy for Miller and Mitzel to find substantial numbers of patients of the two types to study.

Two of the most interesting sick-building cases occurred in the then recently remodelled Environmental Protection Agency building in Washington DC, in which approximately 200 people were apparently sickened with cases of MCS (Miller, 2001) and in Brigham and Women's Hospital in Boston, part of the Harvard Medical School complex. The latter case was described in detail in a US government publication (Kawamoto *et al*., 1997), where subsequent decreases in chemical usage and increases in air flow led to substantial decreases in new cases of chemical sensitivity and related illnesses, suggesting a causal relationship between chemical exposure and illness initiation. Ashford and Miller (1998) suggested that the decreases in required air flow in buildings in the USA, as a response to the energy crises of the 1970s, led to major increases in the incidence of MCS. In an important study, occupational medicine patients differed from general patients in responses to the Toronto MCS questionnaire in much the same way that self-identified MCS patients did, albeit to a lesser extent (McKeown-Eyssen *et al*., 2001), suggesting that chemical exposure in the occupational environment may initiate substantial numbers of MCS cases. Zibrowski and Robertson (2006) reported increased prevalence of MCS-like symptoms among laboratory technicians exposed to organic solvents, as compared with similar laboratory technicians with no apparent exposure. An epidemiological study, estimating the prevalence of MCS in various occupations, including those expected to have substantial chemical exposure to classes of chemicals implicated in MCS as a consequence of the occupation, reported increased prevalence of MCS in several occupations involving such chemical exposure, again suggesting a causal role of chemical exposure (Maschewsky, 1996; 2002). Yu *et al*. (2004) found high prevalences of MCS-like symptoms among solvent-exposed printing workers, as compared with non-chemically exposed controls. There are at least a dozen studies reporting high prevalences of reactive airways disease, a common aspect of MCS, among workers occupationally exposed to organic solvents.

In addition to organic solvents and related compounds and the organophosphorus and carbamate pesticides, there are additional classes of chemicals that are reported to apparently initiate cases of MCS. These include the organochlorine pesticides chlordane, lindane, dieldrin and aldrin (Corrigan *et al*., 1994; Ziem and McTamney, 1997; Lohmann *et al*., 1996; Wallace, 1995; Pröhl *et al*., 1997) and also a variety of pyrethroid pesticides (Corrigan *et al*., 1994; Lohmann *et al*., 1996; Altenkirch, 1995; Altenkirch *et al*., 1996). Lindane has been shown to initiate animal models of MCS (Gilbert, 2001; Cloutier *et al*., 2006) as has another $GABA_A$ (γ-aminobutyric acid A receptor) antagonist (Adamec, 1994). There are reports that hydrogen sulfide exposure can initiate cases of MCS-like illnesses (Kilburn, 1997; 2003). Donnay (1999; 2000) has reviewed evidence suggesting that carbon monoxide exposure may be able to initiate cases of MCS. Furthermore, mercury and mercurial compounds are also reported to apparently initiate some cases of MCS (Eneström and Hultman, 1995; Latini *et al*., 2005; Brent, 2001; Stejskal *et al*., 1999) and dental assistants working with mercury amalgams were reported to have higher prevalences of neurological symptoms including MCS-like symptoms (Moen *et al*., 2008).

Mould exposure is also suggested to initiate cases of MCS in sick-building situations characterized by mould-infested buildings (Redlich *et al*., 1997; Claeson *et al*., 2002; Lee, 2003; Mahmoudi and Gershwin, 2000; Straus *et al*., 2003). Here, we cannot say much about what mycotoxins may be involved, although there is some evidence that *Stachybotrys* moulds may be often involved (Mahmoudi and Gershwin, 2000; Hintikka, 2004; Straus *et al*., 2003; Pestka *et al*., 2008). Hirvonen *et al*. (1999) reported that mouldy 'sick' buildings produced increases

in nitric oxide (NO) and inflammatory cytokines in nasal passages of exposed people and similar responses were also reported in the lungs of similarly exposed people (Akpinar-Elci *et al*., 2008). NO and inflammatory cytokines are important aspects of the MCS mechanism developed in this review.

3 A COMMON RESPONSE TO INITIATING CHEMICALS: INCREASED NMDA ACTIVITY

One of the great puzzles about MCS is how can such a diverse group of chemicals produce a common biological response? In fact, one of the MCS skeptics, Ronald Gots (1996) has argued that MCS cannot possibly be a physiological response to chemicals because the diverse chemicals implicated in MCS cannot possibly produce a common response in the human body. Clearly one needs to find such a common physiological response in order to develop a compelling model of the mechanism of MCS. An important role for excessive NMDA (*N*-methyl-D-aspartate) receptor activity in MCS was first suggested by Thomas (1998) and by Dudley (1998). Pall (2002) argued that elevated NMDA[a] receptor activity is likely to have a key role in MCS and that chemicals were likely to act, in most cases indirectly, to increase such activity. There were several types of evidence reviewed in that paper suggesting a role of elevated NMDA activity:

1. MCS patients are hypersensitive to monosodium glutamate and glutamate is the common physiological agonist of the NMDA receptors.
2. In studies of the genetic polymorphism of the CCK-B gene, the allele of the gene that acts indirectly to produce higher NMDA activity was associated with increased prevalence of MCS (Binkley *et al*., 2001; see Pall, 2002 for discussion).
3. The NMDA antagonist, dextromethorphan was reported from both clinical observations and anecdotal reports to lower reactions to chemicals in MCS patients.
4. Bell and others have proposed that neural sensitization has a key role in MCS and the probable mechanism for such neural sensitization, called long-term potentiation (LTP), is known to involve increased NMDA activity.
5. Elevated NMDA activity has been shown to play an essential role in several animal models of MCS.
6. Elevated NMDA activity appears to play a role in such related illnesses as fibromyalgia (FM), chronic fatigue syndrome (CFS) and post-traumatic stress disorder (PTSD), with the most extensive evidence for such a role being found in FM (Pall, 2006; Pall, 2007a).

It should be noted that numbers 2 and 5 above suggest that chemicals initiating cases of MCS may act to increase NMDA activity and number 3 suggests that chemicals acting in those already sensitive may also act to increase NMDA activity. In fact, these two sets of chemicals are similar or identical to each other (Ashford and Miller, 1998) so it should not be surprising if they both may act via the same mechanism(s). All of these considerations raise the question about whether there are known mechanisms by which the several classes of chemicals implicated in MCS may act to increase NMDA activity?

3.1 Pesticides and NMDA Stimulation

In that Pall (2002) review, evidence was discussed showing that organophosphorus and carbamate toxicants (including pesticides) can act to produce increases in NMDA activity via the following pathway: these toxicants are acetylcholinesterase inhibitors, producing an increase in acetylcholine, which stimulates the muscarinic receptors, which produce, in turn, increased glutamate release leading to increased NMDA receptor stimulation, as well as stimulating other glutamate receptors (see diagram in **Figure 1**). There are a large number of studies showing that toxic effects of organophosphorus toxicants in mammals can be greatly lowered by using NMDA antagonists (Dekundy *et al*., 2007; Lallement *et al*., 1998; Martin and Kapur, 2008), showing that such increased NMDA activity has a substantial role in producing the response to these toxicants.

What about other pesticides and other groups of implicated chemicals? Let us take the different classes of chemicals one at a time. The organochlorine pesticides, chlordane, lindane, dieldrin and aldrin have all been shown to lower $GABA_A$ receptor activity (Gant *et al*., 1987; Corrigan *et al*., 1994; Cassidy *et al*., 1994; Brannen *et al*., 1998; Narahashi *et al*., 1995) and this, in turn is well known to produce elevated NMDA activity (Blaszczak and Turski, 1998; Watanabe *et al*., 1995; Tusell *et al*., 1992), see **Figure 1**. In fact these same citations show that seizure activity produced by these $GABA_A$ antagonists, including these pesticides, is lowered or blocked by NMDA antagonists, showing that the elevated NMDA activity produced by such toxicants has a key causal role in the mechanism of seizure generation. Because MCS involves the action of short-term stressors producing chronic illness, it may be of special interest that this pathway produces chronic changes in brain function that can be blocked by short-term interruption of the pathway (Kaindl *et al*., 2008).

Pyrethroid pesticides, which also initiate cases of MCS, act to produce long-term sodium-channel opening (Narahashi *et al*., 1995; Valentine, 1990; Wu and Liu, 2003;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

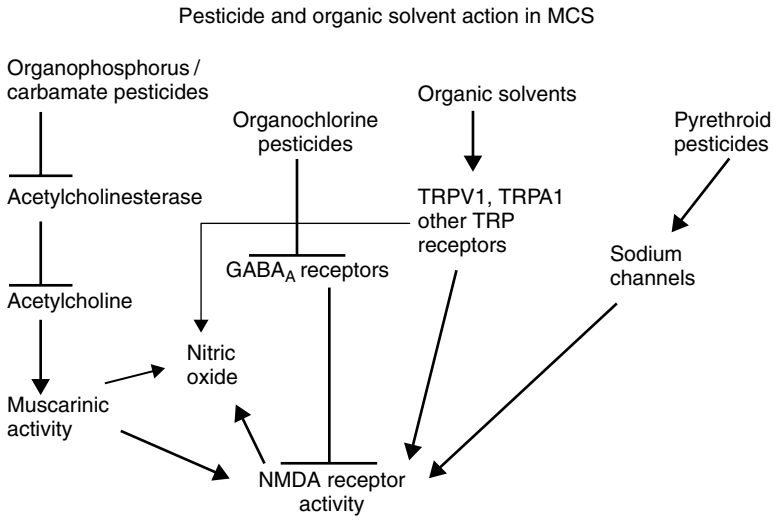

Figure 1 Pathways for action of pesticides and organic solvents. Each chemical class implicated in the initiation of cases of MCS can act along a distinct pathway to generate increases in NMDA activity, as shown in the figure. Each arrow represents a mechanism by which one parameter stimulates another. Some inhibitory (negative) interactions are also indicated. Both the organophosphorus/carbamate toxicants and the organochlorine pesticides have double-negative interactions. Such negative interactions, together with the arrows in the figure, indicate that the each of the four classes of compounds acts along one of these pathways, leading to an increase in NMDA activity.

Bradberry *et al*., 2005; Proudfoot, 2005). This in turn, produces increased NMDA stimulation (Wu and Liu, 2003; Yu, 2006; Doble, 1996), see **Figure 1**. Type II pyrethroids also act as $GABA_A$antagonists (Valentine, 1990) and may be expected, therefore, to also act along the same pathway impacted by the organochlorine pesticides, and thus lead to increased NMDA activity along that pathway as well.

3.2 Organic Solvents, TRP Receptors and NMDA Stimulation

Clearly the greatest puzzle of chemical activity in MCS is how does the huge family of organic solvents act to initiate cases of MCS or elicit sensitivity symptoms in those who have become sensitive? These chemicals are the predominant set of chemicals that trigger reactions on a day-to-day basis in MCS patients. They have also been referred to as volatile organic chemicals and yet it is clear that nonvolatile chemicals ingested or absorbed through the skin can produce reactions, so the volatility is important due to the most common mode of exposure, inhalation, rather than being an essential part of the mechanism of sensitivity. I will refer to this extremely large group of chemicals as organic solvents, even though that does not cover this entire spectrum of chemicals.

Pall and Anderson (2004) argued that the probable target for such organic solvents in MCS is the vanilloid (transfer receptor potential) TRPV1 receptor, and presented 12 distinct types of evidence arguing for such a TRPV1 role in MCS. That paper was extensively documented with 222 citations and while specific references are provided some of this discussion, for the rest the reader is referred back to that paper. One type of evidence that we presented is that some solvents well known to be involved in MCS, such as formaldehyde and other aldehydes, were quite active TRPV1 agonists, and a variety of alcohols are vanilloid agonists and may be converted into still more active aldehydes via alcohol dehydrogenases in the body. It is known that capsaicin, the classic TRPV1 agonist, requires both hydrophobic regions and a hydrogen-bonding group in order to act as an agonist, suggesting that strictly hydrophobic solvents might require cytochrome P450 metabolism in order to act as a vanilloid agonist, or might act synergistically with a solvent that does have a hydrogen-bonding group. There is evidence from animal models of MCS, which are also animal models of Gulf War illness, for such synergistic interactions of organic solvents and related compounds (Research Advisory Committee on Gulf War Veterans Illnesses., 2004): fully 28 studies of synergistically acting stressors, most, but not all, of which were organic compounds, were reviewed in that document.

Some mycotoxins are known TRPV1 agonists, so it is possible that the role of moulds in MCS may be explained through the role of the TRPV1 receptor. Chemical sensitizers, including toluene diisocyanate (TDI) and eugenol, which produce local sensitivity to a wide range of chemicals, are known TRPV1 agonists. MCS patients often report sensitivity to chlorine gas from swimming pools or from drinking water, and chlorine acts as a TRPV1 agonist *in vivo* (Morris *et al*., 2005), producing

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

an irritant response. TRPV1 stimulation produces neurogenic inflammation and also reactive airways disease (Geppetti *et al*., 2008; Jia and Lee, 2007; Planells-Cases *et al*., 2005; Costa *et al*., 2008), often called reactive airways dysfunction syndrome (RADS), a form of asthma showing reaction to a spectrum of chemicals similar or identical to those involved in MCS. Both RADS and neurogenic inflammation are often aspects of MCS cases (Meggs, 1994; 1997).

Millqvist and her colleagues have published a series of papers showing that MCS patients are hypersensitive to capsaicin, the classic TRPV1 agonist, again providing support for a TRPV1 role in MCS (Johansson *et al*., 2002; Millqvist, 2000; Ternesten-Hasséus *et al*., 2002; Millqvist *et al*., 2005; 2008). Many studies have shown that capsaicin treatment leads the TRPV1-stimulated cells in several regions of the body to release glutamate neurotransmitter, leading in turn to NMDA stimulation (10 such studies are cited in Pall and Anderson, 2004). These studies provide further support for the contention that each class of chemicals involved in MCS leads to increased NMDA stimulation.

There is an additional parallel between MCS and TRPV1 stimulation. MCS patients have a phenomenon known as desensitization or masking, such that low-level chronic or repeated chemical exposure leads to decreased reactivity to chemical exposure (Ashford and Miller, 1998). This may be the basis of using low-level chemical exposure to treat MCS patients (Weaver, 1996; Rea, 1997). Low-level chronic or repeated exposure to many TRPV1 agonists leads to lowered TRPV1 activity through a complex series of changes involving increased intracellular calcium levels, complex protein phosphorylation control and probably receptor internalization (Szallasi and Blumberg, 1999; Itagaki *et al*., 2004). Thus the desensitization/masking phenomenon found in MCS may be produced, to part or in whole, by this lowered TRPV1 activity.

While there are many properties suggesting a TRPV1 role in MCS, it is clear now that some of the interpretations given by Pall and Anderson (2004) to some of the relevant data were too narrow. It was argued, for example, that TRPV1 was primarily responsible for the sensory irritation (SI) response, a response elicited by chemicals including alkanes, alkyl benzenes, halogenated benzenes, halogenated alkylbenzenes, alcohols, ketones, ethers, aldehydes, formaldehyde, isocyanates and chlorine (Nielsen, 1991; Alarie *et al*., 1998; Inoue and Bryant, 2005; Cometto-Muñiz and Abraham, 2008), a broad range of chemicals also implicated in MCS. It is now clear that this SI response involves as major players, other members of the TRP family of receptors, not just TRPV1. Specifically Bíró *et al*. (2007) discuss evidence for a role of TRPA1, TRPM8 and TRPV2, 3 and 4 receptors in this response, as well as TRPV1. Bautista *et al*. (2006) implicated specifically the TRPA1 receptor in the response to several environmental irritants. Many of the TRP receptors have roles in responding to xenobiotics (Nilius, 2007) and while our knowledge of such roles has been expanding rapidly in recent years, it is still, no doubt, incomplete. Neurogenic inflammation and reactive airways disease aspects of MCS, discussed above and below, are produced, not only through TRPV1 stimulation, but also through the action of other TRP receptors (Geppetti *et al*., 2008; Jia and Lee, 2007). Whereas some chemical sensitizers act as TRPV1 agonists, sensitizers can also act as TRPV3 agonists (Xu *et al*., 2006).

Others have argued for a central role for the SI response and the receptors involved in that response in MCS (Skov and Valbjorn, 1987; Meggs, 1993; 1997; Anderson and Anderson, 1999a; 1999b; 2003; Millqvist *et al*., 1999; Millqvist, 2000; 2008; Nordin *et al*., 2005).

In Pall and Anderson (2004), we used the desensitization response produced by low-level chronic exposure to capsaicin or other bona fide TRPV1 agonists to assess whether some solvents that had never been tested as possible TRPV1 agonists might have such activity. The reasoning was that if responses to a chemical were reported to be substantially reduced after low-level capsaicin treatment, that chemical should be labelled as a probable TRPV1 agonist, because the response to it was lowered along with TRPV1 desensitization. It is clear now that desensitization of one TRP receptor is often accompanied by desensitization of others. For example, TRPV1 and TRPA1 can undergo cross-desensitization (Rohacs *et al*., 2008; Ruparel *et al*., 2008) and TRPM8 and TRPA1 desensitization can also be produced in parallel (Zanotto *et al*., 2008). In another study, a series of TRPC receptors were desensitized together by a receptor internalization process (Itagaki *et al*., 2004). It seems likely, therefore, that some organic solvents that were argued to be probable TRPV1 agonists, as suggested earlier in this paragraph, may well be agonists of other TRP family receptors.

Of the other TRP family receptors, the one most likely to have a substantial role in MCS, based on current evidence, is TRPA1. TRPA1 is responsible for the activity of a number of different sensory irritants (Bautista *et al*., 2006; Gerhold and Bautista, 2008), with TRPV1 being responsible for others. For a number of such irritants, the chemicals react by reversible covalent modification with the TRPA1 receptor (Hinman *et al*., 2006). Among the TRPA1 agonists are certain aldehydes, including acrolein and aldehydic components of cigarette smoke (Andrè *et al*., 2008; Simon and Liedtke, 2008) and MCS patients are commonly known to be sensitive to cigarette smoke. Formaldehyde which is commonly involved in initiating cases of MCS was shown in a recent study to act via the TRPA1 receptor in a model of inflammatory pain, rather than acting via the TRPV1 receptor (McNamara *et al*., 2007).

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Activation of the TRPA1 receptor has been reported to lead to the release of the neurotransmitter glutamate, leading in turn, to increased NMDA activity (Kosugi *et al*., 2007; Ding *et al*., 2008). Given that such increased NMDA activity is also produced by TRPV1 receptor stimulation, as discussed above, it should not be surprising that organic solvent-produced changes in the nervous system can, in many cases, be blocked or lowered by using NMDA antagonists. For example, there are a number of responses to formaldehyde exposure that have been shown to be greatly lowered by NMDA antagonists (Coderre and Melzack, 1992; McMahon *et al*., 1993; Wiertelak *et al*., 1994; Wang *et al*., 1999).

In conclusion, there are compelling similarities between the diverse organic solvents and related chemicals involved in MCS and the diverse organic chemicals involved in the SI response. It seems likely that the TRP receptors are involved in both, with the two most likely members of this receptor family to be involved in chemical responses in MCS and in SI, based on current evidence, being the TRPV1 and TRPA1 receptors, both of which can produce an increase in glutamate release and consequent NMDA stimulation. These various data suggest, therefore, that the proposed pattern of chemical involvement in MCS acting through increased NMDA activity is likely to be sustained for the organic solvent group of chemicals.

Before leaving this issue of the apparent roles of TRP receptors in MCS, I need to discuss the TRPM2 receptor that may have a role in amplifying responses in MCS. The TRPM2 receptor is known to be stimulated by oxidants, including hydrogen peroxide, with much of the stimulation being produced by adenosine diphosphate (ADP)-ribose, a signalling molecule whose levels can be greatly increased by oxidants (Kühn *et al*., 2005; Fonfria *et al*., 2004; Wilkinson *et al*., 2008; Naziroglu, 2007; Buelow *et al*., 2008; Lange *et al*., 2008). The pathway of synthesis of poly(ADP)-ribose is as follows: oxidants produce nicks in DNA strands in the nucleus of cells which can lead, in turn, to a massive stimulation of poly(ADP)-ribose polymerase activity, producing poly(ADP)-ribosylation of chromosomal proteins. When this poly(ADP)-ribose becomes subsequently hydrolysed, it produces free ADP-ribose which acts as a signalling molecule. One oxidant that is very active in this process is peroxynitrite ($ONOO^-$) (Pacher and Szabo, 2008), a molecule that the author has argued (see below) has a key role in MCS and related illnesses, and whose synthesis is greatly increased by NMDA stimulation (reviewed in Pall, 2002; Moncada and Bolaños, 2006; Brown and Bal-Price, 2003). Consequently, TRPM2 activity is predicted to be elevated in MCS and to be stimulated by chemical exposure. TRPM2 may both directly and indirectly leading to increases in NO and $ONOO^-$ production, thus amplifying the already elevated levels of these compounds (see Yamamoto *et al*., 2008 for discussion). There is some evidence that another TRP receptor, TRPM7, may also have a role in this process (Miller, 2006). The role of TRPM2 and possibly 7 may be one of several interacting mechanisms that may lead to the extraordinary chemical sensitivity reported in MCS patients.

There is evidence that other TRP receptors are elevated in response to oxidants and products of oxidative stress biochemistry, including TRPV1 and TRPA1 (Taylor-Clark *et al*., 2008; Bessac *et al*., 2008; Andersson *et al*., 2008; Trevisani *et al*., 2007; Puntambekar *et al*., 2005; Schultz and Ustinova, 1998; Ustinova and Schultz, 1994), but these effects may be more modest than those on TRPM2. The effects on TRPV1 receptors makes them more susceptible to stimulation by their effectors, whereas with TRPM2, oxidative stress acts to open the receptor channel independently of any effector and so may produce a greater physiological response under many circumstances.

3.3 Other Apparent Initiators and Summary of NMDA Role

Three other apparent initiators of cases of MCS were discussed above, carbon monoxide, hydrogen sulfide and mercury. Do any of these act to increase NMDA activity?

Carbon monoxide has been reported to produce such increased NMDA activity and NMDA antagonists block or lower the toxic responses to carbon monoxide exposure (Thom *et al*., 2004; Liu and Fechter, 1995; Penney and Chen, 1996; Ishimaru *et al*., 1992). Hydrogen sulfide can also produce increased NMDA activity and again its toxic effects are lowered by NMDA antagonists (Cheung *et al*., 2007; Qu *et al*., 2008; Kamoun, 2004). Mercury, acting through its metabolic product methylmercury, also acts to produce increases in NMDA activity, and again methylmercury toxicity is lowered by NMDA antagonists (Juárez *et al*., 2005; Allen *et al*., 2002; Faro *et al*., 2002; Miyamoto *et al*., 2001; Zhang *et al*., 2003; Rossi *et al*., 1997). Methylmercury acts to produce such increased NMDA activity, at least in part, by lowering the transport of glutamate, the most important physiological NMDA agonist (Juárez *et al*., 2005; Allen *et al*., 2002).

In summary, then, we have evidence that all seven classes of compounds reported to initiate cases of MCS can each act to increase NMDA activity (**Figure 1**). At least for some members of each class under some conditions, NMDA antagonists can lower the toxic responses to each of them. While evidence linking any one of these to increased NMDA activity may be coincidental, the pattern of evidence for all seven strengthens the argument that increased NMDA activity is not likely to be coincidental. When coupled to the six types of additional evidence, discussed at the beginning of this section, on the apparent NMDA role in MCS, one can argue that there is very substantial evidence, not only that increased

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

NMDA activity has a role in MCS, but also that chemicals are likely to act indirectly by increasing such NMDA activity.

There is extensive evidence that increased NMDA activity produces increases in NO and also its oxidant product $ONOO^-$ (reviewed in Pall, 2002; Moncada and Bolaños, 2006; Brown and Bal-Price, 2003), and it will be argued below that all three of these, NMDA activity, NO and $ONOO^-$, are likely to have key roles in MCS.

4 GENETIC EVIDENCE FOR CHEMICAL EXPOSURE BEING CAUSAL IN MCS

The pattern of chemical exposure preceding cases of MCS and the common mode of action of these chemicals in increasing NMDA activity strongly suggests causality of those exposures. However, one would like to have independent confirmation of causality. Such independent confirmation has come from genetic studies of susceptibility to MCS. There have been three such studies, each providing evidence that chemicals have causal roles in initiating cases of MCS (summarized in **Table 1**).

The first of these to be published was a study by Haley *et al*. (1999) on Gulf War veterans, including those suffering from what some have called Gulf War syndrome. There are several reports that the Gulf War syndrome veterans suffer from MCS or an MCS-like illness (Proctor *et al*., 2001; Reid *et al*., 2001; Miller and Prihoda, 1999; Thomas *et al*., 2006) and there is also evidence that they suffer from such related illnesses as CFS and FM (Chapter 10 in Pall, 2001a; 2007a). The Gulf War veterans were exposed to over a dozen stressors that may have had a role in initiating their illnesses (Chapter 10 in Pall, 2007a), one of which was exposure to the organophosphorus toxicants, sarin and cyclosarin, which are both potent inhibitors of acetylcholinesterases. What Haley *et al*. (1999) report is that those carrying a form of the gene for PON1 that makes them less able to metabolize these neurotoxicants, were more susceptible to developing the neurological symptoms that comprise Gulf War syndrome. This provides substantial evidence that sarin/cyclosarin had a causal role in initiating cases of Gulf War syndrome and that those less able to detoxify these toxicants were therefore more susceptible to it. Mackness *et al*. (2000) showed that British Gulf War veterans with self-reported Gulf War syndrome tended to have lowered activity for the enzyme encoded by the PON1 gene, the paraoxonase enzyme, suggesting again a link to the organophosphorus toxicants. However, in this case, the low activity was not shown to be caused by the genetic polymorphisms of the PON1 gene, so the argument for causality is weaker than in the Haley *et al*. (1999) study. Another study from the same group (Mackness *et al*., 2003), showed that among farmers using sheep dip containing an organophosphorus pesticide, farmers reporting chronic ill health tended to carry the the PON1 allele that produces lowered metabolism of that pesticide, as compared with farmers reporting good health. Unfortunately, MCS prevalence in these two groups of farmers was not studied.

Two studies somewhat similar to the Haley *et al*. (1999) study have been done, comparing a large number of civilian MCS sufferers with unaffected controls (**Table 1**). One was the Canadian study by McKeown-Eyssen *et al*. (2004) and the second, the German study by Schnakenberg *et al*. (2007). Each of these showed that three distinct polymorphic genes involved in the metabolism of chemicals otherwise implicated in initiation of MCS cases have a statistically significant influence on susceptibility (**Table 1**). In the Schnakenberg *et al*. (2007) study, there was an extremely high level of statistical significance for each of these three genes, so that the probability of getting these results by chance if there is no true correlation is less than one in 10^{11}. In total, in these three studies (Haley *et al*., 1999; McKeown-Eyssen *et al*., 2004; Schnakenberg *et al*., 2007), five genes which help determine the rate of metabolism of chemicals previously implicated in MCS have been found to have statistically significant association with the prevalence of MCS; a sixth genetic polymorphism, for the gene GSTT1 had a statistically significant effect only in conjunction with specific alleles of other implicated genes (**Table 1**). A recent similar, but much smaller study, roughly one quarter of the size of the McKeown-Eyssen *et al*. (2004) study and one ninth the size of the Schnakenberg *et al*. (2007) study, failed to find any statistically significant differences between apparent cases and controls (Wiesmüller *et al*., 2008). Of the three larger studies, we have a pattern of evidence showing that genes that metabolize chemicals otherwise implicated in MCS initiation, have substantial influence on the susceptibility to develop MCS. These results support the inference that chemicals acting as toxicants cause many cases of MCS and that those chemicals must be in their toxic form in order to so act. Therefore, alleles of polymorphic genes that either decrease or increase the metabolism of these chemicals will influence the susceptibility to MCS.

One point that should be emphasized is that genetic studies of this type may well give different results with different populations, because populations may differ in either chemical exposure or in the frequencies of the polymorphic alleles in their gene pools. The genetic roles presumably involved here are what are often described as environment X gene interactions. An apparent example of this comes from studies of autism susceptibility where the susceptibility to autism in the USA and Romania, but not in Italy was apparently influenced by the PON1 gene (Pasca *et al*., 2006; D'Amelio *et al*., 2005). The differences were ascribed to the much higher use of organophosphorus pesticides in the USA and Romania than in Italy (Deth *et al*., 2008).

Table 1 Genetic polymorphisms influencing MCS susceptibility

Gene	Study	Function—chemical metabolism	Comments
PON1	H, M	Detoxification of organophosphorus toxicants	—
CYP2D6	M	Hydroxylation of hydrophobic compounds	Hydroxylation of compounds without hydrogen binding group may be expected to lead to greater activity as a TRPV1 agonist
NAT2	M, S	Acetylation	May produce more or less activity depending on the specific compound involved
GSTM1	S	Provide reduced glutathione for conjugation	Should increase detoxification and excretion
GSTT1	S	Glutathione conjugation	Should increase detoxification and excretion
GSTP1	S	Glutathione conjugation	Should increase detoxification and excretion; only statistically significant role was in conjunction with specific alleles of other genes

H, Haley *et al*. (1999); M, McKeown-Eyssen *et al*. (2004); S, Schnakenberg *et al*. (2007).

Are there any alternative interpretations to these genetic data, other than that the metabolism of these chemicals influences their role as toxicants in initiating cases of MCS? There is an alternative for two of the five genes, but not for the other three (**Table 1**). The gene for glutathione reductase has a very important role in the body's protective response to oxidants and oxidative stress, and the PON1 gene has a role in dealing with some of the lipid oxidation products produced by oxidative stress (Draganov and La Du, 2004), at least in lipoproteins in the blood. It follows that the roles of these two genes may be interpreted in an alternative way, but those of the other three genes cannot. The only consistent interpretation for these studies, taken as a whole, is that chemicals act as toxicants in the initiation of cases of MCS. By determining the rate of the metabolism of these chemicals, the genes help determine the incidence and prevalence of MCS.

There is strong, I would argue compelling, evidence that chemical exposure is causal in the initiation of many cases of MCS. What we need to do is to determine what physiological mechanisms are likely to be involved in such initiation. Furthermore, because low levels of similar, if not identical chemicals, trigger sensitivity responses in those already sensitive, similar pathways of action are likely to be involved in such low-level chemical responses.

5 MCS DOES NOT CENTRE ON AN OLFACTORY RESPONSE

The receptors that are implicated in the response to chemicals that are discussed above are not the olfactory receptors (Axel, 2005; Buck, 2005), and yet there have been many descriptions of MCS calling it a reaction to 'odours'. There is no evidence that the olfactory system has a central role here and there is considerable evidence against such a role. Ashford and Miller (1998) reviewed a number of studies where people with severe nasal congestion still reacted to chemical exposures. There are cases of MCS in people with no sense of smell, that is people suffering from anosmia (Doty, 1994). Many MCS patients report reacting at times when they could not smell any chemical odour. There have been three studies of patients where a nose clip was used to block off access of odourants to the nasal epithelia and those MCS patients still reacted to chemical exposure (Joffres *et al*., 2005; Millqvist and Löwhagen, 1996; Millqvist *et al*., 1999). In a recent study, regions of the brain that respond to odours were found to have lowered responses to odourants in MCS patients as compared with controls, not elevated responses (Hillert *et al*., 2007). The author is not arguing that the olfactory mechanism is never impacted in MCS cases, but rather that it does not have any essential role in the chemical sensitivity process and should not be the focus of studies, when trying to assess responses of MCS patients to chemicals. We are looking at a response to chemicals, many of which have odours, not a response to odours.

6 PREVALENCE ESTIMATES

Sorg (1999) reviewed prevalence studies of MCS by concluding that 'prevalence of severe MCS in the United States is approximately 4%'. She also concludes that those with milder chemical sensitivity are about 15–30% of the US population. Several more recent studies of MCS prevalence provide additional information on this issue (Kreutzer *et al*., 1999; Caress and Steinemann, 2003; 2004a; 2004b; 2005). Pall (2007a, Chapter 11) estimated that the prevalence of severe MCS in the USA was probably about 3.5%, with much larger numbers, perhaps 12–25% modestly affected. These

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

estimates are slightly lower than the Sorg (1999) estimate. There have been few studies of MCS prevalence in other countries, but one study each from Canada (Joffres *et al*., 2001), Germany (Hausteiner *et al*., 2005), Sweden (Johansson *et al*., 2005) and Denmark (Berg *et al*., 2008) suggest prevalences of roughly 50–100% of those in the USA. All of these studies suggest that there is substantial impact of MCS on public health.

Caress and Steinemann (2003) estimated that 1.8% of the entire US population have lost their jobs due to chemical sensitivity, suggesting that many of the more severely affected may be unemployed or underemployed due to their MCS. There are no similar figures with regard to housing, but anecdotal reports suggest that the most sensitive often have great difficulty finding housing they can tolerate.

7 CASE DEFINITIONS

Probably the best review of and comparison of different case definitions for MCS was published by the Toronto group (McKeown-Eyssen *et al*., 2001). In that review, they compared seven different proposed case definitions, those of Randolph (1965), Cullen (1987), Thomson *et al*. (1985), the National Research Council, Board on Environmental Studies and Toxicology, Commission on Life Sciences (1992), Ashford and Miller (1998), Nethercott *et al*. (1993) and the 1999 Consensus (MCS Consensus Conference, 1999). These differ from each other in various ways, most notably in whether they require that the symptoms be polysystemic, associated with multiple organs, whether cases must be chronic, whether cases must be acquired as a consequence of one or more chemical exposure events and whether sensitivity responses must be produced by multiple 'unrelated' chemicals.

McKeown-Eyssen *et al*. (2001) compared various groups of patients with each other for their fit to each of these case definitions, using the University of Toronto Questionnaire. They compared the case definitions in several ways using this data, but perhaps the most crucial comparison was how well a specific case definition was able to discriminate between environmental practice patients and general practice patients. By that criterion, the Nethercott *et al*. (1993) case definition and the 1999 Consensus were the best, giving the highest odds ratio in comparing these groups of patients, with both giving odds ratios of roughly 20. The 1999 Consensus case definition (MCS Consensus Conference, 1999) is the one currently used on the Wikipedia site discussion of MCS and may be currently the most widely accepted case definition.

It should be noted that comparing occupational medicine practice patients with general practice patients also produced high odds ratios by these two case definitions, albeit lower ones than did the previously discussed comparison, suggesting that occupational chemical exposure often causes cases of MCS, as defined by these two case definitions (McKeown-Eyssen *et al*., 2001).

In contrast, the Cullen (1987) case definition only had an odds ratio of about eight, much lower than the Nethercott *et al*. (1993) or the 1999 Consensus case definition. The Cullen (1987) case definition has been criticized because of an additional, perhaps more important concern: it requires that 'no widely accepted test of physiologic function can be shown to correlate with symptoms'. However, as will be discussed below, there are a number of such tests that have been reported, tests of objectively measurable responses to low-level chemical exposure. This specific Cullen requirement may also be objected to, because it means, in effect, that we must stay perpetually ignorant of the aetiological mechanism of MCS. It should be discarded in the author's view, therefore, both for empirical and theoretical reasons.

There is one other issue that should be considered here, regarding what should and should not be part of an MCS case definition. Lacour *et al*. (2005) argued that only those patients who suffer from CNS-related complaints in response to chemical exposure should be considered to be true MCS patients. Such CNS-related symptoms include headache, fatigue, confusion and cognitive dysfunction. One possible rationale for this proposal is that Bell and others, as discussed below, have proposed a CNS mechanism for MCS involving neural sensitization in the brain, such that chemical exposure produces changes in synaptic sensitivities over substantial regions of the brain. Lacour *et al*. (2005) report that self-reported complaints of apparent MCS patients most commonly included CNS symptoms with symptoms derived from other regions of the body being less frequent. There is an argument for using a case definition for MCS that excludes patients without CNS-related symptoms.

Let us end this discussion by comparing the 1999 Consensus case definition (MCS Consensus Conference, 1999), listed immediately below with a couple of modifications that the author wishes to suggest for the reader's consideration:

1. Symptoms are reproducible with repeated (chemical) exposures.
2. The condition has persisted for a significant period of time.
3. Low levels of exposure (lower than previously or commonly tolerated) result in manifestations of the syndrome (i.e. increased sensitivity).
4. The symptoms improve, or resolve completely, when the triggering chemicals are removed.
5. Responses often occur to multiple, chemically unrelated substances.
6. Symptoms involve multiple-organ symptoms.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

7.1 Suggestion #1

The main concern here is that it is not clear what chemically unrelated means. If it means that there is no relationship among these chemicals that can be challenged, because they all may act to produce increased NMDA activity. Describing them as being chemically diverse is more accurate. This should not change how the case definition is used in practice.

1. Symptoms are reproducible with repeated (chemical) exposures.
2. The condition has persisted for a significant period of time.
3. Low levels of exposure (lower than previously or commonly tolerated) result in manifestations of the syndrome (i.e. increased sensitivity).
4. The symptoms improve, or resolve completely, when the triggering chemicals are removed.
5. Responses occur to multiple, chemically diverse substances.
6. Symptoms include those derived from multiple organs.

7.2 Suggestion #2

This suggestion includes the requirement for CNS involvement proposed by Lacour *et al*. (2005), and thus may correspond to what some consider to be the most classic aspect of MCS. I am sure that these two suggested case definitions will have much overlap in practice terms, because many will have symptoms derived from multiple organs, one of which is the brain.

1. Symptoms are reproducible with repeated (chemical) exposures.
2. The condition has persisted for a significant period of time.
3. Low levels of exposure (lower than previously or commonly tolerated) result in manifestations of the syndrome (i.e. increased sensitivity).
4. The symptoms improve, or resolve completely, when the triggering chemicals are removed.
5. Responses occur to multiple, chemically diverse substances.
6. Symptoms include those derived from apparent CNS sensitivity, such as chemically elicited headache, fatigue, depression, anxiety, memory and concentration difficulties and confusion and cognitive dysfunction.

There are two additional issues that should be considered when deciding whether a particular patient should be allowed into a study on MCS:

- There is a huge variation in severity among different MCS patients and objective changes that may be obvious in looking at more severe MCS cases may be undiscernible when looking at more modestly affected patients. There is an argument, therefore, that one should limit admission to such studies to perhaps the most affected quarter of such patients, possibly using the Miller Quick Environmental Exposure and Sensitiviy Inventory (QEESI) questionnaire (Miller and Mitzel, 1995; Miller and Prihoda, 1999) to assess severity.
- Another issue is raised by the apparent local nature of chemical reactivity in MCS. If one is, for example, looking at responses in the lungs, one should distinguish between those patients who have asthma-type symptoms from those who do not. Similar divisions should be made for those who appear to be affected in other specific regions of the body.

8 The NO/ONOO$^-$ CYCLE MECHANISM AS THE AETIOLOGICAL MECHANISM FOR MCS AND RELATED ILLNESSES

The many puzzling features of MCS are thought to require a new disease paradigm in order to explain them. This argument has been made by Bronstein (1995), Miller (1999), Rowat (1998) and Arnetz (1999). Even the MCS skeptic Gots (1996) has argued that any physiological explanation for MCS requires such a new disease paradigm. Earlier in this review, an apparently convincing argument has been made that chemicals act as toxicants in MCS, acting via different pathways, but with each producing an increase in NMDA activity. It is well established that NMDA stimulation produces increases in NO and its oxidant product ONOO$^-$ (reviewed in Pall, 2002; Moncada and Bolaños, 2006; Brown and Bal-Price, 2003), so that any or all of these may be involved in generating the properties of MCS.

There are many puzzling features of MCS, each of which must be explained by any proposed new paradigm. One of these is the relationship between MCS and several other related chronic illnesses, including CFS and FM and even PTSD. Several research groups have argued for a common aetiological mechanism for two, three or all four of these illnesses (Miller, 1999; Ziem and Donnay, 1995; Buchwald and Garrity, 1994; Clauw and Chrousos, 1997; Bell *et al*., 1998a; Wessely *et al*., 1999; Yunus, 2001; Pall, 2001a; Pall and Satterlee, 2001; Cohen *et al*., 2002; Buskila and Cohen, 2007). They are all comorbid with each other, they share a large number of symptoms and signs and they all share a common pattern of case initiation: cases of each are often initiated by a short-term stressor, exposure to which is followed by chronic illness. A fourth common

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 2 The stressors implicated in the initiation of these illnesses are summarized

Illness	Stressors implicated in initiation of illness
Chronic fatigue syndrome	**Viral infection, bacterial infection, organophosphorus pesticide exposure**, carbon monoxide exposure, ciguatoxin poisoning, physical trauma, severe psychological stress, toxoplasmosis (protozoan) infection, ionizing radiation exposure
Multiple chemical sensitivity	**Volatile organic solvent exposure, organophosphorus/carbamate pesticide exposure**, organochlorine pesticide exposure, pyrethroid exposure; hydrogen sulfide; carbon monoxide; mercury
Fibromyalgia	**Physical trauma (particularly head and neck trauma), viral infection**, bacterial infection, severe psychological stress, pre-existing autoimmune disease
Post-traumatic stress disorder	**Severe psychological stress**, physical (head) trauma

The stressors indicated in bold are the ones most commonly implicated for that specific disease/illness. It should be noted that the majority of such stressors are implicated in the initiation of more than one illness. Modified from the author's web site, with permission.

feature of these illnesses is that cases of each of them are stunningly variable from one patient to another, such that we need an explanation for this variability.

So what is needed, according to this point of view, is a common aetiological mechanism which explains both the similarities and the differences among cases of these illnesses. A detailed model of these four multisystem illnesses is presented below, focussing mainly on how it plays out in MCS, but also outlining how predicted variations may explain all four of these illnesses. Then and only then will the evidence be reviewed, supporting this model for MCS. Much of this discussion comes from the author's web site, with permission, and much of the evidence for it is provided in Pall (2007a) as well as other publications (Pall, 2000; 2002; Pall and Anderson, 2004).

Short-term stressors that are apparent initiators of these four illnesses are summarized in **Table 2**. You will note that each of these illnesses is initiated by multiple stressors and that these initiators include a variety of infections, physical trauma, severe psychological stress, ionizing-radiation exposure and neurotoxins such as ciguatoxin, in addition to the various chemical classes implicated in MCS initiation. These diverse stressors can all act to increase the levels of NO in the body (Pall, 2007a; 2007b; 2008; see above for MCS initiators). While each of these stressors implicated in initiation of one or more illnesses act to increase NO levels, several of these do *not* act via increased NMDA stimulation. Specifically, viral, bacterial and protozoan infections and also ionizing-radiation exposure act via induction of inducible nitric oxide synthase (iNOS) rather than acting via NMDA stimulation; NMDA receptor activation acts, in contrast, by increasing levels of intracellular calcium which stimulates, in turn, the two calcium-dependent nitric oxide synthases (NOSs), neuronal (nNOS) and endothelial (eNOS) (Pall, 2002; Moncada and Bolaños, 2006; Brown and Bal-Price, 2003). Thus it *may* be the case that MCS initiation requires increases in NMDA activity, but it is clear that CFS and FM initiation do not.

How then might short-term increases in NO produce a chronic illness? It can be argued that NO acts via its oxidant product $ONOO^-$ to initiate a complex biochemical vicious cycle that is then the cause of illness (Pall, 2000; 2001a; 2002; 2007a; 2007b), see **Figure 2**. So with each of these we have an initial cause, the short-term stressors, as well as on ongoing cause, with the ongoing cause being responsible for the properties of the chronic illness.

The vicious cycle initiated by these NO increases is shown in **Figure 2** and is centred on excessive levels of NO and its oxidant product $ONOO^-$. This vicious cycle is now being called the NO/$ONOO^-$ cycle (Pall, 2006; 2007a) (pronounced no, oh no!), based on the structures of NO and $ONOO^-$). Each of the arrows in **Figure 2** represents one or more mechanisms by which one element of the cycle acts to increase the levels of another element of the cycle. The chronic nature of these diseases is thought to be caused by the NO/$ONOO^-$ cycle, propagating itself over time through the mechanisms represented by these arrows. Most of the individual mechanisms in the cycle are based on very well-documented biochemistry (Pall, 2000; 2002; 2007a), supporting the plausibility of the cycle as a whole. Cycle elements, as shown in **Figure 2**, include not only NO and $ONOO^-$, but also superoxide, oxidative stress, the transcription factor NF-κB, the inflammatory cytokines (upper right hand corner), all three NOSs (iNOS, nNOS, eNOS), intracellular calcium levels and two types of receptors found in neuronal and non-neuronal cells, the NMDA receptor (Pall, 2007a) and the several of the TRP receptors (see above discussion; only the TRPV1 (vanilloid) receptor is shown in **Figure 2**). There are 22 distinct mechanisms that are represented by the various arrows, of which 19 are

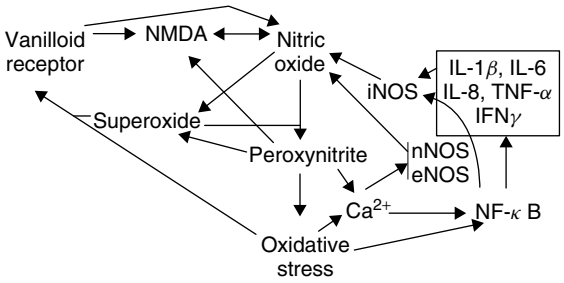

Figure 2 Vicious ($NO/ONOO^-$) cycle diagram. Each arrow represents one or more mechanisms by which the variable at the foot of the arrow can stimulate the level of the variable at the head of the arrow. It can be seen that these arrows form a series of loops that can potentially continue to stimulate each other. An example of this would be that nitric oxide can increase peroxynitrite, which can stimulate oxidative stress, which can stimulate NF-κB, which can increase the production of iNOS, which can, in turn increase nitric oxide. This loop alone constitutes a potential vicious cycle and there are a number of other loops, shown diagramatically in the figure that can collectively make up a much larger vicious cycle. The challenge in these illnesses, according to this view, is to lower this whole pattern of elevations to get back into a normal range. You will note that the cycle not only includes the compounds nitric oxide, superoxide and peroxynitrite, but a series of other elements, including the transcription factor NF-κB, oxidative stress, inflammatory cytokines (in box, upper right), the three different forms of the enzymes that make nitric oxide (the nitric oxide synthases iNOS, nNOS and eNOS), and two neurological receptors, the vanilloid (TRPV1) receptor and the NMDA receptor. (The figure and legend are taken from the author's web site with permission.)

well-established, well-accepted biochemistry and physiology (Pall, 2000; 2002; 2007a; Pall and Anderson, 2004).

Of the other three, there is substantial new evidence for each of them that was not available when that section of the Pall (2007a) book was written. The impact of NO in increasing superoxide generation from the electron-transport chain in mitochondria is now increasingly accepted (Moncada and Higgs, 2006). The effect of oxidants and oxidative stress in increasing activity of TRPV1 (vanilloid receptor) and several other the TRP receptors is also now supported by much more substantial evidence (see above discussion). And Chen *et al*. (2008) have recently provided more evidence on the impact of $ONOO^-$ on the electron-transport chain in the mitochondrion, producing increased superoxide generation. Chen *et al*. (2008) also provides important new evidence on the mechanism involved in producing this increased superoxide generation. Thus all three of the previously more weakly supported mechanisms out of the 22 are now considerably more strongly supported then they were 2.5 years ago. There is a massive amount of evidence supporting the existence of the individual mechanisms proposed to make up the $NO/ONOO^-$ cycle and the only truly original aspect to it is the simple assumption that it fits together in the way that one might assume it does, based on the individual mechanisms.

Much of the mechanism outlined in **Figure 2** is classic inflammatory biochemistry—the NF-κB actions, inflammatory cytokine induction, iNOS induction, leading to increased NO, $ONOO^-$ and oxidative stress, and consequent mitochondrial dysfunction—all of these are found in every inflammatory condition. This raises the question as to whether specific chronic inflammatory diseases, and there are dozens of them, may be $NO/ONOO^-$ cycle diseases?

There are two aspects of the $NO/ONOO^-$ cycle that are not apparent from **Figure 2**. Both add further evidence for important individual mechanisms, as well as the plausibility of the overall cycle:

1. $ONOO^-$, superoxide and NO all can act via known mechanisms to lower mitochondrial function and thus adenosine triphosphate (ATP) generation (Moncada and Bolaños, 2006; Keller *et al*., 1998). $ONOO^-$ is known to attack a number of iron–sulphur proteins, including such proteins that have important roles in both the mitochondrial electron-transport chain and in the citric-acid cycle, and also leads to mitochondrial dysfunction through protein tyrosine nitration and other mechanisms (Radi *et al*., 2002; Cassina and Radi, 1996; Keller *et al*., 1998). $ONOO^-$ is also known to produce nicks in chromosomal DNA, leading in some cases to massive stimulation of poly(ADP)-ribosylation of chromosomal proteins, and because the precursor to such poly(ADP)-ribose synthesis is NAD, this can lead to massive depletion of NAD/NADH pools and consequent lowering of mitochondrial energy metabolism (Szabo, 2003; Moncada and Bolaños, 2006). Superoxide and NO also lower energy metabolism via distinct mechanisms. They both can produce lowered activity of the aconitase enzyme (Gardner *et al*., 1997; Gardner, 1997; Castro *et al*., 1994), as can $ONOO^-$. The cardiolipin in the inner membrane of the mitochondrion is very susceptible to lipid peroxidation and superoxide generated by the electron transport chain in the mitochondrion can indirectly produce major increases in such lipid peroxidation, leading to lowered activity of complexes I, III and IV and therefore lowered ATP generation (Paradies *et al*., 2001; *et al*., 2002; Musatov, 2006). NO is a competitive inhibitor of the enzyme cytochrome oxidase (complex IV) and can therefore lower the activity of the entire mitochondrial electron transport chain by lowering its terminal oxidase activity (Cassina and Radi, 1996; Galkin *et al*., 2007). The lowered ATP generation produced by this combination of mechanisms is not only important in the generation

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

of symptoms as a consequence of the NO/ONOO$^-$ cycle, but is also important as part of the proposed cycle itself; NMDA receptor activity is known to be activated by lowered availability of ATP, acting via two distinct mechanisms that are discussed below. Furthermore, the maintenance of low intracellular calcium levels involves much energy utilization via Ca^{+2}-ATPase and thus lowered ATP availability will tend to increase intracellular calcium levels, another predicted aspect of the NO/ONOO$^-$ cycle.

2. There are reciprocal interactions between ONOO$^-$ and a cofactor for the NOSs, tetrahydrobiopterin (BH4). ONOO$^-$ oxidizes BH4, leading to BH4 depletion and such depletion leads to what is called the partial uncoupling of all three NOSs (Pall, 2007b; Milstien and Katusic, 1999; Kohnen *et al*., 2001; Kuhn and Geddes, 2003). The uncoupled NOSs generate superoxide in place of NO. Thus, in tissues and regions of cells with high NOS activity, partial uncoupling leads to adjacent enzymes generating NO and superoxide, thus leading to almost instantaneous synthesis of ONOO$^-$. In this way, partially uncoupled NOS enzymes can act collectively as ONOO$^-$ synthases (Delgado-Esteban *et al*., 2002; Pall, 2007b). The ONOO$^-$ so generated will oxidize more BH4, thus leading to more partial uncoupling. This partial uncoupling may be central to the entire NO/ONOO$^-$ cycle leading to a shift in the ratio of NO to ONOO$^-$. That shift may be critical to the cycle in multiple ways, including generating increased activity of the transcription factor NF-κB; whereas ONOO$^-$ leads to activation of NF-κB, NO lowers NF-κB activity and thus the ratio of the two may be critical in determining the NF-κB regulatory response (Pall, 2007b).

Both of these aspects of the NO/ONOO$^-$ cycle are shown in **Figure 3**, a much more complete figure of the NO/ONOO$^-$ cycle. In it you will see the reciprocal relation between ONOO$^-$ (abbreviated PRN in the figure) and BH4 depletion. You will also see the role of ATP depletion inserted into the figure. One additional apparent aspect of the cycle is shown in the top left corner of **Figure 3**, indicated for the TRP receptors, specifically TRPV1, TRPA1 and TRPM2. TRPV1 and TRPA1 are both activated by the consequences of oxidative stress (Taylor-Clark *et al*., 2008; Bessac *et al*., 2008; Andersson *et al*., 2008; Trevisani *et al*., 2007; Puntambekar *et al*., 2005; Schultz and Ustinova, 1998; Ustinova and Schultz, 1994), as discussed above. The transfer receptor protein TRPM2, discussed above, is strongly activated by oxidants, presumably including ONOO$^-$, with such activation producing an influx of intracellular calcium which is predicted, in turn, to increase NO synthesis. The TRPM2 role in the NO/ONOO$^-$ cycle has not been proposed prior to this publication, but it may well be an important aspect of the cycle mechanism.

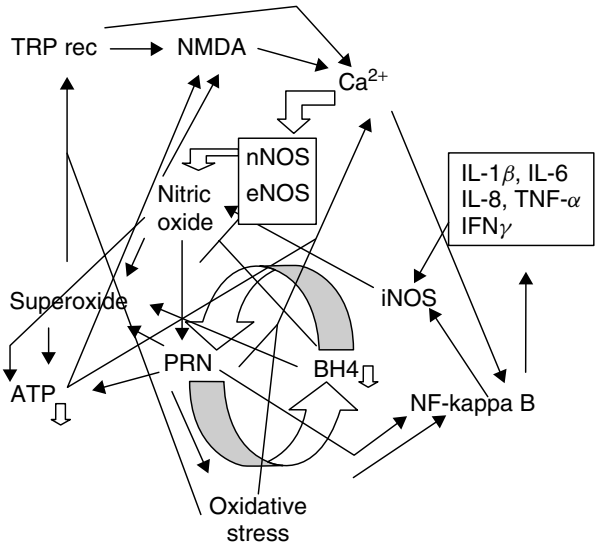

Figure 3 A more complete NO/ONOO$^-$ cycle diagram. Central to the figure are the reciprocal interactions between peroxynitrite, abbreviated as PRN and tetrahydrobiopterin (BH4) depletion. Also indicated is the ATP depletion produced by peroxynitrite, superoxide and nitric oxide. And in the upper left corner, TRP represents the three TRP receptors, TRPV1, TRPA1 and TRPM2, each of which is stimulated via distinct mechanisms by oxidative stress. Each arrow in the figure represents one or more mechanisms by which one element of the cycle stimulates another element of the cycle. (Figure and legend is taken from the author's web site with permission.)

There are three types of generic evidence that support the existence of the NO/ONOO$^-$ cycle (Pall, 2007a). By generic, I mean evidence not linked to any specific disease or illness. These are as follows:

1. Twelve studies have shown that one or both of two drugs that break down to release NO (nitroglycerine and nitroprusside) cause mammalian tissues to synthesize increased amounts of NO via all three NOSs (Chapter 1 in Pall, 2007a). These studies support the existence of a vicious cycle involving all three NOSs, as predicted by the NO/ONOO$^-$ cycle, but do not say anything about other aspects of the cycle.
2. Increased NMDA activity can increase essentially all of the NO/ONOO$^-$ cycle elements that are shown in **Figure 2** (Chapter 3 in Pall, 2007a). NMDA receptor activity directly increases intracellular calcium levels leading to increased NO levels. These studies show that most of the cycle elements can be increased simply by elevating intracellular calcium and NO, thus providing evidence for a cycle similar or identical to the NO/ONOO$^-$ cycle.
3. Hyperalgesia animal models involve all of the cycle elements shown in **Figure 2** in the generation of excessive pain in hyperalgesia (Chapter 3 in Pall,

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

2007a). It is difficult to explain this involvement unless the cycle ties all of these elements together.

The NO/ONOO$^-$ cycle aetiology as an explanatory model is based on five distinct principles (Pall, 2006; 2007a; 2007b; Pall and Bedient, 2007):

1. Short-term stressors that initiate cases of multisystem illnesses act by raising NO synthesis and consequent levels of NO and/or other cycle elements.
2. Initiation is converted into a chronic illness via vicious cycle mechanisms, through which chronic elevation of NO and ONOO$^-$ and other cycle elements is produced and maintained. This principle predicts that the various elements of the NO/ONOO$^-$ cycle will be elevated in the chronic phase of illness.
3. Symptoms and signs of these illnesses are generated by elevated levels of NO and/or other important consequences of the proposed mechanism, that is, elevated levels of ONOO$^-$, NO, inflammatory cytokines, oxidative stress, elevated NMDA, TRPV1 receptor activity and/or other aspects of the cycle.
4. Because the compounds involved, NO, superoxide and ONOO$^-$ have quite limited diffusion distances in biological tissues and because the mechanisms involved in the cycle act at the level of individual cells, *the fundamental mechanisms are local*.
5. Therapy should focus on down-regulating NO/ONOO$^-$ cycle biochemistry.

Of these principles, we have discussed 1 and 2 above. Principle 3 predicts that the symptoms and signs of illness can be generated by elevation of one or more elements of the cycle. Some examples of how symptoms and signs of illness may be explained by the cycle are discussed below.

Principle 4 is so important that it takes up an entire chapter (Chapter 4) in my book (Pall, 2007a). Because NO, superoxide and ONOO$^-$, the three chemical compounds most central to the NO/ONOO$^-$ cycle, have relatively short half-lives in biological tissues, they don't diffuse very far from their site of origin in the body. NO has the longest such half-life and it only diffuses about 1 mm from its origin. Furthermore, most of the mechanisms implicated by the arrows act at the cellular level. The consequence of all of this is that the NO/ONOO$^-$ cycle may be elevated in one tissue of the body, but an adjacent tissue may show little elevation and therefore be little impacted by the cycle. This local nature of the cycle biochemistry means that we can have all kinds of variations in tissue impact from one patient to another, leading in turn to all kinds of variation in symptoms and signs from one individual to another. This striking variation in symptoms from one individual to another has been repeatedly been noted in these illnesses and has been one of the great puzzles about this group of illnesses. The variation can be easily explained by the local nature of the NO/ONOO$^-$ cycle mechanism. Principle 4 does *not* suggest that there are no systemic effects, but rather that much of the cycle effects are local.

Principle 5 states that the focus of therapy should be to down-regulate NO/ONOO$^-$ cycle biochemistry. In other words, therapy should focus on lowering the cause of illness, not just on treating symptoms. This is obviously an important principle for both patients suffering from these illnesses and for conscientious physicians trying to treat them. There is much stronger evidence for principle 5 in CFS and FM (discussed below) than in the related illness MCS.

These five principles are important as a group for three distinct but overlapping reasons:

- Taken together, they produce an essentially complete explanatory model.
- The fit to each of the five produces a very different type of evidence for the causality of the cycle. Are cases of the disease/illness started by agents predicted to initiate the cycle? Are cycle elements elevated in the chronic phase of illness? Can the symptoms and signs of illness be generated by one or more the elements of the cycle? Is there evidence for a local mechanism? Can the disease/illness be treated by agents predicted to down-regulate the cycle?
- Because the fit to each of the five gives a very different type of evidence for causality of the cycle, the fit to each of them provides a distinct criterion as to whether a particular disease/illness is a good candidate for being a NO/ONOO$^-$ cycle disease.

What the author has done, in his book and elsewhere, then, is to use these five criteria to ask whether each multisystem illness and also a number of other diseases are good candidates for inclusion under the NO/ONOO$^-$ cycle mechanism. It is the goal, then in a following section of this chapter to go through each of the criteria to see how good the fit is for MCS.

In summary, there are three distinct types of evidence that support the general notion that the NO/ONOO$^-$ cycle mechanism in an important paradigm of human disease.

1. The individual mechanisms of the cycle, represented by the arrows in **Figures 2** and **3**, are almost all well-documented biochemistry and physiology.
2. There are three generic types of evidence for the existence of the cycle, that is evidence not linked to any specific disease or illness.
3. There are a number of diseases/illnesses where one can argue based on the fit to the five principles outlined above, that they are good candidates for inclusion under the NO/ONOO$^-$ cycle paradigm.

8.1 NO/ONOO$^-$ Cycle Mechanisms for the Generation of Shared Symptoms and Signs of Illness

It has been widely claimed that these multisystem illnesses and even their symptoms are unexplained. Clearly, for the NO/ONOO$^-$ cycle mechanism to be plausible for these multisystem illnesses, it must be possible to explain the symptoms and signs of illness as being generated by one or more elements of the cycle. Such explanations are needed for both the specific symptoms and signs and the shared ones, discussed here (**Table 3**). In Chapter 3 of Pall (2007a), evidence is provided on how these shared symptoms and signs may be generated by the NO/ONOO$^-$ cycle aetiology. The mechanisms listed in **Table 3** are *not presented as established mechanisms in these illnesses*, but they are plausible mechanisms based on substantial scientific information. Each of these only occurs in some multisystem illness sufferers, consistent with the striking variation of symptoms and signs that are a characteristic feature of these illnesses. Indeed it may be argued that the defining symptoms and signs of CFS, MCS, FM and PTSD are found in all sufferers of each of these illnesses because we required them for the diagnosis. In other words, we appear to have a very large spectrum of illness that we have more or less arbitrarily subdivided via particular symptoms.

9 FUSION OF THE NO/ONOO$^-$ CYCLE MECHANISM WITH NEURAL SENSITIZATION AND OTHER PUTATIVE MCS MECHANISMS

While what has become the NO/ONOO$^-$ cycle has produced fairly complete explanations of such illnesses as CFS and FM and also of a number of additional, well-established diseases (Pall, 2007a; Pall and Bedient, 2007), it alone did not produce a compelling explanation for the complexities of MCS (Pall and Satterlee, 2001). It was only when fused with a previous MCS model, the neural sensitization model, that a much more complete explanation became apparent.

Bell and her collaborators (Bell *et al*., 1992; 1999a; 2001a) and others (Antelman, 1994; Rossi, 1996; Friedman, 1994; Sorg and Prasad, 1997) proposed a neural sensitization model, where chemicals were proposed to act to greatly increase neural sensitization in the brain, particularly in the limbic system. The notion here is that if chemicals can act to produce such neural sensitization, greatly increasing the activity of synapses over large regions of the brain, that this could explain the basic mechanism of MCS. In this way, chemicals might generate changes in EEG activity (Lorig *et al*., 1991; Bell *et al*., 1999b; 2001b; Fernandez *et al*., 1999; Muttray *et al*., 1995) and also in brain PET scans (Heuser and Wu, 2001; Hillert *et al*., 2007) and SPECT scans (Simon *et al*., 1994; Heuser *et al*., 1994; Fincher *et al*., 1997a; 1997b) in MCS. There was a New York Academy of Sciences meeting in 2000 that focussed on the proposed neural sensitization mechanism for MCS (Sorg and Bell, 2001) and there is no question that at that time, this neural sensitization view was the most influential view of a possible physiological basis for MCS. Ashford and Miller (1998) listed 10 compelling similarities between MCS and neural sensitization, each of which may be considered to be evidence in favour of a neural sensitization model.

Nevertheless, the neural sensitization interpretation of MCS never generated explanations of how the various classes of chemicals may work nor how the roughly 1000-fold increase in chemical sensitivity that appears to occur in many MCS patients might be generated, nor the similarities to CFS and related illnesses. It did provide a framework for explaining the chronic nature of chemical sensitivity, namely long-term changes in synaptic sensitivity.

The most important mechanism of neural sensitization is that of long term potentiation (LTP), the main mechanism involved in learning and memory. The LTP mechanism is involved on a highly selective basis in strengthening synaptic interactions in the process of learning and memory, and the question raised by its possible role in MCS is what will be the consequences if chemical exposure leads to a massive activation of this process?

In the process of neural sensitization, changes in each synapse involve changes in both the presynaptic and the postsynaptic neurons. LTP is known to involve, as key elements in a complex overall mechanism activated in the postsynaptic neuron, several elements of the NO/ONOO$^-$ cycle, notably NMDA activity, NO and intracellular calcium (Albensi, 2001; Bliss and Collingridge, 1993; Bennett, 2000; Platenik *et al*., 2000; Dineley *et al*., 2001; Prast and Phillippu, 2001; Cotman *et al*., 1988). Superoxide, another cycle element also has a role, albeit a complex one (Knapp and Klann, 2002; Hu *et al*., 2007). Increased NMDA activity in the postsynaptic neuron has a role, as do the increases in intracellular calcium and NO produced by such NMDA stimulation of the postsynaptic neuron (Albensi, 2001; Bliss and Collingridge, 1993; Bennett, 2000; Platenik *et al*., 2000; Dineley *et al*., 2001; Prast and Phillippu, 2001; Cotman *et al*., 1988). NO produced in the postsynaptic neuron, acts as what is called a retrograde messenger, diffusing back to the presynaptic neuron and causing it to be more active in neurotransmitter release, including the release of glutamate, the major physiological agonist of the NMDA

Table 3 Explanations for symptoms and signs

Symptom/sign	Explanation based on elevated nitric oxide/peroxynitrite theory
Energy metabolism/mitochondrial dysfunction	Inactivation of several proteins in the mitochondrion by peroxynitrite; inhibition of some mitochondrial enzymes by nitric oxide and superoxide; NAD/NADH depletion; cardiolipin oxidation
Oxidative stress	Peroxynitrite, superoxide and other oxidants
PET scan changes	Energy metabolism dysfunction leading to change transport of probe; changes in perfusion by nitric oxide, peroxynitrite and isoprostanes; increased neuronal activity in short-term response to chemical exposure
SPECT scan changes	Depletion of reduced glutathione by oxidative stress; perfusion changes as under PET scan changes
Low NK (natural killer) cell function	Superoxide and other oxidants acting to lower NK cell function
Other immune dysfunction	Sensitivity to oxidative stress; chronic inflammatory cytokine elevation
Elevated cytokines	NF-κB stimulating of the activity of inflammatory cytokine genes
Anxiety	Excessive NMDA activity in the amygdala
Depression	Elevated nitric oxide leading to depression; cytokines and NMDA increases acting in part or in whole via nitric oxide.
Rage	Excessive NMDA activity in the periaqueductal grey region of the mid-brain
Cognitive/learning and memory dysfunction	Lowered energy metabolism in the brain, which is very susceptible to such changes; excessive NMDA activity and nitric oxide levels and their effects of learning and memory
Multiorgan pain	All components of cycle have a role, acting in part through nitric oxide and cyclic guanosine monophosphate (cGMP) elevation
Fatigue	Energy metabolism dysfunction
Sleep disturbance	Sleep impacted by inflammatory cytokines, NF-κB activity and nitric oxide
Orthostatic intolerance	Two mechanisms: nitric oxide-mediated vasodilation leading to blood pooling in the lower body; nitric oxide-mediated sympathetic nervous system dysfunction
Irritable bowel syndrome	Sensitivity and other changes produced by excessive vanilloid and NMDA activity, increased nitric oxide
Intestinal permeabilization leading to food allergies	Permeabilization produced by excessive nitric oxide, inflammatory cytokines, NF-κB activity and peroxynitrite; peroxynitrite acts in part by stimulating poly(ADP)-ribose polymerase activity

Taken from the author's web site with permission. It should be noted that while each of these are plausible mechanisms and, in most cases well-documented mechanisms under some pathophysiological circumstances, in most cases their role in generating these symptoms in these multisystem illnesses is *not* established. The role of reduced glutathione depletion in generating SPECT scan changes is documented in Jacquier-Sarlin *et al*., 1996 and in Suess *et al*., 1991.

receptors (Zhang and Snyder, 1995; Kuriyama and Ohkuma, 1995; Williams, 1996). LTP involves not only increased glutamate release, but also changes in the post-synaptic neuron, making its synapses more sensitive to stimulation.

One point that needs to be made is that we have a striking convergence between the demonstrated role of each of the chemicals implicated in MCS, producing increased NMDA activity, and the essential role of NMDA receptors in LTP. This convergence provides, therefore, for the first time, an explanation for that pattern: only chemicals leading to increased NMDA activity may be expected to produce an up-regulation of the LTP mechanism.

Whereas the normal, highly selective role of LTP in learning and memory will not be expected to involve any substantial NO/ONOO$^-$ cycle elevation, a massive stimulation of NMDA activity over substantial regions of the brain, produced by chemical exposure, will be expected to involve substantial NO/ONOO$^-$ cycle elevation. The extraordinary chemical sensitivity seen in MCS, at least in the CNS-related symptoms, may then be generated by the following multiple mechanisms:

1. Subsequent chemical exposure will stimulate regions of the brain with already existing neural sensitization, with that neural sensitization maintained both by the standard LTP mechanism *and* by the local elevation of the NO/ONOO$^-$ cycle. This combination may be exacerbated by a series of mechanisms, each involving elements of the NO/ONOO$^-$ cycle, as follows.
2. NO acting as a retrograde messenger will act to stimulate further glutamate release by the presynaptic neurons.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

3. Energy metabolism dysfunction produced by $ONOO^-$, superoxide and NO will cause NMDA receptors to be hypersensitive to stimulation. It is known that energy-metabolism dysfunction produces a decreased membrane potential which acts, in turn, to cause the NMDA receptors in such cells to be hypersensitive to stimulation (reviewed in Novelli *et al*., 1988; Schulz *et al*., 1997; Turski and Turski, 1993; Pall, 2002).
4. Energy-metabolism dysfunction also acts on glial cells which normally rapidly lower extracellular glutamate via energy-dependent glutamate transport. Lowered energy metabolism will then lead to increased extracellular glutamate, leading in turn to increased NMDA stimulation (Gadea and Lopez-Colome, 2001; Bliss *et al*., 2004).
5. $ONOO^-$ leads to a partial breakdown of the blood–brain barrier, leading to increased chemical access to the brain (reviewed in Phares *et al*., 2007; Pall, 2002; 2003). Kuklinski *et al*. (2003) have reported blood–brain barrier breakdown in MCS patients and there is also an animal model of MCS in which similar breakdown has been observed (Abdel-Rahman *et al*., 2002; Abu-Qare and Abou-Donia, 2003; Abou-Donia *et al*., 2002b).
6. Many of the chemicals implicated in MCS are metabolized via cytochrome P450 activities and these enzymes are known to be inhibited by NO, thus possibly leading to increased accumulation of the active chemical forms (reviewed in Pall, 2002).
7. Finally TRPV1, TRPA1 and some other TRP receptors are activated through the action of oxidants, as discussed above, and organic solvents and other agents that act via these TRP receptors, such as some mould toxins, may be expected to have increased activity due to such TRP receptor activation.

This combination of multiple mechanisms, each multiplying the actions of the others, is predicted to easily produce the roughly 1000-fold increase in sensitivity that appears to occur in many MCS patients. So we have, for the first time, a hypothesis that explains the last major puzzle in MCS, how one can get this stunning increase in apparent sensitivity to such wide variety of chemicals. Having said that, while each of these mechanisms are individually well-documented and we do have aspects of some of them reported to occur in MCS, there is no currently available evidence that directly and convincingly implicates any of them in producing MCS-related sensitivity. This is not surprising, given the extraordinarily low level of research support that has been available for MCS studies.

10 PERIPHERAL SENSITIVITY MECHANISMS

MCS patients typically not only have central sensitivity symptoms that can be attributed to neural sensitization/NO/$ONOO^-$ cycle mechanisms, but also peripheral sensitivities. They often have chemical sensitivity in the upper respiratory tract, leading to rhinitis symptoms on low-level chemical exposure, they have asthma-type symptoms in response to low-level chemical exposures, they have skin sensitivities, with different patterns of skin involved in different patients, they have gastrointestinal (GI) tract sensitivities and additional organ sensitivity may be seen (Ashford and Miller, 1998). These are likely to be local sensitivity mechanisms distinct from the CNS-derived sensitivity discussed in the preceding section.

Meggs (1994; 1997), Meggs *et al*. (1996) and Bascom *et al*. (1997) and others have described the initiation of cases of RADS, where a type of asthma is initiated by chemical exposure to organic solvents and other irritants and the pattern of chemicals involved is similar or identical to those involved in MCS initiation. RADS is characterized by a wide-ranging chemical sensitivity (Meggs, (1994; 1997); Meggs *et al*., 1996; Bascom *et al*., 1997; Krishna *et al*., 1998), in addition to the more commonly studied sensitivities of asthma, those to allergens, exercise and cold. Not only are organic solvents involved, but several classes of pesticides as well (Proudfoot, 2005; Hernández *et al*., 2008; Proskocil *et al*., 2008; Fryer *et al*., 2004). Sensitization of the bronchi in response to chemical exposure, including organic solvent and pesticide exposure and also other irritants may well be commonly involved in causing occupational asthma (Jeebhay and Quirce, 2007; Gautrin *et al*., 1994). Interestingly, cases of asthma can also be apparently initiated, not only by organic solvents or pesticide chemicals, but also by exposure to mould toxins in mould-infested 'sick buildings', another similarity with MCS (Sahakian *et al*., 2008; Lee, 2003; Mahmoudi and Gershwin, 2000). Thus reactive airways disease can be seen as a common aspect of MCS, with a strikingly similar pattern of chemicals involved in the initiation process.

In addition to RADS, there is also reactive upper airways dysfunction syndrome (RUDS), in which there is chemical sensitivity initiated by previous chemical exposure, producing inflammatory responses in the upper airways, leading to rhinitis symptoms as well as ultrastructural changes (Meggs, 1994; 1997; Meggs *et al*., 1996). Similar to RADS and RUDS, there is also a reactive intestinal dysfunction syndrome (RIDS), where chemical exposure can initiate intestinal chemical sensitivity (Lieberman and Craven, 1998).

Peripheral sensitivity in the skin, lungs, upper respiratory tract, GI tract and other tissues, raises the question

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091

of how the mechanism of sensitivity may differ from that found in the central sensitivity discussed above? It seems likely, given the similar spectrum of chemicals involved at least in the RADS/airways response, that it also involves an NMDA stimulation pathway. There is evidence for an excessive NMDA role in asthma (Hirota and Lambert, 1996; Overstreet and Djuric, 1999; Dickman *et al*., 2004; Hoang *et al*., 2006; Said *et al*., 2001) and also for an NMDA role in skin-sensitivity responses produced by formaldehyde (Elliott *et al*., 1995; Coderre and Melzack, 1992). In MCS patients, the NMDA antagonist dextromethorphan seems to lower sensitivity responses, not only associated with central sensitivity, but also associated with peripheral sensitivity (Dudley, 1998). Glutamate ingestion of MCS patients appears to trigger symptoms associated with peripheral sensitivities, not just central (Miller and Prihoda, 1999; Ross, 1997). All of these observations suggest an NMDA mechanism in peripheral sensitivity, although the strength of the evidence on this is relatively weak. However, it seems reasonable, given the broad range of chemicals involved in these peripheral sensitivity responses, and the known action of these chemicals as producing NMDA stimulation, that NMDA receptor stimulation may well be involved in peripheral sensitivity, as it is in central sensitivity.

So what mechanisms may be likely to be involved in generating peripheral sensitivity? Clearly, of the seven mechanisms postulated for central sensitivity, one, the breakdown of the blood–brain barrier cannot be involved, and a second, the role of NO acting as a retrograde messenger is unlikely to be involved. The other five, however, may well have a role. And additional mechanisms may also be involved. Meggs has published biopsy studies of chemically sensitive peripheral tissues suggesting that neurogenic inflammation has an important role in generating the sensitivity of these peripheral tissues (Meggs, 1993; 1997; Bascom *et al*., 1997). Neurogenic inflammation may be expected to be generated by elements of the NO/$ONOO^-$ cycle, including TRPV1 activity, NF-κB activity and NO (Leffler *et al*., 2008; Kajekar *et al*., 1995; Yonehara and Yoshimura, 1999; Ruocco *et al*., 2001; Pall and Anderson, 2004; Lieb *et al*., 1997; Lin *et al*., 2007) and because of its inflammatory action, will be expected, in turn to stimulate the cycle. Mast cell activation, an aspect of neurogenic inflammation (Ruocco *et al*., 2001; Hu *et al*., 2008; Costa *et al*., 2008), has been reported to be involved in MCS (Heuser, 2000; 2001), and observations providing further support for mast-cell activation in MCS have been provided by Kimata (2004) and Elberling *et al*. (2007). Such mast-cell activation by chemical exposure may also be expected to act to exacerbate the cycle, through inflammatory cytokine elevation and other mechanisms. Mast-cell activation is reported to be stimulated by TRPV1 activation and also by NF-κB (Hu *et al*., 2008; Kempuraj *et al*., 2003; Lee *et al*., 2007), both NO/$ONOO^-$ cycle elements.

In summary, we have a number of locally acting mechanisms that are expected to act synergistically with each other to produce high levels of peripheral chemical sensitivity:

1. Chemical stimulation of regions of the body with elevated NO/$ONOO^-$ cycle activities.
2. Lowered mitochondrial function leading to increased NMDA receptor activity.
3. Lowered mitochondrial function leading to lowered local glutamate transport and therefore to increased NMDA stimulation.
4. NO inhibition of local cytochrome P450 activity and thus lowered metabolism of chemicals implicated in chemical sensitivity.
5. Local oxidative stress and $ONOO^-$ elevation, leading to increased activity of TRPV1, TRPA1, TRPM2 and possibly other TRP receptor activities, leading to both increased chemical sensitivity via these receptors and amplification of the inflammatory response by TRPM2.
6. Neurogenic inflammation produced, in part, by TRPV1 stimulation and NO, leading in turn to increased inflammation.
7. Mast-cell activation, generated in part by TRPV1 stimulation and NF-κB activity, leading in turn to increased inflammation.

It should be emphasized that while these individual mechanisms are well documented, their causal role in producing local peripheral chemical sensitivity in MCS is undocumented for most mechanisms and needs further substantial study in the others. At this point, they should be viewed as plausible predictions of the NO/$ONOO^-$ cycle fusion model which produce, in turn, plausible explanations of the peripheral sensitivities found in MCS.

11 THE NO/$ONOO^-$ CYCLE MECHANISM AS EXPLAINING PREVIOUSLY UNEXPLAINED MCS PROPERTIES

The title of the author's book *Explaining 'Unexplained Illnesses'* (Pall, 2007a) is obviously a challenge to those who have repeatedly claimed that this whole group of multisystem illnesses is unexplained, and there is no doubt that MCS has been the most challenging of this group of illnesses to explain. Kuhn, in his famous book *The Structure of Scientific Revolutions* makes clear that new scientific paradigms, developed from what he calls 'revolutionary science' (as opposed to 'normal

science'), are judged in large measure by how well they explain previously unexplained properties of the scientific phenomena to which the paradigm may be expected to apply. That is, one does not only look at the available data and how well it supports the proposed new paradigm, but one needs to look carefully at how well it explains the many relevant, but previously unexplained properties.

Given the previous challenges in explaining MCS, one needs to ask how well the NO/ONOO$^-$ cycle fusion model for MCS explains its many previously puzzling properties. I will go through 12 of these one at a time, using a question-and-answer format. Citations are provided to document issues that were not documented above.

1. How can so many diverse chemicals produce a common response, namely initiating cases of MCS and also eliciting responses in those already chemically sensitive? By acting along different pathways to produce a series of common responses, notably increased NMDA activity, intracellular calcium, NO and ONOO$^-$.
2. Why is MCS chronic? Because the NO/ONOO$^-$ cycle propagates itself over time and probably, in addition, because of long-term changes in the synapses of the brain, leading to neural sensitization.
3. How can MCS patients be so exquisitely sensitive to low-level chemical exposure, with many estimated to be on the order to 1000 times more sensitive than normal? Possibly by a series of mechanisms in the brain predicted to lead to long-term changed neural sensitization, increased short-term sensitization, increased levels of neurotransmitter (glutamate) and increased chemical accumulation. Peripheral sensitivity may involve some of these mechanisms as well and also such mechanisms as neurogenic inflammation and mast cell activation. Two of the transient receptor potential receptors may also have roles in amplifying sensitivity responses. It is through a combination of such mechanisms, acting synergistically with each other, that such high-level sensitivity may be produced.
4. Why is MCS comorbid with such diseases/illness as CFS, FM, PTSD, tinnitus and asthma? Possibly because each of these may be NO/ONOO$^-$-cycle mechanisms and each of them certainly involves elements of the NO/ONOO$^-$ cycle in their aetiology.
5. How can diverse organic solvents be involved in MCS? Probably by stimulating, either directly or through their metabolic products, several of the TRP receptors including the TRPV1 and TRPA1 receptors. This same group of receptors is involved in the SI response to a similar or identical set of organic solvents.
6. Why are symptoms so variable from one patient to another? Because the NO/ONOO$^-$ cycle is fundamentally local, such that one can have both quantitative and qualitative variable tissue impact in different patients. This same mechanism leads to similar variability in cases of CFS, FM and PTSD.
7. Several research groups have reported apparent lowered activity of the porphyrin biosynthetic pathway, leading to accumulation of compounds derived from intermediates at multiple steps in this pathway (Downey, 2001; Matthews, 1998; Morton, 1997; see also Hahn and Bonkovsky, 1997). How can such multiple steps in the pathway be lowered? Probably because of the role of NO in regulating this pathway (Kim *et al*., 1995; Rafferty *et al*., 1996) and possibly because the last step in the pathway is an iron–sulphur protein (Dailey *et al*., 2000) and such iron–sulphur proteins are often inactivated by ONOO$^-$ or NO (Soum *et al*., 2003).
8. How can neurogenic inflammation be involved in MCS? Probably because NO/ONOO$^-$-cycle elements, including TRPV1 receptor activity and NO, can stimulate neurogenic inflammation.
9. How can mast-cell activation be involved in MCS (Pall, 2003)? Probably because both TRPV1 receptor activity and NF-κB can stimulate mast cells.
10. It has been shown that repeated or continuous low-level exposure to organic solvents can lead to desensitization/masking of the MCS response (Ashford and Miller, 1998). What mechanism is involved here? Probably by the lowering of TRPV1 and other TRP receptor activity in response to such exposure to many TRPV1 agonists (Reviewed in Pall and Anderson, 2004; Szallasi, 2002). Interestingly, the TRPA1 receptor, also suggested above to be involved in responding to organic solvents in MCS, is also reported to be down-regulated under these conditions (Akopian *et al*., 2007), consistent with a role for these receptors in masking/desensitization. The desensitization to very small amounts of xenobiotics applied as part of a therapeutic programme (Weaver, 1996; Rea, 1997) may also be produced by this same process.
11. How can moulds in 'sick-building situations' initiate cases of MCS? Probably because mycotoxins produce inflammatory responses and some mycotoxins can stimulate the TRPV1 receptor.
12. How should MCS be treated? Through chemical avoidance and the use of agents that lower aspects of the NO/ONOO$^-$ cycle, including antioxidants, agents that lower NO, ONOO$^-$ and superoxide production, agents that improve mitochondrial function, agents that lower inflammatory biochemistry, agents that lower excitotoxicity, including excessive NMDA activity and agents that help restore BH4.

It can be seen from the above that there are reasonable explanations derived from the NO/ONOO$^-$ cycle mechanism, as it applies to MCS, for each of these puzzling questions. Previously, as best I can determine, only one of these had a good explanation: the chronic nature of MCS could be explained by the long-term synaptic changes produced by neural sensitization, but, even here, this is probably only part of the explanation and additional NO/ONOO$^-$ cycle mechanisms may be likely to be involved.

12 ANIMAL MODEL DATA ON VARIOUS ASPECTS OF THE PROPOSED NO/ONOO$^-$-CYCLE MECHANISM OF MCS

A whole series of animal models suggested as models for MCS have provided evidence for roles of various aspects of the NO/ONOO$^-$ cycle fusion model as it is proposed to apply to MCS. These include the following.

Sorg *et al*. (1998; 2001) developed a rat model showing cross-sensitization to cocaine and formaldehyde. Cocaine is known to also produce increases in NMDA activity (Laso, 2001; McGinty, 1995), as do the various initiators of cases of MCS. Her studies provide evidence for both neural sensitization and cross-sensitization. von Euler *et al*. (1994) described a similar rat model, using primarily toluene instead of formaldehyde as their main sensitizing agent, that appears to provide evidence for both neural sensitization and cross-sensitization.

Cocaine was also used in a mouse sensitization model which produced convincing evidence for cross-sensitization and increased NMDA activity, as well as an essential role of increased NO in producing the neural sensitization (Balda *et al*., 2008; Itzhak and Martin, (1999; 2000); Itzhak *et al*., 1998; Itzhak, 1995).

Gilbert (2001) reviewed an animal kindling model in response to repeated or high-level exposure to lindane and other similar pesticides, in which neural sensitization leads to overt seizure activity. The mechanism is essentially identical to the mechanism outlined earlier in this paper where pesticide produces decreased $GABA_A$ function, leading in turn to increased NMDA activity, increased subsequent intracellular calcium levels, acting in turn to produce LTP and consequent neural sensitization, leading in this situation to overt seizure activity. Cloutier *et al*. (2006) has also discussed the role of lindane in initiating an animal model for MCS and Adamec (1994) has discussed a different $GABA_A$ antagonist as such an initiator.

The mouse model of Anderson and Anderson (1999a, 1999b, 2003) of all MCS animal models is the one that has been shown to be at least superficially most similar to MCS in humans. It involves sensitization to a number of chemical mixtures implicated in MCS, cross-sensitization among different chemicals and chemical mixtures and also linkage to the SI response.

Willis (2001) described a primate model of central sensitization leading to secondary hyperalgesia and allodynia following repeated injections of capsaicin, the classic TRPV1 agonist. It provides evidence for, not only TRPV1 involvement, but also for NMDA, NO and intracellular calcium involvement, in addition, of course, to neural sensitization. Thus we have evidence of roles for five of the important elements of the model. Similar responses were reported earlier from formaldehyde injections.

Abou-Donia and his colleagues have published the most extensive studies on an animal (rat) model of MCS (Abou-Donia, 2002b). The toxicants they studied were all toxicants that the 1991 Gulf War veterans were exposed to and are therefore potentially involved in the initiation of Gulf War syndrome or illness. The Gulf War syndrome veterans suffer from MCS or an MCS-like illness (Proctor *et al*., 2001; Reid *et al*., 2001; Miller and Prihoda, 1999; Thomas *et al*., 2006), along with symptoms of other multisystem illnesses, CFS, FM and PTSD (Chapter 10, Pall, 2007a). Consequently, this rat model may be considered to be a model both for MCS and for the related Gulf War syndrome.

The specific chemicals studied by Abou-Donia and his colleagues, both individually and in combination, included the carbamate acetylcholinesterase inhibitor, pyridostigmine bromide, the insect repellant and irritant DEET (*N,N*-diethyl-*m*-toluamide) (Schoenig *et al*., 1993; Robbins and Cherniack, 1986), the pyrethroid pesticide, permethrin, depleted uranium and several organophosphorus toxicants. Of these only the depleted uranium is apparently not related to initiators of cases of MCS. In these studies, exposure to these toxicants has been found to produce chronic neurological changes, including neurobehavioural changes and sensorimotor deficits, from high-level exposures or from long-term, subclinical exposures (Abou-Donia, 2003; Abou-Donia *et al*., 2001; 2002a; 2002b; 2004; Abdel-Rahman *et al*., 2004a; 2004b). Even doses that show no signs of overt neurotoxicity produce these real, measurable and chronic neurological changes (Abdel-Rahman *et al*., 2004b).

Among the important physiological changes following chemical exposure are elevation of 3-nitrotyrosine levels, a marker of ONOO$^-$ elevation, oxidative stress as measured by elevation of 8-hydroxy-2′-deoxyguanosine levels, disruption of the blood–brain barrier and elevated NO levels (Abou-Donia *et al*., 2002b; Abu-Qare and Abou-Donia, 2001a; 2001b; 2003; Abu-Qare *et al*., 2001; Abdel-Rahman *et al*., 2002), all predicted consequences of the NO/ONOO$^-$ cycle mechanism.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Abou-Donia and coworkers reported synergistic interactions of these chemicals (Abou-Donia *et al*., 1996; Abu-Qare and Abou-Donia, 2001a; 2003; Abdel-Rahman *et al*., 2002) and others have found such synergistic effects in animal models as well (reviewed in Research Advisory Committee on Gulf War Veterans Illnesses., 2004). They suggest at least three mechanisms for the synergistic chemical interactions: competition for a cytochrome P450 degradative enzyme (Abu-Qare and Abou-Donia, 2008); partial breakdown of the blood–brain barrier produced by one chemical, leading to increased brain sensitivity to a second chemical (Abou-Qare and Abou-Donia, 2003) and competition for cellular excretion via P-glycoprotein (El-Masry and Abou-Donia, 2006). The author suggests additional possible mechanisms for such synergism, including the synergistic action of different organic solvents, acting as TRPV1 agonists and chemical action along multiple pathways, each leading to increased NMDA activity. The synergistic interactions among chemicals produce great difficulties for toxicologists attempting to estimate the toxicity of complex mixtures of chemicals from the toxicity of the individual components.

Two chemicals and one mixture of chemicals, all implicated in cases of MCS were studied in a mouse model by Fujimaki and colleagues. They demonstrated increases in inflammatory cytokines and reactive airways disease inflammation, as well as changes in CNS neurological activity (Tin-Tin-Win-Shwe *et al*., 2007; Fujimaki *et al*., 2001; 2004; 2007). A causal role of the cytokine IL-6 in the generation of lung inflammation in response to diesel exhaust was demonstrated by comparing an IL-6 gene knockout mouse with the wild-type (Fujimaki *et al*., 2006).

Low-level exposure of several noxious chemicals, including formaldehyde, to mouse skin generated progressive sensitization, leading to both neurogenic inflammation and increased inflammatory cytokine levels (Nakano, 2007).

Fukuyama *et al*. (2008) reported on an MCS mouse model, in which repeated applications of three chemical sensitizers were used to produce sensitivity, followed by a challenge with the same sensitizer. They found that the levels of several inflammatory cytokines were elevated following sensitization and that the challenge produced a much larger cytokine elevation. Thus the pattern of exposure and the response closely parallel the pattern of chemical exposure and subsequent elicitation of sensitivity responses seen in MCS. One of the sensitizers used, TDI is known to be a TRPV1 agonist.

Plitnick *et al*. (2002) showed that the chemical sensitizers, trimellitic anhydride and dinitrochlorobenzene, known to produce airway chemical sensitivity or skin chemical sensitivity, produced increases in some inflammatory cytokines in a mouse model. Harry *et al*. (2002) also showed sensitizer induction of inflammatory cytokine mRNA in glial cells in culture.

It can be seen from the above, that a surprising number of NO/ONOO$^-$ cycle MCS fusion model elements have been found to be involved in MCS animal models. These include both neural sensitization and cross-sensitization between chemicals, as well as progressive sensitization; chemical agents that are known to act by decreasing acetylcholinesterase or $GABA_A$ activity or increasing TRPV1 or sodium channel activity; chemical linkage to the SI response; increases in NMDA activity, NO, ONOO$^-$, oxidative stress, inflammatory cytokines, intracellular calcium, neurogenic inflammation, airways sensitivity and inflammation; and breakdown of the blood–brain barrier. Most, but not all, of these have been shown to have substantial causal roles in the generation of the animal model response. Although we have evidence from these animal models for roles of many features of the NO/ONOO$^-$ cycle mechanism, as it is proposed to apply to MCS, generally, two to five of these aspects have been looked at in each animal model and it is unclear whether any single animal model will involve all of these. However, given the fact that none of these studies have been done to test the NO/ONOO$^-$ cycle mechanism, and funding for such studies has been very limited, there is a surprising amount of data supporting aspects of the cycle mechanism.

13 POSSIBLE SPECIFIC BIOMARKER TESTS? OBJECTIVELY MEASURABLE RESPONSES TO LOW-LEVEL CHEMICAL EXPOSURE

One of the obvious needs in this area of medical research, is the need for one or more specific biomarker tests that can be used to objectively confirm a diagnosis of MCS. There are similar needs for such tests for CFS and FM as well. Because the aetiological mechanism of each of these is thought to be centred on the NO/ONOO$^-$ cycle and the cycle is mostly inflammatory biochemistry, looking at whole-body markers of the consequences of such inflammatory biochemistry will not be useful as a specific biomarker test. There are many dozens of inflammatory diseases, including many chronic inflammatory diseases, so prolonged elevation of such markers will be nonspecific. Furthermore, because such chronic inflammatory diseases are so common, in most cases such markers for MCS patients will often be in the normal range, because typically abnormally elevated levels are usually defined as being two standard deviations above the norm. It is only when one compares sizable groups of MCS patients with controls that one is likely to see statistically significant differences. All of these issues create difficult challenges in trying to develop specific biomarker tests.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Given these challenges, it may be predicted that specific biomarker tests for any NO/ONOO$^-$ cycle illness must directly or indirectly measure the impact of the cycle on whatever tissue or tissues must be involved in that specific illness. In most cases of MCS, there may be many such tissues, and the obvious way to look at the impact of the cycle on those tissues is to look at the chemical sensitivity responses in one of these tissues. We need to compare the responses of MCS patients with those of controls to low-level chemical exposure, looking at one or more objectively measurable responses. The NO/ONOO$^-$-cycle mechanism predicts that such low-level chemical exposure will produce elevated responses of NO/ONOO$^-$ cycle elements in MCS patients, but little response in normal controls. Alternatively, one might look at the consequences of NO/ONOO$^-$-cycle elevation produced by low-level chemical exposure, rather than specific cycle elements themselves. There have been quite a number of studies reporting elevated responses to low-level chemical exposure in MCS patients, as compared with controls, and this section of the chapter summarizes some of these and compares those reported responses with those predicted from the NO/ONOO$^-$-cycle mechanism of MCS. Studies of neuropsychological changes following low-level chemical exposure will not be reviewed here because the author has no competence to judge such studies.

The most extensive studies of this type are the cough responses studied by Millqvist and her colleagues in response to capsaicin challenge (Johansson *et al*., 2002; 2006; Millqvist, 2000; Ternesten-Hasséus *et al*., 2002; Millqvist *et al*., 2005; 2008). In these repeated studies, MCS patients show much elevated cough responses over normal controls in response to low-level capsaicin challenge. Capsaicin is the classic TRPV1 agonist and because TRPV1 receptor activity is thought, as argued above, to be involved in the responses to many organic solvents and related chemicals, this response appears to be quite consistent with what may be predicted by the NO/ONOO$^-$ cycle mechanism, as it is proposed to play out in MCS. Because the cough response produced by capsaicin is lowered by the use of dextromethorphan and other NMDA antagonists (Kamei *et al*., 1989; Capon *et al*., 1996; Chung, 2005), this pathway of action appears to be identical to that proposed for TRPV1 action in MCS. Millqvist *et al*. (2005) also report substantial increases in nerve growth factor (NG) activity following low-level capsaicin provocation in MCS patients, but not in controls, as predicted by two aspects of the NO/ONOO$^-$ cycle, up-regulation of TRPV1 activity and neurogenic inflammation. These responses are almost certainly local ones, as suggested by Millqvist (2000), so that the minority of MCS sufferers who do not have respiratory tract sensitivity, will not be expected to have such elevated cough responses to such capsaicin provocations.

Hillert *et al*. (2007) reported an interesting brain PET scan study, comparing MCS patients with normal controls both before and after chemical exposure. They used substantial amounts of chemicals for this study, such that both normals and MCS patients showed changes in brain PET scans after chemical exposure, but different changes. Hillert *et al*. (2007) were exploring the hypothesis that the brains of MCS patients might be particularly active in processing odour exposure information in the brain. They found that, whereas two regions of the brain have higher levels of neural activation in response to chemical exposure in MCS patients, as compared with controls, the olfactory processing regions were less responsive in MCS patients vs. controls. So the changes in olfactory processing contradicted their prediction. The two regions showing higher chemically elicited activation in MCS patients were the anterior cingulate cortex and the cuneus-precuneus. The anterior cingulate cortex is part of the limbic system, so the view presented in the current review leads us to ask whether chemical exposure might be expected to produce increased neural sensitization in this region of the brain. The TRPV1 receptor is thought, as discussed above, to often act as a receptor for various organic solvents and related chemicals in MCS, leading one to ask whether the TRPV1 receptor is located in the anterior cingulate cortex. Steenland *et al*. (2006) have found that there are quite high levels of TRPV1 activity in the anterior cingulate cortex, consistent with a local activation by chemicals in this region of the brain. While it is quite possible that this interpretation is oversimplified, it provides us with an interpretation that is compatible with the NO/ONOO$^-$-cycle–neural-sensitization model of what may be happening in the brain to generate MCS-related chemical sensitivity. In any case, the observations of Hillert *et al*. (2007) provide us with an approach to developing a specific biomarker test for MCS-related changes in the brain.

A series of EEG studies have been published in which changes of EEG patterns in MCS patients have been reported in response to low-level chemical exposure, but where normal controls show little or no similar changes (Bell *et al*., 1999b; 2001b; Schwartz *et al*., 1994; Fernandez *et al*., 1999; Lorig *et al*., 1991; Lorig, 1994). These changes, which presumably reflect changes in neural sensitization in MCS, may well provide objectively measurable changes in response to chemical exposure. My own understanding of this area is distinctly limited, so I am unable to give the reader any insights as to the pros and cons of this approach.

Joffres *et al*. (2005) reported increases in skin conductivity in MCS patients, but not in normal controls in response to low-level chemical challenge. Interestingly these skin conductivity increases were more reproducibly linked to the blinded chemical exposures in MCS patients than were there self-reported symptoms. These responses are similar to the responses measured

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

in 'lie-detector tests'. The authors suggest that these responses to low-level chemical exposure may reflect a neural sensitization mechanism, indirectly influencing skin conductivity.

Kimata (2004) reported on changes in serum levels of four substances, comparing responses to low-level chemical exposures in normal controls, MCS patients and also in atopic eczema/dermatitis syndrome (AEDS) patients. The chemicals used were outgassed organic solvents in a recently painted room totalling between 3 and 3.5 $mg\,m^{-3}$. The four substances produced in response to chemical exposure were substance P (SP), vasoactive intestinal peptide (VIP), NG and histamine. The basal levels of SP, VIP and NG were elevated in MCS patients and these three, and also histamine, were elevated in the AEDS patients. These can all be viewed as inflammatory markers with SP, VIP and NG being linked to neurogenic inflammation, as suggested by Kimata (2004) and acting to increase mast-cell activation/degranulation and therefore increased histamine levels. All four of these increased in response to low-level chemical exposure in the MCS patients but *not* in either controls or in AEDS patients, although AEDS patients showed elevation of all four vs. normal controls. The increase of any of these in response to low-level chemical exposure may be useful as a possible specific biomarker test for MCS. The responses to low-level chemical exposure seem to be specific to MCS and are not produced by the inflammation seen in AEDS. Based on the data presented by Kimata, perhaps histamine may be the most interesting of these because the basal levels in MCS patients showed little, if any, elevation over normal controls, but low-level chemical exposure produced an almost doubling of these levels. These involve relatively simple serum testing, making these tests perhaps the most easily accessible in the clinical setting. One comment I have is that the data presented by Kimata (2004) show surprisingly consistent basal levels and also levels after chemical exposure from one MCS patient to another. One can't help wondering whether the patients studied here may have had MCS cases of very similar severity and it is possible that other cases with lowered severity may show lowered responsiveness.

Elberling *et al*. (2007) reported that basophils isolated from chemically sensitive patients responded to perfume exposure by releasing elevated amounts of histamine as compared with basophils isolated from normal controls. These results suggest that one can assay sensitivity even at the level of individual cells from sensitive individuals and that histamine release in response to chemical exposure may be a good assay for such sensitivity. It should be noted that the TRPV1 receptor is present on basophils (Planells-Cases *et al*., 2005), as are some other TRP receptors. It is possible, therefore, that sensitivity to chemicals mediated by these receptors might be expressed at the cellular level.

Peden (1996) reviewed studies of nasal lavage to provide objective measurement of irritant-induced nasal inflammation, including studies of multiple chemical sensitivity or sick-building syndrome. Such nasal lavage samples can be used to measure a large number of inflammatory markers, including inflammatory cytokines, NO, eicosanoid mediators, inflammatory neuropeptides and others. Some studies of this type were reported by Koren and Devlin (1992) and Koren *et al*. (1990; 1992), in which chemically sensitive people with rhinitis responses to chemicals reacted to such chemical exposure with increased measurable inflammatory markers in nasal lavage samples. These studies did not compare their results with those of normal controls without such rhinitis responses, but it would be surprising if there would be a similar inflammatory response in such people. Such controls were performed by Hirvonen *et al*. (1999), who showed that chemically sensitive people previously sensitized in a mould-infested building responded to mould exposure with increased inflammatory cytokines and increased NO production, unlike normal subjects, using nasal lavage to measure such responses. This is a good example of how nasal lavage may be used as an objective measure of sensitivity responses in 'sick-building syndrome' situations.

Interestingly, in a series of studies, Hirvonen *et al*. (1997a; 1997b) and Ruotsalainen *et al*. (1995) showed that one could show similar inflammatory responses to mould and other microbial materials in cells in culture, suggesting that such cell-culture responses could be used as a bioassay to isolate and identify materials from these organisms that produce such an inflammatory response.

In summary, these various objectively measurable responses to chemical exposure reflect three distinct predicted aspects of the $NO/ONOO^-$ cycle mechanism. The cough responses reflect a TRPV1 stimulation leading in turn to increased NMDA activity; several of the other tests presumably reflect neural sensitization responses; still others measure inflammatory responses. Many of these are likely to reflect local sensitivity, which may occur in some MCS patients, but not others. This is expected to be the case with the cough responses and nasal lavage measurements. So their possible role as specific biomarker tests may be expected to be limited to those having lung or upper respiratory tract impact, respectively.

As tests to be used in a clinical setting, perhaps the cough response to low-level capsaicin challenge, the nasal lavage tests, and the histamine and other responses studied by Kimata (2004) may be the most easily applied. One or more of these may be used, then, in a clinical context, to provide confirmation of MCS diagnoses initially based on the fit to an accepted case definition.

It is the author's opinion that the published studies suggest that we have a number of promising possible specific biomarker tests and it is essential, in my view,

that further research be done to establish some of these as specific biomarker tests for MCS to be used for both clinical diagnostic and experimental purposes.

14 PATTERN OF EVIDENCE: FIT TO THE FIVE PRINCIPLES

The five principles underlying the NO/$ONOO^-$ cycle mechanism show how the cycle provides explanations for the wide variety of illness/disease properties. Where there is a good fit to each of the five, one can argue that a particular disease or illness is a good candidate for being caused by the NO/$ONOO^-$ cycle mechanism. In this sense, the five principles function collectively a bit like Koch's postulates. Having described much of the evidence above that is relevant to this issue of fit, it is time to summarize how good the fit is for each of the five principles in the case of MCS. I will not, in most cases, provide citations here, as they have been provided in the preceding sections of this review.

14.1 Short-term Stressors that Initiate Cases of Multisystem Illnesses Act by Raising NO Synthesis and Consequent Levels of NO and/or Other Cycle Elements

Each of the seven classes of chemicals implicated in initiating cases of MCS are known to act to increase NMDA activity and it is known that increased NMDA activity produces, in turn, increases in intracellular calcium, NO and $ONOO^-$. Elevated NMDA activity, intracellular calcium, NO and $ONOO^-$ are all elements of the cycle. It follows that there is an excellent fit to the first principle.

14.2 Initiation is Converted into a Chronic Illness through the Action of Vicious Cycle Mechanisms, through which Chronic Elevation of NO and $ONOO^-$ and Other Cycle Elements is Produced and Maintained

This principle predicts that the various elements of the NO/$ONOO^-$ cycle will be elevated in the chronic phase of illness. Here we need to go through the various elements of the cycle to determine what evidence, if any, is available for their elevation in MCS.

There are numerous types of evidence for elevation of three closely linked elements of the cycle, NO, $ONOO^-$ and oxidative stress (Pall, 2002; 2007a; and see above):

- Several organic solvents implicated in MCS have been shown to produce increases in NO.
- Organophosphorus and carbamate pesticides, through their actions as acetylcholinesterase inactivators, can lead to increased muscarinic activity, which lead in turn to increased NO synthesis.
- Neopterin, a marker of increased iNOS induction (Pall, 2000; Pall and Satterlee, 2001), has been reported to be elevated in the more severely affected MCS patients (Bell *et al*., 1998c).
- Elevated NO has been found in several animal models of MCS and in two of these, it clearly has an essential role in producing the biological response.
- Elevated levels of 3-nitrotyrosine were found in several studies of an MCS animal model and 3-nitrotyrosine is a marker of $ONOO^-$.
- MCS, and the related conditions CFS and FM, have been treated by methods that greatly elevate hydroxocobalamin levels *in vivo*, and hydroxocobalamin is a form of vitamin B_{12} that is known to be a potent NO scavenger. The across-the-board improvement in symptoms suggests that NO has a role, either directly or indirectly, in generating the symptoms of these illnesses.
- It is known that $ONOO^-$ can produce a breakdown of the blood–brain barrier and such breakdown has been reported in both MCS patients and in an animal models of MCS.
- Several types of evidence implicate elevated NMDA receptor activity in MCS and and in related illnesses, including FM. Such elevated NMDA activity is known to produce increases in NO and $ONOO^-$.
- Oxidative stress has been reported in MCS patients (Ionescu *et al*., 1999; Lu *et al*., 2007), as well as in several animal models of MCS. The notion that oxidative stress is central to the pathophysiology of MCS was first explored by Levine (1983a; 1983b) 25 years ago.

There are three types of evidence suggesting that inflammatory cytokine levels are elevated in MCS:

- Nasal lavage studies of MCS patients have reported to have elevated inflammatory cytokine levels and elevated levels of other inflammatory markers.
- Several animal models of MCS have elevated inflammatory cytokines.
- While there have not been any systemic measures of inflammatory cytokines in MCS patients, to my knowledge, there have been multiple such studies of the related illnesses CFS and FM with reported elevations.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are 13 distinct types of evidence implicating elevated NMDA activity in MCS; each of the seven classes of chemicals implicated in MCS can act by producing increased NMDA activity and there are also six additional types of evidence. These are all provided in Section 3 of this chapter.

Pall and Anderson (2004) listed 12 distinct types of evidence suggesting that elevated TRPV1 activity has roles in MCS. Ashford and Miller (1998) listed 10 striking similarities between MCS and neural sensitization, each of which can be viewed as evidence for neural sensitization in MCS; the animal model studies implicating neural sensitization provide an additional type of evidence. In addition, several of the putative specific biomarker tests, discussed above, provide support for a neural sensitization mechanism, providing a 12th type of such evidence.

Although there is extensive evidence for mitochondrial/energy metabolism dysfunction in CFS and FM, the only evidence for such dysfunction in MCS is from PET scan studies. Because the probe used in such PET scan studies is a glucose derivative, its transport and accumulation in the tissues is strongly impacted by mitochondrial dysfunction (Pietrini *et al*., 1998; Holthoff *et al*., 2004; Silverman *et al*., 2001).

In summary, although there have been no studies on either NF-κB elevation or BH4 depletion in MCS, to my knowledge, there are a total of 51 distinct published types of evidence supporting the role of one or more aspects of the NO/$ONOO^-$ cycle in the chronic phase of MCS. Given the paucity of research support that has been available for MCS research, that is a surprising amount of evidence!

14.3 Symptoms and Signs of these Illnesses are Generated by Elevated Levels of NO and/or Other Important Consequences of the Proposed Mechanism, that is, Elevated Levels of $ONOO^-$, NO, Inflammatory Cytokines, Oxidative Stress, Elevated NMDA, TRPV1 Receptor Activity and/or Other Aspects of the Cycle

You have seen above and elsewhere (Pall, 2007a) that we can explain a wide variety of symptoms and signs of MCS through the NO/$ONOO^-$ cycle mechanism. While these proposed explanations are based on well-established mechanisms, their roles in MCS and related illnesses should be viewed as plausible, not established.

14.4 Because the Compounds Involved, NO, Superoxide and $ONOO^-$ have Quite Limited Diffusion Distances in Biological Tissues and because the Mechanisms Involved in the Cycle Act at the Level of Individual Cells, the Fundamental Mechanisms are Local

A local mechanism is supported in MCS and related illnesses basically from two distinct types of observations: The stunning variations in symptoms and signs of illness and in overall severity going from one MCS patient to another is difficult to explain without having a local mechanism that can have variable impact among the tissues of the body. Such tissue distribution can be directly visualized in the brain PET scan and SPECT scans studies, which show striking variations from one patient to another.

14.5 Therapy Should Focus on Down-Regulating NO/$ONOO^-$-Cycle Biochemistry

There have been, unfortunately, few studies of therapy for MCS and except for one, these have been at the level of clinical observation and anecdotal reports, rather than clinical trials. The data we have available to ask for possible fit to the fifth principle are limited to the following:

- Clinical trial data on the related illnesses CFS and FM, where much more extensive data is available
- Evidence on causality from animal models of MCS
- A single clinical trial on MCS patients
- A variety of clinical observations and anecdotal reports.

The last of these is discussed in Chapter 15 of Pall (2007a) and will just be referred to here briefly.

Each of these types of observations provides evidence towards a fit to the fifth principle.

The animal model data that was discussed above provides evidence for causal roles of NO, TRPV1 activity and NMDA activity. Each of these types of studies have used agents that relatively specifically lower these activities and provide evidence, in the animal models, for what are, in effect, therapeutic effects of agents that down-regulate these specific aspects of the NO/$ONOO^-$ cycle.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

There are quite a number of clinical trials with CFS and/or FM showing apparent efficacy of agents predicted to down-regulate various aspects of the NO/$ONOO^-$ cycle (**Table 4**). The citations for these clinical trials are provided in Chapter 15, Pall (2007a), except for the more recent trials. These recent trials are for pregabalin, a drug that indirectly lowers excitotoxicity, including NMDA activity (Mease *et al*., 2008; Crofford *et al*., 2005); D-ribose (Teitelbaum *et al*., 2006; Gilula, 2007); and the antioxidant *Ecklonia cava* extract (Bierman, 2008, see also In Focus, 2007).

As can be seen from **Table 4**, of these 16 classes of agents, many have antioxidant properties, providing evidence that oxidative stress has an important causal role in generating these illnesses. Some of these agents either act as NMDA antagonists, or act indirectly to lower NMDA activity, thus providing strong evidence for a causal role of excessive NMDA activity. Carnitine/acetyl carnitine, coenzyme Q10 and possibly hyperbaric oxygen are likely to act to help improve mitochondrial function, thus providing evidence for a causal role of mitochondrial/energy metabolism dysfunction.

The potent NO scavenger, hydroxocobalamin is a form of vitamin B_{12}, but its role is much more likely to involve scavenging NO. In a clinical trial study (Ellis and Nasser, 1973), there was no correlation between initial B_{12} levels and the clinical response. Furthermore, higher doses are needed to get clinical responses here than are needed to treat a B_{12} deficiency. It seems unlikely, therefore, that hydroxocobalamin is acting to allay a B_{12} deficiency. The potent action of hydroxocobalamin as a NO scavenger is sufficiently well established that hydroxocobalamin has been used in experimental settings to establish a role for NO in biological processes (Pall, 2001b).

There is also weaker evidence for two other aspects of the NO/$ONOO^-$ cycle having a causal role. The long chain omega-3 fatty acids in fish oil are well known to have anti-inflammatory aspects, so that their reported efficacy provides some evidence for an inflammatory causal role, although an alternative interpretation to these observations is also possible. High-dose vitamin C and high-dose folate supplements help restore BH4 levels, suggesting a causal role of BH4 depletion, but again, there are other possible interpretations for their actions, so the evidence for BH4 depletion being causal must be viewed as relatively weak.

There are a number of clinical observations suggesting that these same agents are often helpful in MCS treatment, suggesting a possible similar aetiology. The various types of evidence supporting an NO/$ONOO^-$-cycle mechanism for all three of these illnesses (Pall, 2006; 2007a; 2007b) of course also suggest a common aetiological mechanism.

The only relevant clinical trial on MCS patients is that of Heuser and Vojdani (1997), which used high-dose vitamin C therapy and showed objectively measurable improvements in immune function in response to therapy.

In chapter 15, Pall (2007a), I discuss five different protocols that have used multiple agents predicted to down-regulate different aspects of the NO/$ONOO^-$ cycle. Each of these five uses at least 14 agents/classes of agents. Two of these protocols have been tested in clinical trials, one (Teitelbaum's) with both CFS and FM patients and the other (Nicolson's) with CFS-like patients. Each of the five protocols appears to produce substantially better clinical responses than do single agents. This approach may, then, be promising as a general approach to the treatment of these illnesses. Of these, only the Pall/Ziem protocol has been tried on chemically sensitive patients and the generally favourable response to this protocol is described by Dr. Grace Ziem in that chapter.

Subsequently, the author has developed a somewhat different approach to nutritional support of these patients through the Allergy Research Group, containing 22 different agents/classes of agents predicted to down-regulate different aspects of the NO/$ONOO^-$ cycle. Physicians and others using this approach report favourable responses with a large majority of patients with CFS, FM or MCS. In some cases, people who have been ill for two or more decades report rapid improvements within three or four weeks, improvements that are sustained for periods of six months or more, but do not, in general, clearly progress towards complete recovery. Clearly, the reader needs to maintain a high level of scepticism, at this point. These are unpublished observations, they do not constitute anything approaching a clinical trial and the author has a conflict of interest here, receiving some royalties from the Allergy Research Group.

In summary, there are a number of types of evidence that provide some support for the view that agents that down-regulate various aspects of the NO/$ONOO^-$ cycle produce clinical improvement in patients with MCS and in related illnesses. However, there is a great need for much more clinical study of these approaches. Clinical trial data from the related illnesses, CFS and FM, provide substantial support for the view that oxidative stress, excessive NMDA activity and NO all have causal roles; less convincing evidence suggests that inflammatory biochemistry and BH4 depletion also have causal roles in these illnesses. Various aspects of the cycle also are reported to have causal roles in MCS animal models.

15 PSYCHOGENIC CLAIMS

There have been a whole series of papers published arguing that MCS and/or the related multisystem illnesses are not physiological illnesses but are, rather, what has become known as psychogenic, having some often ill-defined psychological or psychiatric origin. These same authors have often argued that MCS should be called idiopathic environmental intolerance, a name that

Table 4 Clinical trial studies of agents predicted to lower NO/$ONOO^-$ cycle elements in the related illnesses chronic fatigue syndrome and fibromyalgia

Agent or class	Mechanism	Comments
Vitamin C (ascorbic acid)	Chain-breaking antioxidant; lowers NF-κB activity; reported to scavenge peroxynitrite and also help restore tetrahydrobiopterin (BH4) levels by reducing an oxidized derivative of BH4	May require high doses to be effective with the latter two mechanisms; this may be the basis of so-called 'megadose therapy' for vitamin C; clinical trials on CFS and MCS used high-dose IV ascorbate
Magnesium	Lowers NMDA activity and may be useful in improving energy metabolism and ATP utilization	Magnesium is the agent that is most widely studied and found to be useful in the treatment of the multisystem illnesses
Fish oil (long chain omega-3 fatty acids)	Lowers iNOS induction; lowers production of inflammatory eicosonoids; important for brain function	Highly susceptible to lipid peroxidation and may, therefore be depleted; four studies reported improvements in clinical trials, three with CFS and one with FM
Flavonoids	Chain-breaking antioxidants; some scavenge peroxynitrite, some scavenge superoxide; some reported to induce superoxide dismutase (SOD); All three types are found in FlaviNox; some flavonoids may also act to help restore BH4 levels; lower NF-κB activity	Ginkgo extract tested in CFS; anthocyanidin flavonoids in FM; other flavonoids tested in CFS animal model
NMDA antagonists	Lower NMDA activity	Four different antagonists reported to be effective in the treatment of fibromyalgia; anecdotal reports of effectiveness for MCS
Agents that indirectly lower excitotoxicity including NMDA activity	—	Only clinical trials done with pregabalin for fibromyalgia, but other members of this class often used clinically
Acetyl L-carnitine/carnitine	Helps transport fatty acids into mitochondria; may be important here not only directly for energy metabolism but also to restore the oxidized fatty acid residues that may be produced in the cardiolipin of the inner membrane	May also help lower reductive stress; two trials in CFS
Ecklonia cava extract	Polyphenolic chain-breaking antioxidant; reported to help scavenge both peroxynitrite and superoxide; based on its reported properties, it may also help restore BH4 levels	Appears to stay in the body much longer than do the flavonoids, a useful property; reported to be helpful in a clinical trial study of fibromyalgia
Reductive stress relieving agents	These include S-adenosyl methionine (SAM or SAMe), trimethylglycine (betaine), carnitine and choline	SAM reported to be effective in multiple clinical trials with FM and CFS patients; betaine widely used clinically
Hydroxocobalamin form of vitamin B-12	Potent nitric oxide scavenger, lowers nitric oxide levels	Limited intestinal transport; often taken by intramuscular injection or as a nasal spray or inhalant; clinical trial with CFS-like illnesses; widely used for treatment of CFS, FM and MCS
Folic acid	Relatively high doses will lower the partial uncoupling of the nitric oxide synthases by helping to restore tetrahydrobiopterin (BH4)	Reacts with oxidants and therefore may be depleted due to the NO/$ONOO^-$ cycle

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 4 (*continued*)

Agent or class	Mechanism	Comments
Algal supplements	Probably act as antioxidants	—
Hyperbaric oxygen	May act to help restore cytochrome oxidase activity by competing with nitric oxide	My impression is that this approach needs to be used with substantial care—too high or prolonged dosage can cause damage
Trimethyl glycine (betaine), S-adenosyl methionine (SAM), choline, carnitine	Lower reductive stress; also helps with the generation of S-adenosyl methionine (SAM)	While lowering reductive stress may be the main concern, SAM generation may also be of concern; the enzyme methionine synthase is inhibited by nitric oxide and inactivated under conditions of oxidative stress, thus leading to lowered SAM and lowered methylation
Coenzyme Q10 (ubiquinone)	Important in mitochondrial function; important antioxidant, especially in mitochondrion; reported to scavenge peroxynitrite	Optimal dosage may vary considerably among different individuals; suggest taking early in day
D-ribose, RNA or inosine	Two important functions: Provides adenosine for restoring adenine nucleotide pools after energy metabolism dysfunction; when catabolized, the purine bases generate uric acid, a peroxynitrite scavenger	Each of these may act somewhat similarly; however only D-ribose has been tested in a clinical trial and reported to be effective; each of these agents has distinct drawbacks

Modified from the author's web site, used with permission.

denies, in effect, that chemicals cause MCS or have a role in eliciting symptoms in people who suffer from MCS. It also denies that we have a mechanism that may explain the many puzzling features of MCS. The name implies that we have neither initiating causes nor ongoing causes of illness.

What this section does, is to briefly and superficially review this field, making many generalizations, some of which may not be adequately supported. To do a thorough review would take a paper considerably longer than this entire chapter, so there is not space nor time to do so. The reader is referred to Chapter 13 in Pall (2007a), which provides a more comprehensive discussion of this area, not just for MCS, but also for CFS and FM. The reader is also strongly encouraged to look at the papers advocating a psychogenic basis for MCS (**Table 5**) and the Davidoff and Fogarty (1994), the Davidoff *et al*. (2000) and the McCampbell (2001) reviews.

From a toxicological perspective, none of these psychogenic advocate papers considers the question of what chemicals are apparently involved in MCS and how they might act as toxicants in the human body. From a toxicological perspective, therefore, they all must be viewed as being flawed. This section outlines the main issues with regard to psychogenesis of MCS that were developed in Chapter 13 in Pall (2007a) and then discusses several of the reviews that have each been written from a psychogenic perspective.

There are, in the author's view (Pall, 2007a), 10 important issues that challenge the positions of psychogenic advocates of MCS and related multisystem diseases and we are considering these here one at a time.

Many such advocates argue that these multisystem illnesses are caused by 'belief' and that they are somatoform disorders generated by a mechanism called somatization. How well founded are these views? Let's consider the basis of somatoform disorders and somatization.

Somatoform disorders are defined (Smith, 1990) as a group of disorders with somatic symptoms that suggest a physical disorder, but for which no organic aetiology can be demonstrated. There is presumptive evidence of a psychological basis for the disorder.

Somatization is defined as a process whereby psychological distress is expressed in physical symptoms (Smith, 1990). So psychogenic advocates typically argue that MCS and the other multisystem illnesses are somatoform disorders generated by the process of somatization. According to its definition, it is incumbent on such psychogenic advocates to demonstrate that *no organic aetiology can be demonstrated*. That is, they not only need to show that no organic aetiology *has* been demonstrated but that none *can* be. This is a very difficult hurdle for them and none of them, to my knowledge, have even tried to jump it. They rarely, if ever, consider the detailed properties of the mechanism proposed here, or the neural sensitization interpretation or the neurogenic inflammation interpretation, nor have they developed a

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

Table 5 Publications of MCS skeptics

Gots (1996)	Argues for a psychogenic 'mechanism' for MCS based mainly on dualistic reasoning
Barsky and Borus (1999)	Argues the multisystem illnesses are 'functional somatic syndromes'. Unclear whether this argues for psychogenesis, but paper is often cited by those advocating psychogenesis
Kellner (1994)	Argues that multisystem illnesses are somatoform disorders caused by somatization
Staudenmayer (1999)	Staudenmayer's book makes the longest argument for psychogenesis in MCS
Wessely *et al*. (1999)	Argues that the multisystem illnesses may not be distinct and may share an aetiology possibly centred on psychogenesis
Binder and Campbell (2004)	Similar arguments to Gots (1996), Kellner (1994) and Staudenmayer (1999); considers a broader group of illnesses
Staudenmayer *et al*. (2003a)	Goes through the Hill criteria, asking whether MCS (IEI) can be a physiological illness caused by chemical exposure.
Staudenmayer *et al*. (2003b)	Goes through the Hill criteria, asking whether MCS (IEI) can be a psychogenic illness
Wiesmüller *et al*. (2003)	Another proposal to the effect that these multisystem illnesses may be somatization disorders. While considering these illnesses from a predominantly psychiatric perspective and ignoring physiological, biochemical and animal model data, the authors are much more circumspect about their inferences than are the psychogenic advocates
Hausteiner *et al*. (2007)	A psychiatric interpretation of MCS or what they call IEI.
Eis *et al*. (2008)	Complex psychological study; argues against physiological interpretations while providing no data on them
Das-Munshi *et al*. (2006)	Review of provocation studies in MCS
Das-Munshi *et al*. (2007)	Review of MCS, from a group of psychogenic advocates from the Institute of Psychiatry, Kings College, London

compelling argument ruling out *any possible organic aetiology*.

While it may be argued that they have never even attempted to seriously fulfil this requirement, it is also the case that the very concepts of somatoform disorders and somatization have come under increasing attack (Janca, 2005; Epstein *et al*., 1999; Mayou *et al*., 2005; Dalen, 2003; Bradfield, 2006; Sykes, 2006). There are a number of reasons for this, including the issue that the concept of somatoform disorders and somatization is based on a dualistic view of human beings, where the psychological/psychiatric/mental is separate and distinct from the biological/physiological/physical. The process of somatization assumes that all of the initial causes are on one side of this dualism and somehow reach across the divide to generate physical symptoms. However this Cartesian dualism has been rejected by modern science. For example the American Psychiatric Association (1994) states that 'there is much "physical" in "mental" disorders and much "mental" in "physical" disorders'. Dualistic reasoning has been used repeatedly by advocates of psychogenesis of MCS and other multisystem illnesses and has led them astray in many circumstances. Let us consider an example: a letter published by Black (2002) on the apparent effectiveness of the drug paroxetine in the treatment of MCS. Paroxetine has been shown to lower NOS activity (reviewed in Chapter 6, Pall, 2007a) and is also a serotonin reuptake inhibitor and is a drug that has been used to treat certain psychiatric disorders. Black reports that this drug was effective in the treatment of an MCS patient and in other studies, in two other patients and concludes that, 'This case joins two others in showing *that some patients diagnosed with multiple chemical sensitivity have an underlying psychiatric disorder that, when identified, responds to medication therapy*' (italics added). Black concludes that because paroxetine has been effective in the treatment of some psychiatric diseases, it must be acting to correct a psychiatric flaw in these MCS cases. This is the same logical flaw as if one were to argue that: aspirin cures headaches; aspirin decreases blood clotting; therefore headaches cause blood clotting. The logical flaw here is obvious, but because Black is so immersed in an assumed dualism, he cannot apparently see it. I will provide some additional examples of such dualistic reasoning below.

We have discussed, thus far in this section, three weaknesses that show up in the positions of psychogenic advocates of MCS: that they base their arguments on the concepts of somatoform disorders and somatization, concepts that they have never shown to be adequately supported in MCS and concepts that have been attacked on a theoretical basis as well; that much of their position is based on a rejected dualism between the mental/psychiatric/psychological on the one hand and the physical/biological/physiological on the other; and that

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

this rejected dualism has led them, in turn, to make logical flaws. These, then are three substantial flaws underlying psychogenesis—there are others.

Another important issue is that there is a long history of false psychogenic attribution in medicine. In Chapter 13 (Pall, 2007a), there is a discussion of the fact that each of the following diseases has been falsely claimed to have an aetiology that is largely or completely psychological:

1. Multiple sclerosis (MS)
2. Parkinson's disease
3. Lupus
4. Interstitial cystitis
5. Migraine
6. Rheumatoid arthritis
7. Asthma
8. Gastric and duodenal ulcers
9. Ulcerative colitis.

Each of these has been subsequently been shown to be a real physiological disease. Of that list, the psychogenic claim that has been most recently rejected by modern science is number 8, ulcers, for which two Australian physicians, Robin Warren and Barry Marshall won the 2005 Nobel prize in physiology and medicine for showing that the bacterium *Helicobacter pylori* plays a key role in the development of both types of ulcers. Ulcers are a bacterial infectious disease, with ulcers being generated when the inflammation produced by a *Helicobacter pylori* infection becomes sufficiently severe. Ulcers can be treated by a simple antibiotic regimen and this is not a psychogenic illness, as had been confidently claimed for decades.

It is essential, in the author's view, that psychogenic advocates of MCS or other multisystem illnesses show that they are not repeating the same errors that led to false psychogenic claims in the past. However, none of them has ever apparently considered this issue in their publications.

A fifth issue is the role of genetics in dealing with susceptibility to MCS or other multisystem illnesses. There is substantial published evidence for a role of genetics in determining such susceptibility, not only in MCS, but also with CFS, FM and PTSD. The role of specific genes in MCS provides strong support for the inference that chemicals are acting as toxicants in MCS and the role of the CCK-B gene also provides some evidence for a role of the NMDA receptors. Thus the genetic evidence is in very good agreement with the mechanism discussed in this review. The genetics of CFS is also consistent with a $NO/ONOO^-$ cycle mechanism (Chapter 5, Pall, 2007a). But there is a more fundamental issue with a genetic role. Genes act by influencing the structure and amounts of proteins synthesized in the body and by doing so, determine both the physical structure of the body and its biochemical activities. In a dualistic framework, they act to determine the biology and any psychological effect is indirect, produced from the biology. Staudenmayer (1999, p. 20) states that, 'The core supposition of psychogenic theory is that psychological factors are *necessary and sufficient* to account for the clinical presentations of EI [what he calls MCS] patients. Psychogenic theory emphasizes belief, somatization, psychophysiologic stress and anxiety responses, and psychogenic etiology' (italics added). Obviously if psychological factors are *necessary and sufficient*, then there is no room for a genetic role, or for any other biological role. The demonstrated genetic roles in MCS and other multisystem illnesses show that psychological factors are *not* sufficient.

A sixth issue is that psychogenic advocates rarely make clear, testable predictions. The Staudenmayer prediction discussed in the previous paragraph is a rare, perhaps unique, exception to this and as indicated immediately above, the test leads to rejection of the psychogenic hypothesis. The need to make clear, testable (and therefore potentially falsifiable) predictions is essential in science. One of the things that they do, however, is to suggest that because some (but not other) patients with multisystem illnesses clearly suffer from what are classified as psychiatric symptoms, that therefore the multisystem illnesses should be viewed as psychiatric. However, there is a large amount of literature showing that most, perhaps all, serious chronic diseases are characterized as having comorbid psychiatric symptoms, but that does not mean that these serious chronic diseases are psychiatric. The fact that cancer patients and rheumatoid arthritis patients have higher prevalences of PTSD, anxiety and depression, for example, does not make either cancer or rheumatoid arthritis a psychiatric disease.

A seventh issue is that scientists have an obligation to avoid emotion-laden rhetoric and to attempt to provide objective assessments of the scientific literature. Some examples of such emotion-laden statements from the psychogenic advocates are provided elsewhere (Chapter 13 in Pall, 2007a) and will not be repeated here. The focus here is on the need to provide an objective assessment of the literature. Let us consider some specific examples.

The Binder and Campbell (2004) review has relatively brief discussions of several illnesses, including MCS, CFS and FM with relatively few citations provided for each of them. They argue that in these illnesses, cognitive abnormalities are not caused by neurological disease, but rather are caused by 'biological and psychological factors', while concentrating their claims heavily on the psychological side. It is probably reasonable to expect that the relatively few citations on each illness will be carefully chosen to represent some relatively objective assessment of the relevant literature. Let's take a look at some of them here.

On p. 371, Binder and Campbell (2004) argue that the proposed name change from CFS to chronic fatigue and immune dysfunction syndrome was made 'despite the lack of evidence of immune dysfunction in this illness'.

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

The only citation provided is that of the psychiatrist and psychogenic advocate Wessely (1997). They would apparently have us believe that the extensive evidence for immune dysfunction in CFS, reviewed, for example, by Komaroff and Buchwald (1998), by Patarca (2001) and by Klimas and Koneru (2007), does not exist because one psychogenic advocate argues that it does not.

In the MCS section of their paper, Binder and Campbell claim that the substances triggering discomfort in people with MCS are 'aromas rather than neurotoxins', citing the psychologist Bolla (2000) as their only documentation for this. They would apparently have us believe that the hundreds of citations showing that organic solvents are neurotoxicants that are cited in Kilburn (1998) or that the many citations showing that pesticides are neurotoxicants cited earlier in this chapter do not exist.

Binder and Campbell (2004) also state that sensitization 'may be initiated by aversive childhood experiences such as sexual abuse', providing Bell *et al*. (1998b) as their only documentation. What Bell *et al*. (1998b) actually report is that girls with a history of sexual abuse were at apparently greater risk for later becoming chemically sensitive, not that it directly initiated cases of MCS. But what is much more important is that they cite this one study as evidence for a possible causal role of sexual abuse in MCS, while completely ignoring the many dozens of studies showing an apparent causal role for chemical exposure in initiation of cases of MCS—and chemical exposure often leads very quickly to the development of MCS symptoms—as compared with the possible role of sexual abuse as a risk factor in the medical history of the patient. This is, unfortunately, a typical example from the psychogenic literature of only citing evidence that can be interpreted as supporting their viewpoint, while completely ignoring massive literature that contradicts it.

Binder and Campbell (2004) also dismiss a number of physiological changes found in MCS and other multisystem illnesses based on these same changes being found in what are classified as psychiatric diseases. For example they state that, 'Neuroendocrine abnormalities are associated with FM and that the illness is caused by abnormal sensory processing. *However emotional problems also are associated with neuroendocrine disorders. We know of no evidence of neuroendocrine abnormalities specific to that condition.* There was evidence of reduced cerebral blood flow in the thalamus and pontine tegmentum in patients with FM, *but similar findings are nonspecific and occur in psychiatric patients*' (italics added). It should be noted that, as discussed above, similar neuroendocrine abnormalities are also reported in FM and CFS, as well. Later in the same paper they state that, 'A fluorine [sic]-deoxyglucose PET study suggested that hypometabolism of the brain stem was found only in CFS and not in depression, *but a study using the same technique found no differences between a group with CFS and a group with somatization disorder*' (italics added). Again similar brain changes are reported in MCS and CFS, albeit with different tissue distribution. In both of these quotes, Binder and Campbell (2004) dismiss any biological significance of objectively measurable physiological changes in these multisystem illnesses, if similar changes are also reported to occur in psychiatric diseases. By their dualistic reasoning, if a physiological change occurs in a psychiatric disease it is forever dismissed as a biologically significant marker in other illnesses, based on some sort of guilt by association. The obvious inference that when these changes are seen in a psychiatric disease, they are important clues as to the pathophysiology of that disease seems to be completely lost on them.

The dualistic reasoning seen with Binder and Campbell is all too common in the psychogenic literature. The Black (2002) letter with its dualistic reasoning is discussed above. Gots' (1996) paper on MCS is essentially all based on such dualistic reasoning. In it he states, 'Stimulation of a neurotransmitter or release of a hormone occurs in response to stimulus. Evidence of response to stress or phobia, such as EEG changes or elevated cortisol levels, helps to describe part of the organic interface between stimulus and response and supplements our knowledge of how the mind produces symptoms. *These responses, however, are not indicative of organic dysfunction and do not eliminate the role of the mind in the phobic or stress response*' (italics added). The author noted (Chapter 13, Pall, 2007a) that, 'Gots would have us believe that because these are produced in response to psychological stress, cortisol or EEG changes are of no organic consequence, incapable of producing organic dysfunction. Taken to its logical conclusion, this same reasoning would have us believe that if a person responds to psychological stress by committing suicide, he or she is not "organically" dead.' Elsewhere in his paper Gots (1996) makes clear where some of his commitment to this discarded dualism comes from stating that, 'Manufacturers cannot be held responsible for responses that depend on psychological processes'. The legal issues of possible liability for the initiation of MCS cases are often discussed in the papers of psychogenic advocates and they consistently argue against any such liability. Could that be related to their roles as 'expert witnesses' in such liability trials?

In a recent MCS review, Das-Munshi *et al*. (2007), referring to a study by Baines *et al*. (2004), stated that 'a recent study suggested that people with MCS showed a nonsignificant trend towards lymphocyte depletion, but this is also known to occur in major depression, possibly as a result of hypercortisolaemia, and widespread immunological differences have also been shown in people with somatization disorders'. In that one sentence they state that the trend towards lymphocyte depletion in MCS patients was nonsignificant, whereas Baines *et al*. (2004) reported it was highly significant ($p<0.001$);

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

they also discount the biological significance of this by suggesting that because similar changes occur in two apparent psychiatric diseases, major depression and somatization disorders, this aberration has no biological significance in MCS. So we see again, dualistic reasoning discounting any objective physiological changes if they occur in what are considered to be a psychiatric diseases. There is a third flaw in this sentence—that in what is *not* said. This statement, when coupled to the lack of any discussion of other objectively measurable changes in MCS, suggests that lymphocyte depletion is the only such reported change, when clearly it is not.

One of the papers that was reviewed in Chapter 13 on psychogenesis of Pall (2007a), was a paper by Staudenmayer *et al*. (2003a) raising the issue of whether chemical exposure meets the Hill (1965) criteria for initiation of cases of MCS. Hill, in his paper, stated nine criteria that were proposed to be used to help determine whether a particular environmental stressor or group of stressors might have a causal role in the initiation of some particular illness or disease. The goal here is to distinguish chance association from causation. The idea was not that all of them had to be fulfilled in order to infer probable environmental causation, but that if there was reasonably good evidence for most of them, one might infer such causation. So the question that needs to be raised in the context of MCS is whether chemical exposure is apparently causal in initiating cases of MCS, based on the Hill criteria. This seemed to be an interesting paper to analyse because Ashford and Miller (1998), themselves did an analysis of the Hill criteria as it applies to MCS (pp. 273–276), so it would be interesting to see how Staudenmayer *et al*. (2003a) might deal with these questions. Staudenmayer *et al*. (2003a) concluded (p. 244) that 'toxicogenic theory fails to meet any of the nine Hill criteria'.

The Staudenmayer *et al*. (2003a) paper is surprising in three ways: firstly they were apparently unaware of the previous Ashford and Miller (1998) treatment of this same topic in their very influential book. Secondly Staudenmayer and colleagues either did not know about or did not see the relevance of any of the cited literature that Ashford and Miller (1998) used to support their view that there was substantial evidence for fulfilling six of the nine Hill criteria with regard to chemical causation of MCS. Thirdly, in several cases, Staudenmayer failed to even ask the question that Hill requires them to ask in supposedly examining the case for the nine Hill criteria. Let's go through the first four Hill criteria one at a time to see how the Staudenmayer *et al*. (2003a) treatment compares with the scientific literature that appears to be relevant to these Hill criteria.

The first Hill criterion is strength of association. In this case, is exposure to the types of chemicals suggested to have a role in causing MCS associated with increased incidence of MCS? There are three main types of evidence suggesting such a relationship (Pall, 2007a, pp. 218–220). Firstly, there is the great increase in synthetic organic chemical production (15-fold increase from 1945 and 1980) and also a roughly similar increase in the production of pesticides, following World War II through the 1980s, paralleling the apparent incidence of MCS. One has to say apparent because we have no good epidemiological data before 1980, so we have to rely on surrogates, such as the increasing scientific and medical interest in this field around the world, as possible measures of increased MCS incidence. Secondly, we have the great increase in 'sick building syndrome' situations in the USA following the decreased requirement for indoor air flow that was put into place in 1973, after the first oil shock. By the late 1980s the US Environmental Protection Agency was reporting that fully 50% of the environmental complaints that they had to deal with were 'sick building syndrome' types of complaints (much of this information comes from Ashford and Miller, 1998 and is discussed in Pall, 2007a, pp. 218–220). So we have an apparent parallel, both with regard to increased chemical production and decreased air flow, and apparent increased MCS initiation. A third example is the genetic evidence that genes that determine the rate of metabolism of chemicals can influence the prevalence and therefore incidence of MCS. The only study that was available before Staudenmayer *et al*. (2003a) submitted their paper was the Haley *et al*. (1999) study on PON1, but there is, as discussed above, much more data available now. Staudenmayer *et al*. (2003a) state that there is no evidence for increased incidence of IEI (what they call MCS) with occupational chemical exposure; this is not accurate because Zibrowski and Robertson (2006), McKeown-Eyssen *et al*. (2001) and Maschewsky, (1996; 2002) present some data on this, as discussed above, but it is fair to state that we have very limited data. There is extensive data both on the existence of occupational asthma and the role of chemical exposure in it, and that it is part of the MCS spectrum of sensitivity, but clearly Staudenmayer *et al*. (2003a) are unable or unwilling to see that connection. Staudenmayer *et al*. (2003a) spend most of their discussion on what is supposed to be the first Hill criterion criticizing the prevalence data on MCS, rather than asking the question that must be asked for this Hill criterion—is there an association of chemical exposure with MCS incidence and prevalence, however those may be defined. In the author's judgement, the evidence for the first Hill criterion in the case of chemical causation of MCS is suggestive, but not compelling, with the exception of the more recent genetic evidence, which was not published before the Staudenmayer *et al*. (2003a) paper was submitted. However, to state, as they did, that there is no such evidence is simply incorrect.

The second Hill criterion is consistency: is there a fairly consistent illness or disease pattern that has been described in a variety of different places and circumstances? Similar observations have been made in a variety of countries around the world, including the USA, at least

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091

nine European countries, Canada, Australia and Japan. As stated by Miller (1997, p. 445) 'numerous investigators from different geographic regions have published strikingly similar descriptions of individuals who report disabling illnesses *after exposure to recognized environmental contaminants*' (italics added). What Staudenmayer *et al*. (2003a) discuss regarding the consistency criterion is whether or not chemical provocation studies in MCS have been properly performed, ignoring the central issue raised by the second Hill criterion.

The third Hill criterion asks whether there is some specificity to the stressors proposed to initiate a specific disease or illness. Here, Staudenmayer *et al*. (2003a) produce the strongest of their arguments with regard to any of the Hill criteria. The chemicals apparently involved have appeared to have little specificity and many of the case definitions, as seen above, discuss them as being 'unrelated' chemicals. There had been only four papers that had been published before the Staudenmayer *et al*. (2003a) paper had been submitted proposing that chemicals might act via increased NMDA activity and/or increased NO and $ONOO^-$, so perhaps it is not unreasonable that they did not consider that possibility. At this point in time, however, it should be clear that there is a substantial argument for specificity through the common response mechanism of NMDA stimulation, even though diverse chemicals are implicated in MCS initiation and in eliciting symptoms in those already sensitive.

The fourth Hill criterion, that of temporality asks, in the context of MCS, whether chemical exposure precedes or follows the initiation of illness. In Chapter 13 of Pall (2007a), the author led the reader to 30 citations that reported that chemical exposure preceded illness initiation, all apparently published before the submission of the Staudenmayer *et al*. (2003a) paper and there are a dozen additional such citations provided in Section 2 of this review; none of these 42 are cited by Staudenmayer *et al*. (2003a) in what they describe as an 'evidence-based review'. These 42 citations are not a comprehensive list of the literature and there are likely to be many other such publications as well. Among the papers ignored by Staudenmayer *et al*. (2003a) is the highly cited Miller and Mitzel (1995) paper, whose title alone implies that it is relevant to this fourth Hill criterion. How do Staudenmayer *et al*. (2003a) support their contention? They cite a single non-peer-reviewed paper by a psychogenic advocate, Terr (1993), published some 10 years earlier; the Terr paper criticizes people studying the physiological basis of MCS, based on their theoretical models and their methodology for studying the effects of chemical exposure on MCS patients. The Terr (1993) paper is, therefore, irrelevant to the issue of temporality—does chemical exposure precede or follow the initiation of illness. The Terr (1993) paper also refers to MCS as if it were an allergy, which clearly it is not.

It is difficult to see how any objective assessment of the literature can come to the conclusion that the fourth Hill criterion is not supported for MCS and the failure of Staudenmayer *et al*. (2003a) to even consider the easily accessible, extensive and obviously relevant scientific literature may be viewed as a sign of their unacceptable bias.

There is not time time nor space here to go through the other five Hill criteria as they relate to MCS, but the reader is referred to the discussion of this in Chapter 13 of Pall (2007a). The reader is also encouraged to read both the original Hill (1965) paper and also the Staudenmayer *et al*. (2003a) paper. The author's own assessment of the Hill criteria is that there is strong evidence for fulfilling six of the Hill criteria for MCS and weaker, but still suggestive, evidence for fulfilling the other three (Chapter 13, Pall, 2007a). Such evidence is not immune from criticism. It is common, as Hill (1965) suggests, that such evidence can be questioned and it is for that reason that it makes sense to weigh the evidence on nine criteria, rather than just a few, to assess the balance of evidence in the complex consideration of possible environmental causation. It is not necessary, according to Hill (1965), to find support for fulfilling all of the nine criteria in order to make a substantial case for environmental causation, but it is the author's view (Chapter 13, Pall, 2007a) that one can do just that for chemical causation of initiation of MCS cases.

Before leaving the issue of possible psychogenesis of MCS, it is essential to discuss the two masked, placebo-controlled provocation (that is controlled-exposure) studies that have been published, which together, to my knowledge, provide the only evidence that is reasonably claimed to positively argue for a psychogenic aetiology of MCS. Although there are only two such studies, given the relative paucity of direct experimental studies on MCS, it is important to look at them carefully. Both of these report on studies where they performed placebo-controlled provocation studies where the exposures were 'masked' by the presence of a presumably benign masking agent, so that the patients would be unable to tell through odour when they were exposed to the chemical. In both studies, the patients were presumably unable to distinguish the chemical exposure from the masking agent alone. One of these studies was published by Staudenmayer, Selner and Buhr (Staudenmayer *et al*., 1993) and the other was published by Smith and Sullivan (2003). Both were reviewed favourably by Das-Munshi *et al*. (2006), a group that has argued for a psychogenic mechanism of MCS and also other multisystem illnesses (Das-Munshi *et al*., 2006; 2007).

The Staudenmayer *et al*. (1993) study has been criticized for three reasons (Miller, 1997; Bell *et al*., 1997; 1999a; Joffres *et al*., 2005): the masking agent used, a heavy amount of mint, is not always benign for MCS patients (Fernandez *et al*., 1999) and therefore may not

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

be the neutral masking agent that the authors claim; MCS patients can become desensitized when exposed to various chemicals and these experimenters failed to provide the patients with a substantial period away from such exposures before the provocation challenges were performed; and the patients were not chosen using a standard case definition of MCS, so that there is some question whether they were, in fact, MCS sufferers.

Somewhat surprisingly, the more recent Smith and Sullivan (2003) study may have had somewhat similar problems. Smith and Sullivan tested CFS patients, not MCS patients, and although there is a substantial comorbidity between the two, they did not use, as one would argue they should have, MCS patients who fulfilled a well-accepted case definition for MCS. They do report that their patients had self-reported food sensitivities or chemical sensitivity or both, but food sensitivity is not specific for MCS and is common among CFS patients with no apparent chemical sensitivity. Smith and Sullivan (2003) chose the chemicals to be used as follows: chemical substances chosen by an allergist based on 'clinical criteria and patients subjective responses' were previously tested on each patient until a 'reactive substance' was identified. They give trichloroethane as an example of such a reactive substance, but provide no further information on the chemicals used in this study or their frequencies of use and very little information on dosage. The masking substance used was identified as a substance to which the participants did not react—they give vanilla essence as an example, but do not provide any further information on the masking compounds used. It has been reported that vanillin, the main odourant in vanilla essence, is more of an irritant in MCS patients than in normal controls (Hillert *et al*., 2007), suggesting that it is not a neutral masking agent for MCS patients. Clearly if either the original test of the 'reactive substance' was a false positive or if the test of the possible masking compound was a false negative, the experimental test for that specific patient would have been flawed.

There is no description of any procedure being used in Smith and Sullivan (2003) to prevent desensitization of patients, caused by recent chemical exposures prior to provocation, another possible criticism. The choice of CFS patients rather than MCS patients can be criticized for an additional reason. Classical MCS patients have their symptoms resolve in the absence of chemical exposure, whereas CFS patients do not. Because they used neuropsychological tests to measure reactions here, CFS patients will have at best a low signal-to-noise ratio because of the high level of neuropsychological aberrations before any provocation exposure. Therefore, these patients were not well chosen, in my judgement, for use in such a test, even if they all did have comorbid MCS.

It should be clear that these provocation challenge experiments are complex and difficult to perform with anything approaching a bullet-proof protocol. The point here is *not* that these two experiments are flawed and that all of the experiments that support the conclusion that MCS patients react to low levels of chemicals acting as toxicants have no flaws. Rather it is that we need to maintain a high level of objectivity in analysing these complex experiments. When Das-Munshi *et al*. (2006) conclude that the Staudenmayer *et al*. (1993) and Smith and Sullivan (2003) studies have no flaws, but that all of the studies coming to the opposite conclusion have substantial flaws, their objectivity must be questioned.

16 SUMMARY OF THIS WHOLE AREA OF POSSIBLE PSYCHOGENESIS OF MCS AND OTHER MULTISYSTEM ILLNESSES

- Psychogenic advocates have failed to consider how chemicals implicated in MCS may impact the human body and specifically the human brain.
- They have failed to consider animal models of MCS and what lessons they may carry on the mechanisms of MCS.
- They have failed in most instances to provide anything resembling an objective assessment of the scientific literature about MCS. Given that most psychogenic advocates have clear conflicts of interest, either making large amounts of money testifying as 'expert witnesses' in MCS liability trials or as psychiatrists who may make substantial amounts providing psychiatric treatment for patients with multisystem illnesses, their ability or lack of same to provide an objective assessment of the literature must be subject to careful scrutiny.
- Their interpretation of MCS and other multisystem illnesses is dominated by the view that these illnesses are produced by the beliefs of the patients and that these are somatoform disorders generated by a process called somatization. However, they have failed to provide evidence that there cannot be a physiological explanation for MCS and the basic concepts of somatoform disorders and somatization have come under increasing attack.
- Their approach to MCS and other multisystem illnesses is based on the rejected dualism between the mental/psychological/psychiatric and the physical/biological/physiological.
- Belief in that dualism has apparently led them to make many logically flawed arguments.
- There is a long history of false psychogenic attribution in medicine, making it essential that psychogenic advocates show that they are not simply repeating the errors of the past. They have failed to consider this issue.
- Their argument that psychological factors are necessary and sufficient to explain MCS and other multisystem illnesses is falsified by the genetic data;

General and Applied Toxicology, Online © 2009 John Wiley & Sons, Ltd.

DOI: 10.1002/9780470744307.gat091
General and Applied Toxicology was renamed as *General, Applied and Systems Toxicology* in 2011 © 2011 John Wiley & Sons, Ltd.

both the specific genes implicated in MCS and their known function provide for such falsification, but also the general finding that genes have a role in determining susceptibility implicates biological factors because genes act by determining the structure and biochemical activities of the body.
- Psychogenic advocates rarely make clear and testable predictions. One of the rare exceptions to this is clearly falsified by the available data.
- Their papers are full of emotion-laden statements.

Each of these ten considerations creates, in my judgement, great challenges for psychogenic advocates of MCS. Clearly the combination of all ten create still more daunting challenges, completely apart from the main thesis of this review on the $NO/ONOO^-$ cycle and the physiological mechanism(s) of MCS.

17 SUMMARY AND AREAS OF GREATEST RESEARCH NEED

This chapter describes a detailed apparent mechanism for MCS, called the $NO/ONOO^-$ cycle, which explains, when fused with neural sensitization, neurogenic inflammation and other mechanisms, the many challenging aspects of this illness that have never been explained previously. Because new scientific paradigms are tested, often largely, by their ability to explain the many previously unexplained aspects of a scientific field, the power of the $NO/ONOO^-$ cycle as an explanatory model is of great importance. It is my view that the power of the $NO/ONOO^-$ cycle mechanism, when fused with the earlier neural sensitization mechanism as an explanatory model in MCS, and the various aspects of the model that are well supported experimentally, support the inference that the overall model is likely to be fundamentally correct. However, it could certainly be wrong in one or more details and is almost certainly incomplete.

This proposed mechanism is supported by well-established mechanisms of action of seven classes of chemicals implicated in initiating cases of MCS, all of which can act to elevate NMDA activity and produce toxic responses in the human body through such NMDA elevation. It provides mechanisms for the generation of symptoms in MCS patients, both symptoms that are shared with such related illnesses as CFS, FM and PTSD and also chemical sensitivity symptoms that are viewed as being specific for MCS. It is supported by observations implicating excessive NMDA activity, excessive NO levels and oxidative stress, neural sensitization, elevated TRP receptor activity, elevated $ONOO^-$ levels and elevated levels of intracellular calcium in people afflicted with MCS, in animal models or both. While there has been little in the way of published studies on therapy for MCS, clinical trial data on the related illnesses CFS and FM provide support for the inference that such aspects as excessive oxidative stress, NO, NMDA activity, mitochondrial dysfunction and possibly inflammation and BH4 depletion have important causal roles in the generation of this group of illnesses. We have some clinical observations suggesting that complex protocols designed to normalize these several parameters can produce substantial rapid improvement in many MCS patients also avoiding chemical exposure, even among patients who have been ill for decades.

Having said that, there are many aspects of this proposed MCS mechanism that need much study. That is not surprising, given the extraordinarily low level of funding that has been available for such studies. Pall (2002) estimated that although MCS has roughly the same prevalence as does diabetes in the USA, the funding available for research on MCS has been approximately 1/1000th of the funding for diabetes. This low level of funding is despite the fact that what little data we have on comorbid diseases for MCS (Baldwin and Bell, 1998; Bell *et al.*, 1995; Baldwin *et al.*, 1997; 1999) and the substantial impact on employment of MCS patients both suggest that the morbidity associated with MCS and its associated comorbid diseases may be comparable to that found as a consequence of diabetes.

The five areas that are in most need of further study, in my judgement, are:

1. Animal model studies testing various aspects of this mechanism that have never been adequately tested.
2. Studies to establish one or more low-level chemical exposure tests as specific biomarker tests for MCS.
3. Clinical trial studies on agents and groups of agents aimed at down-regulating various aspects of the proposed mechanism as potential therapeutic protocols for the treatment of MCS patients.
4. Studies of some of these same agents in placebo-controlled studies to determine if they can lower responses to low-level chemical exposure in MCS patients. These might be done in conjunction with the specific biomarker tests in item 2.
5. Use of bioassays described above to ascertain likely chemicals in the air of mould-infested 'sick buildings' to determine what mycotoxins are involved and what moulds produce them under what culture conditions. Promising methods have been developed for such bioassays (Hirvonen *et al.*, 1997a; 1997b; Ruotsalainen *et al.*, 1995), but we are still plagued by many examples of such 'sick buildings' due in part to our stunning ignorance about the mycotoxins involved and their mechanisms of action.
