CHAPTER 25

HEALTH EFFECTS OF RADIATION AND RADIOACTIVE MATERIALS

Naomi H. Harley

INTRODUCTION

Among all the branches of toxicology, ionizing radiation provides the most quantitative estimates of health detriments for humans and animals. Five large studies provide data on the health effects of radiation on people. These effects include those due to external X-rays and gamma-ray radiation and internal alpha radioactivity. The studies encompass radium exposures, including those sustained by radium dial painters, atom bomb survivors, patients irradiated with X-rays for ankylosing spondylitis, children irradiated with X-rays for tinea capitis (ringworm), and uranium miners exposed to radon and its short-lived daughter products. The latest data on radon risk comes from over 20 domestic studies of normal radon background. The major health effect subsequent to radiation exposure seen with statistical significance to date is cancer. Some heart and digestive disease has been observed in atom bomb survivors, but only at high dose levels (>0.5 Sv). The various types and the quantitative risks are described in subsequent sections.

All the studies provide a consistent picture of the risk of exposure to ionizing radiation. There are sufficient details in the studies of atom bomb, occupational, and medical exposures to estimate the risk from lifelong low-level environmental exposure. Natural background radiation is substantial, and only within the past two decades has the extent of the radiation insult to the global population from natural radiation and radioactivity been appreciated.

BASIC RADIATION CONCEPTS

The four main types of radiation are alpha particles, electrons (negatively charged beta particles or positively charged positrons), gamma rays, and X-rays. An atom can decay to a product element through the loss of a heavy (mass = 4) charged (+2) alpha particle (He^{+2}) that consists of two protons and two neutrons. The alpha particle is ejected from the nucleus with energy depending upon the element. After it loses its energy, it is a stable helium atom. An atom can decay by loss of a negatively or positively charged electron (e^-, a beta particle or e^+, a positron). Gamma radiation results when the nucleus releases excess energy, usually after an alpha, beta, or positron transition. X-rays occur whenever an inner-shell orbital electron is removed and rearrangement of the atomic electrons results, with the release of the element's characteristic X-ray energy.

There are several excellent textbooks describing the details of radiologic physics (Evans, 1955, 1982; Andrews, 1974; Turner, 1986; Shapiro, 2002; Cember, 1996).

One of the most useful expressions relates the radioactive decay rate to the nuclide half life and the number of atoms (mass) present.

$$\text{Activity } (A) = \lambda N$$
$$\lambda = \ln(2)/T_{1/2} \qquad (25\text{-}1)$$

where $T_{1/2}$ is the half-life of the radioactive element and N the number of atoms in the source.

The expression for activity may be integrated to derive the exponential radioactive decay law

$$A = A_0 e^{(-\lambda T)} \qquad (25\text{-}2)$$

where A_0 is the initial decay rate at T_0 and A the decay rate at T.

Example 1. The average radon (^{222}Rn) concentration in a home is about 40 Bq m^{-3}. How many atoms exist for this concentration.

^{222}Rn $T_{1/2} = 3.8$ days
$\lambda = \ln(2)/T_{1/2} = \ln(2)/(3.8 \times 1440 \times 60) = 2.1 \times 10^{-6}$ s^{-1}
Activity (disintegrations per second) DPS = 40
　　$= (2.1 \times 10^{-6}$ s$^{-1})$ (N)

where $N = 1.9 \times 10^7$ atoms.

There is no analytical method for a stable element that can measure a few million atoms of a substance with ease. Radioactivity provides a massless tracer in many situations.

Energy

The definition of an alpha or beta particle or a gamma ray arises from their energetic nuclear origin. Otherwise they are basically a helium atom, an electron, or a photon. Alpha particles and beta rays (or positrons) have kinetic energy as a result of their rapid motion when ejected from the nucleus. The energy is equal to

$$E = 1/2 m V^2 \qquad (25\text{-}3)$$

where m is the mass of the particle and V the velocity of the particle.

Alpha particles have a low velocity compared with the speed of light, and calculations of alpha particle energy do not require any corrections for relativity. Most beta particles (or positrons) have a velocity near the speed of light, and the basic expression must be corrected for their increased relativistic mass. The energy equivalent of mass is calculated from Einstein's equation $E = mc^2$. Thus, rest mass of the electron is calculated as 0.511 MeV and its total energy (increase in mass due to relativistic correction plus the rest mass) is equal to

$$E = 0.511/(1 - v^2/c^2) + 0.511 \qquad (25\text{-}4)$$

where v is the velocity of the beta particle and c the speed of light.

Gamma rays and X-rays are pure electromagnetic radiation with energy equal to

$$E = hv \qquad (25\text{-}5)$$

where h is the Planck's constant (6.626×10^{-34} J s) and v the frequency of radiation.

The conventional energy units for ionizing radiation are the electron volt (eV) or multiples of this basic unit, kiloelectron volts (keV), and million electron volts (MeV). The conversion to the international system of units, the Système Internationale (SI), is currently taking place in many countries, and the more fundamental energy unit of the Joule (J) is slowly replacing the older unit. The relationship is

$$1 \text{ eV} = 1.6 \times 10^{-19} \text{ J}$$

Authoritative tables of nuclear data such as those of Browne *et al.* (1986) contain the older but more widely accepted units of MeV for energy.

Alpha Particles

Alpha particles are helium nuclei (consisting of two protons and two neutrons), with a charge of +2, that are ejected from the nucleus of an atom. When an alpha particle loses energy, it slows to the velocity of a gas atom and acquires two electrons from the vast sea of free electrons present in most media, and it becomes part of the normal background helium in the environment. All helium in nature is the result of alpha particle decay. The formula for alpha decay is

$$^A_Z X \rightarrow\ ^{A-4}_{Z-2} Y + He^{2+} + \text{gamma} + Q_\alpha$$
where Z = atomic number and A = atomic weight.

The energy available in this decay is Q_i and is equal to the mass difference of the parent and the two products. The energy is shared among the particles and the gamma ray if one is present.

An example of the alpha decay scheme is given by the natural radionuclide radium (^{226}Ra) in Fig. 25-1. The half-lives of radioactive nuclides may be found on the web at hps.org/publicinformation/radardecaydata.cfm

The energy of alpha particles for most emitters lies in the range of 4–8 MeV. More energetic alpha particles exist but are seen only in very short-lived emitters such as those formed by reactions occurring in particle accelerators. These particles are not considered in this chapter.

Although there may be several alpha particles with very similar energy emitted by a particular element such as radium, each particular alpha particle is monoenergetic, i.e., no continuous spectrum of energies exists, only discrete energies.
Figure 25-1. Decay scheme for ^{226}Ra.

Alpha particles are massive relative to beta particles and most alpha particles cannot penetrate a thin sheet of paper. The range of an alpha particle in air is,

$$\text{Range (air)} = 0.325 \ E^{3/2} \ \text{(cm)} \qquad (25\text{-}6)$$

In tissue, the range is about 1/1000 of the range in air.

Example 2. Find the range of the ^{226}Ra alpha particle ($E = 4.8$ MeV) in air and tissue.

$$\text{Range} = 0.325(4.8^{3/2}) = 3.4 \ \text{cm}.$$

In tissue, the range of the ^{226}Ra alpha particle is 3.4/1000 cm, or about 34 μm.

Beta Particles, Positrons, and Electron Capture

Beta particle decay occurs when a neutron in the nucleus of an element is effectively transformed into a proton and an electron. Subsequent ejection of the electron occurs, and the maximum energy of the beta particle equals the mass difference between the parent and the product nuclei. A gamma ray may also be present to share the energy, Q:

$$^A_Z X \rightarrow \ ^A_{Z+1} Y + \text{beta} + Q_\beta$$
An example of a beta decay scheme is given in Fig. 25-2 for lead 210 (^{210}Pb):

$$^{210}_{82}\text{Pb} \rightarrow \ ^{210}_{83}\text{Bi} + \text{beta (0.015 MeV)} + \text{gamma (0.046 MeV)}$$
Figure 25-2. Decay scheme for ^{210}Pb.
Figure 25-3. Decay scheme for ^{64}Cu.

Lead 210 emits a beta particle with energy 0.015 MeV, 80% of the time followed by the 0.046 MeV gamma ray. Twenty percent of the time it emits only a 0.061 MeV beta ray, equal to the total energy available for decay (0.015 + 0.046).

Unlike alpha decay, in which each alpha particle is monoenergetic, beta particles are emitted with a continuous spectrum of energy from zero to the maximum energy available for the transition. The reason for this is that the total available energy is shared in each decay or transition by two particles: the beta particle and an antineutrino. The total energy released in each transition is constant, but the observed beta particles then appear as a spectrum. The residual energy is carried away by the antineutrino, which is a particle with essentially zero mass and charge that cannot be observed without extraordinarily complex instrumentation. The beta particle, by contrast, is readily observed with conventional nuclear counting equipment.

Positron emission is similar to beta particle emission but results from the effective nucleon transformation of a proton to a neutron plus a positively charged electron. The atomic number decreases rather than increases, as it does in beta decay.

Figure 25-3 gives an example of positron decay for the radionuclide copper (^{64}Cu), which decays by beta emission 41% of the time, positron emission 19% of the time, and electron capture 40% of the time:

$$^{64}_{29}\text{Cu} \rightarrow \ ^{64}_{28}\text{Ni} + \ \text{Positron (0.66 MeV)} \quad 19\%$$

$$^{64}_{29}\text{Cu} \rightarrow \ ^{64}_{30}\text{Zn} + \ \text{beta (0.57 MeV)} \quad 41\%$$

$$^{64}_{29}\text{Cu} \rightarrow \ ^{64}_{28}\text{Ni} \ \text{electron capture} \quad 40\%$$

The energy of the positron appears as a continuous spectrum, similar to that in beta decay, where the total energy available for decay is again shared between the positron and a neutrino. In the case of positron emission, the maximum energy of the emitted particle is the mass difference of the parent and product nuclide minus the energy needed to create two electron masses (1.02 MeV), whereas the maximum energy of the beta particle is the mass difference itself. This happens because in beta decay, the increase in the number of orbital electrons resulting from the increase in atomic number of the product nucleus cancels the mass of the electron lost in emitting the beta particle. This does not happen in positron decay, and there is an orbital electron lost as a result of the decrease in atomic number of the product and the loss of the electron mass in positron emission. Positron emission tomography (PET) scans are a useful diagnostic tool in nuclear medicine. The positron is an unstable particle and decays immediately to two 0.511 MeV photons emitted 180° from each other. The positron emitter is typically fluorine 18 (^{18}F). The

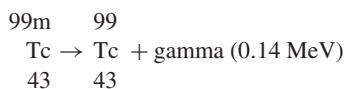
radionuclide is given in a solution that is taken up by the tissues of interest and coincidence counting of the two photons locates their tissue origin precisely.

Electron capture competes with positron decay, and the resulting product nucleus is the same nuclide. In electron capture, an orbiting electron is acquired by the nucleus, and the transformation of a proton plus the electron to form a neutron takes place. In some cases the energy available is released as a gamma-ray photon, but this is not necessary, and a monoenergetic neutrino may be emitted. If the 1.02 MeV required for positron decay is not available, positron decay is not kinetically possible and electron capture is the only mode observed.

Gamma-Ray (Photon) Emission

Gamma-ray emission is not a primary process except in rare instances, but it occurs in combination with alpha, beta, or positron emission or electron capture. Whenever the ejected particle does not utilize all the available energy for decay, the nucleus contains the excess energy and is in an excited state. The excess energy is released as photon or gamma-ray emission coincident with the ejection of the particle.

One of the rare instances of pure gamma-ray emission is technetium 99m (^{99m}Tc), which has a 6.0-hour half-life and is widely used in diagnostic nuclear medicine for various organ scans. Its decay product, ^{99}Tc, has a very long half-life (2.13×10^5 years), and as all ^{99}Tc is ultimately released to the environment, a background of this nuclide is emerging.

$$^{99m}_{43}\text{Tc} \rightarrow {}^{99}_{43}\text{Tc} + \text{gamma (0.14 MeV)}$$


Internal Conversion

In many gamma ray emitters, a photon will not actually be emitted by the nucleus but the excess excitation energy will be transferred to an orbital electron. This electron is then ejected as a monoenergetic particle with energy equal to that of the photon minus the binding energy of the orbital electron. This process is known as internal conversion. In tables of nuclear data such as those of Browne *et al.* (1986), the ratio of the conversion process to the photon is given as e/γ. For example, the e/γ ratio for ^{99m}Tc is 0.11, and therefore the photon is emitted 90% of the time and the conversion electron is emitted 10% of the time. The internal conversion electron is a monoenergetic particle.

INTERACTION OF RADIATION WITH MATTER

Ionizing radiation, by definition, loses energy when passing through matter by producing ion pairs (an electron and a positively charged atom residue). A fraction of the energy loss raises atomic electrons to an excited state (excitation loss). The average energy needed to produce an ion pair is given the notation W and is numerically equal to 33.85 eV in air. This energy is roughly two times the ionization potential of most gases or other elements because it includes the energy lost in the excitation process. It is not clear what role the excitation plays, for example, in damage to targets in the cellular

DNA. Ionization, by contrast, can break bonds in DNA, causing even double strand breaks.

All particles and rays interact through their charge or field with atomic or free electrons in the medium through which they are passing. There is no interaction with the atomic nucleus except at energies above about 8 MeV, which is required for interactions that break apart the nucleus (spallation). Very high-energy cosmic-ray particles, for example, produce ^{3}H, ^{7}Be, ^{14}C, and ^{22}Na in the upper atmosphere by spallation of atmospheric oxygen and nitrogen.

Alpha and beta particles and gamma rays lose energy by ionization and excitation in somewhat different ways, as described in the following sections.

Alpha Particles

The alpha particle is a heavy charged particle with a mass that is 7300 times that of the electrons with which it interacts. The massive particle interacting with a small particle (the electron) has the interesting property that it can give a maximum velocity during energy transfer to the small particle of only two times the initial velocity of the heavy particle. In terms of the maximum energy that can be transferred per interaction is

$$E_{(\text{maximum electron})} = (4/7300)E_{(\text{alpha particle})} \qquad (25\text{-}7)$$

Although alpha particles can lose perhaps 10–20% of their energy in traveling 10 μm in tissue (1 cm in air), each interaction can impart only the small energy, given in the maximum, in Eq. (25-4). Thus, alpha particles are characterized by a high energy loss per unit path length and a high ionization density along the track length. This is called a *high linear-energy-transfer* (LET) or *high-LET* particle.

Hans Bethe (Bethe and Ashkin, 1953) derived an exact expression for the energy loss in matter per unit distance traveled, dE/dx or stopping power. Later modifications to the formula were added by Bloch and others. For alpha energies between 0.2 and 10 MeV, the Bethe–Bloch expression can be simplified to

$$\mathrm{d}E/\mathrm{d}x = 3.8 \times 10^{-25} C\, NZ/E \ln\{548E/I\}\ \mathrm{MeV}/\mu\mathrm{m}^{-1}$$

$$(25\text{-}8)$$

where N is the number of atoms per cm^{-3} in the medium; Z the atomic number of the medium; I the ionization potential of the medium; E the energy of alpha particle; and C the charge correction for alpha particles with energy below 1.6 MeV.

A simple rule of thumb derived by Bloch may be used to estimate the ionization potential of a compound or element.

$$I = 10(Z) \qquad (25\text{-}9)$$

The Bragg additivity rule (Attix *et al.*, 1968) may be used for compounds when the individual values of ionization potential for the elements are available. A tabulation of values of ionization potential is given in ICRU 37 (ICRU, 1984), and the stopping power in all elements has been calculated in ICRU 49 (ICRU, 1993) and by Ziegler (1977). The ionization potentials and stopping power may be found on the web at www.physics.nist.gov/PhysRefData/Star/Text/contents.html.

When alpha particles are near the end of their range, the charge is not constant at +2 but can be +1 or even zero as the particle acquires or loses electrons. A correction factor, C, is needed for energies between 0.2 and 1.5 MeV to account for this effect. Whaling

(1958) published values for the correction factor by which Eq. (25-4) should be multiplied. These factors vary from 0.24 at 0.2 MeV, 0.75 at 0.6 MeV, 0.875 at 1.0 MeV, up to 1.0 at 1.6 MeV.

For the case of tissue, Eq. (25-5) reduces to

$$dE/dx_{\text{tissue}} = [0.126C/E]\ln\{7.99E\} \text{ MeV}\mu\text{m}^{-1} \qquad (25\text{-}10)$$

Example 3. Find the energy loss (stopping power) of a 0.6 and a 5-MeV alpha particle in tissue.

For a 0.6 MeV alpha particle

$$dE/dx = 0.126(0.75)/0.6\ln(7.99 \times 0.6)$$
$$= 0.25 \text{ MeV}\mu\text{m}^{-1}$$

For a 5.0 MeV alpha particle

$$= 0.126(1.0)/5.0\ln(7.99 \times 5.0)$$
$$= 0.093 \text{ MeV}\mu\text{m}^{-1}$$

The slower moving (lower energy) alpha particle has more chance to interact with matter and the energy loss per unit distance is greater. The significance of this energy loss is that it requires about 33.85 eV in tissue to produce an ion pair; therefore, a 0.6 MeV alpha particle can produce $(0.25 \times 10^6 \text{ eV } \mu\text{m}^{-1})/(33.86 \text{ eV/ion pair}) = 7400$ ion pairs in 1 μm, and the 5.0 MeV alpha particle can produce 2700 ion pairs in 1 μm. The diameter of DNA is 0.002 to 0.005 μm, and the nucleosome 0.010 μm; thus, the ionization and dissociation by either a 0.6 or 5.0 MeV alpha particle can cause enough damage to cause a double-strand break (Panajotovic *et al.*, 2006).

The alpha particle therefore disrupts DNA by direct production of ions by ejection of electrons and the electrons in turn may have enough energy to produce further ionization.

Beta Particles

The equations for beta particle energy loss in matter cannot be simplified, as in the case of alpha particles, because of three factors:

1. Even at low energies of a few tenths of a MeV, beta particles travel near the speed of light and relativistic effects (mass increase) must be considered.
2. Electrons interact with particles of the same mass in the medium (free or orbital electrons), so large energy losses per collision are possible.
3. Radiative or bremsstrahlung energy loss occurs when electrons or positrons are slowing down in matter. Such a loss also occurs with alpha particles, but the magnitude of this energy loss is negligible.

Including the effects of these three factors, the energy loss for electrons and positrons has been well quantitated. Tabulations of energy loss in various media have been prepared with the ionization energy loss and the radiative loss detailed. Tables of energy loss for electrons in tissue and many other substances as a function of electron energy can be found in ICRU 37 (1984). The stopping power for electrons may also be found on the web at physics.nist.gov/PhysRefData/Star/Text/contents.html

Gamma Rays

Photons do not have a mass or charge, as do alpha and beta particles. The interaction between a photon and matter therefore is controlled not by the electrostatic Coulomb fields but by interaction of the electric and magnetic field of the photon with the electron in the medium. There are three modes of interaction with the medium.

The Photoelectric Effect The photon interaction (energy exchange) with an orbital electron in the medium is complete, and the full energy of the photon is given to the electron minus the electron-binding energy.

The Compton Effect Part of the photon energy is transferred to an electron, and the photon scatters (usually at a small angle from its original path) (Evans, 1955) with reduced energy. The governing expressions are

$$E' = E\ 0.511/(1 + 1/a - \cos\theta)$$
$$T = E\ a(1 - \cos\theta)/[1 + a(1 - \cos\theta)] \qquad (25\text{-}11)$$

where E, E' is the initial and scattered photon energy in MeV; T the kinetic energy of electron in MeV; $a = E/0.511$; and θ the angle of photon scatter from its original path.

Pair Production Pair production may occur whenever the photon energy is greater than the rest mass of two electrons, $2(0.511 \text{ MeV}) = 1.02$ MeV. The electromagnetic energy of the photon can be converted directly to an electron–positron pair, with any excess energy above 1.02 MeV appearing as kinetic energy given to these particles.

Gamma Ray Energy Loss

The loss of photons and energy loss from a photon beam as it passes through matter are described by two coefficients. The attenuation coefficient determines the fractional loss of photons per unit distance (usually in normalized units of g/cm^2, which is the linear distance times the density of the medium). The mass energy absorption coefficient determines the fractional energy deposition per unit distance traveled. The loss of photons from the direct beam is given by

$$I/I_0 = \exp(\mu/\rho d) \qquad (25\text{-}12)$$

where I is the intensity of photon beam (numbers of photons); I_0 the beam intensity; μ/ρ the attenuation coefficient in medium for energy considered (in m^2 kg^{-2}); and d the thickness of medium in superficial density units kg m^{-2} (thickness in m times density in kg m^{-3}).

Superficial density is convenient in that it normalizes energy absorption in different media. For example, air and tissue have approximately the same energy absorption per kg m^{-2}, whereas in linear dimension, the energy absorption, say, per meter, is vastly different. The energy actually deposited in the medium per unit distance is calculated using the mass energy absorption coefficient as opposed to the overall attenuation coefficient and the energy loss is given by

$$\Delta E = (\mu_{\text{en}}/\rho)E_0 \qquad (25\text{-}13)$$

where pE is the energy loss in medium per unit distance (in MeV m² kg⁻¹); μ_{en}/ρ the mass energy absorption coefficient (m² kg⁻²); and E_0 the initial photon energy.

The values for μ_{en}/ρ as a function of gamma-ray energy are shown in Table 25-1 for air and muscle and on the web for a variety of materials. (physics.nist.gov/PhysRefData/XrayMassCoef/cover.html). Energy loss can then be expressed per unit linear distance by multiplying by the density of the medium (kg m⁻³).

ABSORBED DOSE

Dose and Dose Rate

Absorbed dose is defined as the mean energy, e, imparted by ionizing radiation to matter of mass m (ICRU, 1993, 1998):

$$D = e/m \qquad (25\text{-}14)$$

where D is the absorbed dose; e the mean energy deposited in mass; and m the mass.

The unit for absorbed dose is gray (Gy), which is equal to 1 J kg⁻¹. The older unit of dose is rad, which is equal to 100 erg g⁻¹, a value numerically equal to 100 times the dose in gray. The conversion between the two units is 100 rad = 1 Gy.

For uncharged particles (gamma rays and neutrons), kerma (kinetic energy released in matter) is sometimes used. It is the sum of the initial kinetic energies of all the charged ionizing particles liberated in unit mass. The units of kerma are the same as those for dose.

Exposure often is confused with absorbed dose. Exposure is defined only in air for gamma rays or photons and is the charge of the ions of one sign when all electrons liberated by photons are completely stopped in air of mass m:

$$X = Q/m \qquad (25\text{-}15)$$

where X is the exposure; Q the total charge of one sign; and m the mass of air.

The unit of exposure is coulombs per kilogram of air. The older unit of exposure is roentgen, which is equal to 2.58×10^{-4} C kg⁻¹ of air.

Exposure and dose are used interchangeably in some publications, even though this is not correct. The reason is that the older numerical values of dose in rad and exposure in roentgen are similar. Although they are similar numerically, they are fundamentally different in that exposure is ionization (only in air) and dose is absorbed energy in any specified medium:

$$1 \text{ roentgen } = 0.87 \text{ rad (in air)}$$

The SI units are not numerically similar:

$$1 \text{ C kg}^{-1} = 33.85 \text{ Gy}$$

Dose Rate

Dose rate is the dose expressed per unit time interval. The dose rate delivered to the thyroid by ^{99m}Tc for a nuclear medicine scan, for example, diminishes with time because of the 6.0-hour half-life of the nuclide. The total dose is a more pertinent quantity in this case because it can be related directly to risk and compared with the benefit of the thyroid scan. The total dose over all time is expressed by

$$D = D_0 \times T_{eff}/\ln 2$$

where D_0 is the dose rate at time zero; T_{eff} the effective half-life = $\{T_r \times T_b\}/\{T_r + T_b\}$; T_r the radiologic half-life; and T_b the biological half-life.

In general, substances in the body are removed through biological processes as well as by radioactive decay; therefore, the effective half-life is shorter than the radiologic half-life.

The dose rate from natural body ^{40}K in all living cells, by contrast, is relatively constant throughout life and is usually expressed as the annual dose rate.

Equivalent Dose

Ionizing radiation creates ion pairs in a substance such as air or tissue in relatively dense or sparse distribution depending upon the particle. Alpha particles with large mass produce relatively intense ionization tracks per unit distance relative to beta particles, and beta particles produce more dense ionization than gamma rays. The ability to produce more or less ionization per unit path in a medium is expressed by the linear energy transfer (LET). The LET in a substance such as water is readily calculated from the energy loss expressions in the previous sections.

The calculated LET from alpha and beta particles is much greater than it is for gamma rays. In considering the health or cellular effects of each particle or ray, it is necessary to normalize the various

Table 25-2
Recommended Values of w_r for Various Types of Radiation

TYPE OF RADIATION	APPROXIMATE w_r
X-Rays, gamma rays, beta particles, and electrons	1
Thermal neutrons	5
Neutrons (other than thermal $\gg$ 100 keV to 2 MeV), protons, alpha particles, charged particles of unknown energy	20

Table 25-3
Recommended Values of the Weighting Factors, w_t, for Calculating Effective Dose

TISSUE OR ORGAN	TISSUE WEIGHTING FACTOR, w_t
Gonads	0.20
Bone marrow (red)	0.12
Colon	0.12
Lung	0.12
Stomach	0.12
Bladder	0.05
Breast	0.05
Liver	0.05
Esophagus	0.05
Thyroid	0.05
Skin	0.01
Bone surface	0.01
Remainder	0.05*†

NOTE: The values have been developed from a reference population of equal numbers of both sexes and a wide range of ages. In the definition of effective dose, they apply to workers, to the whole population, and to either sex.
*For purposes of calculation, the remainder is composed of the following additional tissues and organs: adrenals, brain, upper large intestine, small intestine, kidney, muscle, pancreas, spleen, thymus, and uterus. The list includes organs that are likely to be selectively irradiated. Some organs in the list are known to be susceptible to cancer induction. If other tissues and organs subsequently become identified as having a significant risk of induced cancer, they will then be included either with a specific w_t or in this additional list constituting the remainder. The latter also may include other tissues or organs selectively irradiated.
†In exceptional cases in which a single one of the remainder tissues or organs receives an equivalent dose in excess of the highest dose in any of the 12 organs for which a weighting factor is specified, a weighting factor of 0.025 should be applied to that tissue or organ and a weighting factor of 0.025 should be applied to that tissue or organ and a weighting factor of 0.025 should be applied to the average dose in the rest of the remainder as defined above.
SOURCE: Data from NCRP, 1987, and ICRP, 1990.

types of radiation. For a particular biological endpoint, such as cell death in an experiment with mouse fibroblasts, it is common to calculate a relative biological effectiveness (RBE). This is defined as the ratio of gamma ray dose that yields the same endpoint to the dose from the radiation under study, e.g., cell death.

Although giving the same dose to an organ from alpha particles as opposed to gamma rays would result in greater effects from the alpha particles, such refinement in the normalization of endpoints (cancer) in the human is not possible with the available data. An attempt to normalize human health effects from different types of radiation, i.e., to calculate an "equivalent" dose is made through the values for LET of the various types of radiation in water. The ratio of the LET for gamma to the radiation in question is defined as a *radiation weighting factor*, w_r (formerly Q), and the normalized (or weighted) dose is called the equivalent dose. The unit for the *equivalent dose* is sievert (Sv), and the older unit is rem:

$$H = Dw_r \qquad (25\text{-}16)$$

where H is the equivalent dose in sievert (older unit rem); D the dose in gray (older unit rad); and w_r the radiation weighting factor.

Table 25-2 gives the values of LET for different particles or rays and is reproduced from the National Council on Radiation Protection (NCRP, 1993) and the International Commission on Radiation Protection (ICRP, 1990).

Example 4. Find the equivalent dose (in sievert) for a dose to lung from an internal emitter of 0.01 Gy alpha particles and 0.01 Gy from external gamma ray radiation.

$$\text{Alpha, } H = 0.01(20) = 0.20 \text{ Sv}$$
$$\text{Gamma, } H = 0.01(1) = 0.01 \text{ Sv}$$

Effective Dose and Cancer Risk

The term *effective dose* (ED) (formerly *effective dose equivalent*) was introduced formally by the ICRP in 1977 to allow addition or direct comparison of the cancer and genetic risk from different partial-body or whole-body doses (ICRP, 1977). A partial-body gamma-ray dose of 1 Sv to the lung, for example, is thought to give 0.0064 cancers over a lifetime per sievert, whereas a whole-body dose of 1 Sv would result in 0.056 total cancers and early genetic effects over the same lifetime interval. Both values are derived from the human atom bomb follow-up data. The ratio 0.0064/0.056 was defined as a tissue weighting factor, w_t, for lung and is numerically equal to 0.12.

The effective dose, H_E, is defined as a doubly weighted dose, weighted for radiation type and the tissue at risk.

$$H_E = w_t \text{H}(D)(w_r) \qquad (25\text{-}17)$$

This concept is useful in the case of occupational exposure, because H_E values from different sources to different organs can be summed to yield a direct estimate of total cancer and genetic risk.

Table 25-3 is taken from ICRP (1990) and gives the values of w_t for various organs. The occupational guideline for H_E is 20 mSv per annum (NCRP, 1987a; ICRP, 1990). This requires that the sum of all H_E be less than or equal to this value:

$$H_E = \sum w_t \, H \le 20 \text{ mSv} \qquad (25\text{-}18)$$

In 1990, the ICRP revised its 1977 estimates of risk and adopted and published Publication 60. This document includes new estimates of risk for both fatal and nonfatal cancer and new guidelines for the exposure of workers to external and internal radiation. The risk estimates are based largely on the analysis of Japanese atom bomb survivors. The occupational guidelines for radiation protection developed from the 1990 document are 100 mSv in 5 years (average, 20 mSv per year) with a limit of 50 mSv in any single year. This is compared with the 1977 limit of 50 mSv per year.

Table 25-4
Nominal Probability Coefficients for Individual Tissues and Organs

TISSUE OR ORGAN	Probability of Fatal Cancer 10^{-2} Sv^{-1}		Aggregated Getriment 10^{-2} Sv^{-1}	
	WHOLE POPULATION	WORKERS	WHOLE POPULATION	WORKERS

NOTE: The values relate to a population of equal numbers of both sexes and a wide range of ages.
SOURCE: Data from ICRP, 1990.

The ICRP document (ICRP, 1990) is a response to the increase in lifetime cancer risk from ionizing radiation observed in atom bomb survivors. Mental retardation for those exposed in utero is a finding in the atom bomb survivor cohort and is now included in the risk estimates.

The overall risk per unit exposure for adult workers and the risk for the whole population given in the ICRP (1990) are shown in Table 25-4. The risk of fatal cancer is adopted as 0.04 per sievert [4% per sievert (100 rem)] for adult workers and 0.05 per sievert [5% per sievert (100 rem)], for the whole adult population.

The NCRP (1993) chose to limit exposure to 20 mSv per year with a lifetime limit of (age × 10 mSv). The ICRP had been criticized for excluding the effects of nonfatal cancer in previous documents. An attempt to correct this omission was made in ICRP 60 (1990). An attempt was made to calculate the total detriment and is given the notation *aggregated detriment*. The aggregated detriment is the product of four factors: the probability of attributable fatal cancer, the weighted probability of nonfatal cancer, the weighted probability of severe hereditary effects, and the relative length of life lost. The nominal probability of fatal cancer per sievert, F, and the aggregated detriment are shown in Table 25-4. The computation of the aggregated detriment proceeds as follows. A cancer lethality fraction, K (the fraction of total cancer that is lethal), is used as a weighting factor for nonfatal cancers. The total number of cancers (fatal plus nonfatal) Sv^{-1} will be F/K. The total number of nonfatal cancers is $(1 - K)F/K$. The total weighted detriment is then

$$F + K(1 - K)F/K = F(2 - K)$$

The aggregated detriment is then the product of $F(2 - K)$ times the relative length of life lost, l/l_{av}, for a particular can-

cer. The average length of life lost, l_{av}, is 15 years per cancer. The aggregated detriment is tabulated as 7.3^{-2} Sv^{-1} for the whole adult population and 5.6×10^{-2} Sv^{-1} for the working population.

In assessing radiation risk from low-dose, low-dose-rate, low-LET radiation using risk coefficients derived from high-dose, high-dose-rate exposures, a dose and rate reduction factor (DDREF) is applied. This effectively lowers the response to a linear no threshold (LNT) curve. NCRP (1980) and the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR, 1988, 1993, 2000) have shown that the human data cover a range for the DDREF of 2–10. That is, the original risk coefficients derived from the high-dose data are divided by the DDREF factor to obtain the best linear estimate of effects at typical low-dose exposures. ICRP has used 2.5 as the adopted DDREF; however, in ICRP (1990) a DDREF of 2.0 was used, and this is incorporated in the nominal probability coefficients in Table 25-4. Table 25-4 is used universally to assess the effects of occupational exposure. The latest model (NAS BEIR VII, 2006) reduced the DDREF to 1.5.

The overall objective of both NCRP and ICRP dose limitation recommendations is to control the lifetime risk to maximally exposed individuals. ICRP (1990) limits the lifetime occupational effective dose to (20 mSv 50 years) = 1000 mSv. In 1993, NCRP (1993) reduced the U.S. Recommendation for Lifetime Exposure to (age × 10 mSv) or approximately 700 mSv, with an average annual limit of 20 mSv and a maximum annual limit of 50 mSv.

The dose to members of the public is also considered by ICRP and NCRP. For continuous exposure to human-made sources, i.e., other than medical or natural, it is recommended that the annual effective dose not exceed 1 mSv (100 mrem), and for infrequent exposures the annual effective dose should not exceed 5 mSv (500 mrem).

Committed Equivalent Dose

A problem arises with internal emitters in that once they are ingested, there is an irreversible dose that is committed because of the biokinetics of the particular element. The absorbed dose depends on the biological and physical half-times of the element in the body. For this reason, the concepts of committed equivalent dose and committed effective dose were derived to accommodate the potential for the dose to be delivered over long periods after incorporation in the body. The committed dose is taken over a 50-year interval after exposure and is equal to

$$H_{t,50} = \int_{t_0}^{t_0+50} H_t \, dt \qquad (25\text{-}19)$$

where $H_{t,50}$ = 50-year dose to tissue T for a single intake at time t_0, and H_t = equivalent dose rate in organ or tissue T at time t.

The NCRP (1987a,b, 1993) recognizes that for radionuclides with half-lives ranging up to about 3 months, the committed equivalent dose is equal to the annual dose for the year of intake. For longer-lived nuclides, the committed equivalent dose will be greater than the annual equivalent dose and must be calculated on an individual basis. ICRP Publication 30 (ICRP, 1978) provides the details of this calculation for all nuclides.

Negligible Individual Risk Level (Negligible Dose)

The current radiobiologic principle commonly accepted is that of linear, nonthreshold cancer induction from ionizing radiation. Thus, regardless of the magnitude of the dose, a numerical cancer risk can be calculated. For this reason, the NCRP proposed the negligible individual risk level (NIRL) and defined it as "a level of annual excess risk of fatal health effects attributable to irradiation below which further effort to reduce radiation exposure to the individual is unwarranted."

The NCRP emphasized that the NIRL is not to be confused with an acceptable risk level, a level of significance, or a limit.

The NCRP recommended an annual effective equivalent dose limit for continuous exposure of members of the public in some circumstances of 1 mSv (100 mrem). This value is in addition to that received from natural background radiation (about 2 mSv). In this context, the NIRL was taken to be 1/100th of this value or 0.01 mSv (1 mrem). In NCRP (1993) the notation used currently is negligible individual dose (NID).

MECHANISMS OF DNA DAMAGE AND MUTAGENESIS

Energy Deposition in the Cell Nucleus

DNA is a double-helical macromolecule consisting of four repeating units: the purine bases adenine (A) and guanine (G) and the pyrimidine bases thymine (T) and cytosine (C). The bases are arranged in two linear arrays (or strands) held together by hydrogen bonds centrally and linked externally by covalent bonds to sugar-phosphate residues (the DNA "backbone"). The adenine base pairs naturally with thymine (A:T base pair), while guanine pairs with cytosine (G:C base pair), so that one DNA strand has the complementary sequence of the other. The sequence of the bases defines the genetic code; each gene has a unique sequence, but certain common sequences exist in control and structural DNA elements. Damage to

DNA may affect any one of its components, but it is the loss or alteration of base sequence that has genetic consequences (UNSCEAR, 2000).

Ionizing radiation loses energy and slows down by forming ion pairs (a positively charged atom and an electron). Different ionization densities result from gamma rays, beta particles, and alpha particles. Their track structure is broadly characterized as from sparsely ionizing (or low-LET), to densely ionizing (high-LET) radiation. Each track of low-LET radiation, resulting from X-rays or gamma rays, consists of a few ionizations across an average-sized cell nucleus (e.g., an electron set in motion by a gamma ray crossing an 8 μm-diameter nucleus gives an average of about 70 ionizations, equivalent to about 5 mGy (500 mrad) absorbed dose. Individual tracks vary widely about this value because of the stochastic nature of energy deposition, i.e., variability of ion pars per μm and path length through the nucleus. A high-LET alpha particle produces many thousands of ionizations and gives a relatively high dose to the cell. For example, a 4-MeV alpha-particle track yields on average, about 30,000 ionizations (3 Gy, 300 rad) in an average-sized cell nucleus. However, within the nucleus even low-LET gamma radiation will give some microregions of relatively dense ionization over the dimensions of DNA structures due to the low-energy electrons set in motion (UNSCEAR, 2000). The studies of single strand breaks (SSB) with low-energy electrons indicate that the energy threshold is practically zero (Panajotovic et al., 2006).

There was a long-standing belief that the cell nucleus must be irradiated for any biological effect to occur. In the past 15 years, research on epigenetic effects has shown this is not the case. Epigenetic (or nontargeted) effects include genomic instability (the increase in genomic alterations), bystander effects (damage that occurs in cells not traversed by radiation but close by), cytoplasmic/membrane effects (bystander effects after cytoplasm irradiation), clastogenic effects (detrimental effects from irradiated plasma), abscopal effects (partial volume irradiation induces damage in the whole organ), and transgenerational (instability passed through the germ line) effects. The new information concerning epigenetic effects (Little, 2006), although adding immensely to biological and mechanistic understanding, should not affect risk calculations which are based on observed exposure response in human and animal populations. The underlying mechanistic information should lead to better lifetime risk projection models.

Direct and Indirect Ionization

Radiation tracks may deposit energy directly in DNA (direct effect) or may ionize other molecules closely associated with DNA, hydrogen, or oxygen, to form free radicals that can damage DNA (indirect effect). Within a cell, the indirect effect occurs over very short distances, of the order of a few nanometers. The diffusion distance of radicals is limited by their reactivity. Although it is difficult to measure accurately the different contributions made by the direct and indirect effects to DNA damage caused by low-LET radiation, evidence from radical scavengers introduced into cells suggests that about 35% is exclusively direct and 65% has an indirect (scavengeable) component (Reuvers et al., 1973).

It has been argued that both direct and indirect effects cause similar early damage to DNA; this is because the ion radicals produced by direct ionization of DNA may react further to produce DNA radicals similar to those produced by water-radical attack on DNA (Ward, 1975; Cadet et al., 1999).

Douki *et al*. (2006) measured oxidized bases following irradiation of isolated DNA and human monocytes. The study used the heavy ions ^{12}C(6+) and ^{36}Ar(18+) and showed that direct ionization is a small contributor to base damage and hydroxyl radicals are major contributors. There is no consensus on the ratio of direct/indirect damage.

DNA Damage

Ionization frequently disrupts chemical bonding in cellular molecules such as DNA. If the majority of ionizations occur as single isolated events (low-LET radiation), the disruptions are readily repaired by cellular enzymes. The average density of ionization by high-LET radiations is such that several ionizations may occur as the particle traverses a DNA double helix. Therefore, much of the damage from high-LET radiations, as well as a minority of the DNA damage from low-LET radiations, will derive from localized clusters of ionizations that can severely disrupt the DNA structure (Ward, 1994). While the extent of local clustering of ionizations in DNA from single tracks of low- and high-LET radiations will overlap, high-LET radiation tracks are more efficient at inducing larger clusters and hence more complex damage. Also, high-LET radiations will induce some very large clusters of ionizations that do not occur with low-LET radiations; the resulting damage may be irreparable and may also have unique cellular consequences (Goodhead, 1994). When a cell is damaged by high-LET radiation, each track will give large numbers of ionizations, so that the cell will receive a relatively high dose, as noted in the calculation above, and there will be a greater probability of correlated damage within a single DNA molecule. As a consequence, the irradiation of a population of cells or a tissue with a "low dose" of high-LET radiation results in a few cells being hit with a relatively high dose (one track) rather than in each cell receiving a small dose. In contrast, low-LET radiation is more uniformly distributed over the cell population. At doses of low-LET radiation in excess of about 1 mGy (for an average-size cell nucleus of 8 μm in diameter), each cell nucleus is likely to be traversed by more than one sparsely ionizing track.

The interaction of ionizing radiation with DNA produces numerous types of damage; the chemical products of many of these have been identified and classified according to their structure. These products differ according to which chemical bond is attacked, which base is modified, and the extent of the damage within a given segment of DNA. Table 25-5 lists some of the main damage products that can be measured following low-LET irradiation of DNA, with a rough estimate of their abundance (UNSCEAR, 2000). Attempts have also been made to predict the frequencies of different damage types from the knowledge of radiation track structure, with certain assumptions about the minimum energy deposition (number of ionizations) required. Interactions can be classified according to the probability that they will cause a single-strand DNA alteration (e.g., a break in the backbone or base alteration) or alterations in both strands in close proximity in one DNA molecule (e.g., a double-strand break), or a more complex type of DNA damage (e.g., a double-strand break with adjacent damage). Good agreement has been obtained between these predictions and direct measurements of single-strand breaks, but there is less agreement for other categories of damage. While complex forms of damage are difficult to quantify with current experimental techniques, the use of enzymes that cut DNA at sites of base damage suggests that irradiation of DNA in solution gives complex damage sites consisting mainly of closely spaced base damage (measured as oxidized bases of aba-

Table 25-5

Estimated Yields of DNA Damage in Mammalian Cells Caused by Low-LET Radiation Exposures

TYPE OF DAMAGE	YIELD (NUMBER OF DEFECTS PER CELL Gy^{-1})
Single-strand breaks	1000
Base damage*	500
Double-strand breaks	40
DNA protein cross-links	150

*Base excision enzyme-sensitive sites or antibody detection of thymine glycol.
SOURCE: Data from UNSCEAR, 2000.

sic sites); double-strand breaks were associated with only 20% of the complex damage sites (Sutherland *et al*., 2000). It is expected that the occurrence of more complex types of damage will increase with increasing LET, and that this category of damage will be less repairable than the simpler forms of damage. Theoretical simulations have predicted that about 30% of DNA double-strand breaks from low-LET radiation are complex because of additional breaks (Nikjoo *et al*., 1997) and that this proportion rises to more than 70%, and the degree of complexity increases, for high-LET particles (Goodhead and Nikjoo, 1997).

Some of the DNA damage caused by ionizing radiation is chemically similar to damage that occurs naturally in the cell. This "spontaneous" damage arises from the thermal instability of DNA as well as endogenous oxidative and enzymatic processes. Several metabolic pathways produce oxidative radicals within the cell, and these radicals can attack DNA to give both DNA base damage and breakage, mostly as isolated events. The more complex types of damage caused by radiation may not occur spontaneously, because localized concentrations of endogenous radicals are less likely to be generated in the immediate vicinity of DNA (UNSCEAR, 2000).

HUMAN STUDIES OF RADIATION TOXICITY

There have been five major studies of the health detriment resulting from exposure of humans to ionizing radiation. Other studies of large worker populations exposed to very low levels of radiation and environmental populations exposed to radon are ongoing, but they are not expected to provide new data on the risk estimates from ionizing radiation. These worker or environmental populations are studied to ensure that there is no inconsistency in the radiation risk data in extrapolating from the higher exposures. The basic studies on which the quantitative risk calculations are founded include radium exposures, atom bomb survivors, underground miners exposed to radon, patients irradiated with X-rays for ankylosing spondylitis, and children irradiated with X-rays for tinea capitis (ringworm).

Radium Exposures (^{226,228}Ra)

Radium was discovered in the early part of the twentieth century. Its unique properties suggested a potential for the healing arts. It was incorporated into a wide variety of nostrums, medicines, and artifacts. The highest exposure occurred in the United States among radium dial painters who ingested from 10s to 1000s of micrograms (microcuries). These exposed groups, including patients, chemists, and dial painters, have been studied for over 60 years to determine the body retention of radium and the health effects of long-term body burdens.
Figure 25-4. Whole-body radium retention in humans. Summary of all available data for adult humans.
(From Marshall et al., ICRP Report Number 20, 1972.)

The only late effect of ingestion of ^{226,228}Ra seen is osteogenic sarcoma. It is significant that no study has identified a statistically significant excess of leukemia after even massive doses of radium. This implies that the target cells for leukemia residing in bone marrow are outside the short range of the radium series alpha particles (70 μm). Several thousand people were exposed to radium salts either as part of the modish therapies using radium in the era from 1900 to 1930 or occupationally in the radium dial-painting industry around 1920. Radium therapy was accepted by the American Medical Association, and in around 1915 advertisements were common for radium treatment of rheumatism and as a general tonic and in the treatment of mental disorders. Solutions were available for drinking that contained 2 μg/60 cm^3 as well as ampoules for intravenous injection containing 5–100 μg radium (Woodard, 1980). Luminous paint was developed before World War I, and in 1917 there were many plants in New England and New Jersey painting watch dials, clocks, and military instruments (Woodard, 1980).

The first large studies on osteogenic sarcoma in radium-exposed people were done by Martland (1931) and Aub *et al.* (1952), who found 30 cases of bone sarcoma; Evans *et al.* (1969) with 496 cases of sarcoma out of 1064 studied at the Massachusetts Institute of Technology; and Rowland *et al.* (1978), with 61 cases out of 1474 female dial painters (Woodard, 1980).

Radium, once ingested, is somewhat similar to calcium in its metabolism and is incorporated on bone surfaces into the mineralized portion of bone. The long half-life of ^{226}Ra (1600 years) allows distribution throughout the mineral skeleton over life. The target cells for osteogenic sarcoma reside in marrow on endosteal surfaces at about 10 μm from the bone surface. At long times after exposure, target cells are beyond the range of alpha particles from radium not on bone surfaces.

The loss of radium from the body by excretion was determined to follow a relatively simple power function (Norris *et al.*, 1958):

$$R = 0.54t^{-0.52} \qquad (25\text{-}20)$$

where R is the total body retention and t the time in days.

Other models to fit the data were developed as more information became available, the most recent being that of Marshall *et al.* (1972). The entire body of radium data and the various models are shown in Fig. 25-4. It can be seen that the Norris function fits the observed data well except at very long times after exposure. A simplified form of the more complex later model of Marshall *et al.* (1972) which fits the human data over all observed times is

$$R = 0.8_t^{-0.5}(0.5\mathrm{e}^{8t} + 0.5\mathrm{e} - 4^{8t}) \qquad (25\text{-}21)$$

where R is the whole body retention; 8 the rate of bone apposition or resorption $= 0.0001$ day^{-1}; and t the time in days.

For most purposes, the Norris formula is applicable. It can be seen from Fig. 25-4 for the Norris equation that even 1 year after exposure, only about 2% of the radium is retained in the body but that after 30 years, about 0.5% remains. The risk of osteogenic bone cancer after radium exposure has been summarized in the National Academy of Sciences report BEIR IV (NAS, 1988).

Equations were proposed by Rowland *et al.* (1978) for the annual risk of sarcoma (including the natural risk), and expressed as a function of either radium intake or dose from ^{226,228}Ra. Risk per unit intake is

$$I = [0.7 \times 10^{-5} + (7 \times 10^{-8})D^2]\exp[-(1.1 \times 10^{-3})D] \qquad (25\text{-}22)$$

where I is the total bone sarcomas per person year at risk and D the total systemic intake of ^{226}Ra plus 2.5 times total systemic intake of ^{228}Ra (both in microcuries).

Risk per unit dose is

$$I = [10^{-5} + (9.8 \times 10^{-6})D^2]\exp(-1.5 \times 10^{-2}D) \qquad (25\text{-}23)$$

where I is the total bone sarcomas per person year at risk and D the total mean skeletal dose in Gray from ^{226}Ra plus 1.5 times mean skeletal dose from ^{228}Ra.

Raabe *et al.* (1980) modeled bone sarcoma risk in the human, dog, and mouse and determined that there is a practical threshold

dose and dose rate (a dose low enough so that bone cancer will not appear within the human life span). The dose rate is 0.04 Gy per day or a total dose of 0.8 Gy to the skeleton. This practical threshold for bone cancer has useful implications in considering health effects from exposures to environmental radioactivity.

Radium Exposure (^{224}Ra)

In Europe, ^{224}Ra was used for more than 40 years in the treatment of tuberculosis and ankylosing spondylitis. The treatment of children was abandoned in the 1950s, but the ability to relieve debilitating pain from ankylosing spondylitis in adults has prolonged its use. ^{224}Ra is different from ^{226}Ra in that it has a short half-life (3.62 days) and the alpha dose is delivered completely while the radium is still on bone surfaces.

Spiess and Mays (1970) and Mays (1988) studied the health of 899 German patients given ^{224}Ra therapeutically. The calculated average mean skeletal dose was 30 Gy (range, 0.06–57.5 Gy) with injection time spans ranging from 1 to 45 months. There were two groups—juveniles and adults—and the bone sarcoma response was not significantly different for the two. There were 60 patients who developed bone sarcoma (Gossner, 1999), 46 have been studied for histologic type. Further study of this group revealed other solid tumors with statistically significant excesses of male and female breast cancer, thyroid cancer, and liver cancer (Nekolla *et al.*, 1999).

In a second cohort, Wick *et al.* (1986, 1999) studied 1432 adult patients treated for ankylosing spondylitis with an average skeletal dose of 0.65 Gy. This study was originally started by Otto Hug and Fritz Schales and has been continued since their deaths. Four patients in this group have developed osteogenic sarcoma, and one in the control group.

Spiess and Mays (1973) found that the observed effectiveness of the ^{224}Ra in their cohort in producing bone sarcomas increased if the time span of the injections was long. Injections were given in 1, 10, or 50 weekly fractions. They developed an empiric expression to estimate the added risk from this protracted injection schedule:

$$I = \{0.003 + 0.014[1 - \exp(0.09m)]\}D \qquad (25\text{-}24)$$

where I is the cumulative incidence of bone sarcomas after most tumors have appeared (25 years); m the span of injections in months; and D the average skeletal dose in Gy.

Chemelevsky *et al.* (1986) analyzed the Spiess data and developed an equation for the total cumulative sarcoma risk from ^{224}Ra:

$$R = (0.0085D + 0.0017D^2)\exp(-0.025D) \qquad (25\text{-}25)$$

where R is the cumulative risk of bone sarcoma and D the average skeletal dose in Gy.

These two equations for risk predict 5.7 and 5.8 bone sarcomas in the second series of (spondylitis) patients, with two actually observed.

Chemelevsky *et al.* (1986) also showed that in the Spiess study, linearity (sarcoma response with dose) could be rejected. For example, Eq. (25-22) results in a lifetime risk of sarcoma of 0.02 Gy^{-1} at an average skeletal dose of 10 Gy but 0.01 Gy^{-1} at 1 Gy. Also, there was no difference in sarcoma response between juveniles and adults. These data are presented in Fig. 25-5. Again, no excess leukemia was found in either series of ^{224}Ra patients.
Figure 25-5. Lifetime risk per gray versus mean skeletal dose in ^{224}Ra exposed subjects. (From Chemelevsky et al., 1986, with permission.)

Atomic Bomb Survivors

The A-bomb survivor risk estimates are particularly important because the guidelines for occupational exposure are based on their experience. On August 6, 1945, the U.S. military dropped an atomic bomb on the city of Hiroshima, Japan. Three days later a second bomb was dropped on Nagasaki which effectively ended World War II. The weapons were of two different types, the first being ^{235}U and the second a ^{239}Pu device.

Within 1 km of the explosions in both cities, a total of 64,000 people were killed by the blast and the thermal effects as a result of the instantaneous gamma and neutron radiation released by the weapons. Others between 1 and 2 km from the hypocenter (the point on earth directly below the detonation point in air) received radiation doses up to several gray. Beyond 2.5 km there was no additional dose from the weapon, only natural background radiation.

Within a few years it was decided to follow the health of the people in both cities over their lifetime to determine quantitatively the effects of external ionizing radiation. The study of prospective mortality of A-bomb survivors was initiated by the Atomic Bomb Casualty Commission (ABCC) in 1950 and is ongoing by the Radiation Effects Research Foundation (RERF). The main study, called the Life Span Study (LSS), included 120,000 people, 92,228 people within 10,000 m of the hypocenter and 26,850 people who were not in either city at the time of bombing (ATB). The most recent reports of the RERF (1987, 2003) are follow-up of the cancer mortality of a subcohort (DS86 subcohort) of 75,991 persons over the periods 1950–1985, 1950–1990 (Pierce and Preston, 1993) and 1950–1997 (Preston *et al.*, 2004). The cohort includes 86,572 persons with individual dose estimates. The latest update (Preston *et al.*, 2003) report that 440 (5%) of the solid cancer deaths and 250 (0.8%) of the noncancer deaths were associated with the radiation exposure. There have been a total of 9335 cancer deaths and 31,881 noncancer deaths in 47 years of follow up.

In 1978, questions arose that the original dose estimates for persons in the LSS might be somewhat in error and that an effort should be made to improve the dose estimates. This study was published in a United States–Japan joint reassessment of dose called DS86—Dosimetry System 1986 (RERF, 1987).

Dose estimation by reconstruction of the event is always problematic, but direct computation of dose to about 18,500 persons in the LSS with detailed shielding information is complete. The remaining DS86 dose values for 57,000 individuals without detailed

shielding information are also incorporated into the mortality study by various estimation techniques. Of the 75,991 persons in the DS86 subcohort, 16,207 were within 2000 m of the hypocenter, and these are the individuals who received a substantial exposure.

A new study of the A-bomb dosimetry was funded by the U.S. Department of Energy to address questions arising about the accuracy of the calculated neutron and gamma ray dose as a function of distance from the hypocenter. *The report, DS02: A new dosimetry system for A-bomb survivor studies, is available on the web www.rerf.or.jp/top/introe.htm*.

The new calculations and measurements produced during this reassessment confirmed the yield and epicenter for the Nagasaki detonation while refining these values for Hiroshima. Current measurements and calculations confirm a 21-kiloton-yield for the Nagasaki bomb and a burst point to within 2 m of previous assessments. In Hiroshima, the estimated yield has been increased from 15 kilotons to16 kilotons and the epicenter has been repositioned 20 m higher and 15 m to the west. While supercomputing technology made recalculation of the nuclear explosions possible, application of current geographic information systems technology has reconciled the exact hypocenter locations on new, more accurate maps with World War II vintage maps.

Some details from the press release concerning the new dosimetry (DS02) report, "New air over ground calculations together with newly revised fluence to dose factors resulted in recalculated estimates of the free-in-air doses from the Hiroshima weapon of about 8–10% average increase over DS86 in the total gamma-ray doses, and about 10% increase in the average neutron doses but approximately the same variation of dose with distance from the hypocenter as in DS86. Increasing the height of burst and incorporating new information on exact locations of sites relative to the epicenter did, however, improve the agreement with measurements near the hypocenter and with the slope of measurement data versus distance.

The gamma rays account for the preponderance of absorbed radiation doses to the survivors, the neutron absorbed dose at most organ depths (and distances from the hypocenter) being about 1%

of the gamma-ray absorbed dose at Hiroshima. (Note that the equivalent dose from the neutrons depends on the appropriate RBE for the neutrons, e.g., RBE of 20 would yield an equivalent dose for the neutrons of perhaps 20% of the total equivalent dose. In future risk estimations the neutron contribution at Hiroshima, about four times that at Nagasaki, should be accounted for.) Because the new DS02 fluences do not differ by much from those in DS86, one would not expect large changes in organ dose estimates for individual survivors. However, improved estimates of shielding and survivor location may result in some changes in organ dose to some survivors.

A report on the updated cancer risk using DS02 states that "For both solid cancer and leukemia, estimated age–time patterns and sex difference are virtually unchanged by the dosimetry revision. The estimates of solid-cancer radiation risk per sievert and the curvilinear dose response for leukemia are both decreased by about 8% by the dosimetry revision, due to the increase in the gamma ray dose estimates. The apparent shape of the dose response is virtually unchanged by the dosimetry revision."

The National Academy of Sciences assembled a committee (BEIR VII) to estimate the risk from low exposures to external gamma ray exposure based on the updated DS02 A-bomb dosimetry (NAS, 2006). Their estimate of lifetime excess cancer cases for an exposure of 0.1 Sv is 0.8 and 1.3% for men and women respectively. The absolute risk for men and women is similar but the excess risk differs because the baseline rate for women is much lower than for men.

Previous reports of cancer risk estimates were based on the air dose (gamma ray plus neutron tissue kerma in air) adjusted for shielding by structures or terrain. The 1987 and 1988 reports also include DS86 organ dose estimates, and these are about 80% of the shielded kerma (Shimizu *et al*., 1988). The DS02 dosimetry improves the individual's shielding data.

The dose from fallout at Hiroshima and Nagasaki has not been included in the health effects studies. Fallout was found in certain restricted localities in Nagasaki and Hiroshima. The absorbed dose

Table 25-6

Observed and Expected Cases of Cancer in A-Bomb Survivors with DS86 Dose Estimate and Projections of Lifetime Cancer Incidence from Radiation for a Dose of 0.1 Sv

CANCER TYPE	OBSERVED CASES	EXPECTED CASES	MEAN DOSE (Sv)	Projection of Lifetime Cancer Incidence (%) for a Dose of 0.1 Sv*	
				MALES	FEMALES
Esophagus	84	77.4	0.23	0.04	0.02
Stomach	1307	1222	0.23	0.17	0.17
Colon	223	193.7	0.23	0.13	0.19

Other solid cancer				0.26	0.15
Solid cancer				1.16	1.70
Leukemia	141	67.4	0.25	0.05	0.05
Total				1.21	1.75

*Projection of cancer incidence based on the attained age model. Data from UNSCEAR (2000), and a whole-body exposure of 0.1 Sv at age 30. Mortality projections for total cancer 0.67 and 0.99% per 0.1 Sv, for males and females, respectively.

from gamma rays at Nagasaki for persons continuously in the fallout area from 1 hour ranged from 0.12 to 0.24 Gy. The absorbed doses at Hiroshima ranged from 0.006 to 0.02 Gy. Because the region of fallout was quite limited, the total contribution of fallout to survivor dose was probably negligible in Hiroshima but may have been significant for a limited number of survivors in Nagasaki, where an exposure of one-fifth the maximum extends over some 1000 hectares. Estimates of internal dose from ingested ^{137}Cs yield about 0.0001 Gy integrated over 40 years (Harley, 1987; RERF, 1987).

Complete mortality data and the dose estimates are reported in RERF Technical Reports 5-88 (RERF, 1987) and were updated by Pierce and Preston (1993) and in UNSCEAR (2000). The projected lifetime cancer risks as of the follow-up through 1990 are reported in UNSCEAR (2000), and these data are summarized in Table 25-6.

No statistically significant excess cancer of the gallbladder, bone, pancreas, uterus, prostate, or malignant lymphoma has been seen in the LSS to date. The latest data (Preston *et al.*, 2003) show a statistically significant excess of heart disease, stroke, digestive, and respiratory disease. The noncancer diseases were associated with exposures greater than 0.5 Sv.

It is of interest to consider the effect of smoking, as it is the most important factor in assessing lung cancer risk. The analysis performed by Shimuzu *et al.* (1988) examined the interaction of smoking and radiation in detail. The results showed no interaction indicating that smoking and the atom bomb radiation act independently rather than multiplicatively in lung cancer induction.

It is also possible to model the risk over the full life if a projection model is assumed. RERF originally preferred a constant relative risk model (radiation mortality is a constant fraction of the baseline age-specific mortality per gray) for this purpose. However, there is now evidence in the atom bomb mortality and in several other studies discussed later (ankylosing spondylitis patients, uranium miners) that the constant relative risk model is not appropriate. The excess relative risk (ERR) decreases both with time subsequent to exposure and with attained age. One model projects ERR only as a function of age at exposure because this is the stronger effect. These are biologically plausible models suggesting the loss or repair of the damaged stem cell population.

The estimates of lifetime risk of cancer may increase somewhat with time, but given the present age of the population, the final values based on risk projections from the DS02 dosimetry are unlikely to be significantly higher than the values in Table 25-6.

Tinea Capitis (Ringworm) Irradiation

During the period 1905–1960, X-ray epilation in the treatment of tinea capitis was performed regularly in children. The treatment was introduced by Sabouraud in 1904 and was standardized by Kienbock (1907) and Adamson (1909). Over the half century it was used, as many as 200,000 children worldwide may have been irradiated (Albert *et al.*, 1986).

No follow-up studies of the long-term effects of irradiation were performed until Albert and Omran (1968) reported on 2200 children irradiated at the Skin and Cancer Unit of New York University Hospital during 1940–1959. Subsequent publications on this group have appeared at regular intervals (Shore *et al.*, 1976, 1984, 2002, 2003; Shore, 1990). In the follow-up studies to 2002, there were 2224 irradiated children and 1380 in the control group. Since the New York University (NYU) study, a follow-up of 11,000 children irradiated in Israel was performed (Ron and Modan, 1984; Ron *et al.*, 1988, 1991).

Skin (nose)	11
Skin (midneck)	9

The mean age of children irradiated in both the New York and Israeli studies was between 7 and 8 years. The age range in the New York study was 1–15 years at the time of treatment. Dose reconstruction in the NYU series was performed using a head phantom containing the skull of a 7-year-old child covered with tissue-equivalent material (Schulz and Albert, 1963; Harley *et al.*, 1976, 1983). The doses to organs in the head and neck for a typical Adamson–Kienbock five-field treatment of the scalp are shown in Table 25-7, and the dose to the skin is shown in Fig. 25-6.

In the NYU series there were two thyroid cancers with no expected cases and 11 thyroid adenomas with 1 expected. (Shore *et al.*, 2003). In the Israeli series there were 43 thyroid cancers with 10.7 expected cases. In the NYU series there are 128 skin lesions, predominantly basal cell carcinoma, with 24 expected cases, in 41 persons. Fairness of skin is an important factor in the appearance of skin cancer (Shore *et al.*, 1984, 2002; Shore, 1990).

Skin cancer was found primarily in Caucasians even though 25% of the study population consisted of blacks. As of 2002, there were 128 cases of nonmelanoma skin cancer of the head and neck in the irradiated group and 21 in the control group. In the irradiated group 125 cases were Caucasian and 3 were African American. This and the fact that there appears to be a much lower dose response on the hair-covered scalp than on the face and neck (Harley *et al.*, 1983; Shore *et al.*, 2002) suggest that the promotional effects of UV radiation play an important role in skin cancer. The dose estimates for the thyroid in the Israeli study are 0.09 Gy and 0.06 Gy in the NYU study. The skin dose estimates range from 0.1 to 0.5 Gy on the face, but 2.5 Gy near the scalp margins.

A risk projection model was used to estimate the lifetime risk of basal cell carcinoma (BCC) for facial skin and for the hair-covered scalp after X-ray epilation in whites. The model used was a cumulative hazard plot which assumes that the BCC appearance rate in the exposed population remains constant over time (Harley *et al.*, 1983). The result of this risk projection for BCC is shown in Table 25-8.

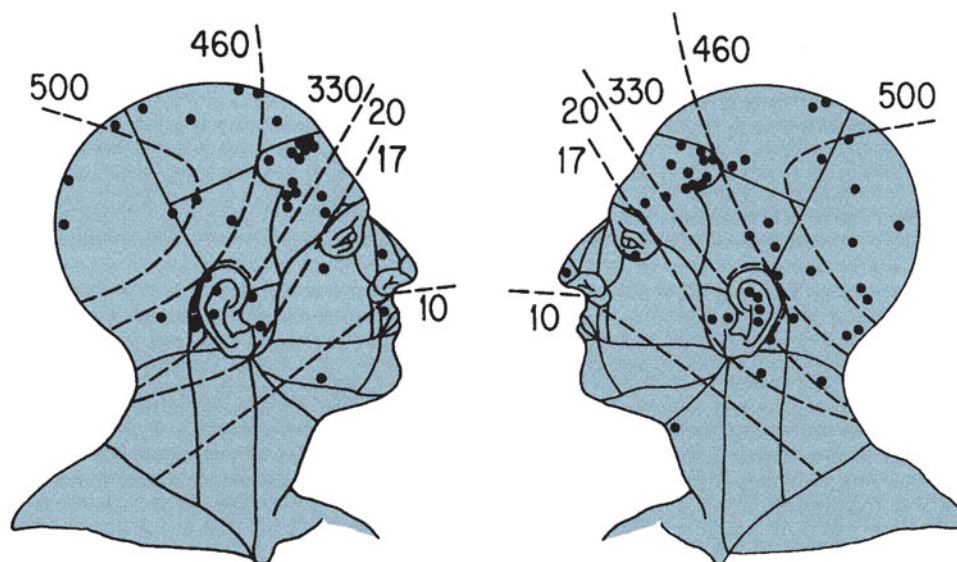
The small numbers of tumors other than skin cancers in the NYU study make it of dubious value in estimating the lifetime risk per Gy although an excess is appearing (Shore *et al.*, 2003). There are (in 2003) 8 leukemia with 1 expected, 7 brain malignancies with none expected, and 6 salivary gland tumors with 2 expected. These are particularly important studies because children were the exposed


Figure 25-6. X-ray dose in rads for the Adamson–Kienbock five-field tinea capitis treatment and locations of basal cell lesions. (From Shore et al., 1984, with permission.)

Table 25-8

Estimated Lifetime Risk Estimates for Basal Cell Carcinoma (BCC) and Thyroid Cancer after X-Ray Irradiation for Tinea Capitis

	TOTAL INCIDENCE, RISK Gy^{-1}	MORTALITY, RISK Gy^{-1}
Skin malignancies (NYU study)		
BCC (facial skin)	0.32	
BCC (hair-covered scalp)	0.01	
Thyroid malignancies (Israeli study)		
Male	0.01	0.001
Female	0.04	0.004

group and because only partial body irradiation was involved. The temporal pattern of appearance of these tumors is also important. The dose was delivered over a short time interval (minutes at NYU and 5 days in Israel), and lifetime patterns are indicative of the underlying carcinogenic mechanisms.

Skin and thyroid cancers are of importance in documenting health effects from ionizing radiation. However, both types of cancer are rarely fatal. NCRP (1985) reported that about 10% of thyroid cancer is lethal. It is estimated that the fatality rate of skin cancer is 1% (NCRP, 1990). The lifetime risk per gray derived by NCRP for total thyroid cancer incidence (0.003 for females and 0.0014 for males for external X-ray or gamma radiation for persons under 18 years of age) is about a factor of 10 lower than that reported by Ron and Modan (1984; Ron *et al.*, 1991) in tinea capitis irradiations. However, the tinea irradiations were given to children with a mean age of about 7 years, also in the Israeli study there is apparently an increased sensitivity resulting from ethnicity.

The effect of ethnicity and sex is also suggested by NCRP (1985) for thyroid cancer. The incidence rates of spontaneous thyroid cancer for persons of Jewish origin in Europe and North Amer-ica are three to four times that for other racial groups. There is an obvious susceptibility of women for thyroid cancer and adenomas in both the NYU and Israeli tinea capitis studies.

After 50 years of follow up in the New York Study, the cumulative incidence of basal cell skin cancer in the irradiated group is 16% and 4% in the control group.

Chernobyl and Radioactive Iodine (^{131}I)-Induced Thyroid Cancer

The Chernobyl accident (April 26, 1986) was the result of efforts to conduct a test on the electrical control system, which allows power to be provided in the event of a station blackout. The details of the accident have been published in reports of the International Atomic Energy Agency (IAEA, 2005) and UNSCEAR (2000). Basically, there was a rapid increase in the reactor power. Part of the fuel in the pressurized water reactor was vaporized, resulting in an explosion that blew the reactor core apart and destroyed much of the containment building. The estimates of the significant radionuclides for health effects released during the accident are 1.8 EBq (4.9×10^7 Ci) ^{131}I and 0.085 EBq (2.3×10^6 Ci) ^{137}Cs, and 0.01 EBq (2.7×10^5 Ci) ^{90}Sr and 0.003 Ebq of plutonium isotopes (UNSCEAR, 2000; IAEA, 2005). (Note 1 EBq $= 10^{18}$ Bq, Becquerel).

The accident caused the deaths within days or weeks of 32 power plant employees and firemen (including 28 deaths that were due to radiation exposure). During 1986, 220,000 people were evacuated from areas surrounding the reactor, and, after 1986, about 250,000 people were relocated from what were at that time three constituent republics of the Soviet Union: Belarus, the Russian Federation, and Ukraine. Large areas in these three republics were contaminated, and deposition of fission product radionuclides was measurable in all countries of the northern hemisphere. In addition, about 280,000 workers, termed "liquidators," were mobilized in 1986 and 1987 to take part in major mitigation activities at the reactor and within the 30-km zone surrounding the reactor. Residual mitigation activities continued until 1990. In all, about 600,000 persons received the special status of "liquidator."

Data From IAEA Chernobyl Forum 2003-2005
Figure 25-7. *Thyroid cancer in children under 18 at the time of the Chernobyl accident. (From IAEA publication, The Chernobyl forum: 2003–2005.)*

The radiation exposures resulting from the Chernobyl accident were due initially to ^{131}I and short-lived radionuclides and subsequently to radiocesium (^{134}Cs and ^{137}Cs) from both external exposure and the consumption of foods contaminated with these radionuclides. UNSCEAR (1988) estimated that, outside the regions of Belarus, the Russian Federation, and Ukraine, thyroid doses averaged over large portions of European countries were 25 mGy for 1-year-old infants. However, the dose distribution was very heterogeneous, especially in countries near the reactor site. For example, in Poland, although the countrywide population-weighted average thyroid dose was estimated to be 8 mGy, the mean thyroid doses for the populations of particular districts ranged from 0.2 to 64 mGy. Individual dose values for about 5% of the children were 200 mGy. UNSCEAR (1988, 2000) estimates that effective dose averaged over large portions of European countries were 1 mSv or less in the first year after the accident and approximately two to five times the first-year dose over a full lifetime.

In 2002, there were 4000 cases of thyroid cancer in children from ^{131}I exposure in milk. The expected number of thyroid cancer cases is not known, but is evidently a small fraction of those observed. In 2002, there were 15 deaths related to the disease. No solid tumors other than thyroid cancer have been identified resulting from the accident. Figure 25-7 shows the sequential increase in the incidence per 100,000 of thyroid cancers in children under the age of 18 at the time of the accident. It is well established that release of ^{131}I presents the major health effect in a nuclear reactor accident. Many countries prepare for such accidents and have ready a large supply of potassium iodide (KI), which effectively blocks the thyroid uptake of radioactive iodine. Had this been available in time, and the fresh local milk supply shut down in favor of other sources, it is questionable whether the large number of tumors would have occurred.

Medical Administration of ^{131}I   Iodine-131 is given medically in three ways. Very large quantities, 3.7×10^9 Bq (100 mCi) or more are administered to ablate the thyroid in thyroid cancer, lesser quantities (about 10 mCi or 3.7×10^8 Bq) are given for hyperthyroidism, and the lowest quantity given (0.1 mCi or 3.7×10^6) is for diagnostic purposes (UNSCEAR, 1994). Individuals have also been exposed to ^{131}I as a result of nuclear weapons testing. Very few thyroid cancers have been found subsequent to these exposures, with the exception of the 243 Marshall Island inhabitants who received a large dose from a mixture of radionuclides (^{131}I, ^{132}I, ^{133}I, ^{134}I, and ^{135}I), tellurium, and gamma-ray radiation from the 1954 Bravo thermonuclear test (Conard *et al.*, 1984; Gilbert *et al.*, 2002) in the Pacific. The mean thyroid dose was estimated to be 3–52 Gy in children and 1.6–12 Gy in adults. Over a 32-year follow-up period, 7 of 130 women and 2 of 113 men developed thyroid cancer.

Attempts have been made to relate external gamma-ray radiation and ^{131}I exposure. The NCRP (1985) estimated from human data that the effectiveness ratio of ^{131}I/gamma-ray radiation is between 0.1 and 1.0. In a more recent review of the human data, Shore (1992) found 8.3 observed excess cancers derived from all ^{131}I studies and 37 cases based on risk estimates from external exposure. The ratio 8.3/37 yields an estimate for the effectiveness ratio of 0.22. The protracted dose to the thyroid during the decay of ^{131}I may explain the difference; however, the nonuniform distribution of ^{131}I in the thyroid also may be a factor (Sinclair *et al.*, 1956).

It is evident that ^{131}I can expose large populations after nuclear weapons testing or nuclear accidents. Generally, it is the ingestion pathway that is most significant. Iodine is ingested quickly either from surface deposition on edible plants or from pasture grass to the cow, to milk, and to the thyroid. A large body of data exists on the transfer coefficients, P_{24} (intake to the body per unit deposition), P_{45} (effective dose per unit intake), and P_{25} ($P_{25} = P_{24}$ H P_{45}) = effective

dose per unit deposition. UNSCEAR (1993) reported the transfer coefficients for ^{131}I to be

$$P_{24} = 0.07 \text{ Bq per Bq m}^{-2}$$
$$P_{45} = 61 \text{ nSv per Bq intake (effective dose for the thyroid)}$$
$$P_{25} = P_{24} \, H \, P_{45} = 4.2 \text{ nSv per Bq m}^{-2}$$
(effective dose for the thyroid).

Ankylosing Spondylitis

About 14,000 persons, mostly men, were treated with X-rays for ankylosing spondylitis at 87 radiotherapy centers in Great Britain and Northern Ireland between 1935 and 1954. Court Brown and Doll (1957) were the first to report that these patients had a leukemia risk substantially in excess of that for the general population. Subsequent publications have developed the time pattern of appearance not only of leukemia but also of solid tumors (Court *et al.*, 1959, 1965; Smith and Doll, 1978, 1982; Smith, 1984; Darby *et al.*, 1985, 1987; Weiss *et al.*, 1995).

A group was selected consisting of 11,776 men and 2335 women all of whom had been treated with X-rays either once or twice. About half the total group received a second X-ray treatment or treatment with thorium. The reports on the ankylosing spondylitis patients attempt to consider health effects from only the first X-ray treatment. For this reason, an individual receiving a second treatment is included in their follow-up only until 18 months after the second course (a short enough time so that any malignancies in this interval cannot be ascribed to the second X-ray treatment).

The appearance of excess leukemia is now well documented, and solid tumors are also apparent in the population. The part of the body in the direct X-ray beam (spine) received the highest dose, but it is thought that other sites received substantial radiation from scatter or from the beam itself.

The importance of this study lies in the health effects of partial body exposure and in the temporal pattern of appearance of solid tumors in irradiated adults. Smith and Doll (1978, 1982), Darby *et al.* (1985, 1987), and Weiss *et al.* (1994, 1995), in the most recent follow-up publications concerning these patients, have shown that the excess risk for solid tumors diminishes with time since exposure, with maximum appearance of 5–20 years after exposure. This has significant implications for risk projection modeling. Many projection models assume a constant rate of appearance either as an absolute number of tumors per person per unit exposure (constant absolute risk) or as a fraction of the baseline age-specific cancer mortality rate (constant relative risk). The emerging pattern is that constant risk models, either absolute or relative, are not correct for certain cancers, such as lung cancer. Thirty-five years after the first treatment, excess lung cancer had completely disappeared.

The most recent mortality study (Weiss *et al.*, 1994) included 15,577 ankylosing spondylitis (AS) patients diagnosed between 1935 and 1957 in the UK, of whom 14,556 received X-ray treatment. By January 1, 1992, over half of the cohort had died. Among the irradiated patients, cancer mortality was significantly greater than expected from the national rates for England and Wales, with a ratio of observed deaths to expected (relative risk, RR) of 1.30, and significant increases individually for leukemia, non-Hodgkin lymphoma, multiple myeloma, and cancers of the oesophagus, colon, pancreas, lung, bones, connective and soft tissue, prostate, bladder, and kidney. Among the unirradiated patients, cancer mortality was lower than expected from national rates (RR = 0.79). Among irradiated patients, the RRs for leukemia, lung cancer, and

Table 25-9

Excess Cancer in 6158 Ankylosing Spondylitis Patients Given a Single X-Ray Treatment as of the Last Follow-up

SITE	OBS	EXP	DOSE, Gy	LIFETIME RISK Gy^{-1}
Leukemia	53	17	4.8	0.0011
Lung*	563	469	2.5	0.0027
Esophagus	74	38	5.6	0.0007

*Lung cancer appearing less than 5 years after exposure is not included as less than the minimum latency for tumor expression. The doses to the pulmonary lung and main bronchi were estimated as 1.8 and 6.8 Gy, respectively. The majority of lung cancer is bronchogenic, and the dose estimates for the main bronchi are probably most pertinent Lifetime risk calculated as 30-year risk.

SOURCE: Data from UNSCEAR, 2000.

all other neoplasms all decreased significantly with increasing time since first treatment following an initial increase. By 35 years after first treatment, the radiation-related excess for lung cancer had completely disappeared, while for other neoplasms the RR remained significantly raised, although at a lower level than in earlier periods. Most irradiated patients received several courses of treatment within a 5-year period. Based on a 1 in 15 random sample, the mean total body dose received in this period was 2.64 Gy, with the heaviest dose to the vertebrae. A linear dose–response model for all neoplasms except leukemia gave an ERR of 0.18 Gy^{-1} in the period 5–24.9 years after first treatment, which decreased significantly to 0.11 Gy^{-1} in the period more than 25 years after the first treatment.

The dosimetry was redone in 1988 (Lewis *et al.*, 1988), and although better estimates of dose are now available, it is still the dose that is most uncertain for the cohort. No details about the X-ray machines used to deliver the exposures, such as output, kilovoltage, and half-value layer, are reported.

The excess cancers and the estimate of lifetime cancer risk at three sites in the ankylosing spondylitis cohort are shown in Table 25-9. For the purpose of calculating lifetime risks as of the time of follow-up, the number of persons used here as the individuals at risk is the number actually receiving only one X-ray treatment (6158). This assumes that those followed for 18 months after the second treatment do not contribute significantly to the malignancies.

The relatively low risk for leukemia (compared with atom bomb survivors) has been suggested to be due to cell sterilization at the high dose delivered. It is also possible that the low risk is due to partial irradiation of the skeletal red marrow. The volume of bone marrow irradiated in the spine, rib, and pelvis is much less than 50% of that in whole-body irradiation.

The deaths resulting from causes other than neoplasms in the total cohort are about 30% higher than expected. This higher total mortality is of significance in risk modeling as the premature deaths resulting from competing causes decrease the observed fractional cancer mortality. Thus, the lifetime risk in this population probably underestimates the risk when projecting the effects of exposure in a healthy population.

Uranium Miners

Radon is ubiquitous on earth. It is found outdoors and in all dwellings as a result of the decay of the parent ^{226}Ra, which is present in all of earth's minerals.

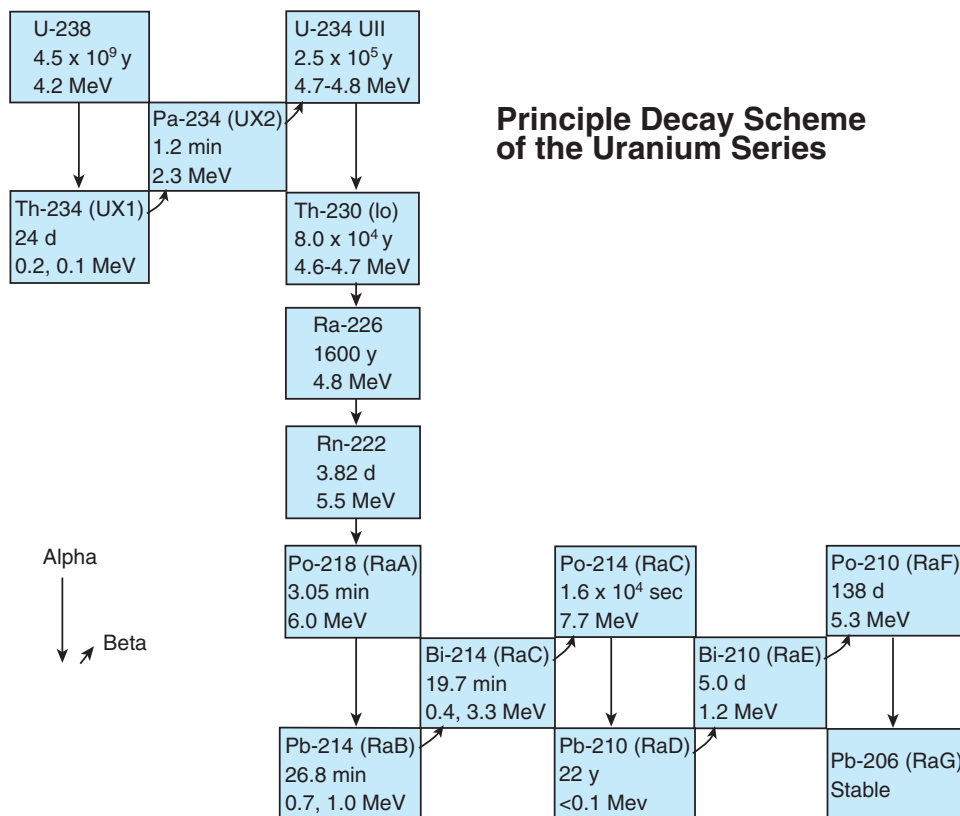
Principle Decay Scheme of the Uranium Series


Figure 25-8. Uranium-238 decay series. (From NCRP, 1987.)

Although the risk of developing lung cancer from radon exposure among underground miners is firmly documented and quantitative risk estimates are available, the current interest lies in whether this risk carries over into environmental situations. Radon levels in homes that are comparable to those in mines surely confer risks to the residents. The question remains: Can the risks in mines for exposures at higher concentrations over short time periods be used to model risks at lower environmental levels over a lifetime?

The results of the domestic epidemiology have answered this question.

Radon Exposure in Underground Mines   There are 11 follow-up studies of underground miners exposed to high concentrations of radon and radon decay products. The documentation of excess lung cancer is convincing (NCRP, 1984; NAS, 1988, 1998; NIH, 1994; UNSCEAR, 2000, 2007). The carcinogen in the case of radon is actually the alpha-emitting short-lived decay products of radon, ^{218}Po, and ^{214}Po. The decay scheme for the entire uranium series, including radon and the daughter species, is shown in Fig. 25-8. The decay products or daughter products are solids and are deposited on the bronchial airways during inhalation and exhalation according to the laws of diffusion. As the airway lining (bronchial epithelium) is only about 40 μm thick, the alpha particles emitted are able to reach and transfer a significant amount of energy to all the cells implicated in lung cancer induction. Although the daughters are the carcinogen, the term *radon* is here used interchangeably for *radon decay products*, because without the parent radon, the daughters could not exist longer than a few hours. The measurements in mines were usually

of the daughter species rather than radon, and the term *working level* (WL) was adopted for occupational exposure. It indicated the total potential energy content in 1 L of air for complete decay of the short-lived daughters.[1] The exposure attributed to miners was developed in working-level months (WLMs), which is the numerical value of WL times the time exposed in multiples of a working month of 170 hours (Holaday *et al.*, 1957).

$$\text{WLM} = \text{WL(hours expose/170)}.$$

Estimating Lung Cancer Risk from Underground Miner Epidemiology   The follow-up studies from 11 large underground mining cohorts in Australia, Canada, Czech Republic, France, Sweden, and the United States have all produced data that show that the excess lung cancer risk from exposure to radon is about 1–3 per 10,000 persons per WLM exposure (Radford and Renard, 1984; Hornung and Meinhardt, 1987; Sevc *et al.*, 1988; Muller *et al.*, 1989; Howe *et al.*, 1986, 1987; Tirmarche *et al.*, 1993; Woodward *et al.*, 1991; NCRP, 1984; NIH, 1994; NAS, 1998; UNSCEAR, 2000, 2007). Expressed another way, radon exposure increases the normal age-specific lung cancer risk by about 0.6% for each WLM exposure. This way of expressing risk leads to the concept that many epidemiologists prefer that the lung cancer risk is proportional to the normal baseline risk. The notation for this is excess relative risk (ERR). This means, e.g.,

---

[1] One working level (WL) is any combination of short-lived daughters in 1 L of air that will result in 1.3 $\times$ 10^5 MeV of alpha energy when complete decay occurs. One working level is approximately equal to 7400 Bq m^{-3} (200 pCi L^{-1}) in a home and 11,000 Bq m^{-3} (300 pCi L^{-1}) in a mine.

10. The direct modeling of the relative risk of lung cancer with duration and rate of exposure.

that the lifetime excess lung cancer risk from radon is different for smokers and nonsmokers (NAS, 1988, 1998; NIH, 1994).

The actual data from the underground studies are not clear-cut with regard to the effect of smoking, and it is apparent from more recent analyses that radon exposure does not simply multiply the baseline risks of the population by a constant factor. This is considered in the discussion of risk, earlier in this chapter. The excess lung cancer risk in each of the exposure cohorts for the 11 major mining populations as of the date of the last published follow-up is summarized in Fig. 25-9. It can be seen in the figure that the range of risks for the same exposure varies by about a factor of 10 among the different studies. The differences are likely accounted for by errors in measuring and estimating total exposure. However, the Czech mine atmosphere contained arsenic as well as radon, and the arsenic contributed to the excess lung cancers observed. A maximum value of 50% lung cancer risk is the highest value ever observed in a mining population and was reported in mines in Saxony at the turn of the century (Muller, 1989). These mines are thought to have had about 100,000 Bq m^{-3} of radon. It is noteworthy that concentrations this high have been reported in a few homes in the United States. In Fig. 25-9, the lowest (well-documented) exposures were in the Ontario (Canadian Eldorado) mines, and in an updated study a mean exposure of 48 WLM has given an excess lung cancer risk (ERR) of about 0.5%.

To date, the most comprehensive epidemiologic analysis of underground miners exposed to high concentrations of ^{222}Rn is a joint analysis of 11 underground mining studies conducted by the National Cancer Institute (NIH, 1994), and updated by NAS (1999). The study encompasses the Chinese, Czechoslovakian, Colorado, Ontario, Newfoundland, Swedish, New Mexico, Beaverlodge, Port Radium, Radium Hill, and French mining data. The joint analysis of the 11 cohorts (NIH, 1994; NAS, 1998) focused on 10 variables:

The relative risk of lung cancer for the Colorado uranium miners is shown in Fig. 25-10 and that for all 11 cohorts—showing only the data for exposures below 400 WLM—is shown in Fig. 25-11.

The pooled cohorts included 2620 lung cancer deaths among 60,570 exposed miners, accumulating 1.2 million person-years of observation. The ERR of lung cancer is seen in Fig. 25-11 to be linearly related to the cumulative radon decay product exposure in units of WLM. The exception is at the highest exposures, where a clear reduction in ERR is evident. This is often noted as an *inverse dose rate effect*. Confusion exists concerning the inverse dose rate effect in that the relative risk is not *higher at lower dose rates* but is *lower at higher dose rates*, in agreement with cell killing and removal of damaged cells from the pool of cells that are potential sites of malignant transformation. This effect is seen in all studies of radiation damage at high doses.

Data on tobacco use were available in six of the cohorts. The lifetime domestic risk projection models based on the data estimated that the ERR/WLM was related to attained age and time since exposure. The joint effect of smoking and ^{222}Rn exposure did not show a clear pattern except that the risk was consistent with a relationship that was intermediate between additive and multiplicative.

Domestic studies now support the projected risk estimates for radon exposure in mines but the results of the domestic studies
Figure 25-11. Relative risk (RR) of lung cancer by cumulative working-level month (WLM) and fitted linear excess RR model for each cohort and for all data combined (WLM <400).

RRs are plotted at mean WLM for category. When the referent category for RRs is not zero exposure, a fitted exposure-response line is adjusted to pass through the mean of the referent category. For the China, Ontario, and Beaverlodge cohorts, the excess RR model was fitted with a free intercept. (From NIH, 1994.)

should be used directly to estimate lung cancer risk. The risk projection models developed from the miner data were conservative and overestimate the domestic risk. The occupational exposure in mines is relatively short compared with that over a full life in homes and the cumulative exposure in mines is generally many times that in homes so it is possible to develop temporal risk models. The radon exposure in homes is much lower and although a value for ERR is

established it is not possible to develop models from the domestic data as yet.

Lung (Bronchial) Dose from Radon Exposure When radon gas decays to its solid decay products, some 8–15% of the ^{218}Po atoms do not attach to the normal aerosol particles. This ultrafine species (unattached fraction) is deposited with 100% efficiency on the upper bronchial airways. In mines the unattached fraction is low (4–5%) because of the normal aerosol loading. The rest of the decay products attach to the ambient aerosol of about 100-nm average diameter (George and Breslin, 1980) and only a few percent of this aerosol is deposited on these airways. Measurements in mines have mostly involved the short-lived radon daughters, as they are the easiest to measure rapidly. The alpha dose from radon gas itself is very low in comparison with that from the daughters, as the daughters deposit and accumulate on the airway surfaces. The upper airways of the bronchial tree are the region where almost all the lung cancers appear. This is true in general, not only for miners exposed to radon daughters but also for smokers.

The alpha dose from radon daughters therefore must be calculated in these airways, not in the pulmonary or gas-exchange regions. Although the dose to the pulmonary region should not be neglected, it is about 15% of that to the airways (Saccomanno *et al.*, 1996). Several calculations regarding the absorbed alpha dose exist for radon daughters (NCRP, 1984; ICRP, 1987; Harley, 1987, 1989; NRC, 1991; UNSCEAR, 2000, 2007). The authors make different assumptions about the atmospheric and biological parameters that go into the dose calculation, and this can cause discrepancies among the models. The most significant variables are the particle size of the ambient aerosol, the assumed breathing rate, and the target cells considered.

Very small particles deposit more efficiently in the airways. Therefore if small particles, such as those from open burning flame
Figure 25-12. Radon decay product bronchial dose as a function of inhaled median aerosol diameter, breathing rate, for an unattached fraction (Fpot) of 0.05.

(From UNSCEAR: Sources to effects assessment for radon in homes and workplaces. Report of the United Nations Scientific Committee on the Effects of Atomic Radiation. New York: United Nations, 2007.)

(Tu and Knutson, 1988; Cohen and Ashgharian, 1990), contribute to the atmosphere, the dose delivered to the bronchial epithelium can be higher per unit WLM exposure than is the dose predicted from an average particle size. Conversely, a hygroscopic particle can increase in size in the humid environment of the bronchial airways, and deposition will be diminished. The particle size of the aerosol in mines is somewhat larger than that for environmental conditions (200 to perhaps 600 nm vs. 100 nm) (George *et al.*, 1975). Figure 25-12 shows the alpha dose per unit exposure as it is related to the variables (particle size, unattached fraction, breathing rate) known to affect dose. The radon concentration in Fig. 25-12 is not the gas concentration. Because it is the decay products that deliver the dose, not the gas, the concentration is expressed in units of the equilibrium equivalent concentration (EEC). Indoors, the radon gas concentration multiplied by the equilibrium factor (Feq = 0.4) gives the EEC, i.e., the gas concentration in equilibrium with its decay products that has the same potential energy as the measured decay products. Outdoors the equilibrium factor (Feq) is 0.6 (UNSCEAR, 2000, 2006).

Example 5. Calculate the annual bronchial lung dose in nSv for a home radon concentration of 40 Bq m^{-3}. Assume 7000 hours is spent at home.
The radon EEC indoors = 0.4(40) = 16 Bq m^{-3}
The dose factor from Fig. 25-12 for a typical home environment is 15 nSv per Bq m^{-3} h (EEC).

Annual dose = 40(0.4)(15)(7000) = 1.7×10^6 nSv = 1.7 mSv

Lung cancer is related to absorbed alpha dose, and Fig. 25-12 shows that particle size is an important determinant of risk. The average dose per unit exposure for miners, shown in Fig. 25-12, is about the same as that for average environmental conditions, assuming 100 nm aerosol in homes and 200–600 nm aerosol in mines. The equilibrium factor in mines is somewhat smaller than for homes (Feq about 0.3).

Radon can deliver a greater or lesser carcinogenic potential by about a factor of 2 over the range of realistic indoor conditions (average particle size ranging from 80 to 300 nm). The allowable effective dose for continuous exposure of the population in the United States is 1 mSv/y (100 mrem/y) (NCRP, 1993). This limit would be delivered by exposure to 10 Bq m^{-3} of radon, or one-quarter the actual average measured indoor concentration in most countries where measurements have been made. Thus, the guidelines for exposure to radon cannot be set in the usual way from dosimetric considerations.

LIFETIME DOMESTIC LUNG CANCER RISK PROJECTIONS FOR RADON EXPOSURE

There are at present five sets of models based on the underground miner epidemiology that attempted to calculate risk for exposure to radon daughters in the home. The following sections describe each in detail.

National Council on Radiation Protection and Measurements

In 1984, the NCRP on Protection and Measurements (NCRP, 1984) developed a model to project the risk derived from miner studies to whole-life risk in the environment. It is a modified absolute risk

model that reduces the risk subsequent to exposure with a half-life of 20 years. Risk is not accumulated until after age 40, the time when lung cancer normally appears in the population. There is no indication that early exposure produces any significant shift to younger ages, even for young miners exposed at significantly higher concentrations. This model was the first to incorporate a time since exposure reduction in risk.

National Academy of Sciences

The National Academy of Sciences report in 1988 (BEIR IV) developed a model based on examination of the raw data from five mining cohorts (NAS, 1988). The data indicated that the highest risk appears from 5 to 15 years after exposure. After 15 years, the risk is one-half that of the 5- to 15-year risk (per unit exposure), and this risk was assumed to persist to the end of life. Again, no significant risk appears before 40, the usual age for the appearance of lung cancer. The NAS model also included a correction for attained age (at age 65, the risk is 0.4 of that for ages 55–64). The BEIR IV committee assumed a relative risk model (risk is proportional to the normal age-specific lung cancer risk per unit radon exposure), but with risk dependent on time from exposure. This was the first modified relative risk model. This means that the risk for smokers and nonsmokers differs because of their different baseline lung cancer values. Although the miners' epidemiology did not support this strictly multiplicative relationship, the NAS chose the relative risk model as a conservative one. Its analysis supported the risk reduction subsequent to exposure by using a two-step risk reduction window.

NAS 1998 (BEIR VI) expanded on the models developed in NAS (1989) using 11 underground mining cohorts rather than four. The models for the 11 cohorts were developed first by NIH (1994), see below, and updated for the NAS report.

International Commission on Radiation Protection

The ICRP (1987) developed two risk projection models: one was based on a constant relative risk and the other was a constant absolute risk model. Although neither risk model is correct because of the temporal reduction pattern of lung cancer subsequent to the cessation of exposure, the numerical values obtained for the lifetime risk of lung cancer from radon exposure are not significantly different from those in other models. Later follow-up of the Czechoslovakian underground uranium miners presented by Kunz and Sevc (1988) indicates that the excess lung cancer risk may actually be reduced to zero 35 years after exposure. If this factor was included in the NAS model (zero risk after 35 years), it would reduce those values by about a factor of 2. The risk values obtained from the various models are shown in Table 25-10. In 1993, ICRP simply adopted a lifetime lung cancer fatality coefficient of 3×10^{-4} per WLM (ICRP, 1993).

NIH Joint Analysis of 11 Underground Mining Cohorts

The pooled analysis from the 11 underground mining cohorts was used to develop two models for full-life risk projection (NIH, 1994). The models are similar to the model used by the NAS (1988), utilizing time since exposure reduction and reduction with attained age. Three time windows for reduction of risk with time since exposure

Table 25-10

Lung Cancer Risk for Continuous Whole-life Exposure to 4 pCi/L (150 Bq m^{-3} or 0.58 WLM per year at Indoor Conditions) as Predicted by Various Models of Domestic Exposure*

MODEL	LIFETIME RISK %	MODEL TYPE	COMMENT
NCRP (1984a)	0.50	Modified absolute risk. Two parameter model.	Risk decreases with time since exposure.
ICRP (1987)	0.90	Constant relative risk.	
ICRP (1987)	0.62	Constant additive risk.	
ICRP (1993)	0.56	Single-value risk per WLM.	Adopted lifetime risk per WLM exposure.
BEIR IV (NRC 1988)	1.1	Modified relative risk. Two-time windows. Two-parameter model.	Risk decreases with time since exposure.
NIH (1994)	1.8	Modified relative risk, three-time windows, age and exposure rate. Three parameter model.	Risk decreases with time since exposure and decreases with very high exposures.
BEIR VI (NRC 1998)	2.0	Modified relative risk. Three time windows, age and exposure rate. Three parameter model.	Risk decreases with time since exposure and decreases with very high exposures.
Meta-analysis of eight domestic case-control studies (Lubin and Boice, 1997)	0.7	Observed mortality.	Linear regression fit to data from eight domestic studies.

*Exposure assumes a home concentration of 148 Bq m^{-3} (4 pCi l^{-1} or 0.56 WLM), calculated with 40 percent decay product equilibrium, and actual exposure is 70 percent of the home exposure.

SOURCE: Data from NAS, 1999.

are used instead of two. Also, an additional parameter is incorporated; one model decreases the risk with increasing exposure rate, and the other decreases the risk with decreasing exposure duration. The lifetime domestic risk for lifetime exposure to unit concentration was not reported. However, the ratio of the relative risk of lung cancer for the BEIR IV and joint analysis model was given as 0.9 for continuous exposure to 4 pCi L^{-1} (1 WLM per year) for the model incorporating exposure duration as a parameter. The joint analysis estimated that there are 15,000 lung cancer deaths in the United States attributable to ^{222}Rn: 10,000 in smokers and 5000 in those who have never smoked.

BEIR VI (NAS, 1998) updated these two models and increased the calculated risk in the United States to 15,400 or 21,800 per year for ever smokers and never smokers for the two model values. The BEIR VI best annual estimate of deaths for ever smokers is stated to be 11,000 per year with 2100 or 2900 calculated deaths for never smokers, depending upon the model chosen. The results of the domestic epidemiology now indicate that the BEIR VI projected estimates of annual deaths is too large perhaps by a factor of 2.

DOMESTIC EPIDEMIOLOGY

The Domestic Studies

There is a very large body of published information on residential exposure to radon and lung cancer. A summary is given here and in the references (Neuberger, 1989, 1992; Samet *et al.*, 1991; Lubin and Boice, 1997; NAS, 1999; Pavia *et al.*, 2003; Darby *et al.*, 2005b; Krewski *et al.*, 2005; UNSCEAR, 2000, 2007).

There are at present 89 published epidemiologic studies relating radon and lung cancer. Of these, the best are 22 case control or cohort studies. One early study in the United States was performed in 1989 by the New Jersey Department of Health (NJDOH)

(Schoenberg and Klotz, 1989; Schoenberg *et al.*, 1990). This is a case-control study of women, 433 lung cancer cases and 402 controls with year long measurements of radon in the homes where the individuals lived for 10 or more years. This study devoted considerable effort to quality control concerning the exposure measurements. The results of this study are slightly positive, suggesting an association of radon and lung cancer even at concentrations of 80 Bq m^{-3}, but the results are not statistically significant. A case-control study of 538 nonsmoking women (1183 controls) in Missouri with an average exposure of 70 Bq m^{23} also showed no statistically significant increase in lung cancer (Alavanja *et al.*, 1994).

One of the largest case-control study to date concerning the effects of residential ^{222}Rn exposure was conducted nationwide in 109 municipalities in Sweden (Pershagen *et al.*, 1993). Radon was measured in 8992 homes for 3 months during the heating season. The geometric and arithmetic concentrations were 60 and 106 Bq m^{-3}. The cumulative exposure for each person from 1947 was estimated. It included all subjects 35- to 74-years old who had lived in one of the 109 municipalities at some time between January 1980 and December 31, 1984, and who had been living in Sweden on January 1, 1947. Fifty-six of the municipalities were known to have elevated ^{222}Rn concentrations on the basis of earlier measurements. There were 1360 cases and 2847 controls.

Thus, an attempt was made to study a large group of persons living in a known area of greater than average ^{222}Rn and to estimate their exposure over a large fraction of life (34 years). The primary aim of the study was to narrow the uncertainty in the estimation of lung cancer risk.

The environmental epidemiologic studies conducted before this study suffered from the small numbers of persons observed and relatively low ^{222}Rn exposures. For this reason, although the risk in underground miners was seen clearly, the outcome regarding the lung cancer risk from residential exposure had been ambiguous.
Figure 25-13. Summary data for 21 domestic case control studies. Data from Pavia et al. (2003) and Krewski et al. (2005).

All the existing domestic studies, including the measurement protocols, have been reviewed (Neuberger, 1992, 1994; Samet, 1989; Samet *et al.*, 1991; Lubin *et al.*, 1990).

The ^{222}Rn concentration in 8992 homes was measured for 3 months during the heating season. The geometric and arithmetic mean concentrations were 1.6 and 2.9 pCi L^{21} (60 and 106 Bq m^{-3}). The cumulative exposure since 1947 was estimated for each subject by the addition of the products of concentration by the length of time the subject lived in each residence.

The data were reported in terms of the relative risk (RR) of lung cancer (ratio of observed to expected lung cancer) normalized to a relative risk of 1.0 for persons who never smoked and who had radon exposure below 50 Bq m^{-3}. The excess risk due to smoking could be seen easily. Smokers smoking less than or more than 10 cigarettes per day with a radon concentration of << 50 Bq m^{-3} had RR of 6.2 (with a confidence interval from 4.2 to 9.2) and 12.6 (CI from 8.7 to 18.4), respectively.

The only statistically significant lung cancer excess resulting from ^{222}Rn was seen in those who smoked fewer than 10 cigarettes per day and had a time-weighted mean ^{222}Rn concentration >400 Bq m^{-3}. Their relative risk was 25.1 (CI 7.7 to 82.4). For those smoking more than 10 cigarettes per day, the relative risk compared with those who had never smoked and had ^{222}Rn concentrations <50 Bq m^{-3} was 32.5 (CI 10.3 to 23.7). Although this relative risk appears higher than that for those smoking <10 cigarettes per day, the result is not statistically significant. If the effect of ^{222}Rn alone is examined by comparing the risk only among smokers, i.e., those with <50 Bq m^{-3} against smokers having >400 Bq m^{-3}, the relative risk due to ^{222}Rn alone is 3.7 (CI 1.1 to 11.7) for those

smoking <10 cigarettes per day and 2.5 (CI 0.8 to 7.9) for those smoking >10 cigarettes per day (Pershagen *et al.*, 1994). Because the confidence interval includes 1.0, it cannot be stated with statistical certainty that there was increased lung cancer caused by ^{222}Rn exposure although the point estimate RR = 2.5 suggests at least an upper bound of risk.

A later study was done for a combined group of men and women (Pershagen *et al.*, 1994). There were no details given concerning lung cancer and sex difference. However, the preliminary report (Pershagen *et al.*, 1994) suggested that women may indeed have had less lung cancer than men for the same exposure conditions. Also of interest in the study of Pershagen *et al.* (1994) was the relative risk of lung cancer by histological type. In the >400 Bq m^{-3} group, only small cell carcinoma and adenocarcinoma had a statistically significant increased risk.

One of the most recent studies conducted in the United States was in Iowa and studied women only (Field *et al.*, 2000). There were 413 lung cancer cases and 614 controls. The ERR found was 0.22 (95% CI = −0.20 to 1.93).

The number of domestic case control studies is now sufficient to establish the lung cancer risk from radon exposure. The results of the studies (odds ratio or relative risk) are shown in Fig. 25-13. The domestic studies indicate that the lung cancer risk from ^{222}Rn exposure is evident at exposures of 100 Bq m^{-3}. It is interesting that the precision of the domestic studies is now better (smaller confidence intervals) than the miner studies. This is probably due to more accurate estimates of the lifetime exposure. The present studies indicate a relative risk of about 1.2 but the confidence intervals mostly include no risk.

Table 25-11

Lifetime Relative Risk (LRR) Calculated from Published Meta Analyses or Pooled Analyses of Domestic Case Control Radon and Lung Cancer Studies

STUDY	NUMBER OF STUDIES INCLUDED	LRR	95% CONFIDENCE INTERVAL
Lubin, Boice, 1997 (Meta)	8	1.14 (per 150 Bq m^{-3})	1.00–1.30
Pavia *et al.*, 2003 (Meta)	17	1.24 (per 150 Bq m^{-3})	1.11–1.38
Lubin *et al.*, 2004	2 China	1.33 (per 100 Bq m^{-3})	1.01–1.36
Darby *et al.*, 2005b	13 European	1.16 (per 100 Bq m^{-3})	1.05–1.31
Krewski *et al.*, 2005	7 North America	1.11 (per 100 Bq m^{-3})	1.00–1.28
Wichmann *et al.*, 2005	2 Germany	1.10 (per 100 Bq m^{-3})	0.98–1.30

Unless a biological marker for radon-induced lung cancer is found, it is unlikely that further domestic epidemiology will refine the existing risk estimates.

Meta-analysis and Joint Analysis of Domestic Epidemiology

In an attempt to combine the largest domestic studies to determine whether any risk from radon exposure in the home is apparent, several meta analyses and joint analyses have been performed. Lubin and Boice (1997) were the first to perform a meta-analysis of eight domestic case control studies. A meta-analysis combines the published information from several studies into one study without actually having the raw data available. The data showed that essentially no study found statistically significant cancer deaths due to radon, but the authors state that the combined trend in the relative risk with increasing exposure was statistically significant, with an estimated RR of 1.14 (95% CI = 1.0–1.3) at an exposure of 150 Bq m^{-3} (4 pCi L^{-1}).

There are now six studies, two meta analyses, and four pooled or joint analyses to estimate the lifetime relative risk (RR) for domestic exposure to radon. The results are shown in Table 25-11.

The best estimate of relative risk (RR) at this time is probably the study of Darby *et al.* (2004), RR = 1.16 (95% CI 1.05–1.31) as this has the largest number of studies included. The lower confidence interval does not include any risk. This value can be used to evaluate a realistic domestic lung cancer risk from radon exposure.

Example 6. The baseline lung cancer risk in the U.S. population including smokers, nonsmokers, men, and women is about 0.05 (5%). Calculate the lifetime lung cancer risk for a continuous home concentration of 40 Bq m^{-3}.

The RR is estimated as 1.16 per 100 Bq m^{-3}. The lifetime risk is therefore increased by 0.16 above the baseline risk for 100 Bq m^{-3}.

Lifetime risk = 0.16 (0.05)(40)/(100) = 0.003 or 0.3% or 3 per 1000 persons.

What is Known about Radon Exposure

Four concepts have emerged from the radon research so far:

1. The mining epidemiology indicates that short exposure to high levels of radon and its daughters produces a clear excess of lung cancer.
2. Particle size can change the actual dose delivered by radon to bronchial tissue, with small particles giving a substantially higher dose per unit exposure. The use of open flames, electric motors, and the like indoors produces a higher dose per unit exposure.
3. Smokers are at higher risk from radon per unit exposure than nonsmokers. The domestic studies show that the relative risk for smokers and nonsmokers is about the same but their age-specific lung cancer mortality is about ten times higher than that for nonsmokers. Thus, the overall lifetime lung cancer risk is many times higher for smokers.
4. Urban areas almost universally have low radon, and apartment dwellers removed from the ground source have particularly low radon exposure at home.

The miners' data show clearly that there is a risk of lung cancer from exposure to high concentrations of radon delivered over short periods and temporal models can be derived from the data.

The results of the domestic studies are now convincing with regard to domestic radon risk. The best pooled risk estimate to date is probably that of Darby *et al.* (2004), who did a joint analysis of 13 European case control studies using the original data.

NATURAL RADIOACTIVITY AND RADIATION BACKGROUND

The occupational, accidental, and wartime experiences detailed in the preceding sections have provided the bases for all the current radiation risk estimates. For many years, the radioisotopes deposited internally were compared with ^{226}Ra to evaluate the maximum permissible body burden for a particular emitter. The present limits for external and internal radiation are based on dose estimates that, in turn, can be related to cancer risks. One standard of comparison has always been the exposure from natural background, and this source is assessed here.

Background radiation from all sources is described in detail in NCRP report 94 (1987b), and some of the information is summarized here.

The risk estimates in the previous sections must be placed in context with the radiation dose received by all humans from natural background radiation. A substantial dose is received annually from cosmic radiation and from external terrestrial radiation present from uranium, thorium, and potassium in the earth's crust. Internal emitters are present in the body as a consequence of dietary consumption and inhalation. For example, potassium is a necessary element in the body and is under homeostatic control. Radioactive ^{40}K constitutes a constant fraction of all natural potassium. Potassium delivers the largest internal dose from the diet of 0.15 mSv per year. However, the data are scanty on the dietary intake of other radionuclides in the U.S. population. Given the usual distribution of intakes across a

SOURCE: Data from NCRP, 1987.

large population, it is probable that other emitters, notably ^{210}Pb and its decay product ^{210}Po, could deliver a significant dose to a fraction of the population. For example, ^{210}Pb is found in all tobacco products and delivers a significant lung dose.

The largest dose received by the population is from the inhaled short-lived daughters of radon. These are present in all atmospheres because radon is released rather efficiently from the ^{226}Ra in rock and soil. The short-lived daughters, ^{218}Po, ^{214}Pb, ^{214}Bi-^{214}Po, have an effective half-life of 30 minutes, but the 3.8-day parent radon supports their presence in the atmosphere. Figure 25-8 shows the entire uranium series decay.

Average outdoor concentrations in every state in the United States have been measured and summarized as 15 Bq m^{-3}, and indoors, as 40 Bq m^{-3} (NAS, 1999). A structure such as a house prevents the rapid upward distribution of radon into the atmosphere, and substantial levels can be built up indoors. The source of radon is the ground; therefore, levels in living areas above the ground are generally one-third to one-fifth the concentrations measured in basements. An effective barrier across the soil–building interface also inhibits the entry of radon to buildings. Ventilation with outdoor air reduces indoor radon. For this reason, industrial buildings with more substantial foundations and higher ventilation rates tend to have lower radon concentrations than do single-family (or detached) houses. Apartments above ground level have radon concentrations about half the average of those in single-family dwellings.

It is of significance that an average radon concentration indoors of 40 Bq m^{-3} results in an equivalent dose to bronchial epithelium of 24 mSv per year or an effective dose of 2 mSv per year.

The equivalent doses for the major natural internal emitters are shown in Table 25-12. These are reproduced from NCRP (1987a,b).

The annual effective dose equivalents for all the external and internal emitters from natural background are summarized in NCRP Report 94 (1987a,b) and are shown in Table 25-13.

The lifetime dose from natural emitters is shown in Table 25-14, assuming an average exposure from birth to a full life of 85 years. It should be recognized that the actual dose accumulated by an individual depends on dietary habits, location (Denver, e.g., at an altitude of 1.6 km, has double the average cosmic-ray exposure), and the dwelling. An apartment dweller would accumulate approximately half the dose from inhaled radon daughters as would a person living in a single-family dwelling. Table 25-14 is informative in considering the effects of radiation exposure from other than

natural sources. For example, in assessing an occupational dose, which might add, say, 10 mSv effective dose equivalent, natural background would be a strong confounder. Any health detriment would have to be calculated rather than observed directly. No study would be able to detect an increase in health effects from 10 mSv above the average whole-life natural background of 260 mSv.

Figure 25-14 shows the average components of natural background in the United States, and Harley (2000) gives a detailed summary of background radiation and internal radioactivity.

LOCAL ENVIRONMENTAL RELEASES

Large- and small-scale accidents will undoubtedly occur that release radioactivity into the environment. The accident at the Windscale nuclear power reactor in 1957 was a local incident in Great Britain. The nearby population has been studied for over 30 years without the appearance of significant health effects.

The nuclear power accident at Three Mile Island caused enormous financial damage, but the containment vessel was not breached and virtually no radioactivity escaped.

The accident at the Chernobyl nuclear power plant was another such occasion, and in this case containment did not exist and some of the radioactivity was widespread over Europe. The United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR, 1988, 1993, 2000; IAEA, 2005) has summarized the committed dose from measurements made in the affected countries from various releases, and these are shown in Table 25-15. Table 25-15 includes environmental releases from most known sources.

Highly radioactive emissions from industrial or medical sources that are "lost," such as the ^{137}Cs and ^{60}Co in Goiania and Thailand, harm the persons involved, often with a few deaths due to very high radiation exposure and dose. The financial cost is usually large for cleanup and monitoring.

The criticality accident on September 30, 1999, at a fuel reprocessing facility in Tokai-Mura, Japan, resulted in the death of two workers and caused neighbors to receive a small local dose of about 2 mSv (Komura *et al.*, 2000).

Local exposures and doses from accidents can only be anticipated to increase, as the use of radioactive materials industrially, for research and for medical diagnosis is widespread.

SUMMARY OF HUMAN CANCER RISKS FROM RADIATION

The details of the five major studies have been given in the preceding sections. The data are summarized in Table 25-16. This table shows the lifetime cancer risks that are significant. The risks are given in units of per gray (or per sievert where appropriate for alpha emitters).

Within the table, leukemia and cancers of the lung and female breast are the most critical. Osteogenic sarcoma is seen in the radium exposures. There is no clear linear dose response for ^{224,226}Ra. This has been attributed to the existence of an apparent threshold. The cancer risk to individual organs from different study groups is in general agreement regardless of radiation type or whole- or partial-body exposure.

PROPERTIES AND TOXICITIES OF ANIMAL VENOMS

John B. Watkins, III

INTRODUCTION

The animal kingdom consists of more than 100,000 species spread through major phyla including arthropods, mollusks, chordates, etc. (Mebs, 2002). Venomous animals are capable of producing a poison in a highly developed exocrine gland or group of cells and can deliver their toxin during a biting or stinging act. The venom is the sum of all natural venomous substances produced in the animal (Ménez *et al.*, 2006). Poisonous animals have no mechanism or structure for the delivery of their poisons, and poisoning usually takes place through ingestion. Venomous or poisonous animals are widely distributed throughout the animal kingdom, from the unicellular protistan *Alexandrium (Gonyaulax)* to certain mammals, including the platypus and the short-tailed shrew. At least 400 species of snakes are considered dangerous to humans. Myriad venomous and poisonous arthropods exist, and toxic marine animals are found in almost every sea and ocean (Russell and Nagabhushanam, 1996; Mebs, 2002).

Animal venom may play a role in offense, as in the capture and digestion of food, in the animal's defense, as in protection against predators or aggressors, or in both functions. In the snake, the venom provides a food-getting mechanism. Its secondary function is its defensive status. The presence of toxic venom in the snake is a superior complement to the animal's speed, size, concealment, or strength. In venomous spiders, toxin is used to paralyze the prey before the extraction of hemolymph and body fluids. The venom is not primarily designed to kill the prey, but it is only to immobilize the organism for feeding. The same can be said for the scorpions, although they

do use their venom in defense. In the fishes, such as the scorpion fishes and stone fishes, and in elasmobranches, such as the stingray, the venom apparatus is generally used in the animal's defense. Venoms used in an offensive posture are generally associated with the oral pole, as in the snakes and spiders, while those used in a defensive function are usually associated with the aboral pole or with spines, as in the stingrays and scorpion fishes. Poisonous animals, on the other hand, usually derive their toxins through the food chain. As such, poison is often a metabolite produced by microorganisms, plants, or animals. Poisons are sometimes concentrated as they pass through the food chain from one animal to another.

PROPERTIES OF ANIMAL TOXINS

Venoms are very complex, containing polypeptides, high- and low-molecular-weight proteins, amines, lipids, steroids, aminopolysaccharides, quinones, glucosides, and free amino acids, as well as serotonin, histamine, and other substances. Some venoms may consist of more than a hundred proteins. The venom is a source of millions of peptides and proteins that act on myriad exogenous targets such as ion channels, receptors, and enzymes within cells and on the cell membrane (Ménez *et al.*, 2006). The venom is important for several reasons. First, the venom is a source of tools with which to study complex physiologic systems, such as the cardiovascular system, nervous system, coagulation, and homeostasis. Second, the venom is a source of potential new drugs, with at least five agents already on the market and dozens undergoing preclinical or clinical

Table 26-1
Intravenous LD_{50}s of Selected Toxins Determined in Mice

TOXIN SOURCE	COMMON NAME	LD_{50} (μg/kg)
Clostridium botulinum	Botulinum toxin	0.0003
Crotalus viridis helleri	Southern pacific rattlesnake	1.3
Crotalus adamanteus	Eastern diamondback	1.5
Oxyuranus scutellatus	Australian taipan	2
Crotalus atrox	Western diamondback	2.2
Agkistrodon piscivorus	Eastern cottonmouth	4
Agkistrodon contortrix	Copperhead	11
Androctonus australis	North African scorpion	17
Notechis scutatus	Australian tiger snake	25
Naja siamensis	Indochinese spitting cobra	75

trials (Menez *et al.*, 2005). Third, additional knowledge on the composition and the function of venoms is hoped to favor development of improved protection against envenomations (Ménez *et al.*, 2006).

Novel instrument developments have permitted the greater application of mass spectrometry, coupled with various separation technologies, to tease out the complexity of natural venoms, thereby identifying the peptide and protein components of venom (Escoubas, 2006). The technology allows considerable resolution of extremely small amounts of venom. Figure 26-1 demonstrates the application of gel filtration and high-pressure liquid chromatography (HPLC), as cone snail venom was fractionated into numerous peptides with varying activities (Olivera *et al.*, 1990). Similar fractionations have been performed on many other venoms. Unfortunately, studying the chemistry, pharmacology, and toxicology of venoms requires isolating and dismantling the venoms and losing the synergy among multiple components. Nevertheless, advanced technology will permit peptide sequencing, and the characterization of post-translational modifications, such as glycosylation, and the discovery of new pharmacophores. Most venoms probably exert their effects on almost every cell and tissue, and their principal pharmacologic properties are usually determined by the amount of a fraction that accumulates at an activity site. It is clear from Table 26-1 that there is an extremely large range in the LD_{50} of different toxic compounds and venoms injected intravenously into mice.

The bioavailability of a venom is determined by its composition, molecular size, amount or concentration gradient, solubility, degree of ionization, and the rate of blood flow into that tissue, as well as the properties of the engulfing surface itself. The venom can be absorbed by active or passive transport, facilitated diffusion, or pinocytosis, among other physiologic mechanisms. Besides the bloodstream, the lymph circulation not only carries surplus interstitial fluid produced by the venom, but also transports larger molecular components and other particulates back to the bloodstream. Thus, the larger toxins of snake venoms, particularly those of Viperidae, probably enter the lymphatic network preferentially and then are transported to the central venous system in the neck (Russell, 2001). Because lymphatic capillaries, unlike blood capillaries, lack a basement membrane and have fibroelastic "anchoring filaments," they can readily adjust their shape and size, facilitating

absorption of excess interstitial fluid along with macromolecules of a venom.

The site of action and metabolism of venom is dependent on its diffusion and partitioning along the gradient between the plasma and the tissues where the components are deposited. Once the toxin reaches a particular site, its entry to that site is dependent on the rate of blood flow into that tissue, the mass of the structure, and the partition characteristics of the toxin between the blood and the particular tissue. Receptor sites appear to have highly variable degrees of sensitivity. In the case of complex venoms, there may be several if not many receptor sites. There is also considerable variability in the sensitivity of those sites for the different components of a venom.

A venom may also be metabolized in several or many different tissues before undergoing excretion. Some components of a venom are metabolized distant to the receptor site(s) and may never reach the primary receptor in a quantity sufficient to affect that site. The amount of a toxin that tissues can metabolize without endangering the organisms may also vary. Organs or tissues may contain enzymes that catalyze a host of reactions, including deleterious ones. Once a venom component is metabolically altered, the end substance is excreted primarily through the kidneys. The intestines play a minor role, and the contributions by the lungs and biliary system have not been determined. Excretion may be complicated by the direct action of the venom on the kidneys themselves.

ARTHROPODS

There are more than a million species of arthropods, generally divided into 25 orders, of which at least 12 are of importance to humans from an economic standpoint. Medically, however, only about 10 orders are of significant venomous or poisonous importance. These include the arachnids (scorpions, spiders, whip scorpions, solpugids, mites, and ticks); the myriapods (centipedes and millipedes); the insects (water bugs, assassin bugs, and wheel bugs); beetles (blister beetles); Lepidoptera (butterflies, moths, and caterpillars), and Hymenoptera (ants, bees, and wasps). Several texts and papers that deal with venomous and poisonous arthropods are available (Bettini, 1978; Pick, 1986; Cohen and Quistad, 1998; Russell, 2001; Kuhn-Nentwig, 2003; Isbister *et al.*, 2004).

The number of deaths from arthropod stings and bites is unknown. In Mexico, parts of Central and South America, North Africa, and India, deaths from scorpion stings, for instance, exceed several thousand a year. Spider bites probably do not account for more than 200 deaths a year worldwide. A common problem faced by physicians in suspected spider bites relates to the differential diagnosis. The arthropods most frequently involved in the misdiagnoses were ticks (including their embedded mouthparts), mites, bedbugs, fleas (infected flea bites), Lepidoptera insects, flies, vesicating beetles, water bugs, and various stinging Hymenoptera. Among the disease states that were confused with spider or arthropod bites or stings were erythema chronicum migrans, erythema nodosum, periarteritis nodosum, pyroderma gangrenosum, kerion cell-mediated response to a fungus, Stevens–Johnson syndrome, toxic epidermal necrolysis, herpes simplex, and purpura fulminans. Any arthropod may bite or sting and not eject venom. Finally, some arthropod venom poisonings accentuate the symptoms and signs of an existing undiagnosed subclinical disease.
Figure 26-1. Multiple biologically active components were obtained from Conus geographus venom by first subjecting the venom to gel filtration on Sephadex G-25 into four fractions and then separation of fraction B (which contains the α-conotoxins) by high-pressure liquid chromatography on a VYDAC C18 column using a trifluoroacetic acid–acetonitrile gradient.

Various peak fractions were then injected intracerebrally into mice and different responses were noted.[†] The fraction was lethal in at least one injected animal. Reprinted with permission from Olivera BM, Rivier J, Clark C, *et al.*: Diversity of *Conus* neuropeptides. *Science* 249, 257–263, 1990.

ARACHNIDA

Scorpions

Of the more than 1000 species of scorpions, the stings of more than 75 can be considered of sufficient importance to warrant medical attention (Keegan, 1980; Polis, 1990; Russell, 2001). Scorpions spend the daylight hours under cover or in burrows. They emerge at night to ambush other arthropods or even small rodents, capture them with their pincers, sting and paralyze them, or tear them apart and digest their body fluids. Because they are carnivorous, the larger ones often feed on the smaller ones. Some of the more important ones of these species are noted in Table 26-2. In addition, members of the genera *Pandinus, Hadrurus, Vejovis, Nebo,* and some of the others are capable of inflicting painful and often erythematous lesions.

The bark scorpion, *Centruroides exilicauda*, is often found hiding under the loose bark of trees or in dead trees or logs, and may frequent human dwellings. Straw to yellowish-brown or reddish-brown in color, it is often easily distinguishable from other scorpions in the same habitat by its long, thin telson, or tail, and its thin pedipalps, or pincer-like claws. Adults of this genus show a considerable difference in length from less than 5 cm in length in *Centruroides noxius* to a length of 9 cm in *Centruroides suffuses*.

Table 26-2
Location of Some Medically Important Scorpions

GENUS	DISTRIBUTION
Androctonus species	North Africa, Middle East, Turkey
Buthus species	France and Spain to Middle East and north Africa, Mongolia, China
Buthotus species	Africa, Middle East, central Asia
Centruroides species	North, Central, South America
Heterometrus species	Central and southeast Asia
Leiurus species	North Africa, Middle East, Turkey
Mesobuthus species	Turkey, India
Parabuthus species	Southern Africa
Tityus species	Central and South America

Many scorpion venoms contain low-molecular-weight proteins, peptides, amino acids, nucleotides, and salts, among other components (Possani *et al.*, 2000; Goldin, 2001; Rodriguez de la Vega and Possani, 2004, 2005). The neurotoxic fractions are generally classified on the basis of their molecular size, the short-chain toxins being composed of 20–40 amino acid residues with three or four disulfide bonds and appear to affect potassium or chloride channels; while the long-chain toxins have 58–76 amino acid residues

(6500–8500 Da) with four disulfide bonds and affect mainly the sodium channels (Mouhat *et al.*, 2004). These particular toxins may have an effect on both voltage-dependent channels. The amino acid content is known for more than 90 species, and there appears to be a high degree of cysteines in most of these venoms. The toxins can selectively bind to a specific channel of excitable cells, thus impairing the initial depolarization of the action potential in the nerve and muscle that results in their neurotoxicity. It appears that the way some scorpion venoms differently affect mammalian, as opposed to insect tissues, is related to the structural basis of the gates in the two organisms. Not all scorpions, however, have fractions that affect neuromuscular transmission. Recently, Rodriguez de la Vega and Possani (2005) constructed a phylogenetic tree using 191 different amino acid sequences from long-chain peptides and discussed their functional divergence and extant biodiversity. The effects of scorpion venom on various potassium channels have been reviewed (Rodriguez de la Vega and Possani, 2004). More intensive research is needed to further understand scorpion toxins.

The symptoms and signs of scorpion envenomation differ considerably depending on the species (Russell, 2001). Common offenders are members of the family Vejovidae, generally found in the southwestern and western United States, Central America, and South America. Their sting gives rise to localized pain, swelling, tenderness, and mild parasthesia. Systemic reactions are rare, although weakness, fever, and muscle fasciculations have been reported. Envenomations by some members of the genus *Centruroides* are clinically the most important, particularly in the western United States, where *C. exilicauda* is found. In children, their sting may produce initial pain, although some children do not complain of pain and are unaware of the injury. The area becomes sensitive to touch, and merely pressing lightly over the injury will elicit an immediate retraction. Usually there is little or no local swelling and only mild erythema. The child becomes tense and restless and shows abnormal and random head and neck movements. Often the child will display roving eye movements. In their review of *Centruroides sculpturatus* stings, Rimsza *et al.* (1980) noted visual signs, including nystagmus roving eye and oculogyric movements, in 12 of 24 patients stung by this scorpion. Tachycardia is usually evident within 45 minutes as well as some hypertension. Although this is not seen in children as early or as severely as in adults, it is often present within an hour following the sting. Respiratory and heart rates are increased, and by 90 minutes the child may appear quite ill. Fasciculations may be seen over the face or large muscle masses, and the child may complain of generalized weakness and display some ataxia or motor weakness. Opisthotonos is not uncommon. The respiratory distress may proceed to respiratory paralysis. Excessive salivation is often present and may further impair respiratory function. Slurring of speech may be present, and convulsions may occur. If death does not occur, the child usually becomes asymptomatic within 36–48 hours.

In adults the clinical picture is somewhat similar, but there are some differences (Russell, 2001). Almost all adults complain of immediate pain after the sting, regardless of the *Centruroides* species involved. Adults do not show the restlessness that is seen in children. Instead, they are tense and anxious. They develop tachycardia and hypertension, and respirations are increased. They may complain of difficulties in focusing and swallowing. In some cases, there is some general weakness and pain on moving the injured extremity. Convulsions are very rare, but ataxia and muscle incoordination may occur. Most adults are asymptomatic within 12 hours, but may complain of generalized weakness for 24 hours or more.

Table 26-3

Some Significant Spiders, Their Toxins and the Targets of the Toxins

SPIDER	PEPTIDE	TARGET[*]
Acanthoscurria gomesiana	Gomesin	PLM
Agelenopsis aperta	ω-AfaI-IVA	Ca^{2+}

PLM, phospholipid membranes; Ca^{2+}, K^+, and Na^+, calcium, potassium, and sodium ion channels; MS, mechano-sensitive ion channels; ASCI, acid-sensing ion channels.

Additional species, their toxins, and their targets may be obtained in the article by Corzo and Escoubas (2003).

Spiders

Of the 30,000 or so species, at least 200 have been implicated in significant bites on humans. Spiders are predaceous, polyphagous arachnids that generally feed on insects or other arthropods. Additional information of spider bites can be found elsewhere (Gertsch, 1979; Maretiĉ and Lebez, 1979; Russell, 2001). Table 26-3 provides a short list of spiders, their toxins, and the targets of their toxins.

All spiders except the Uloboridae family possess a venom apparatus that produces neurotoxins designed to paralyze or kill prey. Spider venoms are complex mixtures of low-molecular-weight components, including inorganic ions and salts, free acids, glucose-free amino acids, biogenic amines and neurotransmitters, and polypeptide toxins. The acylpolyamines, composed of a hydrophobic aromatic carboxylic acid linked to a lateral chain of one to nine aminopropyl, aminobutyl, or aminopentyl units, are voltage-dependent open-channel blockers (sodium, calcium, and potassium channels) and/or blockers of the ion channel associated with glutamate receptors. They also act on nicotinic acetylcholine receptors. The acylpolyamines possess insecticidal activity and induce fast insect paralysis via a reversible block of the insect neuromuscular junction. Polypeptide toxins include the ion channel blockers, pore-forming peptides, and enzymes. In particular, hanatoxins 1 and 2 have allowed characterization of voltage-dependent potassium channels (Swartz and MacKinnon, 1995; Yellen, 2002). The ω-agatoxins have been demonstrated to block voltage-sensitive vertebrate calcium channels (Corzo and Escoubas, 2003). The ω-atracotoxins have greater selectivity on insect voltage-sensitive calcium channels (Wang *et al.*, 2001). Many more spiders and the spider peptide toxins that have been studied to date (Fatehi *et al.*, 1997; Liu *et al.*, 1997; Corzo and Escoubas, 2003; Adams, 2004; Kuhn-Nentwig *et al.*, 2004; Rodriguez de la Vega and Possani, 2004; Ushkaryov *et al.*, 2004; Wilson and Alewood, 2006). The small spider peptide toxins are relatively easy to produce by chemical synthesis or by

Table 26-4

Comparison of Clinical Effects of Bites by Some Spiders of Australia

recombinant means. Peptide toxins from spiders have proved useful in discriminating between different cellular components of native ion channel currents and for the molecular isolation and designation of cellular receptors (Escoubas *et al.*, 2000; Corzo and Escoubas, 2003; Adams, 2004).

Poor case definition and spider identification contribute to the controversy regarding the clinical consequences and inappropriate diagnosis of spider bites worldwide. Many patients never see the spider yet many skin lesions or areas of necrosis are attributed to spider bites. The medically important spiders include the *Latrodectus* spp., *Loxosceles* spp., *Agelenopsis* spp., *Atrax* spp., *Hadronyche* spp., and *Phoneutria* spp. Table 26-4, summarized from Isbister and White (2004), lists local and systemic effects for known cases of major spider groups in Australia.

Agelenopsis Species (American Funnel Web Spiders)   The American funnel web spider (*Agelenopsis aperta*) contains three classes of agatoxins that target ion channels (Adams, 2004). The α-agatoxins appear to be use-dependent, noncompetitive antagonists of the glutamate receptor channels. These are low-molecular-weight acylpolyamines that are devoid of amino acids. Mass spectrometry analysis has identified more than 33 α-agatoxins in *A. aperta* venom (Chesnov *et al.*, 2001). The μ-agatoxins are 36–37 amino acid, C-terminal amidated, peptides with four internal disulfide bridges (Skinner *et al.*, 1989). These μ-agatoxins cause increased spontaneous release of neurotransmitter from presynaptic terminals and repetitive action potentials in motor neurons. In addition, the μ-agatoxins are specific for insect sodium channels. The ω-amatoxins are a structurally diverse group of peptides that are selective for voltage-activated calcium channels. There are four types of ω-amatoxins that can be distinguished by sequence similarity and their spectrum of action against insect and vertebrate calcium channels. The action of the α-agatoxins is synergized by the μ-agatoxins causing channels to open at the normal resting potentials. It is interesting to note that the agatoxins are used as selective pharmacologic probes to characterize ion channels in organs such as brain and heart, and have been evaluated as candidate biopesticides.

Latrodectus Species (Widow Spiders)   Found throughout the world in all continents with temperate or tropical climates, these spiders are commonly known as the black widow, brown widow, or red-legged spider. They, however, have many other common names

in English: hourglass, poison lady, deadly spider, red-bottom spider, T-spider, gray lady spider, and shoebutton spider. Although both male and female widow spiders are venomous, only the female has fangs that are large and strong enough to penetrate the human skin. Mature *Latrodectus mactans* females range in body length from 10 to 18 mm, whereas males range from 3 to 5 mm. These spiders have a globose abdomen varying in color from gray to brown to black, depending on the species. In the black widow, the abdomen is shiny black with a red hourglass or red spots and sometimes with white spots on the venter (Russell, 2001).

The latrotoxins, a family of high-molecular-weight proteins that are found in *Latrodectus* venoms, target different classes of animals including vertebrates, insects, and crustaceans (Grishin, 1998; 1999; Ushkaryov *et al.*, 2004). The toxins are synthesized as large precursors containing around 1000 amino acid residues (around 132–156 kDa) that undergo proteolytic processing to 110–130 kDa and activation in the lumen of the venom gland. Mature latrotoxins are structurally conserved and contain multiple ankyrin repeats. At least seven different latrotoxins have been isolated and all are large acidic proteins (pI $\sim$ 5.0–6.0). Some are called latroinsectotoxins because they affect insects but not vertebrates, and one protein called α-latrocrustatoxin is active only in crayfish. All latrotoxins stimulate massive release of neurotransmitters after binding to specific neuronal receptors.

α-Latrotoxin is the most studied protein that is toxic only to vertebrates and not to insects or crustaceans (Ushkaryov *et al.*, 2004). α-Latrotoxin is a presynaptic toxin that is said to exert its toxic effects on the vertebrate central nervous system depolarizing neurons by increasing intracellular $[Ca^{2+}]$ and by stimulating exocytosis of neurotransmitters from nerve terminals (Holz and Habener, 1998). The purported three-dimensional structure of α-latrotoxin consists of tetrameric complexes with a central channel that inserts into the lipid bilayer. A G-protein-coupled receptor latrophilin and a single-transmembrane receptor neurenin are high-affinity binding sites for α-latrotoxin (Ushkaryov *et al.*, 2004). The latrotoxins act by both calcium-dependent and calcium-independent mechanisms. In fact, a mutant recombinant α-latrotoxin that does not form pores has been invaluable in furthering our understanding of the multiple actions of the toxin (Volynski *et al.*, 2003). α-Latrotoxin and its mutants are versatile tools for the study of exocytosis. In particular, studies with this toxin have helped confirm the vesicular hypothesis of transmitter release (Hurlbut *et al.*, 1990), establish the requirement of calcium ion for endocytosis (Ceccarelli and Hurlbut,

1980), characterize individual neurotransmitter sites in the central nervous system (Auger and Marty, 1997), and identify two families of important neuronal cell-surface receptors (Krasnoperov *et al.*, 1997).

Bites by the black widow are described as sharp and pinprick like, followed by a dull, occasionally numbing pain in the affected extremity and by pain and cramps in one or several of the large muscle masses (Russell, 2001). Rarely is there any local skin reaction except during the first 60 minutes following the bite. Muscle fasciculations frequently can be seen within 30 minutes of the bite. Sweating is common, and the patient may complain of weakness and pain in the regional lymph nodes, which are often tender on palpation and occasionally are enlarged; lymphadenitis is frequently observed. Pain in the low back, thighs, or abdomen is a common complaint, and rigidity of the abdominal muscles is seen in most cases in which envenomation has been severe. Severe paroxysmal muscle cramps may occur, and arthralgia has been reported. Hypertension is a common finding, particularly in the elderly after moderate-to-severe envenomations. Blood studies are usually normal.

Loxosceles Species (Brown or Violin Spiders) These primitive spiders are variously known in North America as the fiddle-back spider or the brown recluse. There are over 100 species of *Loxosceles*. The abdomen of these spiders varies in color from grayish through orange and reddish-brown to blackish and is distinct from the pale yellow to reddish-brown background of the cephalothorax. This spider has six eyes grouped in three dyads. Females average 8–12 mm in body length, whereas males average 6–10 mm. Both males and females are venomous (Russell, 2001).

The venom of *Loxosceles* spiders appears to contain phospholipase, protease, esterase, collagenase, hyaluronidase, deoxyribonuclease, ribonuclease, dipeptides, dermonecrosis factors, and sphingomyelinase D. The venom has coagulation and vasoconstriction properties and it causes selective vascular endothelial damage. There are adhesions of neutrophils to the capillary wall with sequestration and activation of passing neutrophils by the perturbed endothelial cells (Patel *et al.*, 1994). In *Loxosceles intermedia a,* the toxic effects appear to be associated with a 35-kDa protein that demonstrates a complement-dependent hemolytic activity and a dermonecrotic-inducing factor. ^{31}P-Nuclear magnetic resonance assay of the four bands representing proteins, measuring 34 kDa in the venom, produced three proteins with sphingomyelinase D activity (Merchant *et al.*, 1998). An endotoxemic-like shock, showing eosinophilic material in the proximal and distal tubules and tubular necrosis, was the most common histopathologic finding, preceded in mice by prostration, acute cachexia, hypothermia, neurological changes, and hemoglobinuria (Tambourgi *et al.*, 1998).

The bite of this spider produces about the same degree of pain as does the sting of an ant, but sometimes the patient may be unaware of the bite. In most cases, a local burning sensation, which may last for 30–60 minutes, develops around the injury. Pruritus over the area often occurs, and the area becomes red, with a small blanched area surrounding the reddened bite site. Skin temperature usually is elevated over the lesion area. With significant envenomations, the reddened area enlarges and becomes purplish during the subsequent 1–8 hours. It often becomes irregular in shape, and as time passes, hemorrhages may develop throughout the area. A small bleb or vesicle may form at the bite site, increase in size, and rupture with subsequent pustule formation. The red hemorrhagic area continues

to enlarge, as does the pustule. The whole area may become swollen and painful, and lymphadenopathy is common. During the early stages, the lesion often takes on a bull's-eye appearance, with a central white vesicle surrounded by the reddened area and ringed by a whitish or bluish border. The central pustule ruptures, and necrosis to various depths can be visualized (Russell, 2001).

In serious bites, the lesion can measure 8×10 cm^2 with severe necrosis invading muscle tissue. On the face, large lesions resulting in extensive tissue destruction and requiring subsequent plastic surgery sometimes are seen after bites by *Loxosceles laeta* in South America. Systemic symptoms and signs include fever, malaise, stomach cramps, nausea and vomiting, jaundice, spleen enlargement, hemolysis, hematuria, and thrombocytopenia. Fatal cases, while rare, usually are preceded by intravascular hemolysis, hemolytic anemia, thrombocytopenia, hemoglobinuria, and renal failure (Russell, 2001).

Steatoda Species These spiders are variously known as the false black widow, combfooted, cobweb, or cupboard spiders. The female of *Steatoda grossa* differs from *L. mactans* and *Latrodectus hesperus* in having a purplish-brown abdomen rather than a black one. It is less shiny, and its abdomen is more oval than round. It may have pale yellow or whitish markings on the dorsum of the abdomen, and no markings on the venter. The abdomen of some species is orange, brown, or chestnut in color, and often bears a light band across the anterior dorsum (Russell, 2001).

The venom of *Steatoda paykulliana* stimulates the release of transmitter substances similar to *Latrodectus* venom (Cavalieri *et al.*, 1987). The venom is said to form ionic channels permeable for bi- and monovalent cations, and that the duration of time in the open state depends on the membrane potential (Sokolov *et al.*, 1984). *S. paykulliana* venom induces strong motor unrest, clonic cramps, exhaustion, ataxia, and then paralysis in guinea pigs. Bites by *S. grossa* or *Steatoda fulva* in the United States have been followed by local pain, often severe; induration; pruritus; and the occasional break down of tissue at the bite site (Russell, 2001).

Cheiracanthium Species (Running Spiders) The 160 species of this genus have an almost circumglobal distribution, although only four or five species have been implicated in bites on humans (Russell, 2001). *Cheiracanthium punctorium, Cheiracanthium inclusum, Cheiracanthium mildei, Cheiracanthium diversum*, and *Cheiracanthium japonicum* are often implicated in envenomations. The abdomen is convex and egg shaped and varies in color from yellow, green, or greenish-white to reddish-brown; the cephalothorax is usually slightly darker than the abdomen. The chelicerae are strong, and the legs are long, hairy, and delicate. The spider ranges in length from 7 to 16 mm. Like *Phidippus* but even more so, *Cheiracanthium* tends to be tenacious and sometimes must be removed from the bite area. For that reason there is a high degree of identification following the bite of these spiders. The most toxic venom fraction is said to be a protein of 60 kDa, and the venom is high in norepinephrine and serotonin.

The patient usually describes the bite by *C. inclusum* as sharp and painful, with the pain increasing during the first 30–45 hours. The patient complains of dull pain over the injured part. A reddened wheal with a hyperemic border develops. Small petechiae may appear near the center of the wheal. Skin temperature over the lesion is often elevated, but body temperature is usually normal. Lymphadenitis and lymphadenopathy may develop. *C. japonicum*

produces more severe manifestations, including severe local pain, nausea and vomiting, headache, chest discomfort, severe pruritus, and shock (Russell, 2001).

***Theraphosidae* Species (Tarantulas)**   True tarantulas are members of the family Theraphosidae and there are around 800 species that are distributed worldwide, but especially in tropical or semitropical regions. Tarantulas are predators and they feed on various vertebrate and invertebrate preys that are captured after envenomation with venoms that act rapidly and irreversibly on the central and peripheral nervous systems. In humans, reported bites elicit mild-to-severe local pain, strong itching, and tenderness that may last for several hours. Edema, erythema, joint stiffness, swollen limbs, burning feelings, and cramps are common. In more severe cases, strong cramps and muscular spasms lasting up to several hours may be observed. *Poecilotheria* and *Stromatopelma* spp. appear to be most toxic to humans, although no fatalities have been reported (Escoubas and Rash, 2004).

Tarantula venoms have been extensively studied, and modern purification often uses orthogonal HPLC separations that combine reversed-phase and ion-exchange chromatography. Most spider peptide toxins appear to have basic pI in the 9–11 range (Escoubas *et al.*, 2000). Mass spectrometry techniques including electrospray ionization, matrix-assisted laser desorption-ionization (MALDI), and MALDI coupled to time-of-flight analysis have been extensively used for venom characterization. At least 33 peptide toxins have been described from various tarantula venoms. These have a molecular weight of 3000–5700 Da, and targets include voltage-gated potassium, sodium and calcium channels, tetrodotoxin-sensitive channels, and acid-sensing ion channels, which are sensitive to extracellular pH (reviewed by Escoubas and Rash, 2004). At least two distinct structural motifs have been characterized: the Inhibitory Cystine Knot (ICK) with a consensus sequence of $C_I X_{3-7}–C_{II} X_{3-8}–C_{III} X_{0-7}–C_{IV} X_{1-4}–C_V X_{4-13}–C_{VI}$ and disulfide bond pairing of $C_I–C_{IV}$, $C_{II}–C_V$, and $C_{III}–C_{VI}$ (Craik *et al.*, 2001), and the disulfide-directed β-hairpin (DDH) motif that comprises an antiparallel β-hairpin stabilized by two disulfide bridges (Wang *et al.*, 2000). Tarantula toxins have been classified as long-loop ICK, short-loop ICK, or DDH toxins (Escoubas and Rash, 2004).

Theraphosid spiders contain several toxins that are being evaluated for development as antiarrhythmic or as antinociceptive drugs. In particular, *Grammostola* mechanotoxin 4 from *Grammostola spatulata* has considerable promise as an antiarrhythmic. Protoxin I and II from *Thrixopelma pruriens* have promise as analgesics because they inhibit the tetrodotoxin-resistant sodium channels (Middleton *et al.*, 2002).

Future work on the toxins of tarantulas will encompass genomic and proteomic approaches. Expanding knowledge suggests trends in the association of primary and three-dimensional structures with pharmacologic activity. Continued improvement in isolation and purification technologies plus the combination of cDNA library screening with mass spectrometry will prove invaluable in characterization of toxin function and definition of toxin targets.

Ticks

Many of the approximately 900 species of ticks are associated with disease in humans and wild and domesticated animals (Rash and Hodgson, 2002; Barker and Murrell, 2004; Steen *et al.*, 2006). Tick paralysis is caused by the saliva of certain ticks of the families Ixodidae, Argasidae, and Nuttalliellidae. The tick bite involves insertion of cutting, tube-like mouthparts through the host's skin with anchoring so that the tick can feed for hours, days, or weeks. Saliva from the salivarium flows outward initially and the blood meal flows inward afterward. Ticks are known to transmit the organisms causing Lyme disease, Rocky Mountain spotted fever, babesiosis, leptospirosis, Q fever, ehrlichiosis, typhus, tick-borne encephalitis, and others. In fact, the import of immunosuppression by tick saliva in the transmission of flaviviruses has been discussed (Nuttall and Labuda, 2003).

Tick saliva contains a number of active constituents (Steen *et al.*, 2006). For example, saliva from *Ixodes scapularis* contains apyrase (ATP-diphosphohydrolase), which hydrolyzes ADP that is released at the bite site thereby inhibiting ADP-induced platelet aggregation (Mans *et al.*, 1998), kininase (ACE-like protein or angiotensin-converting enzyme-like protein), which hydrolyzes circulating kinins and reduces the host inflammatory response (Francischetti *et al.*, 2003); glutathione peroxidase (Das *et al.*, 2001); serine protease inhibitors, which inhibit coagulation enzymes (Valenzuela, 2004); an anticomplement protein that inhibits an enzyme in the alternative pathway for complement (Valenzuela *et al.*, 2000); an amine-binding protein that binds serotonin, histamine, and other biogenic amines (Sangamnetdej *et al.*, 2002); and prostanoids (PGE_2 and $PGF_{2\alpha}$ (Inokuma *et al.*, 1994). A discussion of toxins from other species may be found elsewhere (Cavassani *et al.*, 2005; Steen *et al.*, 2006).

Potentially 50 species of ticks are associated with clinical paralysis (Russell, 2001). As tick bites are often not felt; the first evidence of envenomation may not appear until several days later, when small macules 3–4 mm in diameter develop that are surrounded by erythema and swelling, often displaying a hyperemic halo. The patient often complains of difficulty with gait, followed by paresis and eventually locomotor paresis and paralysis. Problems in speech and respiration may ensue and lead to respiratory paralysis if the tick is not removed. The saliva of *Ixodes holocyclus* has yielded a peptide holocyclotoxin-1 that may cause paralysis (Masina and Broady, 1999). Peak paralytic activity was found between 60 and 100 kDa, and was a trimer of aneurotoxic protein subunit of 23 kDa (Crause *et al.*, 1993). Symptoms resolve rapidly upon removal of the tick (Russell, 2001).

CHILOPODA (CENTIPEDES)

Found worldwide, these elongated, many-segmented brownish-yellow arthropods have a pair of walking legs on most segments, and they are fast moving, secretive, and nocturnal. They feed on other arthropods and even small vertebrates and birds. The first pair of legs behind the head is modified into poison jaws. Centipedes range in length from 3 mm to almost 300 mm. In the United States, the prevalent biting genus is a *Scolopendra* species. The venom is concentrated within the intracellular granules, discharged into vacuoles of the cytoplasm of the secretory cells, and moved by exocytosis into the lumen of the gland; from thence ducts carry the venom to the jaws (Ménez *et al.*, 1990).

Centipede venoms contain high-molecular-weight proteins, proteinases, esterases, 5-hydroxytryptamine, histamine, lipids, and polysaccharides (Mebs, 2002). Such venom contains a heat-labile cardiotoxic protein of 60 kDa that produces, in humans, changes associated with acetylcholine release (Gomes *et al.*, 1983). The bite produces two tiny punctures, sharp pain, immediate bleeding, redness, and swelling often lasting for 24 hours. Localized tissue changes and necrosis have been reported, and severe envenomations may cause nausea and vomiting, changes in heart rate, vertigo, and

headache. In the most severe cases, there can be mental disturbances (Bush *et al.*, 2001; Russell, 2001; Mebs, 2002).

DIPLOPODA (MILLIPEDES)

Ranging in length from 20 to 300 mm, these arthropods are cylindrical, worm-like creatures, mahogany to dark brown or black in color, and bearing two pairs of jointed legs per segment. In Australia and New Guinea particularly, the repellent secretions expelled from the sides of their bodies contain a toxin of quinone derivatives plus a variety of complex substances such as iodine and hydrocyanic acid, which the animal makes use of to produce hydrogen cyanide. Some species can spray these defensive secretions, and eye injuries are not uncommon. The lesions produced by millipedes consist of a burning or prickling sensation and development of a yellowish or brown-purple lesion; subsequently, a blister containing serosanguinous fluid forms, which may rupture. Eye contact can cause acute conjunctivitis, periorbital edema, keratosis, and much pain; such an injury must be treated immediately (Russell, 2001).

INSECTA

Heteroptera (True Bugs)

The clinically most important of the true bugs are the Reduviidae (the reduviids): the kissing bug, assassin bug, wheel bug, or cone-nose bug of the genus *Triatoma* (Russell, 2001). Generally, they are parasites of rodents and common in the nests of wood rat or in wood piles. These are elongated bugs with freely movable, cone-shaped heads, and straight beaks. The most commonly involved species appear to be *Triatoma protracta, Triatoma rubida, Triatoma magista, Reduvius personatus*, and *Arilus cristatus.* The average length of these bugs is 19 mm. The venom of these bugs appears to have apyrase activity and to lack 5-nucleotidase, inorganic pyrophosphatase, phosphatase, and adenylate kinase activities, but it is fairly rich in protease properties. It inhibits collagen-induced platelet aggregation. Three peptides isolated from the saliva of predatory reduviids are 34–36 amino acid residues in size, are calcium channel blockers similar to ω-conotoxins, and belong to the four loop disulfide bridge scaffold structural class (Corzo *et al.*, 2001). The bites of *Triatoma* species are painful and give rise to erythema, pruritus, increased temperature in the bitten part, localized swelling, and—in those allergic to the saliva–systemic reactions such as nausea and vomiting and angioedema. With some bites the wound area will slough, leaving a depression.

The water-dwelling true bugs are of at least three families, Naucordiae, Belostomatidae, and Notonectidae, which are capable of biting and envenomating humans (Russell, 2001). They are found in lakes, ponds, marshes, quiet fresh water, and swimming pools. *Lethocerus americanus,* a Belostomatidae, ranges in length from 12 to 70 mm, but some water bugs may reach 150 mm. The dorsal side is usually tan or brown, but it may be brightly colored, while the ventral side is brown. They are very strong insects and can immobilize snails, tadpoles, salamanders, and even small fish and water snakes. Water bug saliva is said to contain digestive enzymes, neurotoxic components, and hemolytic fractions. ApoLp-III isolated from the hemolymph of *Lathocerus medius* is about 19 kDa and has an amino acid composition high in methionine. If molested, water bugs will bite, and their bites give rise to immediate pain, some localized swelling, and possibly induration and formation of a small papule.

Hymenoptera (Ants, Bees, Wasps, and Hornets)

Formicidae (Ants)   Most ant species sink their powerful mandibles into the flesh, providing leverage, and then drive their stings into the victim. Most ants have stings, but those that lack them can spray a defensive secretion from the tip of the gaster, which is often placed in the wound of the bite. Ants of the different species vary considerably in length, ranging from less than 1.5 mm to over 35 mm. Clinically important stinging ants are the harvesting ants (*Pagonomyrmex*), fire ants (*Solenopsis*), and little fire ants (*Ochetomyrmex*). The harvester ants are large red, dark brown, or black ranging in size from 6 to 10 mm and having fringes of long hairs on the posterior of their heads (Russell, 2001).

The venoms of the ants vary considerably. The venoms of the Ponerinae, Ecitoninae, and Pseudomyrmex are proteinaceous in character. The Myrmecinae venoms are a mixture of amines, enzymes and proteinaceous materials, histamine, hyaluronidase, phospholipase A, and hemolysins, which hemolyze erythrocytes and mast cells. Formicinae ant venom contains about 60% formic acid. Fire ant venoms are poor in polypeptides and proteins, but are rich in alkaloids such as solenopsine (Russell, 2001; Mebs, 2002). The sting of the fire ant gives rise to a painful burning sensation, after which a wheal and localized erythema develop, leading in a few hours to a clear vesicle. Within 12–24 hours, the fluid becomes purulent and the lesion turns into a pustule. It may break down or become a crust or fibrotic nodule. In multiple stings there may be nausea, vomiting, vertigo, increased perspiration, respiratory difficulties, cyanosis, coma, and even death. Cross-exposure to the venom of other species of ants is possible. Allergic reactions and fatal anaphylactic shock are seen in sensitized victims (Hoffman, 2006). Treatment of ant stings is dependent on their number, whether an allergic reaction is involved, and whether there are possible complications.

Apidae **(Bees)**   This family includes the bumble bees, honeybees, carpenter bees, and yellow jackets. The commonest stinging bees are *Apis mellifera* and the Africanized bee, *Apis mellifer adansonii*, and the incidence of Hymenoptera poisonings is increasing. The venom of the Africanized bee is not remarkably different from that of the European bee, *A. m. mellifer.* The former bee is smaller and gives less venom, but its aggressiveness is such that attacks of fifty to hundreds of bees are not unusual (Russell, 2001).

The venom contains biologically active peptides, such as melittin, apamine, mast cell-degranulating peptide, and others, as well as phospholipases A_2 and B, hyaluronidase, histamine, dopamine, monosaccharides, and lipids (Mebs, 2002). Melittin, which is secreted as prepromelittin of 70 amino acids, consists of 26 amino acids with no cysteines that have natural detergent-like properties and causes erythrocyte lyses. Melittin also forms tetramers that form pores, thereby facilitating ion transport through membranes. In particular, melittin-tetramers cause a break down of the resting potential and rapid depolarization of nociceptors, which induces pain (Demsey, 1990; Bechinger, 1997). The compound apamine contains 18 amino acids cross-linked by two disulfide bridges. Apamine is a blocker of calcium-dependent potassium channels and is thought to be the "lethal factor" (Habermann, 1984). In addition to apamine, mast cell-degranulating peptide is also a basic peptide containing 22 amino acids with two disulfide bonds. Besides stimulating release of histamine, this peptide specifically inhibits voltage-dependent potassium channels (Dreyer, 1990; Baku, 1999).

Bee stings typically produce immediate, sharp or burning pain, slight local erythema, and edema followed by itching. The edema may vary depending on location of the sting. It is said that 50 stings can be serious and lead to respiratory dysfunction, intravascular hemolysis, hypertension, myocardial damage, hepatic changes, shock, and renal failure. With 100 or more stings, death can occur. In patients who are allergic to bee stings, immediate allergic reaction with the risk of anaphylactic shock requires urgent medical treatment (Mebs, 2002; Hoffman, 2006).

Vespidae (Wasps)   This family includes wasps and hornets. These venoms contain a high content of peptides, which include mastoparan in wasps and hornets and crabolin from hornet venom. These peptides release histamine from mast cells and consist of 13–17 amino acids with no disulfide bridges. Other peptides named waspkinins cause immediate pain, vasodilation and increased vascular permeability leading to edema. These venoms also contain phospholipases and hyaluronidases, which contribute to the break down of membranes and connective tissue to facilitate diffusion of the venom. These proteins also contribute to the allergenicity of the venoms (Mebs, 2002; Hoffman, 2006).

Lepidoptera (Caterpillars, Moths, and Butterflies)

The urticating hairs, or setae, of caterpillars are effective defensive weapons that protect some species from predators. The setae are attached to unicellular poison glands at the base of each hair. Both the larvae and the adults are capable of stinging, either by direct contact with the setae or indirectly when the creature becomes irritated. It appears that contraction of the caterpillar's abdominal muscles is sufficient to release the barbs from their sockets, allowing them to become airborne. The toxic material found in the venom glands contains aristolochic acids, cardenolides, kallikrein, and histamine among other substances. Fibrinolytic activity has been found at 16 and 18 kDa (isoelectric point of 8.5); coagulation defects such as prolonged prothrombin and partial thromboplastin times have been detected, and decreases in fibrinogen and plasminogen have been noted. It is thought that the hemorrhagic syndrome cannot be classified as being either totally fibrinolytic or a syndrome such as disseminated intravascular coagulopathy. The spicules of *Thaumetopoea pityocampa* contain a 28-kDa toxin called thaumetopoein, which is a strong dermal irritant and highly allergenic peptide (Kawamoto and Kumada, 1984; Russell, 2001; Mebs, 2002).

In some parts of the world the stings of several species of Lepidoptera give rise to a bleeding diasthesis, often severe and sometimes fatal. Envenomation by members of the family Saturniidae, the buck moths, the grapeleaf skeletonizer (family Zygaenidae), the puss moth (family Megalopygie), and the brown-tailed moth (*Euproctis* species) generally gives rise to little more than immediate localized itching and pain, usually described as burning, followed in some cases by urticaria, edema, and occasionally fever. The hemolymph and spicules contain highly active clotting enzymes, a protease with fibrinolytic activity and an enzyme that activates prothrombin. In the more severe cases—often due to *Megalopygidae, Dioptidae, Automeris, and Hermileucinae* species—there is localized pain as well as papules (sometimes hemorrhagic) and hematomas; on occasions there may also be headache, nausea, vomiting, hematuria, lymphadenitis, and lymphadenopathy. Contacts with larvae of the saturnid moths in South America (*Lonomia acheolus* and *Lonomia oblique*) can cause severe coagulopathy, due to inhibition of clotting Factor XIII by a venom component

called lonomine V. Severe envenomation can cause cerebral hemorrhage and death (Guerrero *et al.*, 1999).

MULLOSCA (CONE SNAILS)

Human interest in this group of mollusks has been due to the beautiful patterns on their shells. Cone snails were known to Roman scholars and natural history collectors, as the shells were often made into jewelry. The first record of fatality from cone snail sting may be found in the book of Rumphius from 1705. The genus *Conus* is a group of some 500 species of carnivorous predators found in marine habitats that use venom as a weapon for prey capture. Cone snails have a venom duct for synthesis and storage of venom and hollow harpoon-like teeth for injection of the venom (Rockel *et al.*, 1995).

Cone snails may be divided into three groups depending on preferred prey. The largest group contains worm-hunting species that feed on polychaetes (segmented marine worms in the phylum Annelida). The second group is molluscivorous and hunts other gastropods. The final group is piscivorous and has venoms that rapidly immobilize fish (Olivera, 1997, 2002; Mebs and Kauferstein, 2005).

There are probably over 100 different venom components per species (Terlau and Olivera, 2004). Components have become known as conotoxins, which may be rich in disulfide bonds, and conopeptides. Molecular targets include G-protein-coupled receptors and neuromuscular transporters, ligand- or voltage-gated ion channels. Some components have enzymatic activity.

Figure 26-2 provides an overview of peptidic *Conus* venom components, indicating gene superfamilies, disulfide bond characteristics, and general targets (McIntosh *et al.*, 1999; Olivera, 2002). The two major divisions of *Conus* toxins are the disulfide-rich conotoxins and the peptides that lack multiple disulfide cross-links. The arrangement of cysteines in the primary sequence is restricted to only a few patterns, which may be diagnostic of the gene superfamily. Most disulfide-rich conotoxins are small and consist of 12–30 amino acids. These toxins contain an unusually diverse complement of posttranslationally modified amino acids, including hydroxyproline, *O*-glycosylated serine or threonine, γ-carboxyl-glutamate, sulfated tyrosine, and D-amino acids (Craig *et al.*, 1999). Apparently, the posttranslational modification enzyme γ-carboxylase is present in their venom ducts (Bandyopadhyay *et al.*, 2002). The enzyme has a recognition signal in the pro region of the precursor that instructs the enzyme to modify specific amino acid residues in the mature toxin region. Thus, the pro region of conopeptide precursors provides potential anchor-binding sites for posttranslational modification enzymes (Hooper *et al.*, 2000).

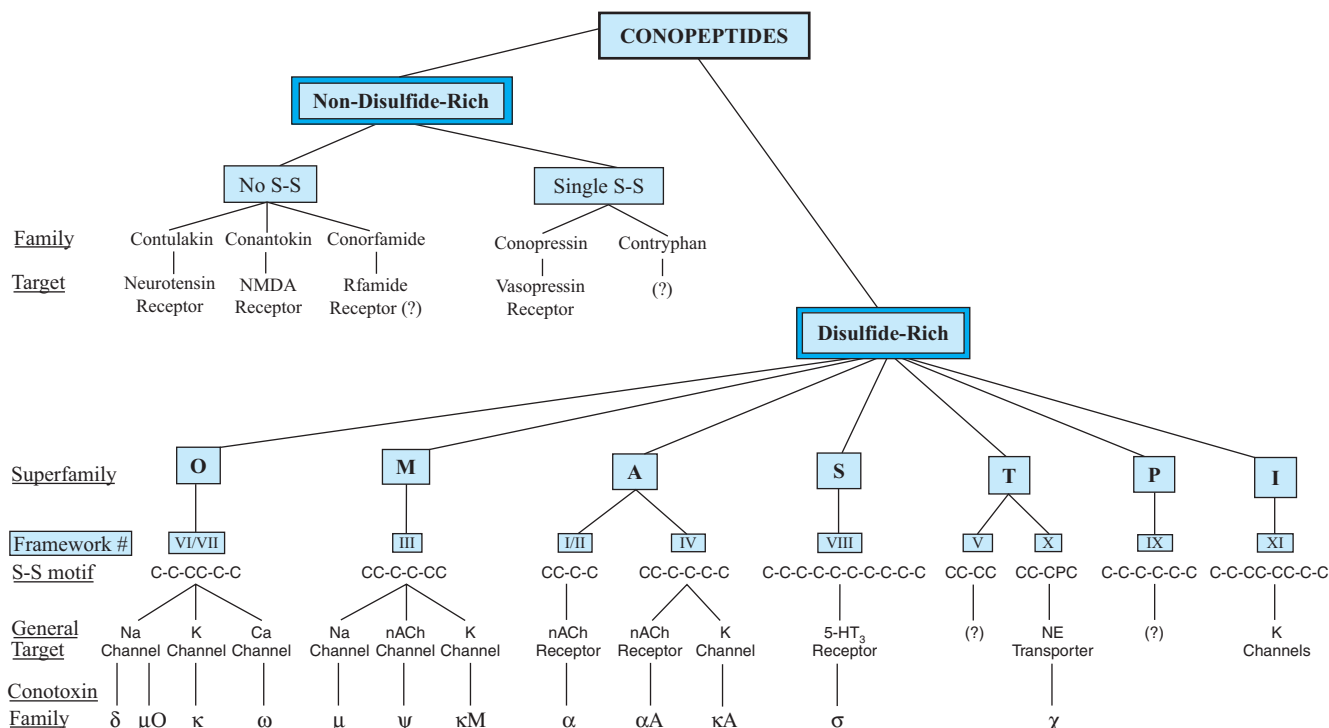
Cone snails could be called sophisticated practitioners of combination drug therapy. After injection, multiple conopeptides act synergistically to affect the targeted prey. The term toxin cabal has been applied to this coordinated action of the conopeptide mixture. The fish-hunting species *Conus purpurascens* apparently has two distinct cabals whose effects differ in time and space. The "lightning-strike cabal" causes immediate immobilization of the injected prey because various venom components inhibit voltage-gated sodium channel inactivation and block potassium channels, resulting in massive depolarization of axons in the vicinity of the injection site and a tetanic state. The second physiologic cabal, the "motor cabal," acts more slowly as conotoxins must be distributed throughout the body of the prey. The overall result is total inhibition of neuromuscular transmission. Various conopeptides inhibit presynaptic calcium channels that control neurotransmitter release, the postsynaptic


Figure 26-2. *Organizational diagram for Conus peptides, indicating gene superfamilies, disulfide patterns, and known pharmacologic targets.*

Only the superfamilies of the disulfide-rich peptides are shown. Used with permission from Terlau H, Olivera BM: *Conus* venoms: A rich source of novel ion channel-targeted peptides. *Physiol Rev* 84:41–68, 2004.

neuromuscular nicotinic receptors, and the sodium channels involved in the muscle action potential (Terlau *et al.*, 1996).

Conopeptides can affect many ion channels (Olivera *et al.*, 1994; Terlau and Olivera, 2004). For example, μ-conotoxins are peptides with 22–25 amino acids and six cysteine residues that block sodium currents by acting at a site that overlaps the tetrodotoxin-sensitive site of sodium channels. The main effect of the unusually hydrophobic δ-conotoxins, which are peptides with an inhibitory cysteine knot motif pattern of disulfide bridges, is the inhibition of the fast inactivation of sodium currents, which affects the shape and duration of the action potential. This can lead to a massive electrical hyperexcitation of the complete organism. The κ-, κA- and κM-conotoxins target potassium channels. The ω-conotoxins are peptides that target calcium channels, and these toxins have been widely used in neuroscience research. A characteristic feature of the ω-conotoxins is their high content of basic amino acids. One peptide, ω-conotoxin MVIIA from *Conus magus*, has been developed as ziconotide (Prialt®) for the treatment of intractable pain (Olivera, 2000). Other conotoxins are being studied as potential antinociceptive agents.

Conopeptides also target ligand-gated ion channels that mediate fast synaptic transmission (Kandel *et al.*, 2000). One major group of ligand-gated ion channels is activated by acetylcholine, serotonin, γ-aminobutyric acid, or glycine. These proteins differ in ligand specificity and selectivity for the permeant ion. The second family activates the glutamate receptors, *N*-methyl-D-aspartate and kainate/AMPA receptors. A third group activates synaptic transmission at certain synapses via the ATP receptors. It is evident from Fig. 26-2 that there are conopeptides that target these three different families of ligand-gated ion channels. It is clear

that our understanding of the structure and function of conopeptides is rapidly expanding and additional information regarding these toxins is available in an excellent review (Terlau and Olivera, 2004).

REPTILES

Lizards

The Gila monster (*Heloderma suspectum*) and the beaded lizards (*Heloderma horridum*) are divided into five subspecies. These large, corpulent, relatively slow moving, and largely nocturnal reptiles have few enemies other than humans. They are far less dangerous than is generally believed. Their venom is transferred from venom glands in the lower jaw through ducts that discharge their contents near the base of the larger teeth of the lower jaw. The venom is then drawn up along grooves in the teeth by capillary action (Brown and Carmony, 1991). The venom of this lizard has serotonin, amine oxidase, phospholipase A, a bradykinin-releasing substance, helodermin, gilatoxin, and low proteolytic as well as high-hyaluronidase activities, but lacks phosphomonoesterase and phosphodiesterase, acetylcholinesterase, nucleotidase, ATPase, deoxyribonuclease, ribonuclease, amino acid oxidase, and fibrinogenocoagulase activities. The clinical presentation of a helodermatid bite can include pain, edema, hypotension, nausea, vomiting, weakness, and diaphoresis. No antivenin is commercially available. Treatment is supportive (Strimple *et al.*, 1997).

The venom has been shown to contain a 25-kDa protein, helothermine, containing 223 amino acids and four pairs of disulfide bonds, which appears to inhibit Ca^{2+} flux from the sarcoplasmic

reticulum (Morrissette *et al*., 1995; Nobile *et al*., 1996). A fraction causing hemorrhage in internal organs and the eye, a glycoprotein of 210 amino acid residues with plasma kallikrein-like properties, has also been described (Datta and Tu, 1997). A 35 amino acid residue, helodermin produces hypotension that is partially attributed to activation of glibenclamide-sensitive K^+ channels (Horikawa *et al*., 1998). In fact, Helospectin I and II and helodermin are nonamidated, vasoactive intestinal peptide-like peptides, isolated from the salivary gland venom of the lizards *H. suspectum* and *H. horridum*, which have strong and potent vasodilator effects (Uddman *et al*., 1999).

Snakes

General Information and Classification   Snakes have a three-chambered heart and rely almost exclusively upon an enlarged right lung (that spans approximately half of the body length) for respiration. Of the approximately 2700 known species of snakes, about 20% are considered to be venomous (Mebs, 2002). Venomous snakes primarily belong to the following families: *Viperida*e (vipers), *Elapidae*, *Atractaspidae*, and *Colubridae*. The vipers are further divided into subfamilies, and example of which is the *Crotalinae*, or pit vipers, which possess a pit between the eyes and nostrils that serves as a heat sensor to detect warm-blooded animals. Some of the subfamilies are regarded as separate families altogether depending on the classification scheme. Overall the *Colubridae* are considered the largest venomous family, and are comprised of nearly 60% of all snakes. The *Atractaspidae* family, recently classified within the *Viperidae*, is known for burrowing into the ground and possessing the ability to expose their fangs without opening their mouth.

Another characteristic that is often used for self-defense or hunting prey is mimicry (O'Shea, 2005). Scale pattern and coloration provide distinct boundaries in the wild and often carry unspoken warnings based upon a reputation for snake venom toxicity for a given species. If a relatively harmless species is able to mimic the physical characteristics, especially color patterns, of a well-known highly toxic counterpart, then other potential predators may recognize both snakes as toxic and not pursue either.

Fang anatomy and dentition are good indicators of such factors as snake habitat and feeding habits (O'Shea, 2005). In general, the anatomical structure of fangs makes it nearly impossible for snakes to chew their prey. The distinct curvature of the fangs is not only engineered for puncturing skin and delivering venom, but also for swallowing whole prey as well. The teeth and jaw structure are relatively mobile and effectively facilitate the positioning of whole prey for swallowing. The skull and jaw possess an extremely high degree of responsiveness to stimuli. The jaw does not actually dislocate; however, it is able to rapidly reposition itself to capture, contain, and swallow prey. In addition to the capabilities of the teeth, fangs, and jaws, the classic fork-shaped tongue is another tool for identifying prey (O'Shea, 2005).

The *Viperidae* fang structure is regarded as the most developed and efficient means of venom, or toxin, delivery to prey. The venom gland is positioned at the base of a long ($\sim$30 mm) hollow retractable fang (Mebs, 2002). Muscle pressure on the gland determines the amount of venom released. Another highly developed venom delivery apparatus is characteristic of the spitting cobras, aptly named for their ability to project venom via glands that protrude from the base of the fang opening (Mebs, 2002). Venom is carried toward the prey, or target, via forceful exhalation that is accompanied by a hissing sound. Toxin delivery via venom exposure is the primary mechanism by which snakes immobilize and kill their prey. Toxin type and specificity is dependent on the species; however, most venom comprises of complex networks of toxins that affect variable organ systems and interact with one another increasing the overall potency.

It is estimated that there are over 2.5 million snakebites annually, and that over 100,000 victims will die (White, 2005). Information resources available to physicians on management of snakebite victims may be found at the Clinical Toxicology Resources Website—www.toxinology.com or other appropriate references (Dart, 2004; Tintinalli *et al*., 2004).

Snake Venoms   These venoms are complex mixtures: proteins and peptides, consisting of both enzymatic and nonenzymatic compounds, make up over 90% of the dry weight of the venom (Phui Yee *et al*., 2004). Snake venoms also contain inorganic cations such as sodium, calcium, potassium, magnesium, and small amounts of zinc, iron, cobalt, manganese, and nickel. The metals in snake venoms are likely catalysts for metal-based enzymatic reactions. For example, in the case of some elapid venoms, zinc ions appear to be necessary for anticholinesterase activity, and calcium may play a role in the activation of phospholipase A and the direct lytic factor. Some proteases appear to be metalloproteins. Some snake venoms also contain carbohydrates (glycoproteins), lipids, and biogenic amines, such as histamine, serotonin, and neurotransmitters (catecholamines and acetylcholine) in addition to positively charged metal ions (Russell, 2001; Mebs, 2002; Ménez, 2003; Ramos and Selistre-de-Araujo, 2006). The complexity of snake venom components is illustrated nicely in Fig. 26-3 (Ramos and Selistre-de-Araujo, 2006).

Actions of snake venoms can be said to be broad ranging in several areas (O'Shea, 2005). A simplistic approach would group toxin components as neurotoxins, coagulants, hemorrhagins, hemolytics, myotoxins, cytotoxins, and nephrotoxins. Neurotoxins produce neuromuscular paralysis ranging from dizziness to ptosis; to ophthalmoplegia, flaccid facial muscle paralysis, and inability to swallow; to paralysis of larger muscle groups; and finally to paralysis of respiratory muscles and death by asphyxiation. Coagulants may have initial procoagulant action that uses up clotting factors leading to bleeding. Coagulants may directly inhibit normal clotting at several places in the clotting cascade or via inhibition of platelet aggregation. In addition, some venom components may damage the endothelial lining of blood vessels leading to hemorrhage. Bite victims may show bleeding from nose or gums, the bite site, in saliva, urine, and stools. Myotoxins can directly impact muscle contraction leading to paralysis or cause rhabdomyolysis or the break down of skeletal muscle. Myoglobinuria, or a dark brown urine, and hyperkalemia may be noted. Cytotoxic agents have proteolytic or necrotic properties leading to the break down of tissue. Typical signs include massive swelling, pain, discoloration, blistering, bruising, and wound weeping. Sarafotoxins, which are found only in burrowing asps of Afro-Arabia, cause coronary artery constriction that can lead to reduced coronary blood flow, angina, and myocardial infarction. Finally, nephrotoxins can cause direct damage to kidney structures leading to bleeding, damage to several parts of the nephron, tissue oxygen deprivation, and renal failure.

Enzymes   At least 26 different enzymes have been isolated from snake venoms, which are comprised of amino acid sequences

(150–1500) (Ménez, 2003). No single snake venom contains all of the enzymes. Some important snake venom enzymes are shown in Fig. 26-3.

Proteolytic enzymes that catalyze the break down of tissue proteins and peptides include peptide hydrolases, proteases, endopeptidases, peptidases, and proteinases. Several proteolytic enzymes may be in a single venom. The proteolytic enzymes have molecular weights between 20,000 and 95,000. Some are inactivated by ethylenediamine tetraacetic acid (EDTA) and certain reducing agents. Metals appear to be intrinsically involved in the activity of certain venom proteases and phospholipases. The crotalid venoms examined so far appear to be rich in proteolytic enzyme activity. Viperid venoms have lesser amounts, whereas elapid and sea snake venoms have minimal, if any, proteolytic activity. Venoms that are rich in proteinase activity are associated with marked tissue destruction (Russell, 2001).

Collagenase is a specific kind of proteinase that digests collagen. This activity has been demonstrated in the venoms of a number of species of crotalids and viperids. The venom of *Crotalus atrox* digests mesenteric collagen fibers but not other proteins. EDTA inhibits the collagenolytic effect, but not the argine esterase effect.

Hyaluronidase cleaves internal glycoside bonds in certain acid mucopolysaccharides resulting in a decrease in the viscosity of connective tissues. The break down in the hyaluronic barrier allows other fractions of venom to penetrate the tissues, causing hyaluronidase to be called "spreading factor." The degree to which hyaluronidase contributes to the extent of edema produced by the whole venom is not known.

Phospholipase A2 (PLA$_2$s) enzymes are widely distributed throughout the tissues of animals, plants, and bacteria, and have been well studied in snake venoms (Ohno *et al.*, 2003; Soares and Giglio, 2003). Mammalian PLA$_2$ enzymes are involved in fertilization and cell proliferation, and have been implicated in respiratory ailments such as asthma, as well as skin conditions such as psoriasis (Kini, 2003; Soares and Giglio, 2003). PLA$_2$ catalyzes the Ca^{2+}-dependent hydrolysis of the 2-acyl ester bond, producing free fatty acids and lysophospholipids. However, liberation of pharmacologically active products and effects independent of enzymatic action may contribute to their overall action. In general, mammalian PLA$_2$s are considered to be nontoxic and do not elicit the same pharmacologic effects as similar enzymes in snake venoms.

As of 2003, over 280 PLA$_2$ enzymes had been classified, sharing at least 40% identify in their amino acid sequences (Kini, 2003; Soares and Giglio, 2003). Many PLA$_2$s have been sequenced. They have approximately 120 amino acids and 14 cysteine residues forming seven disulfide bonds. Surface residue recognition and covalent/non-covalent bonds stabilize complexes for receptor binding. Specific amino acid residues play an important role in the diversification and overall function of the PLA$_2$s. Of note, histidine, lysine, cysteine, and methionine have been well studied for their contribution to enzyme structure and function (Soares and Giglio, 2003). For example, alkylation of His48 diminishes the hydrolytic capabilities of certain toxins. Alkylation of amino acids has proven to effectively mitigate PLA$_2$ toxicity and has been proposed as an antivenom treatment (Soares and Giglio, 2003). PLA$_2$s interact with

other toxins in the venom as well, often resulting in synergistic reactions. Similarly, snake venom PLA$_2$ enzymes can be separated into three major groupings depending on their pharmacologic activities: low-toxicity enzymes (LD$_{50}$ > 1 mg/kg), high-toxicity enzymes (1 mg/kg > LD$_{50}$ > 0.1 mg/kg), and presynaptically acting toxins (LD$_{50}$ < 0.1 mg/kg) (Rosenberg, 1990). Although the sequences of these enzymes are homologous and their enzymatically active sites are identical, they differ widely in their pharmacologic properties. For example, taipoxin, a PLA$_2$ enzyme from the venom of the Australian elapid *Oxyuranus scutellatus*, has an intravenous LD$_{50}$ in mice of 2 μg/kg, whereas the neutral PLA$_2$ from *Naja nigricollis* has an LD$_{50}$ of 10,200 μg/kg, even though *N. nigricollis* PLA$_2$ is enzymatically more active (Russell, 2001).

Arginine ester hydrolase is one of a number of noncholinesterases found in snake venoms. The substrate specificities are directed to the hydrolysis of the ester or peptide linkage, to which an argine residue contributes the carboxyl group. This activity is found in many crotalid and viperid venoms and some sea snake venoms but is lacking in elapid venoms with the possible exception of *Ophiophagus hannah*. Some crotalid venoms contain at least three chromatographically separable arginine ester hydrolases. The bradykinin-releasing and perhaps bradykinin-clotting activities of some crotalid venoms may be related to esterase activity.

Two distinct classes of fibrin(ogen)olytic enzymes, the metalloproteinases and the serine proteinases, have been isolated from venom of *Viperidae*, *Elapidae*, and *Crotalidae* snake families (Swenson and Markland, 2005). These two classes of proteinases differ in mechanism of action and their target in fibrin(ogen), but ultimately they break down fibrin-rich clots and help to prevent further clot formation. The properties of fibrolase, an α-chain fibrinolytic metalloproteinase from *Agkistrodon contortrix contortrix* venom, and β-fibrinogenase, a β-chain fibrinogenase from *Vipera lebetina*, are provided in Table 26-5. Properties of some newly characterized fibrin(ogen)ases are listed in Table 26-6. It is apparent that there are major differences in the properties of these enzymes from different snakes even though they have similar catalytic properties. An exciting development from the research on these enzymes is that one specific recombinant fibrinolytic enzyme derived from fibrolase called alfimeprase is progressing through clinical trials for the treatment of peripheral arterial occlusions.

The snake venom hemorrhagic metalloproteinases (SVMP) are enzymes that disrupt the hemostatic system and they are characterized by their domain structure into four primary classes, PI–PIV. SMVPs are synthesized in vivo as multimodular proteins that

comprise a signal peptide, a prodomain, and a metalloprotease domain (SVMP PI). SVMP potency tends to increase by class and those within the PIV class are larger and comprises additional disulfide bonds (Calvette *et al.*, 2003, 2005). Class PII proteins exhibit a C-terminal disintegrin domain. The PII metalloproteases block the function of integrin receptors, a function that could alleviate a variety of pathological conditions such as inflammation, tumor angiogenesis and metastasis, and thrombosis. The integrin-blocking specificity of this class of metalloproteins is highly dependent on the conformation of the inhibitory loop, and thus the placement and bonding of cysteine residues. More specifically, within the inhibitory loops, RGD-containing disintegrins are specific to the class PII metalloproteases (Calvette *et al.*, 2003, 2005). Class PIII SVMPs exhibit the disintegrin-like domain and the C-type lectin-like domain is present in PIV SVMPs. The metalloproteinase domain or catalytic domain is composed of about 215 amino acids and has metal-dependent endopeptidase activity (Calvette *et al.*, 2005). SVMPs degrade proteins such as laminin, fibronectin, type IV collagen, and proteoglycans from the endothelial basal membrane; degrade fibrinogen and von Willebrand factor enhancing the hemorrhagic action; and inhibit platelet aggregation and stimulate release of cytokines (Ramos and Selistre-de-Araujo, 2006).

The proteolytic action of thrombin and thrombin-like snake venom enzymes is shown in Table 26-7. This table compares ancrod (from *Calloselasma rhodostoma*), batroxobin (from *Bothrops moojeni*), crotalase (from *Crotalus adamanteus*), gabonase (from *Bitis gabonica*), and venzyme (from *A. contortrix*). Table 26-8 shows the molecular size of some thrombin-like enzymes. A recent contribution on snake toxins, using mass spectrometric immunoassay and bioactive probe techniques, has been published by Ramirez *et al.* (1999). Considerable study has been given to the hemostatic properties of venoms (Markland, 1998). The hemostatically active components are summarized in Table 26-9.

Phosphomonoesterase (phosphatase) is widely distributed in the venoms of all families of snakes except the colubrids. It has the properties of an orthophosphoric monoester phosphohydrolase. There are two nonspecific phosphomonoesterases, and they have optimal pH at 5.0 and 8.5. Many types of venom contain both acid and alkaline phosphatases, whereas others contain one or the other.

Table 26-9
Snake Venom Proteins Active on the Hemostatic System

GENERAL FUNCTIONAL ACTIVITY	SPECIFIC BIOLOGICAL ACTIVITY
Procoagulant	Activates factors II, V, IX, X, and Protein C Fibrinogen clotting
Anticoagulant	Factor IX/factor X-binding protein Thrombin inhibitor Phospholipase A
Fibrinolytic	Fibrin(ogen) degradation Plasminogen activation
Vessel wall interactive	Hemorrhagic

SOURCES: Data from Markland (1998) and Russell (2001).

Phosphodiesterase has been found in the venoms of all families of poisonous snakes. It is an orthophosphoric diester phosphohydrolase that releases 5-mononucleotide from the polynucleotide chain and thus acts as an exonucleotidase, attacking DNA and RNA. More recently, it has been found that it also attacks derivatives of arabinose.

Acetylcholinesterase was first demonstrated in cobra venom and is widely distributed throughout the elapid venoms. It is also found in sea snake venoms but is totally lacking in viperid and crotalid venoms. It catalyzes the hydrolysis of acetylcholine to choline and acetic acid. The role of the enzyme in snake venoms is not clear.

RNase is present in some snake venoms in small amounts as the endopolynucleotidase RNase. It appears to have specificity toward pyrimidine-containing pyrimidyladenyl bonds in DNA. The optimum pH is 7–9 when ribosomal RNA is used as the substrate. This enzyme in *Naja oxiana* venom has a molecular weight of 15,900.

DNase acts on DNA to produce predominantly tri- or higher oligonucleotides that terminate in $3'$ monoesterified phosphate. *C. adamanteus* venom contains two DNases, with optimum pH at 5 and 9.

$5'$-Nucleotidase is a common constituent of all snake venoms; in most instances it is the most active phosphatase in snake venoms. It specifically hydrolyzes phosphate monoesters, which link with a $5'$ position of DNA and RNA. It is found in greater amounts in crotalid and viperid venoms than in elapid venoms. The molecular weight as determined from amino acid composition and gel filtration with *Naja naja atra* venom has been estimated at 10,000. The enzyme from *N. naja* venom is enhanced by Mg^{2+}, is inhibited by Zn^{2+}, is inactivated at 75°C at pH 7.0 or 8.4, and has an isoelectric point of about 8.6. That from *Agkistrodon halys blomhoffi* shows a pH optimum of 6.8–6.9, with activity being enhanced by Mg^{2+} and Mn^{2+} and inhibited by Zn^{2+}. The enzyme has a low order of lethality (Russell, 2001).

Nicotinamide adenine dinucleotide (NAD) nucleotidase has been found in a number of snake venoms. This enzyme catalyzes the hydrolysis of the nicotinamide *N*-ribosidic linkage of NAD, yielding nicotinamide and adenosine diphosphate riboside. Its optimum pH is 6.5–8.5; it is heat labile, losing activity at 60°C. Nucleotidases function as ADP scavengers thereby acting as potent inhibitors of platelet aggregation.

L-Amino acid oxidase has been found in all snake venoms examined so far. It gives a yellow color to the venom. This enzyme catalyzes the oxidation of L-α-amino and α-hydroxy acids. This activity results from a group of homologous enzymes with molec-

ular weights ranging from 85,000 to 150,000. It has a high content of acidic amino acids. The mouse intravenous LD_{50} of the enzyme from *C. adamanteus* venom was 9.13 mg/kg body weight, approximately four times less than the lethal value of the crude venom, and this enzyme had no effect on nerve, muscle, or neuromuscular transmission (Russell, 2001).

Polypeptides Snake venom polypeptides are low-molecular-weight proteins that do not have enzymatic activity. More than 80 polypeptides with pharmacologic activity have been isolated from snake venoms. Interested readers will find definitive reviews on these peptides in the works of Lee (1979), Eaker and Wadström (1980), and Gopalakrishnakone and Tan (1992). Most of the lethal activity of the poison of the sea snake *Laticauda semifasciata* was recovered as two toxins, erabutoxin-a and erabutoxin-b, using carboxymethylcellulose chromatography; 30% of the proteins were erabutoxins. More recently, erabutoxin-a, a short-chain curamimetic, has been crystallized in monomeric and dimeric forms (Nastopoulos *et al.*, 1998). Erabutoxin-b is said to be relatively ineffective at the mammalian neuromuscular junction (Vincent *et al.*, 1998). Another curamimetic, a long-chain polypeptide, is α-cobratoxin, while a novel "neurotoxin" from *N. naja atra,* having 61 amino acid residues and eight cystine residues, has been isolated by Chang *et al.* (1997).

Disintegrins are a family of short cysteine-rich polypeptides and are divided into five subgroups based upon the combination of length and number of disulfide bonds of polypeptides. In general, the disintegrins comprise 40–100 amino acids. Their small size coupled with a relatively dense network of disulfide bonds contributes to the tertiary structure of these compounds and high potency of such small compounds. Disintegrins are released in venoms via proteolytic processes of PII metalloproteinases, whereas structures similar in form and function to disintegrins, or disintegrin like, are subject to PIII processes (Calvette *et al.*, 2005). Monomeric disintegrins can vary from about 50 residues and four disulfide bonds as in echistatin and obtustatin, to around 70 amino acid residues and six disulfide bridges as in albolabrin, barbourin, and halysin, to over 84 amino acids and seven disulfide bonds for bitistatin and salmosin-3. Dimeric disintegrins are about 67 amino acids long and contain four intrachain disulfide linkages and two between-chain bonds. Examples include contortrostatin and acostatin. The monomeric disintegrin-like chemicals contain around 100 amino acids and eight disulfide bonds, and include trimelysin-I, bothropasin, and jararhagin (Calvette *et al.*, 2003; Ramos and Selistre-de-Araujo, 2006).

RGD (argine–glycine–asparagine) and non-RGD-containing disintegrins coexist in certain venoms and exhibit affinities for variable ligand receptors. In such cases, one copy of the gene encodes for the more conserved RGD function of platelet aggregation, whereas the duplicated genes have drifted toward facilitating other biological functions. Modeling and structure analysis of cyclic RGD peptides has implicated the importance of amino acid sequences on the C-terminal of the RGD sequence; furthermore, the physical features such as size of the integrin-binding loop contribute to the receptor-binding capabilities (Calvette *et al.*, 2005). In general, the amino acid residues of this region of the RGD sequence are not well conserved and are believed to play a key role in determining integrin receptor-binding specificity. There are additional mechanisms within the C-terminal region, which include conformational epitopes that are utilized to alter receptor-binding capabilities.

The small basic polypeptide myotoxins are widely distributed in *Crotalus* snake venoms. The specific agent crotamine from *Crotalus durissus terrificus* venom induces skeletal muscle spasms and paralysis by changing the inactivation process of sodium channels, which are inhibited by tetrodotoxin and potentiated by veratridine and grayanotoxin, leading to depolarization of the neuromuscular junction. Crotamine is composed of 42 amino acid residues and three disulfide bonds. The crotamine gene contains 1.8 kbp and has three exons that are separated by a long phase-1 and a short phase-2 intron and mapped to chromosome 2. In addition, the three-dimensional structure has been published, and the structural topology is similar to that of other three disulfide bridge containing peptides such as human β-defensins and scorpion sodium channel toxin. These structural properties enable crotamine to have a unique cell penetrating ability allowing the toxin to concentrate in the nucleus by means of a probable receptor-independent mechanism. It is interesting to note that topology and diversification of functional folds are common themes in animal venom peptides acting on ion channels and other targets (Menez, 1998; Mouhat *et al*., 2004; Oguiura *et al*., 2006).

Toxicology   In general, the venoms of rattlesnakes and other New World crotalids produce alterations in the resistances and often in the integrity of blood vessels, changes in blood cells and blood coagulation mechanisms, direct or indirect changes in cardiac and pulmonary dynamics, and—with crotalids like *C. durrissus terrificus* and *C. scutulatus*—serious alterations in the nervous system and changes in respiration. In humans, the course of the poisoning is determined by the kind and amount of venom injected; the site where it is deposited; the general health, size, and age of the patient; the kind of treatment; and those pharmacodynamic principles noted earlier in this chapter. Death in humans may occur within less than 1 hour or after several days, with most deaths occurring between 18 and 32 hours. Hypotension or shock is the major therapeutic problem in North American crotalid bites (Russell, 2001).

Snakebite Treatment   The treatment of bites by venomous snakes is now so highly specialized that almost every envenomation requires specific recommendations. However, three general principles for every bite should be kept in mind: (1) snake venom poisoning is a medical emergency requiring immediate attention and the exercise of considerable judgment; (2) the venom is a complex mixture of substances of which the proteins contribute the major deleterious properties, and the only adequate antidote is the use of specific or polyspecific antivenom; and (3) not every bite by a venomous snake ends in an envenomation. Venom may not be injected. In almost 1000 cases of crotalid bites, 24% did not end in a poisoning. The incidence with the bites of cobras and perhaps other elapids is probably higher. The reader is referred to other appropriate texts for appropriate treatment of snakebites (Russell, 2001; Dart, 2004; Sholl *et al*., 2004; Tintinalli *et al*., 2004; Singletary and Holstege, 2006).

Snake Venom Evolution   Considerable efforts are being expended to examine the complex process by which snake venom components are thought to have changed over the years. This evaluation involves tracing the ancestral roots of toxins, which is made even more cumbersome due to the distinct differences in the speed at which individual components of a venom evolve. The current assemblage of snake venoms with regard to functionality and ancestral protein

Table 26-10
Basal Bioactivities of Some Toxin Types

TOXIN	ACTIVITY
3FTx	α-Neurotoxicity, blocks nicotinic acetylcholine receptor
ADAM	In Viperidae venoms, proteolytic cleavage of C-terminal domains results in direct fibrinolytic activity, liberation of disintegrins, which inhibit platelet aggregation
Cobra venom factor	Causes unregulated activation of complement cascade, hemolysis, cytolysis
Crotamine	Myonecrosis, modifies voltage-gated sodium channels
Factor V	In taipan and brown snake venom, combines with toxic form of factor X to convert prothrombin to thrombin
Kallikrein	Increases vascular permeability, stimulates inflammation, and reduces blood pressure
Kunitz	Inhibits plasmin and thrombin and other serine proteases, blocks L-type calcium channels
L-AMINO OXIDASE	Induces apoptosis, decreases platelet aggregation, inhibits blood factor IX
PLA$_2$	Releases arachadonic acid from phospholipids, resulting in inflammation and tissue destruction
VEGF	Increases permeability of vascular bed causing hypotension and shock
Whey acidic proteins	Inhibit leukoproteinases

SOURCE: Data from Fry (2005).

activity is outlined in Table 26-10 (Fry, 2005). In general, the toxins from ancestral proteins that were constructed of dense networks of cysteine cross-linkages are considered among the most diverse today in terms of toxicological insult.

Recent thinking suggests that the evolution of the PLA$_2$s appears to be directed toward modifying the molecular surface in order to maximize the diversity of the pharmacologic properties of each isozyme component (Kini and Chan, 1999; Li *et al*., 2005). As PLA$_2$s are not crucial for snake survival, mutations in some PLA$_2$ isozymes may be ignored and allowed to progress, thereby expediting the evolution in comparison to other more critical enzymes in which mutations are monitored more closely and not allowed to progress. The functionality of PLA$_2$ isozymes can be significantly hindered by increased rates of mutations within highly conserved regions of the amino acid sequence, which could in turn displace cysteine residues and alter the tertiary protein structure. However, increased mutation of a particular subset of enzymes, such as the PLA$_2$s, may be a result of a shift in ecological niche. A recent study (Li *et al*., 2005) reports a shift in the diet composition of the marbled sea snake as the root cause of decelerated evolution of the PLA$_2$ enzymes. The diet change from live prey to fish eggs essentially negated the need for PLA$_2$ enzymes to immobilize live prey for swallowing and digestion. Future research could focus on

the declining need for PLA$_2$s, and on the altered digestive enzyme composition that has likely occurred as a result of diet shift.

ANTIVENOM

Antivenoms have been produced against most medically important snake, spider, scorpion, and marine toxins. Animals immunized with venom develop a variety of antibodies to the many antigens in the venom. Antivenom consists of venom-specific antisera or antibodies concentrated from immune serum to the venom. Antisera contain neutralizing antibodies: one antigen (monospecific) or several antigens (polyspecific). Monovalent antivenoms have a high neutralization capacity, which is desirable against the venom of a specific animal. Polyvalent antisera are typically used to cover several venoms, such as snakes from a geographic region. Polyvalent preparations usually required higher doses or volumes than monovalent antivenoms. Neutralization capacity of antivenom is highly variable as there are no enforced international standards. Antivenom may cross-react with venoms from distantly related species and may not react with venom from the intended species. Nevertheless, in general, the antibodies bind to the venom molecules, rendering them ineffective.

Antivenoms are available in several forms: intact IgG antibodies or fragments of IgG such as F(ab)$_2$ and Fab. The molecular weight of the intact IgG is about 150,000, whereas that of Fab is approximately 50,000. The molecular size of IgG prevents its renal excretion and produces a volume of distribution much smaller than that of Fab. The elimination half-life of IgG in the blood is approximately 50 hours. Its ultimate fate is not known, but most IgG is probably taken up by the reticuloendothelial system and degraded with the antigen attached. Fab fragments have an elimination half-life of about 17 hours, and are small enough to permit renal excretion.

All antivenom products may produce hypersensitivity reactions. Type I (immediate) hypersensitivity reactions are caused by antigen cross-linking of endogenous IgE bound to mast cells and basophils. Binding of antigen by a mast cell may cause the release of histamine and other mediators, producing an anaphylactic reaction. Once initiated, anaphylaxis may continue despite discontinuation of antivenom administration. Type III hypersensitivity (serum sickness) may develop several days after antivenom administration. In these cases, antigen–antibody complexes are deposited in different areas of the body, often producing inflammatory responses in the skin, joints, kidneys, and other tissues. Fortunately, these reactions are rarely serious. The risks of anaphylaxis should always be considered when one is deciding whether to administer antivenom, and thus antivenom should be given only by intravenous infusion under medical supervision (Heard *et al*., 1999; Russell, 2001; Mebs, 2002; Dart, 2004; Tintinalli *et al*., 2004).

POTENTIAL CLINICAL APPLICATION OF VENOMS

Animal venoms are being used as research and clinical tools based upon their high affinity for specific targets and well-studied pharmacologic properties (Menez, 1998, 2003; Dimarcq and Hunneyball, 2003; Escoubas and Rash, 2004). Toxin specificities for receptors and channels that facilitate the interface and coordination of neuromuscular activity are utilized and manipulated to study, model, diagnose, and sometimes treat acute and degenerative conditions. Upon closer examination of α-bungarotoxin and candoxin nicotinic acetylcholine receptor specificity, plans are under way to utilize the reversible and irreversible receptor binding in muscular and neuronal tissues, respectively, in Alzheimer's patients (Phui Yee *et al*., 2004). In addition to treating neurological diseases, specific α-toxins (longer chained) are also studied for their anti-angiogenic capabilities in treating malignant tumor growth in patients suffering from small cell lung carcinoma (Tsetlin and Hucho, 2004). In cases such as this, there is an inherent trade-off between promoting some degree of neurological deficit in light of combating tumor growth. Toxins such as the snake venom thrombin-like enzymes are valuable tools in both research and therapeutic applications. Similarly, fibrin(ogen)olytic enzymes break down fibrin-rich clots preventing further clot formation may be useful as controls in blood clotting research or to treat heart attacks and strokes (Castro *et al*., 2004; Marsh and Williams, 2005; Swenson and Markland, 2005). To facilitate research, the complement-activating cobra venom factor has been produced by recombinant techniques (Vogel *et al*., 2004). These pharmazooticals include reptilase-R, bothrocethin, stypven, ecarin, and protac.

Other areas of active research indicate that animal venoms contain components that can reduce pain, can selectively kill specific cancers, may reduce the incidence of stroke via effects on blood coagulability, and function as antibiotics. For example, epibatidin comes from the skin of the South American frog, *Epipedobates tricolor*, and a synthetic derivative ABT-594 appears to be more effective than morphine without being addictive. TM 601 is derived from the Israeli yellow scorpion and attacks malignant brain tumors called glioma tumors responsible for two-thirds of the cases of brain cancer, without harming healthy cells. ET 743, which comes from sea squirts, is being tested for treatment of ovarian cancer and soft tissue sarcoma. Ancrod is an anticoagulant with potential to prevent cell damage and death when someone suffers a stroke. The active ingredient comes from the venom of the Malaysian pit viper. In Germany, where Ancrod has been marketed for a number of years, a specially built facility houses about 3000 snakes. Several other sources of anticoagulants are being examined. A substance called magainin 2, which comes from the skin of frogs, is an effective antibiotic to which bacteria do not appear to develop resistance. The clotting enzyme batroxobin is an ingredient in reptilase and has been used in the development of fibrin glue, which is used in surgery to stop diffuse bleeding from liver or lung by covering the surface with a thin layer of fibrin.

Another major area of investigation and success involves the venom components that act as enzyme inhibitors. In particular, venom peptides from *Bothrops jararaca* were initially called bradykinin-potentiating peptides and lowered blood pressure. After further research, it became clear that these peptides were inhibitors of angiotensin I-converting enzyme, and chemical modification lead to orally active agents such as captopril.

Venom toxins can also be used as a component of the toxin–receptor–antibody complex for diagnosis of autoimmune disorders (Ménez, 2003). In addition to providing a promising means for researching and treating muscular and neurological diseases and cancer, work is being conducted on designing methods by which to consistently reconstruct and conform the overall toxin structure to bind to a specific protein, such as HIV (Ménez, 2003).

Additional work is being conducted on animals such as the mongoose, hedgehog, and opossum, which all embody a high level of resistance to snake bites. Blood from these animals contains proteins between 400 and 700 amino acids long that inhibit hemorrhagins. The exact mechanism of the many components in animal

venoms that produce toxicity or resistance to certain toxins has yet to be determined. Further research will require a multidisciplinary approach involving techniques from parasitology, chemistry, molecular biology, genomics, proteomics, physiology, pharmacology, and toxicology.

CHAPTER 27

TOXIC EFFECTS OF PLANTS

Stata Norton

</div>

INTRODUCTION

Plants may cause toxic effects as a result of inadvertent exposure on contact or accidental ingestion of the plant. Examples are "hay fever" (rhinitis) from exposure to airborne plant pollen and oral irritation, especially in children, from biting on a leaf of a plant such as dumb cane (Diffenbachia). Another source of toxicity may be from intentional ingestion of some herbs, especially when they are taken chronically. The possibility also exists for interactions of prescribed drugs with intake of herbal remedies. For example, the chemicals in some herbs affect hepatic cytochrome enzymes (Izzo and Ernst, 2001).

In recent years, information on bioactive chemicals in plants has grown steadily, partly from increased interest in herbal remedies and from interest in identifying novel approaches to medical problems. One result of the latter interest is that toxic effects of plants are being examined for potential usefulness in cancers. This chapter will be restricted primarily to consideration of the toxic effects of plants from unintentional exposure and some intentional exposures, with only brief mention of possible value of toxic bioactive components.

In the course of evolution, plants have been attacked by viruses, bacteria, and fungi, and have been eaten by animals of many kinds. In response, plants have developed various elegant defenses, including synthesis of antimicrobial chemicals and chemicals designed to repel animals by various means. Of the many species of plants that contain toxic chemicals, only a few can be described here. Selection is based on three considerations: frequency with which exposure occurs; importance and seriousness of the exposure; and the scientific understanding of the nature of the action of the chemical.

In considering any chemical synthesized by a plant it is important to note that there may be marked variability in the amount of a toxic chemical produced by a plant. The reasons for variability in concentration of toxic chemicals are several:

1. Different portions of the plant may contain different concentrations of a chemical. An example of localization of bioactive compounds is found in the bracken fern (*Pteridium aquilinum*) in which the carcinogenic terpene, ptaquiloside, is found in high concentrations in the fronds compared with the roots (Rasmussen *et al*., 2003).
2. The age of the plant contributes to variability. Peak concentrations of bioactive compounds often are found at different periods of growth. For example, in lettuce (*Lactuca* species) the concentration of lactucin and other sesquiterpenes increases with maturation, reaching a peak in the latex when the flower stalk is forming (Sessa *et al*., 2000).
3. Climate and soil influence the synthesis of some chemicals. For example, lichens produce carotenoids in direct relation to the amount of sunlight, with the advantage to the plant that carotenoids protect from excessive ultraviolet light.

4. Genetic differences within a species alter the ability of plants to synthesize a chemical. Synthesis of related toxic chemicals is found in some plants as a characteristic of a genus and sometimes as a familial characteristic. For example, species of *Raunculus* (buttercup) produce an acrid juice that releases the irritating chemical, anemonin. Some other genera of the same family (Ranunculaceae) also release anemonin.

TOXIC EFFECTS BY ORGAN

Skin

Contact Dermatitis   Several plants that are common to the temperate regions worldwide contain compounds that produce irritation on contact with the intact plant. The leaves of stinging nettles (*Urtica* species, Urticaceae) bear numerous trichomes, barb-like silicified hairs that puncture skin on contact, releasing an irritating sap. The sap has been reported to contain a mixture of formic acid, histamine, acetylcholine, and serotoin (Kavalali, 2003). Although there are about 100 species of *Urtica* worldwide, *Urtica dioica* and *Urtica urens* are the most common in the United States and Europe and *Urtica ferox* is widespread in New Zealand. Exposure to *U. ferox* (poisonous tree nettle) has caused death in humans and animals. A defense by the plant against ingestion by animals, similar to that of nettles, has been developed by *Mucuna pruriens* (cowhage), a legume with pods covered with barbed trichomes that cause pain, itching, erythema, and vesication. The trichomes contain mucinain, a proteinase responsible for the pruritis (Southcott and Haegi, 1992).

Several species of *Ranunculus* (buttercup) cause contact dermatitis. These plants contain ranunculin, which releases the toxic principle protoanemonin, also present in *Anemone,* another genus of the buttercup family. Protoanemonin is readily converted to anemonin, which has marked irritant properties. In addition to contact dermatitis, ingestion of plants containing protoanemonin may result in severe irritation of the gastrointestinal tract (Kelch *et al.*, 1992).

The genus *Euphorbia* (Euphorbiaceae, spurge family) contains hundreds of species dispersed over temperate and tropical regions. Characteristically, the stems and leaves exude milky latex when damaged. The latex contains diterpene esters that are irritating to the skin. *Euphorbia marginata* (snow-on-the mountain) is a common plant in the United States, growing wild from Minnesota to Texas and cultivated for its attractive foliage. Individuals using the plant in flower arrangements may come in contact with the latex and develop skin irritation (Urushibata and Kase, 1991). Serious eye irritation has been reported (Frohn *et al.*, 1993). The latex of cultivars of *Euphorbia pulcherrima* (poinsettia) may cause contact dermatitis (Massermanian, 1998).

Allergic Dermatitis   Most people are familiar with allergic dermatitis caused by contact with some plants, such as poison ivy. These allergens tend to be located in the outer cell layers of plant organs. In allergic dermatitis to chrysanthemums (*Dendranthema* species) the allergens are sesquiterpene lactones present in small hairs (trichomes) on the stems, undersides of leaves and in flowering heads (McGovern and Barkley, 1999).

Rhus (Anacardiaceae, cashew family) and *Philodendron* (Araceae, arum family) are not closely related plants but both genera contain species causing contact dermatitis as an allergic reaction. *Philodendron scandens* is a common houseplant, while *Rhus radicans* (poison ivy) is widespread in North America. In addition to poison ivy, the toxicodendron group of plants contains *Rhus diversiloba* (poison oak) and *Rhus vernix* (poison sumac). The active chemicals in *P. scandens* are resorcinols, especially 5-*n*-heptadecatrienyl resorcinol (Knight, 1991). In *R. radicans* the allergenic component is a mixture of catechols called urushiol. The most active compound in urushiol is 3-*n*-pentadecadienyl catechol, representing about 60% of urushiol (Johnson *et al.*, 1972). As in allergies in general, there is no response to the initial exposure; even with repeated exposure, individuals show marked variation in severity of response. The allergens in usushiol will sensitize about 70% of persons exposed. Urushiol is fat soluble, penetrates the stratum corneum and binds to Langerhans cells in the epidermis. These haptenated cells then migrate to lymph nodes, where T-cells are activated (Kalish and Johnson, 1990). Ingestion of *Rhus* species has been reported to cause generalized dermatitis (Oh *et al.*, 2003). Allergic dermatitis may also develop with repeated exposure to the sap of the mango fruit. The skin of the mango (*Magnifera indica*, Anacardiaceae) contains oleoresins that cross-react with allergens of poison ivy (Tucker and Swan, 1998).

Flower growers and other individuals who handle bulbs and cut flowers of daffodils, hyacinths, and tulips sometimes develop dermatitis from contact with the sap. The rashes are due to irritation from alkaloids (masonin, lycorin, and several related alkaloids) or to needle-like crystals of calcium oxalate in the bulbs (Gude *et al.*, 1998). Most of these chemicals do not act as allergens but one, tulipalin-A, that causes "tulip fingers" from sorting and peeling tulip bulbs, has allergenic properties. Tulipalin-A, alpha-methylene-gamma-butyrolactone, is present in some cultivars in concentrations up to 2%. A safe threshold for this allergen is considered to be 0.01% (Hausen *et al.*, 1983). The advantage of the tulipalins to the plant is that they are strong antifungal agents (Christensen and Kristiansen, 1999).

An immunoglobulin-mediated hypersensitivity, called the "latex-fruit syndrome," results in cross-sensitivity in some individuals to latex in rubber gloves and some fruits. The major allergen in natural rubber latex from the tree, *Hevea brasiliensis*, is prohevein, a chitin-binding polypeptide found in several plants. Hevein, a 43-amino acid N-terminal fragment of prohevein is the major binding component. The structural analysis has been reported (Kolarich *et al.*, 2005). Individuals sensitive to rubber latex may be sensitized to fruits containing a chitinase with a hevein-like domain, including banana, kiwi, tomato, and avocado (Blanco *et al.*, 1999).

Lichens, such as species of *Usnea* and *Cladonia*, are abundant on trees in areas away from major city smog. Dermatitis from contact with lichens is known in professions where individuals are repeatedly exposed to lichens, including workers in forestry and horticulture. The allergen is usnic acid (a benzofuran) and related acids in lichens (Aalto-Korte *et al.*, 2005). Usnic acid is of current research interest as a non-genotoxic anticancer agent (Mayer *et al.*, 2005b). Usnic acid has been implicated in hepatotoxicity following use of some nonprescription weight-loss supplements (Han *et al.*, 2004).

Photosensitivity   Not all cases of dermititis from plants are due to skin contact. Poisoning of livestock from *Hypericum perforatum* (St. John's wort) has been reported from several countries. The toxic principle is hypericin (a bianthraquinone), present throughout the plant. Sheep are the most commonly affected animals, ingesting the plant in pasturage. The effect in sheep is development of edematous lesions of the skin in areas not well covered with hair, including the ears, nose, and eyes. Hypericin causes photosensitization and the lesions appear from exposure to sunlight (Sako *et al.*, 1993).

Although photosensitization in humans is a rare event after consumption of St. John's wort, enhancement of response in humans to therapeutic exposure to ultraviolet therapy has been reported (Beattie *et al*., 2005).

Respiratory Tract

Allergic Rhinitis Rhinitis from inhalation of plant pollens, also known as "hay fever" or pollinosis, is a seasonal problem for many individuals. A chromosomal association in individuals with seasonal pollen reactivity is under investigation (Blumenthal *et al*., 2006). Many plant species contribute to airborne pollen, especially grass pollens. *Poa* and *Festuca* species are major contributors to the allergic response. Pollen from several genera in the Asteraceae (e.g., mugwort, *Artemisia vulgaris,* in Europe, and ragweed, *Ambrosia artemisiifolia,* in North America) contains allergens causing summer rhinitis. Immunoglobulin antibodies produced by sensitized individuals from the two species cross react. The allergen has been identified as a highly conserved 14-kDa protein, profilin, found as well in birch pollen (Hirschwehr *et al*., 1998). Pollen from pellitory (*Parietaria* species, Urticaceae) is an important cause of pollinosis in the Mediterranean region (Arilla *et al*., 2006). Asthma and rhinitis associated with occupation are also recognized in individuals exposed to certain plants, such as cascara sagrada (*Rhamnus purshiana*) (Giavina-Bianchi *et al*, 1997), or workers in greenhouses in which bell peppers are growing (Groenewoud *et al*., 2006).

Cough Reflex It has been found that workers who handle two types of peppers, *Capsicum annuum* (sweet pepper) and *Capsicum frutescens* (red pepper), have a significantly increased incidence of cough during exposure. The major irritants are capsaicin (*trans*-8-methyl-*N*-vanillyl-6-nonenamide) and dihydrocapsaicin (Surh *et al*., 1998). Capsaicin-sensitive nerves in the airway are involved in the irritation and cough (Blanc *et al*., 1991). Capsaicin activates a subtype of the vanilloid receptor found in the airway, spinal cord, dorsal root ganglion, bladder, urethra, and colon. Capsaicin can also be irritating to the skin, and individuals handling the peppers may experience irritation and vesication.

Toxin-Associated Pneumonia The formation of the pneumotoxin, 4-ipomeanol, in sweet potato roots (*Ipomea batatas*, Convolvulaceae) from the mold *Fusarium solani* has been known for some time. The toxin 4-ipomeanol is activated by human cytochrome *P*450s to a reactive intermediate that binds to DNA (Alvarez-Diez and Zheng, 2004). Differences in the pattern of organ toxicity are related to *P*450 isoforms. In cattle and rabbits, the major *P*450 activator is CYP4B1 in the lung. In the mouse, renal toxicity results from high levels of CYP4B1 in the kidney and in humans multiple subsets of liver *P*450 enzymes bioactivate 4-ipomeanol (Baer *et al*., 2005). Fungal pneumonia from *Acremonium strictum* has been reported (Pusterla *et al*., 2005).

Pyrrolizidine alkaloids in Boraginaceae and Asteraceae families of plants have been implicated in lung toxicity and pneumonitis in humans (Altamirano *et al*., 2005).

Gastrointestinal System

Direct Irritant Effects The most common outcome of ingestion of a toxic plant is gastrointestinal disturbance (nausea, vomiting, and diarrhea) from irritation of the gastrointestinal tract. Many kinds of chemicals may be responsible for this. Some have found a place in medicine as mild purgatives, such as cascara sagrada. Cascara is obtained from the bark of *Rhamnus purshiana* (California buckthorn). The active ingredient is an anthraquinone, emodin.

Tung nut (*Aleurites fordii*) is grown widely in the world. The seeds, from which commercially useful oil is expressed, are the most toxic part. Ingestion of the ripe nuts causes abdominal pain, vomiting, and diarrhea. Outbreaks of poisoning are most common in children (Lin *et al*., 1996).

Buffalo bean or buffalo pea (*Thermopsis rhombifolia*) is a legume growing wild in western United States. Loss of life in livestock has been reported from consumption of the mature plant with seeds. Children develop nausea, vomiting, dizziness, and abdominal pain from eating the beans (McGrath-Hill and Vicas, 1997). The toxic chemicals are quinolizidine alkaloids.

Aesculus hippocastanum (horse chestnut) and *Aesculus glabra* (Ohio buckeye) are common trees with attractive panicles of flowers in the spring. Nuts of both trees contain a glucoside called esculin. When eaten by humans, the main effect is gastroenteritis, which may be severe if several nuts are consumed. Esculin is poorly absorbed from the gastrointestinal tract of humans and its systemic effects are usually limited. In cattle the glucoside may be hydrolyzed in the rumen, releasing the aglycone to cause systemic effects. Cattle develop signs of nervous system stimulation—a stiff-legged gait and, in severe poisoning, tonic seizures with opisthotonus (Casteel *et al*., 1992). While the most common poisoning of cattle occurs from ingestion of nuts, they may also be poisoned in pasture in spring from eating new leaves and buds. Beta-aescin, a triperpene saponin in horse chestnut seed extract, has been studied for use in chronic venous insufficiency in humans (Siebert *et al*., 2002).

Antimitotic Effects *Podophyllum peltatum* (May apple, Berberidaceae) contains the toxic purgative, podophyllotoxin, especially in foliage and roots. In low doses, mild purgation predominates. Overdose results in nausea and severe paroxysmal vomiting (Frasca *et al*., 1997). Podophyllotoxin inhibits mitosis by binding to microtubules, and this property has made the toxin of interest in treatment of cancer (Schacter, 1996).

Colchicine is best known in western medicine for its antimitotic effect, resulting from block of formation of microtubules and failure of the mitotic spindle, for which it is useful in attacks of gout. Colchicine is the major alkaloid in the bulbs of *Colchicum autumnale* (autumn crocus, Liliaceae), native to Asia Minor. Severe gastroenteritis (nausea, vomiting, diarrhea, and dehydration) follows ingestion of the bulbs that may be mistaken for wild garlic. Systemic effects (confusion, hematuria, neuropathy, and renal failure) may develop in severe poisoning. Bone marrow aplasia results from block of mitosis in bone marrow. Additional toxic effects may be due to lectins in the plant. In southern Europe, hay for cattle may contain the wild autumn crocus, and deaths occur if contamination is heavy.

Toxicity from human ingestion of tubers of *Gloriosa superba* (glory lily) similar to that from autumn crocus has been reported. This ornamental lily also contains colchicine. The plant grows wild in Sri Lanka and poisoning by *Gloriosa* tubers has been reported as the most common plant poisoning in that country. Poisoning has also been reported in India (Mendis, 1989).

Protein Synthesis Inhibition Some of the most toxic plant proteins act through inactivating protein systhesis. *Ricinus communis*

(castor bean) is a member of the family Euphorbiaceae, which contains several genera that produce toxic chemicals. The castor bean is an ornamental plant introduced from India. If the attractive, mottled seeds are eaten, children and adults experience no marked symptoms of poisoning for several days. In this interval there is some loss of appetite, with nausea, vomiting, and diarrhea developing gradually. With fatal doses the gastroenteritis becomes severe, with persistent vomiting, bloody diarrhea, and icterus. Death occurs in 6–8 days. The fatal dose for a child can be five to six seeds; it may be as low as 20 seeds for an adult. However, fatality is low— less than 10% when a "fatal" dose is consumed—because the toxic protein is largely destroyed in the intestine. Death from castor beans is caused by two lectins in the beans: ricin I and ricin II. The more toxic is ricin II. Ricin II consists of two amino acid chains. The A-chain (molecular weight 30,000) inactivates the 60s ribosomal subunit of cells by catalytic depurination of an adenosine residue within the 28s rRNA (Bantel *et al.*, 1999) and blocks protein synthesis. The A-chain is endocytosed into the cell cytosol after the B-chain (molecular weight 30,000) binds to a terminal galactose residue on the cell membrane. The two chains are linked by disulfide bonds. Details of binding properties of ricin to glycoproteins have been investigated (Wu *et al.*, 2006).

Toxic lectins are found in the seeds of *Abrus precatorius* (jequirity bean, Leguminosae). They are attractive scarlet and black beans that are sometimes made into necklaces. Abrin-a, one of four isoabrins from the plant, has the highest inhibitory effect on protein synthesis and consists of an A-chain of 250 amino acids and a B-chain of 267 amino acids (Tahirov *et al.*, 1994). The LD50 of abrin injected in mice is less than 0.1 μg/kg, making abrin one of the most toxic substances known. As with ricin, the A-chain inhibits protein synthesis and the B-chain is responsible for penetration of abrin-a molecules into cells (Ohba *et al.*, 2004).

Plants that produce only A-chains offer much less risk when ingested. Young shoots of pokeweed (*Phytolacca americana,* Phytolaccaceae) are sometimes used in the spring as a salad green without toxicity. Mature leaves and berries may cause gastrointestinal irritation with nausea and diarrhea. The plant produces three isozymes of single-chain lectins (PAP, PAPII, and PAP-S; molecular weight of about 30,000) that can inhibit protein synthesis in cells by inactivating rRNA. Single-chain, ribosome-inhibiting proteins do not enter intact cells readily, but if the cell membrane has been breached by a virus, they may enter the cell (Monzingo *et al.*, 1993).

Wisteria floribunda (Leguminosae) is a common ornamental climbing vine or small tree with lilac-colored flowers from which pods with seeds develop in the fall. The seeds of wisteria cause severe gastroenteritis when ingested. A few seeds can result in headache, nausea, and diarrhea within hours, followed by dizziness, confusion, and hematemesis (Rondeau, 1993). The seeds contain a lectin with affinity for *N*-acetylglucosamine on mammalian neurons.

Cardiovascular System

Cardioactive Glycosides   Several different families of plants contain species with cardioactive glycosides, the best known of which is *Digitalis purpurea* (foxglove, Scrophulariaceae). In the lily family, squill (*Scilla maritima*) contains scillaren, and lily of the valley (*Convallaria majalis*) contains convallatoxin in the bulbs. Both glycosides have actions resembling digitalis. Milkweeds (*Asclepias* species, Asclepiadaceae) are noted for the glycosides in the plants, which are consumed by monarch butterfly caterpillars during their development. The glycosides are retained into the adult stage and

help protect the butterflies from predators. The cardiac glycoside [6′-O-(E-4-hydroxycinnamoyl) desglucouzarin] in *Asclepias asperula*, like digitalis, inhibits Na$^+$, K$^+$-ATPase (Abbott *et al.*, 1998). Other species of *Asclepias* also contain cardenolides (Roy *et al.*, 2005). Two plants in the Apocynaceae (oleander family) contain cardioactive glycosides. *Nereum oleander* (bay laurel) is native to the Mediterranean area but is grown ornamentally in many regions. The major glycosides, oleandrin and nerium, may be present in concentrations as high as 0.5 mg/g plant material. The blood level of oleandrin estimated to be toxic to humans is 1–2 ng/mL (Pietsch *et al.*, 2005). In addition to cardiac effects resembling digitalis toxicity, histopathological changes after fatal doses of *N. oleander* leaves to sheep include hemorrhages in several organs (Aslani *et al.*, 2004). A related plant, *Thevetia peruviana* (yellow oleander), is a common ornamental plant in the United States. Human poisoning has also been reported in Australia, Melanesia, Thailand, and India. The seeds are the major source of the cardiac glycosides, the most active of which is thevetin A. The fatal dose to an adult is eight to 10 seeds (Prabhasankar *et al.*, 1993).

Actions on Cardiac Nerves   *Veratrum viride* (American hellebore, Liliaceae), native to eastern North America, produces several toxic alkaloids that are distributed in all parts of the plant. European hellebore (*Veratrum album*) and *Veratrum californicum* in western North America have similar alkaloids. *V. album* was one of the medicinal drugs used for centuries to "slow and soften the pulse." These species of *Veratrum* contain a mixture of alkaloids, including protoveratrine, veratramine, and jervine. After ingestion the alkaloids cause nausea, emesis, hypotension, and bradycardia. The primary effect on the heart is to cause a repetitive response to a single stimulus resulting from prolongation of the sodium current (Jaffe *et al.*, 1990). The bulbs of the wild camas (*Zigadenus paniculatus* and other species of *Zigadenus*, Liliaceae) have been ingested by mistake as wild onions. Severe gastrointestinal toxicity may result (Peterson and Rasmussen, 2003). Cattle are also poisoned in pastures where the plants are common. Several species of *Zigadenus* contain veratrum-like alkaloids.

Aconitum species have been used in western and eastern medicine for centuries. The European plant, *Aconitum napellus* (monkshood, Ranunculaceae) is a perennial grown in gardens for its ornamental blue flowers. The roots of *A. kusnezoffii* (chuanwu) and *A. carmichaeli* (caowu) are in the Chinese materia medica. Poisoning may occur from intentional or accidental ingestion, and the concentration of the alkaloids (aconitine, mesaconitine, and hypoaconitine) varies depending on species, place of origin, time of harvest, and processing procedures (Chan *et al.*, 1994). In addition to cardiac arrhythmias and hypotension, the alkaloids cause gastrointestinal upset and neurologic symptoms, especially numbness of the mouth and paresthesia in the extremities. The alkaloids cause a prolonged sodium current in cardiac muscle with slowed repolarization (Peper and Trautwein, 1967). The neurologic effects are due to a similar action on voltage-sensitive sodium currents in nerve fibers (Murai *et al.*, 1990).

In Greece about 2500 years ago, Xenophon described a serious condition called "mad honey poisoning" that developed in his soldiers after they had eaten honey contaminated with grayanotoxins. The poisoning resembles aconitine poisoning. In severe poisoning there is respiratory depression and loss of consciousness. Grayanotoxins bind to sodium channels in cardiac and muscle cells, increasing sodium conductance (Maejima *et al.*, 2002). Grayanotoxins are

produced exclusively by several genera of Ericaceae (heath family). They have been isolated from *Rhododendron ponticum* (Onat *et al.*, 1991) and *Kalmia angustifolia* (Burke and Doskotch, 1990). The toxin gets into honey from nectar collected by bees. Grayanotoxins are present throughout the plants. The effect of the toxins is marked bradycardia, hypotension, oral paresthesia, weakness, and gastrointestinal upset, resembling aconitine poisoning. Grayanotoxins bind to sodium channels in cardiac and muscle cells, increasing sodium conductance (Maejima *et al.*, 2002). Toxicity has been reported in goats and in sheep eating leaves of *Rhododendron macrophyllum* (Casteel and Wagstaff, 1989).

Vasoactive Chemicals   Mistletoe is a parasitic plant on trees and has over the centuries been considered either holy or demonic. The poisonous qualities of mistletoe were recognized by John Gerard in his herbal in 1597. He described a case of poisoning from mistletoe berries in which the tongue was inflamed and swollen, the mind dostraught, and strength of heart and wits enfeebled. The American mistletoe, *Phoradendron flavescens*, is a member of the same family as the European mistletoe (*Viscum album,* Loranthaceae). The American mistletoe contains phoratoxin, a polypeptide with a molecular weight of about 13,000. Phoratoxin and the viscotoxins cause similar effects: hypotension, bradycardia with negative inotropic actions on heart muscle, and vasoconstriction of the vessels of skin and skeletal muscle. Viscotoxins are basic polypeptides (molecular weight of about 5000). Phoratoxin is only one-fifth as active as the viscotoxins (Rosell and Samuelsson, 1988). Serious poisoning from the plants is rare, and most poisonings include gastrointestinal distress and hypotension. An instance of anaphylaxis to repeated injections of mistletoe extract has been reported (Bauer *et al.*, 2005).

Vasoconstriction is the primary toxic effect of some plant chemicals. Of the various fungi that produce toxic principles, some develop on grains that are used as food. *Claviceps purpurea* (ergot) is a fungus parasitic on grains, especially on rye. The "ergot gene cluster" of several genes is required for production of ergot alkaloids (Haarmann *et al.*, 2005). Ergot has caused outbreaks of poisonings in several European countries since the Middle Ages. The condition was called "St. Anthony's fire" from the blackened appearance of the limbs of some sufferers. The main toxic effect of ergot alkaloids is vasoconstriction, primarily in the extremities, followed by gangrene. Abortion in pregnant women is also common after ingestion of contaminated rye flower. Ergot alkaloids are derivatives of lysergic acid. Some of the alkaloids have been used in therapeutics, especially ergotamine and ergonovine. Ergot alkaloids are produced by some other fungi not closely related to *Claviceps*, such as *Aspergillus fumigatus*, a common airborne fungus (Coyle and Panaccione, 2005).

Another fungus, *Acremonium coenophialum,* grows symbiotically on the forage grass tall fescue (*Festuca arundinacea*) and produces some ergot alkaloids and other lysergic acid derivatives. The fungus causes "fescue toxicosis" in cattle grazing on infected plants (Hill *et al.*, 1994). The condition in cattle includes decreased weight gain, decreased reproductive performance, and peripheral vasoconstriction. In southwestern United States, *Stirpa robusta* (sleepy grass) also may be infected with an *Acremonium* fungus. Horses grazing on infected grass become somnolent, presumably as a result of ingesting lysergic acid amide, ergonovine, and related alkaloids produced by the fungus (Petroski *et al.*, 1992).

LIVER

Hepatocyte Damage   *Senecio* (groundsel, Asteraceae) is a large genus of plants with worldwide distribution. Species containing significant concentrations of pyrrolizidine alkaloids are responsible for liver damage in the form of hepatic veno-occlusive disease associated with lipoperoxidation (Bondan *et al.*, 2005). Hepatitis in cattle grazing on *Senecio* has been reported in Africa and Asia as well as in the United States. The condition is progressive and death occurs after weeks or months of grazing on contaminated pasture. Four genera of Boraginaceae, *Echium* (bugloss), *Cynoglossum* (hound's tongue), *Heliotropium* (heliotrope), and *Symphytum* (comfrey) also contain pyrrolizidine alkaloids. Different animal species show marked differences in susceptibility to the alkaloids. Susceptible species are rats, cattle, horses, and chickens; resistant species are guinea pigs, rabbits, gerbils, hamsters, sheep, and Japanese quail. These differences are in general related to the rate of hepatic pyrrole formation, although other sources of differences must be present (Huan *et al.*, 1998). Human deaths from pyrrolizidine alkaloids have been reported in several countries, including South Africa, Jamaica, and Barbados. In Afghanistan, there was an epidemic of hepatic veno-occlusive disease from consumption of a wheat crop contaminated with seeds of a species of *Heliotropium* (Tandon *et al.*, 1978). The clinical signs associated with the liver damage resemble those of cirrhosis and some hepatic tumors may be mistaken for the hepatotoxicity (McDermott and Ridker, 1990). The clinical condition is a form of the Budd–Chiari syndrome, with portal hypertension and obliteration of small hepatic veins. Human consumption also occurs from *Symphytum* in herbal preparations, such as "comfrey tea" (Rode, 2002). In addition to veno-occlusive damage to the liver, the alkaloids in *Symphytum* have been shown to be tumorigenic and mutagenic in rats (Mei *et al.*, 2005).

Lantana camara (Verbenaceae) has been called one of the 10 most noxious weeds in the world. It is an attractive shrub, native to Jamaica and commonly cultivated in greenhouses. *L. camara* thrives outdoors in hot, dry climates. An unusual property of the plant is that it inhibits the growth of neighboring plants. In India, livestock poisoning from *L. camara* is a serious problem. Cattle grazing on the plant develop cholestasis and hyperbilirubinemia. The leaves are toxic to some nonruminants, including rabbits and guinea pigs. Several triterpenoids have been isolated from the plant. One that has been shown to induce hepatotoxicity is lantadene A (22-beta-angeloyloxy-3-oxo-olean-12-en-28-oic acid) (Sharma *et al.*, 1991).

Mushroom toxins   Many of the nonedible mushrooms may cause gastrointestinal distress but most are not life threatening. Repeated consumption of the false morel, *Gyromitra esculenta*, has been reported to cause hepatitis as well as gastrointestinal disorders (Michelot and Toth, 1991). The toxic principle is gyromitrin (acetaldehyde-*N*-formylhydrazone). Several species of three genera of mushrooms are responsible for most fatal poisoning from consumption of wild mushrooms, *Amanita*, *Galerina*, and *Lepiota* (Karlson-Stiber and Persson, 2003). *Amanita phalloides*, is appropriately called "death cap." *Amanita ocreata* (death angel) is equally dangerous. *A. phalloides* contains two types of toxins, phalloidin and amatoxins. Phalloidin is a cyclic heptapeptide that may be responsible for the diarrhea that develops 10–12 hours after ingestion of *A. phalloides.* Phalloidin combines with actin in muscle cells, but is not readily absorbed from the gastrointestinal tract (Cappell and Hassan, 1992). The alpha-, beta-, and gamma-amanitins are bicyclic peptides (mw 900) and are absorbed. The most toxic,

alpha-amanitin, binds strongly to RNA polymerase II in hepatocytes, thus inhibiting protein synthesis (Jaeger *et al*., 1993). Intestinal mucosa and kidneys are also targets. Serious clinical signs develop slowly, beginning about the third day after ingestion. Treatment in severe cases may require liver transplant. There is a long history of use of the herb *Silybum marianum* (milk thistle, Asteraceae) for treatment of poisoning from amanitins. The active ingredient is silymarin, a flavanolignan. Silymarin and herbal preparations also have been tried in viral hepatitis and alcoholic liver disease (Ball and Kowdley, 2005; Mayer *et al*., 2005a).

Mycotoxins   Various fungi present during harvest, or subsequent storage of food, produce toxins. Exposure to low levels of the mycotoxins by way of ingestion of the moldy foods is common, depending on geographic location and type of food. Most notable toxins are aflatoxins from *Aspergillus* species in stored grain, ochratoxin A, an immunosuppressant chemical produced by *Aspergillus* and *Penicillium* molds, and zearalenone, a mycotoxin produced by *Fusarium* and *Gibberella* species (Al-Anati and Petzinger, 2006; Ding *et al*., 2006). Aflatoxin B1 from *A. flavus* and *A. parasiticus* has been associated with primary hepatocellular carcinoma in humans. The toxin forms guanine adducts and induces apoptotic cell death in human hepatocytes (Reddy *et al*., 2006).

Fumonisins are toxins produced by the fungus *Fusarium*, primarily by *Fusarium moniliforme* and *Fusarium proliferatum* growing on corn. Ingestion by horses of corn contaminated with *Fusarium* mold causes "moldy corn poisoning" or equine leukoencephalomalacia. The signs in affected horses are lethargy, ataxia, convulsions, and death (Norred, 1993). There are several target organs but the liver is a primary target in every species; in horses, it is liver and brain; in pigs, liver and lung; in rats, liver and kidney; in chickens, liver (Riley *et al*., 1994). In humans, an association with esophageal cancer has been suggested (Yoshizawa *et al*., 1994). Fumonisins are diesters of propane-1,2,3-tricarboxylic acid and a pentahydroxyicosane containing a primary amino acid (Gurung *et al*., 1999). The structure of fumonisins is similar to that of sphingosine, and their toxicity has been related to block of enzymes in sphingolipid biosynthesis (Norred, 1993).

Kidney and Bladder

Carcinogens   Bracken fern (*P. aquilinum)* grows worldwide and, in the United States, primarily east of the Rocky Mountains. It has been called one of the five most common plants on the planet and is found locally in heavy concentrations. Bracken fern is the only higher plant known to cause cancer in animals under natural conditions of feeding. The commonest bladder tumors in cattle are epithelial and mesenchymal neoplasms (Kim and Lee, 1998). The major carcinogen is ptaquiloside, a norsesquiterpene glucoside present in high concentrations in the fern, especially in crosiers and young unfolding fronds. Ptaquiloside alkylates adenines, and guanines of DNA (Shakin *et al*., 1999). In the condition called "bovine enzootic hematuria," caused by consumption of bracken fern, the number of chromosomal aberrations is significantly increased (Lioi *et al*., 2004). There is evidence that consumption of young bracken fern shoots by humans is associated with cancers of the upper alimentary tract (Alonso-Amelot and Avendano, 2002).

Kidney Tubular Degeneration   Species of *Xanthium* (cocklebur, Asteraceae) are annual plants found in several countries. Toxicosis

in livestock is most common in spring and early summer due to ingestion of seedlings and young plants of cocklebur. Pigs, sheep, cattle, horses, and fowl can be affected in pastures where two- and four-leaf seedlings are present. The signs are depression and dyspnea. Pathological findings include tubular degeneration and necrosis in the kidney and centrolobular necrosis in the liver (del Carmen Mendez *et al*., 1998). The active ingredient is a glycoside, carboxyatractyloside, which causes microvascular hemorrhages in multiple organs (Turgut *et al*., 2005).

Acute renal failure is the cause of death in poisoning from *Cortinarius* species of mushroom. *Cortinarius* is a large genus of woodland fungi found especially in northern conifer forests. Species vary widely in habit and in edibility. In one series of poisonings from *Cortinarius orellanus* and related species, involving 135 cases in which the mushrooms were eaten, deaths secondary to acute renal failure occurred in almost 15% of the cases. Renal biopsy showed acute degenerative tubular lesions with inflammatory interstitial fibrosis (Bouget *et al*., 1990).

Blood and Bone Marrow

Anticoagulants   Fungal infections in sweet clover (*Melilotus alba*) silage and hay have caused serious toxicity and death in cattle in California and in the northern plains of the United States and Canada (Puschner *et al*., 1998). Deaths are from hemorrhages caused by dicumarol, a fungal metabolite. Dicumarol [3,3-methylene-bis(4-hydroxycoumarin)] is an effective anticoagulant, causing prothrombin deficiency, and is used therapeutically for this purpose.

Bone Marrow Genotoxicity   Some species of poppy, such as *Argemone* (Papaveraceae) produce sanguinarine, a benzophenanthridine alkaloid, that intercalates DNA. Humans may be exposed to argemone oil as an adulterant of mustard oil. A single low dose has been shown to increase chromosomal aberrations in bone marrow cells in mice (Ansari *et al*., 2004). The term "epidemic dropsy" has been applied to the disease in humans and a link to gall bladder carcinoma has been suggested (Das *et al*., 2005).

Cyanogens   Cyanogens are constituents of several different kinds of plants. One that is present in the kernels of apples, cherries, peaches, and related genera in the rose family is amygdalin, found in the highest amounts in the seeds of the bitter almond, *Prunus amygdalus*, var. *amara.* Amygdalin is not present in the seeds of the swe*et al* mond, the nut used for food. The amount of cyanogen in peach (*Prunus persica*) kernels is enough to cause poisoning in small children if several kernels are eaten. The seeds of apples are unlikely to present a problem. In the stomach, amygdalin releases hydrocyanic acid that combines with ferric ion in cytochrome oxidase or methemoglobin. The result of ingestion of several bitter almond seeds is classic cyanide poisoning with death from asphyxia. Amygdalin is a component of some herbal remedies for cancer in some countries and unintentional cyanide poisoning has resulted (O'Brien *et al*., 2005). There may be an interaction with concurrent intake of large doses of vitamin C (Bromley *et al*., 2005).

Cassava is a staple food starch from *Manihot esculenta* (Euphorbiaceae) grown extensively in some parts of Africa as a major food source. The untreated root contains linamarin, a cyanogenic glucoside. During processing of the root for human consumption, the cyanogen is removed. However, local processing may be inadequate. Chronic ingestion of linamarin in cassava has been proposed

as the cause of epidemics of konzo, a form of tropical myelopathy with sudden onset of spastic paralysis (Tylleskar *et al*., 1992). Degeneration of the corticospinal motor pathway in affected individuals may be caused by production of thiocyanate from linamarin with stimulation of neuronal glutamate receptors by thiocyanate (Spencer, 1999). One important improvement in cassava as a food source is that it has been possible to produce transgenic cassava plants with marked reduction in linamarin content in the tubers (Jorgensen *et al*., 2005). Another plant containing linamarin is flax, *Linum ustitatissumum*, the seed of which is the source of linseed oil. In some European countries, as a domestic remedy, the flax seeds are soaked overnight and the extract is used as a laxative, possibly exposing these individuals to cyanide from the linamarin (Rosling, 1993).

Nervous System

Historically, some of the most useful drugs have been plant-derived chemicals that act on the nervous system. However, some unintended serious neurotoxic syndromes may result from ingestion of certain plants.

Epileptiform Seizures The parsley family of plants (Apiaceae) contains some of the most edible (e.g., carrots) and some of the most poisonous plants in the northern hemisphere. The fleshy tubers of *Cicuta maculata* (water hemlock) may be mistaken for other edible wild tubers. A single tuber may cause fatal poisoning, characterized by tonic–clonic convulsions. The toxic principle, cicutoxin (a C17-polyacetylene), binds to GABA-gated chloride channels and this may play a role in the acute neurotoxicity (Uwai *et al*., 2000).

Several members of the mint family (Labiatae) are noted for their essential oils, such as pennyroyal (*Hedeoma*), sage (*Salvia*), and hyssop (*Hyssopus*). These oils contain odorous monoterpenes. For example, sage contains thujone, camphor, and cineole. In high oral doses, well above amounts used for flavoring, these monoterpenes can cause tonic–clonic convulsions. Menthol is a selective modulator of inhibitory ligand-gated channels (Hall *et al*., 2004).

Several species of *Strychnos* (Loganaceae) contain strychnine and brucine (dimethoxystrychnine). Both indoles cause marked CNS stimulation by blocking glycine-gated chloride channels. *Strychnos nux vomixa* is a small tree native to India. Cases of unintentional poisoning from seeds of *Strychnos nux vomica* have been reported (Wang *et al*., 2004). Seeds of *Strychnos ignatii* in the Phillipine islands have caused similar toxic effects.

Excitatory Amino Acids Widely divergent species of plants produce amino acids that mimic the action of glutamate on the central nervous system. Most fast excitatory transmission in the mammalian brain is mediated by inotropic receptors for the amino acid, glutamate, on specialized neurons. Different types of glutamate receptors respond to different excitatory amino acids from plants, acting on one or more of these glutamate receptor subtypes. The consequence of ingestion of excitatory amino acids is excessive stimulation that may result in death of neurons. One of these acids, kainic acid, is present in the marine red alga *Digenia simplex*. Under some climatic conditions the algae reproduce rapidly, causing a "red tide." Filter-feeding mussels eat the algae and humans may be poisoned by eating the mussels. A similar problem exists with the green alga *Chondria aranta* in northern oceans. The alga produces domoic acid, an analog of glutamate, as do several species of the marine diatom

Nitzschia (Kotaki *et al*., 2005). Acute symptoms are gastrointestinal distress, headache, hemiparesis, confusion, and seizures. Prolonged effects are severe memory deficits and sensorimotor neuropathy (Teitelbaum *et al*., 1990).

The fungus *Amanita muscaria* (fly agaric) got its name from its poisonous actions on flies. Poisoning from this woodland mushroom and from *Amanita pantherian* (panther agaric, common in western United States) is due to the content of the excitatory amino acid, ibotenic acid (isoxazole amino acid), and to its derivative, muscimol (Li and Oberlies, 2005). The effects are somewhat variable: central nervous system depression, ataxia, hysteria, and hallucinations. Myoclonic twitching and seizures sometimes develop (Benjamin, 1992). The content of ibotenic acid varies with the time of year; more has been reported in spring than in fall. Several other genera of fungi have hallucinogenic actions, notably *Psilocybe*, containing the indoles, psilocin, and psilocybin (Tsujikawa *et al*., 2003).

Excitatory amino acids are also found in flowering plants. The pea family (Leguminosae) contains several species that produce excitatory amino acids in the seeds. Willardiine [1-(2-amino-2-carboxyethyl)pyrimidine-2,4-dione] has been isolated from *Acacia willardiana*, *Acacia lemmoni*, *Acacia millefolia*, and *Mimosa asperata* (Gmelin, 1961). Willardiine acts as an agonist on glutamate receptors. Other important excitatory amino acids are present in species of *Lathyrus*. *Lathyrus sylvestris* (flat pea) is a perennial indigenous to Europe and central Asia and naturalized in Canada and northern United States. This plant is eaten by livestock in these areas. An acute neurologic condition in sheep begins with weakness and progresses to tremors and prostration, sometimes with clonic movements and seizures (Rasmussen *et al*., 1993). Seeds of *Lathyrus sativus* (grass pea) are used as food in several countries, including India and Ethiopia. The seeds contain the excitatory amino acid, beta-L-ODAP (beta-N-oxalyl-L-alpha, beta-diaminopropionic acid) (Warren *et al*., 2004). Lathyrism develops from consumption of seeds over periods of months or longer. Affected individuals have corticospinal motor neuron degeneration with severe spastic muscle weakness and atrophy but little sensory involvement (Spencer *et al*., 1986).

Motor Neuron Demyelination Paralysis develops from some toxins without primary excitation of neurons. *Karwinskia humboldtiana*, family Rhamnaceae, is a shrub of southwestern United States, Mexico, and Central America. Common names are buckthorn, coyotillo, and tullidora. Anthracenones are found in the seeds, the amount varying with stage of growth; green fruit may be more toxic than ripe fruit (Bermudez *et al*., 1986). Both human and livestock poisonings occur, occasionally in epidemic proportions. The clinical syndrome that develops after a latency of several days is ascending flaccid paralysis, beginning with demyelination of large motor neurons in the legs and, in fatal cases, leading to bulbar paralysis (Martinez *et al*., 1998). Sensory fibers are largely spared. In addition to neurotoxicity, the anthracenones in *Karwinskia*, especially peroxisomicine A$_2$, [3,39-dimethyl-3,39,8,89,9,99-hexahydroxy-3,30,4,49-tetrahydro-(7,10-bianthracene)-1,19-2H,29H-dione], causes lung atelectasis and emphysema and massive liver necrosis. Inhibition of catalase in peroxisomes has been proposed as the mechanism of cell toxicity (Martinez *et al*., 1997).

Cerebellar Neurons Swainsonine is an indolizidine alkaloid found in the legumes *Swainsonia cansescens* (an Australian plant),

Astragalus lentiginosus (spotted locoweed) and *Oxytropis sericea* (locoweed) in western United States. Cattle consume these weeds in pasture. The common name comes from the most obvious consequence of ingestion of locoweeds: aberrant behavior with hyperexcitability and locomotor difficulty. In animals dying from locoweed poisoning, there is cytoplasmic foamy vacuolation of cerebellar neurons. The toxic ingredient, swainsonine, causes marked inhibition of liver lysosomal and cytosolic alpha-mannosidase and Golgi mannosidase II. Inhibition of the Golgi enzyme results in abnormal brain glycoproteins and accumulation of mannose-rich oligosaccharides (Tulsiani *et al.*, 1988). The pathology is not limited to the nervous system and the effects of swainsonine poisoning are found in several tissues. A major effect in animals grazing at high altitudes is congestive heart failure. The condition has been called "high mountain disease" (James *et al.*, 1991). A species of the fungus *Embellisia*, an endophyte on locoweeds, may also produce swainsonine (McLain-Romero *et al.*, 2004).

Parasympathetic Stimulation   Several plant alkaloids affect the autonomic nervous system, mimicking the transmitter acetylcholine at autonomic ganglia (nicotinic receptors) or the peripheral endings of the parasympathetic system (muscarinic receptors). The postsynaptic receptors at terminations of the parasympathetic nerve fibers are called "muscarinic" after the selective stimulation of these receptors by muscarine, a quaternary ammonium furan, that was first extracted from the mushroom *A. muscaria*. However, this mushroom contains only trace amounts of muscarine, and poisoning is due to its content of ibotenic acid. Some mushrooms of the genera *Inocybe, Clitocybe*, and *Omphalatus* contain significant amounts of muscarine, and consumption of toxic species causes diarrhea, sweating, salivation, and lacrimation, all referable to stimulation of parasympathetic receptors (de Haro *et al.*, 1999).

Parasympathetic Block   The belladonna alkaloids (atropine, L-hyoscyamine, and scopolamine), known for their block of muscarinic receptors, are found in several genera of Solanaceae, the nightshade family. The plants are widely distributed. *Datura stramonium* (jimson weed) is native to India and contains primarily scopolamine; *Hyoscyamus niger* (henbane) is native to Europe and contains primarily L-hyoscyamine; *Atropa belladonna* (deadly nightshade), also native to Europe, contains atropine; *Duboisia myoporoides* (pituri) in Australia contains L-hyoscyamine. Scopolamine has the greater action on the central nervous system. The effects of modest doses of L-hyoscyamine or atropine are referable to muscarinic receptor block: tachycardia, dry mouth, dilated pupils, and decreased gastrointestinal motility. Large doses of either or of scopolamine affect the central nervous system with confusion, bizarre behavior, hallucinations, and subsequent amnesia. In severe intoxication, tachycardia may be absent (Caksen *et al.*, 2003). Deaths are rare, although recovery may take several days.

Datura suaveolens (angel's trumpet, Solanaceae) an ornamental houseplant, contains significant quantities of atropine and scopolamine (Smith *et al.*, 1991). Seeds of *Datura ferox* contain belladonna alkaloids and are contaminants of animal feed in some parts of Europe. In areas where millet, wheat, rye, corn, and bean seeds are used for human consumption, and where *D stramonium* and *Datura metel* are common weeds, the grain sometimes has been contaminated with *Datura* seeds. Symptoms from eating bread made from contaminated flour are typical of poisoning from belladonna alkaloids (van Meurs *et al.*, 1992). The amount needed to poison an

adult is about 20 seeds. An unusual source of belladonna poisoning has been reported from eating wasp honey. *Polistes* species of wasps store honey, and atropine-like poisoning has been reported from consuming the honey when the wasps have gathered nectar from *Datura inoxia* (Ramirez *et al.*, 1999).

The seeds of *Solanum dulcamara* (bittersweet) are brilliant red-orange and are gathered in the fall for flower arrangements. The seeds contain solanine, a glycoalkaloid, responsible for the acute toxicity from ingested seeds, including tachycardia, dilated pupils, and hot, dry skin, as in atropine poisoning (Ceha *et al.*, 1997).

Sensory Neuron Block   Several plant toxins are being studied for agonist actions on sensory receptors of the vanilloid-type (VR1), especially capsaicin found in species of *Capsicum* (*C. annuum*, sweet pepper, and *C. frutescens*, red pepper, Solanaceae). Capsaicin produces a burning sensation on VR1 sensory endings, but also desensitizes the transient potential vanilloid 1 receptor (TRPV1) of sensory endings of C-fiber nociceptors to stimuli. This long-term sensory neuron blocking effect has therapeutic use in chronic pain (Szalcsany, 2002). The sensory desensitization produced by capsaicin is not due to acute cell death and long-lasting changes in mitochondria in cultured dorsal root ganglion cells have been demonstrated (Dedov *et al.*, 2001). It has recently been suggested that capsaicin may also have an action on another ion channel, the 4-aminopyridine-sensitive K^+ channel, and may inhibit contractile mechanisms by release of Ca^{2+} from intracellular storage sites (Fujimoto *et al.*, 2006).

Another plant toxin, polygodial, a sesquiterpene found in *Polygonum hydropiper*, has a capsaicin-like action on the TRPV1 (Andre *et al.*, 2006). Resiniferatoxin, a homovanillic ester from *Euphorbia resinifera* (Euphorbiaceae), is a potent agonist of TRPV1 and causes sustained depolarization of the vanilloid receptor. The long-lasting effect of resiniferatoxin on nerve terminals is related to slow activation of TRPV1 with excessive influx of Ca^{2+} without generating action potentials (Raisinghani *et al.*, 2005).

Skeletal Muscle and Neuromuscular Junction

Neuromuscular Junction   Block of the neuromuscular junction of skeletal muscle may result from either block of postsynaptic acetylcholine receptors (nicotinic receptors) by an antagonist or by an agonist causing excessive stimulation of the receptor followed by prolonged depolarization. Nicotine stimulates autonomic ganglia as well as the neuromuscular junction. An isomer of nicotine, anabasine, present in *Nicotiana glauca* (tree tobacco, Solanaceae), produces prolonged depolarization of the junction. Consumption of the leaves of the plant has caused flexor muscle spasm and gastrointestinal irritation, followed by severe, generalized weakness, and respiratory compromise (Mellick *et al.*, 1999). Curare, the South American arrow poison is a potent neuromuscular blocking agent used clinically. Curare is obtained from tropical species of *Strychnos* and *Chondrodendron.* Not all plants blocking the neuromuscular junction are tropical in origin. In warm weather, blooms of blue-green algae are not uncommon in farm ponds in temperate regions, particularly ponds enriched with fertilizer. Under these conditions, one species of alga, *Anabaena flosaquae*, produces a neurotoxin, anatoxin A, that depolarizes and blocks acetylcholine receptors, both nicotinic and muscarinic, sometimes causing death in animals that drink the pond water. The lethal effects develop rapidly, with death in minutes to hours from respiratory arrest (Short and

Edwards, 1990). Anatoxin A is 2-acetyl-9-azabicyclo(4.2.10)non-2-ene (Hyde and Carmichael, 1991).

Methyllycaconitine is a norditerpenoid present in *Delphinium barbeyi* (tall larkspur, Ranunculaceae) and in some related species. The plant contaminates western pastures in the United States and causes death of livestock. Poisoned cattle show muscle tremors and ataxia followed by prostration and respiratory arrest in fatal cases. The compound has a high affinity for the acetylcholine receptor at the neuromuscular junction like curare. Physostigmine has been used successfully as an antagonist in some cases of methyllycaconitine poisoning (Pfister *et al*., 1994).

Skeletal Muscle   Direct damage to skeletal muscle fibers has been demonstrated in some plant poisonings. Species of *Thermopsis* (Leguminosae) are common in the foothills of the Rocky Mountains. Mature seeds of these plants form in attractive pods, as in many legumes. Seeds of the poisonous species of *Thermopsis* contain quinolizidine alkaloids, principally anagyrine and thermopsine. Human poisoning from eating the seeds is rare, but cases have been reported in young children (Spoerke *et al*., 1988). The symptoms are abdominal cramps, nausea, vomiting, and headache lasting up to 24 hours. Serious poisoning has occurred in livestock grazing on *Thermopsis montana* (false lupine). The animals develop locomotor depression and recumbancy. Microscopic areas of necrosis in skeletal muscle are found on autopsy (Keeler and Baker, 1990).

Seeds of *Cassia obtusifolia* (sicklepod, Leguminosae) have been found as a contaminant of animal feeds. Consumption of the seeds in cattle, swine, and chickens causes a degenerative myopathy in cardiac and skeletal muscle. Extracts of *C. obtusifolia* inhibit NADH-oxidoreductase in bovine and porcine mitochondria in vitro (Lewis and Shibamoto, 1989) possibly related to the anthraquinone content of the seeds.

Ingestion of white snakeroot (*Eupatorium rugosum*, Asteraceae), a common plant in central and western United States, causes tremors in cattle and "milk sickness" in humans after ingestion of milk from cows pasturing in fields infected with the plant (Beier *et al*., 1993). The toxic effect thought to be caused by tremetone, a benzofuran, that blocks gluconeogenesis from lactate, resulting in acidosis, tremor, and death (Polya, 2003).

Bone and Tissue Calcification

Bone and Soft Tissue   Worker and Carrillo (1967) proposed that a decrease in bone calcification and a wasting disease in cattle grazing along the eastern coastal plains of South America was due to the consumption of *Solanum malacoxylon* (Solanaceae). The disease, known in Argentina as "enteque seco" is characterized by calcification of the entire vascular system, especially the heart and aorta. Lungs, joint cartilage, and kidney are affected in the worst cases. Sheep and cows are both affected by ingestion of the plant. The general picture resembles vitamin D intoxication. A water-soluble vitamin D-like substance, a glycoside of 1,25-dihydroxycholecalciferol, has been isolated from the plant (Skliar *et al*., 1992).

Cestrum diurnum (day-blooming jasmine, Solanaceae) causes hypercalcemia and extensive soft tissue calcification in grazing animals in Florida, resembling the action of *S. malacoxylon.* A dihydroxyvitamin D_3 glycoside in the leaves is the toxic agent (Durand *et al*., 1999). *Cestrum laevigatum* causes a similar deposition of calcium in chickens (Mello and Habermehl, 1992). This species is occasionally a contaminant of hay in Europe. However, in

cattle, marked hepatotoxicity occurs with centrolobular and mid-zonal necrosis (Peixato *et al*., 2000).

Reproduction and Teratogenesis

Abortifacients   The active alkaloid in the legumes *Astragalus* and *Oxytropus* is swainsonine. In addition to actions on the nervous system, swainsonine frequently causes abortions when locoweeds are ingested by pregnant livestock (Bunch *et al*., 1992).

Two genera of tropical legumes, *Leucaena* and *Mimosa*, contain a toxic amino acid, mimosine [beta-*N*(3-hydroxy-4-pyridone)a-alpha-aminopropionic acid]. Mimosine is found in large amounts in foliage and seeds of *Leucaena leucocephala*, *Leucaena glauca*, and *Mimosa pudica.* In cattle the amino acid causes incoordinated gait, goiter, and reproductive disturbances including infertility and fetal death (Kulp *et al*., 1996). Mimosine arrests the cell cycle in late G1-phase (Perry *et al*., 2005).

Lectins that are ribosome-inactivating proteins may have many effects on reproduction when ingested, including antifertility, abortifacient, and embryotoxic actions. A lectin from bitter melon seeds (*Momordia charantia*, Curcurbitaceae) has been shown to have such effects. The lectins are alpha- and beta-momorcharins, single-chain glycoproteins with molecular weight of about 29,000. The momorcharins are known to induce midterm abortion in humans (Wang and Ng, 1998).

Caulophylline (*N*-methylcytisine) is a quinolizidine from *Caulophyllum thalictroides* (blue cohosh, Berberidaceae). The plant is widely distributed in temperate North America and eastern Asia. Caulophylline is teratogenic in rats (Kennelly *et al*., 1999). Neonatal and maternal toxicity has been reported from maternal ingestion of herbal preparations of blue cohosh to terminate pregnancy (Jones and Lawson, 1998). The maternal signs resemble the action of an agonist to nicotinic acetylcholine receptors (Rao and Hoffman, 2002).

Many pastures of tall fescue (*Festuca arundinacea*, Poaceae) are infected by the endophytic fungus *Neotyphodium coenophialum.* The presence of the endophyte is related to production in the fescue plant of ergovaline, an ergopeptine alkaloid that acts as an agonist to dopamine D2 receptors. Ergovaline inhibits prolactin release and acts as a vasoconstrictor. Pregnant mares are most susceptible toward the end of gestation, resulting in damage to the fetus and maternal loss of milk (Blodgett, 2001). Regulation of levels of different alkaloids in grasses as a result of *Neotyphodium* infestation is closely related to plant genotype as well as the presence of the endophyte (Spiering *et al*., 2005).

Teratogens   *Veratrum californicum* (Liliaceae) is native to the mountains of North America where sheep are grazed. An incidence of teratogenesis as high as 25% has been reported in pregnant sheep in these areas, along with early embryonic death as high as 75% (Keeler, 1990). The teratogenic manifestations are dependent on the developmental stage at the time of exposure, as with many teratogens. Malformations of the offspring involve cyclopia, exencephaly, and microphthalmia. During the 4th and 5th weeks of gestation, limb defects are common; on gestational days 31–33, the result of ingestion is fetal stenosis of the trachea (Omnell *et al*., 1990). The alkaloids in *Veratrum* that are responsible for the defects are jervine, 11-deoxojervine and 3-*O*-glucosyl-11-deoxojervine. Although there is species difference in sensitivity, birth defects occur in cows and goats grazing on *V. californicum*. Birth defects have been produced experimentally in chickens, rabbits, rats, and mice (Omnell *et al*., 1990), hamsters (Gaffield and Keeler, 1993), and rainbow trout embryos

(Crawford and Kocan, 1993). The *Veratrum* alkaloids cause teratogenesis by blocking cholesterol synthesis and thus the response of fetal target tissue to the sonic hedgehog gene (Shh). The Shh locus has a role in developmental patterning of head and brain, and block of cholesterol synthesis has been shown experimentally to result in loss of midline facial structures (Cooper *et al.*, 1998).

A cluster of fetal malformations characterized by deformation of limbs and spinal cord is found after maternal ingestion of related alkaloids from different species of plants during a sensitive gestational period. The syndrome has been found in cattle grazing on *Lupinus caudatus* and *Lupinus formosus* (lupines, Luguminosae), *Nicotiana glauca* (tree tobacco, Solanaceae), and *Conium maculatum* (poison hemlock, Solanaceae). Poison hemlock is known historically as the plant that Socrates drank when condemned to death in Athens. The fatal actions of the poison have been described by Plato in his *Phaedo.* The active alkaloids in these plants are anagyrine (*L. caudatus*), ammodendrine (*L. formosus*), anabasine (*N. glauca*), and coniine (*C. maculatum*). It has been proposed that these alkaloids depress fetal movements during susceptible gestational periods and in this way cause malformations (Lopez *et al.*, 1999). Not all species are equally affected by coniine. Notably, rats and hamsters do not show teratogenesis in response to coniine, but goat and chick embryos are susceptible (Forsyth *et al.*, 1996).

SUMMARY

A great variety of toxic chemicals have been produced by plants for their own protection from the environment and from predators, including pathogenic organisms. These defensive chemicals have been both deleterious and beneficial to humans. Throughout history a select number have been incorporated into therapy against disease and to combat morbidity, often with considerable success. Morphine from the latex of the opium poppy is an ancient historical example. If fungi are included with plants (as they are in this chapter), defensive chemicals of plants are responsible for some of our more successful therapies, such as antibiotics of the penicillin type and therapy for cancer. On balance, in spite of the long list of dangerous toxic chemicals from plants, it is fair to conclude that plants have proved therapeutically more useful than harmful to humans. Finally, there is simply the pleasure of scientific inquiry into the successful adaptations of plants to their complex and often hostile environments.

CHAPTER 28

AIR POLLUTION*

Daniel L. Costa

AIR POLLUTION IN PERSPECTIVE

The second half of the twentieth century witnessed remarkable changes in environmental perspective. Until that time, national pride and prosperity were often visually depicted as an expanse of urban factories with smokestacks belching opaque clouds of industrial effluent into a seemingly neutral sky. The price of unchecked human progress through the first half of the century had led to a number of environmental catastrophes, which demonstrated the profoundly detrimental impact that such reckless prosperity could have on the natural environment. These images of "modern" prosperity gradually gave rise to public outcry for governmental action to protect environmental quality, wildlife, as well as public health.

The ensuing fifty years of regulatory legislation in the United States and Western Europe have now made such industrial scenes rare in most technologically developed nations. But, ironically, even as regulatory control measures began to reduce much of the stationary sources of air pollution, large populations have fled the cities in pursuit of a cleaner, safer lifestyle. This change in demographics post World War II altered the composition and distribution of polluted air. The commute from suburban home to city workplace back to suburban home, led to increasingly congested vehicular thoroughfares, creating a photochemical cauldron of oxidant air pollution around these newly formed, rapidly expanding metropolitan areas. More-

over, postwar population growth and rising expectations for a better (peace time) standard of living led to unrestrained consumption of inexpensive fossil fuels for energy production and recreational transportation needs. The result has been a world-wide destruction of limited environmental resources and an adverse effect on global climate, as energy-related polluted air masses drift and disperse across hundreds, even thousands of miles.

And so, air pollution remains a twenty-first-century reality, and while great legislative strides have been made to reduce emissions from both stationary and mobile sources, nonetheless, unsatisfactory air quality now plagues much broader geographic areas. More than half the U.S. population resides in counties that are not in compliance with current National Ambient Air Quality Standards (NAAQS) (Fig. 28-1). These noncompliant areas correspond well with the spread of population growth from major urban and industrial centers.

Episodes of extreme air pollution are rare in the Western world today. Occasionally, these areas experience unusual meteorological stagnations that coincide with "normal or expected" air pollution patterns that intensify the pollution over broad regions (e.g., 1995 in the United Kingdom and Western Europe). Conversely, specific locales dominated by a single, major pollutant source (e.g., Utah Valley smelter—through the 1980s and 1990s) can experience extremely poor air quality especially when exacerbated by meteorological inversions, with serious public health consequences. More typically, however, public exposures are characterized by prolonged periods of relatively low-levels of complex mixtures of photochemically transformed industrial and mobile emissions with periodic moderate excursions due to weather. This pattern of pollution now

extends even into remote wilderness areas, where considerable damage to flora and fauna has occurred.

In contrast, many developing countries experiencing rapid population growth, industrialization, and economic expansion choose to ignore the lessons of Western industrial expansion and the consequences of inadequate air pollution control. Air pollution in some of these nations now rivals the atmospheric conditions that existed in Western Europe and America preceding the catastrophic air pollution episodes of the twentieth century. For example, two Hong Kong marathoners died in February 2006 while running during severe air pollution. In addition, industrial emissions from some developing nations and emerging economies, now contribute substantially to the global burden of many air pollutant constituents. A willingness to balance worldwide economic growth and industrialization using lessons learned from the misadventures of the Second Industrial Revolution and the Age of the Automobile will determine the impact of the "new" global economy on the health of both the earth and its inhabitants.

Previously, the scientific information regarding the impacts of air pollution on human health had largely been collected on the individual constituents that make-up air pollution's complex mixture. In turn, this knowledge was used to develop both public health standards and to establish regulatory controls. Despite the obvious complexities of urban air pollution, it was felt that single pollutant regulations were the best path to success. Indeed, great strides have been made. However, research agendas have slowly been evolving

to include the study of the interaction and transformation of individual pollutant components within atmospheric systems—a truer reflection of real-world exposure complexities.

This chapter will present an overview of the current state of knowledge regarding the production of air pollution and its subsequent impact on human health. Also, the complexities of regulatory decisions and risk assessment will be addressed. Hopefully, these topics will provide the reader with both a fundamental knowledge and appreciation of the nature of the problem, as well as a sense of the uncertainties in need of future investigation.

A Brief History of Air Pollution and Its Regulation

For most of history, air pollution has been a problem of microenvironments and domestic congestion. The smoky fires of early cave and hut dwellers choked the air inside their homes. When the emissions were vented outdoors, they combined with those of the neighbors to settle around the village on damp cold nights. With urbanization and a concomitant decrease in forest wood as a source of fuel to heat and cooking, the need for energy led to the burning of cheap coal and ambient release of sulfurous, sooty smoke. Likewise, kilns to make quicklime for construction and metal smelters pushed smoke and chemical materials into the air of active "modern" cities. Unfortunately, the city dwellers had to endure the bad air, while those with wealth frequently had country homes to which they could escape from time to time. The poor quality of urban

air was captured by many writers from Charles Dickens in his writings about London's fogs to the ancients: Seneca, the Roman philosopher, in AD 61 wrote: "As soon as I had gotten out of the *heavy air* of Rome, and from the *stink* of the chimneys thereof, which being stirred, poured forth whatever *pestilential vapors and soot* they had enclosed in them, I felt an *alteration to my disposition*" (emphasis added: Miller and Miller, 1993).

As in today's world efforts to regulate air pollution competed with the industrial economies and as a result, they evolved slowly. Early on, in the time of Greece and Rome, individual civil suits could be levied against local polluters, although these were of marginal success. Beginning in the thirteenth century, community-based outcries received some recognition by governing officials, one example being the banning of "sea coal" from lime kilns and domestic heaters in London by Edward I. Enforcement, however, was not effective and people largely resigned themselves to polluted air as part of urban life. By the seventeenth century, England, in the middle of several decades some refer to as "the little ice age," experienced further reductions in wood harvests, which only increased reliance on sea coal for domestic heating. Despite Percival Pott's discovery that soot was related to the incidence of scrotal cancer in chimney sweeps, the health community offered only a simple recommendation: "Fly the city, shun its turbid air; breathe not the chaos of eternal smoke . . . " (Brimblecombe, 1999)—advice hardly advanced from that of Seneca 1600 years earlier. In the late eighteenth century, the industrial revolution, which was powered by the burning of "cleaner" mined coal, added a second dimension to urban air pollution. These emissions were more acidic and hung in the air longer than the fluffy soot of the cheaper sea coal. Continued soiling of buildings and damage to nearby crops brought community boards to address sanitary reforms to cut the worse of the pollution peaks and episodes, but any gains were soon offset by growth. By the end of the nineteenth century and into the early twentieth century, power plants were being built to provide energy for factories and eventually to light homes. Steel mills and other industries proliferated along riverbanks and lakeshores, oil refineries rose in port cities and near oil fields and smelters roasted and refined metals in areas near large mineral deposits.

By 1925, air pollution was common to all industrialized nations, but people grew less tolerant of the nuisance of acidic-soot corrosion of all exposed surfaces and the general discomfort that came with smoky air—this acidic, sooty form of air pollution has been termed "reducing" air pollution. Public surveys were initiated—as in Salt Lake City in 1926, New York City in 1937, and Leicester, Great Britain, in 1939—to bring political attention to the problem and promote the implementation of controls (Miller and Miller, 1993). However, it was not until the great air pollution disasters in the Meuse Valley, Belgium, in 1930; Donora, Pennsylvania, in 1948; and the great London fog of 1952 that air pollution was indicted primarily as a health issue. In the United States, California was already leading the way with passage of the Air Pollution Control Act of 1947 to regulate the discharge of opaque smokes. Visibility problems in Pittsburgh during the 1940s had also prompted efforts to control smoke from local industries, but it was the initiative of President Truman that provided the federal impetus to deal with air pollution. This early effort culminated in congressional passage of a series of acts starting with the Air Pollution Control Act of 1955.

The prosperity and suburban sprawl of the late 1950s provided the third and perhaps most chemically complex dimension of air pollution. The term *smog,* though originally coined to describe the mixture of smoke and fog that hung over large cities such as London, was curiously adopted for the eye-irritating photochemical reaction products of auto exhaust that blanketed cities like Los Angeles. Early federal legislation addressing stationary sources was soon expanded to include automobile-derived pollutants (the Clean Air Act of 1963, amended in 1967, and the Motor Vehicle Air Pollution Control Act of 1965). The landmark Clean Air Act (CAA) of 1970 evolved from the early legislation, and despite being only an amendment, it was revolutionary. It recognized the problem of air pollution as a national issue and set forth a plan to control it. The Act established the U.S. Environmental Protection Agency (USEPA) and charged it with the responsibility to protect the public from the hazards of polluted outdoor air. Seven "criteria" air pollutants—ozone (O_3), sulfur dioxide (SO_2), particulate matter (PM), nitrogen dioxide (NO_2), carbon monoxide (CO), lead (Pb), and total hydrocarbons; the last now dropped from the list, leaving six criteria pollutants—were specified as significant health hazards in need of *individual* National Ambient Air Quality Standards (NAAQS). These NAAQS were mandated for review every 5 years as to the adequacy of the existent standard to protect human health (Table 28-1), although in many instances adherence to this schedule has not been achieved. The explosion in the literature databases for the criteria pollutants and the extensive review process has often led to delays in completing the process on schedule. For each of the criteria pollutants, a Criteria Document or science assessment is developed, which provides a
Figure 28-2. Excess mortality due to outdoor and indoor particulate matter in various international economic groupings.

Bottom and top of each bar represent the lower and upper estimates of mortality, respectively, computed using the methodology of Schwela (2000): Established Market Economics (EME); Eastern Europe (EE); China; India; South East Asia/Western Pacific (SEAWP); Eastern Mediterranean (EM); Latin America (AL); and sub-Saharan Africa (SSA). (Modified from Figure 2.6 by D. Schwela: Air Pollution in the Megacities of Asia - SEOUL WORK-SHOP REPORT: Urban Air Pollution Management and Practice in Major and Megacities of Asia—*http://www.asiairnet.org/seoulreport.asp*).

detailed summary of the available literature on that pollutant. This assessment of the science is then integrated into a Staff Paper to develop a range of proposed standards based on risk analyses. The EPA Administrator considers proposals from both "evidence" and "risk" based assessments to establish policy and set the NAAQS (www.epa.gov/ttn/naaqs/naaqs_process_report_march2006.pdf). In 2006, this process was changed with the steps in the process coming to be termed: Science Assessment, Risk Assessment and Policy Assessment to replace the Criteria Document and Staff Paper. With regard to the Primary NAAQS, only health criteria can be considered in the development of the standard, including safety considerations for potentially susceptible groups. The Secondary NAAQS considers agricultural and structural welfare. Economic impacts are not to be involved in standard setting itself—only in assessing the cost of the implementation procedures. Other hazardous air pollutants (HAPs), of which there were eight listed at the time, were to undergo health assessments to establish emission controls. The CAA of 1970 was by far the most far-reaching legislation to date.

The accidental release of 30 tons of methyl isocyanate vapor into the air of the shanty village of Bhopal, India, on December 3, 1984, killed an estimated 3000 people within hours of the release, with several thousand delayed deaths, and 200,000 injured or permanently impaired. The tragedy shocked the world, and raised the issue of HAPs in the United States to a new level of concern. While such a disaster has never struck the United States, accidental industrial releases or spills of toxic chemicals are surprisingly common, with 4375 cases recorded between 1980 and 1987, inflicting 11,341 injuries and 309 deaths (Waxman, 1994). The HAPs, which had been the stepsister of the criteria pollutants for more than a decade after the passage of the 1970 CAA, have since garnered more public and policy attention. There is concern not only for accidental releases of

fugitive or secondary chemicals—such as phosgene, benzene, butadiene, and dioxin, into the air of populated industrial centers—but also for potential chronic health effects, with cancer often being the focus of attention. The slow progress of regulatory decisions on HAPs (only eight between 1970 and 1990) led to a mandated acceleration of the process under the CAA amendment of 1990. Section 112(b) currently lists 188 chemicals or classes of chemicals for which special standards and risk assessments are required. The chemicals listed are those of greatest concern on the basis of toxicity (including cancer) and estimated release volumes. Currently, there is a list of 33 HAPS from the list of 188 that are deemed to be of greatest concern, so-called a list of the "dirty thirty." Emissions are of HAPS are mandated for control to the maximal achievable control technology (MACT), and any residual health risk after MACT is to be considered in a separate quantitative risk assessment. The database for this process utilizes existing knowledge or, if necessary, mandates further research by the emitter. While many of these chemicals are now better controlled than in the past, most residual risk estimates are yet to be completed. The database from which these assessments are made is called the Integrated Risk Information System (IRIS—www.epa.gov/iris/index.html).

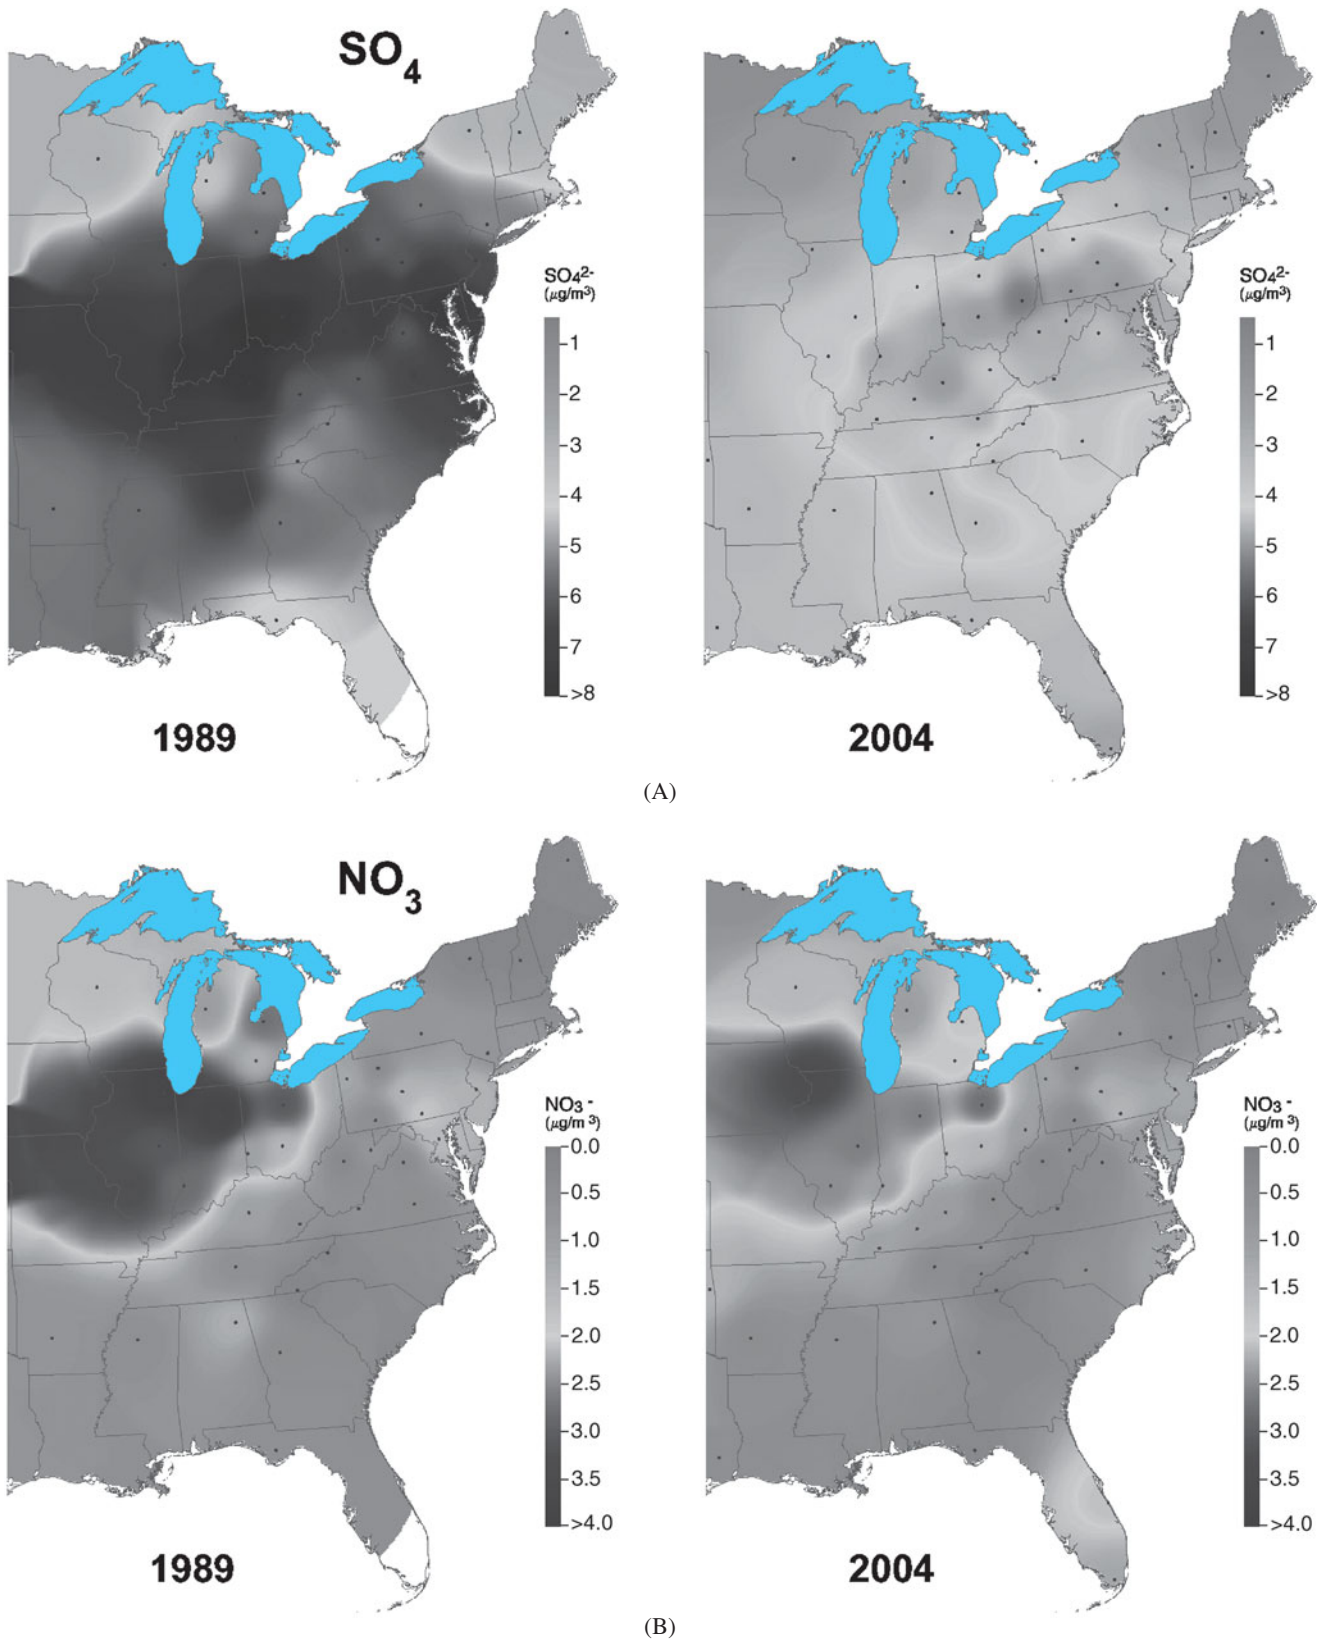
Emissions from motor vehicles are addressed primarily under the CAA Title II, Emission Standards for Mobile Sources. The reduction of emissions from mobile sources is complex and involves both fuel and engine/vehicle reengineering. Despite continued refinements in combustion engineering through the use of computerized ignition and timing, fuel properties have drawn recent attention for improvement. For example, to reduce wintertime CO, several oxygenates (including ethers and alcohols) have be formulated into fuels both to reduce cold-start emissions and enhance overall combustion. Perhaps the most prominent of the ethers is MTBE (methyl


Figure 28-3. *Reduction in ambient particulate sulfate and nitrate concentrations between 1989 and 2004 in the eastern half of the United States (from CASTNet monitoring data).*

Sulfates and nitrates arising from industrial centers of the Midwest contribute to acid rain deposition (see Fig. 28-11). Sulfates are readily dispersed by toward the eastern half of the country. Nitrates arise from the industrial centers as well as metropolitan areas and show both a local and dispersed pattern. (Adapted from Clean Air Status and Trends Network—http://www.epa.gov/castnet/mapconc_e.html).

tertiary butyl ether), which became a controversial additive in the early 1990s, arising in part from odor and reports of asthma-like reactions by some individuals during auto refueling at service stations. Today, the controversy has taken an unexpected twist; MTBE has now been removed from fuel, not because health concerns associated with airborne exposure but rather due to leakage from service-station storage tanks into groundwater. Ironically, this prescribed remedy for an air problem has evolved into a new problem: groundwater contamination. This example illustrates the broad complexity of pollution control, measures that transcend engineering. Meanwhile, other fuel additives have been promoted or developed to boost octane ratings of fuels and/or improve engine performance and combustion (e.g., organic oxygenates, methylcyclopentadienyl manganese tricarbonyl (MMT), platinum compounds for diesel, etc.). These additives are being carefully reviewed under Title II because of concerns regarding the potential changes in combustion product reactivity or the introduction of metals into the environment, reminiscent of use lead in fuels from the 1930s to 1970s, when lead fuel additives were banned.

Internationally, the magnitude and control of air pollution sources vary considerably, especially among developing nations, which often forgo concerns for health and welfare because of cost and the desire to achieve prosperity. Figure 28-2 illustrates the international variation in air pollution related mortality (outdoor and indoor) based on economic groupings. It is clear that there are wide differences reflecting economic imbalances—particularly prominent are the indoor particulate levels in developing nations where biomass combustion is used for heating and cooking. Likewise, these regions contain many of the megacities of the world with major air pollution problems. The political upheaval in Eastern Europe since 1990 has revealed the consequences of decades of uncontrolled in-

dustrial air pollution. While vast improvements are now becoming evident in this area, as industries are being modernized and emissions controlled, many Asian, African, and South American cities have virtually unchecked air pollution. Some nations as well as the World Health Organization (WHO) have adopted air quality standards as a rational basis for guiding control measures, but the lack of binding regulations and/or economic fortune has impeded significant controls and improvements (Lipfert, 1994). In addition to local socioeconomic and political concerns, emissions of air pollutants will, in all probability, spawn problems of "international pollution" as we enter the twenty-first century, when the impact of long-range transport of polluted air masses from one country to another fully matures as a global issue (Reuther, 2000). This was the subject of some controversy between Canada and the United States in the late 1980s and into the 1990s as a result of the air mass transport of acid sulfates from industrial centers of the Midwestern United States to southern Ontario. However, reduction in SO_2 emissions has somewhat relieved the tension over the last several years (Fig. 28-3A). Improvement in NOx, also a product of stationary source fossil fuel burning, is also apparent (Fig. 28-3B).

ASSESSING RISKS ASSOCIATED WITH AIR POLLUTION

"Risk Assessment" has become a formalized process, originally described in the landmark 1983 National Research Council Report, whereby toxicity, exposure, and dose-dependent outcome data can be systematically integrated to estimate risk to a population. Figure 28-4 provides a modified version of the paradigm of the NAS incorporating recent interest in providing evidence of "accountability" that the regulations indeed did have impacts. The health database

Table 28-2
Strengths and Weaknesses of Disciplinary Approaches for Obtaining Health Information

DISCIPLINE	POPULATION	STRENGTHS	WEAKNESSES
Epidemiology	Communities	Natural exposure	Difficult to quantify exposure
			Many covariates
	Diseased groups	No extrapolation	
		Isolates susceptibility trait	Minimal dose–response data
		Long-term, low-level effects	Association vs. causation
	Field/Panel groups	Good exposure data	Usually short-term
		Fewer covariates	Volunteers
		Focus on host traits	Expensive
		Utilizes clinical evaluations	
Clinical studies	Experimental	Controlled exposures	Artificial exposures
	Diseased subjects	Few covariates	Acute effects only
		Isolates susceptibility trait	Hazards
		Cause–effect	Volunteers
Toxicology	Animals	Maximum control	Human extrapolation
		Dose-response data	Realistic models of human disease?
		Cause–effect	
	In vitro systems	Rapid data acquisition	In vivo extrapolation
		Mechanisms	

SOURCE: Data modified from Boubel *et al.*, 1994.

for any air pollutant may comprise data from animal toxicology, controlled human studies, and/or epidemiology. But, because each of these research approaches has inherent strengths and limitations, an appropriate assessment of an air pollutant requires the careful integration and interpretation of data from all three methodologies. Thus, one should be aware of the attributes of each (Table 28-2).

Epidemiologic studies reveal associations between exposure to a pollutant(s) and the health effect(s) in the *community* or *population* of interest. Because data are garnered directly under real-world exposure conditions and often involve large numbers of people, the data are of direct utility to regulators assessing pollutant impacts. With proper design and analysis, studies can explore either acute or long-term exposures and theoretically can examine trends in mortality and morbidity, accounting irreversible effects as well as responses in population subsets (i.e., sensitive groups). Why, then, is this approach to the study of air pollution not the exclusive choice of regulators in decision making? The problem is that it is difficult to control confounding personal variables in the population. Factors such as genetic diversity and lifestyle differences among individuals, and population mobility are difficult to control. Perhaps most problematic is the lack of adequate exposure data—especially on a personal basis. Exposure assessment is often one of the major weaknesses of an epidemiologic study, not only because of the difficulties of assessing exposure (as a measure of dose) to the pollutant of interest, but because it is difficult to segregate a single pollutant from correlated co-pollutants and other environmental influences, such as meteorology. Thus, only associations, and not causality, can be drawn between the broad-based exposure data and effects. Frequently, the effects are of mortality, hospitalizations, etc. Causal relationships are sometimes inferred in the presence of strong statistical significance, but such determinations are likely to be criticized. However, recent advances in exposure estimation and study design and analysis (e.g., time series) have allowed epidemiologists to examine relationships with greater confidence and specificity. These models limit the impact of covariates and longer time-based influences and thus allow epidemiologists to tease out effects

of short-term pollution not accessible formerly (Schwartz, 1991). Similarly, newer approaches that employ field studies—sometimes called *panel studies*—incorporate time-series design and multiple-regression analyses of more focused and complete exposure data (ideally personal) and targeted clinical endpoints in the exposed population under study. The endpoints often derive from empirical human and animal studies and therefore have a priori conceptual ties. The advent of new genetic approaches for characterizing polymorphisms of potentially influential traits (e.g., GSTM1—glutathione-S-transferase M1—Tujague *et al.*, 2006) opens the genomic door for assessing gene-environment interactions. These factors may well underlie much of human susceptibility to air pollution. Novel approaches such as this are evident in the most recent studies of PM air pollution (see below).

Studies that involve controlled human exposures have been used extensively to evaluate the criteria air pollutants regulated by the USEPA. Because most people are exposed to these pollutants in their daily lives, human volunteers can be ethically exposed to them in a highly controlled fashion (with the exception of Pb, which has cumulative and irreversible effects). Exposures are conducted in a controlled environment (usually in a chamber or with a mask) and are generally of short or limited repeat durations, given assurances that all responses are reversible. Clearly, data of this type are very valuable in assessing potential human risk, because they are derived from the species of concern and are rooted in well-established clinical knowledge and experience.

Suspected "susceptible or sensitive" individuals representing potential higher-risk groups can also be studied to better understand the breadth of response in the exposed public. However, clinical studies have several practical limitations. Ethical issues are involved in every aspect of a clinical test; potentially irreversible effects and carcinogenicity are also always of concern, along with the definition of an acceptable level of hyper-responsiveness in so-called sensitive individuals who volunteered to participate in the study. Likewise for any test subject, there are obvious restrictions on the invasiveness of biological procedures, although sophistication in medical

technology has made accessible a large array of molecular biomarkers from peripheral blood and nasal, bronchial, and alveolar lavage fluids as well as biopsied cells from airway segments (Devlin *et al.*, 1991; Salvi *et al.*, 1999). As noted above, the advent of cutting-edge genomic and proteomic high-through-put technologies provide new tools to dissect human responses and their relationships to susceptibility. Obviously, the issue of cost, the limited numbers of subjects that can be practically evaluated, and the inability to address chronic exposure issues remain constraints on human testing. Where partnerships with animal toxicology studies have been established, studies in laboratory animal species can sometimes provide ethical justification for at least limited direct human exposure to address critical questions. Analogously, in vitro studies in both human and animal cell and tissue systems, often augmented with similar genomic tools, allow the elucidation of mechanisms of toxicity. These basic biological responses inform extrapolation models that link animal data to humans, and they support the feasibility and prescribe some of the ethical limitations of human study with some toxic air pollutants (see below).

Animal toxicology is frequently used to predict or corroborate suspected effects in humans. In the absence of human data, animal toxicology constitutes the essential first step of risk assessment: *hazard identification*. Animal toxicology is often required before any controlled human exposure can be conducted. It is particularly useful in elucidating pathogenic mechanisms involved in toxic injury or disease, providing basic knowledge that is critical to extrapolating databases across species, to estimating uncertainties, and determining the relevance of information to humans. Knowledge of the toxic mechanism(s) provides the underpinnings to the "plausibility" of findings in the human context and, under carefully defined and highly controlled circumstances, may allow *quantitative* estimates of risk to human populations. Animal toxicology studies have been used to investigate all of the criteria air pollutants and many of the HAPs as well. The strength of this discipline is that it can involve methods that are not practical in human studies and can provide more rapid turnaround of essential toxicity data under diverse exposure concentrations and durations. The minimization of uncontrolled variables (e.g., genetic and environmental) may be the greatest strength of the animal bioassay.

The clear limitation of animal studies in human risk assessment lies in the unknowns that weaken the extrapolation of findings in animals to the day-to-day human life scenario. Ideally, a test animal is selected with knowledge that it responds in a manner similar to that of the human (*homology*). *Qualitative* extrapolation of homologous effects is not unusual with many toxic inhalants, but *quantitative* extrapolation is frequently clouded by uncertainties of the relative *sensitivity* of the animal or specific target tissue compared with that of the human. Uncertainties about the target tissue dose also loom large, constituting the first obstacle to quantitative extrapolation (see below). With respect to the target tissue dose, however, most animal toxicologists make every effort to keep exposure concentrations at 5- to 10-fold that of the anticipated human exposure until appropriate dosimetric data can be ascertained. An often overlooked issue is that the dose to the target (lung region) for the test animal is less than that of the human under similar exposure conditions — especially when exposures are conducted during dormancy for the animals (Wichers *et al.*, 2006). Most human studies involve exercise exposure paradigms. Additionally, higher doses may be needed to achieve a group response among a limited pool of genetically similar animals (maybe 6–10) to represent a large population effect, where perhaps only a few of hundreds or thousands may actually be

responsive if analyzed separately. Nevertheless, it must be appreciated that mechanisms may well differ at different dose levels and some responses may be misleading at the higher dose levels. Despite these limitations, however, animal studies have provided the largest database on a wide range of air toxicants and have proven utility in predicting human adverse responses to chemicals.

To be effective, any health assessment should consider the strengths and weaknesses of the approaches selected to estimate actual toxic risk. In the larger picture, other scientific disciplines can be highly valuable to a more accurate assessment of the impact of air pollution on society. The atmospheric sciences (including the chemical and physical sciences) provide insight into actual exposures by characterizing what is in the air. Better pollutant characterization, linked to exposure assessment, can only strengthen epidemiological outcome associations. Similarly, these data support toxicity evaluations based on biological test systems. In the latter case, more controlled exposures provide better insights into biological outcomes, especially with defined pollutant physicochemical attributes and interactions. Recreating realistic exposure environments to the extent possible is invaluable to developing models to estimate human risk.

Lastly, data derived from studies of botanical responses are now appreciated more than ever. Not only are commercial and native vegetation affected by pollution but some plant species are being exploited as sensitive "sentinels," warning of the impacts of pollution on both human and environmental receptors. When considered collectively, economists can inform regulators and the public at large of the cumulative impact and adversity of pollution on our quality and standard of living (Maddison and Pierce, 1999). Interestingly, some basic mechanisms (e.g., the involvement of antioxidants) between plants and animals have remarkable parallels.

Animal-to-Human Extrapolation: Issues and Mitigating Factors

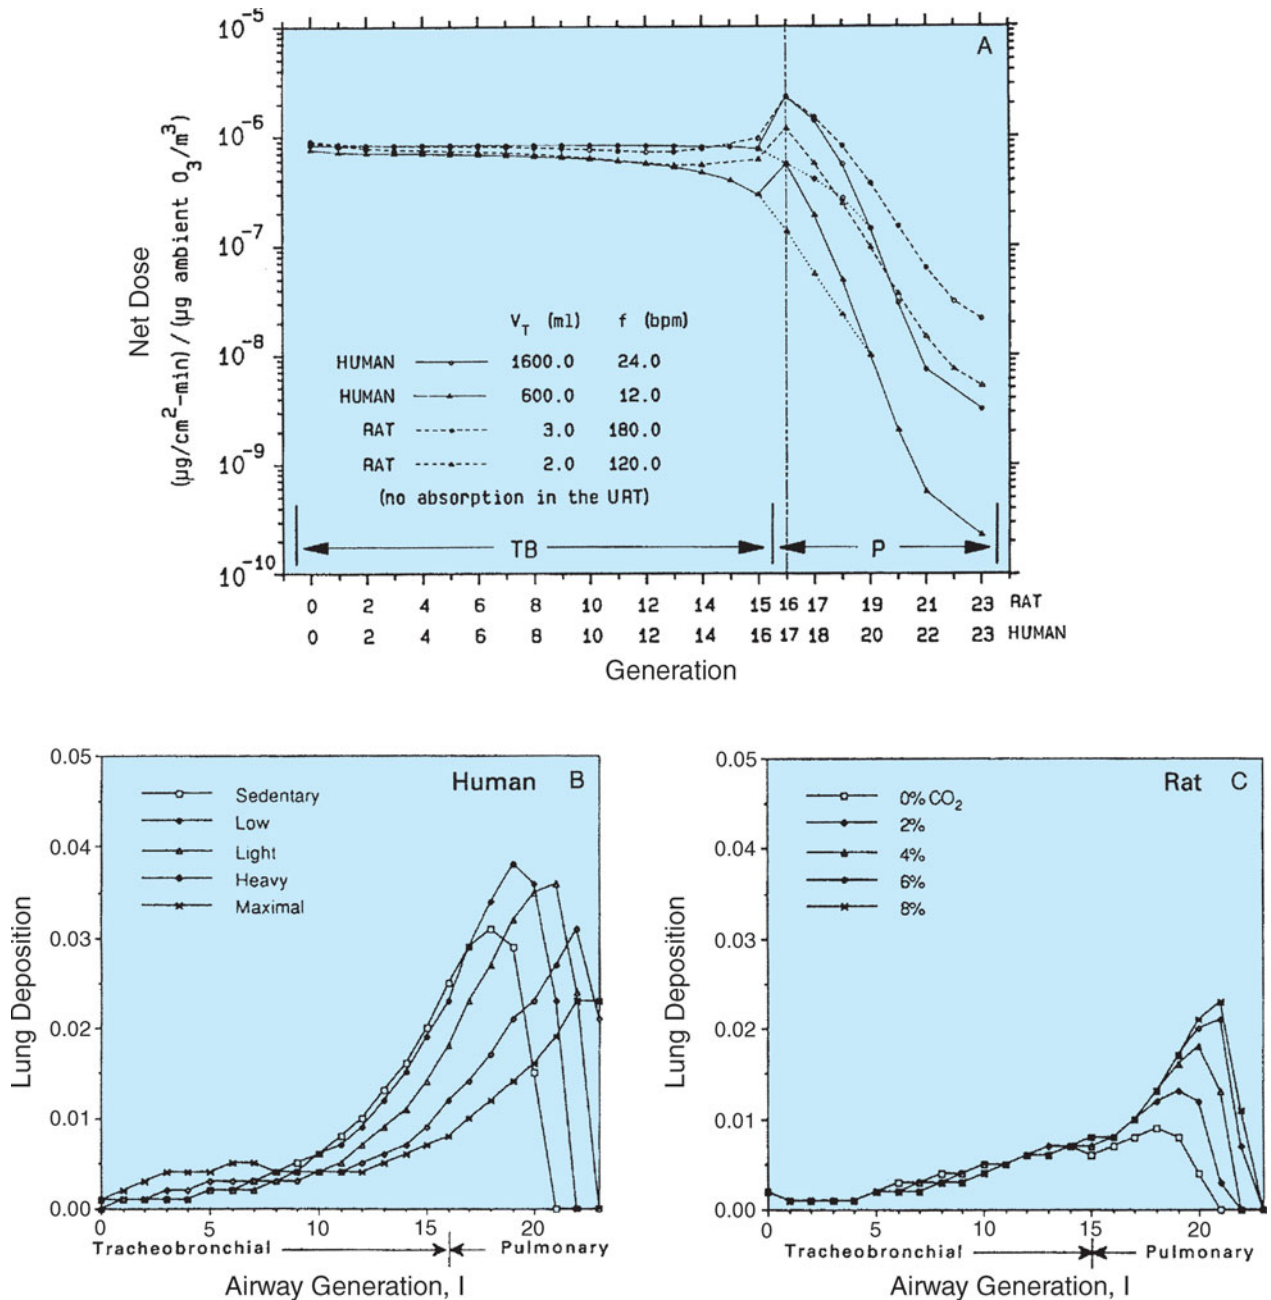
The utility and value of animal toxicology is highly dependent on the ability to extrapolate or relate empirical findings to real-world scenarios. Several factors of study design play into the process of extrapolation (e.g., exposure concentration, duration, and patterns, etc.), but most important is the selection of the animal species that will serve as the toxicological model. Therefore, this selection should involve more than considerations of cost and convenience. Whenever possible, effects that are homologous and involve the same mode of action between the study species and the human should guide the decision of the most appropriate test species. For example, if upper airway irritant responses like bronchoconstriction are anticipated (e.g., SO_2 or formaldehyde), then the guinea pig, with its human-like labile and reactive airway reflexes, should be selected over the rat, which is not particularly responsive in this regard. However, if the underlying molecular events in tissue remodeling are of interest, the rat might better serve as model because of cellular mechanistic parallels with human tissue responses. In part, the availability of probes to aid in such studies would factor into the selection of the rat as well. As strains of rats differ in their neutrophilic responsiveness to deep lung inhalants (e.g., O_3), contrasting the mode of action may be more revealing and support their selection for study (Costa *et al.*, 1985). Other innate differences in sensitivity among species may also relate to differences in lung structure, specific regionality of cell metabolism, genetic polymorphisms, or antioxidant defenses (Paige and Plopper, 1999; Slade *et al.*, 1985). Thus, ideally, when such nuances are unclear or unknown, the replication of responses in multiple species builds confidence in the finding as being


Figure 28-5. Theoretical (normalized to the concentration in inspired air) uptake curves for the reactive gas ozone in a resting/exercising human and a rat (A). Likewise, the percent deposition in the airways of a 0.6 μm insoluble particle in the respiratory tracts of a resting/exercising human (B) and rat (C).

Eight percent inspired CO_2 in the rat augments ventilation up to threefold. Airway generation refers to that airway branch numbered from the trachea (0). [Panel (A) is from Overton and Miller, 1987, and panels (B) and (C) are from Martonen *et al.*, 1992. Reproduced with permission.]

homologous or having species-conserved modes of action that are relevant to the human.

An essential, but often overlooked, part of extrapolating responses from species to species is an accurate assessment of the relative dosimetry of the pollutant along the respiratory tract. Significant advances in studies of the distribution of gaseous and particulate pollutants have been made through the use of empirical and mathematical models, the latter of which incorporate parameters of respiratory anatomy and physiology, aerodynamics, and physical chemistry into predictions of deposition and retention. Empirical

models combined with theoretical models aid in relating animal toxicity data to humans and help refine the study of injury mechanisms with better estimates of the target dose. Figures 28-5A and B illustrate the application of such an approach to the reactive gas O_3 and insoluble 0.6-μm spherical particles, respectively, as each is distributed along the respiratory tract of humans and rats. Anatomic differences between the species clearly affect the deposition of both gases and particles, but the qualitative and to a large extent quantitative similarities in deposition profiles are noticeable. This is not surprising if one argues teleologically that the lungs of each species

evolved with similar functional demands (i.e., O_2–CO_2 exchange, blood acid/base balance), mechanical impediments, and environmental stresses. One needs only a cursory review of the comparative lung physiology literature to appreciate the allometric consistency of the mammalian respiratory tract to meet the challenge of breathing air. This design coherency has provided the fundamental rationale for the use of animal models for the study of air pollutants.

Susceptible subpopulations who may show exaggerated responsiveness to pollutants merit special mention. The existence of hyperresponsive individuals and groups is well accepted among those who conduct air pollution health assessments, but little is actually known about the host traits that make certain individuals responsive. This appreciation for sensitive populations is specifically noted in the CAA, where their protection is mandated in the promulgation of NAAQS. There are some definable subgroups that are considered inherently more susceptible, including children, the elderly, and those with a preexisting disease (e.g., asthma, cardiovascular disease, lung disease). The importance of susceptibility in air pollutant responses is gaining more and more attention as test subject responses that were once considered "outliers" may well be evidence of unusual responsiveness. In some cases susceptibility may simply reflect differences in dosimetry. Children who spend more time outdoors than adults, who are more active, and who have basal ventilation rates that exceed adults on a volume to body weight ratio, may experience overall greater dose to the lungs. Certainly, rapidly growing tissues may also factor in and may have contributed, perhaps with dosimetry factors, to recent findings that polluted urban air retards lung growth (Gauderman *et al.*, 2004). Similarly, adult humans and animals with obstructive airway disease, for example, may have "hotspots" of particle deposition in the airways that exceed normal local tissue doses manyfold (Kim and Kang, 1997; Sweeney *et al.*, 1995). Another often underappreciated aspect of susceptibility relates to the loss of functional reserve or compensation due to age or disease, perhaps altering a response threshold or impairing normal homeostasis or recovery. As already noted, there is also growing interest in gene-environment interactions where genetic differences determine responsiveness. In humans, GSTM1 polymorphisms affect ~50% of the population and thus, may in theory undermine antioxidant defenses in some individuals (McCunney, 2005). In the end, susceptibility may be due to differences in dose, sensitivity, and/or compensation. Clearly, outcomes may be similar, but their underlying causes may be multifactorial.

Because the study of susceptibility in compromised human subjects is limited, ethically, studies must confined to subjects of only modest suspected risk (e.g., mild asthmatics). However, inroads have been made in recent years, in part because of more thorough pre-study assessments of potential risk factors, allowing researchers to design studies that need not carry undue risk. Additionally, the development of more appropriate animal models of disease or dysfunction provides a useful adjunct to explore susceptibility factors prior to study in humans and in more depth. Hence, studies in animals and human subjects are now being better coordinated, to investigate specific questions regarding the roles of diet (e.g., antioxidant content), exercise (as it relates to dosimetry), age, gender, and race, as well as disease associated frailty. The goal is to elucidate patterns or common factors that may inform potential intervention or mitigation strategies as well as basic information to reduce the uncertainties regarding risk (Kodavanti *et al.*, 1998).

Recent advances in molecular biology have provided tools to assess traits in animal models that are under the control of identifiable genes that are homologous to humans. Natural variants in

mouse genetics and specially bioengineered transgenic and knock-out strains (and in some cases rats), are now widely used to address mechanistic as well as risk hypotheses regarding responses to air pollutants. These new biological tools hold great promise in better understanding responses and establishing gene-environment interactions that may underlie variation in human responsiveness. Transgenic strains can be devised to express desired traits derived from humans as well as other animals, while knockout models can be made devoid of specific traits to isolate the impact of that trait on responsivity to a toxic challenge. These animal models add to the availability of natural mutants that have been inbred historically to purify a desired genotype to achieve a specific phenotype (Ho, 1994; Glasser *et al.*, 1994). Current technology can also target genes for specific expression in the lung (e.g., linked to surfactant protein C), and in some cases control genes can be provided with which an investigator can switch the gene of interest on or off using a pharmacologic or chemical prechallenge. Such advances allow the dissection of underlying mechanisms under very controlled scenarios and avoid the problems of having a gene be inappropriately active or inactive through all life stages (Kistner *et al.*, 1996).

To date, the emphasis of studies using these genetically modified animal models have been on mechanisms associated with disease pathogenesis (Recio, 1995; Suga *et al.*, 2000; Yoshida and Whitsett, 2006). Among the most popular uses of knockout and transgenic mice has been in the study of inflammatory cytokines and associated products in asthma, as the expression of many of these mediators are thought to be under the control of single genes (e.g., Kakuyama *et al.*, 1999; Kuhn *et al.*, 2000). Clearly these genetically modified mice are well suited for the study of mechanism of action where a specific mediator-based hypothesis can be tested as it relates to an impaired function, pathology, or altered inflammatory pattern. When these models are derived to exhibit a desired pathology or disease due to a genetic defect—for example involving lung structure or growth (e.g., emphysema or fibrosis), such that by adulthood the animal exhibits the disease—the model may serve as a surrogate of the human condition (e.g., O'Donnell *et al.*, 1999). Analogous mouse models (e.g., ApoE$^{-/-}$) are currently being used to assess atherosclerosis and cardiac disease in long term air pollution studies (Sun *et al.*, 2005).

The use or genetically modified animal models in air pollution research has lagged behind that of basic science and toxicology in general. The reasons for this are unclear and may relate to the difficulties in incorporating such data into conventional risk-assessment paradigms. However, with recent interest in susceptible groups, there has been a definitive upswing in the use of pharmacologically or naturally altered, as well as bioengineered animals (Kodavanti *et al.*, 1998) to more closely link mechanistic profiles to basic human biology. Ozone has frequently been the test pollutant in these new studies, because more is known about O_3 and its effects in humans than about any other air pollutant. Frequently, these studies address aspects of inflammation and antioxidant capacity relative to challenge by O_3 and other oxidants (Johnston *et al.*, 1999; Kleeberger *et al.*, 2000). But with the current interest in PM health effects, these and other models are being redirected. Examples include: strain differences and acid coated PM (Ohtsuka *et al.*, 2000); hypertransferrinemic mice and metal-rich PM (Ghio *et al.*, 2000); and metallothionein-null mice and mercury vapor (Yoshida *et al.*, 1999). Among rats, the Spontaneously Hypertensive Rat (SHR) has gained considerable popularity for use in studies of PM because of its resemblance to human hypertension with serum oxidant
Figure 28-6. Emission trend for volatile organic compounds (VOC), nitrogen oxides (NO$_x$), sulfur dioxide (SO$_2$), and particulate matter (PM < 10 μm) from 1900 (or when records began) to 1998.

Note that since the passage of the Clean Air Act of 1970, most emissions have decreased or, in the case of nitrogen oxides, have leveled off (Reproduced from National Air Pollutant Emission Trends Report, 1998).

imbalances, heart disease, as well as its sensitivity to lung injury from inhalants (Kodavanti *et al*., 2005). The curious are directed to the rapidly evolving literature in this area of research.

Air Pollution: Sources and Personal Exposure

In terms of tons of anthropogenic material emitted annually in the United States (as of 2002), five major air pollutants account for 98% of pollution: CO (112 thousand tons), SO$_2$ (15.3 thousand tons), volatile organic compounds (VOCs; 16.5 thousand tons), PM (6.8 thousand tons), and NO$_x$ (21.1 thousand tons). The remainder consists of Pb, which is down >98% since 1973, when phase-out from gasoline began, and a myriad of other compounds considered under the category of HAPs. On a national basis, aggregate emissions since 1970 have been cut 48%, while at the same time the U.S. Gross National Product (GNP) has increased 164%. Energy consumption has increased 42%, and vehicle miles driven have increased 155% (National Air Quality and Emissions Trends Report, 2003). The changing profile of pollutant emissions since 1900 is reflected in Fig. 28-6. Since 1993, air quality has generally continued to improve with reductions in ambient SO$_2$ being largest (−39%) but with O$_3$ changing the least, if at all. Obviously, for any specific locality, air quality can vary depending on the emission profiles of local sources, geographic topography, and meteorology. In the vicinity of a smelter for example, SO$_2$, metals, and/or PM may dominate the pollutant profile, while a refinery air shed might be dominated by VOCs and other carbonaceous products. In suburban areas, where the automobile is the main source of pollution, CO, VOCs, and NO$_2$ would prevail along with their primary photochemical product, O$_3$. NO$_x$ releases (including NO$_2$) by stationary sources also contribute to the local O$_3$ levels along with that derived secondarily from auto emissions. In all, about 146 million people in the United States live in counties that have violations of the NAAQS designed to minimize risks to the criteria pollutants.

The Evolving Profile of Air Pollution Classically, air pollution has been distinguished on the basis of the chemical redox nature of its primary components. Dickens's eighteenth-century "London's

particular," was characterized by SO$_2$ and smoke from incomplete combustion of coal accumulated during an inversion as a chilled, acidic fog. This acidic mix reacts with surfaces, corroding metal and eroding masonry, characteristic of reductive chemistry. Historically, reducing-type atmospheres have been associated with smelting and related combustion-based industries (as along the Meuse River in 1930 and Donora, Pennsylvania, in 1948) as well as large, coal-based urban centers such as London (1952) and New York (1962). In contrast, Los Angeles has always had a characteristically "oxidant-type" pollution consisting of NO$_x$ and many secondary photochemical oxidants, such as O$_3$, aldehydes, and electron-hungry hydrocarbon radicals. Los Angeles uniquely traps auto emissions by virtue of regional topography and summer meterology, while other areas, such as Atlanta, have stagnant summer air.

The classic types of air pollution were implicitly seasonal. Reducing air pollution occurred during winter periods of oil and coal combustion and meteorological inversions, while the oxidant atmospheres occurred during the summertime, when sunlight is most intense and can catalyze reactions among the constituents of auto exhaust. Today the distinction between reducing and oxidant smogs is largely academic. Most urban areas have virtually eliminated smoky, sulfurous emissions but now have a proliferation of automobiles that contribute tons of oxidant precursors into the air. However, in the Midwest there remains heavy industry that continues to emit SO$_2$, albeit much less than decades ago. These emissions undergo complex cloud chemistry to form sulfate that disperses regionally – hence the term, regional haze. Metropolitan areas in the eastern half of the United States, now have atmospheres comprising regional reducing pollutants as well as local oxidant pollutants. Sulfates may still predominate over nitrates in the air, in contrast to the Southwest United States, but no longer is the Northeastern air pollution simply a sulfur-based problem. Not only has the composition of the haze changed, but the chemistry has affected it temporal patterns. Long extended periods of O$_3$ now prevail rather than the prototypic spike patter of Los Angeles (although challenged by Houston for the number-one spot in 1999).

Outside the U.S., however, many megacities remain plagued by the classic forms of air pollution. For example, uncontrolled industrial emissions surrounding cities like Beijing and the northern sectors of Mexico City are dominated by oil, coal, and industrial emissions, whereas southern Mexico City, Santiago, and Tokyo have substantially (but not so exclusively) automobile-derived oxidant smogs. As noted above, air pollution is a worldwide problem, where the estimate of people exposed to O$_3$ at potentially harmful levels exceeds 480 million (Schwela, 1996), with WHO estimates of PM-related mortality at 500 thousand per year.

Indoor Versus Outdoor Air Pollution People in the United States (and in most industrialized nations) spend in excess of 80% of their time indoors at work, at school, and at home or between these places in an automobile (Robinson and Nelson, 1995). Generally, the time spent indoors is disproportionately higher for adults, who have relatively less time to participate in outdoor activities, especially during the day, when outdoor pollutants are usually at their highest levels. Children and outdoor workers, by contrast, are much more likely to encounter outdoor air pollution at its worst; in fact, because of the relatively high activity levels of these subgroups compared with inactive office workers, their lungs may incur a considerably larger dose of any given pollutant. Thus, whereas it is important to characterize and track pollution levels in outdoor air, the most
Figure 28-7. Illustration of contributors to the total personal exposure paradigm showing how these indoor and outdoor factors interact.

appropriate measure for exposure should involve a paradigm that addresses the total personal exposure of the individual or group of concern, and taken one step further, also dose to the lungs. However, defining typical paradigms of personal exposure can be extremely difficult, as personal monitoring is tedious, expensive, and complex. Outdoor pollutants can be encountered, with total exposure being influence by the personal dynamics and lifestyle of the individual. Individual monitoring is often expensive and difficult, so whenever possible, groups of people are monitored to develop models to estimate more specific exposure values.

The indoor environment has gained appreciation as a major contributor to total personal exposure. The energy crisis of the 1970s spurred efforts to increase home and building insulation, reduce infiltration of outside air, and minimize energy consumption. At the same time, indoor sources of air contaminants have been on the rise from household products and furnishings, which—when combined with poorly ventilated heating systems and overall reductions in air-exchange rates—give rise to potentially unhealthy indoor air environments. As people began to notice patterns of odors, microbiologic growth, and even ill health, measures of indoor air became a significant part of environmental assessment. Personal exposure has, therefore, come to include the myriad of potential sources, both outdoors and indoors.

It is clear now that indoor air can at times be more complex than outdoor air. The national monitoring network for the criteria pollutants has been shown to reflect human exposure reasonably well for some pollutants. Indeed, outdoor air permeates the indoor environment in spite of the reduced air exchange in most buildings. However, many variables determine how well components of the outdoor air infiltrate. The current evidence suggests that the average insulated home has about one air change per hour, resulting in indoor concentrations of pollutants that range from 30 to 80% of those outdoors. For nonreactive gases (e.g., CO), there could likely be nearly a 1:1 indoor/outdoor ratio in the absence of a "sink" for that gas;

the ratio for fine PM (<2.5 μm) could also be fairly high (~ 0.4–0.7), because these particles can easily penetrate through cracks and open spaces. In contrast, the indoor/outdoor ratio of O_3 would likely be low (<0.3) because of its reactivity. Obviously, household differences in the use of window ventilation and air conditioning would be important variables. Where there are independent sources of contamination indoors, the ratio of an indoor pollutant to that outdoors can even exceed 1 (e.g., NO_2). Particles and gases from tobacco smoke, unvented space heaters and poorly vented fireplaces and wood stoves as well as fresh paint and cleaning agents can be significant indoor sources. However, attention now is being directed toward the many and varied insidious sources of indoor contaminants: certain soils and construction masonry (radon), gas cooking appliances (NO_x), sidestream tobacco smoke (PM, CO, and a host of carcinogenic polyaromatics), and carpets, furnishings, dry-cleaned clothes, and household air fresheners (VOCs). Some of these chemicals can even interact with one another as has been found to occur with O_3 diffused indoors reacting with VOCs emitted from household cleaners. The complexity of these multiple sources underscores the importance of appreciating the total exposure scenario if we are to understand the nature of air pollution and its potential effects on human health (Fig. 28-7).

EPIDEMIOLOGIC EVIDENCE OF HEALTH EFFECTS

Outdoor Air Pollution

Acute and Episodic Exposures   A number of air pollution incidents have been documented where concentrations of contaminants have risen to levels that are clearly hazardous to human health. When a single chemical has been accidentally released (e.g., methyl isocyanate in Bhopal, India), establishing the relationship between cause and ill effect is straightforward. However, most air pollution

situations involve complex atmospheres, and establishing a specific cause other than the air pollution incident itself can be difficult. Three acute episodes of community air pollution are considered classic (Meuse Valley, Belgium; Donora, Pennsylvania; and London, United Kingdom). In each event, community inhabitants were clearly affected adversely; hospitalizations were concomitant with an elevated mortality rate. In each case, a meteorological inversion (cold air capped above by a blanket of warm air, with little or no vertical air mixing) prevailed for 3 or 5 days, during which time the concentration of pollutants rose well above the normal levels for these already heavily polluted areas. No actual measurements of pollution were made in the Meuse Valley and Donora, but crude measurements of the London fog recorded daily averages of smoke and SO_2. These were estimated at 4.5 mg/m^3 and 1.34 ppm, respectively, on the worst day. Brief (on the order of hours) peak concentrations probably reached even higher levels. During the Meuse Valley episode, 65 people died, while in Donora the number was 20. These deaths were considered "excess" deaths when compared with normal mortality rates for that time of year.

The famous "London smog" of 1952 is estimated to have resulted in 4000 excess deaths during the event itself. Hospital admissions increased dramatically, mainly among the elderly and those with preexisting cardiac and/or respiratory disease. Even otherwise healthy pedestrians, their visibility limited to as little as 3 ft, covered their noses and mouths in an attempt to minimize their exposure to the "choking" air. Many reports of sudden death were reported among workers commuting on bicycle or on foot with symptoms described as "choking." People with preexisting cardiac and lung problems were particularly affected. It is ironic that 16 years earlier, shortly after the Meuse Valley episode that 3200 deaths would occur should an analogous smog episode occur in London (Firkert, 1936). Although the London 1952 incident brought the issue of air pollution to the public consciousness, many additional episodes occurred, with the 1956 and 1962 incidents being among the most notable. Interestingly, in December 1991, London experienced a winter inversion smog-alert, but one with a very different pollutant profile: NO_2 at 423 ppb, black smoke at 148 μg/m^3, and SO_2 at 72 ppb (five, four times and twice the seasonal average, respectively). The difference between this episode and previous episodes were that the air pollution was not of the same magnitude and was largely vehicular and not the result of domestic coal burning (Anderson, 1999). Mortality and hospital admissions were difficult to discern overall, but regional comparisons suggested impacts among the elderly and cardiopulmonary-impaired (mortality: ↑14% cardiovascular and ↑22% respiratory; ↑43% for respiratory admissions). The component (and source) of the smog responsible was not clear, but overall the effects were of lesser magnitude than might have been expected.

London has not been alone among industrialized cities significantly affected by air pollution episodes in the more recent past. New York City, Steubenville, Ohio; Pittsburgh, Pennsylvania; Athens, Greece, and entire regions of Western Europe from the Netherlands to the Ruhr Valley of Germany have all had air pollution episodes of note between 1970 and 1995. While major episodes of anthropogenic air pollution continue to decrease over time in the modern world, both in their frequency and intensity, one should be aware of more "natural" events like the vegetation/forest fires of Indonesia of 1997 and 1998 can have significant impacts on air quality and health of the exposed populations. Even the forest fires of the Northwest United States in 2003 could be tracked as the plumes dispersed across the country.

So much has the air improved from the 1960s into the 1970s that many thought that the problem of sulfur-based industrial pollution was on its way to full resolution. Smokes were less visible and the air epidemiology of the times showed little health impact. However, in the late 1980s, there were revelations regarding acidic particle pollution of lakes and defoliation of forests (Calvert et al., 1985). There were also new studies showing increased emergency room visits among potentially susceptible populations—e.g., asthmatics (Bates and Sizto, 1987). A series of studies showed acute effects of regional summer haze in areas of central and Northeastern North America. These 2–3 day episodes of haze were typified by increases in O_3 and acid and neutralized (ammonium) sulfates, characteristic of the new generation of pollution in most U.S. urban areas. Interestingly, the apparent combined temporal or sequential patterns of O_3 and sulfate were associated with the health effects, but neither constituent seemed to be acting alone. Similar results were reported for the upstate New York area as well (Thurston et al., 1992), but the acidity as [H$^+$] of the haze was thought to play a more dominant role. Studies of children at summer camps, where children are active and outdoors most of the day, had reported decrements in daily measured pulmonary function on days of haze when both O_3 and acidity levels were elevated. The responses appeared to exceed those predicted by chamber studies of O_3 alone suggesting dose differences or interactions between haze components (Lippmann, 1989). Clinical studies in adolescent asthmatics and animal studies have lent further support to the belief that H$^+$ can affect airway function, particularly in the presence of O_3. Studies in the South and Southwest similarly have found effects in young asthmatics, but these appear to relate more specifically to O_3, because sulfate is less prominent in the ambient air. Early data from the Los Angeles area showed strong correlation between diminished performance among high school athletes and increased oxidant levels.

Of the many air pollution studies over the last 10–15 years, none has had more impact on the perception of pollutant risk and the direction of research today than a series of epidemiological studies that have shown association between PM and daily mortality. These studies were a novel application of time-series analyses of human health data records linked to regional air monitoring data. These studies showed significant and consistent associations between health outcomes of ambient PM at levels previously thought to be safe. Prior to this period, measurable effects of PM and SO_2 were not easily detected below the 24-hour means for smoke and SO_2—250 μg/m^3 and 0.19 ppm, respectively. In fact, the new findings showed effects, as evidenced by increases in mortality and morbidity rates at or below contemporaneous NAAQS levels [1987: 50 μg/m^3, annual mean; 150 μg/m^3 daily maximum for PM of diameter <10 μm (PM$_{10}$)]. Time-series analyses are based on Poisson regression modeling to distinguish changes in daily death counts associated with short-term changes in PM air pollution. The studies initially found effects with cruder measures of PM—total particulate material, which includes virtually all particles <35 μm in mass median aerodynamic diameter (MMAD—a median particle size normalizing the particle to unit density and spherical shape for aerodynamic comparison). These studies were followed with stronger associations with particles considered almost fully inhalable—PM$_{10}$ (an MMAD at which PM is aerodynamically separated at an initial 50% efficiency at 10 μm and increasingly at smaller sizes). Most recently, even stronger associations have been found with an analogous but fully and deeply respirable particle—PM$_{2.5}$. As the PM gets smaller, it better represents anthropogenic sources of pollution. The statistical methodology applied in these studies had an
Figure 28-8. Schematic of the multiple mechanisms thought to function in cardiopulmonary response(s) to air pollutants— derived from current hypothesized mechanisms for particulate matter.

advantage over conventional regression analyses in that it could detect short-term trends and minimized the effects of other pollutants and potential confounders with longer time constants (Schwartz, 1991; reviewed by Pope and Dockery, 2006).

In contrast to the three epidemiologic studies used to develop the 1987 PM$_{10}$ NAAQS, there were more than thirty studies for the 1997 revision and the promulgation of the new index, PM$_{2.5}$ NAAQS [15 μg/m^3, annual mean; 65 μg/m^3 daily maximum for PM of diameter <2.5 μm (PM$_{2.5}$)]. These studies showed a significant health impact of PM, linked to mass and not necessarily sulfate or any other constituent. In 2006, the PM NAAQS is again under review. More than 100 short- and long-term time-series studies have been considered, along with three major and several lesser long term cohort studies have been considered (USEPA, 2004).

The major health outcome uncovered in the study of PM is the involvement of the heart. Whereas the heart, as part of the cardiopulmonary system, has always held an indirect role in health impacts or disease from air pollution, both epidemiological and toxicological studies pointed to major cardiac involvement. Current thinking is that cardiac-mediated effects are more germane to the PM-associated mortality findings than pulmonary effects, although this concept remains under debate. Not surprisingly, effects are most apparent in subpopulations already compromised by cardiopulmonary and perhaps vascular diseases (e.g., diabetes). There exists no one generally accepted mechanism or mode of action to account for these findings (Schwartz, 1994; Costa, 2000). However, several pathways have been proposed that attempt to link exposure and cardiac effects that may or may not include pulmonary mediation. These potential mechanisms are illustrated in Fig. 28-8.

From a toxicological perspective, it has been difficult to accept that the association between particles and health outcomes is not somehow linked to PM composition rather than mass alone. The linkage to mass and not composition is counterintuitive, especially in light of the fact that all PM is not constitutively identical. The actual "biochemical lesion" caused by PM is generally thought to involve oxidant mechanisms (generation of reactive oxygen and perhaps nitrogen species) by constituents or attributes (reactive surface area) of the particles at the cell or molecular level. Initially, there was a credibility hurdle (biologically plausibility) that day-to-day fluctuations in the mass concentration of ∼10 μg/m^3 airborne PM result in an increase of about 0.6–1% (excess) mortality. However, there now exist several plausible hypotheses that have some degree of empirical support: metals, organics, size difference, stable oxidants to name those most prominent. In addition to mortality, morbidity (in terms of hospital visits, inhaler use by asthmatics, and school absenteeism) has also been associated with ambient PM levels; other factors such as temperature, humidity, O$_3$, SO$_2$, and other pollutants per se do not explain the observed effects. Generally speaking, the consistency of the phenomenon from one geographic site to another and over time is remarkable (Pope and Dockery, 2006). Even revisiting the mortality data from the 1952 London incident demonstrates that PM was likely the pollutant of most prominence in terms of the adverse health consequences back almost 50 years (Schwartz and Marcus, 1990).

The direction and design of hybrid clinical-epidemiology studies today, frequently referred to as panel studies, are largely person-based, where groups of people are studied (e.g., nursing home residents, schoolchildren) in their immediate environment using non-invasive or minimally invasive clinical tools (e.g., pulmonary or cardiac function, symptoms, blood screenings, genomic profiles, etc.) to correlate effects with ambient and/or personal environmental and air pollutant measures. These studies sacrifice the power of large group numbers for more direct and individual data and controlled estimation of exposure and effect in an attempt to link biomarkers with exposure. These novel approaches have the promise of eventually offering clues as to causality, which is not possible with conventional epidemiology, and recent studies are showing increasingly more subtle changes in cardiopulmonary function with exposure to very modest air pollution.

Long-Term Exposures   Epidemiologic studies of the chronic effects of air pollution are difficult to conduct by the very nature of the goal: outcomes associated with long-term exposures. Looking back in time with retrospective, cross-sectional studies is a common approach, but one frequently confounded with unknown variables and inadequate historical exposure data. A good example of the problem of confounding is cigarette smoking. Without extensive control of both active and passive smoking, the ability to discern the impact of an air pollution disease outcome, such as chronic bronchitis and emphysema, would be greatly impaired because of the high background of disease attributable to smoking and the imprecision of most indices of smoking exposure. In contrast, prospective studies have the advantage of more precise control of confounding variables, such as the tracking of urinary cotinine as an index of tobacco smoke exposure, but they can be very expensive and require substantial time and dedication on both the part of the investigators as well as the study population. Depending on the study size and design, exposure assessments can be complex, and the loss of subjects due to dropout is sometimes unpredictable.

Despite these deficiencies and problems, there are both retrospective and prospective epidemiology studies that have tackled the issue of long-term air pollution health effects. In general, these studies have suggested a positive association between urban pollution and progressive pulmonary impairments. On the one hand, cross-sectional studies in the Los Angeles Air Basin have found evidence of accelerated "aging-like" loss of lung function in people living for extended periods in regions of high oxidant pollution when compared with areas where sea air circulation lowers overall pollutant concentrations (Detels *et al*., 1991). Similarly, exposure to SO_2 and PM in the Netherlands over a 12-year period was shown prospectively to gradually impair lung function (Van De Lende *et al*., 1981). And even rural areas in western Pennsylvania, which are swept by reducing-type pollutants transported from Midwestern industrial centers, have been shown to have a higher incidence of respiratory symptoms as determined from a questionnaire-based design (Schenker *et al*., 1983). Whereas the role of any specific pollutant in these studies is difficult to dissect, the message that air pollution contributes to deterioration of lung health seems clear.

Among the most detailed prospective epidemiologic studies of chronic health effects across a range of levels of air pollution has been the so-called Harvard Six Cities Study begun in the early 1970s. The cities were chosen to represent a range of air quality based on SO_2 and PM. Initially, there was great dependence on routine regional air-monitoring data, but over time the investigators themselves conducted the air analyses of exposure microenvironments (local and indoor). The initial design of these studies included the gathering of parental questionnaire data (including some 20,000 people) about the prevalence of respiratory problems in schoolchildren and has continued over twenty years along with periodic assessments of pulmonary function. When compared across cities, $[H^+]$ (measured in four of the six cities) was correlated (Fig. 28-9*A*) better than was sulfate with the prevalence of bronchitis in children age 10–12 years (Speizer, 1989). However, as the assessment program evolved, a more detailed study revealed mortality associations with PM as represented in Fig. 28-9B through D. However, the role of $[H^+]$ in relation with acute mortality was less convincing than that associated with the sulfate or fine ($\leq$2.5 μm) PM (sulfates co-associate with fine PM in the atmosphere) (Dockery *et al*., 1993). More importantly with regard to long-term health, this study showed very significant effects of PM on the life spans of people living in Steubenville, Ohio—the dirtiest of the industrial centers.

Over a 15-year period, the average human life span was reduced by about 2 years due to PM exposure. These findings were corroborated by a prospective cohort-based mortality study using a database collected on over 500 thousand people by the American Cancer Society (ACS) across 151 cities from 1982 to 1989 (Pope *et al*., 1995). The study showed a 15–17% increased mortality risk over 7 years due to PM, about equivalent to the risk of smoking over that period. Subsequently, Pope *et al*. (2002) reported results of a 10-year follow-up study of the ACS cohort. This updated analysis, which included gaseous co-pollutant and new fine-particle measurements, and more comprehensive personal information on the enrollees, confirmed the linkage of health effects, including a small risk of lung cancer, with $PM_{2.5}$ exposures. These findings reinforce the concerns for potential chronic health impacts of PM and the heightened risk of premature death from lifelong air pollution exposure. There is currently a 10-year study (results expected ~2015) to assess the impact of air pollution, with emphasis on PM, on atherosclerosis in humans as part of the MESA AIR (Multi Ethnic Study of Atherosclerosis Air Pollution—http://depts.washington.edu/mesaair/).

The role of air pollution in human lung cancer is difficult to assess because the vast majority of respiratory cancers result from cigarette smoking. The ACS study noted above for particles showed a linkage between air pollution particles and lung cancer, but in general it has been difficult to show these effects for the many HAP compounds that occur as urban air pollutants that are thought to be carcinogenic. However, most of the HAPs and even fewer (about 10%) of the more than 2800 compounds that have been identified in the air have been assayed for carcinogenic potency. Figure 28-10 gives estimates of the relative contributions of various chemicals to the lung cancer rate that is *not* associated with cigarette smoking, which, for outdoor air, is estimated to be about 2000 cases per year (Lewtas, 1993). This compares with about 2000 cases per year for passive environmental tobacco smoke and >100,000 cases per year for smokers. Volatile organic compounds (VOCs) and nitrogen-containing and halogenated organics account for most of the compounds that have been studied with animal and genetic bioassays. Most of these compounds are derived from combustion sources ranging from tobacco to power plants to incinerators. Other potential carcinogens arise from mobile sources as products of incomplete combustion and their atmospheric transformation products as well as fugitive or accidental chemical releases. This profile of carcinogens contrasts with that of indoor air, where the sources are thought to derive largely from environmental tobacco smoke and radon, with some contribution from the off-gassed organics (e.g., adhesives, carpet polymers).

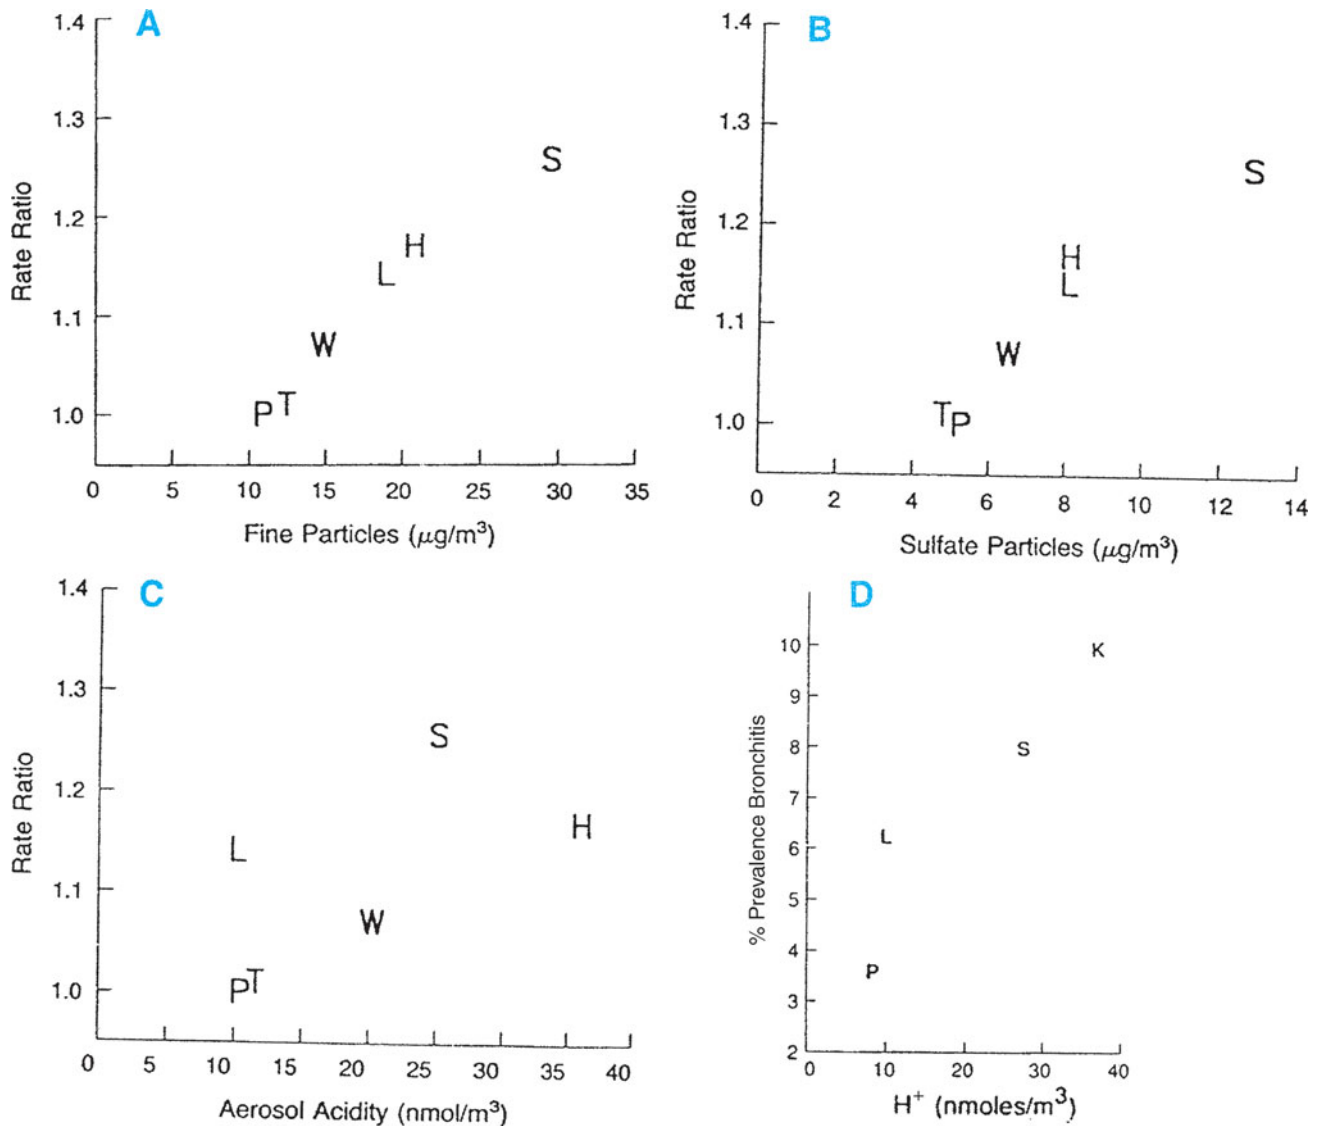
The cancer risk of any individual should be some function of the carcinogenic nature of the substance, the amount of material deposited, which is itself a function of the concentration in the ambient air and the cumulative volume inhaled. Of course the innate susceptibility of the individual (including genotype and environmental factors such as diet, etc.) can also be important. A significant body of data suggests that the majority of cancer risk from ambient air pollution lies within the PM fraction. Among the many potent chemicals are the polycyclic organic chemicals, along with a group of less-volatile organics sometimes referred to as "semivolatiles" (including nitroaromatics). These persistent organics associate with the particulate matrix and thus could have a prolonged residence time at deposition sites within the respiratory tract. Genetic bioassays have revealed the potent mutagenicity, and presumably carcinogenicity, of various chemical fractions of ambient aerosols (Lewtas, 1993). Some of these compounds require metabolic transformation


Figure 28-9. Data from the Harvard Six Cities Study indicating the superior relationship of PM_{10} and sulfate to mortality rates (A–C) in contrast to acidity (D), which correlates better with the prevalence of bronchitis in children [Reproduced with permission from Speizer, 1989 (D) and Dockery et al., 1993 (A–C)].

to activate their potency whereas others may be detoxified by their metabolism.

The cells lining the respiratory tract turn over relatively quickly, because they continuously interface with the ambient environment. Conceptually, their DNA would thus be vulnerable to carcinogenic or oxidant-induced replication errors that, when fixed as mutations, could be tumorigenic. Co-pollutants, such as irritant gases, that initiate inflammation may promote carcinogenic activity by damaging cells and further enhancing their turnover. For example, there is experimental evidence that benzo(a)pyrene inhaled by rats whose respiratory tracts have been chronically exposed to SO_2 are prone to bronchogenic carcinomas. Likewise, epidermoid carcinomas were produced in mice that inhaled ozonized gasoline vapors, containing many reactive organic products, but only if these mice had been previously infected with influenza virus and presumably had inflamed lungs. Many suspect that the so-called rural–urban gradient of lung cancer, apparent even when corrected for cigarette smoking,

is a product of these complex interactions. Thus, while the phenomenon of environmental lung cancer remains poorly understood, there is general sentiment for the early opinion expressed by Kotin and Falk in 1963: "Chemical, physical and biological data unite to form a constellation that strongly implicates the atmosphere as one dominant factor in the pathogenesis of lung cancer." At the time of this statement, however, the role of tobacco smoke was not widely appreciated.

Indoor Air Pollution

As outdoor air quality has improved over the last 35 years, there has been a growing awareness of the potential for indoor air pollution to elicit adverse health effects. The concerns about indoor air that at first brought skepticism have gained an element of respectability as various attributes of the indoor environment and its effect on health and well-being have been investigated. However, the issue
Figure 28-10. Relative contribution of individual airborne hazardous pollutants to lung cancer rates after removal of tobacco smoke cancer.

The total number of cancers from nontobacco-smoke sources is estimated to be about 2000 per year. (Reproduced with permission from Lewtas, 1993). PIC = products of incomplete combustion.

remains controversial because many of the health problems associated with indoor air pollution generally involve nonspecific symptomatology and appears to involve a wide range of potential toxicants and sources (Molhave *et al*., 1986). The responses to indoor air pollution also appear to be affected by ambient comfort factors such as temperature and humidity. Two broadly defined illnesses that are largely unique to the indoor environment are discussed below (Brooks and Davis, 1992).

Sick-Building Syndromes   This collection of ailments, defined by a set of persistent symptoms enduring at least 2 weeks (Table 28-3), occurs in at least 20% of those exposed and is typically of unknown specific etiology, but is relieved sometime after an affected individual leaves the offending building (Hayes *et al*., 1995). Frequently but not always, this syndrome occurs in new, poorly ventilated, or recently refurbished office buildings. The suspected causes include combustion products, household chemicals, biological materials and vapors, and emissions from furnishings; they are exacerbated by the effect of poor ventilation on comfort factors. The perception of irritancy to the eyes, nose, and throat ranks among the predominant symptoms that can become intolerable with repeated exposures. Controlled clinical studies have shown concentration- and duration-dependent worsening of sensory discomfort after exposure to a complex mixture of 22 VOCs commonly found in the indoor environment (Molhave *et al*., 1986). The many factors contributing to such responses are poorly understood but include various host susceptibility factors, such as personal stress and fatigue, diet and alcohol use. Current biomarkers of response used in the

laboratory include sensory irritancy to the eyes in volunteer test subjects and sometimes in animals. However, in general, animal studies using standard measures of sensory irritation or other corporal endpoints have had limited success in assessing sick-building syndromes (SBS) and related syndromes. The biggest problem generally lies in the VOC concentrations required to achieve responses in a limited pool of animals that relate to unique human scenaios is too high to establish a plausible link to the human condition.

Building-Related Illnesses   This group of illnesses, in contrast to the SBS, consists of well-documented conditions with defined diagnostic criteria and generally recognizable etiology. These illnesses

typically call for a conventional medical treatment strategies, because simply exiting the building where the illness was contracted may not readily reverse the symptoms. Several biocontaminant-related illnesses (e.g., legionnaires' disease, hypersensitivity pneumonitis, humidifier fever) fall into this group, as do allergies to animal dander, dust mites, and cockroaches. Medical treatment and mitigation of exposure (source elimination or personal protection) are generally needed to abate symptoms. Some outdoor pollutants can also be problematic indoors—most notably, CO from poorly vented heaters. Indoor exposures to NO_2 can pose problems as well, especially in people who may be sensitive—such as asthmatics. At times, however, when the concentrations of CO, NO_2, and many VOCs (passively emitted from new furniture or rugs, or from molds in the ventilation system) result in less discernible or definable signs and symptoms, the responses may be misdiagnosed as SBS, which can complicate assessment of the situation.

It should be noted that many inhalants, such as NO_2 and trichloroethylene (a VOC common to the indoor air arising from chlorinated water or dry-cleaned clothes), have been shown in animal toxicology studies to suppress immune defenses and allow opportunistic pathogens to proliferate in the lung. The involvement of immunologic suppression is a particularly controversial, yet an important attribute of indoor pollution because of its insidious nature and its implications for all building-related illnesses. This problem is further complicated in that complex indoor environments comprising of chemicals and biologicals (dust mites, fungi, molds etc.) may also lead to in unexpected interactions that remain virtually unstudied and thus are underappreciated in the assessment of indoor pollution.

POLLUTANTS OF OUTDOOR AMBIENT AIR

Classic Reducing-Type Air Pollution

The acute air pollution episodes of this century have made it clear that high concentrations of the reducing-type air pollution, characterized by SO_2 and smoke, are capable of producing dramatic human health effects. Empirical studies in human subjects and animals have long stressed the irritancy of SO_2 and its role in these incidents, while the full potential for interactions among the co-pollutants in the smoky, sulfurous mix has a mixed record of replication in the human exposure laboratory. Nevertheless, the irritancy of most S-oxidation products in the atmosphere is well documented, and there are both empirical and theoretical reasons to suspect that such products act to amplify the irritancy of fossil fuel emission atmospheres via chemical transformation. Because of its history, SO_2 is often thought of as the prototypic air pollutant of the industrial age. It is an irritant gas that has a toxicology of its own and, through atmospheric reactions, can transform into sulfites or sulfates within an irritant particle. As such it has a detailed literature base and while current levels of SO_2 in the ambient air of United States is less a threat than 30 years ago, it stands to demonstrate the role of toxicology in moving regulation to bring this contaminant under ever-increasing control.

Sulfur Dioxide
General Toxicology   Sulfur dioxide is a water-soluble irritant gas. As such, it is absorbed predominantly in the upper airways. It is a sensory irritant and can stimulate bronchoconstriction and mucus secretion in a number of species, including humans. Early studies

with relatively high exposure concentrations of SO_2 showed airway cellular injury and subsequent proliferation of mucus-secreting goblet cells. This attribute of SO_2 has led to its use (>250 ppm) in the production of laboratory animal models of bronchitis and airway injury (Kodavanti *et al.*, 2000). At much lower concentrations (<1 ppm), such as might be encountered in the polluted ambient air of industrialized areas, long-term residents experience a higher incidence of bronchitis. In fact, prior to the breakup of the Soviet block, many eastern European cities were renowned for widespread public affliction with bronchitis; now, 20 years later, the prevalence of bronchitis is greatly reduced (von Mutius *et al.*, 1994). While other factors (diet, access to health care, other pollutants) may well have been involved in this reversal, reductions in ambient smoke and SO_2 are generally thought to be most important.

The concentrations of SO_2 likely to be encountered in the United States are lower still—on average, considerably less than 0.1 ppm. Mandated use of cleaner (low-S) fossil fuels by industry as well as in diesel vehicles and emission control devices that scrub S have largely been responsible for the reductions (1970: 31,218 tons vs. 2005: 15,353 tons). Rare down-drafting of smokestack plumes due to meteorological inversions near point-sources may result in focal low-ppm levels of SO_2 that could pose a hazard to some individuals. A 2-minute exposure to 0.4–1.0 ppm can elicit bronchoconstriction in exercising asthmatics within 5–10 minutes (Gong *et al.*, 1995). However, concern remains that low-level, long-term erosion of pulmonary defenses may carry risk of reduced resistance to infection. Studies have shown that SO_2 is itself capable of impairing macrophage-dependent bacterial killing in murine models. Exposed mice have a greater frequency and severity of infection, which has been suggested to be linked to diminished ability to generate endogenous oxidants for bacterial killing. Analogously, rats exposed for 70–170 hours to 0.1, 1.0, and 20 ppm exhibited reduced clearance of inert particles, while dogs exposed to 1 ppm for a year had slowed tracheal mucocilliary transport. The fact that the low-concentration exposures showed marked effects when extended over longer periods is consistent with the epidemiologic associations between SO_2 exposure and bronchitis. The evidence is not clear, however, as some studies show no overt long-term pulmonary pathology. Guinea pigs and monkeys, for example, showed no effect on lung function or pathology after a year of continuous exposure to concentrations of 0.1–5 ppm (Alarie *et al.*, 1970, 1972).

The penetration of SO_2 into the lungs is greater during mouth as opposed to nose breathing. An increase in the airflow in deep rapid breathing augments penetration of the gas into the deeper lung. As a result, persons exercising would inhale more SO_2 and, as noted with asthmatics, are likely to experience greater irritation. Once deposited along the airway, SO_2 dissolves into surface lining fluid as sulfite or bisulfite and is readily distributed throughout the body. It is thought that the sulfite interacts with sensory receptors in the airways to initiate local and centrally mediated bronchoconstriction. Labeled $^{35}SO_2$ studies indicate, however, that some residual S (presumably as protein reaction products) persists in the respiratory system for a week or more after exposure, and is slowly excreted in the urine (Yokoyama *et al.*, 1971). In both rabbits and human subjects, sulfite that reaches the plasma has been shown to form *S*-sulfonate products of reaction with the disulfide bonds in plasma proteins (Gunnison and Palmes, 1974). The toxicological significance of *S*-sulfonate proteins is unknown, but they might serve as markers of exposure.

Pulmonary Function Effects   The basic pulmonary response to inhaled SO_2 is mild bronchoconstriction, which is reflected as a

measurable increase in airflow resistance due to narrowing of the airways. Concentration-related increases in resistance have been observed in guinea pigs, dogs, and cats as well as humans. Exposure of isolated segments of the nose or airways of dogs and guinea pigs appeared to alter resistance in a manner consistent with receptor-mediated sensory stimulation. Airflow resistance increased more when the gas was introduced through a tracheal cannula than via the nose, since nasal scrubbing of the water-soluble gas was bypassed. Isolated nasal exposures increased nasal airflow resistance through the nose largely as a result of mucosal swelling, but the irritant effect appeared to signal to the more distal airways as well. Direct exposure of the trachea had a more dramatic effect on airflow resistance. Exposure of the intact nose also induced some response, consistent with the existence of a nasal neural network being involved in bronchoconstriction (Frank and Speizer, 1965; Nadel *et al.*, 1965). Intravenous injection of atropine (a parasympathetic receptor blocker) or cooling of the cervical vagosympathetic nerves abolishes bronchoconstriction in the cat model; rewarming of the nerve reestablishes the response. The rapidity of the response and its reversal emphasize the parasympathetic tonal change in airway smooth muscle. Studies in human subjects have confirmed the predominance of parasympathetic mediation, but histamine from inflammatory cells may play a secondary role in the bronchoconstrictive responses of asthmatics (Sheppard *et al.*, 1981).

Human subjects exposed to 1, 5, or 13 ppm SO_2 for just 10 minutes exhibit a rapid bronchoconstrictive response, with 1–3 ppm being a threshold for most if exercise is involved. Healthy individuals at rest seem to have a clear response at about 5 ppm, though there is considerable variation among individuals (Frank *et al.*, 1962). Even 0.25–1 ppm for a few hours can induce bronchoconstriction in adult and adolescent subjects with clinically defined mild asthma (Sheppard *et al.*, 1981; Koenig *et al.*, 1981). Findings such as these (responses <0.5 ppm) have raised concerns about potential adverse effects in this sensitive subpopulation when

it is exposed to peaks of SO_2 that are known to occur near point sources.

Chronic Effects   Only a few long-term studies have been conducted with SO_2 at levels approaching those found in ambient air. Alarie *et al.* (1970) exposed guinea pigs to 0.13, 1.01, or 5.72 ppm SO_2 continuously for a year without adverse impact on lung mechanics. Similarly, monkeys exhibited no alteration in pulmonary function when exposed continuously for 78 weeks to 0.14, 0.64, and 1.28 ppm SO_2 (Alarie *et al.*, 1972). Even in the presence of 0.1 mg/m³ sulfuric acid, dogs exposed 16 hours a day for 18 months to 0.5 ppm SO_2 showed no impairment in pulmonary function (Vaughan *et al.*, 1969). Higher levels of SO_2 for protracted periods of time [dogs to 5 ppm for 225 days (Lewis *et al.*, 1969); rats to 350 ppm for 30 days (Reid, 1963)] have been shown to alter airway mucus secretion, goblet cell topography, or lung function, but these results are of little relevance to typical SO_2 levels in ambient air.

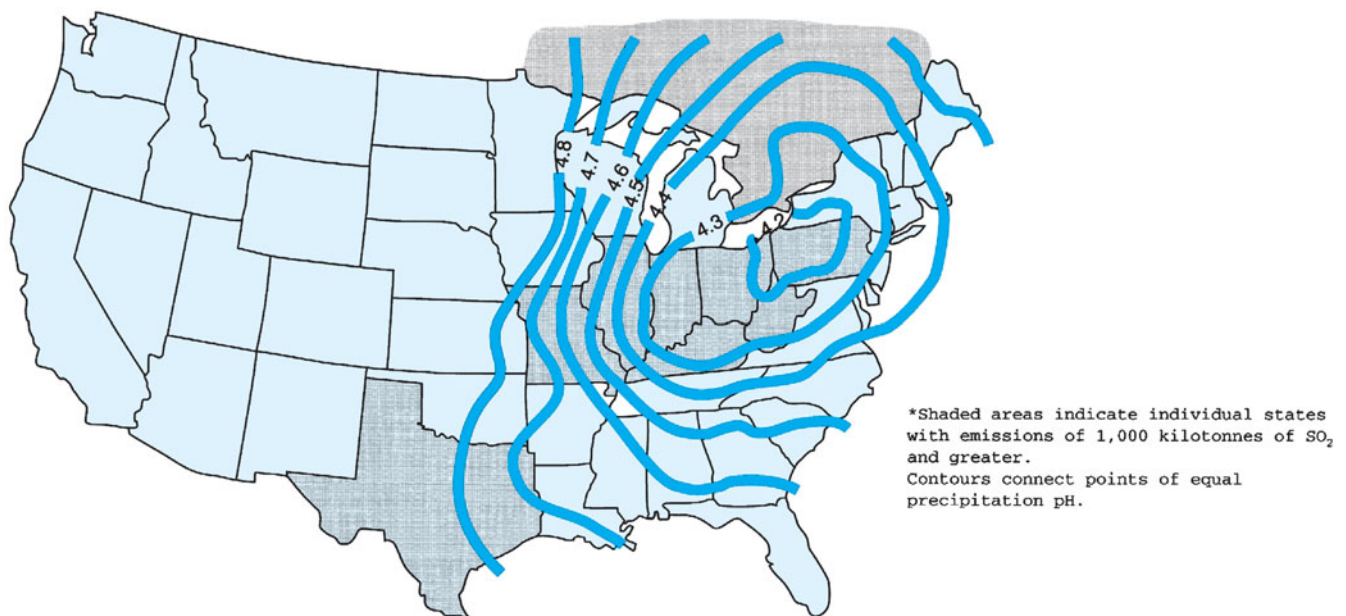
Sulfuric Acid and Related Sulfates   The conversion of SO_2 to sulfate is favored in the environment with subsequent ammonia neutralization to ammonium sulfate [$(NH_4)_2SO_4$] or as ammonium bisulfate [NH_4HSO_4]. During oil and coal combustion or the smelting of metal ores, sulfuric acid condenses downstream of the combustion processes with available metal ions and water vapor to form submicron sulfuric acid fume and sulfated fly ash. Sulfur dioxide continues to oxidize to sulfate within dispersing smokestack plumes, which can be augmented by the presence of free soluble or partially coordinated transition metals such as iron, manganese, and vanadium within the effluent ash. When coal is burned, the acid may adsorb to the surface or solubilize in ultrafine (<0.1 μm) metal oxide particles during emission. These sulfates on the surface of coal ash may constitute as much as 9% of the emitted S—the rest is emitted as SO_2 gas. Photochemical reactions in the troposphere also promote acid sulfate formation via both metal-dependent and independent


Figure 28-11. Areas in 1988 where precipitation in the East fell below pH 5: acid rain.

The acidity of the air in the east is thought to result from air mass transport of fine sulfated particulate matter from the industrial centers of the Midwest (National Air Pollutant Emission Trends Report, 1998).

mechanisms, but studies have shown that most of the oxidation of SO_2 occurs within plumes as they disperse in the atmosphere. Stack emissions may undergo long-range transport to areas distant from the emission source, allowing considerable time for sunlight-driven chemistry. Although the fine-particle sulfates may exist as fine sulfuric acid (the primary source of free H^+), partially or fully neutralized forms sulfate predominate, due to the abundance of natural atmospheric ammonia. As fine PM sulfates are transported long distances, they may contribute to regional summer haze and pose not only a health hazard to certain groups such as asthmatics (Koenig et al., 1989), and may also stress the general environment as acid rain (Calvert et al., 1985) (Fig. 28-11). The reduction of S emissions since the CAA and subsequent regulations (e.g., Acid Rain Program) have greatly curtailed the environmental acidification problems in North America associated with transport and deposition of acidic products formed from stack emissions. Western Europe has also made regulatory advances and similarly seen substantial recovery of acidified lakes and forest damage, although some of the Eastern Block countries continue to have problems.

General Toxicology   Sulfuric acid irritates by virtue of its ability to protonate (H^+) receptor ligands and other biomolecules. This action can either directly damage membranes or activate sensory reflexes that initiate inflammation. Ammonia, which exists in free air at about 25 ppb and in much higher concentrations within the mammalian naso-oropharynx (in the human up to 350 ppm), is capable of neutralizing most of the irritant acidic sulfates (Utell et al., 1989). The efficiency of this process is dependent on temperature, relative humidity, and air mixing and thus is a likely source of variability in biological responses. For this reason, most human test subjects rinse orally with citrus juice before a sulfuric acid study, so as to minimize this phenomenon. Neutralization can also be quite efficient in standard whole-body animal exposure-studies, in which excreta and bacteria in the chambers interact, giving rise to in-chamber ammonia concentrations up to 1100 ppb—more than enough to fully neutralize neat sulfuric acid up to several mg/m^3 (Higuchi and Davies, 1993).

Interestingly, there is considerable species variability in sensitivity to sulfuric acid, with guinea pigs being quite responsive to acid sulfates, in contrast to rats, which seem generally resistant. The reasons for this difference are not fully understood but relate to receptor type and their density in the airways, and probably not on differences in neutralization by ammonia in the airway. The sensitivity of healthy humans appears to fall somewhere in between, with asthmatic humans being perhaps best modeled by the guinea pig. Overall, however, the collective data involving animals and humans are remarkably coherent, as reviewed in an article by Amdur (1989). To illustrate this point, Table 28-4 compares the acute toxicity of SO_2 and sulfuric acid in animals and human subjects, using indices detailed below, airway resistance, and bronchial clearance. To allow direct comparisons, the concentrations are presented as μmol/m^3 of the two compounds.

Pulmonary Function Effects   Sulfuric acid produces an increase in flow resistance in guinea pigs due to reflex airway narrowing, or bronchoconstriction, which impedes the flow of air into and out of the lungs. This response might be thought of as a defensive measure to limit the inhalation of air containing noxious gases, but this explanation may be more teleological than fact. The magnitude of the response is related to both acid concentration and particle size (Amdur, 1958; Amdur et al., 1978). Early studies indicated that as particle size was reduced from 7 μm to the submicron range, the

concentration of sulfuric acid necessary to induce a response and the time to the onset of the response fell significantly. With large particles, even the sensitive guinea pig was able to withstand an exceedingly high (30 mg/m^3) challenge with little change in pulmonary resistance, in contrast to the <1 mg/m^3 challenge needed with the 0.3 μm particles (Amdur et al., 1978). Human asthmatics exposed to 2 mg/m^3 of acid fog (10 μm) for 1 hour, a very high concentration for an asthmatic, experienced variable respiratory symptoms suggesting irritation, but no changes in spirometry were elicited (Hackney et al., 1989). The apparent reason for this PM size-based differential is probably the scrubbing of large particles in the nose, while small particles are able to penetrate deep into the lung. The thicker mucus blanket of the nose may blunt (by dilution or neutralization by mucus buffers) much of the irritancy of the deposited acid, thus limiting its effects to mucous cell stimulation and a minor increase in nasal flow resistance. In contrast, the less shielded distal airway tissues, with higher receptor density, would be expected to be more sensitive to the acid particles reaching that area (Costa and Schlegele, 1998). Regional sensitivity and the longer residence times of a deposited particle relative to SO_2 gas is reflected in the relatively protracted recovery times observed in acid-exposed guinea pigs compared with animals exposed to SO_2 alone.

Asthmatics appear to be somewhat more sensitive to the bronchoconstrictive effects of sulfuric acid than are healthy individuals, but published studies have been inconsistent in this finding (Koenig et al., 1989; Utell et al., 1984). Asthma generally is characterized by hyperresponsive airways, so their tendency to constrict at low acid concentrations would be expected, just as asthmatic airways are sensitive to nonspecific airway smooth muscle agonists (e.g., carbachol, histamine, exercise) (Hanley et al., 1992). The variability may well relate to differences in the degree of impairment or underlying inflammation in the subjects, but this hypothesis remains to be confirmed. Airway hyperreactivity has been observed as an acute response in guinea pigs 2 hours after a 1 hour exposure to 200 μg/m^3 sulfuric acid, and appears to be associated with pulmonary inflammation. Likewise in rabbits, increased airway reactivity was associated with arachidonate metabolites, products of epithelial cells as well as inflammatory cells. The general correlation between airway responsiveness and inflammation that appears to be important in grading asthma severity and risk of negative clinical outcomes may also be predictive of responses to environmental stimuli.

Effects on Mucociliary Clearance and Macrophage Function   Sulfuric acid alters the clearance of particles from the lung. Using insoluble, radioactively labeled ferric oxide particles as a probe, as little as a single 1 hour exposure in donkeys, rabbits, and human subjects can slow clearance. Mucus clearance appears to vary directly with the acidity ($[H^+]$) of the acid sulfate, with sulfuric acid having the greatest effect and ammonium sulfate the smallest (Schlesinger, 1984). Curiously, there appears to be a biphasic response to acid. In general, brief, single exposures of <250 μg/m^3 accelerate clearance, while high concentrations of >1000 μg/m^3 clearly depress clearance. With repeated daily exposures to low levels, there appears to be a cumulative (concentration times duration) dose-related depression of clearance. Longer-term exposure of rabbits to low-level acid also results in hyperplasia of airway mucosecretory cells (Gearhart and Schlesinger, 1989). Acidification of mucus by H^+ (i.e., a fall in pH), even if localized, is thought to have potential effects on mucus rheology and viscosity (Holma, 1989) as well as on mucus secretion and ciliary function. These effects are not unreasonable in light of

Table 28-4
Comparative Toxicity of SO$_2$ and H$_2$SO$_4$ in Acute Studies

	μmol		
	SO$_2$	H$_2$SO$_4$	REFERENCE
Guinea pigs: 1 h; 10% ↑ airway resistance	6	1	Amdur, 1974

	20	1	Koenig *et al.*, 1989

the drop in macrophage intracellular pH reported with acid exposure (Qu *et al.*, 1993).

Collectively, there seems to be coherence in the data to rank sulfate irritancy: sulfuric acid > ammonium bisulfate > ammonium sulfate. Acidity [H$^+$] appears to be the primary driver on most respiratory effects attributable to the acid sulfates even at the level of pulmonary macrophages. Lavaged rabbit macrophage phagocytosis was affected more after a single exposure to 500 μg/m^3 sulfuric acid than after 2000 μg/m^3 ammonium bisulfate (Schlesinger *et al.*, 1990). However, there is some evidence at the level of cellular activation that arachidonate metabolism might involve the anionic component of the aerosol as well. Nevertheless, in the complexity of summer haze, it remains unclear whether the bioactive form of [H$^+$] is more appropriately assayed as free ion concentration (as pH) or as total available ion concentration (titratable H$^+$).

Chronic Effects   Not surprisingly, sulfuric acid induces qualitatively similar effects in the airways as found at high concentrations of SO$_2$. As a fine aerosol, sulfuric acid deposits deeper along the respiratory tract, and its high specific acidity imparts greater effect on various cells (e.g., phagocytes and epithelial cells). Thus, a primary concern with regard to chronic inhalation of acidic aerosols is the potential for bronchitis, because this has been a problem in occupational settings in which employees are exposed to sulfuric acid mists (e.g., battery plants). Early studies in the donkey (later confirmed in a rabbit model) have provided fundamental data on this issue. The depression of clearance observed in donkeys exposed repeatedly (100 μg/m^3 1 hour per day for 6 months) raises concerns that a similar response (i.e., chronic bronchitis) can occur in humans. Studies with cigarette smoke showed parallel responses.

Studies conducted with sulfuric acid in the rabbit are in general agreement with the early findings in the donkey (Schlesinger *et al.*, 1979; Schlesinger, 1984). These studies have expanded our knowledge of the biological response and its exposure-based relationship. The initial early stimulation of clearance with subsequent depression has been shown to occur over 12 months with as little as 2 hour per day at 125 μg/m^3 sulfuric acid (Schlesinger *et al.*, 1992). Related studies also have demonstrated that the airways of exposed animals become progressively more sensitive to challenge with acetylcholine, showed a progressive decrease in diameter, and experienced an increase in the number of secretory cells, especially in the smaller airways (Gearhart and Schlesinger, 1989).

Unlike other irritants, such as O$_3$ (see below), inhaled sulfuric acid does not appear to stimulate a classic neutrophilic lung inflam-

mation. Rather, eicosanoid homeostasis appears to be disturbed, resulting in macrophage dysfunction and altered host defense. Long-term disease attributable to connective tissue disturbances induced by sulfuric acid seems to be of lesser concern than is the impact on mucociliary function and the potential effect on ventilation and arterial oxygenation (Alarie *et al.*, 1972, 1975). Therefore, it seems reasonable to postulate that chronic daily exposure of humans to ~100 μg/m^3 sulfuric acid may lead to impaired clearance and mild chronic bronchitis. As this is less than an order of magnitude above haze levels of sulfuric acid, the possibility that chronic irritancy may elicit bronchitis-like disease in susceptible individuals (perhaps over a lifetime or in children because of dose differences) appears to be reasonable.

Particulate Matter

Particulate matter was referred to as "soot" in the "reducing-type" air pollution of the classic episodes. The major constituents of this soot consisted of incompletely burned carbonaceous materials, acid sulfates, various metals, and silicates associated with the solid nature of the fuel. Metals were abundant, with a considerable amount of zinc in the form of zinc sulfate—as reported from post-episode analyses of the Donora PM. Soot is indicative of poorly (inefficiently) combusted fuel. Over time, combustion technology and improved fuels provided gains by increasing efficiency and minimization of gross soot emissions. Improvements in combustion methods simultaneously reduced the size of emitted particles and overall less mass. A side benefit of the smaller particles was the reduction in light diffraction through the emissions and hence a less visible plume. As such, much of the early clean-up was largely achieved through technological improvements. Carbon in fuel that is not fully oxidized to CO$_2$ persists in elemental form or as products of incomplete combustion—organic carbon. Oxidized S becomes sulfate and many of the metals appear as oxides. As noted above, sulfate was long suspected as the culprit of most health impacts associated with stationary sources, but this relationship is less discernable in contemporary particle epidemiology and toxicology.

In the last 15 years, PM has reemerged as the dominant issue in the air pollution community, overtaking O$_3$ as the pressing air pollution health issue. The reason for this shift was the emergence of epidemiology data repeatedly showing mortality, which is an adverse effect of greatest import with major impact on the cost/benefit analyses. As already noted the collective studies showed health impacts (both morbidity and mortality) at levels of PM thought to be

"safe" with no apparent threshold (reviewed in Pope and Dockery, 2006). Over time, scientific advances and reanalyses have confirmed the initial mortality findings. Several hypotheses that lend "biologic plausibility" to the findings have emerged along with several "ancillary" impacts of PM on health not previously realized. Unlike any other air pollutant, PM and its demonstrable impact on mortality rates has kept this issue in the forefront of air pollution toxicology.

Particulate matter in the atmosphere can be solid, liquid, or a combination of both with a mélange of organic, inorganic, and biological compounds. The compositional matrix of PM can vary significantly depending on the emission source and secondary transformations, many of which involve gas to particle conversions. Long-range transport of emissions or transformation products can contribute significantly to the regional matrix of PM, particularly in the case of eastern sulfate of fine PM (<2.5-μm; $PM_{2.5}$). Particles of larger size tend to have more local sources being that they are formed from dispersed dust and attrition of materials. Being of larger size, they tend to "fall out" or settle from the air due to gravity (although winds can in fact carry these particles great distances—e.g., Sahara desert particles have been found on the U.S. east coast). Particles in the range of 10–2.5 μm ($PM_{10-2.5}$; coarse PM) are highly inhalable by humans. The size selection of fine and coarse particles is based on their relative respirability—those in the range of PM_{10} are inhalable into the larger thoracic airways, while the $PM_{2.5}$ is inhalable into the deeper reaches (gas exchange areas) of the lung (see Chap. 15).

The large epidemiologic database contending that PM elicits both short- and long-term health effects is largely founded on data from monitoring networks for PM regulation (Dockery and Pope, 2006). As such the PM-associated effects appear to be dependent on the gravimetric measures that these networks yield. From this, it might then be argued that the effects are not influenced by particle composition (e.g., inorganic and organic components). Further, because the findings strengthen with decreasing particle size (e.g., Total Suspended Particulate mass [pre-1978 index], PM_{10}, $PM_{2.5}$), it is the mass concentration of PM, despite compositional complexity and variation, that is the index of choice. However, toxicologists argue that a mass-based relationship contradicts the basic tenets of conventional air pollution toxicology, which is rooted in the concept of chemical-specific toxicities. A number of hypotheses that draw upon various physical and chemical attributes of PM have also been offered in search of a "biologically plausible" explanation for the reported epidemiologic observations. No one constituent has been identified as singularly determinant of health impact, although most of the suspect constituents correlate inversely with particle size, i.e., the smallest particles derive from anthropogenic combustion activities. Prominently included among the causative hypotheses that tie to particle characteristics are metals, organics, acidity, size distribution (focusing on the unique bioactivity of ultrafine PM – PM < 0.1 μm), PM oxidant activity or reactivity, and the presence of potentially toxic or allergenic biologicals. However, at present, there remains insufficient understanding of the relative importance of these theories to choose one over another (especially if the spectrum of heath effects is included). As a result, there seems to be insufficient reason to unseat the PM mass-based correlation with health outcomes. Although the animal and human toxicological database is growing rapidly with regard to the issue of causation, much remains to be learned before new regulatory indices can be considered.

From research directed initially toward potential occupational hazards, it is known that several metals and silicates that make up much of the inorganic phase of PM can be cytotoxic to lung cells.

Organic constituents, as well, can induce toxicity either directly or via metabolism product—some of which are genotoxic. Other PM attributes may also come into play. Studies focusing on very small, ultrafine particles suggest that although these particles are low in mass, they are high in number and thus provide substantial reactive particle surface to interact with biological substances. Less is known about the role of biologically derived materials, such as endotoxin, other plant glycoproteins, and bioallergen fragments, which may elicit rudimentary inflammatory responses in the lung. The involvement of biologicals may be greatest in agricultural and indoor exposure environments. Finally, in the early days of air pollution toxicology, there was considerable interest in PM–co-pollutant interactions, but our knowledge in this area beyond the data derived largely from one laboratory (Amdur *et al.*, 1986) is very limited. In this regard, toxicologists need to better access the experience and knowledge of atmospheric scientists as to atmospheric interactions that are most relevant to biologic outcomes.

Metals   There have been many standard acute and subchronic rodent inhalation studies with specific metal compounds, often as oxides, chlorides, or sulfates. These exposure studies relate most appropriately to occupational exposures. The varied systemic toxicities of metal compounds are presented in detail elsewhere in this text; however, it should be appreciated, that the effects of metals delivered by inhalation may differ from their impacts when administered by other routes. Metals may arise from natural as well as anthropogenic activities, and as a result metals area common constituent in ambient PM. The metal profiles differ appreciably in concentration and type and they also differ by the size mode of PM. Coarse PM (2.5–10 μm) arises largely from natural sources and thus has prominent earthen metals such as iron, sodium, silica, and magnesium – usually in oxide forms. Combustion derived metals reflect the fuel source. For example, oil may have vanadium, nickel, and perhaps zinc and iron, whereas coal may have zinc and selenium. Their chemical forms vary from water-soluble salts to oxide and phosphate forms. Other metals are emitted from vehicles burning fuels to which metal compounds were added to alter functionally (e.g., lead, manganese, platinum) or as engine wear and catalyst by-products. Similarly, metals may also derive from brake (copper, iron), tire (zinc) and dispersed road (earthen silicates) wear. As metals have many biologic properties, some essential to life while others being directly toxic to cells or act indirectly in a pro-oxidant toxic fashion. Thus metals have garnered considerable interest regarding their role in PM toxicity (Costa and Dreher, 1997).

Metal compounds can be separated nominally by physicochemical characteristics: those that are essentially water-insoluble (e.g., metal oxides and hydroxides such as those that might be released from high-temperature combustion sources or derived from the geocrustal matrix) and those that are soluble or somewhat soluble in water (often chlorides or sulfates such as those that might form under acidic conditions in a smoke plume or leach from acid-hydrated silicate particles in the atmosphere). Solubility appears to play a role in the toxicity of many inhaled metals by enhancing metal bioavailability (e.g., nickel from nickel chloride versus nickel oxide), but insolubility can also be a critical factor in determining toxicity by increasing pulmonary residence time within the lung (e.g., insoluble cadmium oxide versus soluble cadmium chloride). Moreover, some metals, either in their soluble forms or when partially coordinated on the surface of silicate or bioorganic materials, can promote electron transfer to form reactive oxidants (Ghio *et al.*,

1992). Complexes with particulate organic material in a partially hydrated form (as might be promoted by the presence of sea salt) have been shown to interact with poorly soluble metals to free coordination sites that again are pro-oxidant (Kieber *et al.*, 2005). Thus, caution is warranted in assessing inhaled PM-associated metals, as both their chemical and physical attributes as well as their interaction with co-contaminants in PM may influence their apparent toxicity. Simply measuring total metal mass to estimate effects in the lung can be misleading.

Gas-Particle Interactions   As already noted, these interactions can be extremely complex involving multiple components of the particles, gases/vapors, and sunlight. However, more than 30 years ago, generic binary interactions between particles and gases in the absence of light was shown to alter the toxicity of either the particle or the gas acting alone. The guinea pig bronchoconstriction model used for many years by Amdur and associates showed earlyon that SO_2 can interact with hydrated metal salts to potentiate particle irritancy. The mechanism(s) behind this interaction has yet to be fully discerned, but it appears to involve solubility of SO_2 in a hydrated aerosol and the ability of the metal to catalyze the oxidation of the dissolved SO_2 to sulfate. In the case of sodium chloride aerosol, potentiation appeared to be governed primarily by the solubility of SO_2 in the salt droplet and enhanced respiratory penetration. The metal salts of manganese, iron, and vanadium, on the other hand, catalyzed the formation of sulfate (Amdur and Underhill, 1968). The degree of response to the mixture was dictated by the aerosol concentration, indicating that it was the proximate irritant. Studies in humans have been less revealing about such interactions, but this database affirms the need to consider the complexity of the atmospheric challenge in estimating biological outcomes.

Complex chemistry also occurs within the effluent of the combustion source. Using a laboratory scaled furnace, the emission mix of sulfuric acid and metal oxide particles common to metal smelting and coal combustion was used to explore potential plume interactions that might impact respiratory irritancy (Amdur *et al.*, 1986). These emitted metal oxide particles, once aged and cooled, were a mixture of singlet and agglomerated ultrafine particles that would be expected to distribute throughout the lung upon inhalation. Exposures in guinea pigs of 30–60 µg/m³ sulfuric acid combined with ultrafine zinc oxide produced progressive decreases in DL_{CO}, total lung capacity, and vital capacity and increases in cells, protein, and a variety of enzymes in lavage fluid that were not completely resolved 96 hours after exposure (Amdur, 1989). It is unclear whether the acid was on the surface of the particles or dissolved the particles, but the combination was clearly more toxic than acid alone. These effects greatly exceeded the changes in airway resistance found with relatively simple, binary mixture of SO_2 and water soluble metal salts.

Combustion studies using different coals again emphasized the significance of surface associated acidic *S*-compounds. Ultrafine combustion particles from Illinois No. 6 coal had a layer of sulfuric acid adsorbed on the surfaces resulting in greater effects in guinea pigs than the more alkaline Montana lignite. Despite the greater sulfur content of this coal, this emission ultrafine particle had adsorbed the less irritating neutralized sulfate (Chen *et al.*, 1990). Similar studies using inert carbon black appear consistent with its role as carrier for reactive gases such as O_3 and various aldehydes to enhance delivery of toxic materials to the deep lung (Jakab, 1992). The result of the latter study was enhanced infectivity when the test animals were subsequently exposed to pathologic bacteria.

Similar interactions may result from gaseous pollutants that impair the clearance of particles from the lung or otherwise alter their metabolism. Studies by Laskin at New York University in the 1960s showed an intriguing interaction of SO_2 and benzo(*a*)pyrene. It was thought that impaired clearance and greater residence time in the lung led to the enhanced the probability of carcinogenic expression of the particle. Similarly, rats exposed to an urban 8-hour daily profile of O_3 for 6 weeks, followed by a 5 hour exposure to asbestos, were found to retain three times as many fibers as did the controls 30 days postexposure. The fibers were deposited in the distal airways and penetrated more deeply into airway tissues making them less accessible to phagocytic removal (Pinkerton *et al.*, 1989). These studies, together with those focusing on irritancy and infectivity, raise the prospect that realistic exposure scenarios of gaseous and particulate pollutants can interact through either chemical or physiologic mechanisms to enhance health risks of complex polluted atmospheres.

Ultrafine Carbonaceous Matter   Ultrafine particles typically result from high temperature oxidation or as the product the atmospheric transformation involving organic vapors and sunlight. The size of these particles allow them to slip between gas molecules moving primarily by diffusion and principles of Brownian motion. Agglomeration on surfaces or other particles in the air is their primary mode of dissipation. When concentrations exceed ∼million per cc, they rapidly agglomerate with each other to form larger clumps or chains of ultrafine particles. Fine PM consist in part of agglomerates of carbonaceous material which may be partially solubilized in water or coassociated organic condensate. Estimates of the carbonaceous content of ambient fine PM vary considerably, but are nominally considered to be about 30–60% of the total mass. The sources of organic carbon are varied and include the combustion products of natural smoke (e.g., forest fires), engine exhaust, and stationary sources as well as transformed condensates from VOCs in the air. Elemental carbon in diesel PM frequently combines into long ultrafine chains, with variably complex organics associated with its surface depending on the combustion conditions. It has been estimated that diesel contributes about 7% of the fine urban PM emissions, which, when expressed as an annual U.S. average, are about 2 µg/m³ (USEPA, 1993)—but focus estimates (urban canyons) vary widely. The higher use of diesel fuel in Europe and areas of concentrated trucking in the United States has led to estimates as high as 30% of ambient fine PM mass.

As an air pollutant, elemental carbon particles generally do not exist as singlets except when emitted from high temperature sources. Elemental carbon can also be release by photocopiers and is used as a filler in some products, and as a result, some human exposure potential can occur incidentally. Elemental carbon is generally considered to be of low toxicity, although long-term, high-concentration exposure conditions in rats can lead to lung "overload" where there is evidence of lung damage and carcinogenicity (addressed below). In the environment, carbon has the potential to act as a carrier of certain irritant gases, as was noted earlier. However, carbon in the ultrafine mode (<0.1 µm) has been suggested to be more toxic than the fine-mode (2.5 µm) form, perhaps due to enhanced surface reactivity or tissue penetration (Oberdorster *et al.*, 1994, 2002; Donaldson *et al.*, 1998). Size is not the only factor as it appears that composition of the ultrafine particle also contributes to its effects and behavior (Kreyling *et al.*, 2002). Ultrafine particles in the environment exist in extremely high numbers but contribute negligibly to mass. Recent

commercial introduction of "engineered" nanoparticles brings many of the same concerns as ultrafines, by virtue of their similar sizes. Additionally, being "engineered" particles they may possess design features that "natural" combustion ultrafine (or nano) particles do not.

Because diesel particulate emissions are largely ultrafine, there has been growing interest in ultrafine ambient particles. Diesel particles vary widely in the ratio of organic and elemental carbonaceous materials, which in empirical studies has been shown to influence toxic outcomes, such as to their inflammatory and carcinogenic potential (Singh *et al.*, 2004). Some diesel particles also appear to have adjuvant activity when tested with bioallergens in both animals and humans (Diaz-Sanchez *et al.*, 1999). When reacted in vitro with O_3, there appears to be an enhancement of lung inflammation relative to the diesel or O_3 alone (Madden *et al.*, 2000). However, it is important to realize that diesel particles should not be equated with whole diesel exhaust which also contains significant amounts gaseous pollutants: NO_x, CO, and SO_x as well as various VOCs and carbonyl irritants. Exposure to diluted diesel exhaust in humans reveals that the exhaust mix is very inflammogenic and to a degree cytotoxic to airway cells (Salvi *et al.*, 1999). The use of diesel particles alone in toxicology studies does not seem to display similar toxicity, thus underscoring the potential importance of interactions among air pollutants as a critical consideration in air pollution toxicity (Mauderly, 2006).

Chronic Effects and Cancer Chronic exposure studies have been conducted with a number of particles ranging from titanium dioxide and carbon to diesel exhaust and coal fly ash aerosol. Of these substances, diesel exhaust has been the most extensively studied (reviewed by Cohen and Nikula, 1999). The primary concern with diesel has been the suspicion that it can induce lung cancer (thus its IARC classification as a Class B carcinogen). However, the evidence from over forty occupational studies (primarily railway yard, truck, and bus workers) implicating diesel exhaust as a mild carcinogen continues to be debated because of a variety of confounding issues. Taking the empirical data alone, however, carcinogenicity is suggested by several chronic exposure studies in animals and in vitro data indicating mutagenicity in *Salmonella* bacteria and enhanced sister chromatid exchange rates in Chinese hamster ovary cells. (These latter genotoxic effects have been linked to the nitroarenes associated with the diesel PM.) Rodent studies, unfortunately, have not fully resolved the question of human carcinogenic risk because of the overload need to yield positive results, and the tumors develop only in the rat. At high concentrations of diesel PM (3.5 and 7 mg/m³), normal mucociliary clearance in the rodent models become overwhelmed, resulting in a progressive buildup of particles in the lungs. By 12 months in the rat, clearance irreversibly decreases to cessation with concomitant inflammation, oxidant generation, epithelial hyperplasia, and fibrosis. Rats seem to react more to this circumstance. Particle agglomerates within the alveolar lumen become the focus of inflammation, injury, and the eventual development of adenosarcomas and squamous cell carcinomas. At lower concentrations, where the particle buildup does not occur, tumors do not develop.

"Overload" is a common finding at the highest exposure concentrations of chronic particle inhalation bioassays. Whereas this phenomenon is not likely in humans exposed to ambient PM, it is a hypothesis worthy of consideration in a discussion of particle health effects, as it relates to the interpretation of toxicological data relevant to product use and industrial exposures. Several poorly

soluble particles (PSPs) have induced lung tumors in chronic rat bioassays under conditions of overload; tumors have not developed under similar conditions in mice and hamsters. Among these particles are titanium dioxide, carbon black, toner dust, talc, and diesel emission; the potential for tumors is especially marked when the particles are in the ultrafine mode. In the rat, the time course and pattern of accumulation, chronic inflammation, epithelial hyperplasia, and tumorigenesis are essentially the same for all of the particles. In contrast, the degree of active inflammation in the mouse and hamster under similar overload conditions appears less intense, and thus is an important distinction among the species that relates to their relative sensitivities. On the one hand, such exposures do not demonstrate classic in vivo genotoxicity, but on the other, mutation of the *hprt* (hypoxanthine guanine phosphorybosyl transferase) gene was found in rat epithelial cells cultured with bronchoalveolar lavage from chronic carbon black and titanium dioxide treated rats (Driscoll *et al.*, 1997). The interpretation is that the mutation is a biomarker of genotoxicity mediated cancer, but not surprisingly, generalizing this finding to other overload cancers remains controversial. The closest analogy in humans would be coal miners who do not appear to have an enhanced risk of lung cancer, when smoking is not involved.

The issue, then, is whether rat bioassay cancer data under conditions of overload are relevant to risk assessment. A review by an expert panel (ILSI, 2000) concluded that rats, while apparently unique in this response, may represent a sensitive subgroup, and that tumorigenesis data from the rat bioassay under conditions of overload cannot be summarily dismissed as not relevant to the consideration of cancer risk in humans. However, the data should be interpreted and weighed in the context of lower concentrations and the tumor incidence and pathology found therein.

Photochemical Air Pollution

Photochemical air pollutants (notably O_3) remain the most elusive of the criteria pollutants to bring under control. It arises secondarily from a series of complex reactions in the troposphere activated by the ultraviolet (UV) spectrum of sunlight. In addition to O_3, it comprises a mixture of nitric oxides (NO_x), aldehydes, peroxyacetyl nitrates (PAN), and a myriad of aromatics and alkenes along with analog reactive radicals. If SO_2 is present, sulfates may also be formed and, collectively, they yield "summer haze." Likewise, the complex chemistry can generate organic PM, nitric acid vapor, and various condensates. Attempts to mitigate photochemical smog (especially O_3) by controlling hydrocarbon and/or NO_x emissions have proven difficult due to the complex stoichiometry of atmospheric photochemistry. Some progress has been made in controlling peak values (regulated by the 1 hour NAAQS), but the longer time frame 8 hour NAAQS has seen much smaller progress.

From the point of view of the toxicology of photochemical air pollutant gases, O_3 is by far the toxicant of greatest concern. It is highly reactive and more toxic than NO_x, and because its generation is fueled through cyclic hydrocarbon radicals, it reaches greater concentrations than the hydrocarbon radical intermediates. The gaseous hydrocarbons, so integral to the chemistry, are no longer listed collectively as a criteria pollutant because they do not have a strong health-based driver. In general, the concentrations of the hydrocarbon precursors in ambient air do not reach levels high enough to produce acute toxicity, although some individual compounds fall under the HAPs rule. Rather, the importance of these hydrocarbons stems from their role in the chain of photochemical reactions.

Although O_3 is of toxicological importance in the troposphere, in the stratosphere it plays a critical protective role. About 10 km above the earth's surface, UV light directly splits molecular O_2 into atomic $O^\bullet$, which then combines with O_2 to form O_3. The O_3 also dissociates back but much more slowly. The result is an accumulation of O_3 to several hundred ppm within a thin strip of the stratosphere forming an effective "permanent" barrier by absorbing the short-wavelength UV in the chemical process. This barrier had in recent years been threatened by various anthropogenic emissions (Cl_2 gas and certain chlorofluorocarbons) that enhance O_3 degradation (creation of an "O_3-hole") but recent restrictions in the use of these degrading chemicals seem to have been effective in reversing this process. The benefits are believed to be reduction of excess UV light infiltration to the earth's surface and reduced risk skin cancer risk and less risk of immune system dysfunction.

The issue is quite different in the troposphere, where accumulation of O_3 serves no known purpose and poses a threat to the respiratory tract. Near the earth's surface, NO_2 arising from combustion processes efficiently absorbs longer-wavelength UV light, from which a free O atom is cleaved, initiating the following simplified series of reactions:

$$NO_2 + h\nu \text{ (UV light)} \rightarrow O^\bullet + NO^\bullet \qquad (28.1)$$

$$O^\bullet + O_2 \rightarrow O_3 \qquad (28.2)$$

$$O_3 + NO^\bullet \rightarrow NO_2 \qquad (28.3)$$
This process is inherently cyclic, with NO_2 regenerated by the reaction of the $NO^\bullet$ and O_3. In the absence of unsaturated hydrocarbons (olefins and substituted aromatics) arising from fuel vaporization or combustion, as well as biogenic terpenes, this series of reactions would approach a steady state with little buildup of O_3. The free electrons of the double bonds of unsaturated hydrocarbons are attacked by free atomic $O^\bullet$, resulting in oxidized compounds and radicals that react further with $NO^\bullet$ to produce more NO_2. Thus, the balance of the reactions sequence shown in Eqs. 28-1 to 28-3 is tipped to the right, leading to buildup of O_3. This reaction is particularly favored when the sun's intensity is greatest at midday, utilizing the NO_2 provided by morning traffic. Carbonyl compounds (especially short-chained aldehydes) are also byproducts of these reactions. Formaldehyde and acrolein account for about 50% and 5%, respectively, of the total aldehyde in urban atmospheres. Peroxyacetyl nitrate (CH_3COONO_2), often referred to as PAN, and its homologs also arise in urban air, most likely from the reaction of the peroxyacyl radicals with NO_2. In the evening when sun intensity wanes, the second rush-hour peak of NO_2 shifts the balance back by reacting with O_3 bringing the daytime peak concentration slowly down.

Short-Term Exposures to Smog

In the 1950s to 1960s, early air pollution toxicologists were challenged by the complexity of photochemical air pollution to ascertain both its potential to affect human health adversely and to determine what about these atmospheres was responsible for the effects. The focus was immediately placed on O_3 because its toxicity was found to be very high even at low ppm concentrations. Concerns that the complex atmosphere was even more hazardous led to a number of studies with actual (outdoor-derived) or synthetic (photolyzed laboratory-prepared atmospheres) smog in an attempt to assess the potency of the actual pollution mix. When human subjects were exposed to real-world photochemical air pollution (Los Angeles

ambient air pumped into a laboratory exposure chamber), they experienced changes in lung function similar to those described in controlled clinical studies of O_3 alone (i.e., reduction in spirometric lung volumes; see below), thus supporting the view that this oxidant was the pollutant of primary concern. Acute animal studies using synthetic atmospheres (usually irradiated auto exhaust) provided supportive evidence indicating deep lung damage, primarily within the small airway and proximal alveolar epithelium.

While O_3 appeared to be the prime toxicant in many of these studies, there was some evidence that other co-pollutants were involved in the effects observed with smog. When guinea pigs were exposed to irradiated auto exhaust, airway resistance increased quickly, in contrast to the pattern of O_3 alone, where less effect is seen on resistance than on breathing rate. This indicated that a more soluble irritant(s) probably was active, presumably reactive aldehydes. Thus, the array of effects of a complex atmosphere may be more diverse than would be predicted if it were assumed that O_3 alone was responsible. Interestingly, the focus over time has been almost exclusively on O_3, perhaps with the emphasis coming from the regulatory perspective tied to this single pollutant.

Chronic Exposures to Smog

Epidemiological studies in human populations as well as empirical studies in animals have attempted to link degenerative lung disease with chronic exposure to photochemical air pollution. Cross-sectional and prospective field studies have suggested an accelerated loss of lung function in people living in areas of high pollution. However, as with many studies of this type, there were problems with confounding factors (meteorology, imprecise exposure assessment, and population variables). Studies have been conducted in children living in modern-day Mexico City, which has oxidant and PM levels today far in excess of any city in the United States These studies have focused on the nasal epithelium as an exposure surrogate for pulmonary tissues, using biopsy and lavage methodologies to assess damage. Dramatic effects were found in exposed children, consisting of severe epithelial damage and metaplasia as well as permanent remodeling of the nasal epithelium. When children migrated into Mexico City from cleaner, nonurban regions, even more severe damage was observed, suggesting that the tissue remodeling in the permanent residents imparted some degree of incomplete adaptation. Because the children were of middle-class origin, these observations were less likely confounded by socio-economic variables (Calderon-Garcidueñas *et al*., 1992). More recently, changes in lung hyperinflation as estimated by X-ray tomography and impaired lung function has been reported among similarly exposed children living in Mexico City (Calderon-Garcidueñas *et al*., 2003), raising further concerns of long term effects.

A now classic synthetic smog study in animals was undertaken at the Cincinnati EPA laboratory in the mid-1960s in an attempt to address the potential for long-term lung disease. Beagle dogs were exposed on a daily basis (16 hours) for 68 months, followed by a clean-air recovery period of about 3 years (Lewis *et al*., 1974). A series of physiologic measurements were made on the dogs after the exposure, and after their 3-year recovery. They were then moved to the College of Veterinary Medicine at the University of California at Davis. The lungs of the dogs then underwent extensive morphologic examination to correlate with the physiology. Seven groups of 12 dogs each had been studied. The dogs had been exposed to non-irradiated auto exhaust (group 1), irradiated auto exhaust (group 2), SO_2 plus sulfuric acid (group 3), the two types of exhaust plus the

sulfur mixture (groups 4 and 5), and a high and a low level of NO_x (groups 6 and 7). The irradiated exhaust contained oxidant (measured as O_3) at about 0.2 ppm and NO_2 at about 0.9 ppm. The raw exhaust contained minimal concentrations of these materials and about 1.5 ppm NO. Both forms of exhaust also contained about 100 ppm CO. The controls did not show time-related lung function changes, but all the exposure groups had abnormalities, most of which persisted or worsened over the 3-year recovery period in clean air. Enlargement of airspaces and loss of interalveolar septa in proximal acinar regions were most severe in dogs that were exposed to NO_x and SO_x with irradiated exhaust (Hyde *et al*., 1978). These studies described a morphologic lesion that was degenerative and progressive in nature, not unlike that of chronic obstructive pulmonary disease (COPD)—a condition most often associated with lifelong tobacco smoking.

Long-term "sentinel" studies in polluted cities have been attempted whereby the animals live in the same highly polluted air to which people are exposed. Such approaches have had a troubled past, but newer studies appear to have been better controlled for the problems of infection, inappropriate animal care (e.g., heat), and variable exposure atmospheres. One such study, conducted in rats exposed for 6 months to the air of São Paulo, Brazil, found considerable airway damage, lung function alterations, and altered mucus rheology (Saldiva *et al*., 1992). The concentrations of O_3 and PM in São Paulo frequently exceed daily maximum values (in the summer months of February and March) of 0.3 ppm and 75 $\mu g/m^3$, respectively. This collage of effects is not unlike a composite of injury one might suspect from a mixed atmosphere of oxidants and acid PM in controlled laboratory animal studies. Strangely enough, however, a seven week study in rats exposed to the polluted Mexico City air, which had induced significant lesions in children, did not reveal in F-344 rats any nasal or lung histopathology (Moss *et al*., 2001). Whereas there is no clear reason for the apparent differences in the findings, it is important to appreciate that all sentinel studies have elements of exposure that may be uncontrolled and hence at times can yield conflicting findings.

Ozone

General Toxicology   Ozone is the primary oxidant of concern in photochemical smog because of its inherent bioreactivity and its concentration relative to other reactive species. Depending on the meteorological conditions of a given year, 60–80 million Americans live in areas not in absolute compliance with the NAAQS. Los Angeles frequently attains and occasionally exceeds 1-hour levels of 0.2–0.3 ppm. Unlike SO_2 and the reducing-type pollution profile discussed above, current mitigation strategies for O_3 have been only marginally successful despite significant reductions in individual automobile emissions. These reductions have been offset by population growth, which brings with it additional vehicles and vehicle miles driven. With suburban sprawl and the downwind transport of air masses from populated areas to more rural environments, the geographic distribution of those exposed has expanded, as has the temporal profile of individual exposure. In other words, O_3 exposures are no longer stereotyped as brief 1- to 2-hour peaks. Instead, there is more typically a prolonged period of exposure of 6 hours or more at or near the NAAQS level. This recently noted change in the exposure profile to O_3 has given rise to concerns that cumulative damage over an exposure of several hours may be more significant than brief pulse-like exposures, and that as a result many more peo-

ple are at risk than was previously thought. With the revision of the O_3 NAAQS in 1997 to include an 8-hour daily average of 0.08 ppm, more cities and suburban areas find themselves in violation of the standard. If indeed the damage to the lung is cumulative over an 8-hour time period, then people in areas in compliance but near the standard may be affected. The American Lung Association estimates that nearly 50% of U.S. inhabitants live in counties that are not in O_3 compliance (State of the Air, 2006). Perhaps of greater significance is that of those who might be considered susceptible due to age and/or preexistent cardiopulmonary impairments, 80–90% live in these areas that fail to comply with the present O_3 NAAQS.

Ozone induces a variety of effects in humans and experimental animals at concentrations that occur in many urban areas (Lippmann, 1989). These effects include morphologic, functional, immunologic, and biochemical alterations. Because of its low water solubility, a substantial portion of inhaled O_3 penetrates deep into the lung, but its reactivity is such that about 17% and 40% is scrubbed by the nasopharynx of resting rats and humans, respectively (Hatch *et al*., 1994; Gerrity *et al*., 1988). The reason for the higher degree of scrubbing in humans is unclear, but the finding is reproducible. Moreover, the mouth appears to scrub as well as the nose. Nevertheless, regardless of species, the region of the lung that is predicted to have the greatest O_3 deposition (dose per surface area) is the centriacinar region, from the terminal bronchioles to the alveolar ducts, also referred to as the proximal alveolar ductal region (Overton and Miller, 1987). Because O_3 penetration increases with increased tidal volume and flow rate, exercise increases the dose to the target area. Using $^{18}O_3$ (a nonradioactive isotope of oxygen), Hatch and coworkers have shown that the dose to the distal lung and the degree of damage to the lung as determined by leakage of plasma protein into the alveolar space (as collected by bronchoalveolar lavage) in exercising human subjects exposed to 0.4 ppm for 2 hours with intermittent periods of 15 minutes of exercise (threefold normal ventilation on average) are similar to those in resting rats exposed for the same length of time to 2.0 ppm. Thus, it is important to consider the role of exercise in a study of O_3 or any inhalant before making cross-study comparisons, especially if that comparison is across species. With so many years invested in the study of O_3, it is surprising that only now is the nature of species differences with regard to exercise-associated dosimetry being appreciated.

Animal studies indicate that the acute morphologic responses to O_3 can involve epithelial cells along the entire respiratory tract. The pattern of injury parallels the dosimetry profile, with the majority of damage occurring in the distal lung. Along the airways, ciliated cells appear to be most sensitive to O_3, while Clara cells and mucus-secreting cells are the least sensitive. Studies in the rat nose indicate that O_3 also is an effective mucus secretagogue. In the alveolar region, type 1 epithelia are very sensitive to O_3 relative to type 2 cells, which have an active metabolic machinery. The more resistant type 2 cells serve as the stem cells for the replacement of type 1 cells. Ultrastructural damage to alveolar epithelia can be observed in rats after a few hours at 0.2 ppm, but sloughing of cells in the distal airway generally requires concentrations above 0.8 ppm. Recovery occurs within a few days, and there appears to be no residual pathology. Hence, from animal studies, it would appear that a single exposure to O_3 at a relatively low concentration is not likely to cause permanent damage. On a gross level, when a bronchoscope is used to peer into the human bronchus after O_3 exposure, the airways appear "sunburned" and, as with mild skin sunburn, recovery is typical. What is uncertain is the impact of repeated "sun-burning" of the airways and lung.
Figure 28-12. Major reactions pathways of O_3 with lipids in lung lining fluid and cell membranes. (Adapted with permission from the Air Quality Criteria Document for Ozone and Photochemical Oxidants. 600/P-93/004cF, NCEA Research Triangle Park, NC: U.S. EPA, 1996).

Studies have shown particular sensitivity to O_3-induced inflammation in neonatal rats that decreased with age into adulthood. However, enhanced sensitivity to O_3 again appears in older rats as evidenced by interstitial edema that is not seen in younger adult animals. Older rats have lower ascorbate in the lung and this diminishment of antioxidant capacity may be in part responsible. Elderly humans, however, seem less responsive to the lung function impacts of high ambient O_3. The reasons for this are unclear, but caution in linking lung function and inflammation in the O_3 response is warranted as these events appear separated in time by about 18 hours.

The mechanisms by which O_3 causes injury have been studied using cellular as well as cell-free systems. As a powerful oxidant, O_3 seeks to extract electrons from other molecules. The surface fluid lining the respiratory tract and cell membranes that underlie the lining fluid contain a significant quantity of polyunsaturated fatty acids (PUFA), either free or as part of the lipoprotein structures of the cell. The double bonds within these fatty acids have a labile, unpaired electron which is easily attacked by O_3 to form ozonides that progress through a less stable zwitterion or trioxolane (depending on the presence of water); these ultimately recombine or decompose to lipohydroperoxides, aldehydes, and hydrogen peroxide. These pathways are thought to initiate propagation of lipid radicals and autooxidation of cell membranes and macromolecules (Fig. 28-12).

Evidence of free radical-related damage in vivo includes detection of breath pentane and ethane and tissue measurements of diene conjugates. Damage to the air-blood interface disrupts its barrier function and promotes inflammation. Inflammatory cytokines (e.g., interleukins 6, 8 and others, TNF, etc.) are released from epithelial cells and macrophages that mediate early responses and initiate repair. This inflammatory process is generally transient, but it may also interact with neural irritant responses to affect lung function acutely. This latter response may have implications for those with preexistent inflammation or disease.

Pulmonary Function Effects   Exercising human subjects exposed to 0.12–0.4 ppm O_3 experience reversible concentration-related decrements in forced exhaled volumes [forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV$_1$)] after a 2–3 hours of exposure (McDonnell *et al.*, 1983). With the recent concern that prolonged periods of exposure (6–8 hours) may lead to cumulative effects, similar protocols with lower exercise levels were ex-

tended up to 6.6 hours. In these studies, exposures to 0.12, 0.10, and 0.08 ppm induced progressive lung function impairment during the course of the exposure (Horstman *et al.*, 1989). The pattern of response was linearly cumulative as a function of exposure time such that changes not detectable at 1 or 2 hours reached significance by 4–6 hours. Decrements in FEV$_1$ after 6.6 hours at 0.12 ppm averaged 13.6% and were comparable to that observed after a 2 hour exposure to 0.22 ppm with much heavier exercise. It is not clear to what extent human lung dysfunction (in terms of changes in FEV$_1$) from O_3 is vagally mediated, but the response can be abrogated by analgesics such as ibuprofen and opiates, which also reduce pain and inflammation (see below). Thus pain reflexes involving C-fiber networks are thought to be important in the reductions in forced expiratory volumes. On the other hand, animal studies show a prominent role for vagal reflexes in altered airway reactivity and bronchoconstriction. There is also evidence to implicate vagal reflexes in cardiac as well as thermal regulation, at least in rodents. Airway hyperreactivity to nonspecific agonists in humans is reported after acute 2- to 6-hour exposures to O_3 to sub-NAAQS levels of 0.08, 0.10, and 0.12 ppm (by 56, 86, and 121%, respectively, to methacholine). It is widely thought that hyperreactive airways may be a marker of predisposition to other pollutants such as sulfuric acid or aeroallergens, but such evidence is limited.

When compared with field studies, chamber exposures may underestimate responses for a given exposure to O_3. For a given concentration of O_3, greater decrements in pulmonary function have been reported in children playing outdoors at summer camps than were observed in controlled exposure studies involving exercise (Lippmann, 1989). The reasons for this difference are uncertain but might relate more to cumulative exposure in the children at camp, as they were outside all day, or to the fact that the ambient exposures probably involve other haze co-pollutants, such as H$^+$. The responses to the ambient exposures also have slightly altered temporal patterns and pre-exposure histories (Kinney *et al.*, 1988). Animal studies are consistent with the fact that both duration and concentration are important in assessing the response to O_3 exposure (Costa *et al.*, 1989). Pulmonary function decrements increased with $C \times T$ (concentration times time) in rats exposed for 2, 4, or 8 hours to O_3 at 0.2, 0.4, and 0.8 ppm. Rats exposed for 7 hours to 0.5 ppm with 8% CO_2 added to increase ventilation, produced functional decrements similar to those observed in human chamber studies of 6.6 hours at 0.12 ppm when ventilation-adjusted $C \times T$ products were factored in. This would imply that rats and humans respond with about the same sensitivity and opens the door to the study of various scenarios of exposure to predict human responses. It should be cautioned, however, that it is unknown whether CO_2-stimulated breathing in the rat might alter response thresholds beyond mere incrementing of the dose. However, in related studies without stimulated breathing, lavage fluid protein content (an index of permeability) 24-hours postexposure was also nearly linearly cumulative, with exaggerated responses at the higher concentrations suggestive of an exponential pattern (Highfill *et al.*, 1992) common to other biological functions.

Inflammation of the Lung and Host Defense   The mechanism by which O_3 produces decrements in pulmonary function is not fully understood. In contrast to sulfuric acid and SO_2, O_3-induced lung dysfunction does not appear correlate with nonspecific hyperreactivity, and appears not to be enhanced in asthmatics (the distress may be due to less functional reserve), as appears to be the case with sulfated acids. It was hypothesized that lung inflammation might reflect parallel sensitivity to lung dysfunction suggesting mechanistic

linkages. Koren *et al*. (1989) found an eightfold increase in *neutrophils* in bronchoalveolar lavage fluid recovered from human subjects 18 hours after a 2-hour exposure to 0.40 ppm with intermittent exercise. There was also evidence of increased epithelial permeability (a twofold increase in serum proteins and albumin). However, when compared to lung function the inflammatory markers did not correlate. Arachidonate metabolites, including the prostaglandins PGE_2 and PGF_{2a} and the leukotriene thromboxane B_2, have also been seen to increase in human bronchoalveolar lavage fluid after 0.4 ppm O_3 for 2 hours (Seltzer *et al*., 1986). Pretreatment with the anti-inflammatory agents, indomethacin and ibuprofen (both cyclooxygenase inhibitors), decreased the pulmonary function deficit and PGE_2, but other indicators of cell injury and vascular leak in lavage fluid (neutrophils, extravasated protein, and lactate dehydrogenase) were not attenuated after exposure (Hazucha *et al*., 1996). Because PGE_2 can have either pro- or anti-inflammatory functions under certain conditions as well as bronchodilatory action on constricted airways, it remains unclear what if any causal relationship exists between arachidonate metabolites and changes in FEV_1. Studies in animal models suggests a role for C-fiber mediated responses that might tie to pain on inspiration in the human as the limit to full inhalation for the forced expiratory maneuvers.

Sensitivity to O_3 appears to have a genetic component as well. Studies in inbred stains of mice have shown that O_3-induced pulmonary neutrophilia and permeability are governed by a single gene linked to the Toll4 locus that has been associated with endotoxin sensitivity (Kleeberger *et al*., 2000). The growth of genomic and proteomic technologies has made it possible to begin studies in humans to define genetic linkages to O_3 sensitivity. Again using Mexico City as a backdrop, it has been found that polymorphism in GSTM1 (as noted above with regard to PM) appears to convey O_3 sensitivity as well (Romieu *et al*., 2004). More detailed controlled O_3 exposures may identify even more genes associated with responsiveness.

The potential for O_3 to influence allergic sensitization or challenge-responses has received limited investigation in either humans or animals. In general, animal studies have shown the ability of O_3 to enhance the sensitization process under certain conditions (Osebold *et al*., 1980), but evidence of this in humans is lacking. Controlled studies of heightened antigen responsiveness in allergic subjects have only been suggestive, with enhancement of allergic rhinitis after 0.5 ppm for 4 hours providing the only credible data to date. However, diary studies of asthmatic nurses reported worsened allergy symptoms, as well as durations thereof, at concentrations of O_3 near the NAAQS (Schwartz, 1992).

Exposure to O_3 before a challenge with aerosols of infectious agents produces a higher incidence of infection than is seen in control animals (Coffin and Blommer, 1967). Studies have demonstrated that this effect in a mouse model using an aerosol of *Streptococcus* (group C) bacteria is a direct result of altered phagocytosis by macrophages in the O_3-exposed animals (Gilmour *et al*., 1993), allowing the bacteria to develop a thickened capsule that reduces their attractiveness to phagocytes and enhances their virulence. This host resistance model has shown responsiveness to an exposure as low as 0.08 ppm for 3 hours. The susceptibility of mice and hamsters to *Klebsiella pneumoniae* aerosol is also increased by prior exposure to O_3. In the rat, altered microbe-killing may relate to membrane damage in macrophages, thus impairing the production of bactericidal superoxide anions. The rat appears less susceptible than mice because it has a more vigorous PMN response to bacteria than do mice, which seems to compensate for macrophage impairments. This is yet another example of where susceptibility lies more in the

inability to compensate than in the initial responsiveness to a given challenge.

Chronic Effects   Morphometric studies of the centriacinar region of rats exposed for 12 hours per day for 6 weeks to 0.12 or 0.25 ppm O_3 have shown hyperplasia and hypertrophy of type 1 alveolar cells (smaller and thicker cells) coupled with damage and alterations in ciliated and Clara cell populations in small airways (Barry *et al*., 1988). A collective cross-protocol analysis of type 1 cell hypertrophy was conducted, type 1 cell thickness appeared to be linearly related to the O_3 $C \times T$ (Chang *et al*., 1991, 1992). This finding suggested that over a season, the impact of O_3 in the distal lung may be cumulative and perhaps more importantly may be without threshold. The biological significance of this change is unclear—it may be part of a compensatory response to "thicken" that part of the alveolar duct junction that receives the greatest dose and is most affected. This response may be protective as the thickened cells were also smaller, offering therefore a smaller exposure-surface to the incoming O_3. This changed morphology could limit membrane damage. When returned to clean air, most of the epithelial morphologic changes regressed, but there was evidence of residual interstitial remodeling below the epithelium in the alveolar duct region. Examination of autopsied lung specimens from young smokers shows many analogous tissue lesions that come to be described as the "smoldering" precursor of emphysema.

Studies involving episodic exposures of rats and monkeys using a pattern of alternating months of O_3 (0.25 ppm) for 18 months indicate that there may be carry-over effects, notably thickening of interstitial fibrous matrix (Tyler *et al*., 1988, 1991). These interstitial changes were quantitatively similar regardless of the twofold difference in the cumulative exposure dose (i.e., $C \times T$). This would imply that a pattern of exposure resembling seasonal O_3 patterns might result in more serious lesions than predicted by dose alone—indeed more than would have occurred had the exposure been continuous. Hence, the concept of "more dose . . . more effect" may not hold in chronic episodic scenarios, as it appears to do with uninterrupted exposures. The number of episodes experienced may well be more significant to long-term outcomes than total dose—a phenomenon not unlike that of repeated sun-burning and deterioration of the skin.

Studies of lung function in rodents exposed chronically to O_3 have been conducted, but have yielded mixed results. Generally, the dysfunction is reflective of stiffened or fibrotic lungs, particularly at higher concentrations. There have been two prominent chronic O_3 studies—the EPA 18-month chronic study fashioned after a realistic urban exposure profile with a peak exposure of 0.25 ppm (Chang *et al*., 1992; Costa *et al*., 1995) and the National Toxicology Program (NTP)—Health Effects Institute (HEI Report, 1994/1995) study of 0.125–1 ppm for 20 months (square wave; 6 h/d; 5d/week). From an environmental relevance perspective, the $C \times T$ doses for these studies were similar, but the urban profile study produced evidence for centriacinar interstitial fibrosis suggesting a possible influence of the exposure pattern. There was no general biochemical evidence for fibrosis (Last *et al*., 1994), as reported in monkey and rat studies that had been conducted at higher O_3 concentrations. If one attempts to compare these results with the Cincinnati beagle study, one finds that the synthetic smog atmosphere showed degenerative and not fibrotic lung lesions. However, it should be noted that the air pollutant mixture used in the beagle study was both more complex and involved considerably higher concentrations than more recent studies.

The ability of O_3 to induce tolerance to itself is a curious phenomenon that has implications for both episodic and chronic exposures. Classic O_3 tolerance takes the form of protection against a lethal dose in animals that received a very low initial challenge 7 days before. This term, *tolerance*, is sometimes used to describe "adaptation" or acclimatization over time to near-ambient levels of O_3, and as such, has led to some confusion. However, with regard to "adaptation" to O_3, the process begins during and immediately after the initial exposure and progresses to completion in at most 2–4 days. This adaptive phenomenon has been well established in humans with regard to lung function and recently has been correlated with several inflammatory endpoints (Devlin *et al*., 1993). Lavage lactate dehydrogenase (LDH; a marker of cell injury) and elastase (enzymatically active against lung matrix), interestingly, do not appear to adapt in humans based on the Devlin study. An analogous pattern of adaptation of functional and biochemical endpoints (including LDH and elastase) in rodents also takes place with repeated exposures up to a week. But to date, the linkages between acute, adaptive, and long-term process remain unclear, because over longer periods of exposure both morphologic and functional effects do appear to develop. The precise mechanism for O_3 adaptation is not known and several theories abound, including changes in cell profiles, lung surface fluids, and induced antioxidants. Few studies have tackled the problem but in rats the adaptation of the neurtophilic response appears to be related to the induction of an endogenous acute-phase response (McKinney *et al*., 1998). On the other hand, adaptation to lung function changes in rats after chronic exposure appears linked to lung antioxidants (Wiester *et al*., 2000) such as ascorbic acid. The significance of this finding in humans is uncertain because ascorbic acid is not endogenously synthesized as it is in the rat. However, self-administration of ascorbate has been shown to reduce O_3-induced lung function decrements in adults (Samet *et al*., 2001; Mudway *et al*., 1999), and in children, supplementation with ascorbate and α-tocopherol lessened nasal inflammatory responses to O_3 in Mexico City (Sienra-Monge *et al*., 2004). Despite these interesting findings, it remains unclear if antioxidant supplements can protect humans from long-term O_3 effects given the many mechanisms that may be involved in the various responses. How these interplay with long-term adaptation and the likelihood of degenerative disease is unclear.

Ozone Interactions with Copollutants   An approach simplifying the complexity of synthetic smog studies, yet addressing the issue of pollutant interactions involves the exposure of animals or humans to binary or more complex synthetic mixtures of pollutants that occur together in ambient air. The most frequent combination involves interactions of O_3 and NO_2 or O_3 and sulfuric acid. Not surprisingly, study design adds a level of complexity in interpretation such that evidence exists supporting either augmentation or antagonism of lung function impairments, lung pathology, and other indices of injury (Kleinman *et al*., 1985). This apparent conflict in the findings only emphasizes the need to carefully consider the myriad of factors than might affect studies involving multiple determinants and the nature of the exposure that is most relevant to reality.

When O_3 and NO_2 (1 ppm and 14 ppm, respectively) were administered to rats from a premixed retention chamber, the resulting damage evident in bronchoalveolar lavage exceeded that of either toxicant alone, regardless of the temporal sequence of exposure (Gelzleichter *et al*., 1992). Biochemical and histological indices of fibrogenesis also were increased in related studies (Last *et al*., 1994). In retrospect, it was hypothesized that the two oxidants formed rela-

tively stable intermediate nitrogen radicals that were more toxic than either gas alone. At lower, more realistic concentrations (0.3 ppm O_3 and 3.0 ppm NO_2), where this reaction would not be favored, the impact of these irritants on rabbits was only additive (Schlesinger *et al*., 1991). This contrast in response serves to illustrate that the tenets of dose-dependency that hold for any single-toxicant response may be of equal or more importance when two or more pollutants coexist and have the potential to interact.

Studies of O_3 mixed with acid aerosols also have shown enhanced or antagonistic responses that were time dependent during the period of exposure. On the one hand, as noted above, field studies of children in camps and studies of asthma admissions in the Northeast and in Canada, suggested an interaction of acid and O_3 underlying responses to summer haze. Yet, in an experimental setting with rabbits exposed over an extended period, there was exposure duration-specific evidence of enhanced as well as antagonized secretory cell responses with combined O_3 (0.1 ppm) and sulfuric acid (125 $\mu g/m^3$) over the course of the 1-year exposure (Schlesinger *et al*., 1992). As the number of interacting variables increases, so does the difficulty in interpretation. Studies of complex atmospheres involving acid-coated carbon combined with O_3 at near-ambient levels also show varied evidence of interaction on lung function and macrophage receptor activity (Kleinman *et al*., 1999). As such, the platform of any multicomponent study is its statistical design and the ability to either separate or determine the nature of the interacting variables. However, it is indeed the complex mixture to which people are exposed that we wish to evaluate. Creative approaches to understanding mixture responses are a likely part of the new agenda that toxicologists will need to address in the next decade (Mauderly, 1993, 2006).

Nitrogen Dioxide

General Toxicology   Nitrogen dioxide, like O_3, is a deep lung irritant that can produce pulmonary edema if it is inhaled at high concentrations. It is a much less potent irritant and oxidant than O_3, but NO_2 can pose clear toxicological problems. Potential life-threatening exposure is a real-world problem for farmers, as near-lethal high levels of NO_2 can be liberated from fermenting fresh silage. Being heavier than air, the generated NO_2 and CO_2 displace air and oxygen at the base of silo and diffuse into closed spaces where workers can inadvertently get exposed to very high concentrations perhaps with depleted oxygen. Typically, shortness of breath rapidly ensues with exposures nearing 75 to 100 ppm NO_2, with delayed edema and symptoms of pulmonary damage. Not surprisingly, the symptoms are collectively termed "silo-filler's disease." Nitrogen dioxide is also an important indoor pollutant, especially in homes with unventilated gas stoves or kerosene heaters (Spengler and Sexton, 1983). Under such circumstances, very young children and their mothers who spend considerable time indoors may be especially at risk. Sidestream tobacco smoke is yet another source of indoor NO_2, although the levels from this source are not likely to generate NO_2 levels of acute concern. In general, indoor environments with NO_2 sources achieve concentrations far in excess those observed outdoors. However, protocols that simulate an urban (rush-hour) or household (cooking) patterns of two daily peaks superimposed on a low continuous background concentration have elicited effects in experimental animals that continuous exposure to NO_2 did not evoke, suggesting an important dependency on exposure profile. Among the common air pollutants, empirical studies of NO_2 have

frequently shown greater effects with higher peak concentrations at equivalent $C \times T$ steady-state concentrations.

Although the distal lung lesions produced by acute NO_2 are similar among species, there exist differences in species sensitivity. Where direct comparison is possible, guinea pigs, hamsters, and monkeys appear more sensitive than rats, although comparative dosimetry information might explain some of this difference. As in the case of O_3, theoretical dosimetry studies indicate that NO_2 is deposited along the length of the respiratory tree, with preferential deposition being in the distal airways. Not surprisingly, the pattern of damage to the respiratory tract reflects this profile: damage is most apparent in the terminal bronchioles, just a bit more proximal in the airway than is seen with O_3. At high concentrations, the alveolar ducts and alveoli are also affected, with type 1 cells again showing their sensitivity to oxidant challenge. In the airways of these animals there is also damage to epithelial cells in the bronchioles, notably with loss of ciliated cells, as well as a loss of secretory granules in Clara cells. The pattern of injury of NO_2 is quite similar to that of O_3, but its potency is about an order of magnitude lower.

Pulmonary Function Effects Exposure of normal human subjects to concentrations of ≤ 4 ppm NO_2 for up to 3 hours produces no consistent effects on spirometry. However, a study has shown slightly enhanced airway reactivity with 1.5–2.0 ppm. Interestingly, ascorbic acid pretreatment of human subjects appeared to protect them from this hyperreactivity (Mohsenin, 1987). Whether asthmatics have a particular sensitivity to NO_2 is a controversial issue. A number of factors appear to be involved (e.g., exercise, inherent sensitivity of the asthmatic subject, exposure method). Some studies have reported effects in some individuals at 0.2 ppm, which approximates an ambient level in a household with an unvented gas stove. Recent meta-analyses, which have incorporated the findings of many studies to achieve a weight-of-evidence perspective, support an effect of NO_2 on asthmatics. As for an appropriate animal model, only very high concentrations (10 ppm NO_2) invoke an irritancy response in guinea pigs (tachypnea); these levels are well above those a person probably would encounter in everyday life. However, recently, NO_2 has been found to be associated with mortality in some time-series studies of air pollution attempting to tease out specific pollutant effects (focusing mainly on PM) (Gold *et al.*, 2000). NO_2 in these studies is thought to be a marker for vehicular traffic rather than as an indication of a specific NO_2 effect. These studies have found correlates with cardiovascular deaths, which have raised new questions of the mechanisms by which pollutants might affect health in susceptible subgroups (Rosenlund *et al.*, 2006).

Inflammation of the Lung and Host Defense Unlike O_3, NO_2 does not induce significant neutrophilic inflammation in humans at exposure concentrations encountered in the ambient outdoor environment. There is some evidence for bronchial inflammation after 4–6 hours at 2.0 ppm, which approximates the highest transient peak indoor levels of this oxidant. Exposures at 2.0–5.0 ppm have been shown to affect T lymphocytes, particularly CD8$^+$ cells and natural killer cells that function in host defenses against viruses. Although these concentrations may be high, epidemiologic studies variably show effects of NO_2 on respiratory infection rates in children, especially in indoor environments. Animal models, by contrast, have for years shown associations between NO_2 and bacterial infection (Gardner, 1984). As noted for other effects, the incidence of infection in exposed models appears to be governed more by the peak exposure concentration than by exposure duration. The effects are

ascribed to suppression of macrophage function and clearance from the lung, in the form of suppressed bactericidal and/or motility functions of macrophages from rabbits exposed to 0.3 ppm for 3 days (Schlesinger, 1987). Similar effects have been reported in humans exposed to 0.10 ppm for 6.6 hours (Devlin *et al.*, 1991).

Toxicological studies of the interaction of NO_2 with viruses also suggest enhanced infectivity. Squirrel monkeys infected with nonlethal levels of A/PR-8 influenza virus and then exposed continuously to 5 or 10 ppm NO_2 suffered high mortality rates; 6/6 monkeys exposed to 10 ppm died within 3 days, while only 1/3 exposed to 5 ppm died (Henry *et al.*, 1970). Other experiments suggest that exposure of squirrel monkeys for 5 months to 5 ppm NO_2 depresses the formation of protective antibodies against the A/PR-8 influenza virus. Controlled human studies with virus challenges, however, have been inconclusive, perhaps because of low subject numbers. One study showed decreased virus inactivation by alveolar macrophages recovered from 4 of 9 subjects when cultured and exposed for 3.5 hours to 0.6 ppm NO_2 in vitro. The responsive macrophages produced interleukin-1, a known cytokine modulator of immune cell function (Frampton *et al.*, 1989). Thus, the potential for augmented risk of viral infection associated with NO_2 exposure remains unclear and suggests a role for underlying host susceptibility. This concern would be greatest for children who have less mature pulmonary immune function, especially during seasonal use of unvented gas-heaters.

Chronic Effects Concern about the chronic effects of NO_2 stem from observations that a continuous 30 day, 30-ppm exposure produces emphysema in hamsters. Whether the result of this exposure scenario relates to cyclic human exposures at 1/100th that level is unclear. On the one hand, an 18-month study in rats exposed to an urban pattern of NO_2 in which a background of 0.5 ppm for 23 hours per day peaked at 1.5 ppm for 4 hours each day showed little ultrastructural damage to the distal lung (Chang *et al.*, 1988). On the other hand, mice exposed for a year to a base level of 0.2 ppm NO_2 with a 1-hour spike of 0.8 ppm twice a day 5 days per week (Miller *et al.*, 1987) displayed effects that differed between the base-only and peak-only exposure groups. The base level produced no effects, while the overlaid peaks induced slight functional impairment and augmented susceptibility to bacterial infection. Early studies (Ehrlich and Henry, 1968) showed that clearance of bacteria from the lungs is suppressed with 0.5 ppm NO_2 through 12 months of exposure. Interestingly, studies with a similar double diurnal peak design for NO_2, with NO used as a negative control, showed more pronounced effects of NO on alveolar septal remodeling than did NO_2 (Mercer *et al.*, 1995). Apparently, NO acts intercellularly to interrupt collagen metabolism; the potential for NO_2 to act in this manner is not known. These and similar studies utilizing varied peak-plus-baseline NO_x exposures indicate the importance of exposure profile for at least this pollutant.

Other Oxidants A number of other reactive oxidants have been identified in photochemical smog, however most are short-lived because of their reaction with copollutants. Peroxyacetyl nitrate (PAN), which is thought to be responsible for much of the eye-stinging activity of smog, is known to exist in smog situations. It is more soluble and reactive than O_3, and hence rapidly decomposes in mucous membranes before it can penetrate into the respiratory tract. The cornea is a sensitive target and is prominent in the burning/stinging discomfort often associated with oxidant

smogs. A few studies with high levels of PAN have shown that it can cause lung damage and have mutagenic activity in bacteria, but it is not likely that these scenarios are relevant to ambient levels of PAN.

Aldehydes Carbonyl compounds, notably short-chained (2–4 C) aldehydes, are common photo-oxidation products of unsaturated hydrocarbons. Two aldehydes are of major interest by virtue of their concentrations and irritancy: formaldehyde (HCHO) and acrolein ($H_2C{=}CHCHO$). They contribute to the odor as well as eye and sensory effects of smog. Formaldehyde accounts for about 50% of the estimated total aldehydes in polluted air, while acrolein, the more irritating of the two, accounts for about 5% of the total. Acetaldehyde (C_3HCHO) and many other longer chain aldehydes make up the remainder, but they are not as intrinsically irritating, exist at low concentrations, and have less solubility in airway fluids. Formaldehyde and particularly acrolein are also found in mainstream tobacco smoke (~90 and ~8 ppm, respectively, per puff) and are likely to be found at lower levels in sidestream smoke as well. Formaldehyde is also an important indoor air pollutant and can often achieve higher concentrations indoors than outdoors due to out-gassing by new upholstery or other furnishings.

Empirical studies have shown that formaldehyde and acrolein are competitive agonists for similar irritant receptors in the airways. Thus, irritation may be related not to "total aldehyde" concentration but to specific ratios of acrolein and formaldehyde. Their relative difference in solubility, with formaldehyde being somewhat more water-soluble and thus having more nasopharyngeal uptake, may distort this relationship under certain exposure conditions (e.g., exercise). On the other hand, acrolein is very reactive and may interact easily with many tissue macromolecules.

Formaldehyde Formaldehyde is a primary sensory irritant. Because it is very soluble in water, it is absorbed in mucous membranes in the nose, upper respiratory tract, and eyes. The dose–response curve for formaldehyde is steep: 0.5–1 ppm yields a detectable odor; 2–3 ppm produces mild irritation; and 4–5 ppm is intolerable to most people. Formaldehyde is thought to act via sensory C-fibers that signal locally as well as through the trigeminal nerve to reflexively induce broncheoconstriction through the vagus nerve. In guinea pigs, a 1 hour exposure to about 0.3 ppm of formaldehyde induces an increase in airflow resistance accompanied by a smaller decrease in compliance (Amdur, 1960). Respiratory frequency and minute volume also decreased, but these changes were not statistically significant until >10 ppm. The no observed effect level (NOEL) using these lung function criteria is about 0.05 ppm. The general pattern of the irritant response and its rapid recovery is similar to that produced by higher concentrations of SO_2. Like SO_2, breathing through a tracheal cannula to bypass nasal scrubbing greatly augments the irritant response, indicating that deep lung irritant receptors can also be activated by this vapor.

The irritancy of inhaled formaldehyde vapor, again like SO_2, has been shown to be potentiated by water-soluble salt aerosols. Irritancy appears to be augmented in proportion to the aerosol concentration, but the potentiation could not be accounted for by a simple aerosol "carrier" effect (Amdur, 1960). Moreover, reversal of bronchoconstriction was slower than had been observed with SO_2. Thus it appeared that the vapor-aerosol itself constituted a new irritant species, the product of a chemical transformation of formaldehyde—perhaps methylene hydroxide (Underhill, 2000). In

addition to interactions with water-soluble particles, formaldehyde has been shown to interact with carbon-based particles (Jakab, 1992) to augment bacterial infectivity in a murine model. In this case, the potentiation appears to correlate with the surface carrying capacity of the inhaled particle.

Two aspects of formaldehyde toxicology have brought it from relative obscurity to the forefront of attention in recent years. One is its near ubiquitous presence in indoor atmospheres as an off-gassed product of construction materials such as plywood, furniture, or improperly polymerized urea-formaldehyde foam insulation (Spengler and Sexton, 1983). Complaints of formaldehyde irritation in industry have been reported at 50 ppb (Horvath *et al.*, 1988). In studies relating household formaldehyde to chronic effects, children were found to have significantly lower peak expiratory flow rates (about 22% in homes with 60 ppb) than did unexposed children, and asthmatic children were affected below 50 ppb. Thus, this irritant vapor can cause respiratory effects, and perhaps act as an allergen, at commonly experienced exposure levels (Krzyzanowski *et al.*, 1990).

A longtime concern regarding formaldehyde has been its potential carcinogenicity. In 2004, IARC concluded, based on a through review of the published data, that formaldehyde was a probable carcinogen; IARC deemed that there was "sufficient" epidemiologic evidence that formaldehyde causes nasopharyngeal cancer, "strong but not sufficient" evidence of leukemia, and limited evidence of sinonasal cancer, along with "sufficient" evidence that formaldehyde causes nasal cancer in animals (Cogliano, 2005). Nasal cancer had been induced empirically with formaldehyde vapor in a 2-year study where rats were exposed to 2, 6, or 14 ppm 6 hours per day, 5 days per week. The incidence of nasal squamous cell carcinomas was zero in the control and 2-ppm groups, 1% in the 6-ppm group, and 44% in the 14-ppm group. Exposure-related induction of squamous metaplasia occurred in the respiratory epithelium of the anterior nasal passages in all exposed groups. A 20-fold increase in cell proliferation in the nasal epithelium occurred after 5 days to 14 ppm. Mice were much less sensitive; only one carcinoma was seen at 14 ppm. The detection of DNA adducts in the two species paralleled the difference in the incidence of tumors as well as regional dosimetry. Formaldehyde, with its large and diverse database and potential public health impact, has remained the focus of considerable debate among modelers and risk assessors. The arguments behind this debate crosses both cancer and noncancer considerations and is beyond that which can be discussed in this chapter. The reader is encouraged to sample the recent literature (e.g., Connolly *et al.*, 2004).

Acrolein Because acrolein is an unsaturated aldehyde, it is more reactive than formaldehyde. It penetrates a bit deeper into the airways and may not have the same degree of sensory irritancy but it may cause more damage. Concentrations below 1 ppm cause irritation of the eyes and the mucous membranes of the respiratory tract. Exposure of guinea pigs to ≥0.6 ppm reversibly increased pulmonary flow resistance and tidal volume and decreased respiratory frequency (Murphy *et al.*, 1963). With irritants of this type, flow resistance is increased by concentrations below those that cause the classic decrease in frequency seen with sensory irritants. This suggests that increases in flow resistance would be produced by far lower concentrations of acrolein than were tested. The mechanism of increased resistance appears to be mediated through both local C-fiber and centrally mediated cholinergic reflexes. Ablation of the C-fiber network and atropine (muscarinic blocker) block this response. On the other

hand, aminophylline, isoproterenol, and epinephrine (sympathetic agonists) partially or completely reversed the changes, whereas the antihistamines pyrilamine and tripelennamine had no effect.

Exposures of rats to 0.4, 1.4, or 4.0 ppm for 6 hours per day, 5 days per week for 13 weeks resulted in paradoxical effects on lung function (Costa *et al.*, 1986). The lowest concentration resulted in hyperinflation of the lung with an apparent reduction in small-airway flow resistance, while the highest concentration resulted in airway injury and peribronchial inflammation and fibrosis. The intermediate concentration was functionally not different from the control, although airway pathology was evident. It appears that the high-concentration response reflected the cumulative irritant injury and remodeling as a result of the repeated acrolein, while the low-concentration group had little overt damage and appeared to have slightly stiffened airways, perhaps a result of the protein cross-linking action of acrolein. The pathology in these rats contrasts with that found in formaldehyde studies of similar duration, where more upper airway involvement was observed. Ambient exposure to acrolein probably would be about 10–20% the low concentration used in the subchronic study discussed above. However, these concentrations of acrolein are well below those found in mainstream tobacco smoke and the occupational Threshold Limit Value.

Thus, as a class the aldehydes can be very irritating and may constitute a significant fraction of the discomfort and sensation experienced during an oxidant pollution episode, especially in mixed atmospheres containing particles.

Carbon Monoxide   Carbon monoxide is classed toxicologically as a chemical asphyxiant because its toxic action stems from its formation of carboxyhemoglobin, preventing oxygenation of the blood for systemic transport. The fundamental toxicology of CO and the physiologic factors that determine the level of carboxyhemoglobin attained in the blood at various atmospheric concentrations of carbon monoxide are detailed in Chap. 11.

The normal concentration of carboxyhemoglobin (COHb) in the blood of nonsmokers is about 0.5%. This is attributed to endogenous production of CO from heme catabolism. Blood COHb is a function of the concentration in air, the length of exposure, and the ventilation of the exposed individual. Uptake is said to be ventilation-limited, implying that virtually all the CO inspired in a breath is absorbed and bound to the available hemoglobin. Thus, continuous exposure of human subjects to 30 ppm CO leads to an equilibrium value of 5% COHb. The Haldane equation is used to compute the COHb equilibrium under a given exposure situation. The equilibrium values generally are reached after 8 hours or more of exposure. The time required to reach equilibrium can be shortened by physical activity.

Analysis of data from air-monitoring programs in California indicates that 8 hour average values can range from 10 to 40 ppm CO. Depending on the location in a community, CO concentrations can vary widely. Vehicle emissions are the major source of CO outside accidental domestic exposures and tobacco smoke. Concentrations predicted inside passenger compartments of motor vehicles in downtown traffic were almost 3 times those for central urban areas and 5 times those expected in residential areas. Occupants of vehicles traveling on expressways had CO exposures somewhere between those in central urban areas and those in downtown traffic. Concentrations above 87 ppm have been measured in underground garages, tunnels, and buildings over highways.

No overt human health effects have been demonstrated for COHb levels below 2%, while levels above 40% cause fatal asphyxiation. A 90-minute exposure to about 50 ppm CO would likely result in COHb levels of ∼2.5%, with a resultant impairment of time-interval discrimination; at approximately 5% COHb, there is an impairment of other psychomotor faculties. At 5% COHb in nonsmokers (the median COHb value for smokers is about 5%), however, maximal exercise duration and maximal oxygen consumption are reduced (Aronow, 1981). Cardiovascular changes also may be produced by exposures sufficient to yield COHb in excess of 5%. These include increased cardiac output, arteriovenous oxygen difference, and coronary blood flow in patients without coronary disease. Decreased coronary sinus blood PO_2 occurs in patients with coronary heart disease, and this would impair oxidative metabolism of the myocardium. In the early 1990s, a series of studies in subjects with cardiovascular disease were conducted in several laboratories under the sponsorship of the Health Effects Institute (HEI) to determine the potential for angina pectoris when they exercised moderately with COHb levels in the range of 2–6% (Allred *et al.*, 1989). The results of these studies indicate that premature angina can occur under these conditions but that the potential for the induction of ventricular arrhythmias remains uncertain. Thus, the reduction in ambient CO brought about by newer controls should reduce the risk of myocardial infarct in predisposed persons.

The recent introduction of gasoline oxygenates like MTBE and other ether derivatives was an attempt to enhance fuel combustion and reduce CO emissions. The ensuing problems with MTBE have been discussed earlier, but the goal of achieving lower CO was only partially successful. This finding reinforces the need to carefully consider whether resolution of one problem has the potential for generating others.

Hazardous Air Pollutants   Hazardous air pollutants (so-called air toxics or HAPs) represent an inclusive classification for air pollutants that are of anthropogenic origin that are generally of measurable quantity in the air, and are not covered in the Criteria Pollutant list. They are covered under Section 112 of the Clean Air Act. Selected regulatory issues of the HAPs were discussed above. Most exposure estimates for these pollutants are derived from emission inventories that are modeled into the National Air Toxics Assessment (www.epa.gov/ttn/atw/nata/sitemap.html). The most recent NATA assessment (2002) used 1999 data on the 33 HAPs (so-called "dirty 30" noted above), plus diesel emissions. The diverse nature of even 33 of the 188 HAPs complicates a general discussion of their toxicology because the group includes various classes of organic chemicals (by structure, e.g., acrolein, benzene), minerals (e.g., asbestos), polycyclic hydrocarbon particulate material [e.g., benzo(*a*)pyrene], and various metals and metal compounds (e.g., mercury, beryllium compounds) and pesticides (e.g., carbaryl, parathion).

The focus to date on the HAPs has been on their potential carcinogenicity, as shown in chronic bioassays, mutagenicity tests in bacterial systems, structure-activity relationships, or—in a few special cases (e.g., benzene, asbestos)—their known carcinogenicity in humans. These cancers need not be, and generally are not, pulmonary. Noncancer issues frequently relate to direct lung toxicants that, upon fugitive emissions or accidental release, which might risk those with preexisting diseases (e.g., asthma) or which might lead to chronic lung disease. The assessment of noncancer risk by air toxics to any organ system is based on the computation of long-term risk reference exposure concentrations (RfCs) to which individuals

may be exposed over a lifetime without adverse, irreversible injury. This approach to hazardous air pollutant assessment is discussed in detail by Jarabek and Segal (1994). An analogous short-term RfC method has been developed for exposures up to 30 days. Of the noncancer risks deemed highest in this analysis, acrolein ranks at the top based on emission inventories, the potential for exposure, and its inherent irritancy. Discussion of this topic and an approach to mixed exposures to noncancer HAPs has been reviewed (Costa, 2004).

Accidental versus "Fence-Line" Exposures   The relationship between the effects associated with an accidental release of a large quantity of a volatile chemical into the air from a point source such as a chemical plant and the effects associated with a chronic low-level exposure over many years or a lifetime is not clear. With regard to cancer, which defaults to a linearized model of dose and effect (through some alternative models can be used if there is some data), the issue is fairly straightforward. Any exposure must be minimized if not eliminated if cancer risk is to be kept as close to zero as possible. With noncancer risks, the roles of nonspecific or specific host defenses, thresholds of response, and repair and recovery after exposure complicate the assessment of risk. In large part the issue here relates to $C \times T$. Can we better relate disease or injury to *cumulative dose* or *peak* concentration for protracted exposures? Is there an exposure peak beyond which a cumulative approach fails (i.e., the effect is concentration-driven), or is concentration always the dominant determinant? Many of these questions have yet to be answered, not to mention their specificity with regard to individual compounds and tissues affected.

Methyl isocyanate provides a contrast between the effects of a large accidental release versus those produced by cyclic or continuous small fugitive vapor releases. The reactive nature of methyl isocyanate with aqueous environments is of such magnitude that upon inspiration, almost immediate mucous tissue corrosion can be perceived. The vapor undergoes hydrolysis within the mucous lining of the airways to generate hydrocyanic acid, which destroys the airway epithelium and causes acute bronchoconstriction and edema. The damage is immediately life-threatening at concentrations above 50 ppm; at 10 ppm, it is damaging in minutes. These concentrations are in the range of the dense vapor cloud that for several hours enshrouded the village of Bhopal bordering the Union Carbide pesticide plant. Studies in guinea pigs showed the immediate irritancy of this isocyanate, which in just a few minutes also resulted in significant pathology (Alarie *et al.*, 1987). Rats exposed to 10 or 30 ppm for 2 hours also showed severe airway and parenchymal damage, which did not resolve in surviving rats; transient effects were seen at 3 ppm. Even 6 months after exposure, the airway and lung damage remained, having evolved into patchy, mostly peribronchial fibrosis with associated functional impairments (Stevens *et al.*, 1987). There was also cardiac involvement secondary to the damage to the pulmonary parenchyma and arterial bed. As a result, there was pulmonary hypertension and right-sided heart hypertrophy. This same spectrum of health effects has resulted in disability and deaths of thousands of initial survivors since the incident.

In the United States, methyl isocyanate has been measured in Katawba Valley, Texas, as a result of small but virtually continual fugitive releases of the vapor into the community air ("fence-line") from an adjoining region with several chemical plants. While these levels of methyl isocyanate are not sufficient to cause the damage seen in Bhopal, there is concern that low-level exposure over many years may have more diffuse, chronic effects. Residents complain of odors and a higher frequency of respiratory disorders, but clear evidence of injury or disease is lacking.

Phosgene is best known for its use as a war gas, but it is also one of the most common intermediate reactants used in the chemical industry, particularly in pesticide formulation. It is also a constituent of photochemical smog. Because of its direct pulmonary reactivity, it lends itself to use as a model pulmonary toxicant for studies addressing $C \times T$ relationships. These studies suggest that there may be a threshold below which compensatory and other bodily defenses (e.g., antioxidants) may be able to cope with long-term low-level exposure (tolerance). For phosgene, this appears to be at or below the current threshold limit value of 0.1 ppm for 8 hours. At higher concentrations, however, concentration appears to be the primary determinant of injury or disease regardless of duration. Thus, even though there is some adaptation with time, there continues to be a concentration-driven response that exceeds that predicted by $C \times T$. This relationship appears to be different from that of O_3 at ambient levels, which can be approximated acutely by the $C \times T$ paradigm.

WHAT IS AN ADVERSE HEALTH EFFECT?

Any attempt to establish criteria to define an "adverse effect" of air pollution is likely to be questioned. Some effects would pass uncontested as adverse, e.g., death, acute life-threatening dysfunction or disease, irreversible impairments, and pain. Other effects that may reflect minor and temporary dysfunctions or discomfort could be argued by some as not warranting significant or costly concern, especially if effects are minor or transient. The goal of air-quality management is clearly to avoid or, at worse, limit negative impacts of air pollution on public health. However, one must appreciate the distinction between risk to the individual and to a population. Clearly, risk to an individual can be beyond an acceptable limit and can put that person's health in jeopardy, but this response may be lost in a population index. On the other hand, risk to a population is the summation of individual risks such that there is a shift in the normal distribution putting unspecified individuals at risk. These two forms of risk are clearly related, but most often in practice, the population risk is considered most appropriate and most reasonably quantifiable. This population-based risk or susceptibility is that identified in the CAA.

In 1985, the American Thoracic Society issued a position paper that attempted to define an adverse effect related to air pollution. This definition has recently been revised because of the many advances in clinical medicine and empirical health sciences (ATS, 2000). This statement considers seven broad areas: biomarkers, quality of life, physiologic impacts, symptoms, clinical outcomes, mortality, and population health versus individual risk. The summary conclusion states that caution should be exercised in evaluating the many new biomarkers of effect (especially cell and molecular markers), as there is need for validation that *small* changes in these markers represent a progression along a course to disease or permanent impairment. Admittedly, in the clinical environment many of these markers may appear as salient features of a disease or injury, but the health implications of minor changes in these biomarkers remains uncertain. Significant alterations of standard clinical measures of health due to pollution are clearly adverse. However, a shift from the 1985 ATS statement is that transient pulmonary function deficits (where a 10% or more drop in FVC was defined as adverse) may not necessarily be adverse. On the other hand, any irreversible reduction in pulmonary function would be adverse either for an individual or
Figure 28-13. *Schematic illustration of the elements of the dose response to an air pollutant(s) of a susceptible versus a healthy individual.*

The hypothetical susceptible individual may be more sensitive or may have a *loss of reserve*, either of which results in an *inability to maintain homeostasis*. The *leftward shift or increased slope* in the dose–response curve suggests an increase in responsiveness. Either situation may contribute to sensitivity and the likelihood of enhanced progression from subtle to severe outcomes.

across a population. Any population for which a significant mortality risk can be detected must be considered adverse. Of course, a common thread through all these subject areas is the influential role of susceptibility, which can take the form of hyper-responsiveness or loss of reserve. What was a minor reversible effect may now be a dysfunction that cannot be reversed or compensated (Fig. 28-13). Obvious examples would be cardiopulmonary compromised individuals who function with little or no reserve. In the end, however, the ATS statement realizes the limits of definitions and the importance of value judgment in the final assessment. Implied in this

position is that a loss of quality of life due to air pollution as well as enduring its associated effects may also be designated as adverse. As science continues to advance, especially in the realm of molecular biology where small signals can be detected that may forecast an adverse effect or otherwise may identify individuals or groups at risk, the definition of adverse will certainly need re-examination. That same sensitivity in measurement that serves to predict an adverse effect must be separated from signals that are essential for homeostasis and the maintenance of life. Clearly, dissecting and defining these phenomena will have implications not only for assessing clinical adversity but will have implications for predictive toxicology.

CONCLUSIONS

In writing this textbook chapter on air pollution toxicology, the author's goal has been to relate empirical studies in animals to phenomena known to occur in humans through epidemiologic or controlled clinical study. The breadth and complexity of the problem of air pollution—from the development of credible databases to supporting regulatory action and decision making—has been the theme throughout. The classic and still most important air pollutants provide a foundation for understanding and appreciating the nuances of the issues and strategies for air pollution control and protection of public health. The key role of the toxicologist is to develop sensitive methods to assay responses to low pollutant concentrations, apply these methods to relevant exposure scenarios and test species, and develop paradigms to relate empiric toxicological data to real life through an understanding of mechanism. Last, the toxicologist must continually integrate laboratory data with those of epidemiology and clinical study to ensure their maximum utility.

ECOTOXICOLOGY

Richard T. Di Giulio and Michael C. Newman

INTRODUCTION

Ecotoxicology is the science of contaminants in the biosphere and their effects on constituents of the biosphere (Newman and Unger, 2003). It follows from this definition that ecotoxicologists examine large-scale ecological phenomenon (Preston, 2002) in addition to those normally addressed in toxicology: ecotoxicology has an overarching goal of explaining and predicting effect or exposure phenomena at several levels of biological organization (Fig. 29-1). Essential explanations and models include those applied in conventional toxicology and a range of environmental sciences.

Although Truhaut's original definition of this new science encompassed effects to humans (Truhaut, 1977), most recent definitions of ecotoxicology do not. Relevant effects to nonhuman targets range from biomolecular to global. Taking on the classic toxicology vantage initially, suborganismal and organismal effects were emphasized during ecotoxicology's nascent stage; however, studies of higher level effects and interactions are becoming increasingly commonplace as the science matures. Such indirect effects[1] were initially considered problematic and reluctantly relegated to secondary importance (Fleeger *et al.*, 2003) relative to direct effects to individuals. Indirect effects are now known to be as important as direct effects to nonhuman targets (Fleeger *et al.*, 2003; Chapman, 2004). As the need to predict major effects to populations, communities, ecosystems, and other higher level entities has become increasingly apparent, more cause–effect models relevant to these higher levels of biological organization are added to the conventional set of toxicology models applied by pioneering ecotoxicologists.

Contaminant chemical form, phase association, and movement among components of the biosphere are also central issues in ecotoxicology because they determine exposure, bioavailability, and realized dose. The context of these biogeochemical studies has expanded in the last several decades to encompass issues of larger and larger scale such as global movement of persistent organic pollutants (Wania and Mackay, 1996).

From a practical vantage, ecotoxicology informs decision makers about ecological risks associated with contamination. Risk to ecological entities are estimated or predicted by combining exposure and effect information. Risk might involve diminished fitness of individuals, increased risk of local population extinction, a drop in species diversity, or reduced nutrient cycling or primary productivity. Because potential ecological endpoints are so diverse, the ecological risk framework tends to be more flexible than that of the conventional human health risk assessment (Fig. 29-2). This important role of ecotoxicology in ecological risk assessment will be discussed in more detail below.

SOME DISTINCT ASPECTS OF EXPOSURE

Predicting exposure and effect is difficult for all relevant ecological entities. In contrast to human toxicology in which information about a few species might be used to predict harm to one (humans), ecotoxicology commonly uses sparse information for a few species to predict effects to many species and their interactions. Exposure pathways, bioavailability, bioaccumulation, and toxicant transfer for all relevant ecological entities are also difficult issues requiring considerable effort to adequately understand.

Relevant exposure routes are the conventional ingestion, inhalation, and dermal absorption. But, unique features of exposure

---

[1] Indirect effects are effects of toxicants mediated by another ecosystem component (Krivtsov 2004) such as those that might occur to a flowering plant if a pesticide were to eliminate its primary insect pollinator.
Figure 29-1. Ecological scales relevant to ecotoxicology.

Solely biological scales relevant to ecotoxicology range from the molecular to the community levels: solely abiotic scales range from the chemical to the entire habitat. Biotic and abiotic components are usually combined at levels above the ecological community and habitat. The ecological community and physicochemical habitat combined to form the ecosystem. Ecological systems can be considered at the landscape scale, i.e., the combination of marine, freshwater, and terrestrial systems at a river's mouth. Recently, the continental and biospheric scales have become relevant as in the cases of ozone depletion, acid precipitation, and global warming.

pathways must be accommodated for species that ingest a wide range of materials using distinct feeding mechanisms, breathe gaseous or liquid media using different structures, and come into dermal contact with a variety of gaseous, liquid, and solid media.

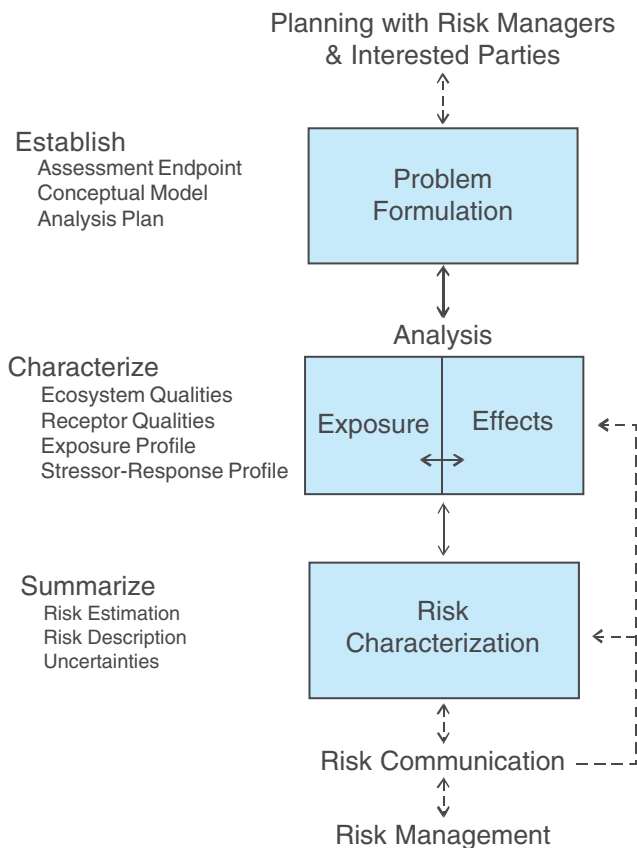
Prediction of oral exposure can be limited because species feed on different materials; however, conventional principles regarding oral bioavailability remain relevant. As an example, some birds are uniquely at high risk of lead poisoning because they ingest and then use lead shot as grit. Shot are ground together in their gizzards under acidic conditions, releasing significant amounts of dissolved lead (Kendall *et al*., 1996). As true with humans (i.e., the ionic hypothesis of Mathews, 1904), the dissolved form of lead is more available to do harm than solid lead shot. Similar high risk of lead poisoning is present for some raptors feeding on game birds whose tissues can contain lead shot (Wayland and Bollinger, 1999). Complex sorting of filtered materials on the gills of bivalve molluscs strongly influences the metal content and bioavailability of the material that eventually passes into their guts (Allison *et al*., 1998). Some invertebrate species have elaborate feeding structures that are also involved in respiration (e.g., lugworms and bivalve molluscs) or locomotion (copepods and other zooplankton species). Some zooplankton species feed and digest algal cells in such a way that only metals soluble in the algal cytosol are bioavailable (Reinfelder and Fisher, 1991). Unlike mammalian species, many invertebrate species are capable of sequestering large amounts of metals in intracellular granules (Mason and Nott, 1981). Incorporation of metals into granules by prey species reduces metal bioavailability to predators (Nott and Nicolaidou, 1993). Just as noted with 5-fluoruracil administration or chronic ethanol consumption, some pollutant exposures cause malabsorption by damaging the intestine wall. A relevant sit-


Figure 29-2. The general form of an ecological risk assessment including problem formulation, analysis, and risk characterization stages.

Problem formulation is done in dialog with risk managers and stakeholders, and involves a clear statement of the ecological entity to be assessed, a conceptual model for the process, and a plan for conducting the assessment. The analysis stage involves exposure and effects characterizations. Using the context developed during problem formulation and information organized together in the analysis stage, a statement of risk and associated uncertainties are made in the risk characterization stage.

uation would be intestinal damage to otters caused by ingestion during grooming of oiled fur (Lipscomb *et al*., 1996; Ormseth and Ben-David, 2000). The principles remain the same in all of these cases but critical exposure pathway details are different.

Many techniques applied to determining human oral bioavailability are available to the ecotoxicologist; however, as just illustrated, modifications are needed for the many pathways for nonhuman species exposure. Typical are those associated with estimating contaminant bioavailability in aquatic environments. As an example, biomimetic and related extraction methods used to predict human oral bioavailability can be modified to predict sediment-bound contaminant bioavailabilities. Sediments are placed into contact with biomimetic solutions (Chen and Mayer, 1998; Leslie *et al*., 2002) or digestive fluids taken from organisms (Mayer *et al*., 1996; Weston and Maruya, 2002), and the amount of extracted contaminant used to estimate bioavailability.

Estimation of chemical speciation is central to predicting bioavailability of water-associated contaminants. Speciation can determine the bioavailability of dissolved metals. Movements of nonionic and ionizable organic compounds across the gut or gills are strongly influenced by lipid solubility and the pH partition theory, respectively. Consequently, determination of a compounds

lipophilicity or calculation of pH- and pK_a-dependent ionization facilitates some predictive capability for bioavailability. A common application of this approach would be estimation of water pH effects on ammonia toxicity as the consequence of the ease with which un-ionized ammonia passes through gills relative to ionized ammonia (Lloyd and Herbert, 1960). The Free Ion Activity Model (FIAM) states that uptake and toxicity of cationic trace metals are best predicted from their free ion activity or concentration (Campbell and Tessier, 1996) although exceptions exist to this extension of the ionic hypothesis. Consequently, dissolved metal exposure assessments often begin by estimating the amount of a metal present as the free ion. Normally, such calculations require only thermodynamic modeling based on measured concentrations of dissolved cations and anions. Lipid partitioning is often used to predict dissolved, nonionizing organic compound accumulation in and effects to aquatic biota. The propensity for an organic compound to accumulate in aquatic organisms increases with lipid solubility as often described with a simple Quantitative Structure Activity Relationship (QSAR) (Neely *et al.*, 1974; Mckay, 1982; Chiou, 1985; Connell, 1990). The log of the octanol–water partition coefficient (log K_{ow}) is used to predict measures such as the bioconcentration factor (the quotient of the concentration in the organism and that in the water from which the organic compound is being accumulated):

$$Bioconcentration\ Factor\ (BCF) = \frac{C_{Organism}}{C_{Water}}$$

Bioavailability, bioaccumulation, or exposure concentrations for sediment-associated toxicants are also approached by considering chemical speciation and phase partitioning. Metals in sediments are either incorporated into one of many solid phases or dissolved in the interstitial waters surrounding the sediment particles. Bioavailabilities of metals in these different forms are difficult to predict (Luoma, 1989) but, nonetheless, various schemes have been applied to that end. Bioavailable metals have been estimated by normalizing sediment metal concentrations to easily extracted iron and manganese concentrations because solid iron and manganese oxides sequester metals in poorly bioavailable solid forms (Luoma and Bryan, 1978). Other chemical extraction methods have been applied with some success (Tessier *et al.*, 1984). A pragmatic method for predicting sediment metal bioavailability has emerged that is based on the assumption that the sediment metal form of most concern is the dissolved metal. Further, for many metals and sediments, the dissolved interstitial metal concentrations are determined by equilibrium between solid (iron and manganese) sulfides and the interstitial water.

$$Cd^{2+} + FeS_{Solid} \longleftrightarrow CdS_{Solid} + Fe^{2+}$$
Because the equilibrium so favors formation of metal sulfide (CdS in this case) at the expense of FeS, insignificant amounts of dissolved metal will be present in the interstitial waters if enough FeS is present. This premise has given rise to a standard technique for determining if sediments might contain enough metal to warrant concern (Di Toro *et al.*, 1990). First, a sediment aliquot is extracted with cold hydrochloric acid. Then the amounts of sulfide (acid volatile sulfides, AVS) and simultaneously extracted metals (SEM) are measured in that extract. The difference between the SEM and AVS suggests whether or not enough metal will be dissolved in the interstitial waters to warrant concern. This method has enjoyed wide application and was recently refined by Di Toro *et al.*

(2005) by including metal partitioning to sediment organic matter. Some ecotoxicologists such as Lee *et al.* (2000) suggest that further refinement remains to be done because metal exposure of organisms that ingest sediment particulates is not fully defined by interstitial water concentrations alone.

Bioavailability and accumulation of sediment-associated organic compounds are predicted with tools similar to those described for waters. The bioavailability of ionizable organic compounds can be approximated with the pH-partition hypothesis that relates the availability of an ionizable compound to the diffusion of its unionized form through membranes as determined by pH and pK_a. Availability of nonionizing organic compounds for accumulation can often be estimated with its log K_{ow} and equilibrium partitioning theory as described already for accumulation from waters. The challenge with nonionizing organic compounds becomes adequately defining the phases between which the compound is partitioning. This might be done by estimating the partitioning of the compound between sediment solid phases and the interstitial water as done by Di Toro *et al.* (1991). Descriptions of nonionizing organic compound bioaccumulation from sediments can also entail normalization of concentrations to phases thought to be dictating partitioning:

$$Biota\ Sediment\ Accumulation\ Factor\ (BSAF)$$
$$= \frac{\mu g/kg\ lipid}{\mu g/kg\ organic\ carbon}$$

where the mass of compound in the organisms is divided by kg of organism-associated lipid and the mass of compound in the sediment is divided by kg of sediment-associated organic carbon.

Another issue of importance to the ecotoxicologist is the possibility of biomagnification, the increase in contaminant concentration as it moves through a food web. As will be described below, biomagnification can result in harmful exposures to species situated high in the food web such as birds of prey.

TOXICANT EFFECTS

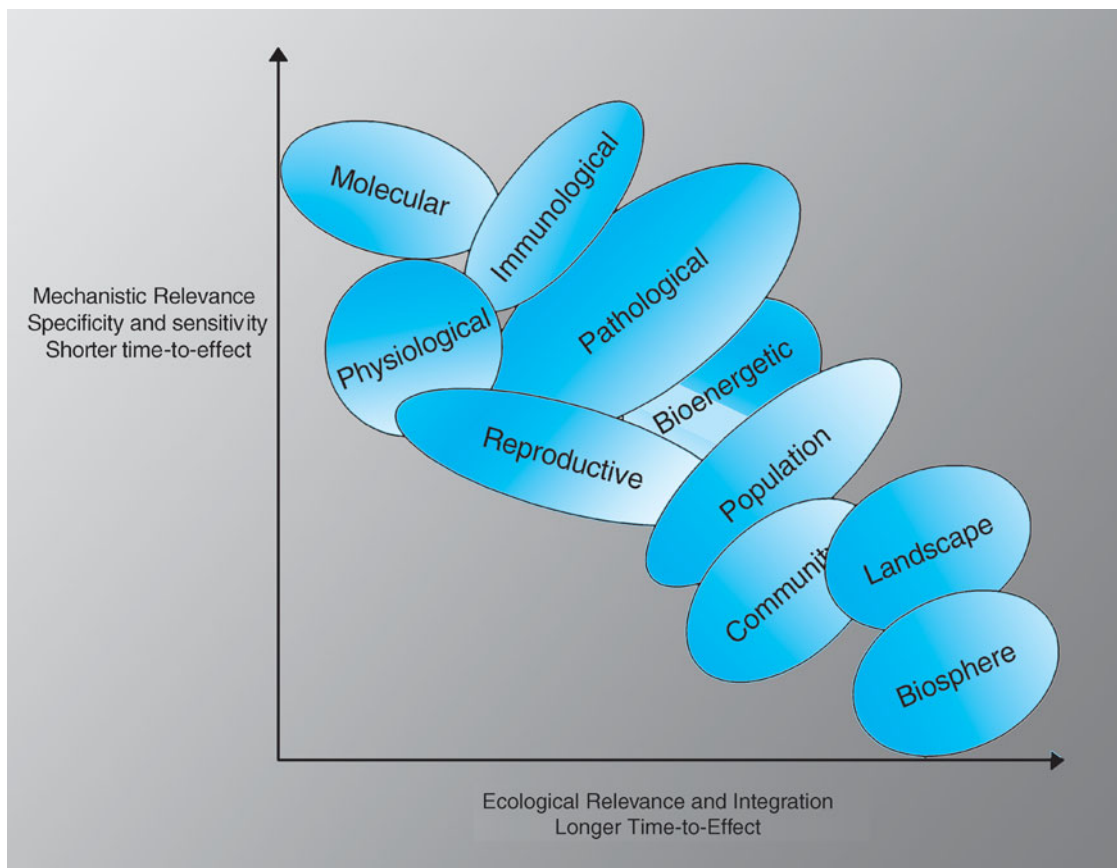
While determining *exposure* comprises one-half of the risk assessment paradigm, the other half, understanding chemical effects, lies at the heart of toxicology and hence, comprises the focus of this chapter. The effects, or deleterious consequences of chemical exposures, can be enormously diverse as demonstrated by previous chapters, and investigated by numerous techniques. One approach to this complex topic of ecotoxicological effects, which we employ here, is to organize effects according to biological levels of organization. Thus, one may consider effects, in ascending order, at the subcellular (molecular and biochemical), cellular, organismal, population, community, and ecosystem levels of organization. As noted earlier, an important distinction between traditional biomedical, or human health-oriented, toxicology and ecotoxicology is the emphasis by the latter on higher levels of biological organization, specifically populations, communities, and ecosystems, while biomedical toxicology focuses on lower levels, from organismal and below. This difference arises from the focus of biomedical toxicology on one species and concerns for protecting the health of individuals of that species. Ecotoxicology, in contrast, deals with, theoretically at least, all species; and in line with other aspects of natural resource management, the primary concern is one of sustainability. That is, policies and regulations surrounding chemical effects in natural ecosystems are designed to protect ecological features such as population dynamics,


Figure 29-3. Hierarchical types of effects considered in ecotoxicology, indicating relative attributes such mechanistic vs. ecological relevance and time lags between exposure and observable effect.

Based on artwork kindly provided by S.Marshall Adams, Oak Ridge National Laboratory.

community structures, and ecosystem functions. In this light, the individual organism is essentially viewed as expendable, as long as these higher level variables are protected. An exception here is that of endangered or threatened species, where the loss of an individual may have unacceptable legal or ecological consequences.

While higher levels of organization comprise the ultimate focus of those concerned with chemical pollution of natural systems, the science of ecotoxicology includes studies across the entire range. Studies at lower levels (cellular and below) provide insights into mechanisms of toxicity that can be valuable for making predictions among related compounds or species, and establishing cause–effect relationships in field studies, for generating useful "biomarkers" of chemical exposure and effect, and for providing insights into higher level, particularly population level, effects. Studies at the organism level have historically played a dominant role in regulatory ecotoxicology; many traditional bioassays, described later, can be viewed as organismal level queries. Again, understanding effects at the population and higher levels can be viewed as the "gold standard" in ecotoxicology. However, because these effects can require a relatively long time beyond the initial exposure of a system to emerge, their quantification is often difficult, and they generally do not serve to identify the nature of the stressor. Thus, the elucidation of effects of chemical pollutants, as well as other stressors, in natural systems draws upon multiple approaches and conclusions are generally based on the weight of evidence available. Examples of effects, or endpoints, that can be measured spanning levels of organization and

their relative sensitivities and ecological relevancies are illustrated in Fig. 29-3. The originator of this figure, S.M. Adams (Oak Ridge National Laboratory) has discussed the importance of integrating studies across levels of organization and mathematical approaches for accomplishing this (Adams *et al.*, 2000).

In the following sections, we describe important chemical effects that have been addressed at different levels of biological organization in ecotoxicological contexts, including illustrative examples. It is beyond the scope of this chapter to provide discussions of all chemicals that have received ecotoxicological attention. Other chapters in this text, particularly those in Unit 5 (Toxic Agents) provide detailed information for most classes of chemicals of concern as pollutants of natural systems, albeit in a primarily mammalian context. Many of the effects described are relevant to other animals, and of course mammals do occur in natural systems! Some plant-specific effects will be addressed herein. It should be noted that, while we have employed a biological level of organization approach as a meaningful way to organize and convey a complex array of information, the phenomena we have categorized into various levels are ultimately interwoven, as will become apparent.

Molecular and Biochemical Effects

This lowest level of organization includes fundamental processes associated with the regulation of gene transcription and translation, biotransformation of xenobiotics, and the deleterious
Figure 29-4. *A simplified model of estrogen receptor signaling including the estrogen receptor (ER), which upon binding to native hormone ligand (estrogen) or xenoestrogen (see Fig. 29–5) forms the transcriptionally active ER homodimer complex that binds to genes containing estrogen response elements (ERE) and thereby upregulates transcription and translation of genes/proteins regulated by the system, such as vitellogenin (Vtg). biochemical effects of xenobiotics on cellular constituents including proteins, lipids, and DNA. These effects have been described elsewhere throughout this book in various contexts related to human health. Here we will highlight some aspects of subcellular effects that have received particular attention in the context of ecotoxicology. Research in this area has been performed for a variety of reasons, including the elucidation of mechanisms of adaptation and toxicity, understanding species similarities and differences (e.g., to compare selected wildlife species with standard mammalian models, and to identify particularly sensitive species), and to develop useful biomarkers of chemical exposure and toxicity for environmental assessments. More in depth discussions are provided in monographs such as Hoffman *et al.* (2003), Newman and Unger (2003), Mommsen and Moon (2005), and Di Giulio and Hinton (in press).

Gene Expression and Ecotoxicogenomics

A long-standing mechanistic issue in toxicology concerns chemical effects on gene and protein expression. Xenobiotics can affect gene transcription through interactions with transcription factors and/or the promoter regions of genes that bind transcription factors in the process of activating transcription. In the context of environmental toxicology, perhaps the most studied xenobiotic effects involve ligand-activated transcription factors. These intracellular receptor proteins recognize and bind specific compounds, thus forming a complex that binds to specific promoter regions of genes, thereby activating transcription of mRNAs, and ultimately translation of

the associated protein. Two examples of substantial importance in ecotoxicology that illustrate these interactions involve the estrogen receptor (ER) and the aryl hydrocarbon receptor (AHR).

Estrogen Receptor   A number of chemicals have been shown to perturb various components of the endocrine system, and the identification and elucidation of "endocrine disruptors" has been a subject of much research and regulatory action in recent years, in the contexts of both human and wildlife health (see Chap. 10; Rotchell and Ostrander, 2003). Perhaps the most studied component of the vertebrate endocrine system in this context is the estrogen receptor, particularly estrogen receptor α (ER), and responses associated with it. The dominant natural ligand for this nuclear receptor is estradiol (E2); binding of E2 with ER produces a complex that can then bind to estrogen response elements (ERE) of specific genes that contain one or more EREs, thereby causing gene transcription (see Fig. 29-4). Genes regulated in this manner by E2–ER play various important roles in, for example, sexual organ development, behavior, fertility, and bone integrity (Deroo and Korach, 2006).

A number of chemicals including certain drugs and environmental pollutants can serve as ligands for ER; in most cases these "xenoestrogens" activate gene transcription, i.e., similar to estradiol, acting as receptor agonists. The first xenoestrogen identified was diethylstilbestrol (DES), a drug used to prevent miscarriage in the 1940s to the 1970s until it was discovered to have profound developmental effects in some offspring of women receiving the treatment (Trimble, 2001). In recent years, a number of environmental
Figure 29-5. Estrogen receptor agonists, including a native estrogen (17β-estradiol), the drug diethylstilbestrol (DES), a surfactant component (nonylphenol), an industrial intermediate (bisphenol A), and several pesticides (remainder).

pollutants with estrogenic activity have been identified, including certain chlorinated hydrocarbon insecticides (e.g., DDT, methoxychlor, endosulfan), surfactants (nonyl-phenol), some PCBs, bisphenol A (used in plastics manufacturing), and ethinyl estradiol, a synthetic estrogen used in birth control pills and observed in municipal effluents and surface waters (Shelby *et al.*, 1996; Larsson *et al.*, 1999; van der Oost *et al.*, 2003; see Fig. 29-5). With the exception of ethinyl estradiol, these pollutants exhibit relatively low binding affinities to ER, as compared to E2 or DES (Shelby *et al.*, 1996); however, environmental exposures may be sufficient to perturb reproduction or development.

Evidence for such "endocrine disruptions" by environmental xenoestrogens appears to be overall stronger for wildlife than for humans, likely due to instances of elevated exposures that are less prone to confounding factors than is typically the case for human exposures. Also, egg-laying vertebrates provide a unique biomarker of estrogen exposure that has contributed to ecotoxicological studies in this area. Vitellogenin (Vtg) is a protein that is normally produced by the liver of females and transported via the bloodstream to the ovary where, as a key component of yolk, it provides nourishment to the developing embryo. The production of Vtg is regulated by the estrogen–estrogen receptor system. Interestingly, males of egg-laying vertebrate species contain the molecular machinery to produce Vtg, but production and circulating levels are normally very low, due to low titers of estrogen. However, exposures of males to estrogen and xenoestrogens upregulate Vtg production, which can be readily measured in blood samples. Consequently, elevated Vtg in males of these species is a useful biomarker of estrogenic chemical exposures (Sumpter and Jobling, 1995; see **Biomarker** discussion below). Examples include rainbow trout (*Oncorhynchus mykiss*) caged in surface waters below industrial or municipal effluent sources enriched in alkylphenolic surfactants in the UK (Harries

et al., 1997) or natural and synthetic estrogens in Sweden (Larsson *et al.*, 1999), and whitefish (*Coregonus lavaretus*) caged near paper mill effluents in Finland (Mellanen *et al.*, 1999). While the bulk of research related to estrogenic compounds in natural systems have focused on fish, this approach has merit for other egg-laying vertebrates (Lorenzen *et al.*, 2003; Huang *et al.*, 2005), and for some invertebrates that produce Vtg-like proteins (Porte *et al.*, 2006).

Aryl Hydrocarbon Receptor   The aryl hydrocarbon receptor (AHR) is a member of the basic helix–loop–helix Per ARNT Sim (bHLH-PAS) family of receptors/transcription factors that play roles in development, as sensors of the internal and external environment in order to maintain homeostasis, and in establishment and maintenance of circadian clocks (Denison and Nagy, 2003; Hahn *et al.*, 2005). The AHR is among the most intensively studied receptors in toxicology due to its role in regulating a number of genes coding for proteins involved in xenobiotic metabolism, and its responsiveness to a number of widespread environmental contaminants, as well as some drugs and endogenous compounds. The AHR is a ligand-activated cytosolic receptor that upon binding to a ligand traverses to the nucleus where it complexes with another transcription factor, the AHR nuclear translocator (ARNT) protein (Fig. 29-6) to form a transcriptionally active dimer. This AHR–ARNT complex binds to promoter sequences of genes regulated by the AHR system; these promoters are most often referred to as "xenobiotic response elements" (XRE) or "dioxin response elements" (DRE).

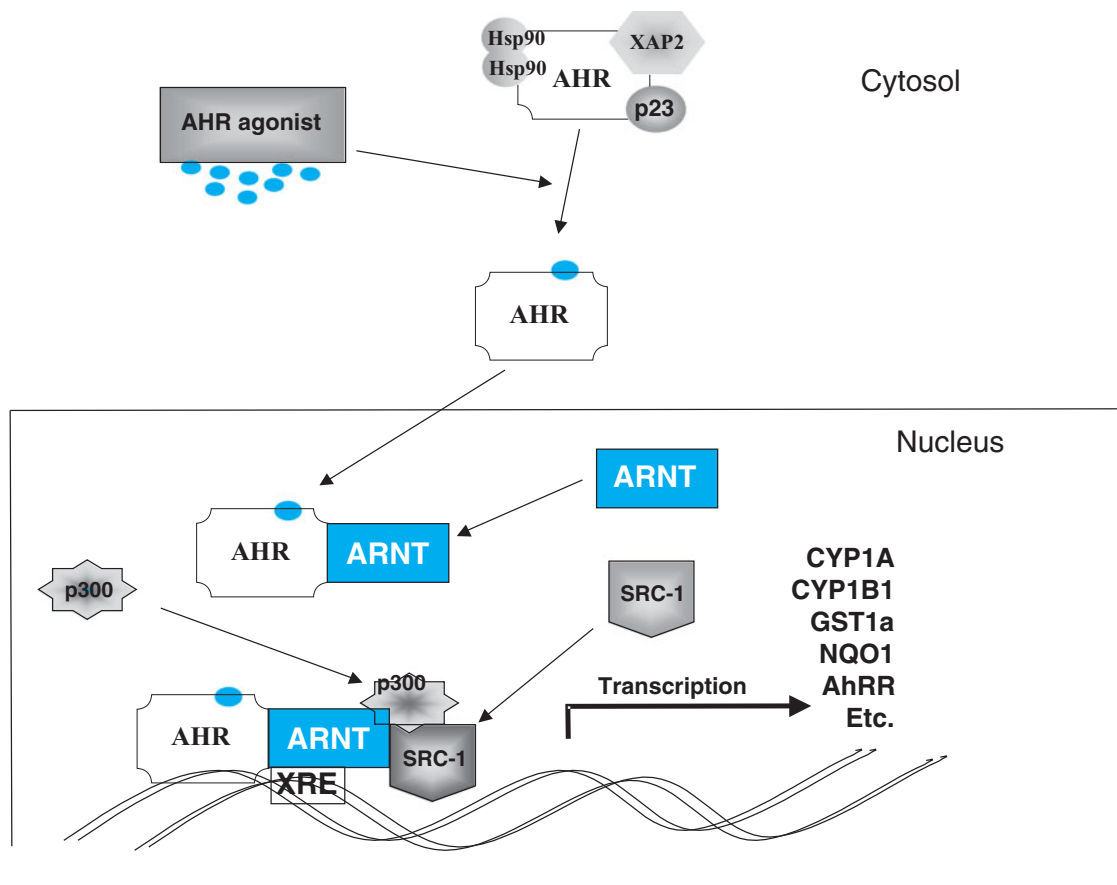
Characterized genes that are upregulated by the AHR system in large part code for enzymes involved in the metabolism of lipophilic chemicals, including organic xenobiotics and some endogenous substrates such as steroid hormones. These enzymes include specific cytochrome P450s (mammalian CYP1A1, 1A2, and 1B1 and


Figure 29-6. *A simplified model of the aryl hydrocarbon receptor (AHR) including activation by AHR ligands (see Fig. 29-7) that allows for dimerization with the AHR nuclear transporter (ARNT) that forms the transcriptionally active complex that binds to xenobiotic response elements (XRE) and thereby upregulates a number of genes, including several involved in biotransformation, indicated here, as well as the AHR repressor (AHRR) that provides negative feedback control of the system.*

their counterparts in other vertebrates), a glutathione transferase (GST), a glucuronosyl transferase (UDPGT), an alcohol dehydrogenase (ALD), and a quinone oxidoreductase (NQO). In addition to these enzymes, AHR–ARNT upregulates the AHR repressor protein (AHRR), which then competes with AHR for ARNT. This results in a transcriptionally inactive complex and effectively provides a negative feedback loop for controlling AHR-mediated gene transcription (Hahn *et al.*, 2005). The biotransformation enzymes regulated by the AHR system are described in detail in Chap. 6. Briefly, they play key roles for transforming many lipophilic chemicals, including numerous common organic contaminants, into more water soluble, and hence excretable, products. However, this biotransformation activity can result in production of highly reactive products that are more toxic than their parent compounds, i.e., "activation."

Of particular relevance to the present discussion, however, is the ability of some ubiquitous pollutants to act as AHR ligands and markedly upregulate gene transcription via the AHR–ARNT signaling pathway described above (Denison and Nagy, 2003). In some cases, this can be interpreted as an adaptive response—the organism is reacting to exposure to a lipophilic xenobiotic in order to enhance its elimination. However, as noted above, biotransformation can also lead to enhanced toxicity of some substrates. The two

major classes of pollutants that have members that act as ligands for the AHR and upregulate gene expression (and thereby "induce" biotransformation enzymes), and have received the greatest attention in ecotoxicology are the polycyclic aromatic hydrocarbons (PAHs) and the polyhalogenated aromatic hydrocarbons (pHAHs); examples of both are provided in Fig. 29-7. The most studied pHAHs are particular "coplanar" polychlorinated biphenyls (PCBs) and chlorinated dioxins. Whereas some PAHs and pHAHs share the ability to activate the AHR, important differences between these classes exist. PAHs, whether they are ligands for the AHR or not, are overall very good substrates for the biotransformation systems upregulated via the AHR, which can act to both detoxify and enhance the toxicity of some PAHs (discussed below under section "Cancer"). In general, pHAH-type AHR ligands are more potent AHR ligands and enzyme inducers than PAHs, but due to extensive halogenation are much poorer substrates for biotransformation. One of the most potent ligands for the AHR is the dioxin, 2,3,7,8-tetrachlorodibenzodioxin (TCDD), which is highly recalcitrant to biotransformation (Denison and Nagy, 2003).

In similarity with xenoestrogen-mediated inductions of Vtg via the ER, the inducibility of biotransformation enzymes via the AHR by xenobiotics has been used for biomonitoring. In this
Figure 29-7. Representative ligands of the aryl hydrocarbon receptor, including 2,3,7,8-tetrachlorodibenzodioxin (TCDD), a co-planar polychlorinated biphenyl (PCB 126), two poly-cyclic aromatic hydrocarbons (benzo(a)pyrene—BaP, and 3-methlycholanthrene—3-MC), and a flavone (β-naphthoflavone—BNF).

regard, enzymatic activities associated with the CYP1As have been the most widely used AHR-related biomarker, particularly an activity that appears highly specific for these CYPs, ethoxyresorufin O-deethylase (EROD), which is most often measured in liver tissue of vertebrates. Elevated activities of EROD in various vertebrates have been associated with exposures to PCBs, dioxins, PAHs, and complex mixtures of these associated with, for example, harbor sediments, municipal effluents, paper mill effluents, refinery effluents, and crude oil spills (Custer *et al.*, 2001; van der Oost, 2003; Miller *et al.*, 2005). Invertebrate AHR homologues examined do not bind to ligands similarly to vertebrate AHRs and do not demonstrate protein inductions analogous to those observed in vertebrates (Butler *et al.*, 2001; Hahn, 2002; Chaty *et al.*, 2004). Polycyclic aromatic hydrocarbon and pHAH toxicities and the potential roles played by their interactions with the AHR will be discussed at various points in subsequent sections of this chapter, and related discussions from a human health standpoint appear in other chapters.

Genomics and Ecotoxicogenomics   Recent advances in gene sequencing and associated techniques for investigating mechanism underlying gene expression have revolutionized molecular biology. These advances are rapidly permeating many areas of biological research, including toxicology and environmental science. Underlying these advances are very large projects to sequence the entire genomes of various species, such as the highly publicized Human Genome Project that was completed in 2003 (Little, 2005). Other species that have been completely or largely sequenced include the mouse, rat, cow, dog, chimpanzee, chicken, zebrafish (*Danio rerio*), puffer fish (*Fugu rubripes*), medaka (*Oryzias latipes*), fruit fly (*Drosophila melanogaster*), a sea urchin (*Strongylocentrotus purpuratus*), a soil nematode (*Caenorhabditis elegans*), a yeast (*Saccharomyces cerevisiae*), and rice (*Oryza sativa*), and the number of species sequenced is anticipated to expand rapidly (see www.genome.gov; Crollius and Weissenbach, 2005). Genome sequencing set the stage for genome-wide analysis of gene expression ("transcriptomics"); cDNAs for known genes can be spotted on glass

slides, or chips, resulting in "microarrays" that can be employed to quantify relative levels, i.e., expression, of mRNAs for those genes in samples of interest. The study of changes in gene expression arising from chemical exposures is a key component of "toxicogenomics" (Schmidt, 2002). Microarrays for genomes or genome components of interest (such as genes associated with stress responses, carcinogenesis, and development) are commercially available for many species, and rapidly expanding. Also advancing rapidly are related analyses of global changes in proteins (the translation products of mRNAs), refereed to as "proteomics," and resulting metabolite profiles (amounts of sugars, lipids, amino acids, etc. in various tissues that are controlled in part by enzyme activities), referred to as "metabolomics." A major complexity in these global analyses is the extremely large data sets that arise, for example, when one examines the responses of thousands of genes from organisms exposed to one or more concentrations of a chemical at one or more time points. This has led to the development of the field of "bioinformatics" that includes the application of sophisticated statistical and computing approaches for revealing biologically meaningful patterns of gene expression such as relationships to cellular signaling pathways. "Omics" is a term used to refer collectively to these interrelated approaches (i.e., transcriptomics, proteomics, metabolomics, and bioinformatics).

Omics have spread into the science and applications of ecotoxicology, collectively termed ecotoxicogenomics. As is the case for human health-oriented toxicogenomics, ecotoxicogenomics has great potential for elucidating impacts of chemicals of ecological concern and ultimately for playing an important role in ecological risk assessments and regulatory ecotoxicology (Snape *et al.*, 2004; Ankley *et al.*, 2006; Watanabe and Iguchi, 2006). Specific areas to which this emerging field can contribute include prioritization of chemicals investigated in ecological risk assessments, identification of modes of action of pollutants, identification of particularly sensitive species, and effect prediction at higher levels of organization. As in other areas of ecotoxicology, a major complexity faced is the vast array of species of potential concern. This is a particularly problematic issue in ecotoxicogenomics which requires

substantial species-specific molecular information. However, as mentioned earlier, the number of ecologically relevant species for which this information is becoming available is expanding rapidly, and is likely to accelerate as tools are refined. Moreover, as information grows, genomic approaches hold great promise for identifying appropriate surrogate species for laboratory studies used in basic ecotoxicological research and in support of regulatory ecotoxicology (Benson and Di Giulio, 2006).

Protein Damage   The study of chemical effects on proteins, particularly enzymes, has a long history in toxicology. Of particular interest within ecotoxicology are the inhibitions of acetylcholinesterase (AChE) by certain pesticides and of delta-aminolevulinic acid dehydratase (ALAD) by lead. AChE degrades the neurotransmitter acetylcholine, and in so doing, controls nerve transmission in cholinergic nerve tracts. The widely used organophosphate and carbamate classes of insecticides kill by inhibiting AChE, and this mechanism is operative for "non-target" organisms including invertebrates, wildlife, and humans. (See Chap. 22 for a detailed discussion of these pesticides and AChE inhibition.) Of particular ecological concern have been the ingestions of AChE-inhibiting insecticides with food items or granular formulations (mistaken as seed or grit) by birds and exposures to aquatic animals from agricultural run-off (Mineau, 1991; Carr *et al.*, 1997; Wilson *et al.*, 2001). In many field studies, effects of these insecticides on mortality, and relationships between AChE inhibition and mortality, have been of primary concern. However, relationships between AChE inhibition and important sublethal impacts such as behavior have also been observed (Sandhal *et al.*, 2005). ALAD catalyzes the rate-limiting step of heme synthesis, a key component of cytochromes, hemoglobin, and myoglobin, and ALAD activity is very sensitive to inhibition by lead (ATSDR, 1999). This sensitivity has been exploited widely as a biomarker for lead exposure in humans and wildlife. In wildlife, concerns for lead exposure have included ingestion by birds of spent lead shot used in hunting (Kendall *et al.*, 1996), accumulation of lead by wildlife living near highways (Birdsall *et al.*, 1986), and aquatic organisms inhabiting surface waters contaminated by lead from mine run-off and other industrial activities (Schmitt *et al.*, 2005). In addition to enzyme inhibition, chemicals can damage proteins in other ways, including oxidative damage as described below, and by forming stable adducts similar to those formed with DNA, also discussed below.

Oxidative Stress   The classic depiction of aerobic respiration shows molecular oxygen (O_2) as the terminal electron acceptor, with its reduction resulting ultimately in water as high-energy intermediates (NADH, $FADH_2$) are oxidized and cellular energy is captured as ATP. This reduction of O_2 to H_2O requires four electrons that are sequentially added; this process is tightly coupled so that the one, two, and three electron intermediates are released at low amounts (less than 0.1% of O_2 inspired; Fridovich, 2004). These intermediates are, in sequence, the superoxide anion radical (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($\cdot$OH). This tight coupling is fortunate because these intermediates, produced during aerobic respiration and other O_2 consuming or producing processes (such as photosynthesis and CYP-mediated biotransformations) are potentially deleterious products that can indiscriminately damage cellular components; hence they are referred to as "reactive oxygen species" (ROS). Some ROS, including O_2^- and $\cdot$OH, are free radicals, i.e., they possess an unpaired electron; among ROS, $\cdot$OH is particularly reactive and toxic. In order to defend themselves from the damag-

ing effects of ROS, all aerobic organisms have evolved complex antioxidant defense systems that include enzymatic and nonenzymatic components (Halliwell and Gutteridge, 1999). Antioxidant enzymes include superoxide dismutases that convert O_2^- to H_2O_2, catalases and peroxidases that detoxify peroxides including H_2O_2, and enzymes involved in the production and maintenance of reduced glutathione (GSH) such as glutamate–cysteine ligase (GCL) and glutathione reductase (GR). Low molecular weight, nonenzymatic antioxidants include vitamins A, C, and E, and GSH.

Oxidative stress has been defined as "a disturbance in the prooxidant-antioxidant balance in favor of the former, leading to potential damage" (Sies and Cadenas, 1985)—i.e., the point at which the production of ROS exceeds the capacity of antioxidants to prevent damage. Numerous environmental contaminants can act as prooxidants and enhance the production of ROS. The resulting oxidative damage can account wholly or partially for toxicity (Halliwell and Gutteridge, 1999). Mechanisms by which chemicals can enhance ROS production include redox cycling, interactions with electron transport chains (notably in mitochondria, microsomes, or chloroplasts), and photosensitization.

Redox cycling is perhaps the most common mechanism by which a diverse array of chemicals including many environmental pollutants generates intracellular ROS. Redox cycling chemicals include diphenols and quinones, nitroaromatics and azo compounds, aromatic hydroxylamines, bipyridyliums, and certain metal chelates, particularly of copper and iron (Di Giulio *et al.*, 1989; Halliwell and Gutteridge, 1999). These include compounds of broad industrial use, many pesticides, ubiquitous elements, and metabolic products of numerous pollutants. In the redox cycle, the parent compound accepts an electron from a reduced cofactor, such as NADH or NADPH; this reaction is typically catalyzed by a reductase such as xanthine oxidase or cytochrome P450 reductase (Kappus, 1986). In the presence of O_2, the unpaired electron of the radical metabolite is donated to O_2, yielding O_2^- and regenerating the parent compound; importantly, the parent compound can repeat this cycle until it is cleared or metabolized to an inactive product. In the course of each redox cycle, two potentially deleterious events occur—a high-energy reducing equivalent is expended (the oxidation of NADPH to $NADP^+$, for example), and an oxygen radical is produced. A generalized redox cycle that includes associations with cellular toxicities and antioxidant defenses comprises Fig. 29-8.

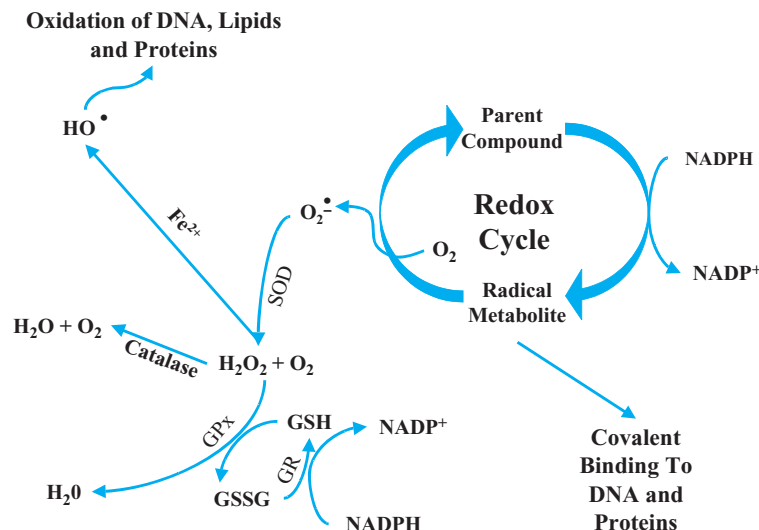
Additionally, pHAH AHR ligands such as coplanar PCBs and TCDD can enhance ROS production, possibly by inducing CYP1A activity and concomitantly interfering with electron flow mediated by these enzymes (Schlezinger and Stegeman, 2001). Polycyclic aromatic hydrocarbons can also upregulate CYP1A and can enhance the production of ROS-generating redox-active quinone metabolites, in contrast to uncoupling mechanisms proposed for pHAHs; Nebert *et al.* (2000) discuss potential mechanisms by which AHR agonists can produce oxidative stress. The herbicide paraquat is phytotoxic due to interference with chloroplast electron transport. Interestingly, it is a very potent lung toxicant because of its specific uptake by this tissue and subsequent redox cycling (Halliwell and Gutteridge, 1999). Another important mechanism particularly significant in aquatic systems is photosensitization. Ultraviolet (UV) radiation (specifically UVB and UVA) radiation can penetrate surface waters to depths dependent on the wavelength of the radiation and the clarity of the water. The ultraviolet radiation generates ROS and other free radicals either via excitation of photosensitizing chemicals, including common pollutants of aquatic systems (Larson and Weber, 1994). For example, due to photosensitization, many


Figure 29-8. Overview of oxidative stress, including reactive oxygen species stimulation initially by redox cycling, key antioxidant defenses, and potential deleterious biochemical effects.

"Parent compound" in redox cycle could include a number of chemicals such as quinones, nitroaromatics, azo dyes, paraquat and diquat, and transition metal chelates.

PAHs are orders of magnitude more acutely toxic to aquatic organisms in the presence of UV radiation than in its absence (Arfsten *et al.*, 1996; Ankley *et al.*, 1997). The ecological relevance of photosensitization, however, is controversial (McDonald and Chapman, 2002).

As noted, ROS are generally indiscriminant molecules and can potentially damage any cellular component. Well-characterized biochemical impacts of ROS include oxidations of unsaturated lipid components of membranes ("lipid peroxidation"), oxidations of amino acids and proteins (resulting in, for example, the addition of carbonyl groups), and DNA oxidations resulting in products such as 8-hydroxy-guanosine and thyme glycol (Halliwell and Gutteridge, 1999). Another important impact is perturbed redox status (Schafer and Buettner, 2001). Healthy cells typically maintain high ratios of cofactors in their reduced, high-energy state relative to their oxidized state (e.g., $NADH/NAD^+$, $NADPH/NADP^+$, and GSH/GSSG), as the reduced forms are those most employed for energy production, biosynthesis, and antioxidant defense, for example. The ROS can drive redox status to a more oxidized state by several direct and indirect mechanisms, potentially reducing cell viability. These ROS-mediated impacts and others have been associated with a number of human diseases including atherosclerosis, arthritis, cancer, and neurodegenerative diseases such as Alzheimer's disease, Parkinson's disease, and amyotrophic lateral sclerosis (Halliwell and Gutteridge, 1999). With the exception of cancer (see below), the role of ROS in specific diseases in wildlife has received little attention. However, numerous studies have documented oxidative stress-mediated biochemical and cellular effects in wildlife associated with environmental contamination (Bainy *et al.*, 1996; Livingstone, 2001; van der Oost, 2003; Dorval *et al.*, 2005). As with humans and various animal models for human disease, it is reasonable to assume that oxidative stress comprises an important mechanism accounting in part for the toxicity of diverse pollutants to free-living organisms. Also, oxidative stress is involved in the effects of air pollutants on plants and likely plays a role in forest die-backs observed downwind

of industrialized areas (Richardson *et al.*, 1989; Hippeli and Elstner, 1996).

DNA Damage The importance of DNA as a molecular target in toxicology is indicated by the devotion of Chapter 9 of this text to genetic toxicology. As indicated, perhaps the most pressing human health issue associated with xenobiotic–DNA interactions is cancer. Cancer is also an important health outcome associated with chemical exposures in wildlife, particularly for bottom-dwelling fishes, as discussed under section "Cancer" below. Of greater concern in ecotoxicology versus human health are other, multi-generational effects of pollutants on genetic structures and resulting phenotypes of populations and communities, through both direct effects on DNA (mutations) and indirect effects (selection); this topic is discussed under **Population** effects below.

Chemical contaminants can damage DNA through several mechanisms, including the formation of DNA–xenobiotic adducts, by causing strand breaks, and by oxidations of DNA bases. In the context of ecotoxicology, the most widely studied form of damage has been the formation of stable DNA adducts, particularly by PAHs. In order to form these adducts, PAHs must first be activated to reactive metabolites by enzyme systems such as the cytochrome P450s. The bulk of PAHs metabolized to various oxidized products (such as phenols, diols, and epoxides) is subsequently conjugated by phase II enzymes (such as glutathione, sulfate, and glucuronosyl transferases; see Chapter 6); however, some fraction can react with DNA, mainly through covalent bonding with DNA bases. The most studied example of this is benzo(*a*)pyrene (BaP) which can be metabolized to the highly reactive benzo(*a*)pyrene diol epoxide (BPDE) that can bond to DNA. In field studies, the resulting large adducts of DNA with BPDE and other activated PAHs and related compounds can be measured with the highly sensitive ^{32}P-postlabeling assay (Phillips, 1997). This technique has been used extensively to monitor DNA adducts in benthic fish and

bivalves inhabiting systems contaminated with hydrocarbons, particularly PAHs (Maccubbin, 1994; Reichert *et al.*, 1998; Shugart, 2000; Amat *et al.*, 2004). Other forms of DNA damage that have been investigated in ecotoxicological studies include DNA strand breaks and oxidized DNA bases (Shugart, 2000; Malins *et al.*, 2006).

Once DNA damage has occurred, whether from chemical exposures or other causes (respiration, UV radiation, viral interactions, normal wear and tear), several subsequent outcomes can occur, including: the damage can be properly repaired, the damage can lead to cell death, or a resulting change in DNA structure (base sequence) can become fixed and passed on to daughter cells, i.e., mutation occurs. Complex DNA repair systems have been elucidated in prokaryotic and eukaryotic organisms (see Chapters 8 and 9), and while these systems have received relatively little attention in species of ecological relevance, it is a safe assumption that these conserved systems are qualitatively similar across diverse phyla. Overall, these systems exhibit a remarkable capacity for surveying the cellular genome, detecting damage such as oxidations, adducts, and strand breaks, and repairing the damage by, for example, removing a damaged base and replacing it with the correct base. However, misrepair does sometime occur, with the result that an incorrect base is incorporated. Depending on the gene involved and the site within the gene, this change may lead to cell death, or may result in a mutation that may have no effect (occurs at noncritical base sequence) or one that leads to functional change in the protein coded by the gene. Some chemicals cause cancer by mutating genes that play pivotal roles in cellular growth and differentiation, particularly oncogenes and tumor suppressor genes. Examples of discoveries of activated genes (in liver tumors) in field studies include the *K-ras* oncogene in tomcod (*Microgadus tomcod*) from the Hudson River, NY (Wirgin *et al.*, 1989) and in winter flounder (*Pseudopleuronectes americanus*) collected from Boston Harbor (McMahon *et al.*, 1990), and the retinoblastoma (*Rb*) tumor suppressor gene in the marine flatfish, dab (*Limanda limanda*) from the UK (du Corbier *et al.*, 2005).

Cellular, Tissue, and Organ Effects

Cells   Cellular organelles that have received attention as targets in species of ecological interest include mitochondria, lysosomes, and nuclei. Most free-living organisms routinely experience energy deficits. For example, food resources are often highly depleted during the winter for many animals, which adapt by conserving energy (by hibernating or lowering metabolism) or by storing energy beforehand (as the case for many migratory birds). Thus, effects of pollutants on mitochondrial energy metabolism can be of particular importance to wildlife. For example, Sokolova and coworkers (Sokolova, 2004; Cherkasov *et al.*, 2006) have elegantly described the effects of cadmium on several aspects of mitochondrial function in isolated gill and hepatopancreas cells from the eastern oyster (*Crassostrea virginica*), and noted a marked synergy between the metal and increasing environmental temperatures. Lysosomes are involved in the degradation of damaged organelles and proteins, and also sequester a wide variety of environmental contaminants, including metals, PAHs, and nanoparticles (Moore *et al.*, 2005). The accumulation of xenobiotics by lysosomes can elicit membrane damage, or "membrane instability," that has been used as an early warning measure of pathological chemical effects in both invertebrates and vertebrates (Hwang *et al.*, 2002; Kohler *et al.*, 2002; Moore *et al.*, 2006).

In addition to specific damage to DNA bases described above, chemical effects on nuclei have been examined in ecological

contexts with additional techniques. Micronuclei are chromosomal fragments that are not incorporated into the nucleus at cell division, and chemical exposures can markedly increase their frequency. Elevated micronuclei numbers have been observed, for example, in fish erythrocytes from polluted coastal sites in California (Hose *et al.*, 1987) and in hemocytes in clams from a PCB-polluted harbor in Massachusetts (Dopp *et al.*, 1996). Also, a standardized higher plant (*Tradescantia*) assay for micronuclei has been used for monitoring air pollution (Solenska *et al.*, 2006). A cell-based assay that has been used widely in environmental applications is the Comet assay. In this assay, cells are imbedded in agarose, lysed and subjected to gel electrophoresis, and the features of the resulting "comets tail" on the gel used to assess DNA damage. With appropriate manipulations, the comet assay can be employed to detect and distinguish among a variety of genotoxicities including strand breaks, oxidative damage, and adducts (Moller, 2006). It has been used in a variety of field applications, particularly with bivalves (Steinert, 1996; Nigro *et al.*, 2006), fish (Heuser *et al.*, 2004), and mice (Husby and McBee, 1999).

Histopathology   The detailed microscopic analysis of the structure of cells and tissues can provide important links among chemical exposures, cellular targets and mechanisms, and effects at the organismal level (Hinton, 1994). Moreover, the determination that tissue damage has occurred as demonstrated by histopathological analysis is extremely useful for inferring that a significant deleterious effect has occurred. However, the substantial expertise required for proper histopathological analyses of this nature and the oftentimes time- and labor-intensive nature of these analyses has perhaps limited the application of this powerful approach in ecotoxicological contexts. Nevertheless, histopathological analysis has played an important role in confirming chemically mediated tissue damage in numerous laboratory and field studies. For example, Pacheco and Santos (2002) integrated histopathological analysis with biochemical studies of the effects of various environmental contaminants on the European eel (*Anguilla anguilla*), and Devlin (2006) similarly incorporated this approach in studies of the effects of methylmercury in fathead minnows (*Pimephales promelas*). Handy *et al.* (2002) relied upon histopathology in a study of fish health in rivers in southern England. Wester *et al.* (2002) reviewed the application and potential contributions of histopathology in aquatic toxicology, particularly in the context of small fish models. In subsequent sections concerning organismal-level impacts, other examples of the use of histopathology will be provided.

Target Organs   Descriptions of chemical impacts on all organ systems of the myriad species relevant to ecotoxicology are beyond the scope of this chapter. Other chapters in this volume address key target organs in the mammalian context, and much of this is relevant to other vertebrates. Target organ toxicology is also the subject of comprehensive reviews by Schlenk and Benson (2001) concerning marine and freshwater fishes, and by Gardner and Oberdorster (2005) concerning reptiles. Relevant information in marine mammals was reviewed in Vos *et al.* (2002). We are unaware of similar reviews for birds or invertebrates. The unique properties of the avian respiratory system and its utility for investigating respiratory system toxicity and air pollution were reviewed by Brown *et al.* (1997).

Another important target organ in ecotoxicology that is not covered elsewhere in this text is the respiratory organ of nonmammalian aquatic vertebrates and many invertebrates, the gill; gills of

fishes have received the most attention as targets of toxicants. The gill epithelium is the major site of gas exchange, ionic regulation, acid–base balance, and nitrogenous waste excretions for fishes and other aquatic animals (Evans, 1987). Gills are immersed in a major exposure medium for these animals (surface water) so metabolically active epithelial cells are in direct contact with this medium. They also receive blood supply directly from the heart, through the ventral aorta. Thus, it is not surprising that gills comprise a very important target for many environmental pollutants, due to their critical physiological functions, central position in blood circulation pathways, and intimate relationship with the environment. The basic structure of fish gills is comprised by branchial arches from which extend numerous filaments; from the filaments extend the lamellae (Wendelaar Bonga and Lock, in press). The lamellae are covered by a layer of epithelial cells that function in gas exchange, whereas the filament epithelium is dominated by other cell types, including pavement cells, mucous cells, and chloride cells; chloride cells are the primary location for ATPase activity and ion channels involved in ion transport.

Common structural lesions in gills caused by a diverse array of chemicals include cell death (via necrosis and apoptosis), rupture of the epithelium, hyperplasia and hypotrophy of various cell populations that can lead to lamellar fusion, epithelial swelling, and lifting of the respiratory epithelium from the underlying tissue (Wendelaar Bonga and Lock, in press). Chloride cells have received particular attention due to their key role in ionic homeostasis. For example, metals such as cadmium, copper, lead, silver, and zinc have been shown to interfere with their function in ion transport. In some cases, this may be due to inhibition of ATPase activities and/or increased membrane permeability (Spry and Wood, 1985; Wendelaar Bonga and Lock, 1992; Li *et al*., 1998; Rogers *et al*., 2003; Bury, 2005). The stress response, which results in elevated blood concentrations of epinephrine and cortisol, and associated responses such as increased cardiac output and elevated blood pressure, can also perturb ionic balance by promoting passive loss of ions such as Na^+ and Cl^- (McDonald and Milligan, 1997). A variety of contaminants have been shown to evoke the stress response in fish, sometimes concomitantly with perturbations in ionic balance (Hontela, 1997; Webb and Wood, 1998; Chowdhury *et al*., 2004). Also, gill damage appears to be the primary cause of the acute toxicity of PAH-mediated phototoxicity in fish (see section "Oxidative Stress", above). Weinstein *et al*. (1997) reported histopathological impacts of UV + fluoranthene in gills of fathead minnows including severe damage to mucosal cells, inflammation, and apparent accumulation of lipid peroxidation products; these effects likely resulted in respiratory stress, and lethality. This study elegantly demonstrates a progression from biochemical mechanism (oxidative stress) to target organ damage (gill respiration) to an important organismal impact (death). Mortality and important sublethal organismal impacts that have received substantial attention among ecotoxicologists comprise the following section.

Organismal Effects

Mortality In similarity with impacts on human health, chemical pollution of the environment does not in most cases attain levels sufficient to outright kill wildlife. Concern in the ecotoxicological context is overall more for long-term, chronic impacts on organismal variables such as reproduction and development, behavior, and disease susceptibility, and how such impacts parlay into impacts at population and higher levels of organization. However, numerous cases of wildlife mortalities (particularly birds) due to exposures to chemical pollution have been observed, including cases associated with chronic oil discharges (Wiese and Robertson, 2004) and major oil releases from events such as the Exxon Valdez tanker wreck in Alaska (Peterson *et al*., 2003) and the 1991 Gulf War (Evans *et al*., 1993), lead from spent shot (Clark and Scheuhammer, 2003) and mines (Henny, 2003), and pesticide exposures (Mineau *et al*., 1999). While not a direct toxic chemical effect, hypoxia can be an important cause of fish and invertebrate mortality in aquatic systems; anthropogenic inputs of nutrients associated with sewage or fertilizers that enhance the growth of phytoplankton can cause or exacerbate hypoxia (Paerl *et al*., 1998; Wu, 1999). While direct mortality may not be a commonplace effect of toxic chemicals in natural systems, mortality comprises a major endpoint in toxicity testing, discussed later.

Reproduction and Development Impacts on reproduction and development comprise perhaps the greatest concern among potential sublethal effects of xenobiotics on animals inhabiting natural systems. This is due to sensitivities of the physiological processes involved that have been described for a number of pollutants, and the importance of reproduction and development to population dynamics, a key ecological concern. Moreover, the discovery of the effects of some organochlorine insecticides on avian reproduction (particularly eggshell thinning) and resulting population crashes of several predatory bird species, and the public's awareness through the publication of Rachel Carson's Silent Spring in 1962, can be associated with the birth of ecotoxicology. Concern for reproductive and developmental effects has blossomed in recent years, with the widespread detection of endocrine disruptors in the environment.

A variety of environmental contaminants have been associated with reproductive and/or developmental effects in wildlife populations, with this association supported by controlled laboratory studies. Chlorinated hydrocarbons have continued to generate concerns although many (DDT and other insecticides, and PCBs) have had their production and use sharply curtailed. For example, DDT, its major metabolite in birds (DDE), and PCBs have been associated with reproductive and developmental impacts in bird populations in the Great Lakes, southern California, the Puget Sound and the Arctic (Fry, 1995; Custer *et al*., 1999; Bustnes *et al*., 2005). Also, alligators (*Alligator mississippiensis*) inhabiting a DDT-polluted lake in Florida have exhibited reproductive and developmental perturbations (Guillette *et al*., 2000). Evidence also indicates that PCBs impact marine mammal reproduction, including that of bottlenose dolphins (*Tursiops truncates*) (Schwacke *et al*., 2002; Wells *et al*., 2005).

Deleterious impacts on fish reproduction have been associated with environmental exposures to a number of contaminants. Case studies include PAHs (and other chemicals) accumulated in sediments in urban areas and harbors in the Puget Sound (Johnson *et al*., 1993) and northeastern United States (Johnson *et al*., 1994) or associated with oil spills such as the Exxon Valdez (Sol *et al*., 2000). Other examples include effluents from bleached paper mills in various locations, including Canada (Munkittrick *et al*., 1991), and selenium, for example, emanating from coal-fired power plant fly ash stored near freshwater lakes (Lemly, 2002) or in streams due to coal mine run-off (Holm *et al*., 2005). Notably, selenium produced severe developmental effects in water birds feeding in a created wetland in central California (Kesterson National Wildlife Refuge) that concentrated naturally occurring selenium (Ohlendorf, 2002). Additionally, severe developmental anomalies have also been observed

in natural populations of marine gastropods exposed to tributyltin (TBT), which has been used extensively as an anti-fouling paint on ship hulls (Ruiz *et al*., 2005).

The developmental effects of dioxins (TCDD) and coplanar PCBs on vertebrate development have received substantial attention. To some extent, this work was motivated by analyses that indicated that these compounds were responsible for population crashes of Great Lakes' fisheries (particularly lake trout, *Salvelinus namaycush*, in Lake Ontario) in the 1950s and 1960s, as well as for developmental impacts on other wildlife, particularly piscivorous birds and mammals in the region (Gilbertson *et al*., 1991; Cook *et al*., 2003). Laboratory investigations, largely with fish and bird models, have shown that embryo development is very sensitive to these compounds, and such effects likely underlaid the population crashes (Fairbrother *et al*., 1999; Cook *et al*., 2003). These investigations have included elegant mechanistic studies that revealed cardiac development was particularly sensitive to these chemicals, and concluded that developmental perturbations are largely receptor mediated, that is, they are dependent upon binding of the chemical (such as TCDD) with the aryl hydrocarbon receptor (AHR) described above (Hankinson, 1995; Heid *et al*., 2001; Tanguay *et al*., 2003; Antkiewicz *et al*., 2005). Much of the more recent work in this area has been done with zebrafish (*Danio rerio*), a powerful model for molecular and developmental toxicology due to ease of visually examining development through a clear chorion, rapid development (~4 days from fertilization to hatch), and abundant genetic information, including gene sequences (Carney *et al*., 2006). For example, with a known gene sequence, one can design morpholinos to block translation of specific mRNAs; morpholinos are oligonucleotides with a modified "backbone" that renders them stable (resistant to DNA/RNA-ase activities) and thus able to transiently block translation of specific protein targets. Carney *et al*. (2004) employed morpholinos to knock down AHR translation in zebrafish embryos, which greatly reduced the developmental toxicity of TCDD, confirming the role of the AHR in dioxin toxicity. Morpholinos were also employed to investigate the role of CYP1A; for example, its upregulation via TCDD activation of the AHR could enhance oxidative stress. Teraoka *et al*. (2003) observed marked reductions of TCDD toxicity with either AHR or CYP1A morpholinos, while Carney *et al*. (2004) observed protection with the AHR but not the CYP1A morpholino. While the role of CYP1A in dioxin effects on development remain unclear, pathways downstream of the AHR other than CYP1A are likely involved.

Similar concerns have emerged for the developmental effects of PAHs, particularly in fish. Hydrocarbons, in large part PAHs, associated with oil spills, contaminated sediments, paper mill effluents, and creosote used for wood treatment have profound developmental effects in fish embryos (Billiard *et al*., 1999; Carls *et al*., 1999; Meyer *et al*., 2002). In many cases, the effects observed visually appear similar to those observed in fish embryos exposed to dioxins and co-planar PCBs, and include malformed hearts ("tube heart"), craniofacial deformities, hemorrhaging, and edema of the pericardium and yolk sac, the latter resulting in a distended, faintly blue yolk sac and hence a name given this syndrome—"blue sac disease" (Spitsbergen *et al*., 1991). The mechanisms by which PAHs produce this effect are unresolved, and likely include more than a single mechanism—not surprising in light of the myriad of chemicals comprising hydrocarbon/PAH mixtures in the environment. In some cases, effects appear to be AHR-independent. Incardona *et al*. (2005) concluded in studies with zebrafish and employing morpholinos, that in weathered crude oil, tricyclic PAHs (such as phenanthrene

and dibenzothiophene—DBT, the latter a sulfur-substituted PAH) accounted for the bulk of cardiovascular teratogenesis, and rather than mediating toxicity, the AHR-CYP1A pathway afforded some protection. Wassenberg and Di Giulio (2004a) and Wassenberg *et al*. (2005) observed marked synergies in the developmental toxicity to killifish (*Fundulus heteroclitus*) embryos between higher molecular weight PAHs that are AHR agonists (BaP and BNF) and PAHs that inhibit CYP1A (α-naphthoflavone—ANF, fluoranthene, DBT, and carbazole—a nitrogen-substituted PAH). Also, ANF enhanced the toxicity of a water-based extract of sediments contaminated with weathered creosote (Wassenberg and Di Giulio, 2004b). In subsequent studies with zebrafish embryos investigating the synergistic toxicity of BNF and ANF, the AHR morpholino provided protection, while the CYP1A morpholino enhanced toxicity (Billiard *et al*., 2006). Collectively, these PAH studies suggest that in the context of embryo toxicity, CYP1A plays a protective role, presumably by mediating metabolism and clearance of these metabolically labile compounds. This is in contrast to the metabolism-resistant dioxin-like compounds, where CYP1A appears to either play a role in mediating toxicity, or has no effect. For some PAHs, such as lower molecular weight (tricyclic) PAHs that have little or no activity as AHR ligands, developmental toxicity appears AHR-independent, while the developmental toxicity of some higher molecular weight PAHs that are AHR agonists appears in part AHR-mediated. In addition, oxidative stress may play a role in the developmental toxicity of some PAHs to fish embryos (Bauder *et al*., 2005). Polycyclic aromatic hydrocarbons comprise a ubiquitous class of contaminants that appear to be generally increasing in the environment, reflecting urbanization, population growth, and use of fossil fuels (Van Metre and Mahler, 2005).

Contaminant effects on development are often difficult to discern in field studies, due to the small size of embryos and the fact that developmental impacts are generally either lethal or greatly reduced survival. However, early life stages of most organisms are generally more sensitive to xenobiotics than other life stages; thus developmental impacts merit careful attention by ecotoxicologists.

Disease Susceptibility   Disease plays an important role in regulating and sometimes seriously impacting populations of free-living organisms. Of great concern are interactions between disease organisms and environmental contaminants, particularly potential impacts of chemicals on immune systems that render organisms more susceptible to disease. The question is often raised about how chemical pollution elevates the role of disease in population viability and dynamics.

Both field observational and laboratory experimental studies motivate this concern. For example, forensic evidence suggested that pHAHs such as dioxins and PCBs may have played a role in mass mortalities of seals and other marine mammals in the Baltic Sea that were directly attributed to viral infections (Ross *et al*., 1996). Captive harbor seals (*Phoca vitulina*) fed fish from the Baltic Sea displayed a number of immune system deficits relative to seals fed fish from uncontaminated Atlantic Ocean sites, including impaired natural killer (NK) cell activity, in vitro T-lymphocyte function, antigen-specific in vitro lymphocyte proliferative responses, and in vivo delayed-type hypersensitivity and antibody responses to ovalbumin. These effects were correlated with greater concentrations of TCDD equivalents in fish from the Baltic Sea. In a case-control study using long-term data from studies of marine mammal strandings in the UK, Hall *et al*. (2006) concluded that each 1 mg/kg

increase in total PCB concentrations in blubber resulted in an average increase in mortality due to infectious disease of 2% in harbor porpoises (*Phocoena phocoena*). In a study of free-ranging loggerhead sea turtles (*Caretta caretta*) collected in North Carolina, Keller *et al.* (2006) observed significant correlations between selected immune responses (lysozyme activity and lymphocyte proliferation) and concentrations of PCBs and chlorinated insecticides (DDE and chlordanes); these correlations were supported by in vitro studies with these chemicals in isolated turtle leukocytes. Similarly, Auffret *et al.* (2006) observed responses associated with immunosuppression in mussels (*Mytilus galloprovincialis*) that generally tracked chemical pollution gradients in the western Mediterranean Sea. Using available laboratory and field data, Loge *et al.* (2005) developed a model to assess the effects of environmental stressors, including chemicals, on disease susceptibility in migrant juvenile salmon in the Columbia River Basin, Washington. They concluded that chemical and nonchemical stressors contributed equally to disease-induced mortalities that were predicted to range from 3% to 18% of the population, depending on residence time.

Numerous laboratory studies have demonstrated chemical impacts on immune systems in animals of ecological relevance. These include effects of pesticides in amphibians (Christen *et al.*, 2004), PCBs in channel catfish (*Ictalurus punctatus*) (Rice and Schlenk, 1995), heavy metals in rainbow trout (Sanchez-Dardon *et al.*, 1999), PAHs in bivalves (Wootten *et al.*, 2003), and flame retardants (polybrominated diphenyl ethers, PBDEs) in American kestrels (*Falco sparverius*) (Fernie *et al.*, 2005). Fairbrother *et al.* (2004) reviewed the literature concerning effects of chemicals on immune systems of birds, emphasizing potential impacts on wildlife species, and Zelikoff *et al.* (2002) performed a similar review for fish. The potential effects of chemicals on immune function and disease susceptibility in wildlife is clearly a very important subject in ecotoxicology and one likely to see significant advances in the near future as powerful genomic tools become more available for representative species.

Behavior   The impacts of chemicals on animal behavior have received significant attention among ecotoxicologists. Relatively subtle effects on behaviors associated with, for example, mating and reproduction, foraging, predator–prey interactions, preference/avoidance of contaminated areas, and migration have potentially important ramifications for population dynamics. However, difficulties in objective quantifications of behaviors and laboratory to field extrapolations appear to have limited the application of this area to ecological risk assessments, and by extension, perhaps to funds available for basic research. In some cases, however, biochemical mechanisms underlying behavioral effects have been elucidated that may assist with these issues and provide useful biomarkers for behavioral toxicants in field studies.

As noted by Rand (1985), chemicals causing behavioral effects in wildlife are often known from mammalian studies to be neurotoxicants. For example, in an early study, Grue *et al.* (1982) noted reduced nest attentiveness in female starlings dosed with the AChE-inhibiting organophosphate insecticide dicrotophos; this study took advantage of the relative ease of attracting wild starlings to artificial nest boxes that is advantageous for detailed studies, a phenomenon that has been employed in subsequent avian ecotoxicological studies (Parker and Goldstein, 2000). Grue *et al.* (1997) and Walker (2003) reviewed the behavioral effects in birds of these and other neurotoxic insecticides.

Behavioral effects of insecticides have also been observed in fish. For example, Scholz *et al.* (2000) reported adverse impacts of the organophosphate diazinon on olfactory mediated behaviors such as the alarm response and homing in the Chinook salmon (*Oncorhynchus tshawytscha*), and Sandhal *et al.* (2005) observed similar thresholds for the effects of another organophosphate (chlorpyrifos) on swimming and feeding behaviors and on AChE inhibition in coho salmon (*O. kistich*). The effects of pollutants, including pesticides, on fish behavior were reviewed by Scott and Sloman (2004).

Mercury, particularly as methylmercury, comprises another potent neurotoxin that has been shown to perturb behavior in wildlife. For example, golden shiners (*Notemigonus crysoleucas*) fed diets containing methylmercury that resulted in tissue mercury concentrations consistent with those observed in this species in northern U.S. lakes exhibited perturbed predator avoidance behaviors (Webber and Haines, 2003). In a study employing fish captured in the field and brought into the laboratory for behavioral analysis, Smith and Weis (1997) observed that killifish captured from a mercury-polluted tidal creek in New Jersey exhibited reduced feeding activity and greater mortality due to predation than killifish from an uncontaminated site. Using mercury concentrations in feathers as a marker for exposure, Heath and Frederick (2005) observed a negative correlation between mercury exposure and nesting activity among White Ibises (*Eudocimus albus*) in the Florida Everglades that may be related to behavioral effects. In studies with wild mink (*Mustela vision*) collected in Canada, Basu *et al.* (2005) observed significant correlations between mercury concentrations in brains and densities of neurochemical receptors (cholinergic and dopaminergic) associated with animal behavior. The effects of mercury on wildlife, including behavioral impacts, were reviewed by Wolfe *et al.* (1998).

Environmental contaminants not generally thought of as neurotoxicants have also been shown to perturb behavior. For example, cadmium and copper have been shown to impact olfactory neurons and associated behaviors (preference/avoidance to chemicals, including pheromones) in several fish species (Saucier *et al.*, 1991; Baker and Montgomery, 2001; Baldwin *et al.*, 2003). Copper exposure in zebrafish also led to loss of neurons in the peripheral mechanosensory system ("lateral line"), which could lead to altered behaviors associated with schooling, predator avoidance, and rheotaxis (physical alignment of fish in a current) (Linbo *et al.*, 2006). Carvalho and Tillitt (2004) reported loss of retinal ganglion cells in rainbow trout exposed to TCDD; these cells link the eye with the brain, and in this study deficits in visual acuity and prey capture rates were noted in TCDD-exposed fish. Clearly, numerous mechanisms of chemical toxicity can result in behavioral impacts, including direct toxicity to neurons, alterations in hormones that modulate behaviors, and impaired energy metabolism. In some cases, impaired behavior may comprise a sublethal impact with substantive ecological consequence (Scott and Sloman, 2004).

Cancer   Beginning in the 1960s, numerous cases of cancer epizootics in wildlife that are associated with chemical pollution, particularly in specific fish populations, have been reported in North America and northern Europe (Harshbarger and Clark; 1990; Vethaak, 1992). As in humans, cancer in these animals occurs largely in relatively older age classes and therefore is oftentimes considered a disease unlikely to directly impact population dynamics or other ecological parameters. However, this may not always be the case, particularly in species that require many years to attain sexual

maturity and/or have low reproductive rates. In any event, the occurrence of high incidences of cancer in wildlife populations raises serious concerns for environmental quality at those locations experiencing these epizootics. For these reasons, as well as for concerns for human health in these areas, and the advantages of alternative models such as fish for understanding chemical carcinogenesis, these epizootics have motivated substantial research in several areas relevant to human health and ecotoxicology.

In field studies of cancer outbreaks in aquatic and marine systems, typically only selected species exhibit elevated cancer rates associated with chemical contamination. A major contributor to this differential cancer susceptibility in wild fish populations is clearly lifestyle; benthic (bottom-dwelling) species such as brown bullhead (*Ameriurus nebulosus*) and white sucker (*Catostomus commersoni*) in freshwater systems, and English sole (*Parophrys vetulus*) and winter flounder (*Pseudopleuronectes americanus*) in marine systems generally exhibit the highest cancer rates in polluted systems (Baumann, 1998). The bulk of chemicals in these systems associated with cancer epizootics, such as PAHs, PCBs, and other halogenated compounds, reside in sediments; benthic fish live in contact with these sediments and prey in large measure on other benthic organisms. Thus benthic fish experience greater exposures to carcinogens than other species in these systems. Inherent biological differences may also play a role in species susceptibilities to chemical carcinogenesis; for example, laboratory studies have revealed marked differences among fish species in their abilities to activate PAH procarcinogens to DNA adduct-forming metabolite as well as to detoxify them through phase II metabolism (Collier *et al*., 1992; Hasspieler *et al*., 1994; Ploch *et al*., 1998).

In their analysis of cancer epizootics in fish, Harshbarger and Clark (1990) concluded that cancers of the liver (hepatocellular neoplasms) had the strongest associations with chemical pollution, although cancers have been observed in other tissues in wild fish as well (Ostrander and Rotchell, 2005). Polycyclic aromatic hydrocarbons appear to be the most implicated class of carcinogens associated with liver neoplasms in fish cancer epizootics. Studies implicating a key role for PAHs (and key PAH sources) include English sole in the Puget Sound (various urban and industrial sources; Malins *et al*., 1987), brown bullhead in the Black River, Ohio (a coal-coking facility; Baumann and Harshbarger, 1998) and in the Potomac River watershed near Washington, DC (various point and nonpoint discharges; Pinkney *et al*., 2001), and killifish in the Elizabeth River, Virginia (a wood treatment plant using creosote; Vogelbein *et al*., 1990). As stated earlier, PAHs appear to comprise a class of contaminant generally increasing in the environment. The metabolism of PAHs such as BaP to reactive metabolites that form DNA adducts that initiates carcinogenesis, or conversely to excretable conjugates, was described earlier. It is noteworthy that the molecular and biochemical pathways underlying chemical carcinogenesis, such as PAH metabolism, DNA damage, and effects on oncogenes, are qualitatively similar between most fish and mammalian species examined.

This recognition of shared pathways has in part contributed to the use of various fish models for studying chemical carcinogenesis from a human health as well as from a broader environmental standpoint. An important historical event was the identification in Italy, France, and the U.S. during the 1950s and 1960s of aflatoxin as a potent liver carcinogen in farm-raised rainbow trout (Sinnhuber *et al*., 1977). Subsequently aflatoxin, a fungal toxin produced by *Aspergillus flavus* that is of concern where grains and nuts are stored in wet conditions, was found to be carcinogenic to mammals including humans. Thus, the rainbow trout observations led to the discovery of a new and important class of chemical carcinogens, and the recognition that fish can be very sensitive to chemical carcinogenesis. Since that time, other fish species have been employed for laboratory studies related to chemical carcinogenesis, particularly medaka (*Oryzias latipes*) and platyfish/swordtails hybrids (*Xiphophorus* spp.); zebrafish also show promise as a laboratory model (Ostrander and Rotchell, 2005). Compared to rodent models, fish models have advantages of reduced costs for propagation and housing, briefer time intervals between exposures and the expression of tissue changes indicative of carcinogenesis, and greater feasibility of performing large-scale studies with many animals to quantify dose–response relationships.

It is noteworthy that the great bulk of reports of elevated cancer rates in free-living animals occur in fish, with few reports of potentially chemically related cancers to our knowledge in other vertebrates. California sea lions (*Zalophus californianus*) stranded along the central California coast were found to have elevated cancer rates (18%), and concentrations of DDT and PCBs were greater in animals with cancer versus those determined to die of other causes (Ylitalo *et al*., 2005). Martineau *et al*. (2002) reported elevated cancer rates (also 18%) in carcasses of beluga whales (*Delphinapterus leucas*) stranded along the shores of the St. Lawrence River estuary in Quebec, a system with elevated levels of PAHs. The authors noted that beluga was the only species of marine mammal among 20 inhabiting this system that exhibited elevated cancer rates, and that cancers are rare worldwide in marine mammals. It is likely that elevated exposures play an important role in the relatively high frequency of reports of cancers in benthic fishes; relative inherent sensitivities among mammals, birds, reptiles, and amphibians, and fishes are unclear.

Population

A population is a collection of individuals of the same species that occupy the same space and within which genetic information can be exchanged. The study of populations is a central theme in ecological sciences and ecotoxicology is no exception. Assessment of toxicant effects upon populations has been important in ecotoxicology since its inception (Newman, 2001). A well-known, early instance is the sharp drop and then slow recovery of coastal populations of osprey (Spitzer *et al*., 1978) and brown pelican (Anderson *et al*., 1975) that occurred as a consequence of widespread DDT and DDE spraying and eventual banning. Another was the enhanced, genetically based tolerance of pest insect populations chronically sprayed with pesticides (Mallet, 1989). Industrial melanism, the premier example in biology textbooks of natural selection in wild populations, is another example of population ecotoxicology (Newman, 2001). Population ecotoxicology covers a wide range of topics with core research themes being (1) epidemiology of chemical-related disease, (2) effects on general population qualities including demographics and persistence, and (3) population genetics.

The level of belief warranted for possible contaminant-related effects in nonhuman populations is assessed by applying routine epidemiological methods. Many methods described in epidemiology textbooks (Anders, 1993; Woodward, 2005) are applied to nonhuman populations although with a slightly different balance because much more experimental exposure data are potentially available for nonhuman populations than for human populations. Rules of thumb for gauging the level of belief warranted by evidence that emerged from human epidemiology are also applied in population

Table 29-1

A Summary of One Popular Set of Rules of Thumb (Data from Fox, 1991) for Assessing Plausibility of a Causal Association in an Ecological Epidemiology

RULE	DESCRIPTION
1. Strength of association	How strong the association is between the possible cause and the effect, e.g., a very large relative risk
2. Consistency of association	How consistently is there an association between the possible cause and the effect, e.g., consistent among several studies with different circumstances
3. Predictive performance	How good is the prediction of effect made from the presence/level of the possible cause
4. Monotonic trend	How consistent is the association between possible cause and effect to a monotonic trend (i.e., either a consistent increase or decrease in effect level/prevalence with an increase in exposure)
5. Inconsistent temporal sequence	The effect, or elevated level of effect, occurs before exposure to the hypothesized cause
6. Factual implausibility	The hypothesized association is implausible given existing knowledge
7. Inconsistency with replication	Very poor reproducibility of association during repeated field assessments encompassing different circumstances or repeated formal laboratory testing

NOTE: According to Fox, the first four rules are most useful in supporting a causal hypothesis if found to be true (i.e., very strong, consistent, predictive, or monotonic association). The others are most useful for lessening belief in the causal hypothesis if true.

ecotoxicology. Hill's nine aspects of human disease association (Hill, 1965) might be used directly or after minor modification. As an example, Fox (1991) (Table 29-1) modified such rules of thumb to accommodate slight differences in the subject matter and approaches in population ecotoxicology. Conventional epidemiological descriptors and models are also applied. For example, Horness *et al*. (1998) quantified prevalence and relative risks for neoplastic liver lesions in English sole inhabiting areas with different sediment concentrations of polycyclic aromatic hydrocarbons. Logistic regression models were also used to identify relationships between these lesions and chemical and biological risk factors (Myers *et al*., 1994).

Defining and predicting alterations in population size, dynamics, and demographic composition due to toxicant exposure has always been central in ecotoxicology and has become increasingly so in the last 15 years as regulatory agencies such as the U.S. Environmental Protection Agency clearly reinforced their long-standing commitment to understanding chemical exposure effects on natural population viability.

Protecting populations is an explicitly stated goal of several Congressional and Agency mandates and regulations. Thus it is important that ecological risk assessment guidelines focus upon protection and management at the population, community, and ecosystem levels . . .

EPA (1991)

Ecological theory and research (e.g., Forbes and Calow, 1999) also indicate that metrics of effect to individuals are not especially good metrics of toxicant exposure effects to populations.

Models of exposed population dynamics suggest that reductions on population densities are not the only important changes brought about by chemical exposure. Some species populations fluctuate within a range of densities. These fluctuations are characteristic of the species strategy for maintaining itself in various types of habitats and toxicant exposure could potentially change this range (Simkiss *et al*., 1993). Combined with decreases in population densities driven by external forces such as weather events, these toxicant-induced modifications of the average population densities and dynamics can increase the risk of a population's

density falling so low that local extinction occurs (Newman, 1995).

Demographic qualities can change with toxicant exposure in ways that influence the risk of local population extinction. Toxicants can change a species population's vital rates, i.e., age- and sex-dependent death, birth, maturation, and migration rates, in complex ways. These changes in combination determine the population density and distribution of individuals among ages and sexes during exposure. The population's ability to resist external forces that reduce its size is determined by these demographic features (Gard, 1992; Sherratt *et al*., 1999; Kammenga and Lawkowski, 2000; Aubone, 2004). Consequently, considerable research effort is being spent on demographic methods for predicting exposed population changes and risks of extinction.

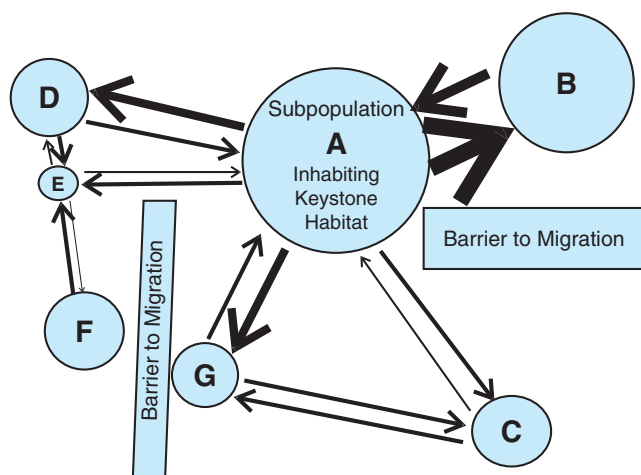
Demography explores vital rates of populations composed of individuals that differ in age and sex. Individuals in field populations can also differ in their spatial distribution and this influences the impact of toxicants (Newman, 2001). Individuals of the same species often are grouped into subpopulations within a habitat and all of these subpopulations together comprise a metapopulation (Fig. 29-9). Subpopulations in the metapopulation have different levels of exchange and different vital rates that depend on the nature of their habitat. Spatial distances and obstacles or corridors for migration influence migration among patches: habitat quality determines vital rates. An inferior habitat, such as a grossly contaminated one, can act as a sink into which individuals migrate from nearby superior (source) habitat. Migration can rescue a subpopulation or reduce its risk of local extinction. An individual migrating from the contaminated habitat to an uncontaminated one can express an adverse effect despite its present distance from the contamination, i.e., the action-at-distance hypothesis of ecotoxicology (Spromberg *et al*., 1998). The viability of the metapopulation can also be as strongly influenced by maintaining important migration corridors among subpopulations and protecting high-quality habitats (i.e., keystone habitats) as by the general level of contamination within the metapopulation's habitat (Maurer and Holt, 1996; O'Connor, 1996; Spromberg *et al*., 1998; Newman, 2001).


Figure 29-9. Metapopulations are composed of subpopulations that differ in their vital rates and tendency to exchange individuals.

In this illustration, subpopulation A occupies a keystone habitat. The loss of subpopulation A would devastate the metapopulation. Also, loss of the migration corridor between subpopulations A, B, and D would devastate the metapopulation. In contrast, the loss of subpopulation F would not influence the metapopulation to the same degree.

The genetics of exposed populations are studied to understand changes in tolerance to toxicants and to document toxicant influence on field populations. The capacity of some populations to become more tolerant of toxicants via selection is well documented. A few examples include increased tolerance of pine mice to endrin (Webb and Horsfall, 1967) and rats to warfarin (Partridge, 1979) after years of application of these agents for rodent control. More recently, Ownby *et al.* (2002) documented enhanced tolerance in populations of an estuarine fish chronically exposed to PAHs. Although genetically based increases in tolerance are well documented in wild populations, many exposed populations probably find themselves in situations in which they cannot adapt adequately because of their genetic resources, nature of the toxicant, or spatial/temporal context within which the enhanced tolerance must evolve are inadequate. Also, in an ecotoxicological sense, all cases of increased tolerance do not fit the conventional context manifested in the examples just given. Some do not involve suborganismal changes to biochemical or anatomical features resulting in enhanced tolerance. For example, industrial melanism increases a peppered moth's fitness in the presence of soot by reducing its likelihood of being taken by a predator. The dominant light form of this moth has a lowered fitness in the presence of dark soot, and genetically based changes in color increases its fitness. The selective mechanism here is ecological, i.e., fitness relative to avoiding visual predators.

Genetic qualities are also used to infer past toxicant influence in an exposed population. For example, Mulvey *et al.* (2002, 2003) showed distinct genetic qualities in estuarine fish populations exposed to high concentrations of PAHs. Another piece of evidence demonstrating past toxicant influence on populations can be a change in genetic diversity. A drop in genetic diversity in populations is thought to be an adverse effect because genetic diversity is required in populations to evolutionarily adapt to environmental changes. Toxicants can influence genetic diversity by purely stochastic means. Genes can be lost in the population if the population is so drastically reduced in size that the chance of a rare gene being lost between generations becomes very high. Also, the

average rate at which the frequency of a rare gene decreases through time due to genetic drift increases as the effective population size decreases. The effective population is the number of individuals contributing genes to the next generation so toxicant-related changes in demographic qualities can also accelerate genetic drift.

Community

An ecological community is an interacting assemblage of species populations occupying a defined habitat at a particular time. Populations in a community interact in many ways and, because these many interactions are complex, a community has properties that are not predictable from those of its component populations. Some species have such a crucial role (keystone species) or numerical dominance (dominants) that they are essential to maintaining community structure.[2] Other species contribute to the nature of the community in more subtle ways.

Ambiguity exists about the importance of all the species in a community relative to maintaining overall structure and balancing essential functions such as nutrient cycling, primary productivity, community respiration, and detritus processing. The redundant species hypothesis suggests that species function redundantly: if a species were lost, another with a similar function would increase in numbers to compensate. Only certain critical species such as dominant or keystone species are essential to the community. The rivet popper hypothesis suggests otherwise. Each species in a community is similar to one of the many rivets holding an airplane fuselage together. Each lost rivet contributes to a gradual weakening of the fuselage that will lead eventually to a failure in function. By analogy, each species disappearance diminishes a community's functioning.

Ecotoxicologists remain divided about which hypothesis is most relevant. Pratt and Cairns (1996) argue from evidence and a conservative stance that the rivet popper is the most appropriate. Ecotoxicologists and regulators who pragmatically set standards based on concentrations that will not harm more than a specified percentage of species in a community (e.g., Stephan *et al.*, 1985) assume that the redundant species hypothesis is more pertinent. Although the redundant species hypothesis is assumed to be correct in many ecological risk assessments (Solomon and Sibley, 2002), recent theory (Loreau 2004), modeling (Naeem *et al.*, 1994), and experimental evidence (Tilman, 1996; Tilman *et al.*, 1996; Salminen *et al.*, 2001) seem to support the rivet popper hypothesis. Biodiversity tends to foster community stability and function.

Communities take on characteristic structures as predicted by the Law of Frequencies: the number of individual organisms in a community is related by some function to the number of species in the community (Fig. 29-10). Ecotoxicants[3] can alter the resulting community structure in predictable ways by either directly impact-

---

[2] In its most rudimentary context, community structure refers to the number of species present and the numbers of individuals present in each of these species. It can also refer to the distribution of species among different functional groups such as decomposers, detritivores, primary producers, primary consumers such as herbivores, secondary consumers such as carnivores that consume herbivores, etc.

[3] The conventional context for the term toxicant becomes difficult to retain without some qualification when dealing with populations, communities, and other higher level entities because an agent does not necessarily have to directly interact with the individual in order to harm it. As an example, an agent might eliminate a prey species, leading indirectly to the disappearance of a predator species that depended on it for sustenance. The "toxicant" did not poison the predator yet it caused its demise nonetheless. A distinct term, ecotoxicant, is often applied to avoid confusion in such cases.
Figure 29-10. *Log-normal model of species abundance for an unexposed (solid line and black points) and toxicant-exposed community (dashed line and open points).*

Communities have distinct structure as shown here with the typical log-normal species abundance model. As first described by data from Patrick (1973), ecotoxicants tend to lower the mode of the species abundance curve and stretch the right tail outward. Ecotoxicants result in fewer intermediate abundance species and more extremely abundant species.

ing the fitness of individuals in populations that make up the community or by altering population interactions. Community ecotoxicologists spend considerable effort trying to understand and predict ecotoxicant influences on community structure and essential functions.

Direct effects involve removal of a population or metapopulation from the community by reducing the Darwinian fitness of individuals enough that the population falls below some critical minimum size. Indirect effects can involve interference with interspecies competition, predator–prey interactions, host–disease/parasite interactions, or symbiotic relationships such as pollination. The simplest competition model (Lotka–Volterra Model) can be used to illustrate the potential for both direct and indirect effects on populations:

$$\frac{dN_1}{dt} = r_1 N_1 \left[1 - \frac{N_1}{K_1} - \frac{\alpha_{12} N_2}{K_1} \right]$$

$$\frac{dN_2}{dt} = r_2 N_2 \left[1 - \frac{N_2}{K_2} - \frac{\alpha_{21} N_1}{K_2} \right]$$

where N_1 and N_2 = population size of competitors 1 and 2, K_1 and K_2 = carrying capacities of the environment for competitors 1 and 2, r_1 and r_2 = intrinsic rate of population increase (i.e., birth rate—death rate) for competitors 1 and 2, α_{12} = competition coefficient quantifying the impact of the presence of competitor 2 on competitor 1, and α_{21} = impact of competitor 1 on competitor 2. Not only can exposure directly impact birth rates, death rates, and carrying capacity of each species, it can influence species persistence by shifting competition coefficients in favor of another species. Mathematically, it can be shown that the two competitors depicted in the Lotka-Volterra Model can co-exist only if two conditions are met, $K_1 < K_2/\alpha_{21}$ and $K_2 < K_1/\alpha_{12}$. So, a population can be lost from a community as readily by changing its competitive interactions as by directly changing its death and reproductive rates. Similar statements can be made about changes in predator–prey, host–disease, and various symbiotic interactions. As an example,

concern expressed recently about unintended pesticide reductions in the number and diversity of pollinators in European farmlands (Newman *et al.*, 2006) could be partially responsible for the recently reported decline in insect-pollinated plant species in Britain and The Netherlands (Biesmeijer *et al.*, 2006). In another instance, reduced habitat cover and insect densities in European farmlands has had a significant impact on grey partridge populations (Rands, 1985; Chiverton, 1999). As another and final example involving predator–prey interactions, amphibian tadpole exposure to endosulfan increases the risk of predation by dragonfly larvae (Broomhall, 2002). None of these examples involves a direct poisoning by a toxicant, but instead, involves an ecotoxicant that adversely modifies species interactions.

Structural changes to communities can be detected in species abundance plots (see Fig. 29-10) or shifts in conventional community metrics calculated from community samples taken in the proximity of contaminated sites. Common metrics for species richness, diversity, and evenness are used to express changes in biodiversity. Richness is simply the number of species in the sampled community, or if a relative number of species in different communities is all that is needed, the number of species expected in a specified sample size such as a rarefaction richness estimate of 12 species in a sample of 100 individuals from a community. Evenness is a measure of how equitably the individuals in a community are spread among the species. Finally, diversity (heterogeneity) indices combine the elements of richness and evenness into one number. Generally, but not always, ecotoxicants lower species richness, evenness, and overall diversity. The regulatory premise is that these changes reflect a diminished community.

Recently, structural and functional qualities in communities have been combined to generate multimetric indices such as the Biotic Index of Integrity (IBI) (Karr, 1991). Ecological insight is used to select and then numerically combine community qualities such as species richness, health of individual animals in a sample, and the number of individuals in a sample belonging to a particular functional group, such as number of piscivorous fish. The IBI score for a study site is calculated and compared to that expected for an unimpacted site in order to estimate its biological integrity.

Another central theme in community ecotoxicology is toxicant transfer during trophic interactions. Toxicant concentrations can decrease (biodiminution), remain constant, or increase (biomagnification) with each trophic transfer within a food web. Persistent organic pollutants with moderately high lipid solubility ($5 < \log K_{ow} < 7$ or 8; Thomann, 1989; Connell, 1990) and minimal metabolic breakdown in an organism can biomagnify to harmful concentrations. Metals that biomagnify are mercury and the alkali metals, cesium and rubidium. Zinc, an essential metal that is actively regulated in individuals, can exhibit biomagnification or biominification depending on whether ambient levels are below or above those required by the organism to function properly. Biominification is facilitated in a marine food web after sequestration in intracellular phosphate granules of molluscan prey species (Nott and Nicolaidou, 1993) and biomagnification by active regulation in zinc-deficient terrestrial communities (Beyer, 1986). The biomagnification of mercury is enhanced by its microbial transformation to methylmercury. Biomagnification of the potassium analogs, cesium and rubidium, is facilitated by the differences in their influxes and effluxes that favor retention in organisms (Rowan and Rasmussen, 1994; Campbell *et al.*, 2005).

Quantifying the trophic position of a species in a community is essential to modeling biomagnification. Most trophic systems are
Figure 29-11. Modeling ecotoxicant concentration versus trophic position as quantified with $\delta^{15}N$.

Power models were applied to octachlorodibenzo-*p*-dioxin/dibenzofuran concentrations in a North Baltic food chain (Data from Broman *et al.*, 1992) and the ΣDDT (sum of primarily the *p*, *p'* isomers of DDD, DDE, and DDT) in food webs of Lake Malawi (Data from Kidd *et al.*, 2001). Biomagnification and minification were evident for ΣDDT and octachlorodibenzo-*p*-dioxin/dibenzofuran, respectively.

not simple "food chains." Most individuals in a community can feed on different species depending on their life stage, seasons, and relative abundances of prey species. These trophic interactions are best described as occurring in a trophic web, not a trophic chain.

Conveniently, trophic position of an individual within a complex food web can be quantified with nitrogen isotopes. Generally, ^{14}N passes through biochemical pathways faster than ^{15}N, resulting in excretion of waste with a slightly higher $^{14}N/^{15}N$ ratio than in ingested food. The relative amounts of ^{14}N and ^{15}N will be slightly biased toward the heavy isotope in tissues of a species relative to those of its foodsource(s). This discrimination between the heavy and light N isotopes continues through food webs, allowing the trophic position of each participating species to be estimated. The metric used for this purpose, the $\delta^{15}N$, expresses the quotient of these two isotopes in the biological tissue of interest relative to the quotient expected in the atmosphere.

$$\delta\ ^{15}N = 1000 \left[\frac{[^{15}N_{\text{Tissue}}]/[^{14}N_{\text{Tissue}}]}{[^{15}N_{\text{Air}}][^{14}N_{\text{Air}}]} - 1 \right]$$

The change in toxicant concentrations within food webs is modeled using the $\delta^{15}N$ which quantifies trophic position of the species from which the tissue sample was taken (Fig. 29-11). Linear and exponential models are commonly applied.

$$Concentration = a + b\delta\ ^{15}N$$
$$Concentration = 10^{a+b\delta\ ^{15}N}\quad or \quad e^{a+b\delta\ ^{15}N}$$

Ecosystem to Biosphere

Ecosystems are the functional unit of ecology composed of the ecological community and its abiotic habitat. Systems ecologists try to describe and predict energy and mass cycling in and flow from ecosystems. The ecotoxicologist's interest in ecosystems includes understanding how toxicants diminish an ecosystem's capacity to
Figure 29-12. Examples of scales relevant to assessments of ecotoxicant distributions.

The smallest scale example (top left) is the vertical distribution of α-hexachlorocyclohexane (HCH) in a stratified region of the Sea of Japan (Data from Chernyak *et al.*, 1995). A slightly larger scale is reflected in the change in the polychlorinated biphenyl congener PCB-138 in tissues of fish inhabiting European lakes at different altitudes (top right panel, Data from Fernandez and Gromalt, 2003). Representing a subcontinental scale study is the temporal change in atmospheric α-hexachlorocyclohexane concentrations in temperate and boreal regions of central northern Europe (bottom left panel, Data from Wania *et al.*, 1999). The largest scale encompasses the entire Earth, showing the influence of latitude on hexachlorobenzene (HCB) concentration in tree bark (bottom right panel, Data from Simonich and Hites 1995).

perform essential functions and to understand toxicant movement enough to assess exposure within different ecosystem components.

Many of the effects described above for exposed communities are relevant here. As an example, Allred and Giesy (1988) demonstrated that elevating cadmium concentrations in an artificial stream reduced decomposition rates of dead leaves. Odum (1985) suggested that other changes to be expected with increased ecosystem stress include an increased loss of nutrients, increased community respiration, and an imbalance of primary production and respiration.

Studies of toxicant movement within ecological systems are conducted at extremely different scales (Fig. 29-12). Conventional ecosystem studies involve descriptions of contaminant concentrations and movements in easily defined ecosystems such as lakes, forests, or fields. Some toxicants, especially those subject to wide dispersal by air or water, cannot be completely understood in this framework so a landscape scale might be chosen instead. As an example, acid precipitation might be examined in the context of an entire watershed, mountain range, or even a continental region. As another example (see Fig. 29-12, top right panel), the fish tissue concentrations of a PCB congener and other persistent organic pollutants (POPs) were measured in high mountain region lakes of Europe. Concentrations for several were related to the altitude at which a lake sat. The relationships between altitude and concentrations of the various POPs was interpreted based on atmospheric movement of the POPs and each POP's propensity to either volatilize or condense at a particular altitude-dependent temperature regime. Still other ecotoxicants require a global context in order to

fully understand their movements and accumulation. As an example, hexachlorobenzene concentration in tree bark collected worldwide showed a clear latitudinal gradient. Its global distribution and those of other sampled POPs were a function of their relative volatilities. The volatile hexachlorobenzene moved more readily toward the poles than less volatile POPs such as endosulfan and DDT. The differential global movement of POPs due to differences in volatility and partitioning behavior was called global distillation (Wania and Mackay, 1996). The balance between a POP's tendency to condense or evaporate at different latitude-related temperatures determines its atmospheric mobility and its ultimate global deposition pattern (Wania and Mackay, 1996).

APPROACHES

Many approaches have been developed to detect and quantify contaminant effects. These span the levels of organization described above. Approaches widely applied in ecotoxicology include standardized toxicity tests deigned to meet regulatory needs and biomarkers for organismal exposure and effects. For higher levels, a range of ecological methods exists for population, community, and ecosystem effects. Other techniques such as Geographic Information System (GIS) analysis of impacts allow the ecotoxicologist to assess impact encompassing large spatial scales. These approaches and examples of their applications are described in this section.

Toxicity Tests

Toxicity testing encompassing representative animals and plants at different levels of organization offers a practical approach to characterize chemical effects on biological systems. While it is widely known that toxicity tests cannot mimic the complex interactions and variable conditions of natural ecosystems, they address the potential direct effects of toxic substances on individual ecosystem components in a controlled and reproducible manner. A number of testing guidelines have been put forth by regulatory bodies and organizations worldwide to meet requirements for chemical registration or authorization (OECD, 1981; MAFF, 1985; US EPA OPPTS, 1996a; ASTM International, 2006), with numerous subsequent revisions. Different sets of guidelines apply to specific countries, regions, or products, and can differ significantly in their requirements. The harmonized guidelines put forth by the U.S. EPA Office of Prevention, Pesticides and Toxic Substances (U.S. EPA OPPTS, 1996a) were created in an attempt to lessen variations in testing requirements, and bring together requirements from the Organisation for Economic Co-Operation and Development (OECD), the U.S. EPA Office of Pollution Prevention and Toxics (OPPT) and the Office of Pesticide Programs (OPP).

Ecotoxicology tests feature a wide variety of aquatic (including algae, invertebrates, tadpoles, bivalves, shrimp, fish), avian (quail, duck), and terrestrial species (soil microorganisms, crops, honey bees, earthworms, wild mammals). Species are selected based on their traditional use as laboratory animals, but also on ecological relevance, which further complicates global harmonization of ecological testing. In addition, special considerations apply to testing of aquatic species due to the unmistakable differences in the way aquatic species are exposed to toxicants (U.S. EPA OPPTS, 1996b). For instance, water quality monitoring, investigation of the solubility and stability of the test substance under the conditions of testing, along with determination of nominal versus measured concentrations are common practices in aquatic toxicology. Testing can be conducted in aqueous systems without renewal of the test substance (static), renewal at predetermined time intervals (static-renewal), or continuous flow of test substance through the test compartment (flow-through).

Acute toxicity testing consists of single species exposed to various concentrations of the test substance. The most common endpoint in acute tests is death, although abnormal behavioral or other gross observations are commonly noted, and nonlethal endpoints occasionally apply (e.g., immobilization for daphnids, shell deposition in oysters). Variations in acute toxicity studies comprise testing of different species (such as fresh versus saltwater fish, bobwhite quail versus mallard duck), life-stages (embryo, larva, juvenile), environmental influences (e.g., presence of organic material), or sediment exposures. Data from different test concentrations and time points are used to derive concentration–response curves and predicted values such as the LC_{50} (median lethal concentration), EC_{50} (median effective concentration), or IC_{50} (median inhibition concentration). The LC_{50} represents the concentration of test substance killing 50% of the tested animals and EC_{50} the concentration of test substance affecting 50% of the test population during a specified period of time, such as growth; the IC_{50} is the concentration causing a 50% reduction in a nonquantal measurement (such as movement) for the test population. More quantitative values derived from acute tests are the lowest observed effect concentration (LOEC), i.e., the lowest concentration where an effect is observed, and the no-observed-effect-concentration (NOEC), the highest concentration resulting in no adverse effects.

Short-term laboratory studies conducted with single species are useful for rapid screening, provide information on thresholds for effects, selective and comparative toxicity, and can be used as range finders to guide subsequent, often more involved studies. Long-term and reproductive studies evaluate the effects of substances on organisms over extended periods of time and/or sequential generations (chronic toxicity, life cycle, reproduction). Endpoints include both quantal (such as mortality) and nonquantal (reproduction, growth) measurements, and can be used to derive additional values, other than previously mentioned in acute toxicity tests. These include the calculation of threshold values, such as the MATC (maximum acceptable toxicant concentration) which is the maximum chemical concentration not toxic to test organisms, and the BCF (bioconcentration factor) which estimates the tissue concentration in relation to the average exposure concentration in the test medium (e.g., water).

Unique to ecotoxicology are the more elaborate microcosm, mesocosm, and field studies. Microcosms are representative aquatic or terrestrial ecosystems created under laboratory conditions that include a number of relevant species (such as protozoa, plankton, algae, plants, invertebrates). Simulated field studies or mesocosms can be created in the laboratory or in the field (e.g., artificial streams, ponds) or consist of enclosures of existing habitats, containing representative soil, water, and biota. Lastly, full-scale field studies (aquatic organisms, terrestrial wildlife, pollinators) evaluate the effects of a substance on wildlife under real-life scenarios of actual use conditions of a product (e.g., pesticide field usage rate), and thus, are more complicated, subject to considerable variability, and require extensive background knowledge of the local population and community dynamics.

As a final point, plant studies are a significant component of ecological toxicity testing, particularly for pesticide registration, and involve tiered testing of both target area and nontarget terrestrial and aquatic plants. Target area plants are those that are present in the area where the substance will be routinely used (application area), but

which are not anticipated to be affected. Nontarget plants are those outside of the intended use area. Endpoints of phytotoxicity include seedling emergence and growth, vegetative vigor, and rhizobium-legume toxicity, among others, and central to the toxicity testing with plants are the substrate and environmental conditions, which greatly influence plant health.

Biomarkers

The National Academy of Sciences (1987) defined a biomarker as "a xenobiotically induced variation in cellular or biochemical components or processes, structures, or function that is measurable in a biological system or sample." In the context of ecotoxicology, this definition has been modified slightly to refer to biochemical physiological or histological indicators of either exposure to, or effects of, xenobiotic chemicals at the suborganismal or organismal level (Huggett *et al.*, 1992). The term is most often employed to refer to molecular, physiological, and organismal responses to contaminant exposure that can be quantified in organisms inhabiting or captured from natural systems. A response that is limited to laboratory studies falls outside the generally held concept of a biomarker.

By definition, biomarkers do not directly provide information concerning impacts on the higher levels of organization that ecotoxicology ultimately endeavors to discern. Nevertheless, biomarkers often provide important ancillary tools for discerning contaminant exposures and potential impacts of ecological importance. The development and use of biomarkers in ecotoxicology is motivated by several factors. These include the inherent instabilities of many contaminants (such as PAHs and many pesticides) that make measures of exposure by direct tissue residue analysis difficult, the relative biological sensitivity of many biomarkers, the chemical specificity of some biomarkers that serve to contribute to the identification of chemicals having biological effects, and relatedly, the linkage of some biomarkers to underlying mechanisms of toxic action. Additionally, while populations and higher level effects are of greatest concern, variables associated with these levels are oftentimes relatively insensitive to chemicals and other stressors, take long periods of time to become manifest, and/or methods for their analysis are difficult or imprecise. Thus, biomarkers can provide sensitive early warning signals of incipient ecological damage (van der Oost *et al.*, 2003), in essence an ecological counterpart to the "canary in the coal mine" approach for preventing harm to coal miners. However, biomarkers do not provide adequate standalone data in the context of ecological assessments of contaminant effects. At this time and for the foreseeable future, such assessments generally involve a "weight of evidence approach," coalescing information obtained from chemical analyses, toxicity tests, biomarkers, and ecological indicators (sometimes referred to as "bioindicators").

In earlier discussions, a number of contaminant effects at the organismal level and below that have been utilized as biomarkers were pointed out. These include effects with some degree of chemical specificity and relationship to a mechanism of toxicity (AChE inhibition by organophosphate and carbamate insecticides, ALAD inhibition by lead, DNA-PAH adducts), responses associated with exposures to chemicals acting through a common receptor (Vtg induction by estrogen receptor agonists such as natural and synthetic estrogens, some surfactants, plasticizers, and pesticides; CYP1A induction by aryl hydrocarbon receptor agonists such as certain pHAHs and PAHs), and broader indices of cellular stress or tissue damage, such as markers of oxidative stress, lysosomal membrane stability, and histopathology. Numerous other identified

mechanisms of toxicity, indices of chemical exposure, and cellular and organismal impacts have been exploited, with varying degree of success, as biomarkers (see reviews by Huggett *et al.*, 1992; Peakall, 1992; Adams, 2002; van der Oost *et al.*, 2003). In addition, new biomarkers continue to emerge; for example, considerable attention is now being given to biomarkers arising from advances in genomic technologies, discussed above.

In considering the development or use of a selected biomarker, several issues and limitations warrant consideration. For example, while sensitivity is overall an advantage of many biomarkers, it can sometimes raise important questions surrounding interpretation. For example, some molecular and biochemical measures are very sensitive to chemical exposures, but their ramifications for organismal health are unclear. For this reason, some distinguish between biomarkers of exposure and biomarkers of effect (see reviews cited above). However, this distinction is often blurred and is subject to an individual's view of what constitutes a significant biological chemical effect; some may say the formation of DNA adduct is a significant effect, while others will argue that such adducts only indicate exposure and will require tumor formation to occur before denoting an effect. Certainly most would agree that the tumor is a clearer marker of effect than the adducts, and something more readily grasped by policy makers and the general public. On the other hand, tumors are far less sensitive as a biomarker, a key *raison d'etre*; such trade-offs merit consideration.

Chemical specificity among biomarkers is also highly variable and is imbued with trade-offs. In some cases, such as where one has a good idea of the nature of contaminants likely to occur at a site, chemical-specific biomarkers will likely be most informative. In contrast, if such information is lacking, or mixtures encompassing several classes of chemicals likely occur, nonspecific markers may be superior. In most cases, suites of biomarkers prove to be most effective, although the larger the suite, the more time-intensive and costly the analysis will be, another trade-off. Another important consideration is the influence of the biomarker to variables other than those of concern (chemical contamination). Effects of environmental variables such as temperature, time of day or year, salinity and dissolved oxygen, and physiological variables such as sex, age, reproductive status, and nutritional status need to be controlled for or at least understood and accounted for. Many biomarkers are invasive and require sacrifice of the organism in order to obtain needed tissues. This can be problematic, particularly in cases involving rare species or charismatic species such as marine mammals. In such cases, and in others where feasible, the use of noninvasive biomarkers is either preferred or required (Fossi and Marsili, 1997). In summary, biomarkers can provide powerful tools as early warning signals of ecological damage, to assist in assessments of environmental contamination, and in determining the effectiveness of various environmental management decisions such as clean-ups. However, careful case-specific thought must go into the selection of biomarkers, and they rarely are efficacious alone.

Population

Population-level effects are quantified with both field and laboratory approaches (see Newman, 1995, 2001). Population density is the most common of field population qualities measured in surveys of contaminated habitats. Quadrat, mark-recapture, and removal-based methods are applied. The density of individuals in a series of random quadrats within the area of interest is used to estimate

densities in quadrat methods. The total population size can be estimated with knowledge of the total number of quadrats in the area of interest. In cases in which individuals are mobile and capable of avoiding being counted in a quadrat, a mark-recapture method might be applied instead. This involves marking a subset of individuals from the population, allowing them to randomly mix back into the population, and resampling the population. The number of marked and unmarked individuals taken, and the total number originally marked, can be used to estimate population size. Removal-based methods involve repeated sampling of the population without replacement, noting how the number collected per unit of effort declines through the sequence of samplings, and extrapolating this trend down to the point (total number caught previous to a sampling) at which no more individuals will be taken. This point is an estimate of the population size. Obviously, this approach is useful only if sampling decreases the catch noticeably between sampling episodes.

As noted earlier in discussions of metapopulations, the spatial distribution of individuals in a habitat is important to understand. Fortunately, well-established methods are available for this task. Methods vary depending on whether the sampling units are discrete or arbitrary. An arbitrary unit might be the number of razor clam per square meter of beach or number of a zooplankton species per cubic meter of water. A discrete sampling unit might be the number of mallard ducks per pond or squirrels per oak tree. Some methods associated with discrete sampling units attempt to fit the spatial pattern to a specific distribution. Methods for arbitrary sampling units include quadrat-based or distance-to-nearest neighbor approaches as described by Krebs (1998).

Demographic surveys or experiments can be conducted for exposed populations. Some studies explore age-specific vital rates but others are designed to explore vital rates for different life ages such as nestling, fledgling, juvenile, and adult. Most result in data sets that can be analyzed profitably using either a simple life table or more involved matrix analysis. The matrix method allows one to describe the population state and also to understand the sensitivity of the population to effects occurring to vital rates for various ages or stages (Caswell, 2001). The value of such studies lies in the ability to integrate effects to several effects into a projection of population consequences. Demographic studies are becoming more common in ecotoxicology, especially with species amenable to laboratory manipulation (Jensen *et al*., 2001; Tanaka and Nakanishi, 2001; Chandler *et al*., 2004).

Conventional studies of increased tolerance after generations of exposure and molecular genetic surveys of exposed populations are the primary approaches by which genetic consequences are assessed. Increased tolerance is usually detected by subjecting individuals from the chronically exposed population and a naïve population to toxicant challenge and formally testing for tolerance differences. A recent example is the study by Ownby *et al*. (2002) of enhanced tolerance for a PAH-exposed population of killifish from Elizabeth River (Virginia). Alternatively, a change associated with a tolerance mechanism might be examined in chronically exposed and naïve populations. As an example, Meyer *et al*. (2003) found upregulated antioxidant defenses in the same populations of exposed Elizabeth River killifish studied by Ownby *et al*. (2002). Close examinations of population genetics associated with contaminated habitats are also used to infer consequences of multi-generational exposure. Continuing with the Elizabeth River killifish example, Mulvey *et al*. (2002, 2003) examined the genetic qualities of fish sampled within the Elizabeth River estuary using allozymes and mDNA. Clear evidence was found using both tools for the influence of contamination

on the population genetics of killifish subpopulations within the estuary.

Community and Ecosystem

Most community and ecosystem effects studies by ecotoxicologists use modified methods developed in community and systems ecology (see Magurran, 1988, for method descriptions). Recent books such as Newman (1995) and Clements and Newman (2002) provide some details of ecotoxicological applications of these methods. Several general approaches are taken. The approach affording the most control and ability to replicate treatments involves laboratory microcosms. A microcosm is a simplified system that is thought to possess the community or ecosystem qualities of interest. The experimental control and reproducibility associated with microcosms come at the cost of losing ecological realism. Is the laboratory microcosm actually responding in a way that provides insight about how the actual community or ecosystem would respond? Microcosm studies are so common throughout the ecotoxicological literature that standard methods have been proposed for their execution (Taub, 1997). As a microcosm example, Clarke (1999) established invertebrate communities in the laboratory to determine the influence of oil drilling muds on offshore benthic communities. Relative to the issue of community redundancy discussed above, zinc-amended soil microcosms was used in another case by Salminen *et al*. (2001) and provided minimal evidence to support the current reliance on the redundant species theory by ecological risk assessors. Gaining back some realism by giving up some degree of tractability, outdoor mesocosms are also applied to community and ecosystem ecotoxicology. Mesocosms are larger experimental systems, usually constructed outdoors that also attempt to simulate some aspect of an ecosystem such as community species composition. Often, terrestrial ecotoxicologists apply the term enclosure instead of mesocosm for such experimental units. Aquatic mesocosms can be artificial ponds such as those developed by Woin (1998), streams such as those used by Kreutzweiser *et al*. (2000), or river segments such as those used by Culp *et al*. (2000). Terrestrial mesocosms can be pens, enclosures, or large soil plots depending on the effects being quantified. An example of a terrestrial mesocosm study is that conducted by Korthals *et al*. (1996) of the effects of long-term copper exposure to soil nematode communities. Field studies are the third means of exploring effects at the community or ecosystem level. The high realism of associated findings from field studies is balanced against the difficulty of achieving true replication and sufficient control of other factors influencing the system's response. Field studies can involve manipulations such as introducing toxicant into replicate water bodies; however, the majority of field studies involve biomonitoring of an existing, notionally impacted, community or ecosystem. This might involve close examination of species composition and comparison to that expected or measured in a similar, but uncontaminated, system. Most biomonitoring efforts focus on community structure instead of function because it is generally believed that changes in community structure will be seen before those to functions. As examples, metal effects on invertebrate and plant community structure were studied by Peeters *et al*. (2000) and Strandberg *et al*. (2006), respectively. Despite the tendency to study community structure, study of functions can provide valuable insights as in the case of Day (1993), who found changes in photosynthesis in periphytic algae in response to herbicide exposure. Because mesocosm and field studies involve data generation in the presence of many uncontrolled variables and poor replication or pseudoreplication, multivariate statistical techniques for recognizing patterns among locations or through

time are commonly applied, for example, Landis *et al.* (1997) and Kedwards *et al.* (1999).

Landscape to Biosphere

The creation and eventual convergence of several key technologies facilitate ecotoxicological study at the landscape to biosphere vantages. These same technologies have also allowed the emergence of large context, environmental disciplines such as landscape[4] ecology (Forman and Godron, 1986), global ecology (Rambler *et al.*, 1989), and global biogeochemistry (Butcher *et al.*, 1992) that contribute concepts to large-scale ecotoxicology efforts.

Technologies for acquiring, processing, and analyzing large amounts of information have been essential. Archived and new imagery from satellites and high-altitude platforms are now integrated with off-the-shelf Geographic Information Systems (GIS) software with affordable computers. Much of this imagery is gathered with remote sensing technologies, i.e., technologies that do not require physical contact with the feature being measured. However, arrays of sensors are rapidly coming together such as the network coastal observing systems that are quickly linking to form a readily accessible real-time data stream for all of our oceans. Remote sensing data from satellites or aircraft provide information for wide spatial areas and the rapidly emerging, ground- or water-based observing system networks have begun to produce extremely rich data streams. Such technologies facilitate ecotoxicological explorations at spatial scales that were impossible to consider only a few decades ago.

ECOLOGICAL RISK ASSESSMENT

Ecological risk assessment (ERA) applies ecotoxicological knowledge in support of environmental decision making. The ERA approach is an adaptation of human risk assessment methods, notably those articulated in the National Academy of Sciences paradigm (National Research Council, 1983). Adaptations are needed to accommodate differences in exposure pathways and the entities for which risk is to be estimated. Risk might be to an endangered or threatened species, or to a damaged natural resource for which remuneration might be required from a responsible party. In such cases, the ERA might estimate risk to individuals. Alternatively, as emphasized in the above EPA quote, the risk might be to a local species population or to the integrity of an ecological community. A widely dispersed ecotoxicant such as acid precipitation or widely used product such as the herbicide, atrazine, might require assessment of risk at a landscape or subcontinental scale. A recent example of such a risk assessment is that for atrazine, an herbicide used throughout North America (Solomon *et al.*, 1996). Ecotoxicants requiring a global ERA might include greenhouse gases contributing to global warming, hydrofluorocarbons depleting the ozone layer, and POPs that accumulate to harmful concentrations in polar regions far from their point of release at highly industrialized latitudes.

Adaptations are based on the context of an ERA. Some ERAs address existing situations. Considerable field information might be available for such a retroactive ERA and epidemiological methods might be applied advantageously. In contrast, predictive ERA assess possible risk associated with a future or proposed toxicant

exposure. In this case, the ERA might rely more heavily on exposure modeling and laboratory-derived effects data. A special case of predictive risk assessment is a life cycle assessment in which "cradle-to-grave" predictions are done for a product that includes all aspects of its raw material extraction, manufacture, distribution, use, and final disposal. Finally, an ERA will be structured slightly differently if it compares the ecological risk of one or more options. An example would be the comparative risk associated with a spill of Bunker oil versus Orimulsion® (a bitumen-based fossil fuel). Such a comparative risk assessment might draw insight and data from existing spill sites, laboratory tests, and exposure models. Despite adaptations and differing contexts, most ERA have the same general form (see Fig. 29-2).

Risk assessors, risk managers, and key stakeholders engage in initial planning together with the intention of formulating a clear statement of the problem. What valued ecological entity or quality is being assessed (assessment endpoint) is defined. A conceptual model is created that links the assessment endpoint and the toxicant, including descriptions of exposure pathways and possible effects. A clear statement of possible or predicted effects (risk hypothesis) is formulated. A clear formulation of the problem with concurrence of key stakeholders is critical to the ERA because of the diversity of possible assessment endpoints and exposure pathways.

Exposure characterization describes or predicts contact between the toxicant and the assessment endpoint. Depending on the ERA context, this could involve a simple calculation of average exposure, or a temporally and spatially explicit description of amounts present in relevant media. Toxicant sources, transport pathways, kinds of contact, and potential co-stressors are also defined.

Ecological effects characterization describes the qualities of any potential effects of concern, describes the connection between the potential effects and the assessment endpoint, and describes how changes in the level of exposure might influence the effects manifesting in the assessment endpoint. Normally, a statement about the strength of evidence associated with the descriptions is presented in the ecological effects characterization. As a common example of evidentiary uncertainty often requiring explanation is the measurement endpoint. It is not always desirable to derive effects information directly from an assessment endpoint such as an endangered species so uncertainty is introduced by gauging effects to a surrogate (measurement endpoint). Ecological effects characterizations must describe the justifiable confidence in extrapolating from measurement to assessment endpoints.

Risk characterization uses the analysis of exposure and ecological effects to address the risk question(s) posed in the problem formulation. This can involve an explicit statement of risk, that is, the probability of a specified intensity of an adverse effect occurring to the assessment endpoint. Often, the information needed to make such an explicit statement is absent and a qualitative statement of the likelihood of an adverse effect is made instead. Regardless of whether a quantitative or qualitative statement of risk is produced, the risk characterization must provide details surrounding the statement, including important uncertainties.

INTERCONNECTIONS BETWEEN ECOSYSTEM INTEGRITY AND HUMAN HEALTH

As noted at the beginning of this chapter, while the original definition of ecotoxicology included effects on humans, most subsequent treatments exclude discussions of humans except as a source of

---

[4] A landscape is formally defined by Forman and Godron (1986) as a heterogeneous landscape that is "composed of a cluster of interacting ecosystems that is repeated in a similar form throughout." Each ecosystem is a part of a whole landscape much as a tessera is part of a mosaic or a subpopulation is part of a metapopulation.

contaminants, with some notable exceptions (e.g., Newman and Unger, 2003). This ecotoxicology chapter, imbedded in a book focused on human or biomedical toxicology, describes the younger science of elucidating chemical effects in natural systems. While ecotoxicology has features distinct from biomedical toxicology, it is important to consider parallelisms in the two fields and more broadly, interconnections between human health and ecological integrity, or health. While obviously related, biomedical and ecological toxicology have historically exhibited relatively little coordination or collaboration among scientists across these fields. This is likely due to a number of reasons, including the different levels of biological organization considered, as well as different academic cultures populating the two fields. However, it is questionable if this gulf has been in the best interest of understanding chemical effects, and ultimately protecting both human and ecological health. This concern has prompted several broad discussions intended to bridge this divide and enhance interdisciplinary natural and social scientific research in these areas (see reviews by Costanza *et al*., 1992; Di Giulio and Monosson, 1996; Di Giulio and Benson, 2002).

This gulf has resulted in two fields that, while largely disconnected, parallel one another and share common paradigms such as dose–response, toxicokinetics, mechanisms of action, and risk assessment frameworks. However, by generally ignoring how chemicals and other anthropogenic stressors that degrade ecosystems can ultimately impact human health and well-being, and vice versa, an opportunity to holistically understand the results of environmental contamination is lost. Miranda *et al*. (2002) developed a conceptual model for elucidating the interconnections paradigm that links natural and social systems in a circular manner with continuous feedbacks, as opposed to parallel linear models (exposure to response, either in humans or ecosystems) that dominate toxicology currently. In this conceptual model, the natural system produces both positive outputs (such as natural resources, raw materials) and negative outputs (e.g., hurricanes, disease vectors) to the social system. The culture and institution of the social system in turn transforms the natural system outputs in various ways and subsequently delivers various positive outputs (consumer goods, conservation efforts) and negative outputs (pollution, deforestation) to the natural system. These outputs influence the quantity and quality of life (human and nonhuman) of the natural system, and the circular flow of resources continually creates conditions that influence the well-being of individuals, societies, and ecosystems, now and in the future.

This rather abstract model formalizes the interconnections between human and ecological health that most of us intuitively sense. Some of these connections, in the context of environmental pollution, are obvious. Chemical contamination of seafoods valued by humans is one example. Others are less clear but potentially very significant, such as human impacts on aquatic systems that foster the propagation of human disease vectors, or human impacts on global climate that may concomitantly impact humans and ecosystems in varied and complex ways. Also important to consider is the matter of human perceptions of their environment; people's sense of the health of the environment in which they live (whether their perception is correct or not) can have substantial impacts on their mental and physical health (O'Keefe and Baum, 1996). As noted by Kendall *et al*. (2001), "the indirect effects of environmental pollution may, in the end, be more important than the direct effects for human health."

There are significant indications that these fields are converging and meaningful interactions are increasing. The inclusion of an ecotoxicology chapter in this text is favorable evidence. This trend is motivated in part by the genomics revolution which provides powerful methods for evaluating fundamental biological similarities across species, including those employed in biomedical and ecotoxicological research. Research in this area has revealed genetic similarities, or conservation, in many genes and the proteins they code for that are important to organismal adaptations and impacts due to environmental stressors, including chemicals (Eaton *et al*., 2006). Certainly many important species differences also exist that contribute to the great complexity of understanding human-ecological interconnections, but as pointed out by Winston *et al*. (2002), "in the final analysis, the biological similarities across living systems are probably more impressive than the differences." Discussions among diverse scientists of the promises, limitations, and potential applications of genomics for elucidating cross-species extrapolations are provided by Benson and Di Giulio (2006). Such cross-fertilizations among biomedical and environmental scientists, as well as social scientists and policy-makers, are likely to enhance all areas, and catalyze the integrated protection of human and ecosystem health.

APPLICATIONS OF TOXICOLOGY

This page intentionally left blank

FOOD TOXICOLOGY

Frank N. Kotsonis and George A. Burdock

INTRODUCTION TO FOOD TOXICOLOGY

The typical Western diet contains hundreds of thousands of substances naturally present in food and many more which form in situ when food is cooked or prepared. Many of these substances affect the nutritional and esthetic qualities of food including appearance and organoleptic properties (i.e., conferring flavor, texture, or aroma) that determine whether or not we will even try the food or take a second bite, respectively. Whereas substances present in food may be nutritional and/or gratifying, they may not necessarily be "safe" in *any* amount or for *any* intended use. The Federal Food, Drug and Cosmetic (FD&C) Act gives the federal government the

authority to ensure that all food involved in interstate commerce is safe. Congress, in writing the Act (and its subsequent amendments), understood that safety cannot be proved absolutely and indicated instead that the safety standard for substances added to food can be no more than a *reasonable certainty of no harm*. As will be pointed out in other sections of this chapter, the language of the FD&C Act effectively provides for practical and workable approaches to the assessment of safety for food, food ingredients, and food contaminants. Because food is highly complex, the legal framework provided by Congress for the regulation of food and substances in food was kept simple so that it would work.

The basic element of the framework is that food, which is defined as articles or components of articles used for food or drink for humans or animals, bears the presumption of safety [Sections 201(f) and 402(a)(1) of the FD&C Act]. This means that a steak or a potato is presumed to be safe unless it contains a poisonous or deleterious substance in an amount, which is shown to make it *ordinarily injurious* to health. In essence, this presumption of safety was born of necessity. If the hundreds of thousands of substances naturally present in food were subject to the same strictures and limitations that apply to added substances, virtually all food would be suspect and food shortages could easily result. To avoid such crises, Congress developed a safety standard that would not force regulatory authorities to ban common, traditional foods. In cases where the substance is not naturally present in food but is a contaminant or added ingredient, the safety standard is quite different. This standard decrees a food to be adulterated if it contains any poisonous or deleterious substance that *may render it injurious*.

Thus, for additives and contaminants, Congress recognized that these substances are not as complex as food and should therefore meet a higher standard of safety. However, because neither the law nor Food and Drug Administration (FDA) or U.S. Department of Agriculture (USDA) regulations explicitly define the term "safety" for substances added to food, scientists and their legal and regulatory counterparts have worked out operational definitions for the safety of such substances.

As with food, a practical and workable approach must be found for the contaminants of added ingredients, because all substances contain a myriad of contaminants at trace or even undetectable amounts with current technology. In this case, the approach involves setting specification limits on contaminants that are intended to exclude the possibility that the level present in an additive *may render* the food to which the substance is added, *unsafe*. It should be emphasized that specifications can serve their purpose of assuring suitable purity only if the manufacturing processes used are adequately controlled to assure consistency in the quality and purity of the product. The philosophy by which specifications are established for substances added to food embodies the belief that not all risks are worthy of regulatory concern and control (i.e., the concept of *de minimis*).[1] Implicit in this philosophy is the important unifying concept of *threshold of regulation* in food safety assessment (Flamm *et al.*, 1994, 2002).

Food, as stated earlier, contains hundreds of thousands of substances, most of which have not been fully characterized or tested. The presumption that a food is safe is based on a history of common use and that the consumption of certain foods is deeply rooted in tradition. When the uncertainty about the risk of the added substance is

small compared with the uncertainties attending food itself, the standard of "reasonable certainty of no harm" for the added substance has been satisfied. Thus, for food-like substances, the presumption is that the substance resembles food, is digested and metabolized as food, and consequently raises fewer toxicological and safety-related questions than do non-food-like substances. Moreover, when non-food-like substances are added in only very small or trace amounts, the low levels of exposure aid in demonstrating that the intended conditions of use of these substances are safe. These broad generalizations, however, do not suffice to exempt these food ingredients from the requirements of thorough safety evaluation.

Over the past decade, there has been increasing interest on the part of consumers about the health-enhancing properties of foods and the components they contain. Substances such as phytosterols from vegetable oils and isoflavones from soy have been isolated and added to other foods at elevated levels to impart cholesterol-lowering abilities. Such products have raised regulatory questions about whether these substances are functioning as drugs, and should be regulated as such, or whether they should be viewed as new nutrients and allowed in foods, as are vitamin C and iron. Recently, experts in nutritional science concluded that the concept of nutrients should be expanded to include a growing number of desirable food constituents that produce quantifiable health benefits related to disease prevention (Sansalone, 1999). This isolation of, and fortification with, new food components will necessitate a thorough evaluation of safety at the intended level of intake and for the population at large (Mackey and Kotsonis, 2002).

Finally, it should be recognized that in most of the world, microbiological contamination of food represents by far the greatest food-borne risk facing consumers. Thus, while vigilance in assuring the safety of substances added to food under their intended conditions of use is appropriate, we should not lose sight of the major concern of food safety.

Uniqueness of Food Toxicology

The nature of food is responsible for the uniqueness of food toxicology. Food occupies a position of central importance in virtually all cultures, and because most food cannot be commercially produced in a definable environment under strict quality controls, food generally cannot meet the rigorous standards of chemical identity, purity, and good manufacturing practice met by most consumer products. The fact that food is harvested from the soil, the sea, inland waters, or is derived from land animals, which are subject to the unpredictable forces of nature, makes the constancy of raw food unreliable. Experience has supported the safety of commonly consumed foods, and the good agricultural practices (GAP) under which food is produced mandates the need for quality controls (i.e., current Good Manufacturing Practice, cGMP). Nevertheless, it is clear that food is held to a different standard as a practical matter dictated by necessity.

Food also acquires uniqueness from its essential nutrients, which, like Vitamin A, may be toxic at levels only 10-fold above those required to prevent deficiencies. The evaluation of food ingredients often must rely on reasoning unique to food science in the sense that such substances may be normal constituents of food or modified constituents of food as opposed to the types of substances ordinarily addressed in the fields of occupational, environmental, and medical toxicology. Assessing the safety of such substances, which are added to food for their technical effects, often focuses on digestion and metabolism occurring in the gastrointestinal (GI) tract. The reason for this focus is that in many cases an ingested

---

[1] *de minimis non curat praetor* or *de minimis non curat lex*, in the sense that law is not interested in trivial matters. In this sense, a risk so small it is not worthy of concern.

Table 30-1

Food as a Complex Mixture

NUTRIENTS	NON-NUTRIENTS
Carbohydrates	Naturally occurring substances
Proteins	Food additives
Lipids	Contaminants
Minerals	Products of food processing
Vitamins

substance is not absorbed through the GI tract; only products of its digestion are absorbed, and these products may be identical to those derived from natural food.

Nature and Complexity of Food

Food is an exceedingly complex mixture of nutrient and non-nutrient substances whether it is consumed in the "natural" (unprocessed) form or as a highly processed ready-to-eat meal such as a "Meal Ready to Eat" (MRE) (Table 30-1). Among the "nutrient" substances, the Western diet consists of items of caloric and noncaloric value; that is, carbohydrates supply 47% of caloric intake, fats supply 37%, and protein supplies 16% (all three of which would be considered "macronutrients"), whereas minerals and vitamins, the "micronutrients," obviously have no caloric value but are no less essential for life.

Non-nutrient substances are often characterized in the popular literature as being contributed by food processing, but nature provides the vast majority of non-nutrient constituents. For instance, in Table 30-2 one can see that even among "natural" (or minimally processed) foods, there are far more non-nutrient than nutrient constituents. Many of these non-nutrient substances are vital for the growth and survival of the plant, including hormones and naturally occurring pesticides (estimated at approximately 10,000 by Gold *et al.* (1992)). Some of these substances may be antinutrient (e.g., lectins, saponins, trypsin, and/or chymotrypsin inhibitors in soybeans, phytates that may bind minerals (present in soybeans) and anti-thiamines in fish and plants) or even toxic (e.g., tomatine, cycasin) to humans. An idea of the large number of substances present in food is given in the series *Database of Volatile Compounds in Food* (BACIS, 1999), in which approximately 5500 volatile substances are noted as occurring in one or more of the 246 different foods. However, this is only the tip of the iceberg, as the number of unidentified natural chemicals in food vastly exceeds the number that has been identified (Miller, 1991).

Non-nutrient substances are also added as a result of processing, and in fact, 21 CFR 170.3(o) lists 32 categories of direct additives, of which there are about 3000 individual substances. Approximately 2000 of these are flavor ingredients, most of which already occur naturally in food and are non-nutritive (Burdock, 2002). Of the 2000 flavoring ingredients that may be added to food, approximately one-third are used at concentrations below 10 ppm (Hall and Oser, 1968), about the same concentration as is found naturally.

Importance of the Gastrointestinal Tract

It is essential to appreciate the fact that the gut is a large, complex, and dynamic organ with several layers of organization and a vast absorptive surface that has been estimated to be from 200 to 4500 m^2 (Concon, 1988). The GI transit time provides for adequate exposure of ingesta to a variety of environmental conditions (i.e., variable pH), digestive acids and enzymes (trypsin, chymotrypsin, etc., from the pancreas and carbohydrases, lipases, and proteases from the enterocytes), saponification agents (in bile), and a luxuriant bacterial flora providing a repertoire of metabolic capability not shared by the host (e.g., fermentation of "nondigestible" sugars such as xylitol and sorbitol) (Drasar and Hill, 1974). The enterocytes (intestinal epithelium) possess an extensive capacity for the metabolism of xenobiotics that may be second only to the liver, with a full complement of phase (type) I and phase (type) II reactions present. The enteric monooxygenase system is analogous to the liver, as both systems are located in the endoplasmic reticulum of cells, require NADPH and O$_2$ for maximum activity, are inhibited by many of the same substances, and are qualitatively similar in their response to enzyme induction (Hassing *et al.*, 1989). Induction and inhibition of xenobiotic metabolism and effects on transporter *P*-glycoprotein are discussed in another section (see section Food–drug interactions).

The constituents of food and other ingesta (e.g., drugs, contaminants, inhaled pollutants dissolved in saliva and swallowed) are a physicochemically heterogeneous lot, and because the intestine has evolved into a relatively impermeable membrane, mechanisms of absorption have developed that allow substances to gain access to the body from the intestinal lumen. The four primary mechanisms for absorption are passive or simple diffusion, active transport, facilitated diffusion, and pinocytosis. Each of these mechanisms characteristically transfers a defined group of constituents from the lumen into the body (Table 30-3). As is noted in the table, xenobiotics and other substances may compete for passage into the body.

Aiding this absorption is the rich vascularization of the intestine, with a normal rate of blood flow in the portal vein of approximately 1.2 L/h/kg. However, after a meal, there is a 30% increase in blood flow through the splanchnic area (Concon, 1988). It follows then, that substances, which affect blood flow, also tend to affect the absorption of compounds; an example is alcohol, which tends to increase blood flow to the stomach and thus enhances its own absorption. Few stimuli tend to decrease flow to this area, with the possible exception of energetic muscular activity and hypovolemic shock.

Lymph circulation is important in the transfer of fats, large molecules (such as botulinum toxin), benzo[*a*]pyrene, 3-methylcholanthrene, and *cis*-dimethylaminostilbene (Chhabra and

Table 30-3
Systems Transporting Enteric Constituents

SYSTEM	ENTERIC CONSTITUENT
Passive diffusion	Sugars (e.g., fructose, mannose, and xylose, which may also be transported by facilitated diffusion), lipid-soluble compounds, water
Facilitated diffusion	D-xylose, 6-deoxy-1,5-anhydro-D-glucitol, glutamic acid, aspartic acid, short-chain fatty acids, xenobiotics with carboxy groups, sulfates, glucuronide esters, lead, cadmium, zinc
Active transport	Cations, anions, sugars, vitamins, nucleosides (pyrimidines, uracil, and thymine, which may be in competition with 5-fluorouracil and 5-bromouracil), cobalt, manganese (which competes for the iron transportation system)
Pinocytosis	Long-chain lipids, vitamin B_{12} complex, azo dyes, maternal antibodies, botulinum toxin, hemagglutinins, phalloidins, *E. coli* endotoxins, virus particles

Eastin, 1984). Lymph has a flow rate of about 1–2 mL/h/kg in humans, and few factors are known to influence its flow, with the exception of tripalmitin, which has been shown to double the flow and therefore double the absorption of *p*-aminosalicylic acid and tetracycline (Chhabra and Eastin, 1984). Another factor that lends importance to lymph is the fact that the lymph empties via the thoracic duct into the point of junction of the left internal jugular and subclavian veins, preventing "first-pass" metabolism by the liver, unlike substances transported by the blood.

Many food ingredients are modified proteins, carbohydrates, fats, or components of such substances. Thus, understanding the changes these substances undergo in the GI tract, their possible effect on the GI tract, and whether they are absorbed or affect the absorption of other substances is critical to an understanding of food toxicology and safety assessment. Some of the factors that may affect GI absorption and the rate of absorption are listed in Table 30-4.

SAFETY STANDARDS FOR FOODS, FOOD INGREDIENTS, AND CONTAMINANTS

The FD&C Act Provides for a Practicable Approach

The FD&C Act presumes that traditionally consumed foods are safe if they are free of contaminants. For the FDA to ban such foods, it must have clear evidence that death or illness can be traced to consumption of a particular food. The fact that foods contain many natural substances, some of which are toxic at a high concentration, is in itself an insufficient basis under the Act for declaring a food as being unfit for human consumption. Examples of this concept include acceptance of Generally Recognized As Safe (GRAS) status and the implementation of tolerances.

The Application of Experience: Generally Recognized as Safe (GRAS) The FD&C Act permits the addition of substances to food to accomplish a specific technical effect if the substance is determined to be GRAS. The Act does not require the FDA to make this determination, though it does not exclude the agency from making such decisions. The Act instead requires that scientific experts base a GRAS determination on the adequacy of safety, as shown through scientific procedures or through experience based on common use in food before January 1, 1958, under the intended conditions of use of the substance [FD&C Act, section 201(s)].

In addition to allowing GRAS substances to be added to food, the Act provides for a class of substances that are regulated food additives, which are defined as "any substances the intended use of which results in its becoming a component...of any food...if such substance is not generally recognized...to be safe." Hence,

Table 30-4
Factors Affecting Intestinal Absorption and Rate of Absorption

FACTOR	EXAMPLE
Gastric emptying rate	Increased fat content
Gastric pH	Antacids, stress, H_2-receptor blockers
Intestinal motility	Diarrhea due to intercurrent disease, laxatives, dietary fiber, disaccharide intolerance, amaranth
Food content	Lectins of *Phaseolus vulgaris* (inhibition of glucose absorption and transport)
Surface area of small intestine	Short-bowel syndrome
Intestinal blood flow	Alcohol
Intestinal lymph flow	Tripalmitin
Enterohepatic circulation	Chlordecanone (prevented by cholestyramine)
Permeability of mucosa	Inflammatory bowel disease, celiac disease
Inhibition of digestive processes	Catechins of tea which inhibit sucrase and therefore glucose absorption
Concomitant drug therapy	Iron salts/tetracycline

SOURCE: Modified from Hoensch HP, Schwenk M: Intestinal absorption and metabolism of xenobiotics in humans, in Schiller CM (ed): *Intestinal Toxicology*. New York: Raven Press, 1984, pp. 169–192. With permission from Lippincott Williams &Wilkins.

a legal distinction is drawn between regulated food additives and GRAS substances. Regulated food additives must be approved and regulated for their intended conditions of use by the FDA under 21 CFR 172–179 before they can be marketed. Under section 409 of the Act, the requirements for data to support the safe use of a food additive are described in general terms. The requirements or recommended methods for establishing safe conditions of use for an additive are available in the form of guidelines issued by the FDA. These guidelines, referred to as the Redbook, provide substance and definition to the safety standard applicable to regulated food additives: "reasonable certainty of no harm under conditions of intended use" (Burdock and Carabin, 2004).

Use of Tolerances If a food contains an *unavoidable* contaminant even with the use of current good manufacturing practice (cGMP), it may be declared unfit as food if the contaminant may render the food injurious to health. Thus, for a food itself to be declared unfit, it must be ordinarily injurious, while an unavoidable contaminant in food need only pose the risk of harm for the food to be found unfit, and subject to FDA action. The reason for the dichotomy is practicality. Congress recognized that if authority were granted to ban traditional foods for reasons that go beyond clear evidence of harm to health, the agency would be subject to pressure to ban certain foods.

Foods containing unavoidable contaminants are not automatically banned because such foods are subject to the provisions of section 406 of the FD&C Act, which indicates that the quantity of unavoidable contaminants in food may be limited by regulation for the protection of public health and that any quantity of a contaminant which exceeds the fixed limit shall be deemed unsafe. This authority has been used by the FDA to set limits on the quantity of unavoidable contaminants in food by regulation (tolerances) or by informal action levels which do not have the force of law. Such action levels have been set for aflatoxins, fumonisins, and patulin (Table 30-5). Action levels have the advantage of offering greater flexibility than is provided by tolerances established by regulation. Whether tolerances or action levels are applied to unavoidable contaminants of food, the FDA attempts to balance the health risk posed by unavoidable contaminants against the loss of a portion of the food supply. In contrast, contaminants in food that are *avoidable* by cGMP are deemed to be unsafe under section 406 if they are consid-

ered poisonous or deleterious. Under such circumstances, the food is typically declared *adulterated* and unfit for human consumption. The extent to which consumers who are already in possession of such food must be alerted depends on the health risk posed by the contaminated food. If there is a reasonable probability that the use of or exposure to such a food will cause serious adverse health consequences or death, the FDA will seek a Class I recall which provides the maximum public warning, the greatest depth of recall, and the most follow-up. Classes II and III represent progressively less health risk and require less public warning, less depth of recall, and less follow-up (21 CFR 7.3).

Food and Color Additives

An intentionally added ingredient, not considered GRAS, is either a direct food additive or color additive. As with all ingredients intentionally added to food, there must be a specific and justifiable functionality. While a color additive has only one function, a food additive may have any one of 32 functionalities (Table 30-6).

The term "color additive" refers to a material which is a dye, pigment, or other substance made by a process of synthesis or extracted and isolated from a vegetable, animal, or mineral source [FD&C Act 201(t)]. Blacks, whites, and intermediate grays also are included in this definition. When such additives are added or applied to a food, drug, or cosmetic or to the human body, they are capable of imparting color. Color additives are not eligible for GRAS status.

There are two distinct types of color additives that have been approved for food use: those requiring certification by FDA chemists and those exempt from certification. Certification, which is based on chemical analysis, is required for each batch of most organic synthesized colors because they may contain impurities that may vary from batch to batch. Most certified colors approved for food use bear the prefix FD&C. Certification involves in-depth chemical analysis of major and trace components of each individual batch of color additives by FDA chemists and is required before any batch can be released for commercial use. Such color additives consist of aromatic amines or aromatic azo structures (FD&C Blue No. 1, Blue No. 2, Green No. 3, Red No. 3, Red No. 40, Yellow No. 5, and Yellow No. 6) that cannot be synthesized without a variety of impurities. Orange B and Citrus Red No. 2 are the only certified food colors that lack the FD&C designation (21 CFR 74 Subpart A).

Despite the fact that aromatic amines are generally considered relatively toxic substances, the FD&C colors are notably nontoxic. Table 30-7, which is adopted from a publication of the National Academy of Sciences (NAS) (Committee on Food Protection, 1971), shows that certified food colors have a low order of toxicity. The principal reason involves sulfonation of the aromatic amine or azo compound that constitutes a color additive. Such sulfonic acid groups are highly polar, which, combined with their high molecular weight, prevents them from being absorbed by the GI tract or entering cells. All the FD&C food colors have been extensively tested in all Concern Level (CL) III tests (Table 30-8) and have been found to be 'remarkably' nontoxic.

Food colors that are exempt from certification typically have not been subjected to such extensive testing requirements. The exempt food colors are derived primarily from natural sources. Whereas synthetic food colors have received the majority of public, scientific, and regulatory attention, natural color agents are also an important class. Currently, 26 color additives have been given exemption from certification in 21 CFR 73. These agents consist

Table 30-5

FDA Action Levels for Mycotoxins

COMMODITY	LEVEL, ng/g
Aflatoxins	
All products, except milk, designated for humans	20
Aflatoxins: Milk	0.5
Patulin: Apple juice	50
Deoxynivalenol (DON or vomitoxin): All finished wheat products that may be consumed by humans	1000
Fumonisins, Total ($FB_1 + FB_2 + FB_3$)	
Degermed dry milled corn product	2000
Cleaned corn intended for popcorn	3000
Cleaned corn for masa production	4000

Table 30-6
Direct Food Additives by Functionality

NUMBER	DESIGNATION	DESCRIPTION	EXAMPLES
170.3(o) (1)	Anticaking agents and free-flow agents	Substances added to finely powdered or crystalline food products to prevent caking, lumping, or agglomeration	Glucitol, sodium ferrocyanide, silicon dioxide
(2)	Antimicrobial agents	Substances used to preserve food by preventing growth of microorganisms and subsequent spoilage, including fungistats, mold, and rope inhibitors and the effects listed by the NAS/NRC under "preservatives"	Nisin; methyl-, ethyl-, propyl-, or butyl-ester of p-hydroxybenozoic acid; sodium benzoate; sorbic acid and its salts
(3)	Antioxidants	Substances used to preserve food by retarding deterioration, rancidity, or discoloration due to oxidation.	Butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), propyl gallate
(4)	Colors and coloring adjuncts	Substances used to impart, preserve, or enhance the color or shading of a food, including color stabilizers, color fixatives, color-retention agents	FD&C Yellow No. 5 (tartrazine), FD&C Red No. 4, β-carotene, annatto, turmeric
(5)	Curing and pickling agents	Substances imparting a unique flavor and/or color to a food, usually producing an increase in shelf life	Calcium chloride, glucitol
(6)	Dough strengtheners	Substances used to modify starch and gluten, producing a more stable dough, including the applicable effects listed by the NAS/NRC under "dough conditioners"	Calcium bromate, baker's yeast extract, calcium carbonate
(7)	Drying agents	Substances with moisture-absorbing ability used to maintain an environment of low moisture	Calcium stearate, cobalt caprylate, cobalt tallate
(8)	Emulsifiers and emulsifier salts	Substances that modify surface tension in the component phase of an emulsion to establish a uniform dispersion or emulsion	Phosphate esters of mono- and diglycerides, acetylated monoglycerides, calcium stearate
(9)	Enzymes	Enzymes used to improve food processing and the quality of the finished food	Papain, rennet, pepsin
(10)	Firming agents	Substances added to precipitate residual pectin, strengthening the supporting tissue and preventing its collapse during processing	Calcium acetate, calcium carbonate
(11)	Flavor enhancers	Substances added to supplement, enhance, or modify the original taste and/or aroma of a food without imparting a characteristic taste or aroma of their own	Monosodium glutamate, inositol
(12)	Flavor agents and adjuvants	Substances added to impart or help impart a taste or aroma in food	Cinnamon, citral, p-cresol, thymol, zingerone

(*Continued*)

Table 30-6
(Continued)

NUMBER	DESIGNATION	DESCRIPTION	EXAMPLES
(13)	Flour-treating agents	Substances added to milled flour at the mill to improve its color an/or baking qualities, including bleaching and maturing agents	Calcium bromate
(14)	Formulation aids	Substances used to promote or produce a desired physical state or texture in food, including carriers, binders, fillers, plasticizers, film formers, and tableting aids	Palm kernel oil, tallow
(15)	Fumigants	Volatile substances used for controlling insects or pests	Aluminum phosphide, potassium bromide
(16)	Humectants	Hygroscopic substances incorporated in food to promote retention of moisture, including moisture-retention agents and antidusting agents	Arabic gum, calcium chloride
(17)	Leavening agents	Substances used to produce or stimulate production of carbon dioxide in baked goods to impart a light texture, including yeast, yeast foods, and calcium salts listed by the NAS/NRC under "dough conditioners"	Carbon dioxide, adipic acid
(18)	Lubricants and release agents	Substances added to food contact surfaces to prevent ingredients and finished products from sticking to them	Mineral oil, acetylated monoglycerides
(19)	Nonnutritive sweeteners	Substances having less than 2% of the caloric value of sucrose per equivalent unit of sweetening capacity	Acesulfame, aspartame, saccharin
(20)	Nutrient supplements	Substances that are necessary for the body's nutritional and metabolic processes	Calcium carbonate
(21)	Nutritive sweeteners	Substances that have greater than 2% of the caloric value of sucrose per equivalent unit of sweetening capacity	Lactitol, hydrogenated starch hydrolysate
(22)	Oxidizing and reducing agents	Substances that chemically oxidize or reduce another food ingredient, producing a more stable product, including the applicable effects listed by the NAS/NRC under "dough conditioners"	Calcium peroxide, chloride, hydrogen peroxide
(23)	pH control agents	Substances added to change or maintain active acidity or basicity, including buffers, acids, alkalis, and neutralizing agents	Acetic acid, propionic acid, calcium acetate, calcium carbonate, carbon dioxide
(24)	Processing aids	Substances used as manufacturing aids to enhance the appeal or utility of a food or food component, including clarifying agents, clouding agents, catalysts, flocculents, filler aids, and crystallization inhibitors	Carbon dioxide, ammonium carbonate, ammonium sulfate, potassium bromide

(Continued)

Table 30-6
(Continued)

NUMBER	DESIGNATION	DESCRIPTION	EXAMPLES
(25)	Propellants, aerating agents, and gases	Gases used to supply force to expel a product or reduce the amount of oxygen in contact with the food in packaging	Carbon dioxide, nitrous oxide
(26)	Sequestrants	Substances that combine with polyvalent metal ions to form a soluble metal complex to improve the quality and stability of products	Acetate salts, citrate salts, gluconate salt, metaphosphate, edetic acid, calcium acetate
(27)	Solvents and vehicles	Substances used to extract or dissolve another substance	Acetic acid, acetylated monoglycerides
(28)	Stabilizers and thickeners	Substances used to produce viscous solutions or dispersions, to impart body, improve consistency, or stabilize emulsions, including suspending and bodying agents, setting agents, jellying agents, and bulking agents	Calcium acetate, calcium carbonate
(29)	Surface-active agents	Substances used to modify surface properties of liquid food components for a variety of effects other than emulsifiers but including solubilizing agents, dispersants, detergents, wetting agents, rehydration enhancers, whipping agents, foaming agents, and defoaming agents	Sorbitan monostearate, mono- and diglycerides, polysorbate 60, acetostearin
(30)	Surface-finishing agents	Substances used to increase palatability, preserve gloss, and inhibit discoloration of foods, including glazes, polishes, waxes, and protective coatings	Ammonium hydroxide, arabic gum
(31)	Synergists	Substances used to act or react with another food ingredient to produce a total effect different from or greater than the sum of the effects produced by the individual ingredients	Acetic acid, propionic acid
(32)	Texturizers	Substances that affect the appearance or feel of food	Calcium acetate

of a variety of natural compounds generally obtained by various extraction and treatment technologies. Included in this group of colors are preparations such as dried algae meal, beet powder, grape skin extract, fruit juice, paprika, caramel, carrot oil, cochineal extract, ferrous gluconate, and iron oxide. A problem encountered in attempts to regulate these additives is the lack of a precise chemical definition of many of these preparations. With a few exceptions such as caramel, which is the most widely used color, the natural colors have not been heavily used. In part, this may be due to economic reasons, but these colors generally do not have the uniformity and

intensity characteristic of the synthetic colors, therefore necessitating higher concentrations to obtain a specific color intensity. They also lack the chemical and color stability of the synthetic colors and have a tendency to fade with time.

Intake of color additives varies among individuals. The maximal intake of food colors is estimated to be ~53.5 mg/d, whereas the average intake per day is ~15 mg (Committee on Food Protection, 1971). Only about 10% of the food consumed in the United States contains food colors. The foods that utilize food colors in order of the quantity of color utilized are (1) beverages, (2) candy and

Table 30-7

Data on Certified Food Colors Permanently Listed in the United States

COLOR	NO ADVERSE EFFECT DIETARY LEVELS AND ANIMALSTUDIES	SAFE LEVEL FOR HUMANS (mg/day)	ESTIMATED MAXIMUM INGESTION (mg/day/person)

confections, (3) dessert powders, (4) bakery goods, (5) sausages (casing only), (6) cereals, (7) ice cream, (8) snack foods, and (9) gravies, jams, jellies, and so forth (Committee on Food Protection, 1971).

Methods Used to Evaluate the Safety of Foods, Ingredients, and Contaminants

Safety Evaluation of Direct Food and Color Additives The basic concept that forms the foundation for the safety evaluation of direct food and color additives is the recognition that the safety of any added substance to food must be established on the basis of the intended conditions of use in food. Factors that need to be taken into account include (1) the purpose for use of the substance, (2) the food to which the substance is added, (3) the concentration level used in the proposed foods, and (4) the population expected to consume the substance.

The evaluation of a new food additive is a complicated and expensive undertaking, especially when the additive will be widely used in many foods. Each additive can pose unique safety questions depending on its chemistry, stability in use, metabolism, toxicity study results, and estimated human exposure. Integral to a discussion of exposure is the concept of the "whole food additive." This refers to the additive, the degradation or conversion products arising from the use of the additive in foods, and the impurities found in the manufactured additive itself (Kotsonis and Hjelle, 1991, 1996).

Exposure: The Estimated Daily Intake Prior to 1958, the FDA held to the philosophy that food additives (and potential contaminants) should not be harmful at any level. This is impractical, as many substances critical to life are toxic at high doses. For example, distilled water is harmless if consumed at low amounts, but if enough is ingested to cause electrolyte imbalance, fatalities may occur. Other substances that may be toxic at high concentrations, such as acids or bases, are used at low concentrations to control pH or inhibit bacterial growth during the processing of meats and cheeses,

Table 30-9
Food Categories

NUMBER	DESIGNATION	DESCRIPTION	EXAMPLES
170.3(n)			
(1)	Baked goods and baking mixes	Includes all ready-to-eat and ready-to bake products, flours, and mixes requiring preparation before serving	Doughnuts, bread, croissants, cake mix, cookie dough
(2)	Beverages, alcoholic	Includes malt beverages, wines, distilled liquors, and cocktail mix	Beer, malt liquor, whiskey, liqueurs, wine coolers
(3)	Beverages and beverage bases, nonalcoholic	Includes only special or spiced teas, soft drinks, coffee substitutes, and fruit- and vegetable-flavored gelatin drinks	Herbal tea (non-tea-containing "teas"), soda pop, chicory
(4)	Breakfast cereals	Includes ready-to-eat and instant and regular hot cereals	Oatmeal (both regular and instant), farina, corn flakes, wheat flakes

are considered GRAS by the FDA. These examples underscore the fact that exposure level is a major factor in a safety evaluation, and is reflected in the FDA's *Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Food* (FDA, 1982a),[2] a source used to determine which testing methods should be conducted to determine safety levels of a substance.

In food additive safety determinations, exposure is usually referred to an estimated daily intake (EDI) and is based on the daily intake (I) of the food in which the substance will be used, and the concentration (C) of the substance when it is in the food. Many food ingredients are used in several different food categories, but as an example, we will assume that an additive is used only in breakfast cereals. If the substance is added at a concentration that does not exceed 20 μg/g (ppm), and the mean daily intake of breakfast cereals is 175 g/person/day, the EDI is calculated at 3500 μg/person/day. As most food additives are used in many foods, the total exposure is the sum of the exposures from each of the food categories. The formula for exposure to food additive B is

$$\text{EDI}_B = (C_B f \times I_f) + (C_B g \times I_g) + (C \ldots)$$

where $C_B f$ and $C_B g$ are the concentration of B in food category f and g, respectively. I_f and I_g are the daily intake of food category f and g, respectively. Therefore, the EDI is the sum of the individual contributions of B in each of the food categories.

The same principles may be applied to the estimation of the consumption of residue from secondary direct additives (substances not intended to remain in a food after the technical effect has been accomplished; examples include solvents, sanitizers, and defoaming agents), and contaminants. Additional information on the estimation of exposure to direct food additives and contaminants has been made available by the agency's Center for Food Safety and Applied Nutrition.[3]

Calculating the EDI raises several basic questions: (1) How does one determine the amount of a food additive that is added to each food category? and (2) How are food categories determined? To determine the amount of food additive added to each food category, the highest end of the range of use levels for the new substance is used. These food group maximums are not to be exceeded by a food manufacturer, based on the current Good Manufacturing Practice regulation (cGMPs; 21 CFR 110), which binds a manufacturer not to add more of an additive than is reasonably required to achieve the specific technical effect of the food additive (additional information on cGMPs may be found in the Food Chemicals Codex (FCC, 2003).

General food categories have been specified by the FDA. A sample of the categories is presented in Table 30-9. These categories were derived from a survey of food additives conducted by the National Academy of Sciences/National Research Council and published in 1972 (NRC/NAS, 1979). This survey pioneered the use of categorizing foods, but changes in the consumption patterns of the U.S. population, in addition to changes in the types of foods available, have necessitated the generation of additional, more current data.

More contemporary data on food intake has been calculated through the use of food consumption surveys (Table 30-10). Food consumption databases have specific characteristics and are based on particular assumptions. Methods commonly used by regulatory agencies, manufacturers, nutritionists, and general researchers for assessing food consumption by individuals include 24-hour dietary recalls, dietary records, food frequency records, and dietary history accounts (Matulka, 2005). For example, one database may be based on an individual's food intake from the past 24 hours, while another may utilize dietary records taken over a three-day period of time, and yet another may cover average consumption over 14 days. Some databases may provide only general population consumption values, while others may provide a detailed breakout of particular subpopulations (e.g., the elderly, women, teenagers).

In safety assessments, one must consider other sources of consumption for the proposed intended use of the food additive, such as whether it is already used in food for another purpose, is used in nonfood products (e.g., toothpaste, lipstick, drugs), or the additive occurs naturally in foods. In summary, to estimate human consumption of a particular food substance, it is necessary to know (1) the levels of the substance in food, (2) the daily intake of each food containing the substance, (3) the distribution of food intake within the population, and (4) the potential exposure to the substance from nonfood sources (Tennant, 2002).

---

[2] The Agency is in the process of updating the Redbook and is now making Redbook 2000 chapters available electronically (http://www.cfsan.fda.gov/~redbook/red-toca.html). The Redbook 2000 chapters now substitute for, or supplement, guidance available in the 1982 Redbook I and in the 1993 Draft Redbook II, which can be obtained from the Office of Food Additive Safety. As additional chapters of Redbook 2000 are completed they will become available electronically.

Before a food additive is approved, evidence is required by regulatory agencies that indicate the additive is safe for its intended use(s) and that the EDI for the additive is less than its acceptable daily intake (ADI) (Butchko and Kotsonis, 1996). Regulatory agencies may impose restrictions on certain uses of food additives if the EDI exceeds the ADI, or restrict future approvals for new categories of use. Chronic, long-term rodent toxicity studies are usually used in determining the ADI. These studies are used to determine the no-observed-adverse-effect level (NOAEL) for the additive. To provide an adequate level of safety from animal to human extrapolation, a 100-fold safety factor is usually employed to account for species differences and the inter-individual variation among humans, to determine the ADI for a food additive. This factor provides a reasonable certainty in estimating safe doses in humans from animal studies (Lehman and Fitzhugh, 1954).[4]

Assignment of Concern Level (CL) and Required Testing

Structure–activity (SA) relationships are now the basis for developing many therapeutic drugs, pesticides, and food additives. These relationships are put to good use in the Toxicological Principles for the Safety Assessment of Direct Food Additives and Color Additives Used in Foods (FDA, 1982a), which describes a qualitative "decision tree" that assigns categories to substances on the basis of the structural and functional groups in the molecule. Additives with functional groups with a high order of toxicity are assigned to category C, those of unknown or intermediate toxicity are assigned to category B, and those with a low potential for toxicity are assigned to category A. For example, a simple saturated hydrocarbon alcohol such as pentanol would be assigned to category A. Similarly, a substance containing an α,β-unsaturated carbonyl function, epoxide, thiazole, or imidazole group would be assigned to category C. Thus, based on structure assignment and calculated exposure, the Concern Levels (CLs) are assigned (Table 30–11). For example, 0.03 ppm of a substance in Structure Category B would be assigned

to CL II. In contrast, the same dose (i.e., 0.03 ppm) of a substance in Structure Category A would be assigned to the lesser CL I.

Once the CL is established, a specific test battery is prescribed, as shown in Table 30-8. The tests for CL III are the most demanding and provide the greatest breadth for the determination of adverse biological effects, including effects on reproduction. The tests are comprehensive enough to detect nearly all types of observable toxicity, including malignant and benign tumors, preneoplastic lesions, and other forms of chronic toxicity. The tests for CL II are of intermediate breadth. These tests are designed to detect the most toxic phenomena other than late-developing histopathological changes. The short-term (genotoxicity) tests are intended to identify substances for which chronic testing becomes critical. The CL I test battery is the least broad, as is appropriate for the level of hazard which substances in this category may pose. However, if untoward effects are noted, additional assessment becomes necessary. Studies of the absorption, distribution, metabolism, and elimination characteristics of a test substance are recommended before the initiation of toxicity studies longer than 90 days' duration. Of particular importance for many proposed food ingredients is data on their processing and metabolism in the GI tract.

Unique to food additive carcinogenicity testing is the controversial use of protocols that include an in utero phase. Under such protocols, parents of test animals are exposed to the test substance for 4 weeks before mating and throughout mating, gestation, and lactation. Most countries and international bodies do not subscribe to the combining of an in utero phase with a rat carcinogenicity study, as this presents a series of logistical and operational problems and substantially increases the cost of conducting a rat carcinogenicity study. The FDA began requesting in utero studies of the food industry in the early 1970s, when it was discovered from lifetime feeding studies that the artificial sweetener saccharin produced bladder tumors in male rats when in utero exposure was introduced. Subsequently, the FDA required the food, drug, and cosmetic color industries to conduct lifetime carcinogenicity feeding studies of 18 color additives in rats using an in utero exposure phase.

Special note should also be made of genetic toxicity testing. Genetic toxicity tests are performed for two reasons: (1) to test chemicals for potential carcinogenicity and (2) to assess whether a chemical may induce heritable genetic damage. Currently, genetic toxicity assays can be divided into three major groups: (1) forward and reverse mutation assays (e.g., point mutations, deletions), (2) clastogenicity assays detecting structural and numerical changes in chromosomes (e.g., chromosome aberrations, micronuclei), and (3) assays that identify DNA damage (e.g., DNA strand breaks, unscheduled DNA synthesis).

Because the correlation between carcinogens and mutagens has proved to be less than desirable, as has been demonstrated by false–positive and false–negative findings when carcinogens and noncarcinogens have been examined in genetic toxicity tests, it is recommended that several tests be selected from a battery of tests. It should be kept in mind that as the number of tests employed increases, the possibility of false-negative results increases as well. Consequently, the National Toxicology Program (NTP) has advised that only a single gene mutational assay be used (*Salmonella typhimurium*) to optimize the prediction of carcinogenicity (Tennant and Zeiger, 1993).

Safety Determination of Indirect Food Additives   Indirect food additives are food additives that are not added directly to food but

enter food by migrating from surfaces that contact food. These surfaces may be from packaging material (e.g., cans, paper, plastic) or the coating of packaging materials or surfaces used in processing, holding, or transporting food.

Essential to demonstrating the safety of an indirect additive are extraction studies with food-simulating solvents. The FDA recommends the use of three food-simulating solvents—10% ethanol, 50% ethanol, and corn oil or a synthetic triglyceride—for aqueous and acidic, alcoholic, and fatty foods, respectively (FDA, 2002a). The conditions of extraction depend in part on the intended conditions of use. Extraction studies are used to assess the level or quantity of a substance that might migrate and become a component of food, leading to consumer exposure.

To convert extraction data from packaging material into anticipated consumer exposure, the FDA has determined the fraction of the U.S. diet which comes into contact with different classes of material: glass, metal (coated and uncoated), paper (coated and uncoated), and polymers. For each class, the FDA has assigned a "consumption factor" (CF), which is the fraction of the total diet that comes into contact with an individual class of material.

The fraction of individual food types (aqueous, acidic, alcoholic, fatty) for which such packaging material is used is referred to as the food-type-distribution factor (f_T). To calculate cumulative estimated daily intake (CEDI), the following equation is used:

$$\text{CEDI} = \text{CF} \times [(f_{T\,aqueous} + f_{T\,acidic}) \times (\text{ppm of migrating substance}$$
$$\text{in 10\% ethanol}) + (f_{T\,alcoholic} \times \text{ppm of migrating}$$
$$\text{substance in 50\% ethanol}) + (f_{T\,fatty} \times \text{ppm of}$$
$$\text{migrating substance in corn oil})] \times 3\,\text{kg/person/day}$$
$$= \text{mg/person/day}[5].$$

For additives with virtually no migration (<0.5 ppb), in which the CEDIs correspond to 1.5 μg/person/day, no safety studies are recommended. Migration levels, as determined by extraction studies, that are greater than 0.5 ppb to 50 ppb (150 μg/person/day), in vitro genotoxicity tests should include bacterial mutagenicity and cytogenetic evaluation of chromosomal damage using mammalian cells or an in vitro mouse lymphoma assay. Where there is significant migration, i.e., 50 ppb to 1 ppm (3 mg/person/day), genetic toxicity tests should be conducted and the substance should be further evaluated by two subchronic oral toxicity studies (one in a rodent species

and one in a nonrodent species). The studies should provide an adequate basis for determining an acceptable daily intake (ADI) for the indirect additive or a constituent in the indicated range of CEDIs. In addition, the results of these studies will help determine whether longer-term or specialized safety tests (e.g., metabolism studies, teratogenicity studies, reproductive toxicity studies, neurotoxicity studies, and immunotoxicity studies) should be conducted to assess the safety of these substances. For cumulative exposure greater than 1 ppm, FDA recommends submission of a food additive petition (FDA, 2002a).

Safety Requirements for GRAS Substances In spite of the fact that the FD&C Act and the relevant regulations scrupulously avoid defining food except in a functional sense—"food means articles used for food or drink for man or other animals... [and includes] chewing gum, and... articles used for components of any such article"—it regards foods as GRAS when they are added to other food, for example, green beans in vegetable soup (Kokoski *et al.*, 1990; Burdock and Carabin, 2004). It also regards a number of food ingredients as GRAS, and these ingredients are listed under 21 CFR 182, 184, and 186. However, the language used acknowledges that there are substances the FDA considers to be GRAS which are not listed. This accomplishes two things: (1) It leaves the door open for additional nonlisted substances to be affirmed as GRAS by the agency and (2) reinforces the concept that substances can be deemed GRAS whether or not they are listed by the FDA or on a publicly available list. A list of examples of substances regarded as GRAS is given in Table 30-12. It is important to re-emphasize that GRAS substances, though used like food additives, are not food additives. Although the distinction may seem to be one of semantics, it allows GRAS substances to be exempt from the premarket clearance restrictions enforced by the FDA and exempt from the Delaney carcinogens clause, because that clause of the Act pertains only to food additives.[6]

While the courts have ruled that GRAS substances must be supported by the same quantity and quality of safety data that support food additives, this does not mean that the data must be identical in nature and character to those for a food additive. For uses of substances to be eligible for classification as GRAS, there must be common knowledge throughout the scientific community about the safety of substances directly or indirectly added to food (21 CFR

---

[5] The 3 kg is FDA's value for daily food consumption which, when multiplied by mg/kg (ppm) and the weighting factors, reduces to milligrams of the additive *per* day.

186.1374	Iron oxides	Ingredient of paper and paperboard

170.30); this is termed the "common knowledge standard" by FDA.[7] The studies relied on for concluding that a given use of a substance is GRAS ordinarily are based on generally available data and information published in the scientific literature. Such data are unlikely to be conducted in accordance with FDA-recommended protocols, as these studies often are conducted for reasons unrelated to FDA approval. Thus, the first basis for a GRAS determination is by "scientific procedures" (i.e., test data). GRAS status also can be based on experience with common use in food before January 1, 1958,[8] which further distinguishes GRAS data requirements from those demanded of food additives. Such experience need not be limited to the United States, but if it comes from outside the United States, it must be published or corroborated by an independent source. The FDA has made it clear, that while an ingredient may have an extensive history of use prior to 1958, this does not place it beyond regulatory reach, as new data generated must be taken into account—new data trumps history of use.[9]

Importance of the GRAS Concept

The importance of the GRAS provision is obvious from its many applications. Many substances, for example, that are used in food processing have never received formal FDA approval. The use of these substances in the manufacture of food products is considered appropriate under cGMPs, while the substance itself is considered GRAS for such purposes. Similarly, certain substances are permitted as optional ingredients in standardized foods [foods with standards of identity specified by regulation (21 CFR 130-169)] even though they are not approved food additives and are not on any of the GRAS lists.

The GRAS concept as traditionally applied in the United States also has applicability to certain novel foods which may differ only slightly from traditional foods or which, after careful consideration, can be regarded as raising no issues or questions of safety beyond that raised by the traditional foods they are intended to replace. The GRAS approach may therefore permit the introduction of novel foods that contain less saturated fat and/or cholesterol or more fiber or are in other ways modified.

Transgenic Plant (and New Plant Varieties) Policy Crops have been genetically modified using conventional breeding methods for more than a hundred years to produce new plant varieties with improved characteristics. Methods such as wide crosses of distantly related species that normally would not interbreed and mutagenesis of developing seeds using radiation or chemical mutagens have been successfully employed to produce genetic variation for selection of improved plant varieties. Over the past decade, scientists have employed biotechnology to add one or more specific genes into crops like soybean, corn, cotton, and canola, to improve pest and disease management, resulting in agronomic, economic, environmental, health, and social benefits for farmers (Brooker and Barfoot, 2005; James, 2006). For example, much of the corn crop planted in the United States contains a gene from the bacterium Bacillus thuringiensis that produces a Bt insecticidal protein (James, 1999). Bt is a protein toxic to certain caterpillar insect pests that destroy corn plants (EPA, 1988; McClintock *et al*., 1995). By enabling the corn plant to protect itself from this insect pest, the use of this product can reduce the need for and use of conventional insecticides (Gianessi and Carpenter, 1999).

Irrespective of the breeding method used to produce a new plant variety, tests must be done to ensure that the levels of nutrients or toxins in the plants have not changed and that the food is still safe to consume. For food/feed from biotechnology-derived crops, compositional analyses are done to ensure that the levels of key nutrients or toxins are comparable to food from conventional varieties. This is also done for a few conventionally bred crops where levels of important toxins such as glyoalkaloids in potatoes and erucic acid in rapeseed oil have been monitored. The International Life Sciences Institutes (ILSI, 2006) supports a large crop composition database that provides information on the natural variability in composition for conventional corn, soybean, and cotton crops. This database provides a reference for comparing the nutrient composition of new crop varieties (Taylor *et al*., 1999; George *et al*., 2004; Herman *et al*., 2004; Oberdoerfer *et al*., 2005). Animal feeding studies are also done with biotechnology-derived crops fed over several weeks to months to a variety of farm animal species

---

[7] http://www.cfsan.fda.gov/~rdb/opa-g092.html (site visited 10 April 2006).

[8] There are some exceptions to this rule. In at least one case, FDA has indicated that use before 1958 was not sufficient to demonstrate safety. (See GRAS Notice No. GRN 00040 on mineral oil). http://www.cfsan.fda.gov/~rdb/opa-g040.html, site visited 9 April 2006).

[9] http://www.cfsan.fda.gov/~rdb/opa-g071.html (site visited 10 April 2006).

to ensure that the performance (feed efficiency, milk production, etc.) is comparable to that of conventional controls (Flachowsky *et al.*, 2005). Food safety studies have also been done with various biotechnology-derived crops to ensure that there are no treatment-related adverse findings (Brake and Evenson, 2004; Hammond *et al.*, 2005; MacKenzie *et al.*, 2005). Clearly, new proteins produced in plant varieties must be nontoxic and not have the characteristics of proteins known to cause allergies. Thus, the proteins produced in genetically modified crops are evaluated for toxicity (Sjoblad *et al.*, 1992; Harrison *et al.*, 1996; Betz *et al.*, 2000; Pariza and Johnson, 2001) and allergenicity (Metcalf *et al.*, 1996; Astwood *et al.*, 2003). The DNA that is introduced into genetically modified plants to direct the production of such new proteins has been determined to be Generally Recognized As Safe (FDA, 1992).

The safety of new plant varieties (transgenic plants, genetically modified plants) is regulated primarily under the FDA's post-market authority [section 402(a)(1) of the FD&C Act]. This section, previously applied to occurrences of unsafe levels of toxicants in food, is now applied to new plant varieties whose composition has been altered by an added substance. The new policy has been applied to plants containing substances that are GRAS [Federal Register 57(104): 22984–23005]. The *Federal Register* notice (May 29, 1992) indicates that "[i]n most cases, the substances expected to become components of food as a result of genetic modification of a plant will be the same as or substantially similar to substances commonly found in food, such as proteins, fats and oils, and carbohydrates." The notice also indicates the responsibility of the FDA to exercise the premarket review process when the "objective characteristics of the substance raise questions of safety." In regard to substances within the new variety that are not similar to substances commonly found in food, a food additive petition may have to be filed.

The *Federal Register* notice offers points of consideration for the safety assessment of new plant varieties (Table 30-13). Accompanying these points of consideration are a decision flowchart and advice that the FDA be consulted on certain findings, for example, transference of allergens from one plant to another, a change in the concentration or bioavailability of nutrients, and the introduction of a new macroingredient.

In the United States new plant varieties are regulated not only by the FDA, but also by the Environmental Protection Agency (EPA) and U.S. Department of Agriculture (USDA). The FDA is responsible for the safety and labeling of foods and feeds derived from crops, irrespective of the method used to produce the new plant variety. The EPA is responsible for assuring the safety of pesticides, thus in the example cited above whereby a pesticide is produced in a new plant variety, this product would also fall under EPA's juris-

diction. The USDA's Animal and Plant Health Inspection Service has responsibility for the environmental safety of field-testing and commercial planting of new plant varieties.

The developer of a biotechnology-derived crop variety must obtain registration from not only the country of origin but from importing countries as well (OECD, 1993). A variety of European/Global Scientific authorities (WHO, 1995; FAO, 1996; OECD, 1997; Codex, 2003; EFSA, 2004) have provided guidance on the safety assessment process for food and feed derived from biotechnology-derived crops. The process considers two main categories of potential risks: those related to the properties and function of the introduced protein(s), and those related to the whole food crop since insertion of the introduced gene(s) into the plant genome theoretically could cause unintended environmental effects. As in conventional crop breeding, agronomic studies carried out under diverse environmental conditions are used to screen for varieties that exhibit unintended changes so they can be eliminated from development.

Methods for Establishing Safe Conditions of Use for Novel Foods

Novel foods, including those derived from new plant varieties and macroingredient substitutes, present new challenges and may require new methods of determining safety. For example, with each new additive, it has been traditional (and rooted in a regulation such as 21 CFR 170.22) to establish an ADI, which is usually based on 1/100 of the NOEL established in animal testing. This works well for additives projected to be consumed at a level of 1.5 g/d or less (which is equal to or less than 25 mg/kg), for this extrapolates at a 100-fold safety factor to consumption by a rat at a level of 2500 mg/kg/d (about 5% of the rat's diet). The problem arises when a new food or macroingredient substitute becomes a substantive part of the diet (estimated to constitute as much as 15–20%). For example, a macroingredient substitute or food projected to be consumed at a level of just 5% of the diet (150 g/d) would require the test animal (rat) to consume 250 g/kg/d, or slightly more than the rat's body weight. This is an untenable test requirement, for at those levels, the investigator would establish an effect level only for malnutrition, not for the toxicity of the macroingredient. The converse is true for some essential nutrients, such as vitamins A and D and iron, which at doses 100 times the nutritional use level would be toxic (Kokoski *et al.*, 1990). The answer therefore lies in careful interpretation of toxicological data and the conduct, where appropriate, of special studies to assess drug interactions, nutrient interactions changes in gut flora, changes in gut activity, and the like (Munro, 1990; Borzelleca, 1992a,b). Also, it may be appropriate to consider what effect, if any, macroingredients may have on individuals with compromised digestive tracts, those dependent on laxatives, and those on high-fiber diets.

The regulatory approval of a new food additive is generally based on traditional toxicology studies. The rationale is that data from such studies will adequately predict adverse effects that could occur in humans. However, such studies, especially for novel foods, may not be adequate. Therefore, although human studies are not generally required for food additives, in the case of novel foods, human studies are likely essential in evaluating their safety (Stargel *et al.*, 1996).

Another useful tool in ensuring the safety of a food additive is monitoring it after its approval, or postmarketing surveillance. With widespread use of a food additive, *monitoring for consumption* can determine whether actual consumption exceeds the EDI and

Table 30-13

Points of Consideration in the Safety Assessment of New Plant Varieties

Toxicants known to be characteristic of the host and donor species

The potential that food allergens will be transferred from one food source to another

The concentration and bioavailability of important nutrients for which a food crop is ordinarily consumed

The safety and nutritional value of newly introduced proteins

The identity, composition, and nutritional value of modified carbohydrates or fats and oils

monitoring for anecdotal complaints may identify adverse health effects that escaped detection in earlier studies. This could be especially important for novel foods when traditional toxicology studies are not done at large multiples of the EDI (Butchko *et al*., 1994, 1996a). Thus, the combination of traditional toxicity studies, special animal and human studies, and possibly postmarketing surveillance will ensure the safety of consumers and provide evidence to justify a safety factor different from 100.

Nanotechnology   Nanotechnology offers some distinct advantages in delivery systems using micelles and liposomes and other technological advantages as nanoemulsions (emulsion stability), biopolymeric nanoparticles (encapsulation technology), and cubosomes (solubilize hydrophobic, hydrophilic, and amphiphilic molecules, among other uses), thus allowing new and more efficient uses of old products. Nanotechnology can enhance solubility, facilitate controlled release, improve bioavailability, and protect labile substances (including micronutrients and bioactive substances) during processing, storage, and distribution (Chen *et al*., 2006).

Although the GI tract is an organ for absorption, it is also the first barrier to substances that we do not wish to absorb (e.g., large molecules such as colors) or serve their function best by not being absorbed (e.g., fiber). The question then arises as to what impact nanotechnology might have on this balance. Size has always mattered and in the range of what has been accepted as "nano",[10] many of the principles of absorption (as well as distribution, metabolism, and excretion) may be affected (EPA, 2005). Further, a striking observation regarding particle health effects is the ability of particles to generate toxic effects at the site of initial deposition as well as significant systemic toxic responses (EPA, 2004). Another observation that "size does matter" is that degraded carregeenan (MW 30,000) may have carcinogenic properties,[11] while undergraded carrageenan (MW 100,000) apparently does not. Also, food packaging can incorporate the ultraviolet-blocking material, TiO_2, but because titanium dioxide's safety is predicated upon its lack of absorption (IFST, 2006b), the use of nanotechnology may ultimately mandate a new safety review. Presently, the FDA has taken no action on nanotechnology, as it prefers to regulate on a product-by-product basis and does not regulate a technology.[12]

Safety Requirements for Dietary Supplements

Dietary supplements have a special status within the law and the regulations—supplements are regarded as foods or food constituents and not food additives, nor drugs. There is also a different standard of safety, the concept of *reasonable expectation of no harm*, although articulated in the Federal Food Drug and Cosmetic Act (FFDCA) definition of adulterated food (Section 402) as [no] "significant or unreasonable risk of illness or injury."[13] This is a lesser safety stan-

dard than the *reasonable certainty* standard for substances *added to foods*. The basis for this rationale is that consumption of a dietary supplement is by choice, not involuntary as for a food (i.e., food must have a presumption of safety and therefore, the higher standard of safety). Therefore, because there is (1) a deliberate choice involved in consuming a dietary supplement and (2) because the daily recommended intake is clearly stated on the label, there is an implied assumption of some risk on the part of the consumer.

In many respects, passage of the Dietary Supplement Health and Education Act (DSHEA) in October, 1994, was a safety valve, venting consumer discontent with the high degree of restriction placed upon health claims and the narrowing of the window of availability of dietary supplements as the result of actions by the FDA. In response to these pressures, a tacit bargain between Congress and the consumers was struck, whereby Congress granted continued access by the public to dietary supplements by (1) providing for this lower threshold of evidence for safety, (2) changing the role of the FDA from gate-keeper to policeman (i.e., abandoning pre-market approval),[14] and (3) allowing a type of claim (i.e., structure function claims, not health claims). The consumer's concessions were that (1) supplements could not be added to food (because of the lower threshold for safety), (2) consumption will always remain the product of an overt, voluntary act on the part of the consumer (a dietary supplement can never be represented as a food or meal replacement), and (3) because the recommended daily dose is presented on the supplement, the consumer will assume at least some risk[15] from consumption (articulated by the standard of reasonable *expectation* of no harm (21 CFR 190.6(a)[16]). As a final safeguard, Congress empowered the *Secretary* of Health and Human Services HHS (not the *Commissioner* of FDA), to take action through the "imminent hazard" clause of the regulation if a supplement is determined to have an unexpected consequence (Burdock, 2000; Mackey and Kotsonis, 2002; Burdock *et al*., 2006).

Assessment of Carcinogens

Carcinogenicity as a Special Problem   Congress provided the FDA with wide latitude in assessing safety and assuring a safe food supply with one exception. That exception is a provision of the FD&C Act known as the Delaney clause, which prohibits the approval of regulated food additives "found to induce cancer when ingested by man or animals" [sections 409(c)(3)(A), 706(b)(5)(B), and 512(d)(1)(H)].

The Delaney prohibition applies only to the approval of food additives, color additives, and animal drugs; it does not apply to unavoidable contaminants or GRAS substances or ingredients sanctioned by the FDA or USDA before 1958. The clause also does not apply to constituents that are present in food or color additives or animal drugs, provided that the level of such contaminants can be demonstrated to be safe and the whole additive, including its contaminants, is not found to induce cancer in humans or animals.

---

[10] A nonometer is one billionth of a meter (10^{-9} m)—about one ten-thousandth of the diameter of a human hair, a thousand times smaller than a red blood cell, or about half the size of the diameter of DNA (EPA, 2005).

[11] Degraded carrageenan is classified by the International Agency for Research on Cancer (IARC) as 2B, a possible human carcinogen, based on animal study data. Native carrageenan has been classified by IARC as 3, unclassifiable with respect to carcinogenicity in humans.

[12] FDA Regulation of Nanotechnology Products (http://www.fda.gov/nanotechnology/regulation.html) (site visited 9 April 2006).

[13] Also articulated in the FFDCA (§413) as "reasonably be expected to be safe".

[14] FFDCA§402(f)(1) "In any proceeding under this subparagraph, *the United States shall bear the burden of proof* on each element to show that a dietary supplement is adulterated."

[15] FDA has stated that it would use a "reasonable consumer" standard in determining whether a claim is misleading. The reasonable consumer standard replaced the standard of "the ignorant, the unthinking, and the credulous" consumer, used by courts at the request of FDA in the past (Walsh *et al*., 2005).

[16] Referred in the FFDCA (§402(f)(1)(A)) as "significant or unreasonable risk of illness or injury."

Table 30-14
Uncertainty Parameters and Their Associated Range of Risk Factors

UNCERTAINTY PARAMETERS	ESTIMATED RANGE (FACTOR)
Extrapolation model	1–10,000
Total dose vs. dose rate	30–45
Most sensitive sex/strain vs. average sensitivity	1–100
Sensitivity of human vs. test animal	1–1000
Potential synergism or antagonism with other carcinogens or promoters	1–1000?
Total population vs. target population, potential vs. actual market penetration	1–1000
Absorptive rate (gut, skin, lung) for animals at high dose vs. humans at low dose	1–10
Dose scaling: mg/kg body weight, ppm (diet, water, feed) surface area	1–15
Upper confidence on users or exposed	1–10
Specifications or tolerances	1–10
Limits of detection vs. actual levels	1–1000
Additivity vs. nonadditivity of multiple sites	1–3
Survival or interim sacrifice adjustments	1–2
Knowledge of only high-end plateau dose response	1–10
Error or variation in detection methods	1–10
Adjustments for less than lifetime bioassays	1–100
Adjustments for intermittent and less than lifetime human exposure	1–100
Use vs. nonuse of historical data	1–2
Upper confidence and lower confidence limits vs. expected values in extrapolation level of acceptable risk	1–1000
Level of acceptable risk	1–1000
Adding or not adding theoretical risks from many substances	1–100

SOURCE: Flamm WG, Lorentzen RJ: Quantitative risk assessment (qra): A special problem in the approval of new products, in Cothern CR, Mehlman MA, Marcus WL (eds.): *Risk Assessment and Risk Management of Industrial and Environmental Chemicals.* Princeton Scientific Publishing Co., Inc., Princeton, NJ, 1988.

This interpretation of the Delaney clause was set forth by the FDA in its so-called "constituent policy" published on April 2, 1982, as an Advanced Notice of Proposed Rulemaking (ANPR). The policy mandates the development and use of animal carcinogenicity data and probabilistic risk assessment to establish a safe level for the contaminant in the additive under its intended conditions of use.

The constituent policy and, as will be discussed later, the implementation of the so-called DES (diethylstilbestrol) proviso for animal drugs under the Delaney clause have forced the FDA to develop a means for establishing safe levels for carcinogenic substances. The DES proviso allows the addition of carcinogenic animal drugs to animal feed if they leave no residue in edible tissue as determined by an approved analytic procedure. To do this, the FDA has turned to the use of probabilistic risk assessment in which tumor data in animals are mathematically extrapolated to an upper bound risk in humans exposed to particular use levels of the additive. The FDA takes the position that considering the many conservative assumptions inherent in the procedure, an upper bound lifetime risk of one cancer in a million individuals is the biological equivalent of zero.

Much controversy surrounds the use of risk assessment procedures, in part because estimates of risk are highly dependent on the many assumptions that must be made. The common practice of testing at a maximum tolerated dose (MTD) (Williams and Weisburger, 1991) raises the question of appropriateness to human exposure. Do high test doses cause physiological changes unlike those from human exposure? The basic assumption in quantitative risk assessment (QRA) that the dose–response curve is linear beneath the lowest observable effect may result in the calculation of relatively high risks even at doses that are much lower than the lowest dose that produces cancer in experimental animals. QRA is more a process than a science; many steps in the process are based on assumptions, not

proven scientific facts. If only the most conservative assumptions are made throughout the process, many will represent overestimates of human risk by 10- or 100-fold, leading to a combined overestimate of perhaps a million-fold or more. Table 30-14 provides some rough estimates of potential ranges of uncertainty that might lead to large overestimates (Flamm and Lorentzen, 1988).

Historically, the FDA has employed a high threshold for establishing that a food or color additive has been found to induce cancer when ingested by humans or animals. If these additives are found to induce cancer, they cannot be approved for foods or colors no matter how small the estimated risk. In the end, very few substances have been disapproved or banned because of the Delaney clause. Two indirect food additives (Flectol H and mercaptoimidazoline) that migrate from packaging material were banned. Among direct additives, safrole, cinnamyl anthranilate, thiourea, and diethylpyrocarbonate were banned because of the Delaney clause, diethylpyrocarbonate because it forms urethane.

A number of substances (e.g., butylated hydroxyanisole (BHA), xylitol, methylene chloride, sorbitol, trichloroethylene, nitrilotriacetic acid (NTA), diethylhexyl phthalate, melamine, formaldehyde, bentonite) listed in the Code of Federal Regulation as food additives are also listed as carcinogens by National Toxicology Program (NTP), the International Agency for Research on Cancer (IARC), or the state of California (under the Safe Drinking Water and Toxic Enforcement Act of 1986, also known as Proposition 65). How is this possible, and on what basis do these food additive listings continue?

Despite the fact that tests and conditions exist under which each of these substances will produce cancer in animals, the FDA has found it possible to continue listing these substances as food additives. The reasoning applied in almost every case is based

on secondary carcinogenesis. The one exception is formaldehyde, which is carcinogenic only on inhalation, and there are compelling reasons to believe that inhalation is not an appropriate test in this case (Flamm and Frankos, 1985). Therefore, formaldehyde is not treated as a carcinogen prohibited by the Delaney clause.

For BHA, which induces forestomach cancer, the concept has been advanced that its carcinogenicity is attributable primarily to a cycle of irritation and restorative hyperplasia (Clayson *et al.*, 1986). For xylitol, a sugar alcohol, an increase in bladder tumors and adrenal pheochromocytomas is considered secondary to calcium imbalance resulting from the indigestibility of sugar alcohols and their fermentation in the lower GI tract. Sorbitol, another sugar alcohol, behaves in a similar manner. For NTA, the argument is secondary carcinogenesis, and although specific explanations vary, the mechanism involving zinc imbalance has considerable scientific support.

Thus, the FDA has generally interpreted the phrase "found to induce cancer when ingested by man or animals" as excluding cancers that arise through many secondary means. Therefore, to be a carcinogen under the Delaney clause, a food or color additive must be demonstrated to induce cancer by primary means when ingested by humans or animals or to induce cancer by other routes of administration that are found to be appropriate. This is interpreted to mean that the findings of cancer must be clearly reproducible and that the cancers found are not secondary to nutritional, hormonal, or physiological imbalances. This position allows the agency to argue that changing the level of protein or fat in the diet does not induce cancer but simply modulates tumor incidence (Kritschevsky, 1994).

Biological *vs.* Statistical Significance Much can be learned about the proper means of assessing carcinogenicity data by studying large databases for substances that have been tested for carcinogenicity many times. The artificial sweetener cyclamate is an example. The existence of more than a dozen studies on cyclamate and the testing of multiple hypotheses at dozens of different organ and tissue sites in all these studies led to the awareness that the overall false-positive error rate could be inflated if individual findings were viewed out of context (FDA, 1984). Therefore, very careful attention must be paid to the totality of the evidence.

The possibility of false–negative error is always of concern because of the need to protect public health. However, it should be recognized that any attempt to prove absolutely that a substance is not carcinogenic is futile. Therefore, an unrelenting effort to minimize false-negative errors can produce an unacceptably high probability of a false-positive. Further, demanding certainty (i.e., a zero or implicitly an extremely low probability of false-negative error) has negative consequences for an accurate decision-making process. This is the case because it severely limits the ability to discriminate between carcinogens and noncarcinogens on the basis of bioassays (FDA, 1984).

In addition to the false–positive/false–negative trap, which is a statistical matter, there are many potential biological traps. The test substance, typically administered at high MTDs, may affect one or more of the many biological processes known to modulate tumor incidence at a specific organ site without causing an induction of tumors at that or any other site. Nutritional imbalances such as choline deficiency are known to lead to a high incidence of liver cancer in rats and mice. Simple milk sugar (lactose) is known to increase the incidence of Leydig cell tumors in rats. Caloric intake has been shown to be a significant modifying factor in carcinogenesis. Im-

pairment of immune surveillance by a specific or nonspecific means (stress) affecting immune responsiveness and hormonal imbalance can result in higher incidences of tumors at specific organ sites. Hormonal imbalance, which can be caused by hormonally active agents (e.g., estradiol) or by other substances that act indirectly, such as vitamin D, may result in an increased tumor incidence. Chronic cell injury and restorative hyperplasia resulting from treatment with lemon flavor (D-limonene) probably are responsible for renal tumor development in male rats by mechanisms that are of questionable relevance to humans (Flamm and Lehman-McKeeman, 1991). In these examples, the increases in tumor incidence at specific organ sites probably are secondary to significant changes in normal physiological balance and homeostasis. Moreover, the increases in tumor incidence, and hence the increases in the risk of cancer, probably would not occur except at toxic doses (Ames and Gold, 1997).

To preserve the ability of a bioassay to discriminate between carcinogens and noncarcinogens, the possibility of false–positive or false–negative results and the possibility of secondary effects must be considered. To be meaningful, evaluations must be based on the weight of evidence. Particular attention must be given to the many factors that are used in deciding whether tumor incidences are biologically as well as statistically significant. These factors include (1) the historical rate of the tumor in question (is it a rare tumor, or does it occur frequently in the controls?); (2) the survival histories of dosed and test animals (did dosed animals survive long enough to be considered "at risk" and what effect did chemical toxicity and reduced survival have in the interpretation of the data?); (3) the patterns of tumor incidence (was the response dose-related?); (4) the biological meaningfulness of the effect (was it experimentally consistent with the evidence from related studies and did it occur in a target organ?); (5) the reproducibility of the effect with other doses, sexes, or species; (6) evidence of hyperplasia, metaplasia, or other signs of an ongoing carcinogenic process (is the effect supported by a pattern of related non-neoplastic lesions, particularly at lower doses?); (7) evidence of tumor multiplicity or progression; and (8) the strength of the evidence of an increased tumor incidence (what is the magnitude of the p value, for pairwise comparison and for trend?).

A good discussion of the use of these factors by scientists in deciding whether a substance induces cancer in animals is contained in the notice of a final rule permanently listing FD&C Yellow No. 6 (51 *Federal Register* 41765–41783, 1988). An elevation of tumor incidence in rats was identified at two organ and/or tissue sites: (1) medullary tumors of the adrenal glands in female rats only and (2) renal cortical tumors in female rats only. Scientists at the FDA concluded that the increase in medullary tumors of the adrenal glands in female rats did not suffice to establish that FD&C Yellow No. 6 is a carcinogen. The basis for the decision was (1) a lack of dose response, (2) the likelihood of false positives, (3) the lack of precancerous lesions, (4) morphological similarity of adrenal medullary lesions in treated and control rats, (5) an unaffected latency period, (6) a lack of effect in male rats, and (7) a comparison with other studies in which there was no association between exposure to FD&C Yellow No. 6 and the occurrence of adrenal medullary tumors.

A similar judgment was made with respect to the cortical renal lesions in female rats, which were not found to provide a basis for concluding that FD&C Yellow No. 6 can induce cancer of the kidneys. The main reasons leading to this conclusion were (1) the relatively common occurrence of proliferative renal lesions in aged male control rats (28 months or older), (2) the lack of renal tumors in treated males despite their usually greater sensitivity

to renal carcinogens, (3) the lack of malignant tumors indicating no progression of adenomas to a malignant state, (4) the lack of a decreased latency period compared with controls, (5) the coincidence of renal proliferative lesions and chronic renal disease, (6) the lack of genotoxicity, and (7) a lack of corroborative evidence from other studies that suggests a treatment-related carcinogenic effect of FD&C Yellow No. 6 on the kidney. Both these examples emphasize the importance of considering all the evidence in attempting to decide the significance of any subset of data.

As essential elements, vitamins, sugars, and calories by themselves can increase tumor incidence in test animals; the mechanism by which tumors arise as the result of exposure to food or food ingredients is critically important to assessing the relevance of the finding to the safety of the substance under its intended conditions of use in food. McClain (2002) provides an excellent discussion of mechanistic considerations in the regulation and classification of chemical carcinogens.

Carcinogenic Contaminants The Delaney clause, which prohibits the addition of carcinogens to food, could ban many food additives and color additives if strictly interpreted to include contaminants of additives within its definition. Clearly, this was not Congress's intent, and just as clearly, the FDA needed to develop a common sense policy for addressing the problem that all substances, including food and color additives, may contain carcinogenic contaminants at some trace level.

Toward this end, the agency argued (FDA, 1982b) that banning food and color additives simply because they have been found or are known to contain a trace level of a known carcinogen does not make sense because all substances may contain carcinogenic contaminants. The agency asserted in its constituent policy that the mere fact an additive contains a contaminant known to be carcinogenic should not automatically lead the agency to ban that food additive but should instead cause the agency to consider the health risks it poses based on its level of contamination and the conditions of its use (FDA, 1977).

SAFETY OF FOOD

Adverse Reactions to Food or Food Ingredients

In a survey of Americans, 30% indicated that they or someone in their immediate families has a food sensitivity of one type or another. Although this number is likely too high, as much as 7.5% of the population may be allergic (i.e., their body's immune system is activated due to exposure to food ingredient) to some food or component thereof, such as a peanut allergy (Taylor *et al.*, 1989). Lactose intolerance (a deficiency of the disaccharide enzyme, lactase) is high among some groups; for example, there is an incidence of 27% in black children age 12–24 months, which may increase to 33% by age six years (Juambeltz *et al.*, 1993). The percentage of young northern European children allegedly intolerant to food additives ranges from 0.03 to 0.23% (Wuthrich, 1993) to 1–2% (Fuglsang *et al.*, 1993). Further, there are certain drug–food incompatibilities about which physicians and pharmacists are obligated to warn patients, such as monoamine oxidase (MAO) inhibitors and tyramine in cheese or benzodiazapenes and naringenin in grapefruit juice. People who are prescribed tetracycline also must be alerted not to take milk with this antibiotic. By any standard, there are large numbers of real and perceived adverse reactions to or incompatibilities with food (Thomas and Cotter, 2002). The first step in understanding

these reactions is to define the nomenclature, a task undertaken by the American Academy of Allergy and Immunology (Committee on Adverse Reactions to Foods) and the National Institute of Allergy and Infectious Diseases (Anderson and Sogn, 1984). An adaptation of their definitions and classification is represented in Table 30-15. In the table, the definitions proceed from general to more specific. Obviously, there is little to distinguish the terms "adverse reaction" and "sensitivity" to a food or a food "intolerance," except perhaps in the lexicon of the individual, colored by his or her own experience. That is, an "adverse reaction" may indicate something as simple as an unpleasing esthetic or hedonic quality such as an unpleasant taste, which may in fact have a genetic basis as in the ability to taste phenylthiocarbamide (Guyton, 1971), or may indicate a fatal outcome resulting from an immune or toxic reaction.

Clinical descriptions of adverse reactions to food are not new. Hippocrates (460–370 B.C.) first recorded adverse reactions to cow's milk that caused gastric upset and urticaria, and Galen (AD 131–210) described allergic symptoms to goat milk. However, the immunologic basis of many adverse reactions to food was not established until the passive transfer of sensitivity to fish was described in the early 1960s (Frankland, 1987; Taylor *et al.*, 1989; Taylor and Hefle, 2002). This test, which evolved into the (skin) prick test and later the Radioallergosorbent (RAST) test, allowed a distinction to be made between immunologically based adverse reactions (true allergies) and adverse reactions with other causation.

Food Allergy

Description Food hypersensitivity (allergy) refers to a reaction involving an immune-mediated response. Such a response is generally IgE-mediated, although IgG_4- and cell-mediated immunity also may play a role in some instances (Fukutomi *et al.*, 1994). What generally distinguishes food allergy from other reactions is the involvement of immunoglobulins, basophils, or mast cells (the latter being a source of mediating substances including histamine and bradykinin for immediate reactions and prostaglandins and leukotrienes for slower-developing reactions) and a need for a prior exposure to the allergen or a cross-reactive allergen. An allergic reaction may be manifested by one or more of the symptoms listed in Table 30-16. The list of foods known to provoke allergies is long and is probably limited only by what people are willing to eat. Although cutaneous reactions and anaphylaxis (i.e., severe allergic reaction, resulting in a drop of blood pressure, and may be fatal) are the most common symptoms associated with food allergy, the body is replete with a repertoire of responses that are rarely confined to only a few foods.

A curious type of food allergy, the so-called exercise-induced food allergy, is apparently provoked by exercise which has been immediately preceded or followed by the ingestion of certain foods (Kivity *et al.*, 1994), including shellfish, peach, wheat, celery, and "solid" food (Taylor *et al.*, 1989; Taylor and Hefle, 2002). The exact mechanism is unknown, but it may involve enhanced mast cell responsiveness to physical stimuli and/or diminished metabolism of histamine similar to red wine allergy (Taylor *et al.*, 1989). Meanwhile, food intolerance in patients with chronic fatigue may have less to do with allergic response and has been shown to be a somatization trait of patients with depressive symptoms and anxiety disorders (Manu *et al.*, 1993).

Chemistry of Food Allergens Most allergens (antigens) in food are protein in nature, and although almost all foods contain one

Table 30-15
Adverse Reaction to Food: Definition of Terms

TERM	DEFINITION	CHARACTERISTICS/EXAMPLES
Adverse reaction (sensitivity) to a food	General term that can be applied to a clinically abnormal response attributed to an ingested food or food additive	Any untoward pathological reaction resulting from ingestion of a food or food additive. May be immune-mediated
Food hypersensitivity (allergy)	An immunologic reaction and may occur only in some patients, may occur after only a small amount of the substance is ingested, and is unrelated to any physiological effect of the food or food additive	Immune-mediated (cellular or humoral response), requires prior exposure to antigen or cross-reacting antigen. First exposure may have been asymptomatic
Food anaphylaxis	A classic allergic hypersensitivity reaction to food or food additives	A humoral immune response most often involving IgE antibody and release of chemical mediators. Mortality may result
Food intolerance	A general term describing an abnormal physiological response to an ingested food or food additive; this reaction may be an immunologic, idiosyncratic, metabolic, pharmacological, or toxic response	Any untoward pathological reaction resulting from ingestion of a food or food additive. May be immune-mediated. Celiac disease (intolerance to wheat, rye, barley, oats)
Food toxicity (poisoning)	A term use to imply an adverse effect caused by the direct action of a food or food additive on the host recipient without the involvement of immune mechanisms. This type of reaction may involve nonimmune release of chemical mediators. Toxins may be contained within food or released by microorganisms or parasites contaminating food products	Not immune-mediated. May be caused by bacterial endo- or exotoxin (e.g., hemorrhagic *E. coli*) fungal toxin (e.g., aflatoxin), tetrodo-toxin from pufferfish, domoic acid from mollusks, histamine poisoning from fish (scombroid poisoning), nitrate poisoning (i.e., methemoglobinuria)
Food idiosyncrasy	A quantitatively abnormal response to a food substance or additive; this reaction differs from its physiological or pharma-cological effect and resembles hypersensitivity but does not involve immune mechanisms. Food idiosyncratic reactions include those which occur in specific groups of individuals who may be genetically predisposed	Not immune-mediated, Favism (hemolytic anemia related to deficiency of erythrocytic glucose-6-phosphate dehydrogenase), fish odor syndrome, beetanuria, lactose intolerance, fructose, intolerance, asparagus urine, red wine intolerance
Anaphylactoid reaction to a food	An anaphylaxis-like reaction to a food or food additive as a result of nonimmune release of chemical mediators. This reaction mimics the symptoms of food hypersensitivity (allergy)	Not immune-mediated. Scombroid poisoning, sulfite poisoning, red wine sensitivity
Food–drug interaction	A change in the pharmacokinetic or pharmacodynamic action of a drug as the result of ingestion of a food	Not immune-mediated. Ingestion of fats, phytates, or fiber to change absorption; upregulation of genes by *Brassica*, polyunsaturated fats; unregulation of polypeptide transporters by St. Johns wort
Metabolic food reaction	Toxic effects of a food when eaten in excess or improperly prepared	Cycasin, vitamin A toxicity, goiterogens, licorice

or more proteins, a few foods are associated more with allergic reactions than are others. For example, anaphylaxis to peanuts is more common than is anaphylaxis to other legumes (e.g., peas, soybeans). Similarly, although allergies may occur from bony fishes, there is no basis for cross-reactivity to other types of seafood (e.g., mollusks and crustaceans), although dual (and independent) sensitivities may exist (Anderson and Sogn, 1984). Interestingly, patients who are allergic to milk usually can tolerate beef and inhaled cattle dander, and patients allergic to eggs usually can tolerate ingestion of chicken and feather-derived particles (Anderson and Sogn, 1984), although in the "bird–egg" syndrome patients can

be allergic to bird feathers, egg yolk, egg white, or any combination of the three (DeBlay *et al*., 1994; Szepfalusi *et al*., 1994).

Some of the allergenic components of common food allergens are listed in Table 30-17. Although food avoidance is usually the best means of protection, it is not always possible because (1) the content of some prepared foods may be unknown (e.g., the presence of eggs or cottonseed oil); (2) there is the possibility of contamination of food from unsuspected sources (e.g., *Penicillium* in cheeses or meat, *Candida albicans* (Dayan, 1993; Dorion *et al*., 1994), and cow's milk antigens in the breast milk of mothers who

Table 30-16
Symptoms of IgE-Mediated Food Allergies

Cutaneous	Urticaria (hives), eczema, dermatitis, pruritus, rash
Gastrointestinal	Nausea, vomiting, diarrhea, abdominal cramps
Respiratory	Asthma, wheezing, rhinitis, bronchospasm
Other	Anaphylactic shock, hypotension, palatal itching, swelling including tongue and larynx, methemoglobinemia*

*An unusual manifestation of allergy reported to occur in response to soy or cow milk protein intolerance in infants.

have consumed cow's milk (Halken *et al.*, 1993)); (3) the presence of an allergen in a previously unknown place (the insertion of Brazil nut DNA into soybeans and subsequent appearance of the allergic 2S protein in soybean products (Nordlee *et al.*, 1996)); and (4) there is a lack of knowledge about the phylogenetic relationships between food sources (legumes include peas, soybeans, and peanuts).

Demographics of Food Allergy and Intolerance　　Although children appear to be the most susceptible to food allergy, with adverse reactions occurring in 4–6% of infants, the incidence appears to taper off with maturation of the digestive tract, with only 1–2% of young children (4–15 years) susceptible (Fuglsang *et al.*, 1993). The increase in the number of adults exhibiting food allergy may be due in part to an expanded food universe, that is, an increased willingness to try different foods. In one study, allergies among young children were most commonly to milk and eggs, whereas allergies that developed later in life tended to be to fruit and vegetables (Kivity *et al.*, 1994).

Familial relationships also play a role. Schrander and colleagues (1993) noted that among infants with cow's milk protein intolerance, 65% had a positive family history (first- or second-degree relatives) for atopy compared with 35% of healthy controls.

Table 30-18
Idiosyncratic Reactions to Foods

FOOD	REACTION	MECHANISM	REFERENCE
Fava beans	Hemolysis, sometimes accompanied by jaundice and hemoglobinuria; also, pallor, fatigue, nausea, dyspnea, fever and chills, abdominal and dorsal pain	Pyramidene aglycones in fava bean cause irreversible oxidation of GSH in G-6-PD-deficient erythrocytes by blocking NADPH supply, resulting in oxidative stress of the erythrocyte and eventual hemolysis	Chevion *et al*., 1985
Chocolate	Migraine headache	Phenylethylamine-related (?)	Gibb *et al*., 1991; Settipane, 1987
Beets	Beetanuria: passage of red urine (often mistaken for hematuria)	Excretion of beetanin in urine after consumption of beets	Smith, 1991
Asparagus	Odorous, sulfurous-smelling urine	Autosomal dominant inability to metabolize methanthiol of asparagus and consequent passage of methanthiol in urine	Smith, 1991
Red Wine	Sneezing, flush, headache, diarrhea, skin itch, shortness of breath	Diminished histamine degradation: deficiency of diamine oxidase (?) Histamines present in wine	Wantke *et al*., 1994
Choline- and carnitine-containing foods	Fish odor syndrome: foul odor of body secretions	Choline and carnitine metabolized to trimethylamine in gut by bacteria, followed by absorption but inability to metabolize to odorless trimethylamine *N*-oxide	Ayesh *et al*., 1993
Milk	Abdominal pain, bloating, diarrhea	Lactase deficiency	Mallinson, 1987
Fructose-containing foods	Abdominal pain, vomiting, diarrhea, hypoglycemia	Reduced activity of hepatic aldolase B toward fructose-1-phosphate	Frankland, 1987; Catto-Smith and Adams, 1993

Food Toxicity (Poisoning)   See "**Substances for which tolerances may not be set**."

Food Idiosyncrasy   Food idiosyncrasies are generally defined as *quantitatively* abnormal responses to a food substance or additive; this reaction differs from the physiological effect, and although it may resemble hypersensitivity, it does not involve immune mechanisms. Food idiosyncratic reactions include those that occur in specific groups of individuals who may be genetically predisposed. Examples of such reactions and the foods that probably are responsible are given in Table 30-18.

Probably the most common idiosyncratic reaction is lactose intolerance, a deficiency of the lactase enzyme needed for the metabolism of the lactose in cow's milk. A lack of this enzyme results in fermentation of lactose to lactic acid and an osmotic effect in the bowel, with resultant symptoms of malabsorption and diarrhea. Lactose intolerance is lowest in northern Europe at 3–8% of the population; it reaches 70% in southern Italy and Turkey and nearly 100% in southeast Asia (Anderson and Sogn, 1984; Gudmand-Hoyer, 1994).

Anaphylactoid Reactions   Anaphylactoid reactions are historically thought of as reactions mimicking anaphylaxis through direct application of the primary mediator of anaphylactic reactions: histamine. Ingestion of scombroid fish (e.g., tuna, mackerel, bonito) as well as some nonscombroid fish (mahimahi and bluefish) that have been acted upon by microorganisms to produce histamine may

result in an anaphylactoid reaction also called "scombrotoxicosis" (Table 30-19) (Clark *et al*., 1999). The condition was reported to be mimicked by the direct ingestion of 90 mg of histamine in unspoiled fish (Van Geldern *et al*., 1992), but according to Taylor (1986), the effect of simply ingesting histamine does not produce the equivalent effect. Instead, Taylor claims that histamine ingested with spoiled fish appears to be much more toxic than is histamine ingested in an aqueous solution as a result of the presence of histamine potentiators in fish flesh. The apparent mechanism of potentiation involves the inhibition of intestinal histamine-metabolizing enzymes (diamine oxidase), which causes increased histamine uptake. Melnik *et al*. (1997) proposed that anaphylactoid responses may be the sum of several mechanisms: (1) an increased intake of biogenic amines (including histamine) with food, (2) an increased synthesis by the intestinal flora, (3) a diminished catabolism of biogenic amines by the intestinal mucosa, and (4) an increased release of endogenous histamine from mast cells and basophils by histamine-releasing food. Scombrotoxicosis in the absence of high histamine levels (less than the FDA action level for tuna of 50 mg histamine/100 g fish) was reported by Gessner *et al*., 1996. Ijomah *et al*. (1991) claimed that dietary histamine is not a major determinant of scombrotoxicosis, because potency is not positively correlated with the dose and volunteers tend to fall into susceptible and nonsusceptible subgroups. Ijomah *et al*. (1991) suggested that endogenous histamine released by mast cells plays a significant role in the etiology of scombrotoxicosis, whereas the role of dietary histamine is minor. An exception to this endogenous histamine theory was described by Morrow *et al*. (1991), who found the

Table 30-19
Anaphylactoid Reactions to Food

FOOD	REACTION	MECHANISM	REFERENCE
Western Australian salmon (*Arripis truttaceus*)	Erythema and urticaria of the skin, facial flushing and sweating, palpitations, hot flushes of the body, headache, nausea, vomiting, and dizziness	Scombroid poisoning; high histamine levels demonstrated in the fish	Smart, 1992
Fish (spiked with histamine)	Facial flushing, headache	Histamine poisoning; histamine concentration in plasma correlated closely with histamine dose ingested	Van Gelderen *et al.*, 1992
Cape yellow tail (fish) (*Seriola lalandii*)	Skin rash, diarrhea, palpitations, headache, nausea and abdominal cramps, paraesthesia, unusual taste sensation, and breathing difficulties	Scombroid poisoning, treated with antihistamines.	Muller *et al.*, 1992
Sulfite sensitivity	Bronchospasm, asthma	Sulfite oxidase deficiency to meta-bisulfites in foods and wine	Smith, 1991
Tuna, albacore, mackerel, bonito, mahimahi, and bluefish	Reaction resembling an acute allergic reaction	Scombroid poisoning treated with antihistamines and cimetidine	Lange, 1988
Cheese	Symptoms resembling acute allergic reaction	Responds to antihistamines; histamine poisoning?	Taylor, 1986

expected increase in urinary histamine in scombroid-poisoned individuals but did not find an increase in urinary $9\alpha,11\beta$-dihydroxy-15-oxo-2,3,18,19-tetranorprost-5-ene-1,20-dioic acid, the principal metabolite of prostaglandin D_2, a mast cell secretory product; thus, no mast cell involvement was indicated.

Smith (1991) described sulfite-induced bronchospasm (sometimes leading to asthma), which was first noticed as an acute sensitivity to meta-bisulfites sprayed on restaurant salads and in wine. Sulfite normally is detoxicated rapidly to inorganic sulfate by the enzyme sulfite oxidase. In sensitive individuals, there is apparently a deficiency in this enzyme, making them supersensitive to sulfites. Thus, the addition of sulfite to food is considered safe only when properly disclosed on the food label.

Food–Drug Interactions   Once known as pharmacological food reactions or as "false food allergies" (Moneret-Vautrin, 1987), these adverse reactions were once thought to be exaggerated responses to pharmacological agents in food and possibly due to receptor sensitization. However, the majority of food and drug interactions are actually the result of food-induced changes in drug bioavailability or metabolism (i.e., *pharmacokinetic* interactions), although some are the result of *pharmacodynamic* interactions. For drugs with a narrow therapeutic index and the need for dose titration, even small changes in the dose–response effects can have great consequences (Schmidt and Dalhoff, 2002). The potential to alter therapeutic effect can be great and in recognition of the role that food plays, test meals are now given to determine their effect on drug therapeutic effect (FDA, 2002b).

Pharmacokinetic effects on absorption (e.g., gastric pH, gastric emptying, lymphatic flow) were described earlier. Examples of foods affecting a number of cytochromes, Phase II enzymes, and transporters are provided in Table 30-20, although the effects on CYP3A4 and P-glycoprotein may be the clinically most important (Harris *et al.*, 2003). Other dietary ingredients that may produce an

effect on the overall pharmacokinetics of drugs would include substances that would change the pH of urine or simply the presence of fiber in the intestine. Examples of pharmacodynamic interactions might include the effect of unsaturated fatty acids in the diet on anticoagulants or membrane potentials of the membranes in which they become incorporated; or high potassium intake from potassium-rich foods and the risk of hyperkalemia during therapy with angiotensin enzyme converting enzyme inhibitors or spironolactone (Schmidt and Dalholf, 2002). Other pharmacodynamic interactions might include phytoestrogens and other estrogen-stimulating substances during treatment for hormonally sensitive cancers (e.g., breast and prostate) and; caffeine or other stimulatory methylxanthines from coffee, chocolate, and soft drinks flavored with guarana, during treatment for hypertension.

Metabolic Food Reactions   Metabolic food reactions are distinct from other categories of adverse reactions in that the foods are more or less commonly eaten and demonstrate toxic effects only when eaten to excess or improperly processed (Table 30-21). The susceptible population exists as a result of its own behavior, that is, the "voluntary" consumption of food as a result of a limited food supply or an abnormal craving for a specific food. Such an abnormal craving was reported by Bannister *et al.* (1977), who noted hypokalemia leading to cardiac arrest in a 58-year-old woman who had been eating about 1.8 kg of licorice per week. In "glycyrrhizism," or licorice intoxication, glycyrrhizic acid is the active component, with an effect resembling that of aldosterone, which suppresses the renin–angiotensin–aldosterone axis, resulting in the loss of potassium. Clinically, hypokalemia with alkalosis, cardiac arrhythmias, muscular symptoms together with sodium retention and edema, and severe hypertension are observed. The syndrome may develop at a level of 100 g licorice/day but gradually abates upon withdrawal of the licorice (Isbrucker and Burdock, 2006).

Table 30-20
Food–Drug Interactions (Activity may be Enhanced or Inhibited)

ENZYME OR TRANSPORTER	FOOD	DRUG
CYP1A2	Caffeine, theophylline, grapefruit juice (naringen and furanocoumarins bergamottin and dihydroxybergamotin), grape juice, cruciferous vegetables, apiaceous vegetables, cooked meat	Clozapine, fluvoxamine, imipramine
CYP2E1	Watercress and possibly other isothiocyanate-containing cruciferous vegetables; polyunsaturated fatty acids (corn oil, menhaden oil)	Ethanol, halothane, enflurane
CYP3A4	Grapefruit juice, orange juice, red wine, possibly other polyphenol-containing substances, St. Johns wort, garlic	Ketoconazole, cyclosporin, erythromycin, protease inhibitors, HMG-CoA reductase inhibitors
UGT &GST	Brussel sprouts, cabbage, watercress, broccoli	Acetaminophen, oxazepam, morphine, ibuprofen
P-glycopeptide &OATP	Vegetables, fruit juice, St. Johns wort	Digoxin, cyclosporine, pravastatin

UGT, uridine diphosphate glycuronosyltransferases; GST, glutathione-S-transferases; OATP, organic anion transporting polypeptides.

Table 30-21
Metabolic Food Reactions

FOOD	REACTION	MECHANISM	REFERENCE
Lima beans, Cassava roots, millet (sorghum) sprouts, bitter almonds, apricot, and peach pits	Cyanosis	Cyanogenic glycosides releasing hydrogen cyanide on contact with stomach acid	Anderson and Sogn, 1984
Cabbage family, turnips, soybeans, radishes, rapeseed, and mustard	Goiter (enlarged thyroid)	Isothiocyanates, goitrin, or S-5-vinly-thiooxazolidone interferes with utilization of iodine	Anderson and Sogn, 1984; van Etten and Tookey, 1985
Unripe fruit of the tropical tree *Blighia sapida,* common in Caribbean and Nigeria	Severe vomiting, coma, and acute hypoglycemia sometimes resulting in death, especially among the malnourished	Hypoglycin A, isolated from the fruit, may interfere with oxidation of fatty acids, so that glycogen stores have to be metabolized for energy, with depletion of carbohydrates, resulting in hypoglycemia	Evans, 1985
Leguminosae, Cruciferae	Lathyritic symptoms: neurological symptoms of weakness, leg paralysis, and sometimes death	L-2-4-Diaminobutyric acid inhibition of ornithine transcarbamylase of the urea cycle, inducing ammonia toxicity	Evans, 1985
Licorice (glycyrrhizic acid)	Hypertension, cardiac enlargement, sodium retention	Glycyrrhizic acid mimicking Mineralocorticoids.	Farese *et al.,* 1991
Polar bear and Chicken liver	Irritability, vomiting, increased intracranial pressure, death	Vitamin A toxicity	Bryan, 1984
Cycads (cycad flour)	Amyotrophic lateral sclerosis (humans), hepatocarcinogenicity (rats and nonhuman primates)	Cycasin (methylazoxymethanol); primary action is methylation, resulting in a broad range of effects from membrane destruction to inactivation of enzyme systems	Matsumoto, 1985; Sieber *et al.,* 1980

Isothiocyanates are present in a number of foods, especially cruciferous vegetables; in mustard and horseradish (as allyl isothiocyanate), providing the 'bite' associated with these foods and in watercress (as methyl isothiocyanate), which confers a slight zaniness to the taste. In mustard seed, the glycoside, sinigrin, is acted upon by myrosin in the presence of water and when the seed is injured, liberating the (allyl)-isothiocyanate, a potent antimicrobial (espe-

cially antifungal). Other members of the *Brassica* family, including broccoli, kale, and cabbage, release thiocyanate ion. Once ingested, both the iso- and thiocyanates bind iodine in the body, preventing its organification, leading to *diffuse hyperplastic* (*iodine-deficient*) *goiter.* Although the degree to which I⁻ is bound by the thiocyanates is not comparable to say, percholorate anion (ClO_4^-), nevertheless, in areas of low iodine and high *Brassica* consumption, pathology

could result (Capen *et al*., 2002; Farwell and Braverman, 2006). Ermans *et al*. (1972) indicate that chronic consumption of thiocyanate may play a role in endemic cretinism. Paradoxically, excess iodine may also cause goiter (i.e., *iodine-excess goiter*). Excess iodine appears primarily to block the release of T_3 and T_4 from thyroglobulin and interferes with peroxidation of $2I^-$ to I_2 and disrupts the conversion of monoiodothyronine to diiodothyronine (Capen *et al*., 2002). The FDA is aware of the possibility of iodine toxicity and has placed limits on iodine in kelp, the products of which have extensive use in food.[17]

This category also includes the ingestion of improperly prepared food such as cassava or cycad, which if prepared properly will result in a toxin-free food. Exposure to cycad seed kernel is an etiologic factor for the westernPacific amyotrophic lateral sclerosis (ALS) and parkinsonism-dementiacomplex (PDC); present also are mutagenic and carcinogenic substances. The neurotoxins found in cycad are *beta-N*-methylamino-L-alanine (BMAA)and methylazoxymethanol *beta-D*-glucoside (cycasin). Cyanogenic glycosides are also found in cassava (as they are in lima beans). The cycad (*Cacaos circinalis*) is a particularly hardy tree in tropical to subtropical habitats around the world. Cycads often survive when other crops have been destroyed (e.g., a natural disaster such as a typhoon or drought) and therefore may serve as an alternative source of food. Among people who have used cycads for food, the method of detoxification is remarkably similar despite the wide range of this plant: The seeds and stems are cut into small pieces and soaked in water for several days and then are dried and ground into flour. The effectiveness of leaching the toxin (cycasin) from the bits of flesh is most directly dependent on the size of the pieces, the duration of soaking, and the number of water changes (Matsumoto, 1985). Shortcuts in processing may have grave consequences.

Fiddleheads (crosiers) of the ostrich fern (*Matteuccia struthiopteris*) are a seasonal delicacy harvested commercially in the northeastern United States and in coastal provinces of Canada. The ostrich fern was a spring vegetable for American Indians of eastern North America and became part of the regular diet of settlers to New Brunswick in the late 1700s. Until recently, it was consumed primarily in the Maritime Provinces of Canada and in the northeastern United States. The ferns are available commercially either canned or frozen, but since the early 1980s, farmers' markets and supermarket chains have sold fresh ferns in season. None of the fiddlehead ferns of eastern and central North America previously have been reported to be poisonous. Although some ferns may be carcinogenic, the ostrich fern has been considered to be safe to eat either raw or cooked. However, in May 1994, outbreaks of food poisoning were associated with eating raw or lightly cooked fiddlehead ferns in New York and western Canada. Approximately 60% of restaurant patrons consuming raw or minimally processed ferns (e.g., light sauté ing) experienced nausea, vomiting, abdominal cramps, and/or diarrhea within hours. Those consuming ferns subjected to more rigorous processing (e.g., boiling for at least 6 minutes) did not experience symptoms. The authors speculated the ferns contained a heat-labile toxin and recommended that ferns be boiled for 10 minutes prior to eating (MMWR, 1994).

Importance of Labeling

The importance of labeling was first realized in its ability to protect consumers from economic fraud by requiring that the weight and exact contents of the product be stated; otherwise, the product was *mislabeled*. Later, it became obvious that labels could also serve a purpose in assuring the safety of the consumer by including safety warnings for particularly susceptible groups.

Food allergies have a considerable impact on modern society. There is no known cure for food allergies and although accidental exposure is common, avoidance of the offending foods is the only successful noninterventional approach. Food allergy is the leading cause of anaphylaxis, a severe type of allergic reaction requiring hospitalization. It is estimated that 2% of adults and about 5% of infants and young children in the United States suffer from food allergies. Approximately 30,000 individuals require emergency room treatment, 2000 are hospitalized, and 150 die because of allergic reactions to food.[18]

Effective January 1, 2006, as a result of the Food Allergen Labeling and Consumer Protection Act of 2004 (FALCPA), manufacturers are required to identify the presence of ingredients that contain protein derived from milk, eggs, fish, crustacean shellfish, tree nuts, peanuts, wheat, or soybeans. These eight major food allergens account for 90% of food allergic reactions. In addition, FALCPA labeling regulations require declaration of the specific type of tree nut (e.g., almonds, pecans, or walnuts), the species of fish (e.g., bass, flounder, or cod), and the kind of crustacean shellfish (e.g., crab, lobster, or shrimp). FALCPA requires with a few exceptions the label on a food product (conventional foods, dietary supplements, infant formula, and medical foods) that is or contains an ingredient (spice, flavoring, coloring, or incidental additive) that includes a "major food allergen" (Carabin and Magnuson, 2006).

Labeling requirements for nonallergens include those for intolerance (e.g., lactose or gluten intolerance) or the presence of phenylalanine for PKU patients, are especially important when these substances may be present in foods where their presence may not be expected. Label warnings also include those warning of a threshold for a laxative effect (e.g., polydextrose, mannitol, sorbitol). The FDA has indicated that, at this time, they are not aware of any information that foods developed through genetic engineering differ as a class in any attribute from foods developed through conventional means that would warrant a special label (Thompson, 2000). The FDA allows companies to include on the label of a product any statement as long as the statement is truthful and not misleading.

TOLERANCE SETTING FOR SUBSTANCES IN FOODS

Pesticide Residues

A pesticide is defined under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), as any substance used to control or mitigate pests (such as insects, rodents, weeds, or fungi), or intended for use as a plant growth regulator, defoliant, or dessicant. In the United States, the regulation of pesticides is the responsibility of the Environmental Protection Agency (EPA) and is accomplished under both FIFRA and the FD&C Act. FIFRA governs the registration, sale, and use of all pesticides. It is illegal to use a pesticide unless it is specifically registered and labeled for the intended use. In order to obtain registration, an applicant must supply EPA with data on pesticide composition, mammalian and ecological toxicity, environmental fate, and potential human and environmental exposures.

---

[17] 21 CFR §172.365.

[18] http://www.cfsan.fda.gov/~dms/alrgact.html (site visited 8 April 2006).

A major part of the registration process for most pesticides involves the establishment of tolerances. The EPA must establish tolerances, or exemptions from tolerances, for all pesticides that may come into contact with food or feed, i.e., those intended for use during the production, storage, transportation, or processing of food or feed crops, on livestock, or in food-handling establishments. The tolerances are intended to represent the highest expected residue levels from legal uses of the pesticide. All pesticide tolerances are now established under Section 408 of the FD&C Act. Prior to 1996, if pesticide residues in processed foods exceeded those in raw agricultural commodities, they were considered to be intentional food additives and were required to be assigned "Food Additive Tolerances" under Section 409 of the Act. If the pesticide chemical in question had been classified by the EPA as a human or animal carcinogen, the Delaney clause would be invoked and the Section 409 food additive tolerance(s) could be denied on that basis. However, the Food Quality Protection Act (FQPA) of 1996 revised Section 201(s) of the FD&C Act to exclude pesticides from the definition of *food additive*—even in the case of concentration residues in processed fractions. Although an additional tolerance for a processed fraction is still required if the pesticide residue in the fraction exceeds the tolerance for the raw agricultural commodity (RAC), that tolerance is now established under Section 408 rather than Section 409. Consequently, although the Delaney clause has *not* been repealed from Section 409, and continues to apply to intentional food additives *other than pesticides*, it is no longer applicable for *pesticides*.

Prior to 1996, the EPA used $100\times$ as a default safety factor when conducting risk assessments to ensure that the necessary food and feed tolerances would be safe for human health. However, FQPA also requires that an additional $10\times$ safety factor "shall be applied for infants and children to take into account potential pre- and postnatal toxicity and completeness of the data with respect to exposure and toxicity to infants and children." It further states, however, that "the Administrator may use a different margin of safety for the pesticide chemical residue only if, on the basis of reliable data, such margin will be safe for infants and children."

Drugs Used in Food-Producing Animals

An animal drug "means any drug intended for use for animals other than man" [section 201(w) of the FD&C Act]. Animal drugs, which typically are used for growth promotion and increased food production, present a complex problem in the safety assessment of animal drug residues in human food. Determination of the potential human health hazards associated with animal drug residues is complicated by the metabolism of an animal drug, which results in residues of many potential metabolites.

The primary factors which must be considered in the evaluation of animal drugs are (1) consumption and absorption by the target animal, (2) metabolism of the drug by the target food animal, (3) excretion and tissue distribution of the drug and its metabolites in food animal products and tissues, (4) consumption of food animal products and tissues by humans, (5) potential absorption of the drug and its metabolites by humans, (6) potential metabolism of the drug and its metabolites by humans, and (7) potential excretion and tissue distribution in humans of the drug, its metabolites, and the secondary human metabolites derived from the drug and its metabolites. Thus, the pharmacokinetic and biotransformation characteristics of both the animal and the human must be considered in an assessment of the potential human health hazard of an animal drug.

When an animal drug is considered GRAS, the safety assessment of the drug is handled as described under the section on GRAS. With respect to new animal drugs, safety assessment is concerned primarily with residues that occur in animal food products (milk, cheese, etc.) and edible tissues (muscle, liver, etc.). Toxicity studies in the target species (chicken, cow, pig, etc.) should provide data on metabolism and the nature of metabolites, along with data on the drug's pharmacokinetics. During this phase, the parent drug and its metabolites are evaluated both qualitatively and quantitatively in the animal products of concern (eggs, milk, meat, etc.). This may involve the development of sophisticated analytic methodologies. Once these data are obtained, it is necessary to undertake an assessment to determine potential human exposure to these compounds from the diet and other sources, pursuant to the establishment of a tolerance.

To comply with the Congressional intent regarding the use of animal drugs in food-producing animals as required in the no residue provision of the Delaney clause, the FDA began to build a system for conducting risk assessment of carcinogens in the early 1970s (FDA, 1977). In the course of developing a policy and/or regulatory definition for "no residue," the FDA was compelled to address the issue of residues of metabolites of animal drugs known to induce cancer in humans or animals. As the number of metabolites may range into the hundreds, it became apparent that as a practical matter, not every metabolite could be tested with the same thoroughness as the parent animal drug. This forced the FDA to consider threshold assessment for the first time. Threshold assessment combines information on the structure and in vitro biological activity of a metabolite for the purpose of determining whether carcinogenicity testing is necessary (Flamm *et al.*, 1994, 2002). If testing is necessary and if the substance is found to induce cancer, the FDA's definition states that a lifetime risk of one in a million is equivalent to the meaning of "no residue" as intended by Congress.

Unavoidable Contamination during Growth, Storage, or Processing

Certain substances, such as polyhalogenated aromatic hydrocarbons (PHAHs), including dioxins, dibenzofurans, and biphenyls, or heavy metals, are unavoidable in food because of their widespread use, presence in the earth's crust which has resulted in their becoming a persistent and/or ubiquitous contaminant in the environment or presence as a product of normal food processing. As a result, foods and animal feeds, principally those of animal (e.g., PHAHs accumulate in dairy/meat products due to lipophilicity of these compounds) and marine origin, contain unavoidable contaminants at some level. Tolerances for residues of unavoidable contaminants are established for foods and food ingredients to ensure that they are safe under expected or intended conditions of use.

Heavy Metals   There are 92 natural elements; approximately 22 are known to be essential nutrients of the mammalian body and are referred to as micronutrients (Concon, 1988). Among the micronutrients are iron, zinc, copper, manganese, molybdenum, selenium, iodine, cobalt, and even aluminum and arsenic. However, among the 92 elements, lead, mercury, and cadmium are familiar as contaminants or at least have more specifications setting their limits in food ingredients (e.g., Food Chemicals Codex (FCC, 2003)). The prevalence of these elements as contaminants is due to their ubiquity in nature but also to their use by humans.

Lead   Although the toxicity of lead is well known, lead may be an essential trace mineral. A lead deficiency induced by feeding rats <50 ppb (vs. 1000 ppb in controls) over one or more generations, produced effects on the hematopoietic system, decreased iron stores in the liver and spleen, and caused decreased growth (Kirchgessner and Reichmayer-Lais, 1981), but apparently not as a result of an effect on iron absorption. Although the toxic effects of lead are discussed elsewhere in this text, it is important to note that the effects are profound (especially in children) and appear to be long-lasting, because mechanisms for excretion appear to be inadequate in comparison to those for uptake (Linder, 1991). Foods may become contaminated with lead if they are grown, stored, or processed under conditions that could introduce larger amounts of lead into the food, such as when a root crop is grown in soil that has been contaminated from the past use of leaded pesticides. Under such conditions, the resulting contamination of the food may pose a health risk to consumers.

Over the years, recognition of the serious nature of lead poisoning in children has caused the World Health Organization (WHO) and FDA to adjust the recommended tolerable total lead intake from all sources of not more than 100 μg/d for infants up to 6 months old and not more than 150 μg/d for children from 6 months to 2 years of age to the considerably lower range of 6–18 μg/d as a provisional tolerable range for lead intake in a 10-kg child. As the result of recent publicity, the FDA is recommending that lead levels in candy products likely to be consumed frequently by small children not exceed 0.1 ppm because such levels are achievable under good manufacturing practices and would not pose a significant risk to small children for adverse effects. This recommended maximum level is consistent with the FDA's longstanding goal of reducing lead levels in the food supply (FDA, 2005).

Initiatives to reduce the level of lead in foods, such as the move to eliminate lead-soldered seams in soldered food cans that was begun in the 1970s, and efforts to eliminate leachable lead from ceramic ware glazes, have resulted in a steady decline in dietary lead intake. Although food and water still contribute lead to the diet, data from the FDA's Total Diet Study indicated a reduction in mean dietary lead intake for adult males from 95 μg/d in 1978 to 9 μg/d in the period 1986–1988 (Shank and Carson, 1992).

Some lead sources are difficult to curtail as lead often survives food processing; for example, lead in wheat remains in the finished flour (Linder, 1991). Therefore, reducing the contribution from dietary sources remains a challenge, but elimination of lead-soldered cans, lead-soldered plumbing, and especially the use of tetraethyl lead as a gasoline additive has produced substantial reductions in lead ingestion. What is needed now is continued vigilance of largely imported lead-based ceramic ware, lead-containing calcium supplements, and lead leaching into groundwater (Shank and Carson, 1992).

Arsenic   Arsenic is a ubiquitous element in the environment; it ranks 20th in relative abundance among the elements of the earth's crust and twelfth in the human body (Concon, 1988). (Because arsenic is discussed in detail elsewhere in this text, the discussion here is limited to its relationship to foods.) There is some competition for arsenic absorption with selenium, which is known to reduce arsenic toxicity; arsenic is also known to antagonize iodine metabolism and inhibit various metabolic processes, as a result affecting a number of organ systems. There are a number of sources of arsenic, including drinking water, air, and pesticides (Newberne, 1987), but arsenic consumed via food is largely in proportion to the amount of seafood eaten (74% of the arsenic in a market-basket survey came from the meat-poultry-fish group, of which seafood has the consistently highest concentration) (Johnson *et al.*, 1981). Although arsenic is used as an animal feed additive, this source does not contribute much to the body burden, as 0.1% arsanilic acid or docecylamine-p-chlorophenylarsonate fed to turkeys resulted in tissue residues of only 0.31 and 0.24 ppm in fresh muscle (Underwood, 1973).

At a time when arsenic use was common as a pesticide, acute poisoning with arsenic often resulted from mistaking arsenic for sugar or baking soda and adding it to food. The time between exposure and symptoms ranged from 10 minutes to several days, and the symptoms include burning of the mouth or throat, a metallic taste, vomiting, diarrhea (watery and bloody), borborigmi (rumbling of the bowels caused by movement of gas in the GI tract), painful tenesmus (spasm of the anal or vesical sphincter), hematuria, dehydration, jaundice, oliguria, collapse, and shock. Headache, vertigo, muscle spasm, stupor, and delirium may occur (Bryan, 1984). Episodes of acute arsenic poisoning are now rare.

Cadmium   Cadmium is a relatively rare commodity in nature and usually is associated with shale and sedimentary deposits. It is often found in association with zinc ores and in lesser amounts in fossil fuel. Although rare in nature, it is a nearly ubiquitous element in American society because of its industrial uses in plating, paint pigments, plastics, and textiles. Exposure to humans often occurs through secondary routes as a result of dumping at smelters and refining plants, disintegration of automobile tires (which contain cadmium-laden rubber), subsequent seepage into the soil and groundwater, and inhalation of combustion of cadmium-containing materials. The estimated yearly release of cadmium from automobile tires ranges from 5.2 to 6.0 metric tons (Davis, 1970; Lagerwerff and Specht, 1971).

Although like mercury, cadmium can form alkyl compounds, unlike mercury, the alkyl derivatives are relatively unstable and consumption almost always involves the inorganic salt. Of two historical incidents of cadmium poisoning, one involved the use of cadmium-plated containers to hold acidic fruit slushes before freezing. Up to 13–15 ppm cadmium was found in the frozen confection, 300 ppm in lemonade, and 450 in raspberry gelatin. Several deaths resulted. A more recent incident of a chronic poisoning involved the dumping of mining wastes into rice paddies in Japan. Middle-aged women who were deficient in calcium and had had multiple pregnancies seemed to be the most susceptible. Symptoms included hypercalciuria; extreme bone pain from osteomalacia; lumbago; pain in the back, shoulders, and joints; a waddling gait; frequent fractures; proteinuria; and glycosuria. The disease was called *itai itai* (ouch-ouch disease) as a result of the pain with walking. The victims had a reported intake of 1000 μg/d, approximately 200 times the normal intake in unexposed populations (Yamagata and Shigematsu, 1970). Cadmium exposure has also been associated with cancer of the breast, lung, large intestine, and urinary bladder (Newberne, 1987).

Chlorinated Organics   Chlorinated organics have been with us for some time, and given their stability in water and resistance to oxidation, ultraviolet light, microbial degradation, and other sources of natural destruction, chlorinated organics will continue to reside in the environment for some time to come, albeit in minute amounts. However, with the introduction of chlorinated hydrocarbons as pesticides in the 1930s, diseases associated with an insect vector such

as malaria were nearly eliminated. In the industrialized world, chlorinated organics brought the promise of nearly universal solvents, and their extraordinary resistance to degradation made them suitable for use as heat transfer agents, carbonless copy paper, and fire retardants (Table 30-22).

As persistent as these substances are in the environment and despite the degree of toxicity that might be implied, the possible hazard from chlorinated substances is relatively low. Ames *et al.* (1987) described a method for interpreting the differing potencies of carcinogens and human exposures: the percentage HERP (human exposure dose/rodent potency dose). Using this method, they demonstrated that the hazard from trichloroethylene-contaminated water in Silicon Valley or Woburn, Massachusetts, or the daily dietary intake from DDT (or its product, DDE) at a HERP of 0.0003–0.004% is considerably less than the hazard presented by the consumption of symphytine in a single cup of comfrey herb tea (0.03%) or the hazard presented by aflatoxin in a peanut butter sandwich (0.03%). The FDA's authority to set tolerances has been used only once in establishing levels for polychlorinated biphenyls (21 CFR 109.15 and 109.30).

There have been only a few incidents of mass poisonings via food, three of which involved contaminated cooking oil. The first became known as *yusho*, or rice oil disease, from rice oil contamination by polychlorinated biphenyls (PCBs). This occurred in 1968 in Japan and affected approximately 2000 individuals. The most vulnerable were newborns of poisoned mothers. The liver and skin were the most severely affected. Symptoms included dark brown pigmentation of nails; acne-like eruptions; increased eye discharge; visual disturbances; pigmentation of the skin, lips, and gingiva; swelling of the upper eyelids; hyperemia of the conjunctiva; enlargement and elevation of hair follicles; itching; increased sweating of the palms; hyperkeratotic plaques on the soles and palms; and generalized malaise. Recovery requires several years (Anderson and Sogn, 1984; Guo *et al.*, 2003). The second incident occurred in 1979 in Yucheng, Taiwan, which also involved PCB-contaminated cooking oil and exposed a similar number of people as the earlier incident in Japan (Guo *et al.*, 2003). The third incident has become known as "Spanish toxic oil syndrome" and although details are still not

fully known, occurred when aniline-contaminated rapeseed oil was distributed as cooking oil in Spain in 1981. Approximately 20,000 people were affected and several deaths occurred. Because symptoms were unique and included respiratory effects, eosinophilia and muscle wasting, but not typical of aniline poisoning, the exact etiologic agent is still unknown. Because the source of the aniline may have been improperly cleaned tank trucks that had imported industrial chemicals, three hypotheses have been offered: the etiologic agent may have been (1) a contaminant in the aniline, (2) a contaminant introduced during transportation or, (3) a reaction product of normal oil components and the potential contaminants (the fraction of the oil most commonly associated with toxicity contained C$_{18:3}$—anilide, also called oleyl anilide and "fatty acid anilide") (Wood *et al.*, 1994; Posada de la Paz *et al.*, 1996; Borda *et al.*, 1998).

Nitrosamines, Nitrosamides, and *N*-Nitroso Substances Nitrogenous compounds such as amines, amides, guanidines, and ureas can react with oxides of nitrogen (NO$_x$) to form *N*-nitroso compounds (NOCs) (Hotchkiss *et al.*, 1992). The NOCs may be divided into two classes: the nitrosamines, which are *N*-nitroso derivatives of secondary amines, and nitrosamides, which are *N*-nitroso derivatives of substituted ureas, amides, carbamates, guanidines, and similar compounds (Mirvish, 1975).

Nitrosamines are stable compounds, while many nitrosamides have half-lives on the order of minutes, particularly at pH $\gg$ 6.5. Both classes have members which are potent animal carcinogens, but by different mechanisms. In general, the biological activity of an NOC is thought to be related to alkylation of genetic macromolecules. *N*-nitrosamines are metabolically activated by hydroxylation at an α-carbon. The resulting hydroxyalkyl moiety is eliminated as an aldehyde, and an unstable primary nitrosamine is formed. The nitrosamine tautomerizes to a diazonium hydroxide and ultimately to a carbonium ion. Nitrosamides spontaneously decompose to a carbonium ion at physiological pH by a similar mechanism (Hotchkiss *et al.*, 1992). This is consistent with in vitro laboratory findings because nitrosamines require S9 for activity and nitrosamides are mutagenic de novo.

Table 30-23
Sources of Dietary NOCs

The use of nitrate and/or nitrite as intentional food additives, both of which are added to fix the color of meats, inhibit oxidation, and prevent toxigenesis.

Drying processes in which the drying air is heated by an open flame source. NO_x is generated in small amounts through the oxidation of N_2, which nitrosates amines in the foods. This is the mechanism for contamination of malted barley products.

NOCs can migrate from food contact materials such as rubber bottle nipples.

NOCs can inhabit spices which may be added to food.

Cooking over open flames (e.g., natural gas flame) can result in NOC formation in foods by the same mechanism as drying.

SOURCE: Adapted with permission from Hotchkiss JH, Helser MA, Maragos CM, *et al*.: Nitrate, nitrite, and *N*-nitroso compounds: Food safety and biological implications, in Finley JW, Robinson SF, Armstrong DJ (eds.): *Food Safety Assessment*. Washington, DC, American Chemical Society, 1992, pp. 400–418.

NOCs originate from two sources: environmental formation and endogenous formation (Table 30-23). Environmental sources have declined over the last several years but still include foods (e.g., nitrate-cured meats) and beverages (e.g., malt beverages), cosmetics, occupational exposure, and rubber products (Hotchkiss, 1989). NOCs formed in vivo may actually constitute the greatest exposure and are formed from nitrosation of amines and amides in several areas, including the stomach, where the most favorable conditions exist (pH 2 to 4), although consumption of H_2-receptor blockers or antacids decreases the formation of NOCs.

Environmentally, nitrite is formed from nitrate or ammonium ions by certain microorganisms in soil, water, and sewage. In vivo, nitrite is formed from nitrate by microorganisms in the mouth and stomach, followed by nitrosation of secondary amines and amides in the diet. Sources of nitrate and nitrite in the diet are given in Table 30-24. Many sources of nitrate are also sources of vitamin C. Another possibly significant source of nitrate is well water; although the levels are generally in the range of 21 μM, average levels of 1600 μM (100 mg/L) have been reported (Hotchkiss *et al*., 1992). However, on the average, Western diets contain 1–2 mmol nitrate/person/day (Hotchkiss *et al*., 1992). Nitrosation reactions can be inhibited by preferential, competitive neutralization of nitrite with naturally occurring and synthetic materials such as vitamin C, vitamin E, sulfamate, and antioxidants such as BHT, BHA, gallic acid, and even amino acids or proteins (Hotchkiss, 1989; Hotchkiss *et al*., 1992).

N-nitrosoproline is the most common nitrosoamine present in humans and is excreted virtually unchanged in the urine. The basal rate of urinary excretion of nitrosoproline, which is claimed to be noncarcinogenic, is 2–7 g/d in subjects on a low nitrate diet (Oshima and Bartsch, 1981). Epidemiological studies have not provided evidence of a causal association between nitrate exposure and human cancer nor has a causal link been shown between *N*-nitroso compounds, pre-formed in the diet or endogenously synthesized, and the incidence of human cancer (Gangolli, 1999).

Food-borne Molds and Mycotoxins Molds have served humans for centuries in the production of foods (e.g., ripening cheese) and have provided various fungal metabolites with important medicinal uses; they also may produce secondary metabolites with the potential to produce severe adverse health effects, including behavioral changes (Cousins *et al*., 2005). It is possible the ergot mycotoxins may have exerted a major role in restricting population expansion and only the reduced dependency on rye cereal as the staple food in

the sixteenth and seventeenth centuries, arising from the introduction of wheat and potatoes, allowed the steady upward movement in population growth (CAST, 2003; IFST, 2006a).

Mycotoxins are secondary fungal metabolites (i.e., not essential for survival of the mold) secreted into the microenvironment around the mold. Mycotoxins represent a diverse group of chemicals that can occur in a variety of plants used as food, including commodities such as cereal grains (barley, corn, rye, wheat), coffee, dairy products, fruits, nuts, peanuts, and spices. A few mycotoxins also can occur in animal products derived from animals that consume contaminated feeds (e.g., milk). However, because commodities are eaten in the greatest amounts, the mycotoxins present in these foods represent the greatest risk (Cousins *et al*., 2005).

The current interest in mycotoxicosis was generated by a series of reports in 1960–1963 that associated the death of turkeys in England (so-called turkey X disease) and ducklings in Uganda with the consumption of peanut meal feeds containing mold products produced by *Aspergillus flavus* (Stoloff, 1977). The additional discovery of aflatoxin metabolites (e.g., aflatoxin M_1 in milk) led to more intensive studies of mycotoxins and to the identification of a variety of these compounds associated with adverse human health effects, both retrospectively and prospectively.

Moldy foods are consumed throughout the world during times of famine, as a matter of taste, and through ignorance of their adverse health effects. Epidemiological studies designed to ascertain the acute or chronic effects of such consumption are few. Data from animal studies indicate that the consumption of food contaminated with mycotoxins has the potential to contribute to a variety of human diseases (Miller, 1991). Reports of acute intoxications are few; however, prolonged exposure to small quantities of mycotoxin may lead to more insidious effects including growth retardation, birth defects, impaired immunity, decreased disease resistance, and tumor formation in humans and decreased production in farm animals (CAST, 2003).

With some exceptions, molds can be divided into two main groups: "field fungi" and "storage fungi." The former group contains species that proliferate in and under field conditions and do not multiply readily once grain is in storage. Field fungi may be superseded and overrun by storage fungi if conditions of moisture and oxygen allow.

Importantly, the presence of a toxigenic mold does not guarantee the presence of a mycotoxin, which is elaborated only under certain conditions. Further, more than one mold can produce the same mycotoxin (e.g., both *Aspergillus flavus* and several *Penicillium*

Table 30-24
Nitrate and Nitrite Content of Food

VEGETABLES	NITRATE (ppm)	NITRITE (ppm)	MEAT	NITRATE (ppm)	NITRITE (ppm)
Artichoke	12	0.4	Unsmoked side bacon	134	12
Asparagus	44	0.6	Unsmoked back bacon	160	8

species produce the mycotoxin cyclopiazonic acid) (El-Banna *et al*., 1987; Truckness *et al*., 1987). Also, more than one mycotoxin may be present in an intoxication; that is, as in the outbreak of turkey X disease, there is speculation that aflatoxin and cyclopiazonic acid both exerted an effect, but the profound effects of aflatoxin would have overshadowed those of cyclopiazonic acid (Miller, 1989). Although there are many different mycotoxins and subgroups (Table 30-25), this discussion will be confined largely to six of the more toxicologically and economically important: aflatoxins, trichothecenes, fumonisins, zearalenone, ochratoxin A, and ergot alkaloids.

Organic foods, produced without the use of insecticides and fungicides, may be more susceptible to mycotoxin contamination than foods produced using conventional agricultural practices. The UK Food Standards Agency found several organic maize meal products highly contaminated with fumonisin mycotoxins whereas conventional produced maize meal products analyzed concurrently had levels below recommended limits (UK Food Standards Agency, 2003). Because European agriculture faces a growing demand by consumers for organic produce, the European Union has established a project called "safe organic vegetables and vegetable products by reducing risk factors and sources of fungal contaminants throughout the production chain" focusing on organic carrots and reduction of alternaria toxins (EU, 2002).

Aflatoxins   Among the various mycotoxins, the aflatoxins have been the subject of the most intensive research because of the extremely potent hepatocarcinogenicity and toxicity of aflatoxin B_1 in rats. Epidemiological studies conducted in Africa and Asia suggest that it is a human hepatocarcinogen, and various other reports have implicated the aflatoxins in incidences of human toxicity (Krishnamachari *et al*., 1975; Peers *et al*., 1976).

Generally, aflatoxins occur in susceptible crops as mixtures of aflatoxins B_1, B_2, G_1, and G_2, with only aflatoxins B_1 and G_1 demonstrating carcinogenicity. A carcinogenic hydroxylated metabolite of aflatoxin B_1 (termed aflatoxin M_1) can occur in the milk from dairy cows that consume contaminated feed. Aflatoxins may occur in a number of susceptible commodities and products derived from them, including edible nuts (peanuts, pistachios, almonds, walnuts, pecans, Brazil nuts), oil seeds (cottonseed, copra), and grains (corn, grain sorghum, millet) (Stoloff, 1977). In tropical regions, aflatoxin can be produced in unrefrigerated prepared foods. The two major sources of aflatoxin contamination of commodities are field contamination, especially during times of drought and other stresses, which allow insect damage that opens the plant to mold attack, and inadequate storage conditions. Since the discovery of their potential threat to human health, progress has been made in decreasing the level of aflatoxins in specific commodities in developed countries. For example, in the United States and Western European countries, control measures include ensuring adequate storage conditions and careful monitoring of susceptible commodities for aflatoxin level and the banning of lots that exceed the action level for aflatoxin B_1.

Aflatoxin B_1 is acutely toxic in all species studied, with an LD_{50} ranging from 0.5 mg/kg for the duckling to 60 mg/kg for the mouse (Wogan, 1973). Death typically results from hepatotoxicity. Aflatoxin B_1 is also highly mutagenic, hepatocarcinogenic, and possibly teratogenic. A problem in extrapolating animal data to humans is the extremely wide range of species susceptibility to aflatoxin B_1. For instance, whereas aflatoxin B_1 appears to be the most hepatocarcinogenic compound known for the rat, the adult mouse is essentially totally resistant to its hepatocarcinogenicity.

Aflatoxin B_1 is an extremely reactive compound biologically, altering a number of biochemical systems. The hepatocarcinogenicity of aflatoxin B_1 is associated with its biotransformation to a highly

Table 30-25

Examples of Selected Mycotoxins Produced by Various Molds and Some of Their Effects and Commodities and Foods that are Potentially Contaminated

MYCOTOXIN	SOURCE	EFFECT	COMMODITIES CONTAMINATED
Aflatoxins B_1, B_2, G_1, G_2	*Aspergillus flavus*, *A. parasiticus*	Acute aflatoxicosis, carcinogenesis	Corn, peanuts, and others
Aflatoxin M_1	Metabolite of AFB_1	Hepatotoxicity	Milk
Fumonisins B_1, B_2, B_3, B_4, A_1, A_2	*Fusarium verticillioides*	Renal and liver carcinogenesis	Corn
Trichothecenes (for example, T-2, deoxynivalenol, diacetoxyscirpenol)	*Fusarium, myrothecium*	Hematopoietic toxicity, meningeal hemorrhage of brain, "nervous" disorder, necrosis of skin, hemorrhage in mucosal epithelia of stomach and intestine, emesis, feed refusal, immune suppression	Cereal grains, corn
Zearalenones	*Fusarium*	Estrogenic effect	Corn, grain
Cyclopiazonic acid	*Aspergillus, Penicillium*	Muscle, liver, and splenic toxicity	Cheese, grains, peanuts
Kojic acid	*Aspergillus*	Hepatotoxic?	Grain, animal feed
3-Nitropropionic acid	*Arthrinium sacchari*, *A. saccharicola*, *A. phaeospermum*	Central nervous system impairment	Sugarcane
Citreoviridin	*Penicillium citreoviride*, *P. toxicarium*	Cardiac beriberi	Rice
Cytochalasins E, B, F, H	*Aspergillus* and *Penicillium*	Cytotoxicity	Corn, cereal grain
Sterigmatocystin	*Aspergillus versiolar*	Carcinogenesis	Corn
Penicillinic acid	*Penicillium cyclopium*	Nephrotoxicity, abortifacient	Corn, dried beans, grains
Rubratoxins A, B	*Penicillium rubrum*	Hepatotoxicity, teratogenic	Corn
Patulin	*Penicillium patulatum*	Carcinogenesis, liver damage	Apple and apple products
Ochratoxin	*Aspergillus ochraceus*, *A. carbonarius, Penicillium verrucosum*	Endemic nephropathy, carcinogenesis	Grains, peanuts, grapes, green coffee
Citrinin	*Aspergillus* and *Penicillium*	Nephrotoxicity	Cereal grains
Penitrem(s)		Tremors, incoordination, bloody diarrhea, death	Moldy cream cheese, English walnuts, hamburger bun, beer
Ergot alkaloids	*Clavicepts purpurea*	Ergotism	Grains

reactive electrophilic epoxide, which forms covalent adducts with DNA, RNA, and protein. Damage to DNA is thought to be the initial biochemical lesion resulting in the expression of the pathological tumor growth (IARC, 2002). Species differences in the response to aflatoxin may be due in part to differences in biotransformation and susceptibility to the initial biochemical lesion (Monroe and Eaton, 1987).

Trichothecenes   Trichothecenes represent a group of toxic substances in which it is likely that several forms may be consumed concomitantly. They represent many different chemical entities, all containing the trichothecene nucleus, and are produced primarily by *Fusarium*, but also by a number of commonly occurring molds, including *Myrothecium*, *Trichothecium*, *Stachybotrys*, and *Cephalosporium*. The trichothecenes were first discovered during attempts to isolate antibiotics, and although some show antibiotic activity, their toxicity has precluded their use as therapeutic agents. Trichothecenes most often occur in moldy cereal grains. There have been many reported cases of trichothecene toxicity in

farm animals and a few in humans. One of the more famous cases of presumed human toxicity associated with the consumption of trichothecenes occurred in Russia during 1944 around Orenburg, Siberia. Disruption of agriculture caused by World War II resulted in millet, wheat, and barley being overwintered in the field. Consumption of these commodities resulted in vomiting, skin inflammation, diarrhea, and multiple hemorrhages, among other symptoms. About 10% of the population was affected and mortality rates were as high as 60% in some counties (Ueno, 1977; Beardall and Miller, 1994), and was subsequently identified as alimentary toxic aleukia (ATA) (CAST, 2003). Trichothecenes are protein synthesis inhibitors known to bind to ribosomes. The extent of toxicity associated with the trichothecenes in humans and farm animals is poorly understood, owing in part to the number of entities in this group and the difficulty of assaying for these compounds (JECFA, 2001). The acute LD_{50}s of the trichothecenes range from 0.5 to 70 mg/kg, and though there have been reports of possible chronic toxicity associated with certain members of this group, more research will be needed before the magnitude of their potential to

produce adverse human health effects is understood (Sato and Ueno, 1977).

Fumonisins   Fumonisins are mycotoxins produced by *Fusarium verticillioides* (formerly known as *F. moniliforme*) and several other *Fusarium* species. Corn products contaminated with *F. verticillioides* are responsible for agriculturally important diseases in horses and swine (ICPS, 2000) and are actively being evaluated to determine how great a threat they pose to public health. Initial evidence of the involvement of *F. verticillioides* produced toxins in human disease, was reported by Marasas *et al*. (1988), who found that an increased incidence of esophageal cancer was associated with the consumption of contaminated corn (maize) by humans in a region in South Africa. Fumonisins have been associated with cancer, reproductive toxicity (neutral tube defects), and acute disease outbreaks where low-quality corn is consumed on a regular basis (Cousins *et al*., 2005). Fumonisins target different organs in different species, but the underlying mechanism is a disruption of lipid metabolism by inhibition of ceramide synthetase, an enzyme integral to the formation of complex lipids for use in membranes (ICPS, 2000; IARC, 2002).

Corn borer insect pests cause damage to the developing grain, which enables spores of the toxin-producing fungi, *Fusarium*, to germinate. The fungus then proliferates, which leads to ear and kernel rot and the production of potentially hazardous levels of fumonisins. Corn varieties which express the Bt insecticidal protein recently have been shown to contain significantly reduced levels of fumonisin because the Bt protein significantly reduces corn borer-induced tissue damage in corn products (Munkvold *et al*., 1997, 1999; Masoero *et al*., 1999; Hammond *et al*., 2004; Papst *et al*., 2005).

Zearalenone   Another mycotoxin produced by some *Fusarium* species is zearalenone. It was first discovered during attempts to isolate a chemical from feeds that produced a hyperestrogenic syndrome in swine that was characterized by a swollen and edematous vulva and vaginal prolapse in severe cases (Stob *et al*., 1962). Zearalenone can occur in corn, barley, wheat, hay, and oats as well as other agricultural commodities (Mirocha *et al*., 1977). Zearalenone consumption can decrease the reproductive potential of farm animals, especially swine.

Ochratoxin A   This mycotoxin is primarily produced by *Aspergillus ochraceous*, *A. carbonarius*, and *Penicillium verrucosum* and human exposure occurs as the result of contamination of small grains (barley, wheat, corn), coffee beans and grapes. The effects of ochratoxin A were discovered as the result of feeding the mycotoxin to pigs, who subsequently drank copious amounts of water, urinated near continuously, and exhibited pain in the area of the kidney. Ochratoxin A is nephrotoxic and carcinogenic in mice and rats. Ochratoxin A is absorbed from the gastrointestinal tract and enters the enterohepatic circulation; it is also absorbed by the proximal and distal tubules of the kidney. It binds tightly to albumin in the blood and can therefore have a very long serum half-life. Epidemiologic evidence indicates nearly half the European population is exposed to ochratoxin A and there is an association of endemic nephropathy and renal tumors in humans in parts of Eastern Europe (CAST, 2003).

Ergot Alkaloids   Produced by several species of *Claviceps*, these mycotoxins are divided into four major groups based on chemical structure: (1) clavines, (2) lysergic acids, (3) lysergic acid amides, and (4) ergopeptines. There are two primary types of ergotism of humans, convulsive and gangrenous. Convulsive ergotism is typified by muscle twitching and spasms, changes in mental state, hallucinations, sweating, and fever lasting for several weeks, all suggestive of serotonergic overstimulation of the CNS (Eadie, 2003). Postmortem findings include bleeding and softening of the brain and lesions in the posterior horns of the spinal cord. Full mental recovery from a nonfatal case is rare (Beardall and Miller, 1994). The gangrenous form of ergotism is characterized by edema, pruritis, necrotic extremities, prickling sensations, and severe muscular pain (CAST, 2003), all of which are likely the result of peripheral vasoconstriction.

Solanine and Chaconine   The humble potato, *Solanum tuberosum*, may produce toxic steroidal glycoalkaloids if exposed to light in the field or during storage or otherwise stressed by mechanical damage or improper storage or sprouting. Previously known only as "solanine" or now, (total) solanaceous glycoalkaloids (SGA), the major players are α-solanine and α-chaconine and are normally present in amounts of <5 mg/100 g of tuber fresh weight although a normal toxin load in the potatoes of 20–100 mg/kg tuber, is considered safe. The toxins are not affected by baking, frying, or microwave cooking. SGAs inhibit cholinesterases and can alter the effects of neuromuscular blocking drugs and anesthetics (Sorensen, 2002). Low doses of these glycoalkaloids can produce gastrointestinal upset with diarrhea, vomiting, and severe abdominal pain. At higher doses, neurological symptoms are evident with drowsiness and apathy, confusion, weakness, and vision disturbances, followed by loss of consciousness and sometimes, death.

Rodents do not absorb solanines well and the LD_{50} is >1000 mg/kg in mice and 590 in the rat; values that are 300–500 times more than the toxic dose of 2 mg/kg in humans and, in which, the estimated lethal dose may be as little as 3–6 mg/kg. There was thought to be an association of potato (and SGA) consumption with neural tube defects in children, although prospective studies have not borne out this hypothesis, nor has this effect been seen in animal testing (ICPS, 1993).

In the 1960s, a scientist bred a new variety of potato, crossing a Delta Gold with a wild type from Peru. The new variety called "Lenape" was excellent for making potato chips and was tested as a "new potato" for roasting with meats and vegetables. Upon eating the potato however, the grower was sickened and upon analysis, the potato was found to have high levels of glycoalkaloids. As a product of the breeding process, the gene for glycoalkaloids was stimulated to produce a high level of SGA. Immediately, all the seed potato growers were contacted and stocks were recalled or destroyed (Fedoroff and Brown, 2004).

Ethyl Carbamate   Ethyl carbamate or urethane, the ethyl ester of carbamic acid, was used for many years as an intravenous anesthetic until its mutagenic and carcinogenic properties became known. It has since been classified by the International Agency for Research on Cancer (IARC) as "possibly carcinogenic to humans" (Group 2B) and "reasonably anticipated to be a human carcinogen" by the National Toxicology Program (NTP, 2004a). The primary use of urethane is as a chemical intermediate in the preparation of amino resins, with lesser uses as a solubilizer in the manufacture of pesticides, fumigants, and cosmetics and as an intermediate for pharmaceuticals and biochemical research. It is allowed in some

anticonvulsant drugs at a level of 1 ppm and is still used as a veterinary anesthetic. Urethane has been found in fermented foods and beverages including liquor, wine, beer, bread, soy sauce, and yogurt. Diethylpyrocarbonate, an inhibitor of fermentation, can form ethyl carbamate.

Ethyl carbamate is easily absorbed and undergoes CYP2E1-mediated metabolic activation to vinyl carbamate epoxide, which binds covalently to nucleic acids and proteins, producing adducts. Ethyl carbamate is a multisite carcinogen with a short latency period. Single doses or short-term oral dosing at 100–200 mg/kg BW/d has been shown to induce tumors in mice, rats, and hamsters. Intake estimates from food and alcoholic beverages range from a mean of 0.015 µg/kg BW/d to 0.080 µg/kg BW/d for high-end users. The BMDL (benchmark dose lower confidence limit) as set by JECFA is 0.3 mg/kg BW/d, which yields a margin of safety of 20,000 (JECFA, 2005).

Trans Fatty Acids *Trans* fatty acids, also known as *trans* fat, are made through the process of hydrogenation of unsaturated bonds that solidifies (liquid) oils. Hydrogenation increases the melting point, shelf life, and flavor stability of these oils and foods that contain them. The hydrogenation process was developed in the 1930s and has been in widespread commercial use since the 1940s. Dietary fats containing hydrogenated fatty acids, such as those used in margarine, have gradually displaced animal fats, such as butter and lard. *Trans* fat is found in vegetable shortenings, and in some margarines, crackers, cookies, snack foods, and other foods. The scientific literature is replete with studies indicating that consumption of *trans* fatty acids contributes to increased blood LDL-cholesterol ("bad" cholesterol) levels, which increase the risk of coronary heart disease (CHD). Recent information from the American Heart Association indicates that CHD causes about 500,000 deaths annually, making it the number one cause of death in the United States (FDA, 1999a,b). To remedy this problem, it is now required to label foods indicating the amount of *trans* fat present.

Furan Furan was once known only as an industrial chemical intermediate in the synthesis of polymers used to prepare temperature-resistant structural laminates and to prepare copolymers used in machine dishwashing products. Furan has recently been found to occur in a number of foods that undergo heat treatment, such as canned and jarred foods, including baby food. It is considered by IARC (1995) to be possibly carcinogenic to humans. According to the NTP, furan is hepatotoxic and shows clear evidence of carcinogenicity to both sexes and both species of mice and rats (NTP, 1993). Furan is produced in a variety of experimental systems, including heating of sugars (e.g. glucose, lactose, fructose, xylose, rhamnose), heating sugars in the presence of amino acids or protein (e.g., alanine, cysteine, casein), and thermal degradation of vitamins (ascorbic acid, dehydroascorbic acid, thiamin) (FDA, 2004).

Furan has been found in a small number of heat-treated foods, including coffee, canned meat, baked bread, cooked chicken, sodium caseinate, filberts (hazelnuts), soy protein isolate, hydrolyzed soy protein, rapeseed protein, fish protein concentrate, and caramel (FDA, 2004). Very little information has been developed on furan levels in food.

Dinoflagellate Poisoning (Paralytic Shellfish Poisoning or PSP; Saxitoxin) In contrast to other seafood toxins, there is a tolerance set for PSP. The etiologic agent in this type of poisoning is saxitoxin or related compounds and is found in mussels, cockles, clams, soft shell clams, butter clams, scallops, and shellfish broth. Bivalve mussels are the most common vehicles. Saxitoxin, originally isolated from toxic Alaskan butter clams (*Saxidomus giganticus*) is actually a family of neurotoxins and includes neosaxitin and gonyautoxins 1 through 4. All block neural transmission at the neuromuscular junction by binding to the surface of the sodium channels and interrupting the flow of Na$^+$ ions; AV nodal conduction may be suppressed, there may be direct suppression of the respiratory center and progressive reduction of peripheral nerve excitability. The toxin produces parathesia and neuromuscular weakness without hypotension and lacks the emetic and hypothermic action of tetrodotoxin. Moderate symptoms are produced by 120–180 µg/person and are reversible within hours or days, whereas 80 µg of purified toxin per 100 g of tissue (0.5–2 mg/person) may be lethal, due to asphyxiation, usually within 12 hours of ingestion. The toxin is an alkaloid and is relatively heat stable. The toxin is produced by several genera of plankton (*Gonyaulax* (now known as *Alexandrium*) *catenella*, *G. acatenella*, and *G. tamarensis*, *Pyrodinium* spp., *Ptychodiscus brevis*, *Gymnodinium catenaturm* and others), and during red tide blooms may reach 20 million to 40 million per milliliter. Toxic materials are stored in various parts of the body of shellfish. Digestive organs, liver, gills, and siphons contain the greatest concentrations of poison during the warmer months. Distribution is worldwide (Bryan, 1984; Clark *et al*., 1999; Liston, 2000). The tolerance for PSP for clams, mussels, and oysters is 80 µg/100 g of meat (Compliance Policy Guideline, 540.250).

Added Substances—Fluoride Fluorine, in the form of fluoride, is nearly ubiquitous in nature. Primary human exposure is via drinking water, although it is also present in some foods, notably some teas, vegetables, and marine fish. Exposure also occurs via processed food made with fluoridated water or produce washed with fluoridated water (the so-called 'halo' effect). The greatest nondietary source is fluoridated toothpaste (NRC, 2006). Fluoride taken in water has a high degree of bioavailability with an absorption of 90% and with food, approximately 50%. Consumption of fluoride results in uptake by bone and in teeth, where enamel crystallites form fluorhydroxyapatite in place the naturally formed hydroxyapatite; the former being stronger and more acid resistant than the latter, resisting and even reversing the initiation and progression of dental caries. Ionic fluoride rarely exists in blood, most is trapped by bone tissue, where new bone growth is stimulated and this mechanism has served as the basis of some treatments for osteoporosis (WHO, 1996).

Fluorosis occurs as the result of high fluoride intake and may be complicated by low calcium intake; it is cumulative and endemic to some areas of the world (e.g., China and India). Fluorosis is dose responsive, producing a range of effects from cosmetic (mottling of teeth) to adverse functionality (skeletal fluorosis). Enamel fluorosis occurs as the result of high fluoride consumption prior to tooth eruption (i.e., in children up to the age of eight years, exposed to water with a fluoride content of ≥ 4 mg/L) and can range from a mild discoloration of the tooth surface to severe (brown) staining and pitting of the teeth to the point of enamel loss (NRC, 2006). In skeletal fluorosis, in the asymptomatic, preclinical stage, patients have an increased bone density. Stage 1 skeletal fluorosis is characterized by occasional stiffness, pain in joints or some osteosclerosis of the pelvis and vertebra. Stage 2 skeletal fluorosis is characterized by sporadic pain, stiffness of joints and osteosclerosis of the pelvis

and spine, although mobility is not severely affected. In Stage 3 (rarely seen in the U.S.), there may be crippling, dose-related calcification of ligaments, osteosclerosis, exotoses, osteoporosis of long bones, muscle wasting, and neurological effects due to hypercalcification of vertebrae (at this point, bone ash fluoride may be 2–3 times that of the bones of normal subjects). While it is agreed that skeletal fluorosis is the result of prolonged exposure to increased amounts of fluoride, because the incidence of crippling skeletal fibrosis continues to be rare even in geographic areas of high exposure, unidentified intervening metabolic or dietary factors may have rendered skeletons more or less susceptible. Other effects attributed to excess fluoride include lower IQ's and decreased thyroid function, increased calcitonin activity, increased parathyroid hormone activity, secondary hyperparathyroidism, impaired glucose tolerance and possible effects on timing of sexual activity (NRC, 2006). The reports of possible carcinogenic effects of fluoride are mixed and inconclusive.

Guidelines for fluoridation of the public water supply recommend addition at levels of 0.7–1.2 mg/L, to achieve target Adequate Intake levels based on a 2 L water/day intake by adults; with adjustments in warmer regions where water intake is high in the summer months, or where fluoride occurs naturally at high levels (e.g., some areas of Colorado, 11.2 mg/L; Oklahoma, 12.0 mg/L; New Mexico, 13.0 mg/L; and Idaho, 15.9 mg/L). Although the essentiality of fluorine has not been described, an Adequate Intake (AI) has been established for various age groups as a balance between caries resistance and possible fluorosis of teeth. For example, the AI for infants at 0.01 mg/d, for adult females and males at 3 and 4 mg/d, respectively and, a range of graduated AI's for intervening age groups (IOM, 1997).

SUBSTANCES FOR WHICH TOLERANCES MAY NOT BE SET

All the contaminants of food described to this point are those associated with synthesis, growth, production, or storage and are regarded by FDA as *unavoidable*. Because they are unavoidable, the FDA sets limits rather than bans them, as described earlier. The substances in this section are regarded as (1) *avoidable* or of such hazard that a safe level cannot be set and as such, FDA has determined that food containing such substances is banned or; (2) are beyond the control of FDA and cannot be regulated (e.g., substances produced in the home).

Toxins in Fish, Shellfish, and Turtles

There are a number of seafood toxins (to be distinguished from marine venoms), many of which are not confined to a single species (over 400 species have been incriminated in ciguatera toxicity) and are therefore most likely to be influenced by the environment. However, some seafood toxins are specific to a single species or genus. A complicating factor in the study of seafood toxins is the sporadic frequency and nonpredictability of the presence of the toxin.

Seafood toxins generally can be classified according to the location of the poison. For example, (1) ichthyosarcotoxin is concentrated in the muscles, skin, liver, or intestines or is otherwise not associated with the reproductive system or circulatory system, (2) ichthyootoxin is associated with reproductive tissue, (3) ichthyohemotoxin is confined to the circulatory system, and (4) ichthyohepatotoxin is confined to the liver. In general, seafood toxins under FDA

policy have a zero tolerance, with any detectable level considered cause for regulatory action.

Neurotoxic Shellfish Poisoning (NSP)   Traditionally limited to the coast of Florida, *Gymnodinium breve* form red tide blooms containing polycyclic ether toxins called brevetoxins (based on the backbone structure of the molecule generally divided into Type 1 or Type 2), with Type 2 the most often found. Brevetoxins bind to voltage-dependent sodium channels and strength of binding varies with the specific affinity of the toxin and thus the relative potency. Symptoms of NSP include nausea, tingling, and numbness of the oral area, loss of motor control and severe muscular ache; all of which resolve in a few days and no deaths have been reported, unlike PSP. An additional route of entry for mammals may result from inhalation of aerosolized toxin as the result of the relative ease of lysis of the unarmored *G. breve* organism during the breaking of waves on the shore. Symptoms of this type of exposure are seen as irritation of the throat and upper respiratory tract. A "kill" of nearly 150 manatees was reported during an unprecedented large outbreak of the toxin, although the specific mode of transmission is uncertain. Human exposure is primarily via consumption of filter-feeding organisms, which may concentrate the toxin (Van Dolah, 2000).

Amnesic Shellfish Poisoning (Domoic Acid)   Consumption of mussels harvested from the area off Prince Edward Island in 1987 resulted in gastroenteritis and many older consumers or those with underlying chronic diseases, experienced neurologic symptoms including memory loss. Despite treatment, three patients (71–84 years old) died within 11–24 days. The poisoning was attributed to domoic acid produced by the diatom *Nitzschia pungens* f. *multiseries* (now called *Pseudonitzschia multiseries*) which had been ingested by the mussels during the normal course of feeding. Occurrence of domoic acid has also been reported in California shellfish and produced by *N. pseudodelicatissima* and in anchovies (resulting in pelican deaths) produced by *N. pseudoseriata* (now called *Pseudonitzschia australis*). Domoic acid has been reported in shellfish in other provinces of Canada, Alaska, Washington, and Oregon and may be as frequent as PSP toxins. Domoic acid has also been reported in seaweed. Domoic acid was reported in Japan in 1958 and was isolated from the red algae *Chondria armata*.

In the Canadian outbreak, mice injected with extracts (as in the PSP assay) died within 3.5 hours. The mice exhibited a scratching syndrome uniquely characteristic of domoic acid that was followed by increasingly uncoordinated movements and seizures until the mice died. Levels of domoic acid >40 μg/g wet weight of mussel meat caused the mouse symptoms (Canadian authorities require cessation of harvesting when levels approach 20 μg/g). Mice and rats can generally tolerate 30–50 mg/kg. Domoic acid is dose-responsive in humans: with no effect at 0.2–0.3 mg/kg, mild gastrointestinal symptoms at 0.9–2.0 mg/kg, and the most serious symptoms at 1.9–4.2 mg/kg with gastrointestinal effects and neurological effects, including dizziness, disorientation, lethargy, seizures, and permanent loss of short-term memory. Although rodents appear to be more tolerant, the fatalities in humans were likely associated with underlying illness. Domoic acid is an analog of glutamine, a neurotransmitter and of kainic acid; the toxicity of all three are similar as they are excitatory and act on three types of receptors in the CNS with the hippocampus being the most sensitive. Domoic acid may be a more potent activator of kainic acid receptors than kainic acid itself.

The stimulatory action may lead to extensive damage of the hippocampus, but less severe injury to the thalamic and forebrain regions (Todd, 1993; Clark *et al.*, 1999; Van Dolah, 2000).

Ciguatera Poisoning   The "cigua" in ciguatera toxin is derived from the Spanish name for the sea snail *Turbo pica* in which the symptoms were first reported. Ciguatera and related toxins (scaritoxin and maitotoxin) are ichthyosarcotoxic neurotoxins (anticholinesterase) and are found in 11 orders, 57 families, and over 400 species of fish as well as in oysters and clams. The penultimate toxin (gambiertoxin) is produced by the dinoflagellate *Gambierdiscus toxicus*, commonly isolated from microalgae growing on or near coral reefs that have ingested the dinoflagellate. The pre-toxin appears to pass through the food chain and is biotransformed upon transfer to or by the ingesting fish to the active, which is consumed by mammals. Other toxins, including palytoxin and okadaic acid, unrelated to gambiertoxin, may be present in ciguarteric fish and may contribute to toxicity. The asymptomatic period is 3–5 hours after consumption but may last up to 24 hours. The onset is sudden, and symptoms may include abdominal pain, nausea, vomiting, and watery diarrhea; muscular aches; tingling and numbness of the lips, tongue, and throat; a metallic taste; temporary blindness; and paralysis. Deaths have occurred. Recovery usually occurs within 24 hours, but tingling may continue for a week or more. The intraperitoneal (i.p.) LD_{50} of maitotoxin in mice is 50 ng/kg (Bryan, 1984; Liston, 2000).

Palytoxin Poisoning   Palytoxin is produced by the zoanthind soft coral of the genus *Palythoa*, and fish, crabs, and polychaete worms living in close association with or eating this mass, may become contaminated with palytoxin. The toxin is not part of the stinging nematocyst of the coral, but may be produced by female polyps and mature eggs of the organism, possibly requiring the presence of an unidentified symbiotic algae (possibly the dinoflagellate *Ostreopsis siamensis*). Palytoxin, in various forms, is produced by any number of species, including *P. tuberculosa* in the tropical waters in the Pacific and Japan, *P. mammilosa* and *P. caribaeorum* in the West Indies, Puerto Rico, and the Bahamas, *P. vestitus* and other *Palythoa* spp. On occasion, the coral becomes detached from its anchorage and becomes a soft floating mass with a seaweed or moss-like appearance, a very attractive feeding ground for fish. Indigenous peoples of Hawaii knew this as *limu-make-o-Hana* (the deadly seaweed of Hana) and some are said to have smeared the moss on spear points to enhance their utility as a weapon (Onuma *et al.*, 1999; Tan and Lau, 2000; Tosteson, 2000).

The toxin has been reported in mackerel, parrotfish, and several species of crabs. Victims report a bitter, metallic taste from the meat (most often muscle, liver, ovary, and digestive tract), followed immediately by nausea, vomiting, and diarrhea. Within several hours, symptoms include myoglobinuria, a burning sensation around the mouth and extremities, muscle spasms, dyspnea, and dysphonia. Cause of death may be the result of mycocardial injury, although it is known in vitro to be a powerful hemolysin.

Although there are several isoforms and possibly minor toxins associated with palytoxin (depending on the producing species), the predominant action is as a oubain-sensitive Na^+K^+-ATPase inhibitor. Unlike oubain, palytoxin has no effect on H^+-, Ca^{2+}-, or H^+/K^+-transporting ATPases. The toxin is quite effective with intravenous LD_{50}s of 0.078, 0.45, 0.033, and 0.089 μg/kg for monkeys, mice, dogs, and rats, respectively. The standard assay is measured in mouse units (MU), the time taken to kill a mouse weighing 20 grams in 4 hours following intraperitoneal (i.p.) injection of 0.25 mL (Tan and Lau, 2000; Tosteson, 2000).

Puffer Fish Poisoning (Tetrodotoxin)   *Tetrodon* or puffer fish poisoning is caused by the improper preparation and consumption of any of about 90 species of puffer fish (fugu, blowfish, globefish, porcupine fish, molas, burrfish, balloonfish, toadfish, etc.); although the toxin has also been reported present in newts, frogs, octopus, starfish, flatworms, various crabs, and gastropods. Pufferfish are found in subtropical and tropical marine waters in the Atlantic (including off the coast of Florida), Pacific, and Indian Oceans. Some puffers live in brackish and fresh water. The toxin (tetrodotoxin) is located in nearly all the tissues, but the ovaries, roe, liver, intestines, and skin are the most toxic. Toxicity is highest during the spawning period, although a species may be toxic in one location but not in another. Tetrodotoxin is associated with the presence of several bacteria on and in fish and shellfish and is an evolutionary advantage providing protection against predators (i.e., they are *endosymbiotic* bacteria). A total of 21 species can produce tetrodotoxins including *Vibros, Pseudomonas*, and *E. coli*, and at least two strains of red algae.

Tetrodotoxin is a neurotoxin and causes paralysis of the central nervous system and peripheral nerves by blocking the movement of all monovalent cations. The toxin is water-soluble and is stable to boiling except in an alkaline solution. A fatal dose may be as little as 1–4 mg/person. The victim is asymptomatic for 10–45 minutes but may have a reprieve for as long as 3 or more hours. Toxicity is manifested as a tingling or prickly sensation of the fingers and toes; malaise; dizziness; pallor; numbness of the lips, tongue, and extremities; ataxia; nausea, vomiting, and diarrhea; epigastric pain; dryness of the skin; subcutaneous hemorrhage and desquamation; respiratory distress; muscular twitching, tremor, incoordination, and muscular paralysis; and intense cyanosis. Fatality rates are high (Bryan, 1984; Liston, 2000).

Moray Eel Poisoning   Although the moray eel (*Gymnothorax javanicus*) and other carnivorous fishes may accumulate ciguatoxin as the result of eating other contaminated fish, the Indo-Pacific moray eel (*Lycodontis nudivomer*) has been shown to possess a mucous skin secretion with hemolytic, toxic and hemagglutinating properties, unrelated to ciguatoxin. The hemolytic properties can be separated from the hemagglutinating properties. The hemolytic property is lost upon treatment with trypsin and is unstable in the presence of heat, acidic or alkaline media (Randall *et al.*, 1981). The skin mucous of other species of eels, the common European eel (*Anguilla anguilla*) and pike eel (*Muraenesox cinereus*) were found to have proteinaceous toxins, immunologically similar to that of the skin mucous toxin from the Japanese eel (*Anguilla japonica*) (Shiomi *et al.*, 1994).

Abalone Poisoning (Pyropheophorbide)   Abalone poisoning is caused by abalone viscera poison (located in the liver and digestive gland) and is unusual in that it causes photosensitization. The toxin, pyropheophorbide a, is stable to boiling, freezing, and salting. It is found in Japanese abalone, *Haliotis discus* and *H. sieboldi*. The development of symptoms is contingent on exposure to sunlight. The symptoms are of sudden onset and include a burning and stinging sensation over the entire body, a prickling sensation, itching, erythema, edema, and skin ulceration on parts of the body exposed to sunlight (Bryan, 1984; Shiomi, 1999). Paralytic shellfish toxin

(PST) has been detected in abalone, probably through consumption of the mossworm, a plankton feeder that also clings to seaweed and some shellfish (Takatani *et al.*, 1997).

Sea Urchin Poisoning   The etiologic agent forms during the reproductive season and is confined to the gonads. The sea urchins involved include *Paracentrotus lividus*, *Tripneustes ventricosus*, and *Centrechinus antillarum*. The symptoms include abdominal pain, nausea, vomiting, diarrhea, and migraine-like attacks (Bryan, 1984). The toxin has been shown to interfere with calcium uptake in nerve preparations (Zhang *et al.*, 1998).

Sea Turtle Poisoning (Chelonitoxin)   The etiologic agent here is chelonitoxin, which is found in the liver (greatest concentration) but also in the flesh, fat, viscera, and blood. Toxicity is described as sporadic or even seasonal, indicating the poison may be derived from toxic marine algae. Most outbreaks occur in the Indo-Pacific region. The turtles involved include the green sea turtle, the hawksbill and leatherback turtles. Local custom in Sri Lanka is to first offer the liver to crows and if the birds eat it, the flesh is regarded as safe, but because the symptoms appear over a few hours to several days, this bioassay requires patience. Symptoms of intoxication in humans include vomiting; diarrhea; sore lips, tongue, and throat; foul breath, difficulty in swallowing; a white coating on the tongue, which may become covered with pin-sized, pustular papules; tightness of the chest; coma; and death. The toxin has been reported transferred to nursing infants from intoxicated mothers. Post-mortem examinations reveal congestion of internal organs, interstitial pulmonary edema, and necrosis of myocardial fibers. Fatality rates of 7% and 25% have been reported (Bryan, 1984; Ariyananda and Fernando, 1987; Chandrasiri *et al.*, 1988; Champetier De Ribes *et al.*, 1997).

Haff Disease   Haff disease is a syndrome of unknown etiology following consumption of certain types of fish found in both salt and fresh water. The syndrome consists of rhabdomyolysis with a release of muscle cell contents into the blood. Patients are often rigid, sensitive to touch and unable to move; urine may have a dark brown color. Symptoms appear 18 hours (with a range of 6–21 hours) after consumption; symptoms resolve within 2–3 days and the fatality rate is approximately 1% (Frenzen, 2004). "Haff disease" was first reported in the 1920s along the Koenigsberg Haff, a brackish inlet on the Baltic sea, although outbreaks have been reported in Sweden, the former Soviet Union and in the United States beginning in 1984. U.S. poisonings have been associated with buffalo fish (*Ictiobus cyprnellus*) caught in California, Missouri, and Louisiana. No etiologic agent has been identified (Anonymous, 1998).

Microbiological Agents—Preformed Bacterial Toxins

Although the United States likely has the safest and cleanest food supply in the world, most food-related illness in the United States results from microbial contamination. Food-borne disease outbreaks are tracked by the Centers for Disease Control and Prevention (CDC) in Atlanta, Georgia. The CDC reports that there are approximately 400 outbreaks of food-borne disease per year involving 10,000–20,000 people. However, the actual frequency may be as much as 10–200 times as high because (1) an outbreak is classified as such only when the source can be identified as affecting two or more people and (2) most home poisonings are mild or have a long incubation time

and are therefore not connected to the ingested food, go unreported and are often felt to be only a "24-hour bug." Naturally, because of differences in virulence and opportunity, some species are more likely than others to cause outbreaks.

If all the microbiological food-borne health concerns could be divided into two categories—*poisonings* and *infections*—the former would include chemical poisonings and intoxications, which may have a plant, animal, or microbial origin. In the infections category, food acts as a vector for organisms that exhibit their pathogenicity once they have multiplied inside the body. Infections include the two subcategories: enterotoxigenic infections (with the release of toxins following colonization of the GI tract) and invasive infections in which the GI tract is penetrated and the body is invaded by organisms.

There are a number of food toxins of microbial origin; however, discussion in this chapter will be limited to pre-formed bacterial toxins—that is, those toxins elaborated by bacteria concomitant to their residence and growth in or on the food *prior* to ingestion. Importantly, the bacteria need not be present for the intoxication to take place because the bacteria may have been killed by heat while the toxin survives. Bacterial toxins may be divided on the basis of activity: *emetic toxins* (i.e., *Bacillus cereus*), which produce their effect by binding to specific receptors in the duodenum, *neurotoxins* (whose action is self explanatory) and, *enterotoxins*, which are protein toxins having action on the *enteric* cells of the intestine. Enterotoxins can be subdivided into cytotoxic enterotoxins which disrupt the cell membrane or other vital functions of the cell and cytotonic enterotoxins, which enter the epithelial cell and cause diarrhea without direct membrane disruption or cell death (Granum, 2006). Bacterial toxins may also be divided on the basis of their origin: an *endotoxin* is generally a lipopolysaccharide membrane constituent released from a dead or dying Gram-negative bacteria, these toxins are nonspecific and stimulate inflammatory responses from macrophages including, but not limited to prostaglandins, thromboxanes, interleukins, and other mediators of immunity; *exotoxins* which are synthesized and released (usually by Gram-positive bacteria) and are not an integral part of the organism, but may enhance its virulence. Some bacteria, such as *Shigella* spp., *Staphylococcus aureus*, or *Escherichia coli* (which releases the shiga-like vero toxin), can elaborate both endotoxin and exotoxin.

Clostridium Botulinum, C. butyricum and C. baratti   Food botulism rarely causes illness because the confluence of conditions required for its germination and toxin production—low acidity, high water activity, absence of preservatives, ambient temperature, and anaerobic environment—such a combination rarely occurs in foods, but botulinum poisoning remains important, the result of its potency (Sobel *et al.*, 2004). All *Clostridia* are Gram-positive, spore-forming anaerobes. Botulism is a product of the toxins: A (the predominant form in the U.S.), B (the predominant form in Europe), E (the predominant form in Northern latitudes), and F that may be produced by one or more strains of *C. botulinum*, *C. butyricum* (Type E only) and *C. baratti*; toxins C and D cause botulism in animals. Type G has not caused any human cases. *C. botulinum* toxins are categorized as Group I to IV on the basis of toxin produced; additionally, Group I is proteolytic in culture (liquefying egg white, gelatin, and other solid proteins). The toxin is elaborated in foods, wounds, and infant gut and is neurotoxic, interfering with acetylcholine at peripheral nerve endings. Botulinum neurotoxins induce blockage of voluntary motor and autonomic cholinergic neuromuscular junctions, which

prevents motor fiber stimulation. Clinical illness is characterized by cranial nerve palsies, followed by descending flaccid muscle paralysis, which can involve the muscles of respiration. Although ptosis and dysarthria may be mistaken for signs of encephalopathy, patients are fully alert, and the results of a sensory examination are normal. Recovery often takes weeks to months (Sobel *et al*., 2004). Although the spores are among the most heat-resistant, the toxins are heat-labile (the toxin may be rendered harmless at 80–100°C for 5–10 minutes). Botulinum toxins are large zinc-metalloproteins of ~150,000 Da, composed of two parts, a 50,000 Da piece, the catalytic subunit and the 100,000 Da piece containing an N-terminal translocation domain and a C-terminal binding domain. The structural features are similar to tetanus toxin. For Types B, D, F, and G (and tetanus toxin), the target protein is VAMP/synaptobrevin, a protein associated with the synaptic vesicle. Types A and E cleave a protein associated with the presynaptic membrane, ANAP25. Botulinum toxin C cleaves SNAP25 and syntaxin, another protein involved in exocytosis. Although intracellular mechanisms of botulinum and tetanus toxins are similar, symptoms are different because different populations of neurons are targeted. The symptoms may include respiratory distress and respiratory paralysis that may persist for 6–8 months. The case fatality rate in the United States is 4% (Sobel *et al*., 2004) and the poison is fatal in 3–10 days; a lethal dose is approximately one nanogram.

Current methods for detecting botulinum toxin include a mouse bioassay and an enzyme-linked immunosorbent assay (ELISA). The mouse bioassay is the accepted standard, where the mouse is injected with a lethal dose, the signs of which should develop in 8 hours and, if not, the mouse is observed for 4 days. The mouse bioassay can also be used to differentiate between the toxin types by mixing neutralizing antibodies with the sample, prior to injection. Determining which mice survive following which combination of toxin and antisera, determines the specific toxin type. The absolute amount of toxin detected in the mouse bioassay is not well defined but is thought to be 10–20 pg/mL for type A (Barr *et al*., 2005).

Sources and reservoirs for *Clostridia* include soil, mud, water, and the intestinal tracts of animals. Foods associated with botulinum toxin include improperly canned low-acid foods (green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, baked potato, cheese sauce, beef stew, olives, and tuna). The toxin also may occur in smoked fish, fermented food (seal flippers, salmon eggs) and improperly home-cured hams. An increasing source of poisonings is from the use of flavored oils or oil infusion, most typically in garlic-in-oil preparations; in 1993, FDA required acidification of such preparations to prevent the growth of *Clostridia*. Whereas a proteolytic strain of *C. botulinum* (Group I) may cause the food to appear and smell "spoiled" (by-products include isobutyric acid, isovaleric acid, and phenylpropionic acid), this is not the case with nonproteolytic strains, many of which can flourish and elaborate toxin at temperatures as low as 3°C (Loving, 1998; Belitz and Grosch, 1999; Crane, 1999; Lund and Peck, 2000).

The successful use of nitrates in meat to prevent spoilage by *C. botulinum* resulted in the petitioning of FDA by the USDA to have sodium and potassium nitrate approved for addition by "prior sanction" (21 CFR 181.33). The mechanism of nitrates is believed to be due to an inactivation by nitric oxide of iron–sulfur proteins such as ferrodoxin and pyruvate oxidoreductase within the germinated cells. The activity is dependent on the pH and is proportional to the level of free HNO_2; 100 mg nitrate/kg of meat is necessary for the antimicrobial effect, although this effect can be enhanced with ascorbates and chelating agents. Other antibacterials that prevent *C. botulinum* include nisin (used in cheese spreads), parabens, phenolic antioxidants, polyphosphates, and carbon dioxide (Belitz and Grosch, 1999; Lund and Peck, 2000).

Clostridium perfringens   Unlike *C. botulinum*, the primary reservoir for *C. perfringens* is the intestinal tract of warm-blooded animals (including humans). Most incidences of *C. perfringens* food poisoning are associated with the consumption of roasted meat that has been contaminated with intestinal contents at slaughter, followed by roasting and inadequate storage, allowing *C. perfringens* growth and enterotoxin (CPE) to be elaborated (although some CPE may actually be released during a "second sporulation" process in the stomach of the victim). Virtually all food poisoning is produced by type A strain, although a particularly severe form (a necrotic enteritis called "pig-bel" among indigenous peoples of the New Guinea highlands or in Germany known as "Darmbrand") and is produced by type C strain, which has a mortality rate of 15–25% even with treatment. The toxin is normally trypsin sensitive, but people with low intakes of protein or who consume trypsin-inactivating foods (e.g., sweet potatoes) are more at risk than carnivorous people with normal trypsin levels (Granum and Brynestad, 1999; Granum, 2006).

CPE is enterotoxic and follows an ordered series of events, first causing cellular ion permeability, followed by macromolecular (DNA, RNA) synthesis inhibition, morphologic alteration, cell lysis, and villi tip desquamation and severe fluid loss. This is manifested by abdominal cramping and diarrhea occurs within 8–16 hours, although symptoms are of short duration, one day or less. Foods associated with *C. perfringens* poisoning include cooked meat or poultry, gravy, stew, and meat pies. *C. perfringens* is also associated with the production of another 11 toxins, including those associated with gas gangrene (Hobbs *et al*., 1953; Hauschild, 1971; Walker, 1975; Hobbs, 1976; Crane, 1999; Labbe, 2000).

Bacillus cereus   *Bacillus cereus* is also a Gram-positive, spore-forming rod, but is an aerobe. *Bacillus cereus* is a causative agent of emetic or diarrheagenic exo- and enterotoxins elaborated in food. The emetic thermostable toxin (surviving 259°F for 90 minutes) is called cerulide (a small cyclic peptide, 1.2 kDa that acts on $5\text{-}HT_3$ receptors stimulating the vagus afferent nerve) and is produced by serotypes 1, 3, and 8; it is also resistant to pH and proteolysis, but is not antigenic. The diarrheagenic thermolabile toxin (133°F for 20 minutes), is produced by serotypes 1, 2, 6, 8, 10, and 19; and may also be produced in situ in the lower intestine of the host. The diarrheal form may actually consist of three toxins, one of which is hemolytic (Granum, 2006). Reservoirs are soil and dust. Foods associated with this organism and its toxic properties, include boiled and fried rice (principally the emetic form), while the diarrheal form has a wider occurrence and may be found in meats, stews, pudding, sauces, dairy products, vegetable dishes, soups, and meat loaf (Goepfert *et al*., 1972; Gilbert, 1979; Bryan, 1984; Crane, 1999; Granum and Lund, 1997). The foods associated with the two types somewhat reflect the geographic distribution of the types, as the emetic type predominates in Japan, while in North America and Europe, the diarrhea type is most often seen.

Evidence is accumulating that other species of *Bacillus* may elaborate food toxins, including *Bacillus thurigensis*, *B. subtilis*, *B. licheniformis*, and *B. pumilis* (Crane, 1999; Granum and Baird-Parker, 2000; Granum, 2006).

Staphylococcus aureus   Staphylococcal intoxication includes staphyloenterotoxicosis and staphylococcus food poisoning. *S. aureus* produces a wide variety of exoproteins, including toxic shock syndrome toxin-1 (TSST-1), the exfoliative toxins ETA and ETB, leukociden and the staphylococcal enterotoxins (SEA, SEB, SECn,[19] SED, SEE, SEG, SHE, and SEI). TSST-1 and the staphylococcal enterotoxins (SE) are also known as pyrogenic toxin superantigens (PTSAgs) on the basis of their biological characteristics. There is a relatively wide degree of molecular diversity among SE toxins and this is thought to be the result of adaptation to allow for a broad range of potential hosts (Monday and Bohach, 1999). Some, but not all, SE require Zn^{++} for superantigen activity. Although enterotoxemia only develops from ingestion of large amounts of SE, emesis is produced as the result of stimulation of the putative SE receptors in the abdominal viscera, following which is a cascade of inflammatory mediator release. All the SE toxins share a number of properties: an ability to cause emesis and gastroenteritis in primates, superantigenicity, intermediate resistance to heat and pepsin digestion, and tertiary structural similarity, including an intramolecular disulfide bond. Induction of emesis separates the SE toxins from TSST-1, but the induction of emesis is not directly correlated to superantigen activity (Granum, 2006). The exact link between superantigenicity and lethality by the SE toxins and TSST-1 is not known, but may be dependent upon cytotoxicity for certain cells, possibly in the kidneys, liver, or vascular endothelium (Monday and Bohach, 1999). Sources of *Staphylococcus* include nose and throat discharges, hands and skin, infected cuts, wounds, burns, boils, pimples, acne, and feces. The anterior nares of humans are the primary reservoirs. Other reservoirs include mastitic udders of cows and ewes (responsible for contamination of unpasteurized milk); and arthritic and bruised tissues of poultry. Foods usually are contaminated after cooking by persons cutting, slicing, chopping, or otherwise handling them and then keeping them at room temperature for several hours or storing them in large containers. Foods associated with staphylococcal poisoning include cooked ham; meat products, including poultry and dressing; sauces and gravy; cream-filled pastry; potatoes; ham; poultry; fish salads; milk; cheese; bread pudding; and generally high protein leftover foods (Cohen, 1972; Bryan, 1976, 1984; Minor and Marth, 1976; Crane, 1999; Dinges *et al.*, 2000).

Escherichia coli   Although *E. coli* does not produce a pre-formed toxin, it deserves mention because of the overwhelming publicity the emergent strain O157:H7 has received (H and O refer to flagellar antigens and virulence markers). There are four categories of *E. coli* associated with diarrheal disease: enteropathogenic (EPEC), enterotoxigenic (ETEC), enteroinvasive (EIEC), and Vero cytotoxin-producing *E. coli* (VTEC). The classification VTEC also includes "shiga-like toxin"-producing *E. coli* (or SLTEC) and "shiga toxin"-producing *E. coli* (STEC). Enterohemorrhagic *E. coli* (EHEC) refers to those strains producing bloody diarrhea and are a subset of VTEC. The reference to shiga toxin is the result of the clinical similarity of the bloody diarrhea caused by EHEC to that caused by *Shigellae*. Each of the diseases presented by the four categories is also associated with one or more toxins (Willshaw *et al.*, 2000).

Because cattle are a significant reservoir of *E. coli*, it is logical that most outbreaks in the United States have been associated with hamburgers and other beef products although raw vegetables (often fertilized with manure) and unpasteurized apple cider and juice have been reported as sources of outbreaks. Outbreaks in Europe are more often associated with contamination of recreational waters (swimming pools, lakes, etc.). Other sources of contamination include person-to-person contact (especially in families and among institutionalized persons) and contact with farm animals especially following educational farm visits (Karch *et al.*, 1999).

The subject of organic food has increasingly captured the public interest. Within this issue, is a debate concerning the use of organic fertilizers (e.g., cow manure) in organic and conventional farming, which may contain *E. coli* O157:H7 (Stephenson, 1997). Data reported to the U.S. Centers for Disease Control and Prevention (CDC) in 1996, and tabulated in a CDC document entitled "Clusters/Outbreaks of *E. coli* O157:H7 reported to CDC in 1996," show that approximately 10% of all *E. coli* O157:H7 infections reported that year were from organically grown lettuce, although organic foods apparently account for less than 1% of the total food supply.

At the basis of the potential problem is the use of inadequately treated manure for fertilizer. Human cases of *E. coli* O157:H7 infection have been reported from consumption of contaminated lettuce, potatoes, radish sprouts, alfalfa sprouts, cantaloupe, and unpasteurized apple cider and juice (Karch *et al.*, 1999). Adequate treatment of manure requires composting the manure for a minimum of 3 months during which, the heap must reach a temperature of 60°C and although this may be adequate to kill vegetative pathogens, it will not destroy spore-formers such as *Clostridium perfringens* or *C. botulinum.* Survival of viruses and protozoa during composting is not known (Anonymous, 1999).

Bovine Spongiform Encephalopathy

Bovine spongiform encephalopathy (BSE) was first identified in Great Britain in 1986. BSE is a neurological disease classified as a transmissible spongiform encephalopathy (TSE) and is similar to TSEs in other species including scrapie (sheep and goats), transmissible mink encephalopathy (ranch-bred mink), chronic wasting disease (mule deer and elk), exotic ungulate encephalopathy (captive exotic bovoids such as bison, orynx, kudu) and feline spongiform encephalopathy (domestic cats and zoo Felidae). TSEs among humans include kuru, Creutzfeldt-Jakob Disease (CJD), and "new variant" CJD (nvCJD) and Gerstmann–Sträussler–Scheinker syndrome (to be distinguished from CJD by an earlier onset and tends to run in families).

Clinically, all these diseases present neurological deterioration and wasting, with the incubation period and interval from clinical onset to inexorable death determined by the dose of infective agent, its virulence and genetic makeup of the victim. The incubation of BSE in cattle is generally 4–5 years (range of 20 months to 18 years) and an interval of 1–12 months from presentation of clinical signs to death. Characteristic histologic lesions in the brain and spinal cord are vacuolation and "spongiform" changes. BSE fibrils (long strands of host glycoprotein called prion protein or PrP) in spinal cord preparations may be seen with electron microscopy following detergent extraction and proteinase K digestion. BSE/scrapie tissues with highest infectivity are brain and spinal cord, followed by retina, spleen, tonsil lymph nodes, distal ileum, and proximal colon. The infective agent can be transferred using preparations of neural tissue from infected animals across species barriers. The most effective method of transfer is direct injection into the brain or spinal cord, but transfer has been reported with intraperitoneal injection and oral

IQ = 2-amino-3-methylimidazo[4,5-f]quinoline; MeIQx = 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline; 4,8-DiMeIQx = 2-amino-3,4,8-trimethyl-3H-imidazo[4,8-f]quinoxaline; Trp-P-1 = 3-amino-1,4-dimethyl-5h-pyrido[4,3-b]indole; Trp-P-2 = 3-amino-1-methyl-5h-pyrido[4,3-b]indole.

dosing. Vertical transfer (mother to offspring) has been reported among domestic cattle and lateral transfer through biting or injury (especially among mink) has also been reported. Indirect transmission of chronic wasting disease (CWD) has been reported recently (Miller *et al*., 2004); CWD of mule deer (*Odocoileus hemionus*) can be transmitted from environments contaminated by excreta 2.2 years earlier or decomposed carcasses ∼1.8 years earlier.

It is generally agreed that the infective agent is likely a variant of scrapie (endemic to sheep) and was transferred to cattle from rendered sheep via inadequately processed meat and bone meal protein supplement. There is strong evidence and general agreement that the outbreak was amplified and spread throughout the UK cattle industry by feeding rendered (contaminated) bovine meat- and-bone meal to young calves. Disputes have arisen about other details of BSE and its relationship to other TSEs and effects in man because of an expectation of conformation by BSE to historical principles of disease transmission. Based on the BSE controversy, the FDA has published a proposed rule (Federal Register 70:58569-58601, 2005), which lists so-called high-risk tissues not allowed in animal or pet food due to potential BSE risk to livestock or pets and ultimately, humans.

The currently most accepted theory is that the infective agent is a modified form of a normal cell surface component known as prion protein PrP^c (*alpha*-helix form), which when introduced into an organism causes a conversion of PrP^c into a likeness of itself (i.e., the isoform), but then designated as the pathogenic form, PrP* or PrP^{sc} for scrapie; or PrP^{res} for protease resistant (beta-pleated sheet form) (Flechsig and Wissmann, 2004; Frosch *et al*., 2005). The agent does not possess nucleic acid. The pathogenic form of the protein, PrP*, is both less soluble and more resistant to enzyme degradation than the normal form. The protein is resistant to heat, antimicrobials, ultraviolet or ionizing radiation, and is not consistently inactivated with alcohol, formaldehyde, glutaraldehyde, or sodium hydroxide. Phenol and sodium hypochlorite disinfection have had variable success.

Investigators have concluded that the agent in nvCJD and BSE is the same strain and may be the same agent in feline spongiform encephalopathy and exotic ungulate encephalopathy. While this information might indicate a simple mode of transmission, workers with the highest potential incidence of exposure to BSE or TSE (sheep farmers, butchers, veterinarians, cooks, and abattoir workers) do not have an unusually high incidence of nvCJD (Prusiner, 1991; Collee, 2000). Likewise, hemophilic patients have not reflected an increased incidence of nvCJD, although CJD transmission has been documented as the result of injections of human growth hormone or gonadotrophin (derived from human pituitary gland), implantation of dura mater and corneas and even infected EEG electrodes and neurosurgical instruments (Prusiner, 1994; Lee *et al*., 1998; Collee, 2000).

Substances Produced by Cooking

Heterocyclic Amines   Tolerances cannot be set for contaminants that are produced as a result of an action taken by the consumer. An example of this type of contaminant is heterocyclic amines, which are generated during cooking. Heterocyclic amines (HCAs) were discovered serendipitously by Japanese investigators who, while examining the mutagenicity of smoke generated by charred foods, found that the extracts of the charred surfaces of the meat and fish were quantitatively more mutagenic than could be accounted for by the presence of polycyclic aromatic hydrocarbons (Sugimura *et al*., 1989). Collectively, there are more than 20 HCAs. They are formed as a result of high-temperature cooking of proteins (especially those containing high levels of creatinine) and carbohydrates. Normally, as a result of such heating, desirable flavor components are formed, for example, pyrazines, pyridines, and thiazoles. Intermediates in the formation of these substances are dihydropyrazines and dihydropyridines, which in the presence of oxygen form the flavor components; however, in the presence of creatinine, HCAs are formed (Table 30-26) (Chen and Chiu, 1998; Schut and Snyderwine, 1999).

These substances are rapidly absorbed by the GI tract, are distributed to all organs, and decline to undetectable levels within 72 hours. HCAs behave as electrophilic carcinogens (Table 30-27). They are metabolized first by N-hydroxylation followed by further activation by O-acetylation or O-sulfonation to react with DNA. DNA adducts are formed with guanosine in various organs, including the liver, heart, kidney, colon, small intestine, forestomach, pancreas, and lung. Unreacted substances are subject to phase II detoxication reactions and are excreted via the urine and feces. In vitro, HCAs require metabolic activation, with some requiring O-acetyltransferase and others not. Although much of the mutagenicity testing has been carried out in TA98 and TA100, these substances are mutagenic in mammalian cells both in vitro and in vivo, *Drosophila*, and other strains of *Salmonella* (Munro *et al*., 1993; Skog *et al*., 1998; Sugimura and Wakahayashi, 1999).

Table 30-27
Mutagenicity and Carcinogenicity of Heterocyclic Amines

HCA	NUMBER OF REVERTANTS u/g (STRAIN TA98)	CARCINOGENICITY	
		SPECIES	STATISTICALLY SIGNIFICANT TUMORS
MeIQ	47,000,000	Mouse	Liver, forestomach
		Rat	Zymbal gland, oral cavity, colon, skin, mammary gland
IQ	898,000	Mouse	Liver, forestomach, lung
		Rat	Liver, mammary gland, Zymbal gland
		Monkey	Liver, metastasis to lungs
MeIQx	417,000	Mouse	Liver, lung, lymphoma, leukemia
		Rat	Liver, Zymbal gland, clitoral gland, skin
Glu-P-1	183,000	Mouse	Liver, blood vessels
		Rat	Liver, small and large intestine, brain, clitoral gland, Zymbal gland
DiMeIQx	126,000	No data

MeIQ = 2-amino-3,4-dimethylimidazo[4,5-f]quinoline; IQ = 2-amino-3-methylimidazo[4,5-f]quinoline; MeIQx = 2-amino-3,8-dimethyl-limidazo[4,5-f]quinoxaline; Glu-P-1 = 2-amino-6-methyldipyrido[1,2-a:3′,2′-d]imidazole; 4,8-DiMeIQx = 2-amino-3,4,8-trimethyl-3H-imidazo[4,8-f]quinoxaline; Trp-P-1 = 3-amino-1,4-dimethyl-5h−pyrido[4,3-b]indole; Trp-P-2 = 3-amino-1-methyl-5h−pyrido[4,3-b]indole; PhIP = 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine; glu-p-2 = 2-aminodipyrido[1,2-a:3′,2′-d]imidazole.

Acrylamide   Prior to 2002, when Swedish investigators detected acrylamide in food (Table 30-28), it was of interest only to specialists in worker safety, as this chemical is an important intermediate in the manufacture of polyacrylamides. Although there are many industrial and manufacturing uses of polyacrylamides, the bulk of production are used as chemical flocculants for water treatment, oil recovery and, in construction of dam foundations, tunnels and sewers—consumer exposure is largely incidental (NTP, 2004b). End users are exposed to polyacrylamide, which is not toxic as long as the monomer is not present. Acrylamide (the monomer) was known to be a neurotoxin, creating morphological changes in peripheral nerves at doses as low as 1 mg/kg BW/d. Much more is now known about acrylamide and its primary metabolite, glycidamide, which is produced from acrylamide by the enzyme CYP2E1; both acrylamide and glycidamide will form adducts with hemoglobin. Acrylamide is absorbed rapidly and extensively (23–48% of the administered dose to rodents) from the gastrointestinal tract. Both acrylamide and glycidamide are largely eliminated as mercapturic acid conjugates. Repeated dosing of acrylamide (in drinking water at 21 mg/kg BW/d for 40 days) produces morphological changes in the brain areas critical for learning, memory, and other cognitive functions (i.e., cerebral cortex, thalamus, and hippocampus) (JECFA, 2005). Acrylamide was classified as "probably carcinogenic to humans" (IARC Group 2A) by the International Agency for Research on Cancer (IARC, 1994) and "reasonably anticipated to be a human carcinogen" by the National Toxicology Program (NTP, 2004b).

Acrylamide is formed in foods that are high in carbohydrate, but low in protein, which are subjected to processing temperatures of at least 120°C. These high-temperature processing conditions are largely the same as required for the Maillard reaction which imparts a toasted, or baked (i.e., "crust") flavor to breads, toast, and other baked goods and, breaded meats and vegetables for sautéing or frying and, most critical in production of French fries and potato chips. Most acrylamide is formed in the final stages of baking, grilling, or frying as the moisture content of the food falls and the surface temperature rises (JECFA, 2005). The presence of ammonium bicarbonate as a leavening agent increases the formation of acrylamide.

A critical element is the presence of asparagine, and amino acids competing with asparagine in the Maillard reaction, which reduce the levels of acrylamide in the final product. Strategies for mitigation focus on reduction of asparagine through use of asparaginase, breeding and selection of low asparagine plants and prolonged yeast fermentation; alternatively, processing temperature could be lowered (JECFA, 2005).

Acrylamide intake estimates range from 0.3 to 2.0 µg/kg BW/d for the average population, with the 90th to 97th percentile at 0.6 to 3.5 µg/kg BW/d at the 99th percentile at 5.1 µg/kg BW/d. Primary sources include French fries (1–30%), potato chips (6–46%), coffee (13–39%), pastry and cookies (10–20%), and bread and rolls/toasts (10–30%). The national average and "high intake users" are 1 and 4 µg/kg BW/d, respectively. The NOEL for morphological change in nerves and for reproductive effects is 200 and 2000 µg/kg BW/d, respectively (JECFA, 2005).

Table 30-28
Representative Concentrations of Acrylamide in Several Foods

FOOD	MEAN CONC. (μg/kg)	REPORTED MAXIMUM (μg/kg)
Cereal-based products		
Breads and rolls	446	3436
Pastry and cookies	350	7834
Breakfast cereals	96	1346
Roots and tubers		
Baked potato	169	1270
Potato chips	752	4080
French fries	334	5312
Coffee		
Coffee, brewed, ready to drink	13	116
Coffee extracts	1100	4948
Coffee, decaffeinated	668	5399
Coffee substitutes	845	7300
Vegetables		
Raw, boiled and canned	4.2	25
Processed (toasted, baked, fried, grilled)	59	202
Infant formula	<5	15
Baby food (biscuits)	181	1217

Miscellaneous Contaminants in Food

Sometimes the items under the miscellaneous heading are the most interesting. For example, Rodricks and Pohland (1981) pointed out an interesting historical case of the possible transfer of a toxic botanic chemical from an animal to humans, which was first identified by Hall (1979). It is found in the Bible, Book of Numbers, 11:31–33, which describes hungry Israelites inundated with quail blown in from the sea; those who ate the quail quickly died. Hall speculated that the quail had consumed various poisonous berries, including hemlock, while they overwintered in Africa. The hemlock berry contains coniine, a neurotoxic alkaloid to which quail are resistant and which can accumulate in their tissue. Humans are not resistant to coniine, and consumption of large quantities of quail tissue containing the neurotoxin could result in death as described in the biblical text.

Mountain laurel, rhododendron, and azaleas all possess andromedotoxin (now called acetylandromedol) and grayanotoxins (I, II, and II) in their shoots, leaves, twigs, and flowers. Honey made from flowers of these plants is toxic to humans, and after an asymptomatic period of 4–6 hours, salivation, malaise, vomiting, diarrhea, tingling of the skin, muscular weakness, headache, visual difficulties, coma, and convulsions occur. Life-threatening bradycardia and arterial hypotension may occur. Needless to say, beekeepers maintain apiaries well away from these species of plants. A similar poisoning occurs with oleander (*Nerium oleander* and *N. indicum*), where honey made from the flowers, meat roasted on oleander sticks, or milk from a cow that eats the foliage can produce prostrating symptoms. The oleander toxin consists of a series of cardiac glycosides: thevetin, convallarin, steroidal, helleborein, ouabain, and digitoxin. Sympathetic nerves are paralyzed; the cardiotoxin stimulates the heart muscles similar to the action of digitalis, and gastric distress ensues (Anderson and Sogn, 1984; VonMalottki and Weichmann, 1996).

Other contaminations include contamination of milk with pyrrolizidine and other alkaloids after a cow has fed on tansy ragwort (*Senecio jacobaea*) and tremetol contamination of milk from white snakeroot (*Eupatorium rugusum*).

CONCLUSION

Food toxicology differs in many respects from other subspecialties of toxicology largely because of the nature and chemical complexity of food. Food consists of hundreds of thousands of chemical substances in addition to the macro- and micronutrients that are essential to life. The federal law defining food safety in the United States, the FD&C Act, provides a scheme for establishing the safety of foods, food ingredients, and contaminants. Whereas the act does not specify how the safety of food and its components and ingredients is to be demonstrated, it emphasizes the need for reasonable approaches in both the application of tests and their interpretation. New policies, consistent with the safety provisions of the Act, are being developed to provide guidance for determination of the safety-in-use of novel foods and those foods derived from new plant varieties.

Contaminants found in food may be divided into two large classes: those that are unavoidable by current good manufacturing practice and those that are not. The former class is represented by substances such as certain chlorinated organic compounds, heavy metals, and mycotoxins which have been determined to be unavoidable by current food-manufacturing practice and for which tolerances or action levels may be established. Additionally, pesticide residues and residues of drugs used in food-producing animals may have tolerances established when necessary to protect public health. For avoidable class of contaminants, tolerances are not set either because public health concerns dictates that the mere presence of the substance or agent demands immediate regulatory action or because

contamination results from food preparation in the home, which is beyond FDA control.

It is important to emphasize that the vast majority of food-borne illnesses in developed countries is attributable to microbiological contamination of food arising from the pathogenicity and/or toxigenicity of the contaminating organism. Thus, the overwhelming concern for food safety in the United States remains directed toward preserving the microbiological integrity of food.

ANALYTIC/FORENSIC TOXICOLOGY

Alphonse Poklis

It is impossible to consider the topic of forensic toxicology without discussing analytic toxicology in detail. However, analytic toxicology has its roots in forensic applications. Therefore, it is logical to discuss these mutually dependent areas together. Analytic toxicology involves the application of the tools of analytic chemistry to the qualitative and/or quantitative estimation of chemicals that may exert adverse effects on living organisms. Generally, the chemical that is to be measured (the analyte) is a xenobiotic that may have been altered or transformed by metabolic actions of the organism. Frequently, the specimen that is to be analyzed presents a matrix consisting of body fluids or solid tissues from the organism. Both the identity of the analyte and the nature of the matrix present formidable problems to an analytic toxicologist.

Forensic toxicology involves the use of toxicology for the purposes of the law (Cravey and Baselt, 1981). Although this broad definition includes a wide range of applications, such as regulatory toxicology and urine testing to detect drug use, by far the most common application is to identify any chemical that may serve as a causative agent in inflicting death or injury on humans or in causing damage to property. Frequently, as a result of such unfortunate incidents, charges of liability or criminal intent are brought that must be resolved by the judicial system. At times, indirect or circumstantial evidence is presented in an attempt to prove cause and effect. However, there is no substitute for an unequivocal identification of a specific chemical substance that is demonstrated to be present in tissues from the victim at a sufficient concentration to explain the injury with a reasonable degree of scientific probability or certainty. For this reason, forensic toxicology and analytic toxicology have long shared a mutually supportive partnership.

Some forensic toxicologic activities have been deemed so important by society that a great effort is expended to initiate and implement analytic procedures in a forensically credible manner as an aid in deciding whether adverse effects have been produced by certain chemicals. Attempts to control drivers whose driving ability may be impaired by ethanol or certain drugs are evidenced by laws prescribing punishment to individuals who are so impaired. The measurement of ethanol in blood or breath at specific concentrations is generally required to prove impairment by this agent (Fisher *et al.*, 1968). Similarly, the decade of the 1980s saw a growing response by society to the threat of drug abuse. Attempts to identify drug users by testing urine for the presence of drugs or their metabolites, using methods and safeguards developed by forensic toxicologists, have become required by law (Department of Health and Human Services, 1988).

The diagnosis and treatment of health problems induced by chemical substances (Blanke and Decker, 1986) and the closely allied field of therapeutic drug monitoring (Moyer *et al.*, 1986) also rely greatly on analytic toxicology. Although the analytes are present in matrices similar to those seen in forensic toxicology, the results must be reported rapidly to be of use to clinicians in treating patients. This requirement of a rapid turnaround time limits the number of chemicals that can be measured because methods, equipment, and personnel must all be available for an instant response to toxicologic emergencies.

Occupational toxicology (see Chap. 33) and regulatory toxicology require analytic procedures for their implementation or monitoring. In occupational toxicology, the analytic methods used to monitor threshold limit values (TLVs) and other means of estimating the exposure of workers to toxic hazards may utilize simple, nonspecific, but economical screening devices. However, to determine the actual exposure of a worker, it is necessary to analyze blood, urine, breath, or another specimen by employing methods similar to those used in clinical or forensic toxicology. For regulatory purposes, a variety of matrices (food, water, air, etc.) must be examined for extremely small quantities of analytes. Frequently, this requires the use of sophisticated methodology with extreme sensitivity. Both of these applications of analytic toxicology impinge on forensic toxicology because an injury or occupational disease in a worker can result in a legal proceeding, just as a violation of a regulatory law may.

Other applications of analytic toxicology occur frequently during the course of experimental studies. Confirmation of the concentration of dosing solutions and monitoring of their stability often can be accomplished with the use of simple analytic techniques. The bioavailability of a dose may vary with the route of administration and the vehicle used. Blood concentrations can be monitored as a means of establishing this important parameter. In addition, an important feature in the study of any toxic substance is the characterization of its metabolites as well as the distribution of the

parent drug, together with its metabolites, to various tissues. This requires sensitive, specific, and valid analytic procedures. Similar analytic studies can be conducted within a temporal framework to gain an understanding of the dynamics of the absorption, distribution, metabolism, and excretion of toxic chemicals.

It is evident that analytic toxicology is intimately involved in many aspects of experimental and applied toxicology. Because toxic substances include all chemical types and because the measurement of toxic chemicals may require the examination of biological or nonbiological matrices, the scope of analytic toxicology is broad. Nevertheless, a systematic approach and a reliance on the practical experience of generations of forensic toxicologists can be used in conjunction with the sophisticated tools of analytic chemistry to provide the data needed to understand the hazards of toxic substances more completely. These concepts are described in detail in the rest of this chapter.

ANALYTIC TOXICOLOGY

In light of the statement by Paracelsus five centuries ago, "All substances are poisons: there is none which is not a poison," analytic toxicology potentially encompasses all chemical substances. Forensic toxicologists learned long ago that when the nature of a suspected poison is unknown, a systematic, standardized approach must be used to identify the presence of most common toxic substances. An approach that has stood the test of time was first suggested by Chapuis in 1873 in *Elements de Toxicologie.* It is based on the origin or nature of the toxic agent (Peterson *et al.*, 1923). Such a system can be characterized as follows:

1. Gases
2. Volatile substances
3. Corrosive agents
4. Metals
5. Anions and nonmetals
6. Nonvolatile organic substances
7. Miscellaneous

Closely related to this descriptive classification is the method for separating a toxic agent from the matrix in which it is embedded. The matrix is generally a biological specimen such as a body fluid or a solid tissue. The agent of interest may exist in the matrix in a simple solution or may be bound to protein and other cellular constituents. The challenge is to separate the toxic agent in sufficient purity and quantity to permit it to be characterized and quantified. At times, the parent compound is no longer present in large enough amounts to be separated. In this case, known metabolites may indirectly provide a measure of the parent substance (Hawks and Chiang, 1986). With other substances, interaction of the poison with tissue components may require the isolation or characterization of a protein adduct (SanGeorge and Hoberman, 1986). Methods for separation have long provided a great challenge to analytic toxicologists. Only recently have methods become available that permit direct measurement of some analytes without prior separation from the matrix.

Gases are most simply measured by means of gas chromatography. Some gases are extremely labile, and the specimen must be collected and preserved at temperatures as low as that of liquid nitrogen. Generally, the gas is carefully liberated by incubating the specimen at a predetermined temperature in a closed container. The gas, freed from the matrix, collects over the specimen's "headspace," where it can be sampled and injected into the gas chromatograph. Other gases, such as carbon monoxide, interact with proteins. These

gases can be carefully released from the protein, or the adduct can be measured independently, as in the case of carboxyhemoglobin.

Volatile substances are generally liquids of a variety of chemical types. The temperature at which they boil is sufficiently low that older methods of separation utilized microdistillation or diffusion techniques. Gas–liquid chromatography is the simplest approach for simultaneous separation and quantitation in favorable cases. The simple alcohols can be measured by injecting a diluted body fluid directly onto the column of the chromatograph. A more common approach is to use the headspace technique, as is done for gases, after incubating the specimen at an elevated temperature.

Corrosives include mineral acids and bases. Many corrosives consist of ions that are normal tissue constituents. Clinical chemical techniques can be applied to detect these ions when they are in great excess over normal concentrations. Because these ions are normal constituents, the corrosive effects at the site of contact of the chemical, together with other changes in blood chemistry values, can confirm the ingestion of a corrosive substance.

Metals are encountered frequently as occupational and environmental hazards. Elegant analytic methods are available for most metals even when they are present at extremely low concentrations. Classic separation procedures involve destruction of the organic matrix by chemical or thermal oxidation. This leaves the metal to be identified and quantified in the inorganic residue. Unfortunately, this prevents the determination of the metal in the oxidation state or in combination with other elements, as it existed when the metal compound was absorbed. For example, the toxic effects of metallic mercury, mercurous ion, mercuric ion, and dimethylmercury are all different. Analytic methods must be selected that determine the relative amount of each form present to yield optimal analytic results. The analytic difficulty in doing this has lent support to the unfortunate practice of discussing the toxicity of metals as if each metal existed as a single entity.

Toxic anions and nonmetals are a difficult group for analysis. Some anions can be trapped in combination with a stable cation, after which the organic matrix can be destroyed, as with metals. Others can be separated from the bulk of the matrix by dialysis, after which they are detected by colorimetric or chromatographic procedures. Still others are detected and measured by ion-specific electrodes. There are no standard approaches for this group, and other than phosphorus, they are rarely encountered in an uncombined form.

The *nonvolatile organic substances* constitute the largest group of substances that must be considered by analytic toxicologists. This group includes drugs, both prescribed and illegal, pesticides, natural products, pollutants, and industrial compounds. These substances are solids or liquids with high boiling points. Thus, separation procedures generally rely on differential extractions of tissue specimens (Fig. 31-1). These extractions often are not efficient, and recovery of the toxic substance from the matrix may be poor. When the nature of the toxic substance is known, immunoassay procedures are useful because they allow a toxicologist to avoid using separation procedures. These compounds can be classified as

1. organic strong acids
2. organic weak acids
3. organic bases
4. organic neutral compounds
5. organic amphoteric compounds

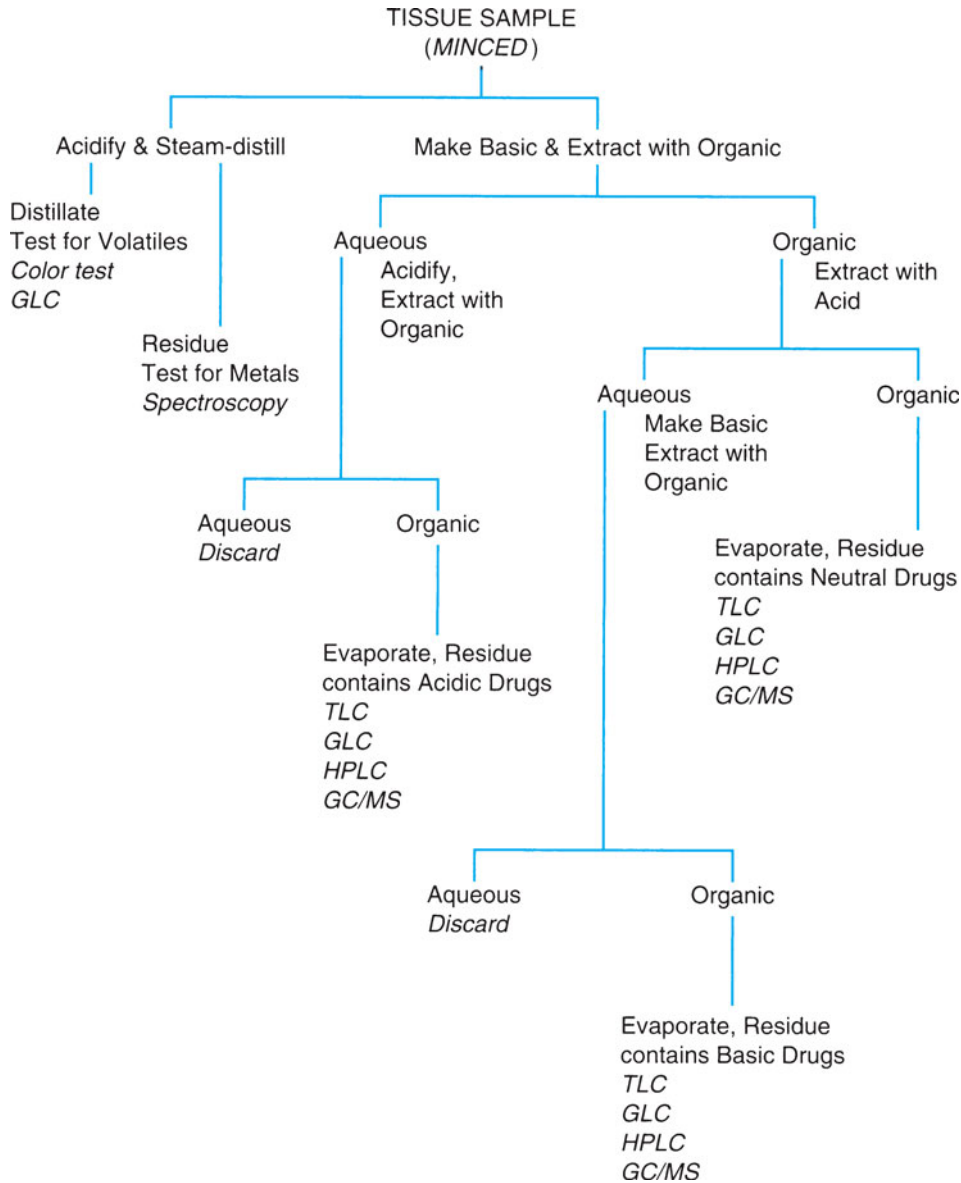
Separation generally is achieved by adjusting the acidity of the aqueous matrix and extracting with a water-immiscible solvent or a solid-phase absorbent material. Finally, a *miscellaneous* category


Figure 31-1. A scheme of separation for poisons from tissues by steam distillation and differential solvent extraction.

Abbreviations: GC/MS, gas chromatography/mass spectrometry; GLC, gas-liquid chromatography; HPLC, high-pressure liquid chromatography; TLC, thin-layer chromatography.

must be included to cover the large number of toxic agents that cannot be detected by the routine application of the methods described above. Venoms and other toxic mixtures of proteins or uncharacterized constituents fall into this class. Frequently, if antibodies can be grown against the active constituent, immunoassay may be the most practical means of detecting and measuring these highly potent and difficult-to-isolate substances. Unfortunately, unless highly specific monoclonal antibodies are used, the analytic procedure may not be acceptable for forensic purposes. Most frequently, specific analytic procedures must be developed for each analyte of this type. At times, biological endpoints are utilized to semiquantify the concentration of the isolated product.

After this brief description of the scope of analytic toxicology, we shall now show how it is applied to a variety of aspects of toxicology.

ANALYTIC ROLE IN GENERAL TOXICOLOGY

In almost all experimental studies in toxicology, an agent, generally a single chemical substance, is administered in known amounts to an organism. It is universally acknowledged that the chemical under study must be pure or the nature of any contaminant must be known to interpret the experimental results with validity. However, it is a common practice to proceed with the experimental study without verifying the purity of the compound. Not only does this practice lead to errors in establishing an accurate dose, but, depending on the nature of the study, other erroneous conclusions may be drawn. For example, the presence of related compounds in the dosage form of a tricyclic antidepressant led to erroneous conclusions about the metabolic products of the drug when it was administered together

with the unidentified contaminants (Saady *et al.*, 1981). An even greater error may result when a small amount of a contaminant may be supertoxic. A well-publicized example of this error involved the presence of dioxin in mixtures of the defoliants 2,4-D and 2,4,5-T (Panel on Herbicides, 1971) used during the Vietnam War as Agent Orange. Some of the adverse effects of Agent Orange may have been due to the low concentration of dioxin in those mixtures. Other researchers have reported that the toxicity of mixtures of polybrominated biphenyls may be due to the high toxicity of specific components, while other brominated biphenyls are relatively nontoxic (Mills *et al.*, 1985).

A related application of analytic toxicology is in monitoring dosage forms or solutions for stability throughout the course of an experimental study. Chemicals may degrade in contact with air, by exposure to ultraviolet or other radiation, by interaction with constituents of the vehicle or dosing solution, and by other means. Developing an analytic procedure by which these changes can be recognized and corrected is essential in achieving consistent results throughout a study (Blanke, 1989).

Finally, analytic methods are important in establishing the bioavailability of a compound that is under study. Some substances with low water solubility are difficult to introduce into an animal, and a variety of vehicles may be tried. However, measuring blood concentrations of the compound under study provides a simple means of comparing the effectiveness of vehicles. Introducing a compound into the stomach in an oil vehicle may not be the most effective means of enhancing the absorption of that compound (Granger *et al.*, 1987). Rather than observing dose–effect relationships, it may be more accurate to describe blood (serum) concentration–effect relationships.

ANALYTIC ROLE IN FORENSIC TOXICOLOGY

The duties of a forensic toxicologist in postmortem investigations include the qualitative and quantitative analysis of drugs or poisons in biological specimens collected at autopsy and the interpretation of the analytic findings in regard to the physiologic and behavioral effects of the detected chemicals on the deceased at the time of death.

The complete investigation of the cause or causes of sudden death is an important civic responsibility. Establishing the cause of death rests with the medical examiner, coroner, or pathologist, but success in arriving at the correct conclusion often depends on the combined efforts of the pathologist and the toxicologist. The cause of death in cases of poisoning cannot be proved beyond contention without a toxicologic analysis that establishes the presence of the toxicant in the tissues and body fluids of the deceased.

Many drugs or poisons do not produce characteristic pathologic lesions; their presence in the body can be demonstrated only by chemical methods of isolation and identification. If toxicologic analyses are avoided, deaths resulting from poisoning may be erroneously ascribed to an entirely different cause or poisoning may be designated as the cause of death without definite proof. Such erroneous diagnoses may have significant legal and social consequences.

Additionally, a toxicologist can furnish valuable evidence concerning the circumstances surrounding a death. Such cases commonly involve demonstrating the presence of intoxicating concentrations of ethanol in victims of automotive or industrial accidents or such concentrations of carbon monoxide in fire victims. The degree

of carbon monoxide saturation of the blood may indicate whether the deceased died as a result of the fire or was dead before the fire started. Arson is commonly used to conceal homicide. Also, licit or illicit psychoactive drugs often play a significant role in the circumstances associated with sudden or violent death. The behavioral toxicity of many illicit drugs may explain the bizarre or "risk-taking" behavior of the deceased that led to his or her demise. At times, a negative toxicologic finding is of particular importance in assessing the cause of death. For example, toxicology studies may demonstrate that a person with a seizure disorder was not taking the prescribed medication and that this contributed to the fatal event.

Additionally, the results of postmortem toxicologic testing provide valuable epidemiologic and statistical data. Forensic toxicologists are often among the first to alert the medical community to new epidemics of substance abuse (Poklis, 1982) and the dangers of abusing over-the-counter drugs (Garriott *et al.*, 1985). Similarly, they often determine the chemical identity and toxicity of novel analogs of psychoactive agents that are subject to abuse, including "designer drugs" such as "china white" (methylfentanyl) (Henderson, 1988) and "ecstasy" (methylenedioxymethamphetamine) (Dowling *et al.*, 1987).

Today, there are numerous specialized areas of study in the field of toxicology; however, it is the forensic toxicologist who is obliged to assist in the determination of the cause of death for a court of law and who has been historically recognized by the title "toxicologist."

Until the nineteenth century, physicians, lawyers, and law enforcement officials harbored extremely faulty notions about the signs and symptoms of poisoning (Thorwald, 1965). Unless a poisoner was literally caught in the act, there was no way to establish the fact that the victim died from poison. In the early eighteenth century, a Dutch physician, Hermann Boerhoave, theorized that various poisons in a hot, vaporous condition yield characteristic odors. He placed substances suspected of containing poisons on hot coals and tested their smells. While Boerhoave was not successful in applying his method, he was the first to suggest a chemical method for proving the presence of poison.

White arsenic (arsenic trioxide) has been widely used with murderous intent for over a thousand years. Therefore, it is not surprising that the first milestones in the chemical isolation and identification of a poison in body tissues and fluids centered on arsenic. In 1775, Karl Wilhelm Scheele, a Swedish chemist, discovered that white arsenic is converted to arsenous acid by chlorine water. The addition of metallic zinc reduced the arsenous acid to poisonous arsine gas. If gently heated, the evolving gas would deposit metallic arsenic on the surface of a cold vessel. In 1821, Serullas utilized the decomposition of arsine for the detection of small quantities of arsenic in stomach contents and urine in poisoning cases. In 1836, James M. Marsh, a chemist at the Royal British Arsenal in Woolwich, applied Serullas' observations in developing the first reliable method to determine the presence of an absorbed poison in body tissues and fluids such as liver, kidney, and blood. After acid digestion of the tissues, Marsh generated arsine gas, which was drawn through a heated capillary tube. The arsine decomposed, leaving a dark deposit of metallic arsenic. Quantitative measures were performed by comparing the length of the deposit from known concentrations of arsenic with those of the test specimens.

The 1800s witnessed the development of forensic toxicology as a scientific discipline. In 1814, Mathieiv J. B. Orfila (1787–1853), the "father of toxicology," published *Traité des Poisons,* the first systematic approach to the study of the chemical and physiological

nature of poisons (Gettler, 1977). Orfila's role as an expert witness in many famous murder trails, particularly his application of the Marsh test for arsenic in the trial of the poisoner Marie Lafarge, aroused both popular and scholarly interest in the new science. As dean of the medical faculty at the University of Paris, Orfila trained numerous students in forensic toxicology.

The first successful isolation of an alkaloidal poison was done in 1850 by Jean Servials Stas, a Belgian chemist, using a solution of acetic acid in warm ethanol to extract nicotine from the tissues of the murdered Gustave Fougnie. As modified by the German chemist Fredrick Otto, the Stas–Otto method was quickly applied to the isolation of numerous alkaloidal poisons, including colchicine, coniine, morphine, narcotine, and strychnine. In the latter half of the nineteenth century, European toxicologists were in the forefront of the development and application of forensic sciences, providing valuable evidence of poisoning. A number of these trials became "causes célèbres" and the testimony of forensic toxicologists captured the imagination of the public and increased awareness of the development and application of toxicology. Murderers could no longer poison with impunity.

In the United States, Rudolph A. Witthaus, professor of chemistry at Cornell University Medical School, made many contributions to toxicology and called attention to the new science by performing analyses for the city of New York in several famous morphine poisoning cases, including the murder of Helen Potts by Carlyle Harris and that of Annie Sutherland by Dr. Robert W. Buchanan. In 1911, Witthaus and Tracy C. Becker edited a four-volume work on medical jurisprudence, forensic medicine, and toxicology—the first standard forensic textbook published in the United States. In 1918, the city of New York established a medical examiner's system, and the appointment of Dr. Alexander O. Gettler as toxicologist marked the beginning of modern forensic toxicology in this country. Although Dr. Gettler made numerous contributions to the science, perhaps his greatest was the training and direction he gave to future leaders in forensic toxicology. Many of his associates went on to direct laboratories within coroners' and medical examiners' systems in major urban centers throughout the country.

In 1949, the American Academy of Forensic Sciences was established to support and further the practice of all phases of legal medicine in the United States. The members of the toxicology section represent the vast majority of forensic toxicologists working in coroners' or medical examiners' offices. Several other international, national, and local forensic science organizations, such as the Society of Forensic Toxicologists and the California Association of Toxicologists, offer a forum for the exchange of scientific data pertaining to analytic techniques and case reports involving new or infrequently used drugs and poisons. The International Association of Forensic Toxicologists, founded in 1963, with over 750 members in 45 countries, permits worldwide cooperation in resolving the technical problems confronting toxicology.

In 1975, the American Board of Forensic Toxicology (ABFT) was created to examine and certify forensic toxicologists. One of the stated objectives of the board is "to make available to the judicial system, and other publics, a practical and equitable system for readily identifying those persons professing to be specialists in forensic toxicology who possess the requisite qualifications and competence." Those certified as diplomats of the board must have a doctor of philosophy or doctor of science degree, have at least 3 years of full-time professional experience, and pass a written examination. In 2000, the board began certifying "forensic toxicology specialists." Specialists must have a master's or bachelor's degree

and 3 years of full-time professional experience and must pass a written examination. At present, there are approximately 225 diplomats and 20 specialists certified by the board. In 1998, the board began an accreditation program for forensic toxicology laboratories. ABFT accredited laboratories must meet standards of qualified, experienced personnel and forensically sound procedures for the handling of evidence, analysis of specimens, and reporting of results. Laboratories must pass periodic on-site inspections involving a review of laboratory procedures and previous casework since the last inspection in order to maintain their continuous accreditation.

TOXICOLOGIC INVESTIGATION OF A POISON DEATH

The toxicologic investigation of a poison death may be divided into three steps: (1) obtaining the case history and suitable specimens, (2) the toxicologic analyses, and (3) the interpretation of the analytic findings.

Case History and Specimens

Today, thousands of compounds are readily available that are lethal if ingested, injected, or inhaled. Usually, a limited amount of specimen is available on which to perform analyses; therefore it is imperative that, before the analyses are initiated, as much information as possible concerning the facts of the case be collected. The age, sex, weight, medical history, and occupation of the decedent as well as any treatment administered before death, the gross autopsy findings, the drugs available to the decedent, and the interval between the onset of symptoms and death should be noted. In a typical year, a postmortem toxicology laboratory will perform analyses for such diverse poisons as prescription drugs (analgesics, antidepressants, hypnotics, tranquilizers), drugs of abuse (hallucinogens, narcotics, stimulants), commercial products (antifreeze, aerosol products, insecticides, rodenticides, rubbing compound, weed killers), and gases (carbon monoxide, cyanide). Obviously, thorough investigation of the death scene including a tentative identification of the administered poison is helpful prior to beginning the analysis (Ernst *et al.*, 1982).

The pathologist at autopsy usually performs the collection of postmortem specimens for analysis. Specimens of many different body fluids and organs are necessary, as drugs and poisons display varying affinities for body tissues (Fig. 31-2). Therefore, detection of a poison is more likely in a tissue in which it accumulates. A large quantity of each specimen is needed for thorough toxicologic analysis because a procedure that extracts and identifies one compound or class of compounds may be ineffective in extracting and identifying others (Table 31-1).

In collecting the specimens, the pathologist labels each container with the date and time of autopsy, the name of the decedent, the identity of the sample, an appropriate case identification number, and his or her signature or initials. It is paramount that the handling of all specimens, their analysis, and the resultant reports be authenticated and documented. A form developed at the collection site that identifies each specimen is submitted to the laboratory with the specimens. The form is signed and dated by the pathologist and subsequently by any individual handling, transferring, or transporting the specimens from one individual or place to another. In legal terms, this form constitutes a "chain of custody" of specimens, documenting by time, date, name, and signature of all persons transferring or receiving the specimens. The chain of custody enables a toxicologist
Figure 31-2. Cocaine tissue distribution in a fatal poisoning. (Data drawn from Poklis A, Mackell MA, Graham M: Disposition of cocaine in a fatal poisoning in man. J Anal Toxicol 9:227–229, 1985.)

to introduce his or her results into legal proceedings, having established that the specimens analyzed came from the decedent.

Specimens should be collected before embalming, as this process may destroy or dilute the poisons present, rendering their detection impossible. Conversely, methyl or ethyl alcohol may be a constituent of embalming fluid, giving a false indication of the decedent's drinking before death.

On occasion, toxicologic analysis is requested for cases of burned, exhumed, and skeletal remains. In such instances, it is necessary to analyze unusual specimens such as bone marrow, hair, skeletal muscle, vitreous humor, and even maggots (Inoue, 1992). Numerous drugs have been successfully identified in bone marrow and bone washings from skeletal remains even after decomposition and burial (Benko, 1985). Similarly, the vitreous humor of the eye is isolated and sequestered from putrefaction, charring, and trauma;

Table 31-1

Suggested List of Specimens and Amounts to be Collected at Autopsy

SPECIMEN	QUANTITY (g)
Brain	100
Liver	100
Kidney	50
Heart blood	25
Peripheral blood	10
Vitreous humor	All available
Bile	All available
Urine	All available
Gastric contents	All available

thus, it is a useful specimen for the detection of most drugs, anions, and even volatile poisons such as alcohols, ketones, and glycols (Coe, 1993). Hair analysis is a rapidly growing technique in forensic toxicology. Recently, numerous therapeutic agents such as antibiotics and antipsychotic drugs as well as drugs subject to abuse (morphine, phencyclidine, and cocaine) have been identified in hair (Tagliro, 1993). Limited data are available to support a direct correlation between hair values and drug doses or between physiologic and behavioral effects; however, qualitative results have been accepted as indicators of drug use. In severely decomposed bodies, the absence of blood and/or the scarcity of solid tissues suitable for analysis have led to the collection and testing of maggots (fly larvae) feeding on the body (Pounder, 1991). The fundamental premise underlying maggot analysis is that if drugs or intoxicants are detected, they could only have originated from the decedents' tissues on which the larvae were feeding. Surprisingly, analysis of maggots is rather straightforward, requiring no special methodology beyond that routinely applied in toxicology laboratories. Case reports have documented the detection of numerous drugs and intoxicants in maggots collected from decomposed bodies. The compounds detected include barbiturates, benzodiazepines, phenothiazines, morphine, and malathion. Controlled studies in which maggots were allowed to feed on tissues to which drugs had been added have demonstrated the accumulation of propoxphene and amitriptyline in the larvae (Goff *et al.*, 1993).

Toxicologic Analysis

Before the analysis begins, several factors must be considered, the amount of specimen available, the nature of the poison sought, and the possible biotransformation of the poison. In cases involving oral administration of the poison, the gastrointestinal (GI) contents are analyzed first because large amounts of residual unabsorbed poison may be present. The urine may be analyzed next, as the kidney is the major organ of excretion for most poisons and high concentrations of toxicants and/or their metabolites often are present in urine. After absorption from the GI tract, drugs or poisons are carried to the liver before entering the general systemic circulation; therefore, the first analysis of an internal organ is conducted on the liver. If a specific poison is suspected to have caused or contributed to a death, the toxicologist may first analyze the tissues and fluids in which the poison concentrates.

A knowledge of drug biotransformation is often essential before an analysis is performed. The parent compound and any major physiologically active metabolites should be isolated and identified. In some instances, the metabolites provide the only evidence that a drug or poison has been administered. Many screening tests, such as immunoassays, are specifically designed to detect not the parent drug but its major urinary metabolite. An example of the relationship of pharmacokinetic and analytic factors is provided by cocaine. The major metabolites of cocaine biotransformation are benzoylecgonine and ecgonine methylester (Fig. 31-3). The ingestion of alcohol combined with the administration of cocaine results in the hepatic transesterification of cocaine to form cocaethylene (Hime *et al.*, 1991) (Fig. 31-3). The disposition of these compounds in various body fluids and hair is shown in Fig. 31-4. Thus, the initial testing of urine to determine cocaine use is performed with immunoassays specifically designed to detect the presence of benzoylecgonine, the major urinary metabolite. If saliva or hair is tested, parent cocaine is the analyte sought. To determine a cocaine profile of each compound present in a specimen, chromatographic procedures such as
Figure 31-3. Biotransformation and pyrolysis products of cocaine.

gas chromatography/mass spectrometry (GC/MS), that allow the simultaneous separation and quantification of each compound, are used.

The analysis may be complicated by the normal chemical changes that occur during the decomposition of a cadaver. The autopsy and toxicologic analysis should be started as soon after death as possible. The natural enzymatic and nonenzymatic processes of decomposition and microbial metabolism may destroy a poison that was present at death or produce substances or compounds with chemical and physical properties similar to those of commonly encountered poisons. As early as the 1870s, the so-called cadaveric alkaloids isolated from the organs of putrefied bodies were known to produce color test reactions similar to those produced

by morphine and other drugs. These cadaveric alkaloids resulted from the bacterial decarboxylation of the amino acids ornithine and lysine, producing putrescine and cadaverine, respectively (Evans, 1963). Similarly, during decomposition, phenylalanine is converted to phenylethylamine, which has chemical and physical properties very similar to those of amphetamine. The hydrolysis, oxidation, or reduction of proteins, nucleic acids, and lipids may generate numerous compounds, such as hydroxylated aliphatic and aromatic carboxylic acids, pyridine and piperidine derivatives, and aromatic heterocyclics such as tryptamine and norharmane (Kaempe, 1969). All these substances may interfere with the isolation and identification of the toxicants being sought. The concentration of cyanide and ethyl alcohol and the carbon monoxide saturation of the blood

PERCENT
Figure 31-4. Disposition of cocaine and cocaine metabolites in human fluids and hair. (Data redrawn from Spiehler V: Society of Forensic Toxicology Conference on Drug Testing in Hair, Tampa, FL, October 29, 1994.)

may be decreased or increased, depending on the degree of putrefaction and microbial activity. However, many poisons—such as arsenic, barbiturates, mercury, and strychnine—are extremely stable and may be detectable many years after death.

Before analysis, the purity of all chemicals should be established. The primary reference material used to prepare calibrators and controls should be checked for purity, and the salt form or degree of hydration should be determined (Blanke, 1989). All reagents and solvents should be of the highest grade possible and should be free of contaminants that may interfere with or distort analytic findings. For example, the chloroform contaminants phosgene and ethyl chloroformate may react with primary or secondary amine drugs to form carbamyl chloride and ethyl carbamate derivatives (Cone *et al.*, 1982). Specimen containers, lids, and stoppers should be free of

contaminants such as plasticizers, which often interfere with chromatographic or GC/MS determinations. Care should be exercised to ensure a clean laboratory environment. This is of particular concern in the analysis of metals, as aluminum, arsenic, lead, and mercury are ubiquitous environmental and reagent contaminants.

Forensic toxicology laboratories analyze specimens by using a variety of analytic procedures. Initially, nonspecific tests designed to determine the presence or absence of a class or group of analytes may be performed directly on the specimens. Examples of tests used to rapidly screen urine are the FPN (ferric chloride, perchloric, and nitric acid) color test for phenothiazine drugs and immunoassays for the detection of amphetamines, benzodiazepines, and opiate derivatives. Positive results obtained with these tests must be confirmed by a second analytic procedure that identifies the particular drug. The detection limit of the confirmatory test should be lower than that of the initial nonspecific test. Some analytic procedures identify specific compounds. Even in such instances, a second test should be performed to identify the analyte. The second test should be based on a chemical or physical principle different from that of the first test. Such additional testing is performed to establish an unequivocal identification of the drugs or poisons present. Whenever possible, the most specific test for the compound of interest should be performed. Today, GC/MS or high-performance liquid chromatography (HPLC)/MS is the most widely applied methodology in toxicology and is generally accepted as unequivocal identification for most drugs. Analyte identification is based upon the retention time in the chromatographic system coupled with the ion fragmentation spectrum in the mass spectrometer. The analyte mass spectrum is the pattern of mass to charge ion fragments and their relative abundance. Even drugs such as amitriptyline and cyclobenzaprine that display similar chromatographic behavior and differ in their chemical structure by only a double bond may be readily identified by GC/MS (Fig. 31-5).

The lower limit of detection, the smallest concentration of analyte reliably identified by the assay, and the specificity of all qualitative methods should be well documented. The laboratory must
Figure 31-5. Electron impact mass spectra of amitriptyline and cyclobenzaprine, scanning ion mass from 60 to 400 m/e. (From Poklis A: Cyclobenzaprine in emergency toxicology. Clin Chem CC96-3:43–57, 1996. American Society of Clinical Pathologists, with permission.)

demonstrate that the assay response to blank or negative calibrators does not overlap with the response of the lowest-positive calibrator. In certain instances, qualitative identification of a poison or drug is sufficient to resolve forensic toxicology issues. However, most cases require reliable estimates of poison concentrations for forensic interpretation. For quantitative analysis, the linearity, precision, and specificity of the procedure must be established. Linearity should be determined by using at least a drug free and three drug added calibrators whose concentrations bracket the anticipated concentrations in the specimen. Precision, which statistically demonstrates the variance in the value obtained, is determined by replicate analyses of a specimen of a known concentration. For a variety of reasons, a quantitative result occasionally will deviate spuriously from the true value. Therefore, replicate quantitative determinations should be performed on all specimens, at least in duplicate (Blanke, 1987).

When unusual samples such as bone marrow, hair, and maggots are analyzed, the extraction efficiency of a procedure may vary greatly, depending on the nature of the specimens. Therefore, all calibrators and controls should be prepared in the same matrix as the specimens and analyzed concurrently with the specimens. Often the matrix is "unique" or impossible to match, such as decomposed or embalmed tissue. In these instances, the method of "standard additions" may be used. Known amounts of the drug or poison of interest are added to specimen aliquots and these are analyzed. The concentration of poison in the test specimen is determined by comparing the proportional response of the "poison added" specimens to that of the test specimens. When comparable results are obtained from analysis of specimens by both direct extraction methods and standard addition, not only is the efficacy of the extraction method validated, but also the accuracy of the results is assured (Poklis *et al.*, 1998).

Interpretation of Analytic Results

Once the analysis of the specimens is complete, the toxicologist must interpret his or her findings in regard to the physiologic or behavioral effects of the toxicants on the decedent at the concentrations found. Specific questions may be answered, such as the route of administration, the dose administered, and whether the concentration of the toxicant present was sufficient to cause death or alter the decedent's actions enough to cause his or her death. Assessing the physiologic or behavioral meanings of analytic results is often the most difficult problem faced by the forensic toxicologist.

In determining the route of administration, the toxicologist notes the results of the analysis of the various specimens. As a general rule, the highest concentrations of a poison are found at the site of administration. Therefore, the presence of large amounts of drugs and/or poisons in the GI tract and liver indicates oral ingestion, while higher concentrations in the lungs than in other visceral organs can indicate inhalation or intravenous injection. The ratio or relative distribution of drugs in different tissues may also differentiate oral from parenteral administration (Fig. 31-6). Drugs may also be detected in the tissue surrounding an injection site following intramuscular or intravenous injection. Smoking is a popular route of administration for abusers of controlled substances such as cocaine, heroin, and phencyclidine. Pyrolysis of these drugs leads to the inhalation not only of the parent drug but also of characteristic breakdown products of combustion. For example, a major pyrolysis product of "crack" cocaine smoking is anhydroecgonine methylester (Martin *et al.*, 1989) (Fig. 31-3). Thus, identification of relatively high concentrations of this compound along with cocaine
Figure 31-6. *Comparison of pentazocine distribution in fatal poisonings due to intravenous injection and oral administration. (Data from Baselt RC: Disposition of Toxic Drugs and Chemicals in Man, 2nd ed. Davis, CA: Biomedical Publications, 1982, pp. 603–606, and Poklis A, MacKell MA: Toxicological findings in deaths due to pentazocine: A report of two cases. Forensic Sci Int 20:89–95, 1982.)*

or cocaine metabolites in urine or other body fluids or tissues indicates smoking as the route of cocaine administration (Jacob *et al.*, 1990).

The presence of a toxic material in the GI tract, regardless of the quantity, does not provide sufficient evidence to establish that agent as the cause of death. It is necessary to demonstrate that absorption of the toxicant has occurred and that it has been transported by the general circulation to the target organ in order to exert its lethal effect. This is established by blood and tissue analysis. An exception to the rule is provided by strong, corrosive chemicals such as sulfuric acid, lye, and phenol, which exert their deleterious effects by directly digesting tissue, causing hemorrhage and shock. The results of urinalysis are often of little benefit in determining the physiologic effects of a toxic agent. Urine results establish only that the poison was present in the body at some time before death. Correlation of urine values with physiologic effects is poor because of various factors that influence the rate of excretion of specific compounds and the urine volume.

The physiologic effects of most drugs and poisons are correlated with their concentrations in blood or blood fractions such as plasma and serum. Indeed, in living persons, this association is the basis of therapeutic drug monitoring. However, postmortem blood has been described as a fluid resembling blood that is obtained from the vasculature after death. Therefore, interpretation of postmortem blood results requires careful consideration of the case history, the site of collection, and postmortem changes. The survival time between the administration of a poison and death may be sufficiently long to permit biotransformation and excretion of the agent. Blood values may appear to be nontoxic or consistent with therapeutic administration. Death from hepatic failure after an acetaminophen overdose usually occurs at least 3 to 4 days after ingestion. Postmortem acetaminophen concentrations in blood may be consistent with the ingestion of therapeutic doses. Therefore, fatal acetaminophen overdose is established by case history, central lobular necrosis of the liver, and, if available, analysis of serum

specimens collected from the decedent when he or she was admitted to the emergency department (Price *et al.*, 1991). Emergency medical treatment—such as the administration of fluids, plasma extenders, diuretics, and blood transfusions—may dilute or remove toxic agents. Similarly, prolonged survival on a mechanical respirator, hemodialysis, or hemoperfusion may significantly reduce initially lethal blood concentrations of poisons.

Until recently, it was generally assumed that postmortem blood drug concentrations were more or less uniform throughout the body. However, in the 1970s, several investigators noted that postmortem concentrations of digoxin in heart blood greatly exceeded those in simultaneously collected femoral blood. They also observed that postmortem blood concentrations, particularly in heart blood, exceeded the expected values at the time of death (Vorpahl and Coe, 1978; Aderjan *et al.*, 1979). This postmortem increase in blood digoxin concentrations was apparently due to release of the drug from tissue stores, particularly the myocardium. Recently, other researchers have demonstrated that for many drugs, blood concentrations in the same body vary greatly depending on the site from which the specimen is collected—subclavian vein, thoracic aorta, inferior vena cava, femoral vein, and so forth. For example, in a case of fatal multiple drug ingestion, analysis of postmortem blood collected from 10 different sites demonstrated imipramine concentrations that differed by as much as 760% (2.1–16.0 mg/L) (Jones and Pounder, 1987). In an extensive investigation, Prouty and Anderson (1990) demonstrated that postmortem blood drug concentrations were not only site-dependent but also increased greatly over the interval between death and specimen collection, particularly in heart blood. This increase over the postmortem interval was most pronounced for basic drugs with large apparent volumes of distribution, such as tricyclic antidepressants.

In an overt drug overdose, postmortem blood concentrations are elevated sufficiently to render an unmistakable interpretation of fatal intoxication. However, in many cases, the postmortem redistribution of drugs may significantly affect the interpretation of analytic findings. For drugs whose volume of distribution, plasma half-life, and renal clearance vary widely from person to person or that undergo postmortem redistribution, tissue concentrations readily distinguish therapeutic administration from drug overdose (Apple, 1989). Therefore, to provide a foundation of reasonable medical certainty in regard to the role of a drug in the death of an individual, it is recommended that, in addition to heart blood, a peripheral blood specimen and tissues be analyzed.

The analysis of tissue specimens is important for the estimation of a "minimal administered dose" or body burden of a drug or poison. In order to calculate a minimum body burden, it is necessary to analyze as many different body tissues and fluids as possible to determine the concentrations of the drug present. The concentration of drug in each separate specimen is then multiplied by the total weight or volume of that particular tissue or fluid. In this manner, the total amount of drug in each different tissue or fluid is determined. The amounts of drug in each separate tissue and fluid are then added together to give the total body burden or minimal administered dose. This simple approach has often proven extremely effective in resolving legal medical issues. For example, lidocaine is commonly administered in 50- to 100-mg bolus injections as an antiarrhythmic agent for ventricular arrhythmia during resuscitation efforts. Because of poor circulation and tissue perfusion during arrhythmias, lidocaine is not well distributed in the body of the victim of a fatal heart attack. Postmortem bloods often exceed 50 mg/L in such cases, while values for effective antiarrythmic prophylaxis do
Figure 31-7. Results of neutron activation analysis for arsenic in sequential sections of hair, demonstrating chronic arsenic poisoning. Increased exposure in the first two sections is consistent with fatal events. Lower values in section 3 are consistent with 2 weeks of hospitalization. (Data from Poklis A, Saady JJ: Arsenic poisoning: Acute or chronic? Suicide or murder? Am J Forensic Med Pathol 11:226–232, 1990.)

not exceed 5 mg/L. Therefore, a blood lidocaine value of 50 mg/L may be an artifact of resuscitation efforts or might represent a fatal overdose. Tissue distribution studies have resolved this issue in both accidental and homicidal poisoning with lidocaine (Poklis *et al.*, 1984).

Postmortem toxicology results are often used to corroborate investigative findings. For example, the analysis of sequential sections of hair provides a reliable correlation with the pattern of arsenic exposure. Significant increases in the arsenic content of the root and the first 5 mm of the hair occur within hours after the ingestion of arsenic (Smith, 1964). The germinal cells are in relativity close equilibrium with circulating arsenic; thus, as arsenic concentrations in blood rise or fall, so does arsenic deposition in growing hair. Normal arsenic content in hair varies with nutritional, environmental, and physiologic factors; however, the maximum upper limit of normal with a 99% confidence limit in persons not exposed to arsenic is 5 mg/kg (Shapiro, 1967). Hair grows at a rate of approximately 12.5 mm (in.) per month. Therefore, analysis of 1.0-cm segments provides a monthly pattern of exposure (Fig. 31-7). Such analyses are often performed in cases of homicidal poisoning to demonstrate that increases in arsenic deposition in the victim's hair correlate with times when a poisoner had an opportunity to administer the poison. Continuously, elevated hair arsenic values indicate chronic rather than acute poisoning as the cause of death.

A new extension of forensic toxicology is the analysis of impurities of illicit drug synthesis in biological specimens. Many drugs of abuse are illicitly manufactured in clandestine laboratories, particularly methamphetamine. There are several popular methods of methamphetamine synthesis; when these are applied in clandestine laboratories, side reactions or incomplete conversion of the reactants yield an impure mixture of methamphetamine and synthetic impurities. These impurities can be characteristic of a particular

synthetic method and their detection in biological specimens can indicate use of an illicitly produced drug that is not a legal pharmaceutical product; suggest the synthetic method that was used to produce the drug; point to a possible common source of illicit production; and provide a link between manufacturers, dealers, and users. An example of impurity analysis was the detection of metabolites of α-benzyl-N-methylphenethylamine (BNMPA) in the urine of abusers of methamphetamine (Moore *et al.*, 1996) and in a case of fatal drug overdose involving methamphetamine (Moore *et al.*, 1996). BNMPA is an impurity arising from the synthesis of methamphetamine via the Leukart reaction using phenyl-2-propanone (P2P) synthesized from phenylacetic acid. Clandestine laboratories often must synthesize the P2P starting material, as its sale and distribution is regulated by the Federal Drug Enforcement Agency.

CRIMINAL POISONING OF THE LIVING

Over the past few decades, forensic toxicologists have become more and more involved in the analysis of specimens obtained from living victims of criminal poisonings. Generally, this increase in testing has arisen from two types of cases: (1) administration of drugs to incapacitate victims of kidnapping, robbery, or sexual assault and (2) poisoning as a form of child abuse.

For centuries, those severely intoxicated from alcohol often became victims of kidnapping, robbery, or sexual assault. In the days of sail, the kidnapping of drunks in seaports was a common way of obtaining sailors for long commercial voyages such as those involved in whaling. Late in the nineteenth century, the mixing of the powerful hypnotic chloral hydrate with alcohol produced the legendary "Mickey Finn." While alcohol is still often a primary factor in cases of alleged sexual assault, common drugs of abuse or other psychoactive drugs are often involved (Table 31-2). Of particular concern are the many potent inductive agents medically administered prior to general anesthesia. Many of these drugs, such as benzodiazepines and phenothiazines, are available today through illicit sources or legal purchase in foreign countries. When administered surreptitiously, they cause sedation and incapacitate the victim while also producing amnesia in the victim as to the events while drugged without causing severe central nervous system depression. These cases often present a difficult analytic challenge to the toxicologist.

Table 31-2

Distribution of Drugs of Abuse Encountered Urine Specimens in 578 Cases of Alleged Sexual Assault

RANK	DRUG/DRUG GROUP	INCIDENCE	PERCENT OF CASES* (%)
1.	No drugs found	167	29
2.	Ethanol	148	26
3.	Benzodiazepines	70	12
4.	Marijuana	67	12
5.	Amphetamines	41	7
6.	Gamma-hydroxybutyrate	24	4
7.	Opiate (morphine/codeine)	20	4
8.	Other drugs	13	3

*Percentages do not add to 100% due to rounding.
SOURCE: Data from ElSohly MA, *et al.*: Analysis of flunitrazepam metabolites and other substances in alleged cases of sexual assault. Presentation at the 50th Anniversary Meeting of the American Academy of Forensic Sciences; San Francisco, CA, February 13, 1997.

Usually, the victim does not bring forth an allegation of assault until 24 hours to several days after the attack. Thus, the intoxicating drug may have been largely eliminated or extensively metabolized such that extremely low concentrations of drug or metabolites are present in the victim's blood, urine, and/or hair specimens. Sophisticated, highly sensitive analytic methods such as GC/MS or HPLC/MS may be required to accurately identify drugs in such specimens. To provide guidance in the choice of analytic approaches to such cases, recommendations for the toxicologic investigation of sexual assaults have recently been formulated by the Toxicology Section of the American Academy of Forensic Sciences (LeBeau *et al.*, 1999).

Poisoning as a form of child abuse involves the deliberate administration of toxic or injurious substances to a child, usually by a parent or other caregiver. The victims of such poisonings range in age from a few months to the teens. Common agents used to intentionally poison children have included syrup of ipecac, table salt, laxatives, diuretics, antidepressants, sedative-hypnotics, and narcotics (Dine and McGovern, 1982). The motivation for such heinous behavior is in the province of psychiatry, not toxicology. However, toxicologists must have some understanding of the nature of these poisonings to aid in the investigation of such cases. In some instances, it is a form of child battering committed by persons with low tolerance to the child's upsetting behaviors. The poison may be given to an infant to stop its crying or be force-fed to older children as a form of punishment. Such behavior is characteristic of persons with a cultural background where violence toward children is common or who have severe personality disorders or other mental illnesses. "Munchausen syndrome by proxy" is another form of child poisoning (Murray, 1997). The term *Munchausen syndrome* (MS) is used to describe patients who seek admission to hospitals with apparent illness along with plausible, dramatic, albeit fictitious medical histories. Such people seek medical treatment solely to assume the role of a patient and receive the attention derived from this deception. "MS by proxy" refers to the situation in which an individual, usually a parent, presents not himself or herself but a child with a fictitious illness often induced by physical or chemical means. The purpose of the poisoning is not to kill the child but to induce signs and symptoms of illness that will assure medical attention. Thereby, the parent as caregiver gains the craved attention. Given a fictitious case history and the obvious illness of the child, these cases are almost always and understandably misdiagnosed. Often, the child may be chronically poisoned at home and in the hospital for as long as a year before suspicion leads to the collection of specimens for extensive toxicologic testing. Although the parent may not have intended such an outcome, some children have died from fatal poisoning in these situations. As in the case of sexual assault, sophisticated GC/MS testing methods may be required to detect such agents as emetine and cephaeline, the emetic alkaloids in syrup of ipecac. Testing in these cases is best performed in a laboratory with forensic experience, as positive drug findings will usually result in some form of legal proceeding.

FORENSIC URINE DRUG TESTING

Concerns about the potentially adverse consequences of substance abuse both for the individual and for society have led to widespread urine analysis for the detection of controlled or illicit drugs (Gust and Walsh, 1989). Currently, such testing is conducted routinely by the military services, regulated transportation and nuclear industries, many federal and state agencies, public utilities, federal and state criminal justice systems, and numerous private businesses and

Table 31-3

Forensic Urine Drug-Testing Analytes and Cutoff Concentrations

	CONCENTRATION (ng/mL)	
	INITIAL TEST	CONFIRMATORY TEST

industries. Significant ethical and legal ramifications are associated with such testing. Those having positive test results may not receive employment, be dismissed from a job, be court-martialed, or suffer a loss of reputation.

To assure the integrity of workplace urine testing, two certification programs currently accredit forensic urine-testing laboratories. Laboratories conducting testing of federal employees are required to be certified under the Department of Health and Human Services Mandatory Guidelines for Workplace Drug Testing as published in the April 11, 1988, *Federal Register* (Department of Health and Human Services, 1988). The College of American Pathologists (CAP) also conducts a certification program for urine-testing laboratories. The federal program regulates a specific program from specimen collection through testing to the reporting of results, whereas the CAP program allows flexibility in the construction of programs servicing a broad range of clients. Both programs involve periodic on-site inspection of laboratories and proficiency testing.

Forensic urine drug testing (FUDT) differs from other areas of forensic toxicology in that urine is the only specimen analyzed and testing is performed for a limited number of drugs. At present, under the federal certification program, analyses are performed for only five drug classes or drugs of abuse (Table 31-3). While FUDT laboratories typically analyze 100–1000 urine specimens daily, only a relatively small number of those specimens are positive for drugs. To handle this large workload, initial testing is performed by immunoassays on high-speed, large-throughput analyzers. A confirmation analysis in FUDT-certified laboratories is performed by GC/MS.

Proper FUDT is a challenge to good laboratory management. As with all forensic activities, every aspect of the laboratory operation must be thoroughly documented—specimen collection, chain of custody, quality control procedures, testing, qualifications of personnel, and the reporting of results. The facility must be constructed and operated to assure total security of specimens and documents. Confidentiality of all testing results is paramount; only specifically authorized persons should receive the results. The presence of a controlled or illicit drug in a single random urine specimen is gen-

erally accepted as proof of recent or past substance abuse. However, positive urine drug findings are only evidence that, at some time before the collection of the sample, the individual was administered the drug, self-administered it, or was exposed to it. Positive urine tests do not prove impairment from the drug abuse or addiction.

FUDT results are reported only as positive or negative for the drugs sought. Cutoff values are established for both the initial and confirmation assays (Table 31-2). The cutoff value is a concentration at or above which the assay is considered positive. Below the cutoff value, the assay is negative. Obviously, drugs may be present below the cutoff concentration. However, the use of cutoff values allows uniformity in the drug testing and reporting of results. All test reports indicate the drug tested and its cutoff value. FUDT laboratories must be thoroughly familiar with all regulatory and analytic issues related to urine testing and devise strategies to resolve uncertainties. Many individuals who are subject to regulated urine testing have devised techniques to mask their drug use either by physiologic means such as the ingestion of diuretics or by attempting to adulterate the specimen directly with bleach, vinegar, or other products that interfere with the initial immunoassay tests (Warren, 1989). Thus, specimens are routinely tested for adulteration by checking urinary pH, creatinine, and specific gravity and noting any unusual color or smell. Recently, a mini-industry has developed to sell various products that are alleged to "fool drug testers." These products often have colorful trade names such as UrinAid, Instant Clean ADD-IT-ive, and Klear. They contain chemicals that, when added to a urine specimen, interfere with either the initial or confirmatory drug test. For example, several of these products contain glutaraldehyde, which will react with the nitrogen atoms of the antibody proteins of the immunoassay screening test, thereby cross-linking the antibodies and inactivating the assay. However, this destruction of the test is so complete that the immunoassay analyzer records almost no signal, thus indicating possible adulteration of the specimen. Another adulterant, for the marijuana metabolite urine test, contains sodium nitrite. In acidic urine, the nitrite salt is converted to nitrous acid, which then converts the marijuana metabolites to nitroso derivatives, rendering them undetectable by routine GC/MS analysis (Lewis *et al.*, 1999). Often, the pH of the urine is insufficiently acidic for complete nitroso conversion of the tetrahydrocannabinol (THC) metabolite, THC–carboxylic acid. Thus, the urine will be screen positive by the initial immunoassay. When urine is acidified to extract the THC acid metabolite for MS confirmation testing, the metabolite is completely oxidized and undetectable. However, the deuterated THC–carboxylic acid added to the sample as the internal standard of the confirmation test is also completely destroyed. Failure to detect the internal standard readily alerts the analyst that an oxidant adulterant had been added to the urine. In such cases, a quantitative test for nitrite is performed. Nitrite may be present in urine from numerous internal and external sources such as foods, drugs, pathologic conditions, and infection from nitrate-reducing microorganisms. However, none of these sources produces urinary nitrite concentrations that even begin to approach those obtained by the addition of adulterant amounts of potassium nitrite = 1000 mg/L (Urey *et al.*, 1998). Most chemical adulterants can be detected in urine by specific colorimetric tests that can be readily adapted to high-volume autoanalyzers (Table 31-4). Thus, FUDT laboratories now routinely test not only for drugs of abuse but also for a wide variety of chemical adulterants. In most instances, a positive test result for adulteration has as serious a consequence as a positive drug test.

Table 31-4

Urine Adulterants Detected by Chemical Test

ADULTERANT	DETECTION METHOD
Acids, baking soda	pH
Bleach	Smell, color test (substituted benzene complex)
Detergents, diuretics, salt	Specific gravity
Diuretics	Creatinine
Glutaraldehyde	Altered immunoassay, GC
Nitrite	Color test (azo dye formation)
Pyridium chromate	Color, AAS (chromate), GC (pyridine)

NOTE: GC, gas chromatography; AAS, atomic absorption spectrophotometry.

There may be valid reasons other than substance abuse for positive drug findings, such as therapeutic use of controlled substances, inadvertent intake of drugs via food, and passive inhalation. For example, the seed of *Papaver somniferum,* poppy seed, is a common ingredient in many pastries and breads. Depending on their botanical source, poppy seeds may contain significant amounts of morphine. Several studies have demonstrated that the ingestion of certain poppy-seed foods results in the urinary excretion of readily detectable concentrations of morphine (ElSohly and Jones, 1989). Morphine is a major urinary metabolite of heroin. Therefore, to readily differentiate heroin abuse from poppy-seed ingestion, analysis may be performed for 6-monoacetylmorphine, a unique heroin metabolite (Fehn and Megges, 1985).

Even over-the-counter medications may present potential problems for laboratories conducting urine drug testing. Methamphetamine may occur as a racemic mixture of D and L optical isomers. D-Methamphetamine, a Schedule II controlled substance, is a potent central nervous system stimulant subject to illicit drug abuse, while L-methamphetamine (L-desoxyephedrine) is an alpha-adrenergic stimulant available in over-the-counter Vicks inhalers as a nasal decongestant. Cross-reactivity of L-desoxyephedrine with the initial immunoassay screening test may occur after excessive use of the Vicks inhaler (Poklis and Moore, 1995). Additionally, the most popular confirmational GC/MS products for amphetamines are achiral. Therefore, if such analyses are performed, a "false-positive" result for D-methamphetamine may be reported. This dilemma is easily resolved if confirmational testing is done with a *chiral* GC/MS procedure, which can readily resolve the stereoisomers of methamphetamine (Fitzgerald *et al.*, 1988).

HUMAN PERFORMANCE TESTING

Forensic toxicology activities also include the determination of the presence of ethanol and other drugs and chemicals in blood, breath, or other specimens and the evaluation of their role in modifying human performance and behavior. The most common application of human performance testing is to determine driving under the influence of ethanol (DUI) or drugs (DUID). While operation of a motor vehicle is a common experience to most people, few appreciate the complexity of mental and physical functioning involved. A driver must simultaneously coordinate fine motor skills in tracking the road course and applying pressure to accelerator or brake—with visual attention immediately in front, to the horizon, and to the periphery of the vehicle—while continuously judging distance, speed, and appropriateness of response to signals, traffic, and unexpected

events. The threshold blood ethanol concentration (BAC) for diminished driving performance of these complex functions in many individuals is as low as 0.04 g/dL, the equivalent of ingestion of two beers within an hour's time. The statutory definition of DUI in the United States is a BAC of either 0.08 or 0.10 g/dL, depending on the particular state law. These concentrations are consistent with diminished performance of complex driving skills in the vast majority of individuals. Over the past half century, an enormous amount of data has been developed correlating blood ethanol concentrations with intellectual and physiologic impairment, particularly of the skills associated with the proper operation of motor vehicles. Numerous studies have demonstrated a direct relationship between an increased BAC in drivers and an increased risk of involvement in road accidents (Council on Scientific Affairs, 1986). Alcohol-impaired drivers are responsible for 25–35% of all crashes causing serious injury in single-vehicle accidents, and 55–65% percent of fatally injured drivers have a BAC of 0.10 g/dL or greater.

During the past decade, there has been growing concern about the deleterious effects of drugs other than ethanol on driving performance. Several studies have demonstrated a relatively high occurrence of drugs in impaired or fatally injured drivers (White *et al.*, 1981; Mason and McBay, 1984). These studies tend to report that the highest drug-use accident rates are associated with the use of such illicit or controlled drugs as cocaine, benzodiazepines, marijuana, and phencyclidine. However, most studies test for only a few drugs or drug classes, and the repeated reporting of the same drugs may be a function of limited testing. Before "driving under the influence of drugs" testing is as readily accepted by the courts as ethanol testing, many legal and scientific problems concerning drug concentrations and driving impairment must be resolved (Consensus Report, 1985). The ability of analytic methodology to routinely measure minute concentrations of drug in blood must be established. Also, drug-induced driving impairment at specific blood concentrations in controlled tests and/or actual highway experience must be demonstrated.

COURTROOM TESTIMONY

The forensic toxicologist often is called upon to testify in legal proceedings. As a general rule of evidence, a witness may testify only to facts known to him or her. The witness may offer opinions solely on the basis of what he or she has observed (Moenssens *et al.*, 1973). Such a witness is called a "lay witness." However, the toxicologist is referred to as an "expert witness." A court recognizes a witness as an expert if that witness possesses knowledge or experience in a subject that is beyond the range of ordinary or common knowledge or observation. An expert witness may provide two types of testimony: objective testimony and "opinion." Objective testimony by a toxicologist usually involves a description of his or her analytic methods and findings. When a toxicologist testifies as to the interpretation of his or her analytic results or those of others, that toxicologist is offering an "opinion." Lay witnesses cannot offer such opinion testimony, as it exceeds their ordinary experience.

Before a court permits opinion testimony, the witness must be "qualified" as an expert in his or her particular field. In qualifying someone as an expert witness, the court considers the witness's education, on-the-job training, work experience, teaching or academic appointments, and professional memberships and publications as well as the acceptance of the witness as an expert by other courts. Qualification of a witness takes place in front of the jury members,

who consider the expert's qualifications in determining how much weight to give his or her opinions during their deliberations.

Whether a toxicologist appears in criminal or civil court, workers' compensation, or parole hearings, the procedure for testifying is the same: direct examination, cross-examination, and redirect examination. The attorney who has summoned the witness to testify conducts direct examination. Testimony is presented in a question-and-answer format. The witness is asked a series of questions that allow him or her to present all facts or opinions relevant to the successful presentation of the attorney's case. During direct examination, an expert witness has the opportunity to explain to the jury the scientific bases of his or her opinions. Regardless of which side has called the toxicologist to court, the toxicologist should testify with scientific objectivity. Bias toward his or her client and prejudgments should be avoided. An expert witness is called to provide informed assistance to the jury. The jury, not the expert witness, determines the guilt or innocence of the defendant.

After direct testimony, the opposing attorney questions the expert. During this cross-examination, the witness is challenged as to his or her findings and/or opinions. The toxicologist will be asked to defend his or her analytic methods, results, and opinions. The opposing attorney may imply that the expert's testimony is biased because of financial compensation, association with an agency involved in the litigation, or personal feelings regarding the case. The best way to prepare for such challenges before testimony is to anticipate the questions the opposing attorney may ask.

After cross-examination, the attorney who called the witness may ask additional questions to clarify any issues raised during cross-examination. This allows the expert to explain apparent discrepancies in his or her testimony raised by the opposing attorney. Often an expert witness is asked to answer a special type of question, the "hypothetical question." A hypothetical question contains only facts that have been presented in evidence. The expert is then asked for his or her conclusion or opinion based solely on this hypothetical situation. This type of question serves as a means by which appropriate facts leading to the expert's opinion are identified. Often these questions are extremely long and convoluted. The witness should be sure he or she understands all the facts and implications in the question. Like all questions, this type should be answered as objectively as possible.

ANALYTIC ROLE IN CLINICAL TOXICOLOGY

Analytic toxicology in a clinical setting plays a role very similar to its role in forensic toxicology. As an aid in the diagnosis and treatment of toxic incidents as well as in monitoring the effectiveness of treatment regimens, it is useful to clearly identify the nature of the toxic exposure and measure the amount of the toxic substance that has been absorbed. Frequently, this information, together with the clinical state of the patient, permits a clinician to relate the signs and symptoms observed to the anticipated effects of the toxic agent. This may permit a clinical judgment as to whether the treatment must be vigorous and aggressive or whether simple observation and symptomatic treatment of the patient are sufficient.

A cardinal rule in the treatment of poisoning cases is to remove any unabsorbed material, limit the absorption of additional poison, and hasten its elimination. The clinical toxicology laboratory serves an additional purpose in this phase of the treatment by monitoring the amount of the toxic agent remaining in circulation or measuring what is excreted. In addition, the laboratory can provide the data needed to permit estimations of the total dosage or the effectiveness of treatment by changes in known pharmacokinetic parameters of the drug or agent ingested.

While the instrumentation and the methodology used in a clinical toxicology laboratory are similar to those utilized by a forensic toxicologist, a major difference between these two applications is responsiveness. In emergency toxicology testing, results must be communicated to the clinician within hours to be meaningful for therapy. A forensic toxicologist may carefully choose the best method for a particular test and conduct replicate procedures to assure maximum accuracy. A clinical laboratory cannot afford this luxury and frequently sacrifices accuracy for a rapid turnaround time. Additionally, because it is impossible to predict when toxicologic emergencies will occur, a clinical laboratory must provide rapid testing 24 hours a day every day of the year. The most commonly encountered intoxicants in emergency toxicology testing and the rapid methodologies to detect their presence in serum and/or urine specimens are presented in Table 31-5.

Primary examples of the usefulness of emergency toxicology testing are the rapid quantitative determination of acetaminophen,

Table 31-5

Most Commonly Encountered Drugs and Methods for Analysis in Emergency Toxicology

RANK	DRUG/DRUG GROUP	SPECIMEN	ANALYTICAL METHOD
1.	Drugs of Abuse (amphetamines, cocaine, opiates, phencyclidine)	Urine	Immunoassays
2.	Ethanol	Serum	GC
3.	Benzodiazepines	Urine/serum	Immunoassay/GC/MS
4.	Acetaminophen, salicylates	Serum	Immunoassay/HPLC
5.	Tricyclic antidepressants	Serum	Immunoassay/HPLC
6.	Ibuprofen	Urine/serum	TLC/HPLC
7.	Dextropropoxyphene	Urine	Immunoassay
8.	Fluoxetine	Urine/serum	TLC/HPLC
9.	Barbiturates (50% phenobarbital)	Urine/serum	Immunoassay/GC
10.	Diphenhydramine	Urine	TLC

NOTE: GC, gas chromatography; GC/MS, gas chromatography/mass spectrometry; HPLC, high-pressure liquid chromatography; TLC, thin-layer chromatography.

Figure 31-8. Serum ethylene glycol and ethanol concentrations monitored during dialysis and ethanol infusion therapy. (Data from the Toxicology Laboratory, Medical College of Virginia Hospital, Richmond, VA.)

salicylate, alcohols, and glycol serum concentrations in instances of suspected overdose. Acetaminophen serum values related to the time after ingestion (see Chap. 32) not only indicate an overdose, but provide a prognosis for possible delayed hepatotoxicity and the need to continue administration of *N*-acetylcystine antidote. In addition, continuous monitoring of serum values permits an accurate pharmacokinetic calculation of the ingested dose (Melethil *et al.*, 1981). Similarly, salicylate serum values related to the time after ingestion may indicate an overdose, providing a prognosis for possible delayed severe metabolic acidosis and the need for lifesaving dialysis treatment. Continuous monitoring of serum salicylate values permits an accurate assessment of the efficacy of dialysis.

Ethanol is the most common agent encountered in emergency toxicology. While little fatal intoxications occur with ethanol, serum values are important in the assessment of behavioral and neurologic function, particularly in trauma cases where the patient is unable to communicate and surgery with the administration of anesthetic or analgesic agents is indicated. Intoxications from accidental or deliberate ingestion of other alcohols or glycols—such as methanol from windshield deicer or paint thinner, isopropanol from rubbing alcohol, and ethylene glycol from antifreeze—are often encountered in emergency departments. Following ingestion of methanol or ethylene glycol, patients often present with similar neurologic symptoms and severe metabolic acidosis due to the formation of toxic aldehyde and acid metabolites. A rapid quantitative serum determination for these intoxicants will indicate the severity of intoxication and the possible need for dialysis therapy. Alcohol infusion, in order to saturate the enzyme alcohol dehydrogenase, blocks the conversion of methanol and ethylene glycol to their toxic metabolites. Continuous monitoring of serum values not only permits an assessment of the clearance of the intoxicant by dialysis but also assures a proper infusion rate of alcohol for effective antidotal concentrations (Fig. 31-8). To provide effective service to the emergency department, laboratories should have available chromatographic methods for the rapid separation and detection of alcohols and glycols (Edinboro *et al.*, 1993).

The utilization of the analytic capabilities of a clinical toxicology laboratory has increased enormously in recent years. Typically, the laboratory performs testing not only for the emergency department but also for a wide variety of other medical departments, as drugs and toxic agents may be a consideration in diagnosis. Urine is analyzed from substance abuse treatment facilities to monitor the administration of methadone or other therapeutic agents and/or to

assure that patients do not continue to abuse drugs. Similarly, psychiatrists, neurologists, and physicians treating patients for chronic pain need to know whether patients are self-administering drugs before such patients undergo psychiatric or neurologic examinations. Analysis for drugs of abuse in meconium and urine obtained from neonates is used to corroborate the diagnosis of withdrawal symptoms in newborns and document fetal exposure to controlled substances. Toxic metal determinations, such as blood lead concentration, are often performed to assess possible toxic metal exposure or severity of toxicity (see Chap. 23). Analysis of heavy metals in 24-hour urine specimens is often used to rule out toxic metal exposure as a cause of symmetrical peripheral neuropathy prior to the diagnosis of neurologic disorders such as Guillian–Barré syndrome. The clinical toxicology laboratory may often perform unique diagnostic tests that require sophisticated analytic capabilities such as GC/MS and HPLC analysis for organic acids and amino acids to detect inborn errors of metabolism in infants and children. Methods for the analysis of abnormal organic acids will also detect acidic drugs and other intoxicants such as salicylates, ethylene glycol, gamma-hydroxybutyric acid, and valproic acid. Another such diagnostic test requiring sensitive chromatography is the timed metabolism of lidocaine to its monoethylglycinexylidide (MEGX) metabolite (O'Neal and Poklis, 1996). The rate of this conversion is a sensitive indicator of hepatic dysfunction and is often used to assess hepatic viability in donor livers prior to transplantation. MEGX formation may also be useful in monitoring the severity of the histologic condition of patients with chronic hepatitis and cirrhosis (Shiffman *et al.*, 1994).

ANALYTIC ROLE IN THERAPEUTIC MONITORING

Historically, the administration of drugs for long-term therapy was based largely on experience. A dosage amount was selected and administered at appropriate intervals based on what the clinician had learned was generally tolerated by most patients. If the drug seemed ineffective, the dose was increased; if toxicity developed, the dose was decreased or the frequency of dosing was altered. At times, a different dosage form might be substituted. Establishing an effective dosage regimen was particularly difficult in children and the elderly.

The factors responsible for individual variability in responses to drug therapy include the rate and extent of drug absorption, distribution, and binding in body tissues and fluids, rate of metabolism and excretion, pathologic conditions, and interaction with other drugs (Blaschke *et al.*, 1985). Monitoring of the plasma or serum concentration at regular intervals will detect deviations from the average serum concentration, which, in turn, may suggest that one or more of these variables need to be identified and corrected.

In a given patient, when the various factors are assumed to be constant, the administration of the same dose of a drug at regular intervals eventually produces a steady-state condition (Fig. 31-9) (Moyer *et al.*, 1986). Monitoring of steady-state drug concentrations assures that an effective concentration is present. For drugs that have a defined correlation between serum values and undesired toxic effects, the lowest serum value immediately prior to dosing (trough) and the highest expected serum concentration (peak) are monitored to assure efficacy and minimize toxicity. Appropriate situations for therapeutic drug monitoring are presented in Table 31-6.

Because the drug being administered is known, qualitative characterization of the analyte generally is not required. Quantitative accuracy is required, however. Frequently, the methodology
Figure 31-9. Fundamental pharmacokinetic relationships for the repeated administration of drugs.

The blue line is the pattern of drug accumulation during the repeated administration of a drug at intervals equal to its elimination half-time, when drug absorption is 10 times as rapid as elimination. As the relative rate of absorption increases, the concentration maxima approach 2 and minima approach 1 during steady state. The black line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based upon the one-compartment model. Average concentration (C_{SS}) when steady state is attained during intermittent drug administration is $C_{SS} = F \times \text{dose}/Cl \times T$, where F = fractional bioavailability of the dose and T = dosage interval (time). By substitution of infusion rate for $F \times \text{dose}/T$, the formula is equivalent to Eq. (1) and provides the concentration maintained at steady state during continuous intravenous infusion. [From Hardman JG, Limbird LE, Molinoff PB, *et al.* (eds.): *Goodman & Gilman's The Pharmacological Basis of Therapeutics,* 9th edn. New York: McGraw-Hill, 1995, p 23.]

applied is important, particularly in regard to its selectivity. For example, methods that measure the parent drug and its metabolites are not ideal unless the individual analytes can be quantified separately. Depending on the drug, metabolites may or may not be active to a different degree than the parent drug. The cardiac antiarrythmic drug procainamide is acetylated during metabolism to form *N*-acetylprocainamide (NAPA). This metabolite has antiarrythmic activity of almost equal potency to that of the parent drug, procainamide. There is bimodal genetic variation in the activity of the *N*-acetyltransferase for procainamide, so that, in "fast acetylators," the concentration of NAPA in the serum may exceed that of the parent drug. For optimal patient management, information should be available about the concentrations of both procainamide and NAPA in serum (Bigger and Hoffman, 1985).

Because absolute characterization of the analyte is not necessary for many drugs, immunoassay procedures are commonly used. This is particularly true of drugs with extremely low serum concentrations, such as cardiac glycosides, and drugs that are difficult to extract because of a high degree of polarity, such as the aminoglycoside antibiotics. In these cases, serum can be conveniently assayed directly by using commercially available kits for immunoassays.

The chromatographic methods in which an appropriate internal standard is added are favored when more than one analyte is to be measured or if metabolites with structures similar to those of the parent drugs must be distinguished. Because the nature of drugs is varied, many different analytic techniques may be applied, including atomic absorption spectrophotometry for measuring lithium used to treat manic disorders. Virtually, all the tools of the analyst may be used for specific applications of analytic toxicology. Drugs that are commonly monitored during therapy, their usual effective therapeutic serum concentrations, "panic values," and typical analytic methodologies applied to serum measurements are presented in Table 31-7. The term *panic value* denotes a serum drug concentration associated with the development of potentially serious toxicity. In clinical laboratories, the panic value alerts the toxicologist that the treating physician must be *immediately* contacted and notified of the test result.

ANALYTIC ROLE IN BIOLOGICAL MONITORING

In the workplace, good industrial hygiene practices require monitoring of the environment to which workers are exposed in order to identify potentially harmful amounts of hazardous chemicals. Despite

Table 31-6
Appropriate Use of Therapeutic Drug Monitoring

USE	EXAMPLES
Optimize efficacy while minimizing toxicity	
Optimal SDC for clinical effect	
Routine, prophylactic peak serum	Aminoglycosides
Poor patient response	Antiarrhythmics, antidepressants
Suspected toxicity	
Resolve complicating factors	
Patient characteristics	Age, smoking, noncompliance
Disease	Renal failure, hepatic disorders
Drug interactions	Induction or inhibition of drug metabolism
Sudden change in physiologic state	Improved cardiac function on lidocaine therapy increases clearance
Dosage regimen design	
Individualize future dosing (single SDC)	
Pharmacokinetic profiling (multiple SDC)	Ideal dosage for aminoglycosides
Follow-up SDC	Single steady-state lidocaine
Verify therapy	Medicolegal lithium

NOTE: SCD, serum drug concentration.

Table 31-7
Drugs Commonly Indicated for Therapeutic Monitoring

THERAPEUTIC USE DRUG	EFFECTIVE SERUM RANGE (mg/L)	PANIC VALUE = OR = (mg/L)	ANALYTIC METHODOLOGY
Antiarrythmic			
Digoxin	0.0005–0.002	0.0024	Immunoassay
Procainamide	4–10	12	Immunoassay
NAPA	5–30	40	Immunoassay
Anticonvulsant			
Carbamazepine	4–12	15	Immunoassay
Gabapentin	2–15	20	GC
Lamotrigine	0.5–8	10	HPLC
Phenobarbital	15–30	50	Immunoassay
Phenytoin	10–20	40	Immunoassay
Tropiramate	2–10	Undetermined	GC
Valproic acid	50–100	200	GC
Antidepressants			
Amitriptyline	0.08–0.250	0.5	HPLC
Desipramine	0.125–0.30	0.4	HPLC
Nortriptyline	0.08–0.250	0.5	HPLC
Antimicrobials			
Tobramycin	0.5–1.5 (trough)	2	Immunoassay
	5–10 (peak)	12	
Vancomycin	5–10 (trough)		Immunoassay
	30–40 (peak)	90	
Immunosuppressant			
Cyclosporine	0.1 (trough, whole blood)		HPLC
Neonatal apnea			
Caffeine	8–20	50	HPLC

these precautions, it has become apparent that monitoring a worker directly can be a better indicator of exposure because it can show what has actually been absorbed. This is biological monitoring, and it can take a variety of forms. Often, environmental exposures are to a mixture of compounds and/or to compounds that are converted to physiologically important metabolites. Thus, analytic methods must be capable of separating a family of chemical agents and their major metabolites (Fig. 31-10). Additionally, methods must be sufficiently specific and sensitive to measure minute concentrations of the compounds in complex biological matrices.

An example of biological monitoring is presented in Table 31-8, which shows data relating to benzene exposure of chemists engaged in pesticide residue analysis in a state regulatory laboratory. Air-monitoring devices in this laboratory indicated that the ambient benzene concentration never exceeded the time-weighted average (TWA) of 32 mg/m^3 (10 ppm). Monitoring of the breathing zones at different locations around the laboratory where benzene was in use showed other concentrations of this material. When expired air was monitored, one worker showed a significantly greater amount of benzene exposure than did others. Upon questioning, she recalled spilling some of the solvent on a laboratory bench, in the process saturating a portion of her laboratory coat. Presumably, her exposure by inhalation and skin absorption was considerably greater than was indicated by the air monitor.

In addition to the measurement of the chemical or its metabolites in the body fluids, hair, or breath of the worker, other, more indirect methods may be employed. Substances that interact with macromolecules may form adducts that persist for long periods.

Fume hood breathing zone	—	51.2

These adducts can be sampled periodically and potentially can serve as a means of integrating exposure to certain substances over long periods. For example, adducts of ethylene oxide with DNA or hemoglobin have been studied in workers. This technique may also be applicable in other situations that are not necessarily related to occupational hazards. Acetaldehyde, a metabolite of ethanol, forms adducts with hemoglobin. This marker may be of use in forensic cases (Stockham and Blanke, 1988).

Another approach that is useful in biological monitoring is to measure changes of normal metabolites induced by xenobiotics. The profile of glucuronic acid metabolites excreted in urine can be altered after exposure to substances that induce monooxygenase activity. Although monitoring the alteration of the urinary excretion of these metabolites may not indicate exposure to specific substances, this technique can be used in a generic fashion to flag a potentially harmful exposure to a hepatotoxic agent (Saady and Blanke, 1990). The early recognition of a toxicologic problem may permit the protection of a worker before irreversible effects occur.

SUMMARY

The analytic techniques initiated by forensic toxicologists have continued to expand in complexity and improve in reliability. Many new analytic tools have been applied to toxicologic problems in almost all areas of the field, and the technology continues to open new areas of research. Forensic toxicologists continue to be concerned about conducting unequivocal identification of toxic substances in such a manner that the results can withstand a legal challenge. The problems of substance abuse, designer drugs, increased potency of therapeutic agents, and widespread concern about pollution and the safety and health of workers present challenges to the analyst's skills. As these challenges are met, analytic toxicologists continue to play a significant role in the expansion of the discipline of toxicology.

CLINICAL TOXICOLOGY

Louis R. Cantilena Jr.

HISTORY OF CLINICAL TOXICOLOGY

Historical Aspects of the Treatment of Poisoning

The history of poisons and poisoners dates back to ancient times. The *Odyssey* and *Shastras* from approximately 600 BC contained references to antidotes. The first documentation of use of a specific antidote may be found in Homer's *Odyssey* where it is suggested to Ulysses that he take moli to protect himself from poisoning. Moli may actually be *Galanthus nivalis*, a plant derived cholinesterase inhibitor that might counteract the effects of the anticholinergic plant *Datura stramonium* (Plaitakis and Duvoisin, 1983).

Galen (AD 129–200) wrote three books called *De Antidotis I, De Antidotis II,* and *De Theriaca ad Pisonem* that described the development of a universal antidote known as a alexipharmic or theriac by King Methridates VI of Pontus who lived from 132–63 BC (Wax, 1997). The antidote reportedly contained 36 or more ingredients and was ingested every day conferring protection against a broad spectrum of poisons such as venomous stings and bites from vipers, spiders, and scorpions (Jarcho, 1972).

The refinement of theriac (antidote) formulations is documented for nearly 2000 years. Andromachus (first century AD) was a physician to Nero and improved the Methridates' theriac by modifying the formula to include up to 73 ingredients (Wax, 1997). The use of these ancient antidotes included treatment of acute poisoning and prophylactic treatment to make one "poison proof." The Methridates' theriac with subsequent modifications remained in use until the early twentieth century. William Heberden wrote *Antitheriaka: An Essay on Mithridatium and Theriaca* in 1745 in which he questioned the effectiveness of these products (Jarcho, 1972). Despite the skepticism concerning these antidote formulations, their use continued for two millenniums.

One of the earliest writings on the prevention of the gastrointestinal absorption of poisons was by Nicander (Major, 1934). In this ancient writing, the induction of emesis by ingestion of an emetic agent or mechanical stimulation of the hypopharynx was described as a method to prevent poison absorption. It was not until the 1600s when the use of ipecacuanha for induction of emesis was recommended by William Piso (Reid, 1970).

The use of oral charcoal, now a mainstay in the treatment of many human poisonings, can be dated to early Greek and Roman civilizations when wood charcoal was used for the treatment of maladies such as anthrax and epilepsy (Cooney, 1995). The antidotal properties of charcoal were demonstrated in the 1800s by the French with dramatic demonstrations of a reduction in lethality when charcoal was ingested with potentially lethal dosages of arsenic trioxide by Bertrand and strychnine by Touery (Holt and Holz, 1963). One of the earliest reported human studies examining the efficacy of charcoal in poisoning was in 1948 by the American physician Rand (Holt and Holz, 1963). The use of superheated steam to treat the charcoal to enhance its absorption capacity was reported by Ostrejko, a Russian scientist in 1900 (Greensher *et al.*, 1987). By the 1960s, the use of activated charcoal was routinely recommended for the treatment of patients poisoned with substances thought to be adsorbed to charcoal.

Introduction of the Poison Control Center

Advances in the field of clinical toxicology have paralleled the evolution of poison control centers. One of the earliest local efforts to systematically collect, analyze and distribute to physicians, clinical information about poisoning was led by Jay Arena, a Duke University pediatrician. In 1939 he published a case series detailing the clinical outcome of 50 cases of lye poisoning (Martin and Arena, 1939). Interest in clinical information regarding the treatment of poisoned patients and resultant patient outcomes was also growing in Europe during approximately the same time. During the 1940s, several European communities developed hospital-based treatment facilities for poisoning (Manoguerra and Temple, 1984). This local, poison information effort continued for several years as further realization of the growing importance of the problem of poisoning occurred. A study by the American Academy of Pediatrics completed in 1952 reported that more than half of childhood accidents involved unintentional poisoning in the United States. Possibly in response to this study, Edward Press and Louis Gdalman started the first United States poison control center in Chicago, Illinois. Mr. Gdalman had collected toxicological information on more than 9,000 commercial and noncommercial products throughout the 1940s and early 1950s. Their Chicago poison center provided telephone advice to health

care professionals as well as collected poisoning data systematically during the information sharing process. These centers became valuable resources for information about product ingredients, potential toxicity, and recommendations for the treatment of poisoned patients. Poison control centers proliferated over the next two decades and peaked at 661 centers in 1978 (Scherz and Robertson, 1978). Most of these centers served small areas; each state had a least one poison center; several states had more than 20 poison centers active at the same time; and there was little standardization throughout the specialty. Through regionalization, consolidation and certification, the number of poison control centers have significantly decreased to 63 centers in 2004 (IOM, 2004).

Staffing of a poison control center usually consists of a medical director (medical toxicologist), administrator or managing director, specialists in poison information, and educators for poison prevention programs. The medical toxicologist, managing director, and specialists in poison information are health care professionals who are credentialed by their respective boards. The American Board of Medical Subspecialties offers a subspecialty certificate in medical toxicology to physicians who successfully complete the certifying examination. The American Board of Applied Toxicology (ABAT) offers a certification examination for nonphysicians and the American Association of Poison Control Centers (AAPCC) provides a certification of the specialists in poison information who are usually nurses or pharmacists. The managing director is usually either the same person as the medical director or a nonphysician certified by the ABAT.

The public health services provided by poison control centers have been well documented. These services include direct information to patients with recommendations for needed treatment, critical diagnostic and treatment information for health care professionals, education for health care personnel and poison prevention activities through public education. Several studies have shown that poison information centers are cost effective. An often cited example of the economic benefit from access to a poison control center comes from a one year forced closure of the Louisiana State Poison Center. When there was no poison center to call, the community was left with the alternative of an emergency room or doctor's office visit for information and possible treatment of their exposure. It was estimated that the increased costs to the state for emergency medical services was $1.4 million for that year (King, 1991). Studies have shown that for each dollar spent to operate a poison control center a saving of approximately $3–6.50 can be realized for the health care system (Miller and Lestina, 1997).

Recently, the Institute of Medicine commissioned an in-depth study of poison prevention and control services in the United States. The resulting report affirmed the need for, and the value of, the poison control centers and recommended several changes in the interest of public safety, standardization, and process improvement including: regional centers continue to serve the population; federal funding be provided to stabilize core functions of each center; and integration of poison control centers with public health agencies at the federal, state, and local level including integration with the Centers for Disease Control and Prevention for chemical and biological terrorism preparedness (IOM, 2004).

CLINICAL STRATEGY FOR TREATMENT OF THE POISONED PATIENT

The initial phases of treatment of a seriously poisoned patient usually occur in the setting of a hospital emergency room but initial treatment in other, less ideal settings such as the battlefield, workplace, home or street setting can be required as well. Most clinical toxicologists agree that a methodically executed, stepwise approach to the treatment of the poisoned patient is recommended for optimal care (Goldfrank, 2006; Ellenhorn, 1997). This section will refer primarily to the treatment of poisoned patients in the Emergency Department (ED) setting. In that setting, the following general steps represent important elements of the initial clinical encounter for a poisoned patient:

1. Stabilization of the patient
2. Clinical evaluation (history, physical, laboratory, radiology)
3. Prevention of further toxin absorption
4. Enhancement of toxin elimination
5. Administration of antidote
6. Supportive care and clinical follow-up

Clinical Stabilization

The first priority in the treatment of the poisoned patient is clinical stabilization. This is the so-called ABCs (Airway, Breathing, Circulation) of initial emergency treatment. Assessment of the vital signs and the effectiveness of respiration and circulation are the primary objectives of this initial encounter. Early in the course of some poisonings there is a varying range of severity of demonstrated toxic effects by patients poisoned with even lethal dosages of toxins. Some chemicals, such as a benzodiazepine can cause pronounced clinical effects early such as sedation but can have a comparatively mild clinical course; while other chemicals, such as camphor, show little clinical effects initially but can produce a fatal outcome. Some chemicals can cause seizures early in the course of their presentation. Control of chemical-induced seizures can be an important component of the initial stabilization of the poisoned patient. The degree of initial clinical stabilization required for a poisoned patient therefore is highly variable. The clinical procedures available to stabilize a critically ill poisoned patient include the initial and ongoing assessment and, if indicated, support of ventilation, circulation, and oxygenation. A detailed description of the various clinical methods available to treat abnormalities in these parameters is beyond the scope of this chapter. The reader is referred to textbooks of emergency medicine and critical care medicine for further information on this subject. Once the poisoned patient is clinically stabilized, the remainder of the assessment and treatment steps can proceed. In critically ill patients, sometimes treatment interventions must be initiated before a patient is truly stable.

Clinical History in the Poisoned Patient

The primary goal of taking a medical history in poisoned patients is to determine, whenever possible, what substance the poisoned patient has been exposed to and to determine the extent and time of exposure. Unfortunately, in contrast to most specialties of medicine, the clinical history available during the initial clinical encounter in the treatment of poisoned patients is sometimes not helpful because it may be either unreliable or unobtainable. In the setting of a suicide attempt, the patient often is not willing to provide a history or may give incorrect information to increase the possibility of success of their attempt to bring harm to themselves. For these reasons, additional sources for the clinical history are often incorporated to aid the clinical team in determining what substances the patient has been exposed to. Examples of possible sources sometimes employed

Table 32-1
Clinical Features of Toxic Syndromes

	BLOOD PRESSURE	PULSE	TEMPERATURE	PUPILS	LUNGS	ABDOMEN	NEUROLOGIC
Sympathomimetic	Incr.	Incr.	Slight Incr.	Mydriasis	NC	NC	Hyperalert, incr. reflexes
Anticholinergic	Slight incr. or NC	Incr.	Incr.	Mydirasis	NC	Decr. Bowel sounds	Altered mental status
Cholinergic	Slight decr. or NC	Decr.	NC	Miosis	Incr. bronchial sounds	Incr. bowel sounds	Altered mental status
Opioid	Decr.	Decr.	Decr.	Miosis	NC or rales (late)	Decr. Bowel sounds	Decr. level of consciousness

to obtain an accurate history include family members, emergency medical technicians who were at the scene, a pharmacist who can sometimes provide a listing of prescriptions recently filled or an employer who can provide a list of chemicals that are in the work environment.

In estimating the exposure level to the poison, generally one should maximize the possible dose received. That is, one should assume that the entire prescription bottle contents were ingested, that the entire bottle of liquid was consumed or that the highest possible concentration of airborne contaminant was present for a patient poisoned by inhalation unless definite evidence exists to the contrary. Maximizing the potential dose or exposure level reduces the probability of encountering an unexpected clinical outcome in a poisoned patient.

With an estimate of dose, the toxicologist can refer to various information resources to determine what the range of expected clinical effects might be from the estimated exposure. The estimation of expected toxicity greatly assists with the triage of poisoned patients. Poison information specialists working in Poison Information Centers routinely give telephone recommendations regarding the level of medical care required for a given ingestion based on the expected clinical effects from the reported ingestion. The vast majority of in-the-home accidental pediatric exposures are treated with at-home observation, home-administered activated charcoal, or the induction of emesis. In the hospital setting, ED staff use the estimation of expected clinical effects to effectively triage the poisoned patient. For example, a three-year-old patient who accidentally ingested 25 children's chewable multivitamins without iron would likely be triaged to a non-critical care area of the ED, whereas another three-year-old who drank a mouthful of caustic alkali drain cleaner would be triaged to a high intensity of care section of the ED.

Estimating the timing of the exposure to the poison is frequently the most difficult aspect of the clinical history when treating the poisoned patient. Often the toxicologist must turn detective to determine the most likely window of time that the exposure occurred. For example, if a pediatric patient was being watched by the babysitter at all times except for a 20-minute period that preceded the onset of symptoms and the discovery of an open prescription bottle for digoxin, then one would estimate that the ingestion occurred in that 20-minute window. Other situations require estimation of a far broader window for exposure. A person found with a suicide note could have taken the contents of the empty prescription bottle (or anything else available) at any time from when they were last seen by someone to a short time before they were discovered.

Due to these and other limitations, obtaining an accurate history of the poisoned patient can be very challenging and in some

cases the treating personnel are not successful. When the history is unobtainable the clinical toxicologist is left without a clear picture of the exposure history in the poisoned patient. When this occurs, treatment proceeds empirically as an "unknown ingestion" poisoning. This type of treatment will be discussed later in this chapter.

Physical Examination

One of the most important aspects of the initial clinical encounter in the treatment of the poisoned patient is the physical examination. A thorough examination of the patient is required to assess the patient's condition, categorize the patient's mental status and, if altered, determine possible additional explanations for the abnormal mental status such as trauma or central nervous system infection. One very helpful tool for the clinical toxicologist is to categorize the patient's physical examination parameters into broad classes referred to as toxic syndromes. These toxic syndromes have been called toxidromes (Mofenson and Greensher, 1970). A toxidrome is a constellation of clinical signs and symptoms that, when taken together, are likely associated with exposure from certain toxicologic classes of chemicals. The major toxic syndromes include narcotic, cholinergic, sympathomimetic, and anticholinergic. Table 32-1 lists the clinical features of these major toxic syndromes.

In certain treatment settings, the chemicals responsible for the poisoning are not known during the critically important phase of initial treatment of the poisoned patient. Categorization of the patient presentation into toxic syndromes allows for the initiation of rationale treatment based on the most likely category of toxin responsible. For example, if a patient presents in a coma, with miosis (pinpoint pupils), hypotension, bradycardia, a markedly reduced respiratory rate, and slight hypothermia with an otherwise non-localizing neurological examination, the clinical toxicologist can characterize the patient's presentation as consistent with the narcotic toxic syndrome. The presence of needle tracks on the skin would support this categorization. The treatment would then be directed at support of respiration and pharmacological reversal with a mu-receptor opioid antagonist such as naloxone. In this example, lifesaving treatment can be administered in a timely manner, even in the absence of definitive identification of the ingested poison.

Occasionally a characteristic odor can be detected on the poisoned patient's breath or clothing which may point toward exposure or poisoning by a specific agent. Table 32-2 lists some of the better recognized odors and the substance associated with the odor. Detection of one of these odors may provide an important historical clue as to the agent responsible for the poisoning.

Table 32-2
Characteristic Odors Associated with Poisonings

ODOR	POTENTIAL POISON
Bitter almonds	Cyanide
Eggs	Hydrogen sulfide, mercaptans
Garlic	As, organophosphates, DMSO, Thallium
Mothballs	Naphthalene, camphor
Vinyl	Ethchlorvynol
Wintergreen	Methylsalicylate

Periodic reexamination of the patient is a very important aspect of clinical toxicology treatment procedures. Follow-up clinical examinations can help gauge the progression of the clinical course of poisoning as well as determine the effectiveness of treatment interventions and gauge the need for additional treatment procedures.

Laboratory Evaluation

A common misconception concerning the initial treatment of poisoned patients is that a definitive diagnosis of the specific agent or poison responsible for the patient's clinical presentation is frequently made by the clinical laboratory during the initial patient evaluation. Unfortunately, the repertoire of specific assays for toxins available in clinical laboratories on a rapid turnaround basis (STAT, e.g., within 1 hour) is very limited. Table 32-3 lists drugs or other chemical substances that are typically available for STAT measurement in a medical center type hospital facility. As one can see, the number of chemicals for which quantitative detection is possible in the rapid turnaround clinical setting is extremely limited compared to the number of possible chemicals that can poison patients. This further emphasizes the importance of recognizing clinical syndromes for poisoning and for the clinical toxicologist to be able to initiate general treatment and supportive care for the patient with poisoning from an unknown substance.

For the relatively few substances that can be measured on a rapid turnaround basis in an ED setting, the quantitative measurement can often provide both prognostic and therapeutic guidance. Several authors have suggested certain "action levels" for specific therapeutic drugs and chemicals which when met or exceeded during the measurement in patient plasma, should trigger specific interventions or predict likely clinical outcomes. In some cases, measurement of an indicator of the biologic effect of a poison provides sufficient information to render definitive treatment to the patient. Measurement of methemoglobin concentration in a patient poisoned by one of many chemicals that can cause this chemical transformation of the hemoglobin molecule is sufficient to initiate treatment for methemoglobinemia without identification of the specific toxin that caused the condition. Similarly, most hospital laboratories have the capability for rapid measurement of carboxyhemoglobin concentrations, which permits treatment of carbon monoxide poisoning based on the laboratory test measuring a surrogate marker for carbon monoxide exposure.

For some commonly ingested drugs, a nomogram has been established to predict the severity of the poisoning and is important in some cases to guide therapeutic intervention based on the measured plasma concentration of the drug and the time elapsed from the exposure. Proper use of such nomograms is necessary for the clinical management of poisoning cases.

Semilogarithmic Plot of Plasma Acetaminophen Levels vs. Time
Figure 32-1. Rumack-Mathew nomogram for acetaminophen poisoning. (From Rumack and Mathew, 1975, with permission. Copyright American Academy of Pediatrics, 1975.)

The clinical usefulness of a drug plasma concentration measured by the clinical laboratory was suggested for salicylates approximately 40 years ago. In 1960, Done published a nomogram to predict the clinical outcome from poisoning with salicylates (Done, 1960).

In 1975, Rumack and Mathews published a nomogram for acetaminophen poisoning shown in Figure 32-1 (Rumack and Mathew, 1975). This nomogram predicts clinical outcome and is also valuable to guide the clinician in the decision as to whether or not to administer *N*-acetyl cysteine (NAC), an antidote for

significant acetaminophen ingestion. Laboratory evaluation of a patient potentially poisoned with acetaminophen is crucial to assess what hepatic injury may have already occurred and to determine plasma concentrations of acetaminophen for prognostic purposes. Accurate estimation of acetaminophen in the plasma should be done on samples drawn at least 4 hours after ingestion, when or past the time that peak plasma levels can be expected. Once an accurate plasma concentration of acetaminophen has been obtained, it should be plotted on the Rumack-Matthew nomogram (Fig. 32-1) to determine whether NAC therapy is indicated. This nomogram is based on a series of patients with and without hepatotoxicity and their corresponding acetaminophen plasma concentrations at presentation.

In the appropriate patient, the decision to treat an acetaminophen-poisoned patient is based on the plasma concentration of parent acetaminophen plotted on the nomogram. Although some authors recommend that NAC treatment only be administered to a patient with an acetaminophen plasma concentration in the "definite toxic" range, most clinical toxicologists agree that NAC should be given at or above the "probably toxic" action level. It should be noted however that proper use of this nomogram is required, namely that certain conditions should be met to apply the nomogram to a specific clinical case. The nomogram was validated for a single acetaminophen ingestion, the time of ingestion is critically important to establish the X-axis coordinate for the data point and the plasma concentration should have been obtained at least 4 hours after ingestion to assure that the peak plasma concentration of parent acetaminophen has occurred.

Similar, though perhaps less well established, predictive relationships of drug plasma concentration and clinical outcome and/or suggested concentrations that require therapeutic interventions are available for several other chemicals including lithium, salicylates, digoxin, iron, phenobarbital, and theophylline. Some authors have identified "action levels" or toxic threshold values for the measured plasma concentrations of various drugs or chemicals (Ellenhorn, 1997). Generally, these values represent mean concentrations of the respective substance that have been retrospectively shown to produce a significant harmful effect. The pharmaco- (or toxico-) dynamic variability for a given toxin or for a combination of toxins is significant, however. For example, a patient with a "normal" or "nontoxic" digoxin level may display significant toxic effects and conversely a patient with an elevated or "toxic" plasma concentration of digoxin may not show any sign of harmful effects. The clinical toxicologist must critically evaluate the laboratory data and treat the patient and not just the laboratory value.

Because of the limited clinical availability of "diagnostic" laboratory tests for poisons, toxicologists utilize specific, routinely obtained, clinical laboratory data to establish a differential diagnosis of what poisons may have been ingested. There are two calculations that toxicologists can perform using clinical laboratory values routinely obtained in an acute clinical setting. The calculations performed on routine clinical labs are the anion gap and the osmol gap. An abnormal anion gap or osmol gap suggests a differential diagnosis for significant exposure of a poisoned patient. Both calculations are used as diagnostic aids when the clinical history suggests poisoning and the patient's condition is consistent with exposure to agents known to cause elevations of these parameters (i.e., metabolic acidosis, altered mental status, etc.).

The anion gap is calculated as the difference between the serum Na ion concentration and the sum of the serum Cl and HCO_3 ion

Table 32-4

Differential Diagnosis of Metabolic Acidosis with Elevated Anion Gap: "AT MUD PILES"

S	Salicylate

concentrations.

$$Anion\,Gap = [Na\,mEq/L - (Cl\,mEq/L + HCO_3\,mEq/L)]$$

$$Normal\,Anion\,Gap \leq 12$$

When there is laboratory evidence of metabolic acidosis in a poisoned patient, the finding of an elevated anion gap would suggest systemic toxicity from a relatively limited number of agents. A popular clinical pneumonic (AT MUD PILES) is commonly employed as a memory aid for this differential diagnosis. Table 32-4 lists the more common agents that have metabolic acidosis with an elevated anion gap as part of the clinical presentation that are included in this pneumonic.

The second calculated parameter from clinical chemistry values is the osmol gap. The osmol gap is calculated as the numerical difference between the measured serum osmolality and the serum osmolarity calculated from the clinical chemistry measurements of the serum sodium ion, glucose, and blood urea nitrogen (BUN) concentrations (Smithline and Gardner, 1976).

$$OsmoGap = Measured\,Serum\,Osmolality\,(mOsm)$$

$$- Calculated\,Serum\,Osmolarity$$

where calculated serum osmolarity $= 2 \times$ Na mEq/L $+$ Glucose mg/dL /18 $+$ BUN mg/dL/2.8,

$$Normal\,osmol\,gap < 10\,mOsm.$$

Note that the serum osmolality must be measured by freezing point depression and not boiling point elevation as the later method can fail to detect the osmolality contribution of volatile, low-molecular-weight substances due to vaporization of the substance during measurement.

An elevated osmol gap in the setting of a poisoned patient suggests the presence of an osmotically active substance in the plasma that is not accounted for by the Na, glucose or BUN concentrations. Table 32-5 lists several substances that when ingested can be associated with an elevated osmol gap in humans.

While calculation of both the anion gap and the osmol gap can provide very useful information from readily available clinical chemistry measurements, these determinations must be interpreted cautiously in certain clinical settings. For example, even though a patient may have ingested a large, significantly toxic amount of

Table 32-5
Differential Diagnosis for Elevated Osmol Gap

Methanol
Ethanol
Ethylene glycol
Isopropanol

methanol, if measured late in the clinical course of the exposure, the osmol gap may not be significantly elevated as most of the osmotically active methanol has left the plasma and has been bio-transformed or cleared but still producing serious clinical effects.

Radiographic Examination

The utility of the radiographic examination to diagnose specific poisonings is relatively limited. The use of clinical radiographs to visualize drug overdose or poison ingestions is also relatively limited. This is due primarily to the lack of radiopacity of many oral forms of medication. Early radiographic surveys of the radiopacity of oral medications revealed that the vast majority of commercially available tablets and capsules surveyed were essentially undetectable by radiograph (Handy, 1971; O'Brien *et al*., 1986). These and other studies have shown that relatively few formulations of drugs are radiopaque and would likely be detectable by plain X-ray of the abdomen. Generally, plain radiographs can detect a significant amount of ingested oral medication containing ferrous or potassium salts. However, a study of the in vitro and in vivo visualization of chewable oral formulations of iron supplements showed that once the chewable iron was ingested it was no longer detectable by plain abdominal radiograph (Everson *et al*., 1989). However, certain formulations that have an enteric coating or certain types of sustained release products are radiopaque and can be visualized (Savitt *et al*., 1987; Nelson *et al*., 1993).

The most useful radiographs ordered in an overdose or poisoned patient include the chest and abdominal radiographs and the computed head tomography study. The abdominal radiograph has been used to detect recent lead paint ingestion in children due to pica for many years. Although the presence of radiographic evidence of lead based paint chips probably underrepresented the proportion of children with moderate to severe lead poisoning in one study, an abdominal radiograph showing pica was associated with significantly elevated blood lead concentrations (McElvaine *et al*., 1992). Another situation in which an abdominal radiograph may be helpful is the setting of a halogenated hydrocarbon such as carbon tetrachloride or chloroform. If a sufficient amount of either liquid is ingested it is likely that these organic solvents will be visualized as a radiopaque liquid in the gut lumen on the abdominal film relatively recently after ingestion (Dally *et al*., 1987). Finally, abdominal plain radiographs have been helpful in the setting where foreign bodies are detected in the gastrointestinal tract. An example of this is in the situation where an international traveler coming to the United States, becomes acutely ill with signs of severe sympathomimetic excess and numerous foreign bodies are visualized throughout the gastrointestinal tract. This patient would be known as a body packer who smuggles illegal substances by swallowing latex or plastic storage vesicles filled with cocaine or some other substance (Beerman *et al*., 1986; McCarron and wood, 1983; Sporer and Firestone, 1997). Occasionally these storage devices rupture and the drug is released into the gastrointestinal tract with serious and sometimes fatal results.

Aside from these relatively uncommon situations, the overall clinical utility for detection and diagnosis of poisons by radiography is limited.

In contrast to the limited clinical utility of plain radiography for the identification of a specific poison or to diagnose poisoning, plain radiography and other types of diagnostic imaging in clinical toxicology can be extremely valuable for the diagnosis of toxin-induced pathology and to aid the clinical toxicologist in the ongoing treatment and patient management phases of the drug overdose. Detection of drug-induced noncardiac pulmonary edema is associated with serious intoxication with salicylates and opioid agonists (Stern *et al*., 1968; Heffner *et al*., 1990). Plain chest radiography can detect this abnormality, which would likely correlate with the findings observed during physical examination of the lungs. This radiographic finding would increase the severity classification of the poisoning and potentially alter the planned therapeutic strategy for the patient.

Another example of the use of radiological imaging in clinical toxicology is with computed tomography (CT) of the brain. Significant exposure to carbon monoxide (CO) has been associated with CT lesions of the brain consisting of low-density areas in the cerebral white matter and in the basal ganglia, especially the globus pallidus. Although not clinically employed for diagnostic purposes in the acute phases of a carbon monoxide poisoning, these CT findings of the brain have been useful for estimating the clinical prognosis of a patient who survives the initial phase of CO poisoning (Miura *et al*., 1985; Jones *et al*., 1994). Finally, concurrent intracranial pathology, such as trauma or hemorrhage can be detected by CT or MRI of the brain to aid in the diagnosis of additional injury or pathology previously not appreciated during the treatment of a poisoned patient.

The initial clinical evaluation of the poisoned patient is a critically important phase of the therapeutic process to treat poisoned individuals. The physical, laboratory and radiological examination all contribute to the initial diagnostic steps for poison treatment. The physical and laboratory examinations are generally utilized more from a diagnostic and acute management standpoint, whereas the radiological examination tends to be more useful for detection and management of toxicant-induced pathology.

Prevention of Further Poison Absorption

During the early phases of poison treatment or intervention for a toxic exposure via the oral, inhalation or the topical route, the treatment team may have an opportunity to prevent further absorption of the poison to minimize the total amount that reaches the systemic circulation. For chemicals presented by the inhalation route, the main intervention to prevent further absorption is removal of the patient from the environment where the chemical is found and to provide adequate ventilation and oxygenation for the patient. For topical exposures, patient clothing containing the toxin must be removed and properly disposed in airtight wrappings or containers to ensure that the rescuers and health care providers are adequately protected from secondary exposure. Most topical exposures require gentle washing of the skin with water and mild soap taking care not to cause cutaneous abrasions of the skin that may enhance dermal absorption.

The optimal time to intervene to prevent continued absorption of an oral poison is as soon as possible after the ingestion. The four primary methods currently available for this purpose are: induction of emesis with syrup of ipecac, gastric lavage, oral administration of activated charcoal and whole bowel irrigation. Historically,

induction of emesis with a variety of agents was the sole modality employed to treat poisoning by seeking to reduce the gastrointestinal absorption of poisons. Tartar emetic was an antimony salt used for induction of emesis and other medicinal purposes. Other emetic agents used later on included mustard mixed in water, concentrated solutions of copper and zinc salts and various botanical substances. In hospitals, apomorphine injection was given even into the 1980s to cause emesis in patients with a history of potentially toxic ingestion.

Currently syrup of ipecac is the only agent available for induction of emesis in the treatment of a potentially toxic ingestion. Previously poison center directed, home use of syrup of ipecac was the most widely used poison treatment intervention. Syrup of ipecac has been available in the United States since the early 1960s. Typically, 15–20 ml of syrup of ipecac is given orally with water and vomiting (usually more than a single episode) can be expected within the ensuing 30 minutes. However, recently the efficacy and potential abuse liability of syrup of Ipecac have significantly impacted on the product's use in the management of poisoning. Controlled studies have demonstrated significant variability in the amount of drug or test markers removed by administration of syrup of ipecac. In addition, the efficacy to remove gastric contents and therefore subsequent absorption of the toxin declines with increase in the time interval between poison ingestion and syrup of ipecac administration (Neuvonen *et al*., 1983). Despite being available as an over-the-counter drug product in the United States since 1965, a citizen's petition was filed with the Food and Drug Administration to request removal of syrup of ipecac from the OTC market in 2002 based on limited efficacy data and published reports of increasing abuse liability for the product. In June, 2003 the FDA's advisory committee for nonprescription drugs met to review the pros and cons of continued OTC availability for this product. Due to a nuance in regulations and FDA policy, if removed from the OTC market, because no prescription "sponsor" is available for the product, syrup of ipecac would effectively be removed from the entire US market (prescription and nonprescription) and unavailable for sale. At the present time, the FDA has yet to decide the fate of the OTC availability for syrup of ipecac. The American Academy of Clinical Toxicology and the European Association of Poisons Centres and Clinical Toxicologists issued a position paper regarding the use of syrup of ipecac in 2004, which stated that the product should not be used routinely in the management of the poisoned patient and that there was insufficient data to either support or exclude ipecac administration soon after poison ingestion (Krenzelok *et al*., 2004). Many clinical toxicologists believe that there remains a limited role for the clinical use of syrup of ipecac, mainly is rural areas where the length of time before a poisoned patient can reach medical care is significant. The accepted contraindications for use of syrup of ipecac are: (1) children less than 6 months of age; (2) in the ingestion of a caustic agent (acid or alkali); (3) in a patient with a depressed level of consciousness or gag reflex or when the toxin ingested is expected to cause either condition within a short period of time; or (4) when there is a significant risk of aspiration of gastric contents such as for ingestion of a liquid hydrocarbon with high aspiration potential.

The use of gastric lavage, the technique of placing an orogastric tube into the stomach and aspirating fluid then cyclically instilling fluid and aspirating until the effluent is clear, has diminished significantly in recent years. The reasons for the decline in use of this technique include a growing appreciation of the risk of aspiration during the lavage procedure and growing evidence that the effectiveness of gastric lavage may be more limited than originally thought. Careful attention to the patient's gag reflex prior to initiation of this procedure is important. If the patient does not exhibit a gag reflex, then endotracheal intubation must be performed to adequately protect the airway and prevent aspiration. Most clinical toxicologists would agree that the current role of gastric lavage, if there is a role at all, would be in the initial treatment of the overdose patient who had a recent (within 1 hour) oral ingestion. It is essential that the orogastric tube be of sufficient size (40–44 French for an adult) to be useful. Even with a large bore orogastric tube some tablets or capsules may not be able to pass through the tube. In the pediatric patient, there are practical limitations to the use of large bore tubes. In this case, orogastric lavage may only be useful to attempt removal of liquid toxins or possibly dissolved tablets or capsules. Due to recent questioning of the effectiveness of the technique and the availability of data showing that other modalities for prevention of further toxin absorption (e.g., oral activated charcoal) are possibly as or more effective, the use of gastric lavage has greatly diminished.

As described earlier, the medicinal use of charcoal dates back more than 150 years. The first reported medicinal use of oral charcoal to adsorb an ingested toxin is credited to the American physician, Hort, who, in 1834, used large amounts of powdered charcoal to successfully treat a patient poisoned with a chloride salt of mercury. A dramatic demonstration of the adsorptive effect of oral charcoal was that by Tourey, a French pharmacist who reportedly mixed a lethal dose of strychnine with charcoal and consumed the combination before his colleagues at the French Academy in 1930 (Andersen, 1946). Early in vitro investigations of the adsorptive properties of activated charcoal demonstrated the effect of charcoal on various chemical substances in aqueous solutions (Andersen, 1946), the effect of pH on charcoal adsorption properties (Andersen, 1947) and the effect of activated charcoal on the adsorption of strychnine from gastric contents (Andersen, 1948).

During the last 20–30 years there has been growing use of oral charcoal as a therapeutic intervention for oral poisoning. For many years, orally administered activated charcoal has been routinely incorporated into the initial treatment of a patient poisoned by the oral route. The term "activated" refers to the substantially increased adsorptive capacity that results from the processing of charcoal obtained from the burning of carbonaceous substances such as wood pulp, sugars, organic material and industrial wastes. The processing involves extensive treatment with steam, carbon dioxide, oxygen, zinc chloride, sulfuric acid, or phosphoric acid at temperatures of 500–900 degrees Fahrenheit "activate" the residue oxidation which leads to a significant increase in surface area through creation of small pores in the material. Many organic molecules are significantly bound to activated charcoal. Generally low-molecular-weight, and polar compounds, such as ethanol, tend to be less well bound to activated charcoal. Substances such as lithium, iron and certain inorganic salts are also not appreciably bound. In acute oral overdose, activated charcoal is typically administered at a dosage of 1.0–1.5 g/kg. When the patient is unable to safely drink the charcoal it is placed into the stomach via orogastric or nasogastric tube.

The usefulness of whole bowel irrigation for the treatment of the poisoned patient is very limited. Whole bowel irrigation is a procedure that in essence "washes" the lumen of the gastrointestinal tract clear of unabsorbed material. The procedure is accomplished with a poorly absorbed, osmotically neutral polyethylene glycol electrolyte solution that is administered orally to expel the contents of the intestines via the rectal route. This procedure is used to prepare the lower intestine for endoscopic medical procedures of the large intestine. The primary role of this technique is for removal of ingested packets of illegal drugs that may or may not be

causing toxic effects due to leakage. Other potential roles for this gastrointestinal technique are to treat ingestion of sustained release formulations of drugs and ingestions of substantial amounts of iron preparations (Tenebein *et al.*, 2004).

Most clinical toxicologists agree that, for the prevention of further absorption following oral ingestion of most toxins, the administration of oral activated charcoal provides the most consistent efficacy and best safety profile (Goldfrank, 2006). The other modalities described above have more limited roles (whole bowel irrigation, syrup of ipecac) or only rare circumstances when their use should be considered at all (gastric lavage). Most treatment centers favor the use of activated charcoal without gastric decontamination (lavage or ipecac) for treatment of oral poisoning and drug overdose. Many poison control centers recommend home use of a premixed slurry of activated charcoal for immediate treatment of potentially significant poisonings. The use of ipecac syrup is largely limited to individual patients in whom it is likely to make a difference in outcome, who are in rural environments, hours away from more definitive medical treatment, in whom it appears to be the most effective method available in that particular set of circumstances, or in whom it is the only method available to attempt gastric emptying.

Enhancement of Poison Elimination

There are several methods available to enhance the elimination of specific poisons or drugs once they have been absorbed into the systemic circulation. The primary methods employed for this use today include: alkalinization of the urine, hemodialysis, hemoperfusion, hemofiltration, plasma exchange or exchange transfusion, and serial oral activated charcoal.

The use of urinary alkalinization results in the enhancement of the renal clearance of certain weak acids. The basic principle is to increase urinary filtrate pH to a level sufficient to ionize the weak acid and prevent renal tubule reabsorption of the molecule. This is also referred to as ion trapping. The ion-trapping phenomenon occurs when the pK_a of the agent is such that after glomerular filtration into the renal tubules, alteration of the pH of the urinary filtrate can ionize and "trap" the agent in the urinary filtrate. Once the toxin is ionized, reabsorption from the renal tubules is impaired, and as a result, more of the drug remains in the urinary filtrate and is excreted in the urine.

Clinical use of this alkalinization procedure requires adequate urine flow and close clinical monitoring including that of the pH of the urine. The procedure is accomplished by adding sterile sodium bicarbonate to sterile water with 5% dextrose for intravenous infusion and titrating the urine pH to 7.5 to 8.5. The drugs for which this procedure has been shown clinically efficacious include salicylate compounds and phenobarbital which have pK_a's of 3.2 and 7.4, respectively. The increase in total body clearance for salicylate for example, by increasing urinary pH from 5.0 to 8.0 can be substantial. The American Association of Poison Control Centers and the European Association of Poisions Centres and Clinical Toxicologists 2004 Position Paper on Urinary Alkalinization recommends this procedure for moderately severe salicylate poisoning for patient not meeting criteria for hemodialysis (Proudfoot *et al.*, 2004).

Theoretically there are similar advantages to be gained from acidification of the urine regarding enhancement of clearance of drugs such as amphetamine and phencyclidine, however there are significant adverse events associated with acidification such as acute renal failure and acid-base and electrolyte disturbances. For this reason, acidification of the urine is not recommended as a therapeutic intervention in the treatment of poisoning.

The dialysis technique, either hemodialysis or peritoneal dialysis, relies on passage of the toxic agent through a semipermeable dialysis membrane (or the peritoneal membrane) so that it can equilibrate with the dialysate and subsequently be removed. Hemodialysis incorporates a blood pump to pass blood next to a dialysis membrane to allow agents permeable to the membrane to pass through and reach equilibrium. In order for this method to be clinically beneficial the chemcial must have a relatively low volume of distribution, low protein binding, a relatively high degree of water solubility and low molecular weight. Use of hemodialysis to attempt to remove a chemical with the later three characteristics but with a high volume of distribution, such as digoxin, would not be clinically beneficial because the vast majority of the drug is not in the physiologic compartment (blood) accessible to the dialysis membrane. Therefore, despite hemodialysis being able to effectively clear the digoxin in plasma during the dialysis run, most of the body burden of digoxin is located outside of the blood compartment and is not appreciably affected by the procedure. Similarly, if a drug is highly protein-bound, only a small percentage (the free fraction) would be available to pass through the dialysis membrane and be cleared from the body. Some drugs, such as phenobarbital, can readily cross these membranes and go from a high concentration in plasma to a lower concentration in the dialysate. Phenobarbital has a relatively low volume of distribution (0.5–0.7 L/kg) and protein binding (30–50%) so there is a reasonable opportunity for enough drug to be removed from the total body burden to make the technique valuable in serious cases of overdose (Brown *et al.*, 1985; Cutler *et al.*, 1987). Drugs and toxins for which hemodialysis has been shown to be clinically effective in the treatment of poisoning by these agents is shown in Table 32-6.

The technique of hemoperfusion is similar to hemodialysis except there is no dialysis membrane or dialysate involved in the procedure. The patient's blood is pumped through a perfusion cartridge where it is in direct contact with adsorptive material (usually

activated charcoal) that has a coating of material such as cellulose or a heparin-containing gel to prevent the adsorptive material from being carried back to the patient's circulation. The principle characteristics for a drug or toxin to be successfully removed by this technique are low volume of distribution and adsorption by activated charcoal. This method can be used successfully with lipid soluble compounds and with higher molecular weight compounds than for hemodialysis. Protein binding does not significantly interfere with removal by hemoperfusion. Because of the more direct contact of the patient's blood with the adsorptive material, the medical risks of this procedure include thrombocytopenia, hypocalcemia and leukopenia. This technique is primarily used for the treatment of serious theophylline overdose, and possibly amanita toxin exposure, paraquat and meprobamate poisoning. The technique is seldom used currently and it is possible that access to the sterile hemoperfusion cartridge necessary for the procedure may be limited, even at major medical centers.

The use of the technique of hemofiltration for the treatment of poisoning is relatively new and consequently there is much less experience with the modality for enhancement of chemical elimination. During this procedure, the patient's blood is delivered through hollow fiber tubes and an ultrafiltrate of plasma is removed by hydrostatic pressure from the blood side of the membrane. Different membrane pore sizes are available for use so the size of the filtered molecules can be controlled during the procedure. The perfusion pressure for the technique is either generated by the patient's blood pressure (for arteriovenous hemofiltration) or by a blood pump (for venovenous hemofiltration). Needed fluid and electrolytes removed in the ultrafiltrate are replaced intravenously with sterile solutions. The procedure has the advantage of continuous use compared to the 4–6 hour limitation for a hemodialysis run. One theoretical advantage of continuous filtration versus intermittent hemodialysis is that the rebound phenomenon is not seen with hemofiltration as it is with certain poisons after hemodialysis. The rebound of serum concentrations occurs when there is redistribution of the dialyzed poison to the blood when dialysis is interrupted. This rebound is commonly seen during hemodialysis for lithium overdose (Bosinski *et al.*, 1998). Whether or not hemofiltration becomes a routine technique employed in poisoning treatment is unclear at this time.

The use of either plasma exchange or exchange transfusions has been relatively limited in the field of clinical toxicology. While the techniques afford the potential advantage of being able to remove high molecular weight and/or plasma protein bound toxins, the clinical utility in poison treatment has been limited. Plasma exchange, or pheresis involves removal of plasma and replacement with frozen donor plasma, albumin or both with intravenous fluid. The risks and complications of this technique include allergic type reactions, infectious complications and hypotension (Mokrzycki and Kaplan, 1994). Exchange transfusion involves replacement of a patient's blood volume with donor blood. The use of this technique in poison treatment is relatively uncommon and mostly confined to the setting of inadvertent drug overdose in a neonate or premature infant in the setting of a neonatal intensive care unit.

Serial oral administration of activated charcoal, also referred to as multiple-dose activated charcoal (MDAC), has been shown to increase the systemic clearance of various drug substances. The mechanism for the observed augmentation of non-renal clearance caused by repeated doses of oral charcoal is thought to be translumenal efflux of drug from blood to be adsorbed to the charcoal passing through the gastrointestinal tract (Berg *et al.*, 1982). In addition, MDAC is thought to produce its beneficial effect by interrupting the enteroenteric-enterohepatic circulation of drugs. After systemic absorption, a drug may reenter the gut lumen by passive diffusion if the intraluminal drug concentration is lower than that in blood. The rate of this passive diffusion depends on the concentration gradient and the intestinal surface area, permeability, and blood flow. The activated charcoal in the gut lumen serves as a "sink" for toxin. A concentration gradient is maintained and the toxin passes continuously into the gut lumen, where it is adsorbed to charcoal. The characteristics of toxins that favor enhanced elimination by MDAC include (1) significant enteroenteric-enterohepatic circulation, including the formation of active recirculating metabolites, (2) prolonged plasma half-life after an overdose, (3) small (<1.0 L/kg) volume of distribution, (4) limited (<60%) plasma protein binding, (5) a pK_a that maximizes transport of drug across cell membranes, (6) sustained-release/resin-form tablets and/or capsules, and (7) onset of organ failure (e.g., kidney) that results in reduced capacity of the major route of elimination of the toxin so that MDAC may make a considerable contribution to total body clearance.

The technique involves continuing oral administration of activated charcoal beyond the initial dosage (described above) every 2–4 hours with approximately one-half the initial dose, or 0.5 g/kg. The charcoal is generally mixed as an aqueous slurry and a cathartic substance is not incorporated due to the potential for electrolyte abnormalities with repeated administration of cathartic agents. An alternative technique for MDAC is to give the activated charcoal via an orogastric tube or nasogastric tube a loading dose of 1.0 g/kg of an aqueous slurry or activated charcoal (not the combination product that contains the cathartic sorbitol) followed by a continuous infusion intragastrically of 0.2 g/kg/h. The duration of gastric infusion depends on the clinical status of the patient and repeated monitoring of plasma drug levels where indicated (Ilkhanipour *et al.*, 1992; Ohning *et al.*, 1986; Chyka, 1995; Goulbourne *et al.*, 1994; Mofenson *et al.*, 1985; Park *et al.*, 1983, 1986; Pollack *et al.*, 1981; Van de Graaff *et al.*, 1982).

Studies in animals and human volunteers have shown that MDAC increases drug elimination significantly, but few prospective randomized controlled clinical studies in poisoned patients have been published demonstrating a significant reduction in patient morbidity or mortality when MDAC is employed. One recent study however does provide a striking example of clinical benefit from the use of MDAC (de Silva *et al.*, 2003). The study showed that patients who intentionally poisoned themselves with yellow oleander seeds (a cardiac poison) and were randomized to MDAC (after all patients received an adequate initial single dose of activated charcoal) had a statistically improved outcome in both mortality and cardiac morbidity. The early use of MDAC is an attractive alternative to more complex methods of enhancing toxin elimination, such

Theophylline

as hemodialysis and hemoperfusion, although only in a relatively small subset of patients. The decision to use MDAC depends on the clinical situation including the specific chemical involved, the presence of contraindications (e.g., intestinal obstruction) to the use of MDAC, and the likely effectiveness of alternative methods of therapy. A list of chemicals for which MDAC has been shown as an effective means of enhanced body clearance is shown in Table 32-7.

Use of Antidotes in Poisoning

A relatively small number of specific antidotes are available for clinical use in the treatment of poisoning. This is partially due to a paucity of effort in drug development for antidotes as drugs. Significant barriers exist for poison antidote drug development including the small projected market for antidotes and the practical difficulties in performing clinical trials in overdose patients, an important component of an application for drug approval. The typical standard for clinical proof of drug safety and efficacy is the prospective, randomized, double-blinded, placebo controlled clinical trial. Practical considerations make it very difficult to perform this type of clinical trial for rare conditions such as specific poisonings. The United States Food and Drug Administration (FDA) placed incentives for sponsors to develop drugs for rare diseases or conditions through the Orphan Drug Act. Via the Orphan Drug pathway, an antidote for a fairly common poisoning was approved using the orphan drug pathway in December, 1997. Fomepizole (4-methylpyrazole), a chemical inhibitor of alcohol dehydrogenase, was approved as an antidote for ethylene glycol (and later methanol) poisoning. Despite that early success there have not been a large number of antidote products approved to this point in time as a result of this regulatory incentive. Another potential stimulus for antidote drug development has been the "post 9/11" federal funding increase for antiterrorism efforts including research for prevention and treatment of chemical, biological and radiologic poisons. Hopefully this large increase in federal spending will result in the development and approval of new antidotes.

The mechanism of action of various antidotes is quite different. For example, a chelating agent or Fab fragments specific to digoxin work by physically binding the toxin, preventing the toxin from exerting a deleterious effect in vivo and in some cases, facilitating body clearance of the toxin. Other antidotes pharmacologically antagonize the effects of the toxin. Atropine, an antimuscarinic, anticholinergic agent is used to pharmacologically antagonize at the receptor level, the effects of organophosphate insecticides or acetylcholinesterase inhibiting nerve gases, which produce cholinergic, muscarinic effects, which if sufficient, can be lethal. Certain chemicals exert their antidote effects by chemically reacting with biological systems to increase detoxifying capacity for the toxin. For example, sodium nitrite is given to patients poisoned with cyanide to cause formation of methemoglobin, which serves as an alternative binding site for the cyanide ion thereby making it less toxic to the body.

The time course for antidote onset of action is highly variable across currently available antidotes. Intravenous naloxone can have a dramatic effect on the level of consciousness of an opiate-poisoned patient within minutes. Chelating agents such as desferoxamine may require multiple dosages over many days before a clinically detectable effect is seen.

The skillful therapeutic use of antidotes is essential to optimize the treatment of the poisoned patient. Many antidotes have a relatively narrow safety margin or low therapeutic index. Excessive dosing with an antidote can in some instances be more harmful than the expected effects of the toxin itself. Some antidotes require an adjustment of their dosage based on a measured blood concentration of the toxin (for example, digoxin Fab fragments) or based on the clinical assessment of the patient such as with sodium bicarbonate usage in a tricyclic antidepressant overdose. A significant part of the clinical training in the field of medical toxicology is devoted to learning how to use antidotes skillfully.

An important area of research in clinical toxicology has been in the study of prognostic indicators of poisoning severity and predictors for the level of treatment required. For practical reasons much of this work has been retrospective in nature but has resulted in significant aids to guide the treatment rendered by clinical toxicologists. Several authors have proposed "action levels" that are a threshold for a certain level of clinical intervention based upon a measured plasma concentration of the toxin or a clinical manifestation of the poisoning. For example, a patient with a measured plasma theophylline concentration of 90 mg/L after a single oral exposure would be expected to exhibit significant toxicity. If the patient's clinical condition correlated with the measured laboratory plasma concentration (i.e., laboratory error was unlikely), the patient would likely require aggressive treatment measures. Another way that prognostic information is studied is when a constellation of clinical signs and symptoms is proven to correlate with a clinical outcome following exposure to a specific poison. An example of this would be a worker with a significant topical methanol exposure who demonstrates a metabolic acidosis with an elevated anion gap, an osmol gap and visual symptoms. Based on clinical signs and symptoms, this patient would likely undergo hemodialysis even in the absence of a confirmatory measurement of the methanol concentration in serum. These relationships, the correlation of serious clinical effects with a theophylline level above 90 mg/L (Weisman, 1998) or visual symptoms in a methanol poisoned patient (Ellenhorn, 1997) have come from years of observational study by investigators in the field of clinical toxicology. Early on in the field, the majority of publications were primarily case reports making it difficult to determine the relative effectiveness of various treatments being assessed. The case series or meta-analysis type of scientific analysis was an important step to advance the study of clinical outcomes and assess the quality of treatment provided to poisoned patients. An example of the case series study includes the publication that described the relationship of the QRS interval on the patient's 12-lead ECG to the severity of poisoning by tricyclic antidepressant drugs (Boehnert and Lovejoy, 1985). This important observational study helped to stratify patients poisoned with an overdose of first generation tricyclic antidepressants into risk categories for development of seizures or cardiac arrhythmias. The field now tries to incorporate the prospective, controlled clinical trials, whenever possible which better enables clinicians to validate (or dismiss) new therapeutic modalities and treatment strategies.

Supportive Care of the Poisoned Patient

Once the initial treatment phase in the clinical management of the poisoned patient has been completed, the care of the patient is generally shifted to an inpatient hospital setting for those patients who will require admission. This supportive care phase of poison treatment is very important. Poisoned patients who are unstable or at risk for significant clinical instability are generally admitted to a medical intensive care unit for close monitoring. In addition, patients who are excessively sedated from their poisoning or those

who require mechanical ventilation or invasive hemodynamic monitoring are usually candidates for an intensive care stay. Not only are there certain poisonings that have delayed toxicity such as acetaminophen, paraquat and diphenoxylate, but there are also toxins that exhibit multiple phases of toxicity that include delayed effects (i.e., ethylene glycol, salicylate).

Similar to other ill, hospitalized patients, patients admitted for continued treatment of poisoning are at risk for nosocomial infections, iatrogenic fluid and electrolyte disturbances as well as potential harmful effects from the initial therapies that they received for treatment of their poisoning. For example, induction of emesis, gastric lavage or orogastric infusion of activated charcoal can cause aspiration and lead to pneumonitis. Any drug that severely alters a patient's mental status causing obtundation can allow aspiration of gastric contents associated with a loss of the gag reflex. Close clinical monitoring can detect these later phase poisoning complications and allow for prompt medical intervention to minimize patient morbidity and mortality. These are but a few of the reasons that close vigilance is a very important component of the support phase of poison treatment.

Another important component of the supportive care phase of poison treatment is the psychiatric assessment. For intentional self poisonings, a formal psychiatric evaluation of the patient should be performed prior to patient discharge. In many cases, it is not possible to perform a psychiatric interview of the patient during the early phases of treatment and evaluation. Once the patient has been stabilized and is able to communicate, the psychiatric evaluation should be obtained in this setting. Generally a patient who has attempted suicide should be constantly monitored until they have been evaluated by the psychiatric consultant and judged to be "safe" to remove from constant surveillance.

CASE EXAMPLES OF SPECIFIC POISONINGS

Acetaminophen

A thirty-six-year-old male patient comes to the ED and reports taking an "overdose" earlier that day in an attempt to commit suicide. Apparently he was discharged from his job one day prior and had "given up." He reports some abdominal pain approximately and two episodes of emesis 3–4 hours prior to arrival in the ED. Initially he refused to identify what substance he ingested during the suicide attempt. He denied regular or recent use of prescription or over-the-counter medications or dietary supplements as well as regular consumption of alcoholic beverages. No other medical history is available.

On physical examination the vital signs were: blood pressure 138/88, pulse 92/min and regular, respiratory rate 20/min, and temperature 37.2 Celsius. He was awake, alert and oriented and responded to questions appropriately. The remainder of the physical examination was significant for normal bowel sounds, mild epigastric tenderness without guarding or rebound, the rectal examination was normal, the stool was without detectable occult blood. The neurologic examination was within normal limits.

Routine clinical laboratory studies were ordered STAT (electrolytes, creatinine, blood urea nitrogen, glucose, complete blood count with differential, coagulation studies, urine analysis and urine toxicology screen) and a plasma acetaminophen level. Chest and abdominal radiography were normal.

The patient was given 1.5 g/kg oral activated charcoal prepackaged with a sorbitol cathartic. The patient was closely monitored in the ED while the laboratory tests were being performed. Within one hour the laboratory results returned significant for a slight increase in white blood cell count, liver transaminase values were slightly elevated but <3 times the upper limit of normal and an acetaminophen concentration of 290 ug/mL. When confronted with the acetaminophen lab data, the patient admitted ingesting an entire bottle of 500 mg acetaminophen capsules. The estimate of the maximum amount of acetaminophen consumed was 25 g, well above what is considered a highly toxic dosage.

The patient did not recall seeing capsule fragments in the emesis material. He denied taking any other medications or substances with the acetaminophen. Based on the Rumack-Mathew nomogram (Fig. 32-1), a plasma acetaminophen concentration of 290 ug/kg at approximately 6 hours after ingestion is well within the "probable hepatic toxicity" range and therefore treatment with N-acetylcysteine (NAC) was required.

The patient received his first dose of intravenous (IV) NAC in the ED and was admitted to the medical ward to complete the treatment course of NAC. Only mild (<4 times the upper limit of normal) elevation of hepatic transaminases was measured on follow-up assessments. The patient was seen by the Psychiatry Consultation service and judged not to be actively suicidal. He was discharged from the hospital 2 days after admission with scheduled psychiatric and medical follow-up appointments.

Acetaminophen has been used as an analgesic and antipyretic since the mid-1950s and has become more prominently recognized as a potential hepatotoxin in the overdose situation since the original British reports in the late 1960s (Proudfoot and Wright, 1970). Work on the mechanisms of the liver toxicity of this drug has provided a theoretical basis for therapy (Mitchell *et al.*, 1973).

The clinical presentation of patients poisoned with acetaminophen is sufficiently confusing in some cases it is difficult to estimate the time of ingestion. Due to the paucity of clinical symptoms with acute overdose, waiting for the appearance of symptoms is an inadequate strategy for the clinical decision making process regarding institution of treatment.

Acetaminophen in normal individuals is inactivated by sulfation (approximately 52%) and glucuronide conjugation (42%). About 2% of the drug is excreted unchanged. The remaining 4% is biotransformed by the cytochrome P-450 mixed-function oxidase system. The P-450 isozyme responsible for acetaminophen biotransformation is CYP2E1. Metabolism by CYP2E1 results in a potentially toxic metabolite that is normally detoxified by conjugation with glutathione and excreted as the mercapturate. Evidence extrapolated from animals estimates that when 70% of endogenous hepatic glutathione is consumed, the toxic metabolite becomes available for covalent binding to hepatic cellular components. However, patients who are concurrently using, or have recently used, agents that induce CYP2E1, such as in the case of chronic ethanol exposure or phenobarbital use, may produce more than 4% of the toxic metabolite. It is therefore important to determine, whenever possible, whether or not the patient's CYP2E1 system may be induced when determining the risk of hepatic necrosis in any given individual. When there is evidence (medical history) of concurrent agents that induce CYP2E1, the treatment nomogram from acetaminophen should be modified to a lower threshold for treatment with NAC (Rumack *et al.*, 1981).

Follow-up liver biopsy studies of patients who have recovered 3 months to a year after hepatotoxicity have demonstrated no long-term sequelae or chronic toxicity (Clark *et al.*, 1973). A very small percentage (0.25%) of patients in the national multiclinic study

conducted in Denver may progress to hepatic encephalopathy with subsequent death. The clinical nature of the overdose is one of a sharp peak of serum glutamic-oxalocaetic transaminase (SGOT) by day 3, with recovery to less than 100 IU/L by day 7 or 8. Patients with SGOT levels as high as 20,000 IU/L have shown complete recovery and no sequelae 1 week after ingestion (Arena *et al.*, 1978).

Laboratory evaluation of a potentially poisoned patient is crucial in terms of both hepatic measures of toxicity and plasma levels of acetaminophen. Accurate estimation of acetaminophen in the plasma should be done on samples drawn at least 4 hours after ingestion, when peak plasma levels can be expected.

Once an accurate plasma level has been obtained, it should be plotted on the Rumack-Matthew nomogram to determine if NAC therapy is indicated (Fig. 32-1). This nomogram is based on a series of patients with and without hepatotoxicity and their corresponding measured plasma acetaminophen concentrations.

Treatment should be instituted in any patient with a plasma concentration in the potentially toxic range. Some clinical toxicologists recommend withholding NAC treatment unless the plasma concentration is at or above the "probably toxic" demarcation but most often the more conservative approach is recommended. Standard support with administration of activated charcoal, or gastric lavage (a seldom used option for very recent acetaminophen ingestions) should be followed by administration of N-acetylcysteine. The protective effect of NAC in oral acetaminophen poisoning was demonstrated when contrasted with controls not receiving antidotal therapy (Rumack *et al.*, 1981; Smilkstein *et al.*, 1988). Because NAC is most effective if it is given within 8–12 hours of acetaminophen ingestion, patients in whom blood levels cannot be obtained should have NAC treatment instituted and therapy terminated only if levels are nontoxic. The dosing regimen for oral NAC is a loading dose of 140 mg/kg orally, followed by 70 mg/kg orally for 17 additional doses (Peterson and Rumack, 1977). The dosage regimen for IV NAC is 150 mg/kg loading dose over 15 minutes, followed by 50 mg/kg over the next 4 hours then 100 mg/kg over 16 hours for a total dose of 300 mg/kg in 20 hours. Anaphylactoid reactions are a significant concern surrounding the use of IV NAC. The decision to use IV instead of oral NAC is not straightforward. Most authors recommend IV NAC for adults without asthma or other contraindications to IV NAC (Howland, 2006). Children can receive IV NAC but the volume required for the dilution can cause electrolyte abnormalities. The potential advantage from using the IV form is that the complete dosage regimen is completed in 20 hours in contrast to the 72 hour oral regimen. Children less than 9–12 years of age have a lower incidence of hepatotoxicity after an overdose than do adults but are still treated with NAC according to the same nomogram. Oral NAC is more frequently given to poisoned pediatric patients. Patients with trivial or "nontoxic" acetaminophen ingestions should not be given NAC therapy because the antidote can produce clinical significant adverse events.

Methanol

A twenty-seven-year-old male was brought to the ED after being found unresponsive in a chemical storage tank at an electrical components manufacturing plant where he worked. The patient was obtunded, responsive to pain and without obvious signs of trauma. At the scene, emergency medical personnel learned that he was last seen entering the 1200 gallon tank with a cleaning solvent 35 minutes prior to a coworker's discovery that he was unconscious. The plant supervisor was not certain as to what the tank had previously con-

tained as it had not been used for approximately 2 years. Coworkers stated that the patient would occasionally talk about drinking some of the chemicals found in the workplace. The emergency medical personnel brought the cleaning solvent container with them to the ED. The solvent listed "methyl alcohol" as its primary active ingredient. All patient clothing was removed, placed in sealed plastic bags and removed from the ED area.

Physical exam was significant for a blood pressure of 105/56, the pulse was 74/min, the respiratory rate was 28/min, and the body temperature 37.0°C. The skin on the patient's distal upper and lower extremities was slightly erythematous. The pupils were 3 mm and reactive to light. The lung and heart examinations were normal. Abdominal examination revealed diminished but present bowel sounds, no tenderness was noted and no organomegaly or masses were detected. The rectal examination was normal; the stool was without detectable occult blood. Neuro exam was nonfocal with a diminished gag reflex.

The patient was placed on a cardiac monitor, an intravenous line was started, clinical laboratory specimens were obtained and he was placed on oxygen, given naloxone, thiamine, and dextrose, intravenously. These four treatments are standard for patients presenting with an altered mental status to an ED. Chest and abdominal radiography was without abnormality. A 12 lead electrocardiogram was also normal. Faced with the uncertainty of oral ingestion versus topical and inhalation exposure a decision was made to proceed with gastric decontamination. Because no direct history from the patient was available, a mixed ingestion could not be ruled out as well. Because of the diminished gag reflex, the patient was endotracheally intubated to protect his airway before an orogastric tube was placed. Gastric lavage was performed and no blood or detectable foreign substances were removed. Activated charcoal (2.0 g/kg) was placed via the orogastric tube into the stomach with a cathartic.

Clinical laboratory results returned showing the following:

Serum Chemistries:

Na = 140 mEq/L   K = 3.0 mEq/L

Cl = 94 mEq/L HCO_3 = 8 mEq/L

BUN = 12 mg/dl   Glucose = 100 mg/dl

Arterial blood gas (ABG):

pH = 7.20; pCO_2 = 20 mm Hg; pO_2 = 98 mm Hg

The complete blood count was normal, the urine analysis was normal, measured serum osmolarity was 330 mOsm/kg, acetaminophen and salicylate levels were below the limits of detection, and the urine toxicology screen was negative.

The laboratory results were interpreted as follows: a metabolic acidosis with elevated anion gap (AG = 38) and an elevated osmol gap (40 mOsm). These findings are consistent with methanol poisoning as well as ethylene glycol (note cross reference Tables 32-4 and 32-5). A blood sample for measurement of methanol and ethylene glycol was sent for analysis but based on the solvent container; the working diagnosis of methanol poisoning was established. The patient was treated with intravenous (sterile) ethanol infusion while fomepizole (4-methylperazole) was requested from the nearby regional hospital. Sodium bicarbonate was given intravenously for the profound metabolic acidosis and the patient was prepared for hemodialysis. After 4 hours of hemodialysis, his acid-base and electrolyte abnormalities corrected. Approximately 9 hours

after the blood specimen was sent, the laboratory reported a "toxic" serum methanol concentration of 67 mg/dL. The patient underwent a second 4-hour course of hemodialysis 8 hours later when his metabolic acidosis recurred. He regained normal consciousness within 12 hours and recovered completely. Subsequently the patient admitted that he spilled the solvent on him after becoming lightheaded in the storage tank and that he drank some of the solvent as well while cleaning the tank. A past medical history of alcoholism was later obtained and a psychiatric consultation recommended inpatient detoxification for what turned out to be an active alcohol dependency problem after he was medically stabilized.

This case demonstrates the importance of utilizing the anion and osmol gap calculations in overdose patients. Although not considered diagnostic (Walker *et al.*, 1986), the presence of both a metabolic acidosis with an anion gap and an osmol gap is highly suggestive of either methanol or ethylene glycol given the patient's presentation despite a scant history. Known access to a methanol containing product clearly made that substance the most likely poison in this case but consideration of alternate substances should always be held open. Initiation of antidote therapy and hemodialysis to increase removal of the poison prior to receipt of the confirmatory laboratory test was also required in this case. It is quite possible that if the clinicians had not instituted therapy until the confirmatory laboratory test (i.e., the methanol level) had returned, the patient may have had a fatal or significantly morbid outcome. It is quite common for hospital clinical laboratories to have to "send out" blood specimens for ethylene glycol and methanol analysis becasuse these are not routinely performed on-site. A turnaround time of 6–12 hours for this test result to be available is not uncommon.

Methanol exerts is primary toxicity after undergoing biotransformation by alcohol dehydrogenase to formaldehyde and then to formic acid by the action of aldehyde dehydrogenase. The formic acid is thought to be responsible for both the ocular (blindness) and the acid-base toxicity of methanol (Swartz *et al.*, 1981). If untreated or treated too late, methanol poisoning can result in fatal cerebral edema with seizures as a preterminal event. Hemodialysis can remove the unmetabolized methanol, eliminating the substrate for production of the toxic metabolite. Administration of an inhibitor or competing substrate for alcohol dehydrogenase can be instituted while transporting the patient to a health care facility where hemodialysis is available. Ethanol (sterile, for intravenous administration) can be given to effectively inhibit the metabolism of methanol and prevent the potentially devastating effects of the poisoning. 4-methylperazole is a commercially available inhibitor of alcohol dehydrogenase that is FDA approved for the treatment of methanol and ethylene glycol poisoning. Finally, the administration of folic acid in animal models has been shown to enhance the in vivo clearance of formate, the toxic metabolite of methanol (McMartin *et al.*, 1977). Folate or folinic acid has been given to methanol poisoned patients and is suggested to hasten formic acid metabolism thereby accelerating its clearance. Many clinical toxicologists will include folic or folinic acid in their therapeutic regimen for methanol poisoned patients.

Tricyclic Antidepressants

An thirty-six-year-old female nurse is brought to the ED by her spouse who tells the desk nurse that she has just taken a drug overdose with a tricyclic antidepressant. The patient was driven to the hospital by her husband and walked into the ED. The patient was immediately taken to the acute or intensive care section of the ED. The husband reports that she took her entire prescription of amitriptyline approximately 40 minutes prior to arrival in the ED in an apparent suicide attempt. The patient denied any other ingestion, which was confirmed by her husband who witnessed the ingestion. The patient's initial vital signs were: blood pressure 125/70, pulse 94/min, respiratory rate 20/min, and temperature 37.2°C. The unit clerk called the patient's pharmacy to confirm a recent prescription of thirty 50 mg tablets of imipramine. Within 15 minutes the patient becomes unresponsive. The vital signs at that time are: blood pressure of 80/55, pulse 135/min, respiratory rate of 8/min and temperature unchanged. Intravenous lines are started, and intravenous fluids are administered as rapidly as possible, the cardiac monitor reveals sinus tachycardia.

The remainder of the physical examination shows the patient to be well dressed without obvious signs of trauma; the skin is warm and dry, without track marks. The pupils are 7 mm and poorly reactive to light. Other significant findings include the examination of the abdomen, which shows markedly diminished bowel sounds. The rectal examination is negative for occult blood. The neurological examination reveals coma without focal motor abnormalities and an absent gag reflex.

Initial laboratories show no significant acid base disturbance, no elevated anion or osmol gaps, normal glucose, liver function tests and renal function tests. The chest and abdominal radiographs are normal. The 12-lead ECG reveals sinus tachycardia, a right axis deviation, 1st degree heart block and a prolonged QRS duration of 125 ms.

A Foley catheter was inserted and 600 ml of urine was obtained. The patient has a generalized seizure lasting approximately 20 seconds. Endotracheal intubation, followed by gastric lavage was performed and only a several pill fragments were seen in the lavage fluid. The patient was placed on a ventilator to support her respiration. Activated charcoal (2.0 g/kg) was administered via the orogastric tube immediately following the lavage procedure. The blood pressure continued to remain low despite intravenous fluid administration. The patient developed intermittent (non-sustained) ventricular tachycardia. Sodium bicarbonate was administered intravenously and an arterial monitor was instituted to closely track the arterial pH. The patient clinically stabilized, with return of normal blood pressure and cardiac rhythm, then transferred to the medical intensive care unit and closely monitored. Alkaline intravenous fluid was continued for 8 hours to maintain the arterial pH at 7.50. MDAC was employed via the gastric tube for approximately 18 hours. The patient regained consciousness and was evaluated by the psychiatry service which recommended transfer to the inpatient psychiatric ward for continued care when medically stable.

Tricyclic antidepressant (TCA) agents can be very deadly in overdose situations. During the 1980s the TCAs were consistently ranked at or near the top of the list of most frequently fatal drug overdose cases reported to the American Association of Poison Control Centers. No diagnostic laboratory tests are available to acutely aid the clinician treating a patient poisoned with a TCA. Clinically, anticholinergic effects appear early. The TCAs are the most deadly cause of the anticholinergic toxic syndrome. The clinical presentation of the TCA overdose is complex, with CNS, cardiovascular, and respiratory components most prominent. Usually, serious toxicity from TCAs appears within 2–3 hours of ingestion. The prognostic value of the QRS duration from the 12-lead ECG was discussed above (Boehnert and Lovejoy, 1985). In this case the prolonged QRS duration predicted the observed systemic toxicity of the reported overdose and specifically, an increased likelihood of seizures.

The TCAs are available in a wide variety of brands, including amitriptyline, doxepin, and imipramine, and also in combination with phenothiazine drugs. TCAs have three primary pharmacological actions: anticholinergic effects, reuptake blockade of catecholamines at the adrenergic neuronal site, and quinidine like (fast sodium channel) effects on cardiac tissue. The latter cardiac effect is responsible for the changes seen in the QRS interval on the ECG. The newer TCAs, such as amoxapine, have a significantly higher incidence of seizures and a lower incidence of cardiac arrhythmia than do the older TCAs. TCA overdose represents a life-threatening episode (Crome, 1986; Frommer *et al.*, 1987). The initial symptoms seen are CNS depression with manifestations of lethargy, disorientation, ataxia, respiratory depression, hypothermia, and agitation. Severe toxicity may be associated with hallucinations, loss of deep tendon reflexes, muscle twitching, coma, and convulsions. The anticholinergic effects of these drugs include dry mouth, hyperpyrexia, dilated pupils, urinary retention, tachycardia, and reduced GI motility, which may result in marked delay of the onset of symptoms. Life-threatening sequelae of the tricyclic antidepressants are the cardiovascular effects, resulting in cardiac arrhythmias such as supraventricular tachycardia, premature ventricular contractions, ventricular tachycardia, ventricular flutter, and ventricular fibrillation that progresses to hypotension and shock. The ECG characteristically demonstrates a prolonged PR interval, widening of the QRS complex, QT prolongation, T-wave flattening or inversion, ST segment depression, and varying degrees of heart block progressing to asystole. Widening of the QRS complex has been reported to correlate well with the severity of the toxicity after acute overdose ingestions (Bigger, 1977). Widening of the QRS complex past 100 ms or greater within the first 24 hours is an indication of severe toxicity (Boehnert and Lovejoy, 1985; Liebelt *et al.*, 1995).

Gastric lavage may be indicated if the oral ingestion was very recent (within one hour), followed by the administration of activated charcoal. Activated charcoal may be beneficial even hours after ingestion due to delayed gastric emptying from the anticholinergic effects of TCA drugs. Patients admitted with TCA overdose but without symptoms should be monitored in the hospital setting for a minimum of 6–8 hours to detect any possible delayed onset of symptoms. Vital signs and the ECG should be monitored in symptomatic patients, as fatal cardiac arrhythmias have occurred late in the course. Hypotension should be treated with fluids and may respond to sodium bicarbonate as well as vasopressors such as dopamine or norepinephrine. Adjustment of blood pH with bicarbonate to pH greater than 7.45, coupled with antiarrhythmia drugs that do not prolong the QRS interval (such as lidocaine) is the primary approach to therapy for cardiac arrhythmias. Seizures may also be responsive to benzodiazepines, barbiturates or propofol.

SUMMARY

The practice of clinical toxicology encompasses the expertise of the specialties of medical toxicology, applied toxicology, and clinical poison information specialists. Basic and clinical science has significantly contributed to the present state of the discipline over the past 50 years. The evolution of the poison control (information) center has paralleled that of the discipline. The incorporation of evidence based, outcome driven practice recommendations has significantly improved the critical evaluation of treatment modalities and methods for poison treatment. Application of a stepwise approach to the poisoned patient as described above is a useful method for the evaluation and treatment of the poisoned patient. A methodically performed, clinical diagnostic approach to a poisoned patient is essential as the important medical history is often absent or unreliable. Skillful use of antidotes is an important component of the practice of Medical Toxicology. Continued research will increase the repertoire of effective treatments for poisoning and ultimately improve patient outcomes.

CHAPTER 33

OCCUPATIONAL TOXICOLOGY

Peter S. Thorne

INTRODUCTION

For centuries the work environment has played a significant role in the occurrence of adverse human health effects due to chemical and biological hazards. Early writings by Agricola (1494–1555) and Paracelsus (1492–1541) revealed the toxic nature of exposures in mining, smelting, and metallurgy. A systematic treatise by Ramazzini (1633–1714) described the hazards as they applied to miners, chemists, metal workers, tanners, pharmacists, grain sifters, stonecutters, sewage workers, and even corpse bearers. Today we continue to be concerned with occupational health and safety in these and other work environments. Although occupational settings are safer now than in the past, the levels of risk deemed acceptable have decreased while the recognition of the causal link of exposures to chronic diseases or diseases with long latencies has increased. As new hazards arise with the emergence of new technologies, we must be prepared to assess the risks and protect the health of workers.

Occupational toxicology is the application of the principles and methodology of toxicology toward understanding and managing chemical and biological hazards encountered at work. The objective of the occupational toxicologist is to prevent adverse health effects in workers that arise from exposures in their work environment. Because nonoccupational exposures can act as confounders or can increase the susceptibility of individual workers, occupational toxicologists must evaluate the entire spectrum of exposures experienced by the work force under consideration. Occupational toxicology is a discipline that draws on occupational hygiene, epidemiology, occupational medicine, and regulatory toxicology. The occupational toxicologist must have an intimate knowledge of the work environment and be able to recognize and prioritize exposure hazards. Because the work environment can present exposures to complex mixtures, the occupational toxicologist must also recognize those that are particularly hazardous when occurring in combination.

It is often difficult to establish a causal link between a worker's illness and job. First, the clinical expressions of occupationally induced diseases are often indistinguishable from those arising from nonoccupational causes. Second, there may be a protracted but biologically predictable latent interval between exposure and the expression of disease. Third, diseases of occupational origin may be multifactorial with personal or other environmental factors contributing to the disease process. Nevertheless, studies have repeatedly shown that the dose of toxicant is a strong predictor of the likelihood, severity, and type of health effect.

WORKPLACES, EXPOSURES, AND STANDARDS

The Nature of the Work Force

The demographics and distribution of the work force in industrialized nations has undergone a progressive shift over the past three decades, moving away from jobs in heavy industry and toward jobs in the service sector and high-technology industries. In some instances, these manufacturing jobs have moved to less developed countries with less stringent worker health protection. There are currently 144.9 million people in the United States in the civilian, paid work force (seasonally adjusted data). The civilian labor force participation rate is 66.2% (USDL, 2006b), a figure that has grown steadily over the past 50 years owing to the increased entry of women into the labor force (Fullerton, 1999). The 25 countries of the EU have an estimated 201.7 million workers (Employment in Europe, 2006), and Japan has about 66.4 million (Japan Statistical Yearbook, 2006). Table 33-1 shows the breakdown of employment in the United States. This illustrates that there are about 24.6 million workers (17%) engaged in manufacturing, construction, natural resources and mining, and agriculture—occupations that have the potential for significant exposure to chemical and biological agents. Furthermore, there are occupations in the service sector, such as

SECTOR	NUMBER EMPLOYED	AVERAGE WORK WEEK, HOURS
Nonfarm*	135,613,000	
Goods-producing	22,427,000	40.3
Manufacturing	14,210,000	45.4
Construction	7,535,000	38.4
Natural resources and mining	682,000	45.1
Service-providing	113,185,600	33.5
Retail trade	15,196,700	30.4
Wholesale trade	5,865,600	38.0
Transportation, warehousing, utilities	4,997,300	37.3
Information	3,058,000	36.9
Finance, insurance, real estate	8,347,000	35.7
Professional and business services	17,413,000	34.4
Education and health services	17,817,000	32.5
Leisure and hospitality services	13,092,000	25.6
Other services	5,411,000	30.7
Government	21,988,000	N.A.[†]
Farm[‡]	2,143,000	42.2[§]
Self-employed	932,000	43.3[§]
Wage and salary workers	1,196,000	40.6[§]
Unpaid family workers[¶]	13,000	36.2[§]
Total[‡]	144,900,000	—

automobile repair; other repair and maintenance; work in gasoline stations, pipeline transportation, truck and rail transportation; waste management and remediation services; and employment in botanical gardens that can also include exposures to hazardous chemicals. Service-producing occupations account for the majority (83.5%) of U.S. nonfarm jobs. On average, employees in the service sector work 6.8 fewer hours per week than in the goods-producing sector. Farm work employs an estimated 2.14 million workers 16 years of age and older, and the U.S. Bureau of Labor Statistics has documented an average of 42.2 hours worked per week. Work in agriculture is markedly different from most other occupations in four fundamental ways. First, 44% of those employed in agriculture are self-employed or unpaid family members. Second, the overwhelming majority of farm establishments (90%) have fewer than 20 employees and these work sites represent 35% of the agricultural work force (USDL, 2006a). Third, although the annual national average hours worked per week is slightly over 42, many farmers, ranchers, and farm workers have periods when they work as many as 20 hours per day, 7 days per week. Fourth, according to the U.S. Bureau of the Census there are in excess of 290,000 children who identify agricultural work as their major employment (GAO/HEHS, 1998). Department of Labor data indicate that, on average, 128,500 hired farm workers between the ages of 14 and 17 were working annually in crop production (GAO/HEHS, 1998). The presence of children in the work force has important ramifications for body burdens, disease latency, toxicokinetics, and biotransformation of toxicants.

Determinants of Dose

Dose is defined as the amount of toxicant that reaches the target tissue over a defined time span. In occupational environments, *exposure* is often used as a surrogate for *dose*. The response to a chemical is dependent upon both host factors and dose. Figure 33-1 illustrates the pathway from exposure to subclinical disease or to adverse health effect and suggests that there are important modifying factors: contemporaneous exposures, genetic susceptibility, age, gender, nutritional status, and behavioral factors. These modifying factors can influence whether a worker remains healthy, develops subclinical disease that is repaired, or progresses to illness. Workplace health protection and surveillance programs (shown in blue) can reduce exposures, disrupt the exposure-dose pathway, or identify internalized dose and early effects before irreparable disease develops. These programs help to ensure a safe workplace and a healthy work force.

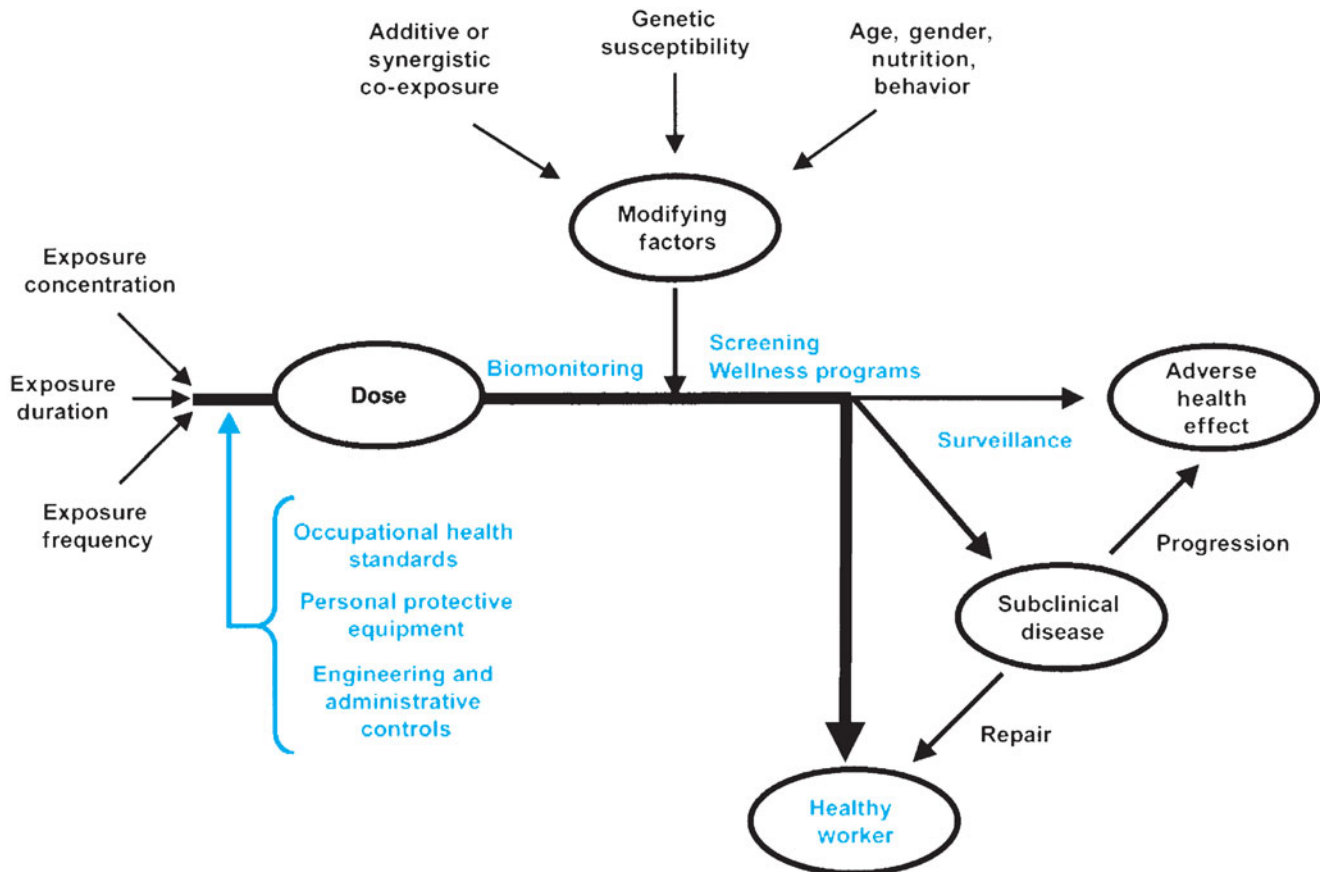
As illustrated in Fig. 33-1, dose is a function of exposure concentration, exposure duration, and exposure frequency. Individual and environmental characteristics can also affect dose. Exposure assessment is the process of quantifying the intensity, frequency, and duration of exposures and their determinants in order to better estimate dose. Table 33-2 indicates determinants of dose for exposure via the inhalation and dermal routes. For determining inhalation exposures, environmental conditions such as concentration, particle size distribution, and properties of the chemical are important. However, respiratory rate and breathing volume as well as other


Figure 33-1. Pathway from exposure to disease, showing modifying factors and opportunities for intervention.

host factors contribute. Protection afforded by personal protective equipment (especially respirators) will reduce but not eliminate exposure. The degree of exposure reduction for a particular respirator (the workplace protection factor) varies with respirator design, fit, maintenance, manner of use, and environmental conditions from less than 5 to 10,000. Thus, for a respirator with a workplace protection factor of 10, when used properly, particulate matter concentrations inside the mask will be one-tenth that outside the mask. A commonly used two-strap fiber respirator for lowering particulate matter exposure, the N95, should reduce exposures by 95% but may fail to meet this criterion for submicron aerosols (Balazy *et al.*, 2006).

Dermal exposures depend upon toxicant concentration; work conditions, including the degree and duration of wetness; and the ambient conditions at the work site (Table 33-2). Some determinants of dermal dosing relate to the physicochemical properties of the chemical as they affect the percutaneous absorption rate. These include solubility, temperature, pH, molecular size, and chemical characteristics of the vehicle. Host factors also influence dermal absorption and distribution. Important factors include the surface area of the skin that is exposed, the integrity of the skin, blood flow, and biotransformation. Because the stratum corneum, the outer layer of the epidermis, is the principal barrier to dermal uptake, the thickness of this layer in the exposed area has great significance. As an example, the absorption of hydrocortisone through the plantar foot arch is 1/25 less than through the back and 1/300 less than through scrotal skin (Bason *et al.*, 1991). The use of protective gloves and clothing or aprons and the application of barrier creams can greatly reduce

exposure. For maximal protection, it is important that the glove be constructed of material tailored to the toxicant(s) of concern.

Occupational Exposure Limits

One of the roles of the occupational toxicologist is to contribute data to the process of establishing standards or determining the appropriateness of those standards. Workplace exposure limits exist for chemical, biological, and physical agents and are recommended as guidelines or promulgated as standards in order to promote worker health and safety. For chemical and biological agents, exposure limits are expressed as acceptable ambient concentration levels (occupational exposure limits) or as concentrations of a toxicant, its metabolites, or a specific marker of its effects in biological systems (biological exposure indices).

Occupational exposure limits (OELs) are established as standards by regulatory agencies or as guidelines by research groups or trade organizations. In the United States, the Occupational Safety and Health Administration (OSHA) under the Department of Labor promulgates legally enforceable standards known as permissible exposure limits (PELs). These standards are determined and supported by the best scientific evidence available and assure "to the extent feasible. . . that no employee will suffer material impairment of health or functional capacity" with regular exposure "for the period of his working life." OSHA has defined an 8-hour time-weighted average (TWA) PEL (Federal Register, 1992) as the "employee's average airborne exposure in any 8-hour work shift of a 40-hour

Table 33-2
Determinants of Toxicant Dose

Inhalation exposure
    Airborne concentration
    Particle size distribution
    Respiratory rate
    Tidal volume
    Other host factors
    Duration of exposure
    Chemical, physical, or biological properties of the hazardous
       agent
    Effectiveness of personal protective devices
Dermal exposure
    Concentration in air, droplets, or solutions
    Degree and duration of wetness

    Percutaneous absorption rate
    Region of skin exposed
    Surface area exposed
    Preexisting skin disease
    Temperature in the workplace
    Vehicle for the toxicant
    Presence of other chemicals on skin

work week which shall not be exceeded." The TWA PEL is established as the highest level of exposure to which an employee may be exposed without incurring the risk of adverse health effects (OSHA, 1995). Although approximately 500 PELs have been promulgated, there are not enough to regulate exposures to the vast number of compounds to which workers are exposed, and some of the existing PELs do not reflect current knowledge.

The National Institute for Occupational Safety and Health (NIOSH), under the Centers for Disease Control and Prevention, publishes recommended exposure limits (RELs) that are more frequently updated and are generally more stringent than PELs. NIOSH also performs research and disseminates information on workplace hazards and their prevention. Most developed countries have governmental inspectorate agencies analogous to OSHA that are responsible for establishing and enforcing OELs. In some countries, the insurance system also plays a significant role.

The European Commission has established legally enforceable binding occupational exposure limit values (BOELV) and biological limit values (BLV) for the protection of health and safety in the workplace. Socioeconomic and technical feasibility factors are also considered in setting these values. The OELs are established based on recommendations of the Scientific Committee on Occupational Exposure Limits (SCOEL), which evaluates published scientific data on hazardous compounds for regulation and provides assessment of exposure limits that "it believes will protect workers from chemical risks"(European Commission, 1995; European Commission, 1998). EU member countries may not promulgate OELs less stringent than these values.

The American Conference of Governmental Industrial Hygienists (ACGIH) is a trade organization that publishes OELs for chemicals and for physical agents. These take the form of threshold limit values (TLVs) and biological exposure indices (BEIs). They are frequently revisited and generally reflect current knowledge in occupational toxicology and industrial hygiene. They are developed as guidelines and are not enforceable standards; however, many in-

dustries adopt TLVs and BEIs as internal OELs. As stated by the ACGIH, "The TLVs and BEIs represent conditions under which ACGIH believes that nearly all workers may be repeatedly exposed without adverse health effects." (ACGIH, 2006 TLV and BEI Book).

Three types of TLVs are suggested, depending on the time scale of adverse effects inducible by the toxicants. The time-weighted average TLV (TLV-TWA) is an OEL for exposures averaged over an 8-hour day, 5-day work week regimen. These are generally applied to toxicants that exert their effects over long periods. The short-term exposure limit (TLV-STEL) is an OEL for a 15-minute measurement period. The TLV-STEL should not be exceeded in any 15-minute sampling window and there should be 60 minutes or more between exposures in this range. The ceiling limit (TLV-C) represents a concentration that should never be exceeded. These are usually applied to toxicants that cause acute effects (such as asphyxia or potent sensory irritation) and for which real-time monitoring devices are available. BEIs are guidelines for biological monitoring and represent levels "most likely to be observed in specimens collected from healthy workers who have been exposed to chemicals to the same extent as workers with inhalation exposure at the Threshold Limit Value" (ACGIH, 2006). BEIs are recommended for analysis of urine, blood, and exhaled air. While hair, fingernails, and other specimens are used in research and forensic toxicology, there are no BEIs for these.

It is important to recognize that OELs do not correspond to exposure conditions devoid of health risk. The concept of acceptable exposure level must be understood as the level of exposure below which the probability of impairing the health of the exposed workers is acceptable. The process of deciding what is an acceptable risk to occupational or environmental hazards blends the scientific disciplines of exposure assessment and toxicology with often vexing policy issues. Historically, acceptable risk in a society is related to the general health of the population and to a host of factors that influence how risks are perceived. To determine that the risks from an occupational hazard are acceptable, it is necessary to characterize the hazard, identify the potential diseases or adverse outcomes, and establish the relationship between exposure intensity or dose and the adverse health effects. If biological markers of exposure or early reversible effects are identified, this can aid in the risk-assessment process.

OCCUPATIONAL DISEASES

Routes of Exposure

Diseases arising in occupational environments involve exposure primarily through inhalation, ingestion, or dermal absorption. In the vast majority of work environments, inhalation of toxicants is a primary concern. Inhalation exposures can occur with gases, vapors, liquid aerosols, particulate aerosols, fumes, and mixtures of these. Dermal exposures are also important and can arise from airborne materials as well as liquids splashed onto the skin, immersion exposures, or from material handling.

Additional exposure hazards exist for infectious agents. Exposures leading to occupational infections may arise through inhalation or ingestion of microorganisms but can also arise from needlesticks in health-care workers or through insect bites among farmers, natural resource workers, and others employed out of doors. Additionally, poisonings from toxic plants or venomous animals can occur through skin inoculation (e.g. zookeepers, horticulturists, or commercial divers).

Table 33-3
Examples of Occupational Diseases and the Toxicants That Cause Them

ORGAN SYSTEM OR DISEASE GROUP	DISEASE	CAUSATIVE AGENT
Lung and airways	Acute pulmonary edema, bronchiolitis obliterans	Nitrogen oxides, phosgene
Allergic rhinitis		Pollens, fungal spores
	Asphyxiation	Carbon monoxide, hydrogen cyanide, inert gas dilution
	Asthma	Toluene diisocyanate, α-amylase, animal urine proteins
	Asthma-like syndrome	Swine barn environments, cotton dust, bioaerosols
	Bronchitis, pneumonitis	Arsenic, chlorine
	Chronic bronchitis	Cotton dust, grain dust, welding fumes
	Emphysema	Coal dust, cigarette smoke
	Fibrotic lung disease	Silica, asbestos
	Hypersensitivity pneumonitis	Thermophilic bacteria, avian proteins, pyrethrum, *Penicillium, Aspergillus*
	Metal fume fever	Zinc, copper, magnesium
	Mucous membrane irritation	Hydrogen chloride, swine barn environments
	Organic dust toxic syndrome	"Moldy" silage, endotoxin
	Upper respiratory tract inflammation	Endotoxin, peptidoglycan, glucans, viruses
Cancer	Acute myelogenous leukemia	Benzene, ethylene oxide
	Bladder cancer	Benzidine, 2-naphthylamine, 4-biphenylamine
	Gastrointestinal cancers	Asbestos
	Hepatic hemangiosarcoma	Vinyl chloride
	Hepatocellular carcinoma	Aflatoxin, hepatitis B virus
	Mesothelioma, lung carcinoma	Asbestos, arsenic, radon, bis-chloro methyl ether
	Skin cancer	Polycyclic aromatic hydrocarbons, ultraviolet irradiation
Skin	Allergic contact dermatitis	Natural rubber latex, isothiazolins, poison ivy, nickel
	Chemical burns	Sodium hydroxide, hydrogen fluoride
	Chloracne	TCDD[†], polychlorinated biphenyls
	Irritant dermatitis	Sodium dodecyl sulfate
Nervous system	Cholinesterase inhibition	Organophosphate insecticides
	Neuronopathy	Methyl mercury
	Parkinsonism	Carbon monoxide, carbon disulfide
	Peripheral neuropathy	N-hexane, trichloroethylene, acrylamide
Immune system	Autoimmune disease	Vinyl chloride, silica
	Hypersensitivity	See entries for allergic rhinitis, asthma, hypersensitivity pneumonitis, allergic contact dermatitis
	Immunosuppression	TCDD[†], lead, mercury, pesticides
Renal disease	Indirect renal failure	Arsine, phosphine, trinitrophenol
	Nephropathy	Paraquat, 1,4-dichlorobenzene, mercuric chloride
Cardiovascular disease	Arrhythmias	Acetone, toluene, methylene chloride, trichloroethylene
	Atherosclerosis	Dinitrotoluene, carbon monoxide
	Coronary artery disease	Carbon disulfide
	Cor pulmonale	Beryllium
	Systemic hypotension	Nitroglycerine, ethylene glycol dinitrate
Liver disease	Fatty liver (steatosis)	Carbon tetrachloride, toluene
	Cirrhosis	Arsenic, trichloroethylene
	Hepatocellular death	dimethylformamide, TCDD[†]
Reproductive system	Male	Chlordecone (Kepone), dibromochloropropane, hexane
	Female	Aniline, styrene
	Both sexes	Carbon disulfide, lead, vinyl chloride

(**Continued.**)

Agents Associated with Diseases

There are a myriad of agents responsible for occupational diseases. While some act on a particular organ such as the liver or kidney, others can affect multiple organ systems. Table 33-3 presents a list of the major occupational diseases and examples of agents that cause them. This is not intended to be all-inclusive. Rather it is meant to highlight what are historically the most prevalent and widely recognized occupational diseases plus those that continue to be prevalent in the workplace. The toxicants listed are those for which there is

Examples of Occupational Diseases and the Toxicants That Cause Them

ORGAN SYSTEM OR DISEASE GROUP	DISEASE	CAUSATIVE AGENT
Infectious diseases*	Arboviral encephalitides	Alphavirus, Bunyavirus, Flavivirus
	Aspergillosis	*Aspergillus niger, A. fumigatus, A. flavus*
	Cryptosporidiosis	*Cryptosporidium parvum*
	Hepatitis B	Hepatitis B virus
	Histoplasmosis	*Histoplasma capsulatum*
	Legionellosis	*Legionella pneumophila*
	Lyme disease	*Borrelia burgdorferi*
	Psittacosis	*Chlamydia psittaci*
	Tuberculosis	*Mycobacterium tuberculosis hominis*

*For more on occupational infectious diseases, see Douwes *et al.*, 2003.
†TCDD = 2,3,7,8-tetrachlorodibenzo-*para*-dioxin.

a strong association with the disease or the most conclusive data to support causality. Examples are shown for cancer and for diseases of the lung and airways, heart, liver, kidney, skin, nervous system, immune system, and reproductive system. Several examples of occupational infectious diseases are also listed to highlight the fact that, in many work settings, infectious agents may constitute the major hazard and may coexist with chemical hazards. Most of the occupational diseases listed in Table 33-3 are associated with industrial chemicals. These are discussed in other chapters throughout this book.

Table 33-4 lists the agents that are known by the International Agency for Research on Cancer (IARC) to be carcinogens in humans (Group 1) and for which there is extensive occupational exposure. This list includes agents such as asbestos, arsenic, benzene, vinyl chloride, and coal tars. IARC Group 1 refers to agents or mixtures that are known to be carcinogenic to humans based on sufficient epidemiologic evidence usually accompanied by limited or sufficient animal evidence.

Occupational Respiratory Diseases

Because inhalation generally represents the most significant route of exposure, many of the major occupational diseases affect the lung and airways. These diseases have been studied extensively and are largely responsible for the creation of the occupational regulatory framework. Deaths due to occupational lung diseases such as coal workers' pneumoconiosis, silicosis, asbestosis, byssinosis, and occupational asthma led to important legislation such as the U.S. Occupational Safety and Health Act (1970). These occupational lung diseases continue to have significant associations with morbidity. Table 33-5 lists the crude U.S. death rate and annual deaths and illustrates that while the death rates are fairly low, there are still about 2780 deaths per year attributable to asbestos, silica, coal dust, and other pneumoconiotic dusts; 2485 malignant mesothelioma deaths; and 57 deaths from hypersensitivity pneumonitis. However, fatalities are just the tip of the iceberg as some resulting diseases are rarely fatal yet may still be debilitating. Every year in the U.S., there are 20,000 hospital discharges related to cases of asbestosis and 188,000 coal workers receive federal Black Lung benefits (NIOSH, 2006). The U.S. Mine Safety and Health Administration has compiled data on inspector- and mine operator-collected samples in coal mining operations and found that 29.3% of these exceeded the PEL for

respirable quartz and 7.5% were over the PEL for respirable coal dust.

Many of the diseases listed in Table 33-3 are known by other names that refer to a particular occupation or agent. One example is hypersensitivity pneumonitis, an allergic lung disease marked by interstitial lymphocytic pneumonitis and granulomatous lesions. Hypersensitivity pneumonitis is also known as extrinsic allergic alveolitis, farmer's lung disease, bagassosis (sugar cane), humidifier fever, Japanese summer house fever, pigeon breeder's lung, and maple bark stripper's lung, depending upon the occupational setting in which it arises. Although we often think of these as the same disease, it is important to recognize that the exposures and physiologic responses they induce are complex and may differ in the manifestation of the disease.

The U.S. Bureau of Labor Statistics tracks data for respiratory conditions arising from exposure to toxic agents and dust diseases of the lung. The former category includes pneumonitis, pharyngitis, rhinitis, and acute lung congestion. Table 33-6 shows data for rates and cases in 2001 by industry division. These data indicate 14,500 cases per year of respiratory conditions attributed to toxic agents and 1300 dust diseases of the lung. These represent a decrease of 10,000 cases per year since 1995. The manufacturing and services industries contributed 69% of the toxic agent exposure cases. Ten manufacturing industries exceed a nonfatal incidence rate of 10 per 10,000 full-time workers for this type of exposure. These are: secondary nonferrous metals; metal plating and polishing; engine electrical equipment; ship building and repairing; motorcycles, bicycles and parts; laboratory apparatus and furniture; photographic equipment and supplies; chocolate and cocoa products; weft knit fabric mills; and plastic bottle manufacturing. The two other industries that exceed 10 per 10,000 are public water supply utilities and recreational vehicle dealers.

Toxic gas injuries are often characterized by leakage of both fluid and osmotically active proteins from the vascular tissue into the interstitium and airways. Important determinants of the severity and location of injury are the concentration and water solubility of the toxic gas or vapor. Anhydrous ammonia, with its extremely high solubility, primarily damages the eyes, sinuses, and upper airways. The vapors combine with water in the tissue and form ammonium hydroxide, quickly producing liquefaction necrosis. Chemicals with lower solubility, such as nitrogen dioxide, act more on the distal airways and alveoli and take longer to induce tissue damage.

Table 33-4

Occupational Exposure Agents Classified by IARC as Definite Human Carcinogens

AGENT	INDUSTRIES AND OCCUPATIONS WHERE SOME WORKERS MAY BE EXPOSED
Particulate matter	
Asbestos	Miners, abatement workers, construction workers, sheet metal workers, steam fitters, shipyard workers
Crystalline silica	Stone and ceramics industry, foundries, construction, abrasives manufacturing
Talc containing asbestiform fibers	Ceramics industry
Erionite	Waste treatment workers, building materials manufacturing
Wood dust	Wood and wood-products industries, pulp and paper industry, wood working trades
Metals	
Arsenic and arsenic compounds	Miners, nonferrous metal smelting, arsenical pesticide manufacturers and applicators
Beryllium	Specialty metallurgy workers, avionics, electronics, nuclear industry
Cadmium and cadmium compounds	Cadmium smelting, battery production, dyes and pigment making, electroplating
Hexavalent chromium compounds	Chromate production plants, dye and pigment making, welders, tanners,
Nickel compounds*	Nickel smelting, welding
Organic chemicals	
Benzene	Refineries, shoe industry, chemical, pharmaceutical and rubber industry, printing industry
Coal tars and pitches	Coke production, coal gasification, refineries, foundries, road paving, hot tar roofing
Mineral oils, untreated and mildly treated	Metal machining and honing, roll steel production, printing
Shale oils or shale-derived lubricants	Mining and processing, cotton textile industry
Soots	Chimney sweeps, heating and ventilation contractors, firefighters, metallurgical workers
Vinyl chloride	Plastics industry, production of polyvinyl chloride products and copolymers
Bis(chloromethyl) ether and Chloromethyl ether (technical grade)	Chemical industry, laboratory reagent, plastic manufacturing
4-Aminobiphenyl	Chemical industry, dyestuffs and pigment manufacturing
Benzidine	Chemical industry, dyestuffs and pigment manufacturing
2-Naphthylamine	Chemical industry, dyestuffs and pigment manufacturing
Ethylene oxide	Chemical industry, dry vegetable fumigation, hospital sterilizing
2,3,7,8-Tetrachlorobibenzo-*para*-dioxin (TCDD)	Hazardous waste processing, chlorophenoxy herbicide production and use, pulp and paper industry
Aflatoxin	Animal feed industry, grain handling and processing
Other agents with occupational exposure	
Environmental tobacco smoke	Restaurant, bar and entertainment industry; other smoke-exposed workers
Mustard gas	Production, soldiers, some research laboratories
Strong inorganic acid mists containing sulfuric acid	Steel industry, petrochemical industry, fertilizer industry, pickling industry
Physical Agents	
Ionizing radiation[†]	Radiology and nuclear medicine staff, nuclear workers, miners, hazardous waste workers
Solar radiation	Farmers, gardeners and landscapers, lifeguards, construction workers

*Certain combinations of nickel oxides and sulfides.

[†]Includes x-rays, γ-rays, neutrons and radon gas.

Occupational asthma may be defined as a "disease characterized by variable airflow limitation and/or airway hyperresponsiveness and/or inflammation due to causes and conditions attributable to a particular occupational environment and not to stimuli encountered outside the workplace" (Bernstein IL *et al.*, 2006). The U.S. National Health Interview Survey has provided data on the prevalence of asthma based upon usual industry and smoking status (Table 33-7). These data indicate that asthma prevalence is highest in general merchandise stores; food, bakery, and dairy stores; furniture, lumber and wood products industries; trucking and ware-

housing; health services; and the primary metals industry. Interestingly, in some industries current smokers demonstrate the higher prevalence while in other industries the higher prevalence is seen among nonsmokers. This may reflect that many people diagnosed with these conditions quit smoking.

There are a variety of industries in which there is increased risk of developing work-related asthma. In chemical-based industries, plastic and rubber polymer precursors, diisocyanates, reactive dyes, and acid anhydrides are recognized low-molecular-weight sensitizing compounds. Biocides and fungicides used in metal fabrication

U.S. Deaths and Crude Death Rates Attributed to Selected Occupational Lung Diseases

DISEASE	NUMBER OF DEATHS	DEATH RATE PER MILLION WORKING AGE PEOPLE
Asbestosis	1265	6.0
Coal workers pneumoconiosis	1003	4.7
Silicosis	187	0.9
Byssinosis	7	0.03
Other pneumoconioses*	318	1.5
Malignant Mesothelioma	2485	11.7
Hypersensitivity pneumonitis	57	0.3

*This includes aluminosis, berylliosis, stannosis, siderosis, and fibrosis from bauxite, graphite fibers, wollastonite, cadmium, portland cement, emery, kaolin, antimony, and mica.

SOURCE: NIOSH Worker Health Chartbook 2004, U.S. Bureau of Labor Statistics.

and machining, custodial services, lawn and turf growing, and agriculture are also chemicals associated with occupational asthma. A number of metals can induce sensitization and asthma, including chromium, cobalt, nickel, platinum, and zinc. Enzymes pose significant risks for occupational asthma (Heederik et al., 2002). Examples include α-amylase among bakery workers and subtilisin, a protease used in laundry detergents (Houba et al., 1998). The enzyme production industry has had to adopt strict environmental and process controls to reduce the incidence of occupational asthma in their production facilities.

Those working with animals or animal products are at increased risk of developing allergy (Elliott et al., 2005) and occupational asthma (Pacheco et al., 2003). Animal handlers, processors, and laboratory technicians who work with animals can become immunologically sensitized to urine or salivary proteins in many vertebrates; proteins in bat guano and bird droppings; animal dander; serum proteins in blood products; dust from horns, antlers, and tusks; or the shells of crustaceans. Very high rates of sensitization can occur in shellfish processors (Glass et al., 1998). Arthropods such as insect larvae, cockroaches, mites, or weevils are recognized inducers of work-related asthma. Plants and plant products (e.g., soy flour, spices, and coffee beans) can also cause asthma among workers. In a variety of occupations, exposure to fungi, especially of the genera *Aspergillus, Penicillium, Rhizopus, Mucor,* and *Paecilomyces*, are associated with allergic rhinitis and asthma. These are especially present in sawmills, woodchip handling, and composting facilities (Duchaine et al., 2000; Eduard et al., 1992; Halpin et al., 1994). Apart from the contaminating microorganisms, certain woods themselves produce chemical sensitizing agents. Examples include western red cedar, redwood, and some tropical hardwoods.

Asthma emerged in the 1980s as a major occupational health concern among health-care workers. In order to reduce the risk of hepatitis B and other infectious diseases, health-care workers adopted the use of natural rubber latex gloves for barrier protection. Proteins from the latex of the rubber tree, *Hevea braziliensis,* led to immunologic sensitization. Thirteen of these high-molecular-weight proteins have now been characterized as allergens (Bernstein et al., 2003). Many other plants of less commercial value produce a similar milky fluid when cut and have similar sensitizing properties. A shift to powder-free and nonlatex examination gloves has reduced the incidence of latex allergy among health-care workers and patients.

Studies of asthma prevalence in occupational settings with exposure to low-molecular-weight agents have suggested prevalence rates of 5–10% for toluene diisocyanate (Baur, 1996; Becklake et al., 2006), 3.2–18% for anhydrides (Venables et al., 1985; Wernfors et al., 1986), 4% for plicatic acid from western red cedar (Chan-Yeung et al., 1984), and 54% in a platinum refinery (Venables et al., 1989). For high-molecular-weight allergens, prevalence

Rate of Nonfatal Occupational Illnesses 2001. Rate Per 10,000 Workers.

INDUSTRY DIVISION	RESPIRATORY CONDITIONS DUE TO TOXIC AGENTS*	DUST DISEASES OF THE LUNG	POISONING	SKIN DISEASES OR DISORDERS[†]
Manufacturing	2.4	0.2	0.8	9.3
Durable goods	2.7	0.3	1.2	10.1
Nondurable goods	1.8	0.2	0.3	8.1
Construction	0.8	0.1	0.2	2.3

Agriculture	4.4	5.0
Chemicals and allied products	3.7	2.8

*The U.S. adult self-reported lifetime asthma prevalence rate is 11.6% for males and 14.9% for females and the prevalence rate for current asthma is 6.1% for males and 10.0% for females (BRFSS, 2004).
SOURCE: National Health Interview Survey, Work-related Lung Diseases Surveillance Report 2003.

among shellfish processors was estimated at 21–26% (Desjardin *et al*., 1995; Glass *et al*., 1998), 11–44% among lab animal workers (Cullinan *et al*., 1994; Fuortes *et al*., 1996, 1997; Hollander *et al*., 1997), and 5–7% among bakers exposed to wheat and alpha-amylase (Houba *et al*., 1998). Surveillance through the NIOSH SENSOR program in California, Massachusetts, Michigan, and New Jersey indicates that of over 2500 cases reported in 1993–1999, 20% were for work-aggravated asthma and 80% for new-onset asthma (NIOSH, 2003).

Agricultural workers exposed to grain dust, cotton dust, or atmospheres in swine or poultry confinement barns are at risk for the development of an asthma-like syndrome. This syndrome is an acute nonallergic airway response characterized by self-limited inflammation with neutrophilic infiltrates and increased proinflammatory cytokines and chemokines (e.g,. TNFα, IL-6, and IL-8) but it does not include persistent airway hyperreactivity, as in occupational asthma (Schenker *et al*., 1998). Asthma-like syndrome includes cough, mild dyspnea, fever, malaise, and cross-shift declines in lung function. Endotoxin in combination with other inflammatory bioaerosols is the likely etiologic agent (Douwes *et al*., 2003; Schwartz *et al*., 1994; Schwartz *et al*., 1995).

Other Occupational Diseases

Occupational diseases of the skin are common but less often fatal that those of the respiratory system. Irritant dermatitis and allergic contact dermatitis have the highest incidence of reported skin conditions. Table 33-6 shows data for rates of skin diseases or disorders in 2001 by industry division. These data indicate that forestry services, agricultural production, and manufacturing carrying the highest risks. However, three-quarters (29,500) of the 38,900 cases reported in 2001 were among workers in the manufacturing and service industries.

Occupational toxicants may induce diseases in a variety of body sites distant from the lung or skin. These include tumors arising in the liver, bladder, gastrointestinal tract, or hematopoietic system and are attributable to a variety of chemical classes. Further discussion of other occupational diseases and the toxicants listed in Table 33-3 can be found in the relevant chapters in Units 4 and 5 of this text.

Nervous system damage can be central, peripheral, or both. It may be acute, as with some organophosphate exposures, or chronic, as with organomercury poisoning or acrylamide-induced neuropathy. Injury affecting the immune system may arise from the immunosuppressive effects of chemicals such as dioxins or toxic metals. Many occupational diseases of the immune system occur due to hypersensitivity leading to respiratory or dermal allergy or systemic hypersensitivity reactions. Autoimmune syndromes have been associated with occupational exposures to crystalline silica and vinyl chloride.

Occupational diseases of the cardiovascular system include atherosclerosis, a variety of arrhythmias, problems with coronary blood supply, systemic hypotension, and cor pulmonale (right ventricular hypertrophy usually due to pulmonary hypertension as with chronic obstructive pulmonary disease). Liver diseases such as carbon tetrachloride-induced fatty liver and hepatocellular death due to toxic concentrations of acetaminophen have classically been used to illustrate chemical mechanisms of cellular injury leading to organ failure. These are thoroughly discussed in Chap. 13. Occupational diseases of the reproductive system can be gender- and organ-specific; but several toxicants—including carbon disulfide, lead, and vinyl chloride—may affect both sexes.

Exposures to infectious agents are a part of a variety of occupations (Thorne and Duchaine, 2007. Veterinarians, health-care workers, and biomedical researchers studying infectious agents have

exposures that are largely known and infection control strategies can limit their risks. For others, such as farmers and foresters, specific risks may be less obvious. Zoonotic diseases such as Q-fever, rabies, leptospirosis, and brucellosis may affect abattoir workers, zookeepers, animal handlers, and veterinarians. Foresters, field biologists, and natural resource workers who spend time in wooded areas experience tick- and mosquito-borne illnesses at a higher frequency than that of the general population. These illnesses include the arboviral encephalitides, Rocky Mountain spotted fever, Lyme disease, and ehrlichiosis. Occupational infections may arise as a result of work settings bringing people into close proximity with other people or animals, thus facilitating the transmission of microorganisms. Occupational infectious diseases attributable to the clustering of people affect workers in such facilities as day care centers, schools, healthcare settings, correctional facilities, dormitories, military barracks, or shelters for the homeless, among others. Industrial settings can place large numbers of workers in a shared space, leading to increased transmission of diseases. This is especially true for diseases with annual outbreaks, such as influenza and Norwalk-like viruses. Exposures to chemicals may increase the susceptibility of workers to infection through irritation of mucosa or the pulmonary epithelium or through immunosuppression leading to impaired host defense.

Both industrial and nonindustrial occupational environments may pose occupational hazards due to the presence of chemical or biological agents. Reports of work environments with ineffective ventilation or decreased ventilation rates and increased utilization of synthetic building materials have demonstrated a rise in complaints associated with occupancy in buildings. In some cases, service sector workers in a problem building develop specific clinical conditions with recognized etiology. This is defined as building-related illness. In other cases, symptoms are nonspecific and disappear when the worker leaves the problem building. When this occurs with sufficient prevalence, it is termed *sick building syndrome*. This can arise from volatile and semivolatile chemicals released from office materials, building materials, floor coverings, furniture, cleaning products, and microorganisms. Office buildings and residential settings comprise a complex ecology consisting of people, molds, mites, volatile organic compounds of microbial and nonmicrobial origin, and sometimes plants, pets, cockroaches, and other vermin (Thorne and Heederik, 1999b). Molds, house dust mites, and animal proteins are potent human allergens that can lead to allergy and asthma. Exposure to chemicals and biomolecules such as endotoxin may enhance this process (Douwes *et al.*, 2003). Workers in laboratory animal facilities exhibit a high prevalence of allergy to rodent urinary proteins. In some cases, the occupied space of a building may be clean and dry, but local amplification sites for molds may develop. These may arise in ventilation systems, utility closets, subfloors or basements that serve as return air plenums, or in local sites of water damage. Such sites can become sources of microorganisms and aeroallergens of sufficient volume to generate significant bioaerosol exposures throughout the environment. Airborne viruses, bacteria, and fungi are responsible for a variety of building-related illnesses arising from organisms that are pathogenic to humans. Nonpathogenic microorganisms may induce symptoms or diseases through inflammatory processes, by stimulating the immune response, or by releasing noxious odors, allergenic compounds, or bioactive macromolecules. These may combine with industrial chemicals released into the air to create complex exposure environments.

TOXICOLOGIC EVALUATION OF OCCUPATIONAL AGENTS

Evaluation of Occupational Risks

In most instances of prolonged exposure to low levels of chemicals, there is a continuum between being healthy and being ill. The exposures may impart biochemical or functional changes that are without signs or symptoms, subclinical changes, or in cases of more significant toxicity, manifest as clinical disease. The health significance of the identified changes resulting from exposure to a particular agent must be assessed in order to determine which effects are adverse. Following this assessment, one must consider the interindividual variability or susceptibility factors that influence the risks. There is no one single dose-effect relationship but a distribution of responses. Therefore, in order to recommend an acceptable exposure level to an industrial chemical, one must attempt to define the risk associated with adverse effects in the most sensitive populations exposed. It then remains to be determined what proportion of exposed subjects may still develop an adverse effect at the proposed acceptable exposure level. This acceptable risk level will vary according to a value judgment of the severity, permanence, and equality of the potential adverse effects and the characteristics of the most susceptible population. Clearly, inhibition of an enzyme without functional consequences will be viewed as more acceptable than a more serious toxic effect, such as teratogenicity leading to a congenital malformation in the offspring of the exposed individual.

Establishing Causality   In complex occupational environments, it may be difficult to establish a causal relationship between a toxic substance and a disease. For this reason a number of systematic approaches have been devised to help define causation. In 1890, Robert Koch proposed postulates for "proving" that a specific organism caused a specific disease. T. M. Rivers extended this approach to viruses in 1937. Sir Austin Bradford Hill suggested epidemiologic criteria for assessing causality in 1965 considering strength, specificity, consistency, temporality, exposure period, exposure gradients, and biological plausibility of the associations. These schema and modern weight-of-evidence determination criteria were later combined to suggest a set of postulates for the evaluation of evidence for disease agents in organic dust (Donham and Thorne, 1994). A matrix was developed and is extended here to evaluate the weight of evidence for a causal association between a toxicant and an occupational disease (Fig. 33-2). Evidence from well-conducted in vitro studies, animal studies, human challenge studies, case reports, and epidemiologic investigations are evaluated with regard to data quality and clarity of evidence in support of the establishment of causality. This evaluation is guided by seven criteria (shown in blue). If a chemical were thoroughly studied in animals, humans, and in vitro studies and produced clear and convincing evidence of an exposure–response relationship in controlled studies that used appropriate models and relevant endpoints, that would constitute compelling evidence of a causal relationship between that chemical and that disease. Figure 33-2 reminds us that a consortium of study types contributes data used for the evaluation of occupational hazards. These are discussed below.

To evaluate with some degree of confidence the level of exposure at which the risk of health impairment is acceptable, a body of toxicologic information is required. Five sources of data may be available to inform the occupational risk-assessment process.

	Assessment of Exposure to Specific Agents	Consideration or Control of Confounders	Evidence of a Dose-Response Relationship	Consistent Results From Different Studies	Objective Clinical Data	Endpoints Related to Human Pathology	Appropriate Subjects or Models
In Vitro Studies	�usied				▓		
Animal Studies					▓		
Human Challenge Studies						▓	
Case Studies						▓	▓
Epidemiology Studies						▓	

For each type of study listed in the first column weight the quality of data from existing studies based on the criteria listed in the column headings as follows:

    0   No evidence or condition is not met
    1   Equivocal evidence or condition is partially met
    2   Some evidence or condition is mostly met
    3   Clear evidence or condition is convincingly met

Figure 33-2. Matrix for assessing the strength of an association between a toxicant and an occupational disease.

- In vitro assays
- Animal toxicology studies
- Human challenge studies
- Case reports
- Epidemiology studies

In Vitro Assays A number of useful in vitro assays have been developed over the past several decades in order to provide screening data and, in some cases, mechanistic insight without the need or expense of exposing animal or human subjects. While at this time there are few validated methods to determine complex toxicologic responses such as immune hypersensitivity or peripheral neuropathy, there are validated and very useful screening assays. Notable examples are the *Salmonella typhimurium* reverse mutation assay, or Ames test, the Corrositex assay for dermal corrosivity potential of chemicals (ICCVAM, 2003; NIH-99-4495, 1999), and the in vitro ocular toxicity test for identifying severe irritants and corrosives (ICCVAM, 2006). In addition, quantitative structure–activity relationships can help suggest potential toxicologic effects for an unstudied compound if structurally similar compounds have been evaluated.

Animal Toxicology Studies Animal toxicology studies serve an important function in terms of identifying adverse effects, providing mechanistic data, establishing dose-response relationships, and aiding the process of establishing standards. Because animal studies can be conducted before there is any human exposure, these studies play an important role in hazard identification and prevention of human disease. There are numerous animal models for occupational injury and illness; these are described throughout this textbook in the context of the affected organ system and the classes of toxicants. Generation of animal toxicology data to predict health effects in workers is a central function of experimental toxicologists.

Toxicologic investigations using animals often serve to establish a tentative acceptable exposure level. Other important information that may also be derived from these investigations concerns the relationships between the metabolic handling of the chemical and its interactions with target molecules (mechanism of action), identification of methods for biological monitoring of exposure and early health effects, and identification of preexisting pathologic states that may increase susceptibility to the chemical. However, animal testing can provide only an estimate of the toxicity of a chemical for humans. Animals do not always respond to a chemical exposure in the same way as humans. For instance, there are very significant species and strain differences in responsiveness to aryl hydrocarbon receptor agonists such as polychlorinated dibenzo-p-dioxins (Abnet *et al.*, 1999; Boverhof *et al.*, 2006). In some instances, interspecies differences in metabolism or mechanism of action cause certain chemicals to induce cancer in rodents but not in humans. One such example is kidney cancer, attributable to the accumulation of a rat-specific protein (α_{2u}-globulin) in proximal tubular cells, and produced in male rats chronically exposed to unleaded gasoline (Hard *et al.*, 1993). There are a few compounds for which predictive animal models have not been found. As discussed further, skin and internal cancers caused in humans by excessive oral exposure to inorganic arsenic were not reproduced during classic carcinogenicity studies in animals (ATSDR, 2005).

Human Challenge Studies Human challenge studies, or clinical exposure studies, are a useful approach for verifying findings from animal toxicology studies in humans and for establishing whether biotransformation pathways in the animal models represent those in exposed humans. Human challenge studies with occupational toxicants are usually designed to answer very specific questions regarding rates of uptake, biotransformation pathways, the time course of metabolite excretion during and after exposure, evaluation of

the threshold concentration for sensory responses (odor, irritation of the nasal mucosa, etc.), and acute effects of toxicant exposure on perception, vigilance, and function. Human challenge studies help to establish biomarkers of exposure. For reversible conditions, they can be useful for testing therapeutic options. They may also be useful for investigating bronchial hyperresponsiveness to inhaled agents. Extreme caution must be exercised to ensure the safety of research subjects. Idiosyncratic responses can cause a subject to be exceptionally sensitive. For inhalation studies, equipment malfunction can result in overexposure, so real-time exposure monitoring is a necessity. In the past 25 years, there have been several serious injuries and fatalities associated with human challenge studies. These have been attributed to hypersensitivity reactions and generally used mock workplace simulations without rigorous control and monitoring of exposures, as is the current standard of practice. Thus, such studies should be undertaken only when the same results cannot be obtained through other means and under circumstances in which the risk for volunteers can reasonably be estimated as negligible.

Case Reports   When new toxicants, new combinations of toxicants, or changes in process conditions occur in the workplace, a case or outbreak of cases can occur. These may be identified through workplace surveillance systems or through workers associating their disease with workplace exposures. In some cases, the problem is identified quickly and resolved, while others take years to resolve. These are often published as case reports and may give rise to animal or epidemiologic studies. Cases of hypersensitivity pneumonitis among machinists exposed to metalworking fluids contaminated with mycobacteria is but one recent example (Thorne *et al*., 2006, Weiss *et al*., 2002). NIOSH has a Health Hazard Evaluation (HHE) program in place in which employees or their authorized representatives or employers at a job site can request an investigation to evaluate a potentially hazardous situation. This program issues HHE Reports to disseminate information regarding the hazard. NIOSH also publishes NIOSH Alerts, Criteria Documents, Special Occupational Hazard Reviews, Occupational Hazard Assessments, and Current Intelligence Bulletins. While useful for hazard identification, case reports and HHE Reports do not establish incidence or prevalence of diseases associated with an occupational hazard.

Epidemiology Studies   Epidemiology studies help to unravel the associations between occupational diseases, exposures, and personal risk factors. Exposure may be characterized using a surrogate measure such as job classification or via questionnaire, or more directly through exposure monitoring or biomonitoring. Adverse effects may be expressed in terms of mortality, incidence or prevalence of clinical disease, irreversible or reversible functional changes, or critical biological changes.

Several types of epidemiologic studies are used to gather data on the association of workplace exposures with human disease. Cross-sectional studies compare disease prevalence or health status between groups of workers classified according to job title, work site, or exposure status. Cohort studies compare exposed workers versus unexposed or less exposed workers either prospectively or retrospectively in order to associate the occurrence of disease with exposure. Because many occupational diseases have a long induction period or occur only rarely, prospective cohort studies may require a long time and need a large number of subjects to

establish significant findings. Retrospective cohort studies can resolve the latency problem but require that relevant exposure data have been collected over time. In the absence of measured exposures, job titles, tasks routinely performed, and years of employment may allow exposure categorization (e.g., low, medium, high). Exposure misclassification is frequently a problem in retrospective studies.

Case-control studies are useful for investigating rare diseases or diseases with long induction periods. As the name suggests, case-control studies compare workers with disease to workers without disease with regard to their past exposure intensity, frequency, and duration, plus other postulated risk factors. In some instances where the exposure–disease relationship is not understood, it may be difficult to identify an appropriate control group. Case-control studies are strongest when accompanied by a rich data set of measured exposures to the candidate causative agents spanning the relevant exposure period. If exposure history is assessed by questionnaire after workers have developed adverse health effects, there arises the potential for recall bias in which those with disease may recall past exposures differently than those who are free of disease. Error can also arise due to selection bias if those who agree to participate in the study are not representative of the population of interest.

Characteristics of observational epidemiology studies are listed in Table 33-8. Occupational epidemiology studies assess relationships between exposures and human health outcomes and, therefore, are particularly useful for risk assessment. Confounding may arise due to exposures of risk factors not associated with the work environment.

Because measures of effect may be subtle and may overlay a background level of incidence, results generally require sophisticated statistical comparisons between a group of exposed workers and a similar group of workers without the exposure of interest. Ideally, the group of unexposed workers should be matched on variables such as age, race, gender, socioeconomic status, and smoking habits. They should also undergo the same standardized clinical, biological, or physiologic evaluation at the same time as the exposed group. Comparison with the general population is ill-advised because an employed population is a highly selected group and may have a higher degree of physical fitness. Because occupational epidemiologic studies often last for several years, all methods of investigation—such as questionnaires, measurement instruments, and analytic techniques—must be validated and standardized before the start of the study. The number of subjects under study should be chosen based on a sample size calculation to be able to detect a difference between exposed and unexposed subjects (should there be a difference) and should take into account labor turnover and those declining participation in any aspects of the study. If exposures are high enough to induce an adverse effect, it is expected that these studies may permit establishment of the relationship between integrated exposure (intensity × time) and frequency of abnormal results and, consequently, a redefinition of the OEL.

In most cases, occupational epidemiologic studies encompass the collection of samples from the subjects or data obtained through interaction with the subjects. Because this often includes identifiable private information, the confidentiality of the data must be protected. U.S., EU, and international laws require that subjects must always have the right to refuse participation and investigators must have written consent from a duly informed volunteer obtained without coercion.

Table 33-8

Comparison of Epidemiologic Studies and Experimental Exposure Studies

	OBSERVATIONAL EPIDEMIOLOGIC STUDIES	EXPERIMENTAL ANIMAL EXPOSURE STUDIES
Toxicant exposure	Reflects true exposure among population at risk	Controlled to represent major toxicant of interest
Character	Complex and variable in space and time	Usually 1 or 2 test compounds
	May include nonoccupational exposures to toxicant or related compounds	May not reflect complexity of human exposures
Frequency and duration	Work day, work week, and years in that job	Acute, sub-acute, sub-chronic, chronic
	May be task specific	
Exposure route	Inhalation, ingestion, percutaneous, or a combination	Injection, inhalation, oral, or dermal. Rarely a combination by design
Appropriateness of dose	Reflect the actual range of exposure	Often doses studied are far higher than human exposures
Assessment	Environmental sampling or measurement of biomarkers	Measurement of administered dose with or without measurement of biomarkers
	May be retrospective and based on employer records, group-based approaches or questionnaires	Sampling of exposure chamber air for inhalation studies
Species considerations	Humans—cohorts or cases and controls	Laboratory animals, usually inbred strains of mice or rats
	Must protect the safety and confidentiality of subjects	Must ensure proper care and use of animals
Representativeness	May exist a selection bias such that the study population may not represent the occupational work force	Experimental animal species may not represent humans
Relevance to human health	Directly relevant if appropriate outcomes are studied	Relevant if species differences are known
		Of limited relevance if species or strain effects on absorption, distribution, metabolism, and disease are unknown
Analytical challenges	Selection bias, misclassification, and confounding in characterization of outcomes	Control of genetics, feeding and housing between exposed and control groups
	Within- and between-subject variance may be high	Low variance in outcomes

Animal Toxicology Testing for Establishing Acceptable Levels of Exposure

It is evident that certainty as to the complete safety of a chemical can never be obtained, regardless of the extent of toxicologic investigations performed on animals. Nevertheless, animal studies provide valuable data from which to estimate the level of exposure at which the risk of health impairment is acceptable. Table 33-8 compares the information gained from animal studies to epidemiology studies. To the extent possible, animal studies should employ species for which the metabolic pathways and disease processes reflect those of humans. Guidelines and protocols for assessing experimentally the toxicologic hazards of chemicals have been formulated by various national and international agencies. These tests include local and systemic acute toxicity tests, tests of toxicity following repeated exposure, investigations of metabolism and mechanism of action, short-term tests for detecting potential mutagens and carcinogens, studies of effect on reproduction and of teratogenic activity, chronic studies to detect carcinogenesis and other long-term effects, interaction studies, tests for immunosuppression, and dermal and pulmonary hypersensitivity tests. The need for performing these testing protocols should be carefully evaluated for the inclusion of any occupational toxicant to which workers will be exposed. In selecting the studies most appropriate for safety evaluation, the toxicologist should be guided by an understanding of the following:

- physicochemical properties of the chemical
- potential for the generation of toxic derivatives when the chemical is submitted to heat, pH changes, and UV light
- conditions of use and route of exposure
- type of exposure (continuous, intermittent, or incidental)
- degree of exposure

Toxicologic information already available on other chemicals with similar chemical structure and reactive chemical groups can suggest potential hazards and reactivity.

Conclusions drawn from any toxicologic investigation are useful only if the composition and physical state of the tested preparation is known. This would include the nature and concentration of impurities or degradation products, speciation of inorganic compounds, characterization of physical properties for inhaled materials, and characterization of the vehicle (if any). Sensitive and specific methods of analysis of the chemical in solution, air, and biological material should also be available. The assessment of the toxicity of malathion conducted in the 1970s illustrates this point. Malathion is an organophosphate insecticide that normally has relatively low human toxicity. This pesticide was responsible for a 1976 episode of mass poisoning among malaria workers in Pakistan because the specific product contained impurities (mainly isomalathion) capable of inhibiting tissue and plasma carboxyesterases (Baker *et al.*,

1978; Aldridge *et al.*, 1979). The toxicity evaluation for malathion had not anticipated isomalathion coexposure.

The duration of tests necessary to establish an acceptable level for occupational exposure is primarily a function of the type of toxic action suspected. It is generally recognized that for systemically acting chemicals, subacute and short-term toxicity studies are usually insufficient for proposing OELs. Subacute and short-term toxicity tests are usually performed to find out whether the compound exhibits immunotoxic properties and cumulative characteristics. They also aid in selection of the doses for long-term-exposure studies and the kind of tests that may be most informative when applied during long-term exposures. A number of studies have drawn attention to the fact that the reproductive system may also be the target organ of industrial chemicals (e.g., glycol ethers, styrene, lead, dibromochloropropane). Thus, studies designed to evaluate reproductive effects and teratogenicity should also be considered during routine toxicologic testing of occupational toxicants.

Information derived from exposure routes similar to those experienced by workers is clearly the most relevant. For airborne pollutants, inhalation exposure studies provide the basic data on which provisional OELs are based. Experimental methodology is much more complicated for inhalation studies than for oral administration experiments and requires more specialized equipment and expertise (Thorne, 2000). For example, in the case of exposure to an aerosol, particle size distribution must be evaluated and the degree of retention in the respiratory tract of the animal species under study should be established. Ideally, particle size should be selected according to the deposition pattern of dry or liquid aerosols in the particular animal species used in order to represent human lung deposition with occupational exposures. Particle deposition and retention curves have been published for human, monkey, dog, guinea pig, rat, and mouse (Asgharian *et al.*, 2003; Hsieh *et al.*, 1999; Schlesinger, 1985). Recent research coupling asymmetric multiple-path models of the bronchial tree and ventilation parameters can provide more accurate prediction of site-specific particle deposition (Asgharian and Price, 2006). It should also be kept in mind that the concentration of the material in the air and the duration of exposure do not give a direct estimate of the dose, because retained dose is also dependent on the minute volume and the proportion of inhaled particles retained. Measurement of pulmonary dust retention following exposure to a radiolabeled or fluorescently tagged test aerosol should be performed prior to conducting acute, subchronic, or chronic studies. This allows one to assess deposition and determine whether the selected levels of exposure may overwhelm pulmonary clearance mechanisms (ILSI, 2000; Oberdörster, 2002).

The choice of studies to perform and their routes of administration must be evaluated scientifically for each toxicant. Important considerations include its target sites and mechanism of action, metabolism, the nature of its adverse effects, and how workers are exposed to the toxicant. The morphologic, physiologic, and biological parameters that are usually evaluated, either at regular intervals in the course of the exposure period or at its termination, are described in Units 4 and 5 of this text. Investigations that can make use of specific physiologic or biochemical tests, based on knowledge of the principal target organ or function, produce highly valuable information and increase confidence in the OEL derived from them.

Worker Health Surveillance

The primary objective of worker health surveillance programs is to provide both periodic screening of general health and wellness plus health and exposure monitoring tailored to recognized hazards of the workplace. The monitoring of exposures to toxicants in the workplace may play an important role in detecting excessive exposures before the occurrence of significant biological disturbances and health impairment. A scheme for biological monitoring of exposure and of early biological effects is possible only when sufficient toxicologic information has been gathered from animal or human studies on the mechanism of action and the metabolism of xenobiotics to which workers are exposed. When a new chemical is being used on a large scale, the careful clinical surveillance of workers and monitoring of workplaces should be instituted in order to address three aims: (1) to identify overexposure or adverse effects on the health of the workers and quickly intervene, (2) to evaluate the validity of an existing or proposed OEL, and (3) to test the validity of a proposed method for biological monitoring.

Evaluation of the validity of the proposed OEL derived from animal experiments through workplace surveillance is the major aim because studies and observations on humans are the final basis for deciding whether an OEL set originally on the basis of animal toxicity testing is truly acceptable as one that will not produce excess health risks. This means that sensitive clinical, biochemical, physiologic, or behavioral tests for detecting an adverse effect of a toxicant should ideally be performed on the workers concurrent with exposure assessment. It is helpful if health surveillance programs can include the same biomarkers as used in prior animal or human exposure studies. Occupational toxicologists and occupational physicians cannot rely solely on the standard diagnostic tools used in clinical medicine, as they were established primarily to reveal advanced pathologic states and not to detect early adverse effects at a stage when they are still reversible. For example, the measurement of serum creatinine is still a widely used clinical test for assessing renal integrity; yet it is known that the glomerular filtration rate of the kidney must be reduced by more than 50% before serum creatinine rises significantly.

The main limitation of current OELs or BEIs is that some are based on limited experimental data or clinical studies in which only late effects have been investigated and correlated with past exposure. Furthermore, several BEIs are derived from the study of external-internal exposure relationships and not from relationships between internal dose and early adverse effects. The validity of an OEL is much stronger if it is based on the study of dose-response relationships in which the dose is expressed in terms of the cumulative target dose and the monitored effect reflects a critical biological event. However, for some chemicals and some adverse effects (e.g., induction of hypersensitivity and possibly genotoxic effects), the frequency of peak exposure may be more important for health risk assessment than the integrated dose. For example, long-term low-level exposures to commercial enzymes rarely induce sensitization. However, a single exposure to a high concentration can produce hypersensitivity and occupational asthma.

In cases where a surveillance program was not instituted before the introduction of a new chemical, it is more difficult to establish the efficacy of the OEL. In this situation, evaluation depends on retrospective cohort studies or case-control studies on workers who have already sustained exposure. Evaluation of a "no observed adverse effect level" (NOAEL) is difficult because information on past exposures is often incomplete and frank effects are generally the focus of retrospective or case-control studies. Provided that a satisfactory assessment of past exposure is possible, cross-sectional studies that rely on preclinical signs of toxicity may, to a certain extent, overcome these difficulties. Whether or not clinical investigations are

planned from the introduction of a new chemical or process, it is essential to keep standardized records of occupational histories and exposure. The need may arise for mortality or case history studies in order to answer an urgent question on a suspected risk.

Careful investigation of overexposures resulting from specific incidents such as containment breaches, chemical spills, or vessel or pipe ruptures can provide useful information. Although such observations are usually not helpful for determining the NOAEL in humans, they may indicate whether human symptomatology is similar to that found in animals and may suggest functional or biological tests that might prove useful for routine monitoring of exposed workers.

Linkage of Animal Studies and Epidemiologic Studies

In the field of occupational toxicology, perhaps more than in other areas of toxicology, close cooperation between those conducting animal studies and studies of workers is essential for examining risks associated with overexposure to chemicals and other toxicants. A few examples will serve to illustrate the complementarity of these disciplines.

Several occupational carcinogens have been identified clearly through combined epidemiologic and experimental approaches (IARC, 1987). For example, the carcinogenicity of vinyl chloride was first demonstrated in rats (Viola *et al*., 1971), and a few years later, epidemiologic studies confirmed the same carcinogenic risk for humans (Creech and Johnson, 1974; Monson *et al*., 1974). This observation stimulated several investigations on the metabolism of vinyl chloride in animals and on its mutagenic activity in in vitro systems. Identification of vinyl chloride metabolites led to the conclusion that there is microsomal oxidation leading to the formation of an epoxide derivative, which acts as a proximate carcinogen (ATSDR, 2006). This finding triggered further studies on the biotransformation of structurally related halogenated ethylenes, such as vinyl bromide, vinylidene chloride, 1,2-dichloroethene, trichloroethylene, and perchloroethylene (Bonse *et al*., 1975; Uehleke *et al*., 1977; Dekant *et al*., 1987). Comparison of their oncogenic activity in relation to their metabolism suggested that an interplay between the stability and reactivity in reaching the DNA target and reacting with it after being formed would determine their genotoxic risk. It is now recognized that vinyl chloride produces promutagenic etheno-DNA adducts including etheno-guanine, etheno-cytosine, and lesser amounts of etheno-adenine (Bolt, 2005; NTP, 2005).

1,3-Butadiene is a known human carcinogen that is used in the manufacture of synthetic rubber products. Experimental studies in rats and mice demonstrated carcinogenicity, with mice being particularly sensitive (NTP, 2005). Subsequent to these findings, 1,3-butadiene was shown to follow the same metabolic pathway in humans as in rats and mice, forming mutagenic and carcinogenic epoxides. That led to cohort and case-control studies establishing 1,3-butadiene as a human carcinogen (NTP, 2005). Recent studies have considered the relative importance of the metabolic pathway leading to formation of the reactive metabolite 1,2-epoxy-3-butene, which reacts with hemoglobin to form 1- and 2-hydroxy-3-butenyl valine adducts (MHBVal) and with DNA to form guanine adducts. Under the assumption of a genotoxic mechanism and cross-species comparisons of hemoglobin and DNA binding, these data facilitate a more informed cancer risk assessment. This analysis suggests that for exposures to 1,3-butadiene, the cancer risk is lower for humans than rats or mice on an equivalent dose basis (Van Sittert *et al*., 2000).

Furthermore, this work illustrates that the measurement of the MH-BVal adducts is a sensitive method for monitoring 1,3-butadiene metabolism via the epoxide-forming pathway in workers.

In 1973, an outbreak of peripheral neuropathy occurred in workers exposed to the solvent methyl butyl ketone (MBK) (Mc-Donough, 1974; Allen *et al*., 1975). The same lesion was reproduced in animals (Mendell *et al*., 1974; Spencer *et al*., 1975). Biotransformation studies were then undertaken in rats and guinea pigs and some MBK metabolites (2,5-hexanedione, 5-hydroxy-2-hexanone) were also found to possess neurotoxic activity (Spencer and Schaumburg, 1975; DiVincenzo *et al*., 1976; DiVincenzo *et al*., 1977). Similar oxidation products are formed from *n*-hexane, the neurotoxicity of which is probably due to the same active metabolite as that produced from MBK. Because methyl isobutyl ketone and methyl ethyl ketone cannot give rise to 2,5-hexanedione, they were suggested as replacement solvents.

These examples demonstrate that studies of the metabolic handling of occupational toxicants in animals are instrumental in the characterization of reactive intermediates and may suggest unsuspected risks or indicate new methods of biological monitoring. Conversely, clinical observations of workers may stimulate studies of the metabolism or the mechanism of toxicity of a toxicant in animals, thereby revealing the health significance of a biological disturbance.

Arsenic is one of the very few compounds for which there are limited data of predictive value from animal studies to human health effects. Arsenic has been used as a medicine since the time of Hippocrates. Initially used to treat ulcers, arsenicals achieved notoriety as medicinals for a wide variety of ailments, and then, in the first half of the twentieth century, for the treatment of syphilis and parasites. Many foods and beverages contaminated with arsenic have been associated with accidental and intentional poisonings. Inorganic pentavalent arsenic (arsenate) is readily absorbed across tissues and converted to the trivalent form (arsenite). This is then methylated to form monomethyl arsenic acid and dimethyl arsenic acid (ATSDR, 2005). These are primarily transported in the blood bound to sulfhydryl groups in proteins. The half-life in humans for arsenic compounds is 2–4 days and the major excretion is via the urine (Nriagu, 1994).

Inorganic arsenic was first noted as a human carcinogen by Hutchinson in 1887 (Hutchinson, 1887). Epidemiologic studies led to classification of arsenic by the IARC as a skin and lung carcinogen in 1980 (IARC, 1980). Since then studies among occupationally exposed populations and populations with high arsenic in their drinking water have shown conclusively that arsenic causes human cancers of the skin, lung, bladder, kidney, liver, nasal tissue, and prostate. There is also evidence for arsenic-associated cutaneous effects, cardiovascular and cerebrovascular disease, diabetes mellitus, and adverse reproductive outcomes (EPA, 2000; WHO, 2001).

A large number of carefully executed cancer bioassays in mice, rats, beagles, and monkeys have been performed using sodium arsenate, sodium arsenite, lead arsenite, arsenic trioxide, and dimethylarsinic acid. These studies have been uniformly negative for cancer. A number of subsequent studies that tested for tumor-promotion activity following dosing with recognized tumor initiators also yielded negative results. Recent studies using transgenic mice, high-dose in utero exposures, or administration of a cocarcinogen have yielded tumors in mice (Hughes, 2006). However, negative results in standard animal carcinogenicity screens have been problematic in the face of unquestionable oncogenic activity in humans.

The examples above demonstrate that the occupational toxicologist cannot rely solely on animal or epidemiologic studies.

A combined approach is necessary in order to identify, elucidate, and prioritize risks and to develop interventions and techniques for worker health surveillance.

EXPOSURE MONITORING

Two important applications of occupational toxicologic investigations are compared below: environmental monitoring and biological monitoring. As described above under "Occupational Health Standards," both are important in worker health surveillance and are essential elements of toxicology studies with dosing via the inhalation or dermal routes.

Environmental Monitoring for Exposure Assessment

An important objective of experimental and clinical investigations in occupational toxicology is the proposal of safe levels of exposure. OELs must be reevaluated at regular intervals as new information on the toxicity of industrial chemicals develops. Adherence to OELs may not protect everyone and, therefore, cannot supplant close medical surveillance of workers. Various private and official institutions regularly review the toxicologic information on chemicals in order to propose or update permissible levels of exposure. These include governmental organizations worldwide and trade organizations such as the ACGIH. A critical element of establishing OELs is the accurate and uniform assessment of exposure. Methodology for exposure assessment must be specifically tailored to the agent under study and the environment in which it appears. To assess airborne exposures for compliance purposes, personal samples taken in the breathing zone are generally used. In a few specific environments, area samples form the basis of an exposure standard (e.g., the OSHA standard for exposure to raw cotton dust specifies use of the vertical elutriator or an equivalent method). Occupational environmental surveys may employ area sampling to determine areas with higher or lower toxicant concentrations. However, concentrations determined from personal samples typically exceed area concentrations, depending on the work practices and environmental controls. For example, geometric mean concentrations of inhalable dust assessed from 159 personal samples in dairy barns were 1.78 mg/m^3, compared with 0.74 mg/m^3 for 252 area samples collected simultaneously in two locations in the same barns (Kullman *et al*., 1998). Thus, in this environment, area sampling alone would underestimate personal exposures by a factor of 2.4.

Repeated random sampling is theoretically the best approach to developing unbiased measures of exposure. However, this is rarely the approach that is taken. Variability in exposure, especially variability over time, is often large; therefore, a considerable number of repeated measurements are needed to obtain an accurate proxy of the true exposure. When the number of repeats is insufficient, the slope of the exposure–response relationship will be biased, usually leading to considerable underestimation of the relationship (Heederik and Attfield, 2000). Recent studies have demonstrated that group-based approaches, assessing exposures to groups rather than to individuals, are more efficient in terms of measurement effort for obtaining a desired level of accuracy (Vermeulen and Kromhout, 2005). In a group-based approach, workers are grouped by job title, task performed, or through exposure modeling studies to elucidate determinants of exposure, and the group mean is used as the average exposure for each worker (Kromhout *et al*., 1996). Further statistical modeling of the exposure data can reduce problems of bias and large

temporal and spatial variability (Preller *et al*., 1995; Tielemans *et al*., 1998). Whereas this approach is gaining acceptance among occupational epidemiologists for evaluating exposure–response data and assessing risks, it is not accepted for compliance monitoring.

Although one cannot assess dose directly through exposure monitoring, it does have several distinct advantages over biomonitoring. Exposure monitoring allows one to quantify workplace exposure by route through selective air monitoring in the breathing zone of the worker and dermal dosimetry using absorptive material affixed to the workers' skin or clothing. Biomonitoring cannot provide route-specific exposure data. Environmental monitoring techniques are generally less expensive and less invasive than techniques involving the collection and analysis of biological samples such as blood or urine. Thus, a larger population of workers can be studied for the same amount of money. Workers are accustomed to wearing personal samplers for exposure assessment and are generally quite willing to do so. However, they are often unwilling to give a blood or urine sample, fearing that the sample will be surreptitiously used for drug testing, DNA testing, or experimentation. Another benefit of air sampling in the workplace is that spatial, temporal, and work practice associations can be established and can suggest better interventions and engineering controls to reduce exposures. Finally, analytic interferences and variabilities are generally lower with environmental samples than with biological samples.

A fully validated sampling and analysis method requires specification of the sampling methods; sample duration, handling, and storage procedures; the analytic method and measurement technique; the range, precision, accuracy, bias, and limits of detection; quality assurance issues; and known interferences. It is also important to document intralaboratory and interlaboratory variability. Once a standard method is established, it must be closely followed in every detail in order to assure consistency of results.

The development of accurate and precise analytic methods for environmental assessment is an ongoing effort. NIOSH publishes the extensive *NIOSH Manual of Analytical Methods* (NIOSH-NMAM, 2006) and these are widely used. The American Society for Testing Materials (ASTM) has also developed a rigorous system for the establishment of methods. It generally requires 5 or more years to establish a new ASTM method for exposure assessment. The International Organization for Standardization (ISO) is a global federation of national standards bodies with over 150 member countries. The subcommittee on workplace atmospheres is administered by the American National Standards Institute (ANSI). ISO has completed harmonization on a number of air sampling methods—for example, the determination of the number concentration of airborne inorganic fibers by phase contrast optical microscopy. The American Industrial Hygiene Association (AIHA) and the ACGIH publish compilations with descriptions of analytic devices and methodology (Cohen and McCammon, 2001; DiNardi, 2003). Methods have also been developed for bioaerosol exposure assessment and these have been reviewed (Heederik *et al*., 2003; Thorne and Heederik, 1999a; Willeke and Macher, 1999).

Biological Monitoring for Exposure Assessment

Biomonitoring consists of the measurement of toxicants, their metabolites, or molecular signatures of effect in specimens from humans or animals, including urine, blood, feces, exhaled breath, hair, finger or toenails, bronchial lavage, breast milk, and adipose tissue. These may serve as biomarkers of exposure, biological effect, or susceptibility. New technologies are emerging that will allow

measurement and monitoring of chemicals in the body and transmission of the data from indwelling biosensors. Biomonitoring data provide a measurement of exposure based upon internalized dose and, thus, account for all exposures by all routes for the assessed analyte.

Depending on the chemical and the analyzed biological material, the term *internalized dose* may have different meanings. The measured biomarker may reflect the amount of chemical absorbed shortly before sample collection, as with the concentration of a solvent in exhaled air or in a blood sample obtained during the work shift. It may reflect exposure during the preceding day, as with the measurement of a metabolite in blood or urine collected after the end of exposure. For toxicants with a long biological half-life, the measured parameter may reflect exposure accumulated over a period of weeks or months as with arsenic in toenails. *Internal dose* may refer to the amount of chemical stored in one or in several body compartments or in the whole body (*the body burden*).

When biological measurements are available to assess the internal dose, they offer important advantages over monitoring the air of the workplace. The greatest advantage is that the biological measure of exposure is more directly related to the adverse health effects than environmental measurements because it reflects the amount of toxicant absorbed. Therefore, it may offer a better estimate of the risk than can be determined from ambient monitoring. Biological monitoring accounts for uptake by all exposure routes. Many industrial chemicals can enter the organism by absorption through the skin or the gastrointestinal tract as well as the lung. For example, some solvents (e.g., dimethylformamide) and many pesticide formulations exhibit substantial exposure via the dermal route. In these situations, exposures determined through monitoring airborne concentrations underestimate true exposure. Monitoring of an early biomarker of effect is useful when the subjects are exposed to a complex mixture and the agents responsible for the effect are unknown or several agents are working in synergy.

Several factors can influence uptake. Personal hygiene habits vary from one person to another, and there is some degree of individual variation in the absorption rate of a chemical through the lungs, skin, or gastrointestinal tract. Use of size-selective air sampling to determine the inhalable or respirable fraction can strengthen the exposure estimate. However, biological factors such as ventilatory parameters can affect the strength of such a correlation. For example, increased workload can markedly increase the respiratory uptake of an airborne toxicant. Because of its ability to encompass and evaluate the overall exposure (whatever the route of entry), biological monitoring can also be used to test the overall efficacy of personal protective equipment such as respirators, gloves, or barrier creams. Another consideration with biological monitoring is the fact that nonoccupational exposures (through hobbies, residential exposures, dietary habits, smoking, second jobs) may also be expressed in the biological sample. The organism integrates the total external (environmental and occupational) exposure into one internal load. Whereas this is beneficial for worker health and safety, it may be confounding in epidemiologic studies or compliance monitoring. Thus, while biomonitoring is an important exposure measurement tool for health risk assessment, it generally does not allow one to relate sources and levels of exposure to adverse health effects (Albertini *et al*., 2006).

The value of biological monitoring is heightened when the relationships between external exposure, internal dose, and adverse effects are established. Normally, biological monitoring of exposure cannot be used for assessing exposure to substances that exhibit their toxic effects at the sites of first contact and are poorly absorbed. Examples include dermally corrosive compounds and primary lung irritants. In this situation, the only useful relationship is that between external exposure and the intensity of the local effects.

Relationships between air monitoring and biological monitoring may be modified by genetic or external factors that influence the fate of an occupational toxicant in vivo. Metabolic interactions can occur when workers are exposed simultaneously to chemicals that are biotransformed through identical pathways. Exposure to chemicals that modify the activity of the biotransformation enzymes (e.g., microsomal enzyme inducers or inhibitors) may also influence the fate of another compound. Furthermore, metabolic interferences may occur between occupational toxicants and alcohol, tobacco, food additives, prescription drugs, natural product remedies, or recreational drugs. Changes in any of several biological variables (weight, body mass, pregnancy, diseases, immune status, etc.) may modify the metabolism of an occupational chemical. These factors have to be taken into consideration when the results of biomonitoring are interpreted. Whatever the parameter measured, whether it is the substance itself, its metabolite, or an early biomarker of effect, the test must be sufficiently sensitive and specific to provide meaningful data in the range of workplace exposures.

Some chemicals have a long biological half-life in various body compartments (e.g., hydrophobic persistent organic pollutants) and the time of sampling may not be critical. For other chemicals, the time of sampling is critical because, following exposure, the compounds or their metabolites may be rapidly eliminated from the body. In these cases, the biological sample is usually collected during exposure, at the end of the exposure period, or sometimes just before the next work shift. When biological monitoring consists of the sampling and analysis of urine, it is usually performed on "spot" urine specimens or on the first morning void. It is a standard practice for most organic compounds to adjust the results for urine output by expressing the results per gram of creatinine in the urine. Analyses performed on very dilute urine samples are not reliable. The WHO has specified acceptable limits for urine specimens of between 0.3 and 3.0 g/L creatinine or 1.010–1.030 specific gravity (ACGIH, 2006). When samples exhibit large interindividual variability or high "background" levels the interpretation of a single measurement may be difficult. In such cases, it may be useful to analyze biological material collected before and after the exposure period and gauge exposure based upon the cross-shift change.

The majority of BEIs listed by the ACGIH refer to analysis of the parent compound or its phase I metabolite. Analytical advances over the past decade have yielded methods for detecting reactive intermediates of metabolism and macromolecular adducts that may induce mutations or cell cycle disruption. These methods are important for comparing human and animal toxicity data for risk assessment and may help to explain differential responses in animal models and susceptibility in human populations. These methods are also useful for occupational health surveillance programs.

Environmental monitoring plays an important role in the evaluation and prevention of excessive exposure to toxicants in the workplace. However, the prevention of acute toxic effects on the respiratory tract, skin, or eye mucosa can only be achieved by keeping the concentration of the irritant substance below a certain level or by eliminating the exposure. Local acute effects of chemicals do not lend themselves to a biological surveillance program. Likewise, biological monitoring is usually not indicated for detecting peak exposure to dangerous chemicals such as arsine (AsH_3), carbon monoxide, or prussic acid (HCN). Furthermore, identification

Table 33-9

Control Approaches for Occupational Inhalation Hazards

Change the process to use or produce less hazardous compounds.
Automate and enclose the process to isolate the compounds.
Incorporate administrative and work practice controls to reduce duration or intensity of exposure.
Install or upgrade local exhaust systems and dilution exhaust.
Institute a comprehensive program for personal protective equipment use where necessary.

of emission sources and the evaluation of the efficiency of engineering control measures are usually best performed by ambient air analysis. Table 33-9 lists the approaches most useful for controlling inhalation exposures in the workplace. It should be emphasized that process changes and application of engineering controls are preferable to reliance on personal protective equipment.

In summary, environmental and biological monitoring should not be regarded as opposites but as complementary elements of an occupational health and safety program. They should be integrated as much as possible to ensure low levels of contaminants and optimal health for workers.

CONCLUSION

The working environment will always have the potential to overexpose workers to various toxicants. Recognition of these risks should not wait until epidemiologic studies have uncovered hazardous levels. A combined experimental, clinical, and epidemiologic approach is most effective for evaluating and managing the potential risks. One can then promulgate scientifically based occupational health standards, apply effective workplace controls to ensure adherence to those standards, and institute worker health surveillance programs to identify unexpected effects in susceptible individuals.
