PREFACE

The seventh edition of *Casarett and Doull's Toxicology: The Basic Science of Poisons*, as the previous six, is meant to serve primarily as a text for, or an adjunct to, graduate courses in toxicology. Because the six previous editions have been widely used in courses in environmental health and related areas, an attempt has been made to maintain those characteristics that make it useful to scientists from other disciplines. This edition will again provide information on the many facets of toxicology, especially the principles, concepts, and modes of thoughts that are the foundation of the discipline. Mechanisms of toxicity are emphasized. Research toxicologists will find this book an excellent reference source to find updated material in areas of their special or peripheral interests.

The overall framework of the seventh edition is similar to the sixth edition. The seven units are "General Principles of Toxicology" (Unit 1), "Disposition of Toxicants" (Unit 2), "Non-Organ-Directed Toxicity" (carcinogenicity, mutagenicity, and teratogenicity) (Unit 3), "Target Organ Toxicity" (Unit 4), "Toxic Agents" (Unit 5), "Environmental Toxicology" (Unit 6), and "Applications of Toxicology" (Unit 7).

This edition reflects the marked progress made in toxicology during the last few years. For example, the importance of apoptosis, cytokines, growth factors, oncogenes, cell cycling, receptors, gene regulation, transcription factors, signaling pathways, transgenic animals, "knock-out" animals, polymorphisms, microarray technology, genomics, proteonomics, etc., in understanding the mechanisms of toxicity are included in this edition. More information on environmental hormones is also included. References in this edition include not only traditional journal and review articles, but, internet sites also. (Readers who would like a Power-Point version of the figures and tables can obtain the same from the publisher.)

The editor is grateful to his colleagues in academia, industry, and government who have made useful suggestions for improving this edition, both as a book and as a reference source. The editor is especially thankful to all the contributors, whose combined expertise has made possible a volume of this breadth. I especially recognize John Doull, the original editor of this book, for his continued support.

PREFACE TO THE
FIRST EDITION

This volume has been designed primarily as a textbook for, or adjunct to, courses in toxicology. However, it should also be of interest to those not directly involved in toxicologic education. For example, the research scientist in toxicology will find sections containing current reports on the status of circumscribed areas of special interest. Those concerned with community health, agriculture, food technology, pharmacy, veterinary medicine, and related disciplines will discover the contents to be most useful as a source of concepts and modes of thought that are applicable to other types of investigative and applied sciences. For those further removed from the field of toxicology or for those who have not entered a specific field of endeavor, this book attempts to present a selectively representative view of the many facets of the subject.

Toxicology: The Basic Science of Poisons has been organized to facilitate its use by these different types of users. The first section (Unit I) describes the elements of method and approach that identify toxicology. It includes those principles most frequently invoked in a full understanding of toxicologic events, such as dose-response, and is primarily mechanistically oriented. Mechanisms arc also stressed in the subsequent sections of the book, particularly when these are well identified and extend across classic forms of chemicals and systems. However, the major focus in the second section (Unit II) is on the systemic site of action of toxins. The intent therein is to provide answers to two questions: What kinds of injury are produced in specific organs or systems by toxic agents? What are the agents that produce these effects?

A more conventional approach to toxicology has been utilized in the third section (Unit III), in which the toxic agents are grouped by chemical or use characteristics. In the final section (Unit IV) an attempt has been made to illustrate the ramifications of toxicology into all areas of the health sciences and even beyond. This unit is intended to provide perspective for the nontoxicologist in the application of the results of toxicologic studies and a better understanding of the activities of those engaged in the various aspects of the discipline of toxicology.

It will be obvious to the reader that the contents of this book represent a compromise between the basic, fundamental, mechanistic approach to toxicology and the desire to give a view of the broad horizons presented by the subject. While it is certain that the editors' selectivity might have been more severe, it is equally certain that it could have been less so, and we hope that the balance struck will prove to be appropriate for both toxicologic training and the scientific interest of our colleague.

L.J.C.
J.D.

Although the philosophy and design of this book evolved over a long period of friendship and mutual respect between the editors, the effort needed to convert ideas into reality was undertaken primarily by Louis J. Casarett. Thus, his death at a time when completion of the manuscript was in sight was particularly tragic. With the help and encouragement of his wife, Margaret G. Casarett, and the other contributors, we have finished Lou's task. This volume is a fitting embodiment of Louis J. Casarett's dedication to toxicology and to toxicologic education.

J.D.

CHAPTER 1

HISTORY AND SCOPE OF TOXICOLOGY

Michael A. Gallo

HISTORY OF TOXICOLOGY

    Antiquity
    Middle Ages
    Age of Enlightenment

MODERN TOXICOLOGY

AFTER WORLD WAR II

Toxicology has been defined as the study of the adverse effects of xenobiotics and thus is a borrowing science that has evolved from ancient poisoners. Modern toxicology goes beyond the study of the adverse effects of exogenous agents to the study of molecular biology, using toxicants as tools. Currently, many toxicologists are studying the mechanisms of endogenous compounds such as oxygen radicals and other reactive intermediates generated from xenobiotics and endobiotics. Historically, toxicology formed the basis of therapeutics and experimental medicine. Toxicology in this and last century (1900 to the present) continues to develop and expand by assimilating knowledge and techniques from most branches of biology, chemistry, mathematics, and physics. A recent addition to the field of toxicology (1975 to the present) is the application of this discipline to safety evaluation and risk assessment.

    The contributions and activities of toxicologists are diverse and widespread. In this biomedical area, toxicologists are concerned with mechanisms of action and exposure to chemicals as a cause of acute and chronic illness. Toxicologists contribute to physiology and pharmacology by using toxic chemicals to understand physiological phenomena. They are involved in the recognition, identification, and quantification of hazards resulting from occupational exposure to chemicals and the public health aspects of chemicals in air, water, other parts of the environment, food, and drugs. Traditionally, toxicologists have been intimately involved in the discovery and development of new drugs, food additives, and pesticides. Toxicologists also participate in the development of standards and regulations designed to protect human health and the environment from the adverse effects of chemicals. Environmental toxicologists (a relatively new subset of the discipline) have expanded toxicology to study the effects of chemicals on flora and fauna. Molecular toxicologists are studying the mechanisms by which toxicants modulate cell growth and differentiation and how cells respond to toxicants at the level of the gene. In all branches of toxicology, scientists explore the mechanisms and modes of action by which chemicals produce adverse effects in biological systems. Clinical toxicologists develop antidotes and treatment regimens to ameliorate poisonings from xenobiotic injury. Toxicologists carry out some or all of these activities as members of academic, industrial, and governmental organizations. In fact, these activities help them to share methodologies for obtaining data for toxicity of materials and to make reasonable predictions regarding the hazards of the material to people and the environment using this data. Although different, these complementary activities characterize the discipline of toxicology.

Toxicology, like medicine, is both a science and an art. The science of toxicology is defined as the observational and data-gathering phase, whereas the art of toxicology consists of utilization of data to predict outcomes of exposure in human and animal populations. In most cases, these phases are linked because the facts generated by the science of toxicology are used to develop extrapolations and hypotheses to explain the adverse effects of chemical agents in situations where there is little or no information. For example, the observation that the administration of TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin) to female Sprague Dawley rats induces hepatocellular carcinoma is a fact. However, the conclusion that it will also have a similar affect in humans is unclear whether it is a prediction or hypothesis. Therefore, it is important to distinguish facts from predictions. When we fail to distinguish the science from the art, we confuse facts with predictions and argue that they have equal validity, which they clearly do not suggest. In toxicology, as in all sciences, theories have a higher level of certainty than do hypotheses, which in turn are more certain than speculations, opinions, conjectures, and guesses. An insight into modern toxicology and the roles, points of view, and activities of toxicologists can be obtained by examining the evolution of this discipline.

HISTORY OF TOXICOLOGY

Antiquity

Toxicology dates back to the earliest humans, who used animal venom and plant extracts for hunting, warfare, and assassination. The knowledge of these poisons must have predated recorded history. It is safe to assume that prehistoric humans categorized some plants as harmful and others as safe. The same is probably true for the classification of snakes and other animals. The Ebers papyrus (circa 1500 BC) contains information pertaining to many recognized poisons, including hemlock (the state poison of the Greeks), aconite (a Chinese arrow poison), opium (used as both a poison and an antidote), and metals such as lead, copper, and antimony. There is also an indication that plants containing substances similar to digitalis and belladonna alkaloids were known. Hippocrates (circa 400 BC) added a number of poisons and clinical toxicology principles pertaining to bioavailability in therapy and overdosage, while the Book of Job (circa 400 BC) speaks of poison arrows (Job 6:4). In the literature of ancient Greece, there are several references to poisons and their use. Some interpretations of Homer have Odysseus obtaining poisons for his arrows (Homer, circa 600 BC). Theophrastus (370–286 BC), a student of Aristotle, included numerous references to poisonous

plants in *De Historia Plantarum*. Dioscorides, a Greek physician in the court of the Roman emperor Nero, made the first attempt to classify poisons, which was accompanied by descriptions and drawings. His classification into plant, animal, and mineral poisons not only remained a standard for 16 centuries but is still a convenient classification (Gunther, 1934). Dioscorides also dabbled in therapy, recognizing the use of emetics in poisoning and the use of caustic agents and cupping glasses in snakebite. Poisoning with plant and animal toxins was quite common. Perhaps the best-known recipient of poison used as a state method of execution was Socrates (470–399 BC), whose cup of hemlock extract was apparently estimated to be the proper dose. Expeditious suicide on a voluntary basis also made use of toxicologic knowledge. Demosthenes (385–322 BC), who took poison hidden in his pen, was one of many examples. The mode of suicide calling for one to fall on his sword, although manly and noble, carried little appeal and less significance for the women of the day. Cleopatra's (69–30 BC) knowledge of natural primitive toxicology permitted her to use the more genteel method of falling on her asp.

The Romans too made considerable use of poisons in politics. One legend tells of King Mithridates VI of Pontus, whose numerous acute toxicity experiments on unfortunate criminals led to his eventual claim that he had discovered an antidote for every venomous reptile and poisonous substance (Guthrie, 1946). Mithridates was so fearful of poisons that he regularly ingested a mixture of 36 ingredients (Galen reports 54) as protection against assassination. On the occasion of his imminent capture by enemies, his attempts to kill himself with poison failed because of his successful antidote concoction, and he was forced to use a sword held by a servant. From this tale comes the term "mithridatic," referring to an antidotal or protective mixture. The term "theriac" has also become synonymous with "antidote," although the word comes from the poetic treatise *Theriaca* by Nicander of Colophon (204–135 BC), which dealt with poisonous animals; his poem "Alexipharmaca" was about antidotes.

Poisonings in Rome reached epidemic proportions during the fourth century BC (Livy). It was during this period that a conspiracy of women to remove men from whose death they might profit was uncovered. Similar large-scale poisoning continued until Sulla issued the *Lex Cornelia* (circa 82 BC). This appears to be the first law against poisoning, and it later became a regulatory statute directed at careless dispensers of drugs. Nero (AD 37–68) used poisons to do away with his stepbrother Brittanicus and employed his slaves as food tasters to differentiate edible mushrooms from their more poisonous kin.

Middle Ages

Come bitter pilot, now at once run on
The dashing rocks thy seasick weary bark!
Here's to my love! O true apothecary!
Thy drugs are quick. Thus with a kiss I die.
        (Romeo and Juliet, act 5, scene 3)

Before the Renaissance, the writings of Maimonides (Moses ben Maimon, AD 1135–1204) included a treatise on the treatment of poisonings from insects, snakes, and mad dogs (*Poisons and Their Antidotes*, 1198). Maimonides, like Hippocrates before him, wrote on the subject of bioavailability, noting that milk, butter, and cream could delay intestinal absorption. Malmonides also refuted many of the popular remedies of the day and stated his doubts about others. It is rumored that alchemists of this period (circa AD 1200), in search

of the universal antidote, learned to distill fermented products and made a 60% ethanol beverage that had many interesting powers.

In the early Renaissance, the Italians, with characteristic pragmatism, brought the art of poisoning to its zenith. The poisoner became an integral part of the political scene. The records of the city councils of Florence, particularly those of the infamous Council of Ten of Venice, contain ample testimony about the political use of poisons. Victims were named, prices set, and contracts recorded; when the deed was accomplished, payment was made.

An infamous figure of the time was a lady named Toffana who peddled specially prepared arsenic-containing cosmetics (*Agua Toffana*). Accompanying the product were appropriate instructions for its use. Toffana was succeeded by an imitator with organizational genius, Hieronyma Spara, who provided a new fillip by directing her activities toward specific marital and monetary objectives. A local club was formed of young, wealthy, married women, which soon became a club of eligible young wealthy widows, reminiscent of the matronly conspiracy of Rome centuries earlier. Incidentally, arsenic-containing cosmetics were reported to be responsible for deaths well into the twentieth century (Kallett and Schlink, 1933).

Among the prominent families engaged in poisoning, the Borgias were the most notorious. However, many deaths that were attributed to poisoning are now recognized as having resulted from infectious diseases such as malaria. It appears true, however, that Alexander VI, his son Cesare, and Lucrezia Borgia were quite active. The deft application of poisons to men of stature in the Catholic Church swelled the holdings of the papacy, which was their prime heir.

In this period Catherine de Medici exported her skills from Italy to France, where the prime targets of women were their husbands. However, unlike poisoners of an earlier period, the circle represented by Catherine and epitomized by the notorious Marchioness de Brinvilliers depended on developing direct evidence to arrive at the most effective compounds for their purposes. Under the guise of delivering provender to the sick and the poor, Catherine tested toxic concoctions, carefully noting the rapidity of the toxic response (onset of action), the effectiveness of the compound (potency), the degree of response of the parts of the body (specificity, site of action), and the complaints of the victim (clinical signs and symptoms).

The culmination of the practice in France is represented by the commercialization of the service by Catherine Deshayes, who earned the title "La Voisine." Her business was dissolved by her execution. Her trial was one of the most famous of those held by the Chambre Ardente, a special judicial commission established by Louis XIV to try such cases without regard to age, sex, or national origin. La Voisine was convicted of many poisonings, with over 2000 infants among her victims.

Age of Enlightenment

All substances are poisons; there is none which is not a poison. The right dose differentiates poison from a remedy.

                                            Paracelsus

A significant figure in the history of science and medicine in the late Middle Ages was the renaissance man Philippus Aureolus Theophrastus Bombastus von Hohenheim-Paracelsus (1493–1541). Between the time of Aristotle and the age of Paracelsus, there was little substantial change in the biomedical sciences. In the sixteenth century, the revolt against the authority of the Catholic Church was accompanied by a parallel attack on the godlike authority exercised

by the followers of Hippocrates and Galen. Paracelsus personally and professionally embodied the qualities that forced numerous changes in this period. He and his age were pivotal, standing between the philosophy and magic of classical antiquity and the philosophy and science willed to us by figures of the seventeenth and eighteenth centuries. Clearly, one can identify in Paracelsus's approach, point of view, and breadth of interest numerous similarities to the discipline that is now called toxicology.

Paracelsus, a physician-alchemist and the son of a physician, formulated many revolutionary views that remain an integral part of the structure of toxicology, pharmacology, and therapeutics today (Pagel, 1958). He promoted a focus on the "toxicon," the primary toxic agent, as a chemical entity, as opposed to the Grecian concept of the mixture or blend. A view initiated by Paracelsus that became a lasting contribution held as corollaries that (1) experimentation is essential in the examination of responses to chemicals, (2) one should make a distinction between the therapeutic and toxic properties of chemicals, (3) these properties are sometimes but not always indistinguishable except by dose, and (4) one can ascertain a degree of specificity of chemicals and their therapeutic or toxic effects. These principles led Paracelsus to introduce mercury as the drug of choice for the treatment of syphilis, a practice that survived 300 years but led to his famous trial. This viewpoint presaged the "magic bullet" (arsphenamine) of Paul Ehrlich and the introduction of the therapeutic index. Further, in a very real sense, this was the first sound articulation of the dose–response relation, a bulwark of toxicology (Pachter, 1961).

The tradition of the poisoners spread throughout Europe, and their deeds played a major role in the distribution of political power throughout the Middle Ages. Pharmacology as it is known today had its beginnings during the Middle Ages and early Renaissance. Concurrently, the study of the toxicity and the dose–response relationship of therapeutic agents was commencing.

The occupational hazards associated with metalworking were recognized during the fifteenth century. Early publications by Ellenbog (circa 1480) warned of the toxicity of the mercury and lead exposures involved in goldsmithing. Agricola published a short treatise on mining diseases in 1556. However, the major work on the subject, *On the Miners' Sickness and Other Diseases of Miners* (1567), was published by Paracelsus. This treatise addressed the etiology of miners' disease, along with treatment and prevention strategies. Occupational toxicology was further advanced by the work of Bernardino Ramazzini. His classic, published in 1700 and entitled *Discourse on the Diseases of Workers,* set the standard for occupational medicine well into the nineteenth century. Ramazzini's work broadened the field by discussing occupations ranging from miners to midwives and including printers, weavers, and potters.

The developments of the Industrial Revolution stimulated a rise in many occupational diseases. Percival Pott's (1775) recognition of the role of soot in scrotal cancer among chimney sweepers was the first reported example of polyaromatic hydrocarbon carcinogenicity, a problem that still plagues toxicologists today. These findings led to improved medical practices, particularly in prevention. It should be noted that Paracelsus and Ramazzini also pointed out the toxicity of smoke and soot.

The nineteenth century dawned in a climate of industrial and political revolution. Organic chemistry was in its infancy in 1800, but by 1825 phosgene ($COCl_2$) and mustard gas (bis[B-chloroethyl]sulfide) had been synthesized. These two chemicals were used in World War I as war gases, and as late as the Iraq–Iran War in the late twentieth century. By 1880 over 10,000 organic compounds had been synthesized including chloroform, carbon tetrachloride, diethyl ether, and carbonic acid, and petroleum and coal gasification by-products were used in trade (Zapp, 1982). The toxicity of benzene was established at the turn of the twentieth century. Determination of the toxicologic potential of these newly created chemicals became the underpinning of the science of toxicology as it is practiced today. However, there was little interest during the mid-nineteenth century in hampering industrial development. Hence, the impact of industrial toxicology discoveries was not felt until the passage of worker's insurance laws, first in Germany (1883), then in England (1897), and later in the United States (1910).

Experimental toxicology accompanied the growth of organic chemistry and developed rapidly during the nineteenth century. Magendie (1783–1885), Orfila (1787–1853), and Bernard (1813–1878) carried out truly seminal research in experimental toxicology and laid the groundwork for pharmacology and experimental therapeutics as well as occupational toxicology.

Orfila, a Spanish physician in the French court, was the first toxicologist to use autopsy material and chemical analysis systematically as legal proof of poisoning. His introduction of this detailed type of analysis survives as the underpinning of forensic toxicology (Orfila, 1818). Orfila published the first major work devoted expressly to the toxicity of natural agents (1815). Magendie, a physician and experimental physiologist, studied the mechanisms of action of emetine, strychnine, and "arrow poisons" (Olmsted, 1944). His research into the absorption and distribution of these compounds in the body remains a classic in toxicology and pharmacology. One of Magendie's more famous students, Claude Bernard, continued the study of arrow poisons (Bernard, 1850) but also added works on the mechanism of action of carbon monoxide. Bernard's treatise, *An Introduction to the Study of Experimental Medicine* (translated by Greene in 1949), is a classic in the development of toxicology.

Many German scientists contributed greatly to the growth of toxicology in the late nineteenth and early twentieth centuries. Among the giants of the field are Oswald Schmiedeberg (1838–1921) and Louis Lewin (1850–1929). Schmiedeberg made many contributions to the science of toxicology, not the least of which was the training of approximately 120 students who later populated the most important laboratories of pharmacology and toxicology throughout the world. Many of today's toxicologists and pharmacologists can trace their scientific heritage back to Schmiedeberg. His research focused on the synthesis of hippuric acid in the liver and the detoxification mechanisms of the liver in several animal species (Schmiedeberg and Koppe, 1869). Lewin, who was educated originally in medicine and the natural sciences, trained in toxicology under Liebreich at the Pharmacological Institute of Berlin (1881). His contributions on the chronic toxicity of narcotics and other alkaloids remain a classic. Lewin also published much of the early work on the toxicity of methanol, glycerol, acrolein, and chloroform (Lewin, 1920, 1929).

MODERN TOXICOLOGY

Toxicology has evolved rapidly during the 1900s. The exponential growth of the discipline can be traced to the World War II era with its marked increase in the production of drugs, pesticides, munitions, synthetic fibers, and industrial chemicals. The history of many sciences represents an orderly transition based on theory, hypothesis testing, and synthesis of new ideas. Toxicology, as a gathering and an applied science, has, by contrast, developed in fits and starts. Toxicology calls on almost all the basic sciences to test

its hypotheses. This fact, coupled with the health and occupational regulations that have driven toxicology research since 1900, has made this discipline exceptional in the history of science. The differentiation of toxicology as an art and a science, though arbitrary, permits the presentation of historical highlights along two major lines.

Modern toxicology can be viewed as a continuation of the development of the biological and physical sciences in the late nineteenth and twentieth centuries (Table 1-1). During the second half of the nineteenth century, the world witnessed an explosion in science that produced the beginning of the modern era of genetics, medicine, synthetic chemistry, physics, and biology. Toxicology has drawn its strength and diversity from its proclivity to borrowing. With the advent of anesthetics and disinfectants and the advancement of experimental pharmacology in the late 1850s, toxicology as it is currently understood got its start. The introduction of ether, chloroform, and carbonic acid led to several iatrogenic deaths. These unfortunate outcomes spurred research into the causes of the deaths and early experiments on the physiological mechanisms by which these compounds caused both beneficial and adverse effects. By the late nineteenth century the use of organic chemicals was becoming more widespread, and benzene, toluene, and the xylenes went into larger-scale commercial production. Interestingly, benzene was used as a drug to treat leukemia in the early 1900s.

During this period, the use of "patent" medicines was prevalent, and there were several incidents of poisonings from these medicaments. The adverse reactions to patent medicines, coupled with the response to Upton Sinclair's exposé of the meat-packing industry in *The Jungle,* culminated in the passage of the Wiley Bill (1906), the first of many U.S. pure food and drug laws (see Hutt and Hutt, 1984, for regulatory history).

A working hypothesis about the development of toxicology is that the discipline expands in response to legislation, which itself is a response to a real or perceived tragedy. The Wiley bill was the first such reaction in the area of food and drugs, and the worker's compensation laws cited above were a response to occupational toxicities. In addition, the National Safety Council was established in 1911, and the Division of Industrial Hygiene was established by the U.S. Public Health Service in 1914. A corollary to this hypothesis might be that the founding of scientific journals and/or societies is sparked by the development of a new field. The *Journal of Industrial Hygiene* began in 1918. The major chemical manufacturers in

Table 1.1
Selection of Developments in Toxicology

Development of early advances in analytic methods
    Marsh, 1836: development of method for arsenic analysis
    Reinsh, 1841: combined method for separation and analysis of As and Hg
    Fresenius, 1845, and von Babo, 1847: development of screening method for general poisons
    Stas-Otto, 1851: detection and identification of phosphorus
Early mechanistic studies
    F. Magendie, 1809: study of "arrow poisons," mechanism of action of emetine and strychnine
    C. Bernard, 1850: carbon monoxide combination with hemoglobin, study of mechanism of action of strychnine, site of action of curare
    R. Bohm, ca. 1890: active anthelmintics from fern, action of croton oil catharsis, poisonous mushrooms
Introduction of new toxicants and antidotes
    R. A. Peters, L. A. Stocken, and R. H. S. Thompson, 1945: development of British Anti Lewisite BAL) as a relatively specific antidote for arsenic, toxicity of monofluorocarbon compounds
    K. K. Chen, 1934: introduction of modern antidotes (nitrite and thiosulfate) for cyanide toxicity
    C. Voegtlin, 1923: mechanism of action of As and other metals on the SH groups
    P. Müller, 1944–1946: introduction and study of DDT (dichlorodiphenyltrichloroethane) and related insecticide compounds
    G. Schrader, 1952: introduction and study of organophosphorus compounds
    R. N. Chopra, 1933: indigenous drugs of India
Miscellaneous toxicologic studies
    R. T. Williams: study of detoxication mechanisms and species variation
    A. Rothstein: effects of uranium ion on cell membrane transport
    R. A. Kehoe: investigation of acute and chronic effects of lead
    A. Vorwald: studies of chronic respiratory disease (beryllium)
    H. Hardy: community and industrial poisoning (beryllium)
    A. Hamilton: introduction of modern industrial toxicology
    H. C. Hodge: toxicology of uranium, fluorides; standards of toxicity
    A. Hoffman: introduction of lysergic acid and derivatives; pscyhotomimetics
    R. A. Peters: biochemical lesions, lethal synthesis
    A. E. Garrod: inborn errors of metabolism
    T. T. Litchfield and F. Wilcoxon: simplified dose-response evaluation
    C. J. Bliss: method of probits, calculation of dosage-mortality curves

the United States (Dow, Union Carbide, and DuPont) established internal toxicology research laboratories to help guide decisions on worker health and product safety.

During the 1890s and early 1900s, the French scientists Becquerel and the Curies reported the discovery of "radioactivity." This opened up for exploration a very large area in physics, biology, and medicine, but it would not affect the science of toxicology for another 40 years. However, another discovery, that of vitamins, or "vital amines," was to lead to the use of the first large-scale bioassays (multiple animal studies) to determine whether these "new" chemicals were beneficial or harmful to laboratory animals. The initial work in this area took place at around the time of World War I in several laboratories, including the laboratory of Philip B. Hawk in Philadelphia. Hawk and a young associate, Bernard L. Oser, were responsible for the development and verification of many early toxicologic assays that are still used in a slightly amended form. Oser's contributions to food and regulatory toxicology were extraordinary. These early bioassays were made possible by two major advances in toxicology: the availability of developed and refined strains of inbred laboratory rodents (Donaldson, 1912), and the analytical chemical capability to assay urine and blood for residues.

The 1920s saw many events that began to mold the fledgling field of toxicology. The use of arsenicals for the treatment of diseases such as syphilis (arsenicals had been used in agriculture since the mid-nineteenth century) resulted in acute and chronic toxicity. Prohibition of alcoholic beverages in the United States opened the door for early studies of neurotoxicology, with the discovery that triorthocresyl phosphate (TOCP), methanol, and lead (all products of "bootleg" liquor) are neurotoxicants. TOCP, which until recently was a gasoline additive, caused a syndrome that became known as "ginger-jake" walk, a spastic gait resulting from drinking adulterated ginger beer. Mueller's discovery of DDT (dichlorodiphenyl-trichloroethane) and several other organohalides, such as hexachlorobenzene and hexachlorocyclohexane, during the late 1920s resulted in wider use of insecticidal agents. Other scientists were hard at work attempting to elucidate the structures and activity of the estrogens and androgens. Work on the steroid hormones led to the use of several assays for the determination of the biological activity of organ extracts and synthetic compounds. Efforts to synthesize steroid-like chemicals were spearheaded by E. C. Dodds and his co-workers, one of whom was Leon Golberg, a young organic chemist. Dodds's work on the bioactivity of the estrogenic compounds resulted in the synthesis of diethylstilbestrol (DES), hexestrol, and other stilbenes and the discovery of the strong estrogenic activity of substituted stilbenes; eventually leading to the Nobel Prize in Medicine. Golberg's intimate involvement in this work stimulated his interest in biology, leading to degrees in biochemistry and medicine and a career in toxicology in which he oversaw the creation of the laboratories of the British Industrial Biological Research Association (BIBRA) and the Chemical Industry Institute of Toxicology (CIIT). Interestingly, the initial observations that led to the discovery of DES were the findings of feminization of animals treated with the experimental carcinogen 7,12-dimethylbenz[a]anthracene (DMBA).

The 1930s saw the world preparing for World War II and a major effort by the pharmaceutical and chemical industries in Germany and the United States to manufacture the first mass-produced antibiotics, and warfare agents. One of the first journals expressly dedicated to experimental toxicology, *Archiv für Toxikologie,* began publication in Europe in 1930, the same year that Herbert Hoover signed the act that established the National Institutes of Health (NIH) in the United States.

The discovery of sulfanilamide was heralded as a major event in combating bacterial diseases. However, for a drug to be effective, there must be a reasonable delivery system, and sulfanilamide is highly insoluble in an aqueous medium. Therefore, it was originally prepared in ethanol (elixir). However, it was soon discovered that the drug was more soluble in diethylene glycol, which is a dihydroxy rather than a monohydroxy ethane. The drug was sold in the diethylene glycol solution but was labeled as an elixir, and several patients died of acute renal failure resulting from the metabolism of the glycol to oxalic acid and glycolic acid, with the acids, along with the active drug, crystallizing in the kidney tubules. This tragic event led to the passage of the Copeland bill in 1938, the second major bill involving the formation of the U.S. Food and Drug Administration (FDA). The sulfanilamide disaster played a critical role in the further development of toxicology, resulting in work by Eugene Maximillian Geiling (a direct scientific offspring of John Jacob Abel and Schmiedeberg) in the Pharmacology Department of the University of Chicago that elucidated the mechanism of toxicity of both sulfanilamide and ethylene glycol. Studies of the glycols were simultaneously carried out at the U.S. FDA by a group led by Arnold Lehman. The scientists associated with Lehman and Geiling were to become the leaders of toxicology over the next 40 years. With few exceptions, toxicology in the United States owes its heritage to Geiling's innovativeness and ability to stimulate and direct young scientists and Lehman's vision of the use of experimental toxicology in public health decision making. Because of Geiling's reputation, the U.S. government turned to this group for help in the war effort. There were three main areas in which the Chicago group took part during World War II: the toxicology and pharmacology of organophosphate chemicals, antimalarial drugs, and radionuclides. Each of these areas produced teams of toxicologists who became academic, governmental, and industrial leaders in the field.

It was also during this time that DDT and the phenoxy herbicides were developed for increased food production and, in the case of DDT, control of insect-borne diseases. These efforts between 1940 and 1946 led to an explosion in toxicology. Thus, in line with the hypothesis advanced above, the crisis of World War II caused the next major leap in the development of toxicology.

If one traces the history of the toxicology of metals over the past 45 years, the role of the Chicago group, and Rochester, is quite apparent. This story commences with the use of uranium for the "bomb" and continues today with research on the role of metals in their interactions with DNA, RNA, and growth factors. Indeed, the Manhattan Project created a fertile environment that resulted in the initiation of quantitative biology, drug metabolism and structure activity relationships (with antimalarials), radiotracer technology, and inhalation toxicology. These innovations have revolutionized modern biology, chemistry, therapeutics, and toxicology.

Inhalation toxicology began at the University of Rochester under the direction of Stafford Warren, who headed the Department of Radiology. He developed a program with colleagues such as Harold Hodge (pharmacologist), Herb Stokinger (chemist), Sid Laskin (inhalation toxicologist), and Lou and George Casarett (toxicologists). These young scientists were to go on to become giants in the field. The other sites for the study of radionuclides were Chicago for the "internal" effects of radioactivity and Oak Ridge, Tennessee, for the effects of "external" radiation. The work of the scientists on these teams gave the scientific community data that contributed to the early understanding of macromolecular binding of xenobiotics,

cellular mutational events, methods for inhalation toxicology and therapy, and toxicological properties of trace metals, along with a better appreciation of the complexities of the dose–response curve.

Another seminal event in toxicology that occurred during the World War II era was the discovery of organophosphate cholinesterase inhibitors. This class of chemicals, which was discovered by Willy Lange and Gerhard Schrader, was destined to become a driving force in the study of neurophysiology and toxicology for several decades. Again, the scientists in Chicago played major roles in elucidating the mechanisms of action of this new class of compounds. Geiling's group, Kenneth Dubois in particular, were leaders in this area of toxicology and pharmacology. Dubois's students, particularly Sheldon Murphy (and his students), continued to be in the forefront of this special area. The importance of the early research on the organophosphates has taken on special meaning in the years since 1960, when these non-bioaccumulating insecticides were destined to replace DDT and other organochlorine insecticides.

Early in the twentieth century, it was demonstrated experimentally that quinine has a marked effect on the malaria parasite [it had been known for centuries that chincona bark extract is efficacious for "Jesuit fever" (malaria)]. This discovery led to the development of quinine derivatives for the treatment of the disease and the formulation of the early principles of chemotherapy. The pharmacology department at Chicago was charged with the development of antimalarials for the war effort. The original protocols called for testing of efficacy and toxicity in rodents and perhaps dogs and then the testing of efficacy in human volunteers. One of the investigators charged with generating the data needed to move a candidate drug from animals to humans was Fredrick Coulston. This young parasitologist and his colleagues, working under Geiling, were to evaluate potential drugs in animal models and then establish human clinical trials. It was during these experiments that the use of nonhuman primates came into vogue for toxicology testing. It had been noted by Russian scientists that some antimalarial compounds caused retinopathies in humans but did not apparently have the same adverse effect in rodents and dogs. This finding led the Chicago team to add one more step in the development process: toxicity testing in rhesus monkeys just before efficacy studies in people. This resulted in the prevention of blindness in untold numbers of volunteers and perhaps some of the troops in the field. It also led to the school of thought that nonhuman primates may be one of the better models for humans and the establishment of primate colonies for the study of toxicity. Coulston pioneered this area of toxicology and remained committed to it until his death in 2003.

Another area not traditionally thought of as toxicology but one that evolved during the 1940s as an exciting and innovative field is experimental pathology. This branch of experimental biology developed from bioassays of estrogens and early experiments in chemical- and radiation-induced carcinogenesis. It is from these early studies that hypotheses on tumor promotion and cancer progression have evolved.

Toxicologists today owe a great deal to the researchers of chemical carcinogenesis of the 1940s. Much of today's work can be traced to Elizabeth and James Miller at Wisconsin. This husband and wife team started under the mentorship of Professor Rusch, the director of the newly formed McArdle Laboratory for Cancer Research, and Professor Baumann. The seminal research of the Millers, and a young Allen Conney, led to the discovery of the role of reactive intermediates in carcinogenicity and that of mixed-function oxidases in the endoplasmic reticulum. Conney's discovery of benzo(a)pyrene hydroxylase induction in the 1950s opened the field of chemical

metabolism that has resulted in the elucidation of the arylhydrocarbon receptor in the 1970s and 1980s. These findings, which initiated the great works on the cytochrome-P450 family of proteins, were aided by two other major discoveries for which toxicologists (and all other biological scientists) are deeply indebted: paper chromatography in 1944 and the use of radiolabeled dibenzanthracene in 1948. Other major events of note in drug metabolism included the work of Bernard Brodie on the metabolism of methyl orange in 1947. This piece of seminal research led to the examination of blood and urine for chemical and drug metabolites. It became the tool with which one could study the relationship between blood levels and biological action. The classic treatise of R. T. Williams, *Detoxication Mechanisms,* was published in 1947. This text described the many pathways and possible mechanisms of detoxication and opened the field to several new areas of study.

The decade after World War II was not as boisterous as the period from 1935 to 1945. The first major U.S. Pesticide Act was signed into law in 1947. The significance of the initial Federal Insecticide, Fungicide, and Rodenticide Act was that for the first time in U.S. history a substance that was neither a drug nor a food had to be shown to be safe and efficacious. This decade, which coincided with the Eisenhower years, saw the dispersion of the groups from Chicago, Rochester, and Oak Ridge and the establishment of new centers of research. Adrian Albert's classic *Selective Toxicity* was published in 1951. This treatise, which has appeared in several editions, presented a concise documentation of the principles of the site-specific action of chemicals.

AFTER WORLD WAR II

You too can be a toxicologist in two easy lessons, each of ten years.
Arnold Lehman (circa 1955)

The mid-1950s witnessed the strengthening of the U.S. Food and Drug Administration's commitment to toxicology under the guidance of Arnold Lehman. Lehman's tutelage and influence are still felt today. The adage "*You too can be a toxicologist...*" is as important a summation of toxicology as the often-quoted statement of Paracelsus: *"The dose makes the poison."* The period from 1955 to 1958 produced two major events that would have a long-lasting impact on toxicology as a science and a professional discipline. Lehman, Fitzhugh, and their co-workers formalized the experimental program for the appraisal of food, drug, and cosmetic safety in 1955, updated by the U.S. FDA in 1982, and the Gordon Research Conferences established a conference on toxicology and safety evaluation, with Bernard L. Oser as its initial chairman. These two events led to close relationships among toxicologists from several groups and brought toxicology into a new phase. At about the same time, the U.S. Congress passed and the President of the United States signed the additives amendments to the Food, Drug, and Cosmetic Act. The Delaney clause (1958) of these amendments stated broadly that any chemical found to be carcinogenic in laboratory animals or humans could not be added to the U.S. food supply. The impact of this food additive legislation cannot be overstated. Delaney became a battle cry for many groups and resulted in the inclusion at a new level of biostatisticians and mathematical modelers in the field of toxicology. It fostered the expansion of quantitative methods in toxicology and led to innumerable arguments about the "one-hit" theory of carcinogenesis. Regardless of one's view of Delaney, it has served as an excellent starting point for understanding the complexity of the biological phenomenon of carcinogenicity and the development

of risk assessment models. One must remember that at the time of Delaney, the analytic detection level for most chemicals was 20 to 100 ppm (today, parts per quadrillion). Interestingly, the Delaney clause has been invoked only on a few occasions, and it has been stated that Congress added little to the food and drug law with this clause (Hutt and Hutt, 1984).

Shortly after the Delaney Amendment and after three successful Gordon Conferences, the first American journal *Toxicology and Applied Pharmacology* dedicated to toxicology was launched by Coulston, Lehman, and Hayes. Since 1960, over 50 journals and innumerable societies have been launched to disseminate toxicological information. The founding of the Society of Toxicology followed shortly afterward, and became its official publication. The Society's founding members were Fredrick Coulston, William Deichmann, Kenneth DuBois, Victor Drill, Harry Hayes, Harold Hodge, Paul Larson, Arnold Lehman, and C. Boyd Shaffer. These researchers deserve a great deal of credit for the growth of toxicology. DuBois and Geiling published their *Textbook of Toxicology* in 1959. The text you are reading is a continuum of the DuBois and Geiling classic.

The 1960s were a tumultuous time for society, and toxicology was swept up in the tide. Starting with the tragic thalidomide incident, in which several thousand children were born with serious birth defects, and the publication of Rachel Carson's *Silent Spring* (1962), the field of toxicology developed at a feverish pitch. Attempts to understand the effects of chemicals on the embryo and fetus and on the environment as a whole gained momentum. New legislation was passed, and new journals were founded. The education of toxicologists spread from the deep traditions at Chicago and Rochester to Harvard, Miami, Albany, Iowa, Jefferson, and beyond. Geiling's fledglings spread as Schmiedeberg's had a half century before. Many new fields were influencing and being assimilated into the broad scope of toxicology, including environmental sciences, aquatic and avian biology, biostatistics, risk modeling, cell biology, analytic chemistry, and molecular genetics.

During the 1960s, particularly the latter half of the decade, the analytic tools used in toxicology were developed to a level of sophistication that allowed the detection of chemicals in tissues and other substrates at part per billion concentrations (today, parts per quadrillion may be detected). Pioneering work in the development of point mutation assays that were replicable, quick, and inexpensive led to a better understanding of the genetic mechanisms of carcinogenicity (Ames, 1983). The combined work of Ames, the Millers (Elizabeth C. and James A.) at McArdle Laboratory, Cooney, and others allowed the toxicology community to make major contributions to the understanding of the carcinogenic process.

The low levels of detection of chemicals and the ability to detect point mutations rapidly created several problems and opportunities for toxicologists and risk assessors that stemmed from interpretation of the Delaney amendment. Cellular and molecular toxicology developed as a subdiscipline, and risk assessment became a major product of toxicological investigations.

The establishment of the National Center for Toxicologic Research (NCTR), the expansion of the role of the U.S. FDA, and the establishment of the U.S. Environmental Protection Agency (EPA) and the National Institute of Environmental Health Sciences (NIEHS) were considered clear messages that the government had taken a strong interest in toxicology. Several new journals appeared during the 1960s, and new legislation was written quickly after *Silent Spring* and the thalidomide disaster.

The end of the 1960s witnessed the "discovery" of TCDD as a contaminant in the herbicide Agent Orange (the original discovery

of TCDD toxicity, as the "Chick Edema Factor," was reported in 1957). The research on the toxicity of this compound has produced seminal findings regarding signal transduction, and some very poor research in the field of toxicology. The discovery of a high-affinity cellular binding protein designated the "Ah" receptor (see Poland and Knutsen, 1982, for a review) at the McArdle Laboratory and work on the genetics of the receptor at NIH (Nebert and Gonzalez, 1987; Thomas *et al*., 1972) have revolutionized the field of toxicology. The importance of TCDD to toxicology lies in the fact that it forced researchers, regulators, and the legal community to look at the role of mechanisms of toxic action in a different fashion. The compound is a potent carcinogen in several species but is not a mutagen.

At least two other events precipitated a great deal of legislation during the 1970s: Love Canal and Kepone in the James River. The "discovery" of Love Canal led to major concerns regarding hazardous wastes, chemical dump sites, and disclosure of information about those sites. Soon after Love Canal, the EPA listed several equally contaminated sites in the United States. The agency was given the responsibility to develop risk assessment methodology to determine health risks from exposure to effluents and to attempt to remediate these sites. These combined efforts led to broad-based support for research into the mechanisms of action of individual chemicals and complex mixtures. Love Canal and similar issues created the legislative environment that led to the Toxic Substances Control Act and eventually to the Superfund bill. These omnibus bills were created to cover the toxicology of chemicals from initial synthesis to disposal (cradle to grave).

The expansion of legislation, journals, and new societies involved with toxicology was exponential during the 1970s and 1980s and shows no signs of slowing down. Currently, in the United States there are dozens of professional, governmental, and other scientific organizations with thousands of members and over 120 journals dedicated to toxicology and related disciplines.

In addition, toxicology continues to expand in stature and in the number of programs worldwide. The International Congress of Toxicology is made up of toxicology societies from Europe, South America, Asia, Africa, and Australia and brings together the broadest representation of toxicologists.

The original Gordon Conference series has changed to Mechanisms of Toxicity, and several other conferences related to special areas of toxicology are now in existence. The Society of Toxicology in the United States has formed specialty sections and regional chapters to accommodate the over 5000 scientists involved in toxicology today. The American College of Toxicology has developed into an excellent venue for regulatory and industrial toxicology, and two boards have been established to accredit and certify toxicologists (The Academy of Toxicological Sciences and the American Board of Toxicology). Texts and reference books for toxicology students and scientists abound. Toxicology has evolved from a borrowing science to a seminal discipline seeding the growth and development of several related fields of science and science policy.

The history of toxicology has been interesting and varied but never dull. Perhaps as a science that has grown and prospered by borrowing from many disciplines, it has suffered from the absence of a single goal, but its diversification has allowed for the interspersion of ideas and concepts from higher education, industry, and government. As an example of this diversification, one now finds toxicology graduate programs in medical schools, schools of public health, and schools of pharmacy as well as programs in environmental science and engineering, as well as undergraduate programs in toxicology at several institutions. Surprisingly, courses in toxicology

are now being offered in several liberal arts undergraduate schools as part of their biology and chemistry curricula. This has resulted in an exciting, innovative, and diversified field that is serving science and the community at large.

Few disciplines can point to both basic sciences and direct applications at the same time. Toxicology—the study of the adverse effects of xenobiotics (and more recently endobiotics)—may be unique in this regard.

PRINCIPLES OF TOXICOLOGY

David L. Eaton and Steven G. Gilbert

INTRODUCTION TO TOXICOLOGY

Toxicology is the study of the adverse effects of chemical or physical agents on living organisms. A *toxicologist* is trained to examine and communicate the nature of those effects on human, animal, and environmental health. Toxicological research examines the cellular, biochemical, and molecular mechanisms of action as well as functional effects such as neurobehavioral and immunological, and assesses the probability of their occurrence. Fundamental to this process is characterizing the relation of exposure (or dose) to the response. *Risk assessment* is the quantitative estimate of the potential effects on human health and environmental significance of various types of chemical exposures (e.g., pesticide residues on food, contaminants in drinking water). The variety of potential adverse effects and the diversity of chemicals in the environment make toxicology a broad science, which often demands specialization in one area of toxicology. Our society's dependence on chemicals and the need to assess potential hazards have made toxicologists an increasingly important part of the decision-making processes.

Different Areas of Toxicology

The professional activities of toxicologists fall into three main categories: descriptive, mechanistic, and regulatory (Fig. 2-1). Although each has distinctive characteristics, each contributes to the other, and all are vitally important to chemical risk assessment (see Chap. 4).

A *mechanistic toxicologist* is concerned with identifying and understanding the cellular, biochemical, and molecular mechanisms by which chemicals exert toxic effects on living organisms (see Chap. 3 for a detailed discussion of mechanisms of toxicity). The results of mechanistic studies are very important in many areas of applied toxicology. In risk assessment, mechanistic data may be very useful in demonstrating that an adverse outcome (e.g., cancer, birth defects) observed in laboratory animals is directly relevant to humans. For example, the relative toxic potential of organophosphate insecticides in humans, rodents, and insects can be accurately predicted on the basis of an understanding of common mechanisms (inhibition of acetylcholinesterase) and differences in biotransformation for these insecticides among the different species. Similarly, mechanistic data may be very useful in identifying adverse
Figure 2-1. Graphical representation of the interconnections between different areas of toxicology.

responses in experimental animals that may not be relevant to humans. For example, the propensity of the widely used artificial sweetener saccharin to cause bladder cancer in rats may not be relevant to humans at normal dietary intake rates. This is because mechanistic studies have demonstrated that bladder cancer is induced only under conditions where saccharin is at such a high concentration in the urine that it forms a crystalline precipitate (Cohen, 1998). Dose–response studies suggest that such high concentrations would not be achieved in the human bladder even after extensive dietary consumption.

Mechanistic data are also useful in the design and production of safer alternative chemicals and in rational therapy for chemical poisoning and treatment of disease. For example, the drug thalidomide was originally marketed in Europe and Australia as a sedative agent for pregnant women. However, it was banned for clinical use in 1962 because of devastating birth defects that occurred if the drug was ingested during a critical period in pregnancy. But mechanistic studies over the past several decades have demonstrated that this drug may have a unique molecular mechanism of action that interferes with the expression of certain genes responsible for blood vessel formation (angiogenesis). With an understanding of this mechanism, thalidomide has been "rediscovered" as a valuable therapeutic agent that may be highly effective in the treatment of certain infectious diseases (e.g., leprosy and AIDS), a variety of inflammatory diseases, and some types of cancer. This provides an interesting example of how a highly toxic drug with selectivity toward a specific population (pregnant women) can be used safely with proper precautions. Following its approval for therapeutic use in 1998, a program was established that required all clinicians, pharmacists, and patients that receive thalidomide to enroll in a specific program (System for Thalidomide Education and Prescribing Safety, STEPS). The population at risk for the potential teratogenic effects of thalidomide (all women of childbearing age) were required to use two forms of birth control, and also have a negative pregnancy test within 24 hours of beginning therapy, and periodically the patients registered with the STEPS program, 6000 were females of childbearing age. Remarkably, after 6 years of use, only one patient actually received thalidomide during her pregnancy. She initially tested negative at the beginning of therapy; on a subsequent test she was identified

as positive, and the drug was stopped. The pregnancy ended up as a miscarriage (Uhl *et al.*, 2006). Thus, a clear understanding of mechanism of action led to the development of strict prescribing guidelines and patient monitoring, thereby allowing a potentially dangerous drug to be used safely and effectively to treat disease in tens of thousands of patients who would otherwise not have benefited from the therapeutic actions of the drug (Lary *et al.*, 1999).

In addition to aiding directly in the identification, treatment, and prevention of chemical toxicity, an understanding of the mechanisms of toxic action contributes to the knowledge of basic physiology, pharmacology, cell biology, and biochemistry. The advent of new technologies in molecular biology and genomics now provide mechanistic toxicologists with the tools to explore exactly how humans may differ from laboratory animals in their response to toxic substances. These same tools are also being utilized to identify individuals who are genetically susceptible to factors in the environment or respond differently to a chemical exposure. For example, it is now recognized that a small percentage of the population genetically lacks the ability to detoxify the chemotherapeutic drug, 6-mercaptopurine, used in the treatment of some forms of leukemia. Young children with leukemia who are homozygous for this genetic trait (about one in 300) may experience serious toxic effects from a standard therapeutic dose of this drug. Numerous genetic tests for polymorphisms in drug metabolizing enzymes and transporters are now available that can identify genetically susceptible individuals in advance of pharmacological treatment (Eichelbaum *et al.*, 2006).

These new areas of "pharmacogenomics" and "toxicogenomics" provides an exciting opportunity in the future for mechanistic toxicologists to identify and protect genetically susceptible individuals from harmful environmental exposures, and to customize drug therapies that enhance efficacy and minimize toxicity, based on an individual's genetic makeup.

A *descriptive toxicologist* is concerned directly with toxicity testing, which provides information for safety evaluation and regulatory requirements. The appropriate toxicity tests (as described later in this chapter and other chapters) in cell culture systems or experimental animals are designed to yield information to evaluate risks posed to humans and the environment from exposure to specific chemicals. The concern may be limited to effects on humans, as in the case of drugs and food additives. Toxicologists in the chemical industry, however, must be concerned not only with the risk posed by a company's chemicals (insecticides, herbicides, solvents, etc.) to humans but also with potential effects on fish, birds, and plants, as well as other factors that might disturb the balance of the ecosystem. Descriptive toxicology is of course not divorced from mechanistic studies, as such studies provide important clues to a chemical's mechanism of action, and thus contribute to the development of mechanistic toxicology through hypothesis generation. Such studies are also a key component of risk assessments that are used by regulatory toxicologists. The recent advent of so-called "omics" technologies (genomics, transcriptomics, proteomics, metabonomics, etc.) form the basis of the emerging subdiscipline of toxicogenomics. The application of these new technologies to toxicity testing is in many ways "descriptive" in nature, yet affords great mechanistic insights into how chemicals produce their toxic effects. This exciting new area of toxicology is discussed in more detail later in the chapter.

A *regulatory toxicologist* has the responsibility for deciding, on the basis of data provided by descriptive and mechanistic toxicologists, whether a drug or other chemical poses a sufficiently low risk to be marketed for a stated purpose or subsequent human or

environmental exposure resulting from its use. The Food and Drug Administration (FDA) is responsible for allowing drugs, cosmetics, and food additives to be sold in the market according to the Federal Food, Drug and Cosmetic Act (FFDCA). The U.S. Environmental Protection Agency (EPA) is responsible for regulating most other chemicals according to the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA), the Toxic Substances Control Act (TSCA), the Resource Conservation and Recovery Act (RCRA), the Safe Drinking Water Act, and the Clean Air Act. In 1996, the U.S. Congress passed the Food Quality Protection Act (FQPA) which fundamentally changed the pesticide and food safety laws under FIFRA and FFDCA requiring stricter safety standards particularly for infants and children, who were recognized as more susceptible to health effects of pesticides. The EPA is also responsible for enforcing the Comprehensive Environmental Response, Compensation and Liability Act [CERCLA, later revised as the Superfund Amendments Reauthorization Act (SARA)], more commonly called the Superfund Act. This regulation provides direction and financial support for the cleanup of waste sites that contain toxic chemicals that may present a risk to human health or the environment. The Occupational Safety and Health Administration (OSHA) of the Department of Labor was established to ensure that safe and healthful conditions exist in the workplace. The National Institute for Occupational Safety and Health (NIOSH) as part of the Centers for Disease Control and Prevention (CDC) in the Department of Health and Human Services is responsible for conducting research and making recommendations for the prevention of work-related injury and illness. The Consumer Product Safety Commission is responsible for protecting consumers from hazardous household substances, whereas the Department of Transportation (DOT) ensures that materials shipped in interstate commerce are labeled and packaged in a manner consistent with the degree of hazard they present. Regulatory toxicologists are also involved in the establishment of standards for the amount of chemicals permitted in ambient air, industrial atmospheres, and drinking water, often integrating scientific information from basic descriptive and mechanistic toxicology studies with the principles and approaches used for risk assessment (see Chap. 4).

In addition to the above categories, there are other specialized areas of toxicology such as forensic, clinical, and environmental toxicology. *Forensic toxicology* is a hybrid of analytic chemistry and fundamental toxicological principles. It is concerned primarily with the medicolegal aspects of the harmful effects of chemicals on humans and animals. The expertise of forensic toxicologists is invoked primarily to aid in establishing the cause of death and determining its circumstances in a postmortem investigation (see Chap. 31). *Clinical toxicology* designates an area of professional emphasis in the realm of medical science that is concerned with disease caused by or uniquely associated with toxic substances (see Chap. 32). Generally, clinical toxicologists are physicians who receive specialized training in emergency medicine and poison management. Efforts are directed at treating patients poisoned with drugs or other chemicals and at the development of new techniques to treat those intoxications. Public contact about treatment and prevention is often through the national network of poison control centers. *Environmental toxicology* focuses on the impacts of chemical pollutants in the environment on biological organisms. Although toxicologists concerned with the effects of environmental pollutants on human health fit into this definition, it is most commonly associated with studies on the impacts of chemicals on nonhuman organisms such as fish, birds, terrestrial animals, and plants. *Ecotoxicology* is a specialized area within environmental toxicology that focuses more specifically on the impacts of toxic substances on population dynamics in an ecosystem. The transport, fate, and interactions of chemicals in the environment constitute a critical component of both environmental toxicology and ecotoxicology.

Toxicology and Society

Information from the toxicological sciences, gained by experience or research, has a growing influence on our personal lives as well as for human and environmental health across the globe. Knowledge about the toxicological effects of a compound affects consumer products, drugs, manufacturing processes, waste clean up, regulatory action, civil disputes, and broad policy decisions. The expanding influence of toxicology on societal issues is accompanied by the responsibility to be increasingly sensitive to the ethical, legal, and social implications of toxicological research and testing.

The convergence of multiple elements has highlighted the evolving ethical dynamics of toxicology. First, experience and new discoveries in the biological sciences have emphasized our interconnectedness with nature and the need for well-articulated visions of human, animal, and environmental health. One vision is that we have "condition(s) that ensure that all living things have the best opportunity to reach and maintain their full genetic potential" (Gilbert, 2005a). Second, we have experience with the health consequences of exposure to such things as lead, asbestos, and tobacco, along with the detailed mechanistic research to understand the long-term risks to individuals and society. This has precipitated many regulatory and legal actions and public policy decisions, not to mention costly and time-consuming lawsuits. Third, we have an increasingly well-defined framework for discussing our social and ethical responsibilities. There is growing recognition that ethics play a crucial role in public health decision-making that involve conflicts between individual, corporate, and social justice goals (Callahan and Jennings, 2002; Kass, 2001; Lee, 2002). Fourth, is the appreciation that all research involving humans or animals must be conducted in a responsible and ethical manner. Fifth, is managing both the uncertainty and biological variability inherent in the biological sciences. Decision-making often includes making judgments with limited or uncertain information, which often includes an overlay of individual values and ethics. Finally, individuals involved in toxicological research must be aware of and accountable to their own individual biases and possible conflicts of interest and adhere to the highest ethical standards of the profession (Maurissen *et al.*, 2005).

Ethical reasoning and philosophy has a long and deep history, but more pragmatic bioethical reasoning can be traced to Aldo Leopold, who is arguably, America's first bioethicist: "A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise." (Leopold, 1949). The essence of toxicology is to understand the effects of chemicals on the biotic community. This broader definition of an ethic became more focused with examples such as the mercury poisoning in Minamata Bay, Japan, thalidomide, and the effects of pesticides as brought to public awareness by Rachel Carson's "Silent Spring" (Carson, 1962). In the United States, these events supported the public and political will to establish the EPA, strengthening of the FDA and other regulations designed to protect human and environmental health. The appreciation that some segments of our society were deferentially at risk from chemical exposures evolved into an appreciation of environmental justice (Coburn, 2002; EPA, 2005; Lee, 2002; Morello-Frosch *et al.*, 2002). The EPA defines

environmental justice as "the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income with respect to the development, implementation, and enforcement of environmental laws, regulations, and policies..." (EPA, 2005). Environmental justice is now an important component of numerous community-based programs of interest, and is relevant to the field of toxicology. There is growing recognition of the direct financial and indirect costs to individuals and society from environmental exposures that are not equally distributed across society (Landrigan *et al.*, 2002).

On a parallel track, biomedical ethics developed out of the lessons of World War II and related abuses of human subjects. The four principle of biomedical ethics—respect for autonomy, beneficence (do good), non-maleficence (do no harm), and justice (be fair)—became well established as a basis for decision-making in health care settings (Beauchamp and Childress, 1994). These principles formed the basis of rules and regulations regarding the conduct of human research. The demands of ethics and science made it clear that the highest standards of care produced the best results in both human and animal research. Rules and regulations regarding the housing and conduct of animal studies evolved similarly. Professional toxicology societies now require their members to adhere to the highest ethical standards when conducting research with humans or animals. A further refinement and expansion of biomedical ethical principles is the development of community-based participatory research that takes into consideration community needs to ensure the best results and benefit to the community (Arcury *et al.*, 2001; Gilbert, 2006; O'Fallon and Dearry, 2002).

A glance at the daily newspaper confirms the number of current, sometimes controversial issues that are relevant to the field of toxicology. Decisions and action are often demanded or required even when there is a certain level of uncertainty in the toxicological data. The classic example of this challenge is establishing causation of the health effects of tobacco products. In part to address issues related to the health effects of tobacco products, Bradford Hill defined criteria for determining causation (Hill, 1965). These criteria are briefly summarized below.

1. Strength of association (relationship between independent and dependent variables)
2. Consistency of findings (replication of results by different studies)
3. Biological gradient (strength of the dose-response relationship)
4. Temporal sequence ("cause" before effect)
5. Biologic or theoretical plausibility (mechanism of action)
6. Coherence with established knowledge (no competing hypotheses)
7. Specificity of association (cause is tightly linked to an outcome)

Quantitative risk assessment was developed in part to address issues of uncertainty related to potential harm. The risk assessment process summarized data for risk managers and other decision makers, who must take into consideration to some degree the qualitative elements of ethical, social and political issues. Whereas risk management clearly has an ethical and values based aspect, risk assessment is not immune from the influence of one's values, bias or perspective. Ultimately action is required and as Bradford Hill (1965) noted: "All scientific work is incomplete—whether it be observational or experimental. All scientific work is liable to be upset or modified by advancing knowledge. That does not confer upon us a freedom to ignore the knowledge we already have or postpone the

action that it appears to demand at a given time." These so-called "Bradford Hill criteria" were developed largely as a "weight of evidence" approach for interpreting a body of epidemiology data, yet are relevant as well to toxicology. Guzelian *et al.* (2005) provide a more detailed, evidence-based approach for determining causation in toxicology, primarily for application in the legal arena.

Although the scientific data may be the same, there are substantial differences in how toxicological data are used in a regulatory framework to protect public health versus establishing individual causation in the courtroom (Eaton, 2003). The approach to regulatory decision-making is in part directed by policy. For example, the experience with thalidomide and other drugs motivated the U.S. Congress to give the FDA broad power to ensure the efficacy and safety of new medicines or medical procedures. In this situation the pharmaceutical company or proponents of an activity must invest in the appropriate animal and human studies to demonstrate safety of the product. We have instituted a very precautionary approach with regard to drugs and medical devices. The approach to industrial chemicals is defined by the Toxic Substance Control Act and does not stipulate such a rigorous approach when introducing a new chemical.

Building on the work of Hill and others particularly from Europe, the Precautionary Principle was defined at the Wingspread Conference, in 1998: "When an activity raises threats of harm to human health or the environment, precautionary measures should be taken even if some cause and effect relationships are not fully established scientifically." (Gilbert, 2005b; Myers and Raffensperger, 2006; Raffensperger and Tickner, 1999). The precautionary principle incorporates elements of science and ethical philosophy into a single statement, acknowledging that ethics and values are part of the decision making process. Although the conceptual value of the precautionary principle to public health protection is obvious, the actual implementation of it in toxicological risk assessment is not straightforward, and remains a point of considerable debate (Marchant, 2003; Goldstein, 2006; Peterson, 2006).

With the increased relevance of toxicological data and evaluation in issues fundamental to society there has been increased awareness of the possibility of conflicts of interest influencing the decision-making process (Maurissen *et al.*, 2005). The disclosure of conflicts of interest as well as the development of appropriate guidelines continues to be a challenge (NAS, 2003; Goozner, 2004; Krimsky and Rothenberg, 2001). These issues go to the core of one's individual values and integrity in the interpretation and communication of research results. Many professional societies, including the Society of Toxicology (http://www.toxicology.org/ai/asot/ethics.asp), have developed codes of ethics for their members.

As the field of toxicology has matured and its influence on societal issues has increased so has the need for the profession to make a commitment to examine the ethical, legal, and social implications of research and practice of toxicology.

General Characteristics of the Toxic Response

One could define a *poison* as any agent capable of producing a deleterious response in a biological system, seriously injuring function or producing death. This is not, however, a useful working definition for the very simple reason that virtually every known chemical has the potential to produce injury or death if it is present in a sufficient amount. Paracelsus (1493–1541), a Swiss/German/Austrian physician, scientist, and philosopher, phrased this well when he noted, "What is there that is not poison? All things are poison and nothing

Table 2.1

Approximate Acute LD$_{50}$s of Some Representative Chemical Agents

AGENT	LD$_{50}$, MG/KG*
Ethyl alcohol	10000
Sodium chloride	4000
Ferrous sulfate	1500
Morphine sulfate	900
Phenobarbital sodium	150
Picrotoxin	5
Strychnine sulfate	2
Nicotine	1
d−Tubocurarine	0.5
Hemicholinium-3	0.2
Tetrodotoxin	0.10
Dioxin (TCDD)	0.001
Botulinum toxin	0.00001

*LD$_{50}$ is the dosage (mg/kg body weight) causing death in 50% of exposed animals.

[is] without poison. Solely the dose determines that a thing is not a poison."

Among chemicals there is a wide spectrum of doses needed to produce deleterious effects, serious injury, or death. This is demonstrated in Table 2-1, which shows the dosage of chemicals needed to produce death in 50% of treated animals (LD$_{50}$). Some chemicals produce death in microgram doses and are commonly thought of as being extremely poisonous. Other chemicals may be relatively harmless after doses in excess of several grams. It should be noted, however, that measures of acute lethality such as LD$_{50}$ may not accurately reflect the full spectrum of toxicity, or hazard, associated with exposure to a chemical. For example, some chemicals with low acute toxicity may have carcinogenic, teratogenic, or neurobehavioral effects at doses that produce no evidence of acute toxicity. In addition, there is growing recognition that genetic factors can account for individual susceptibility to a range of responses.

CLASSIFICATION OF TOXIC AGENTS

Toxic agents are classified in a variety of ways, depending on the interests and needs of the classifier. In this textbook, for example, toxic agents are discussed in terms of their target organs (liver, kidney, hematopoietic system, etc.), use (pesticide, solvent, food additive, etc.), source (animal and plant toxins), and effects (cancer, mutation, liver injury, etc.). The term *toxin* generally refers to toxic substances that are produced by biological systems such as plants, animals, fungi, or bacteria. The term *toxicant* is used in speaking of toxic substances that are produced by or are a by-product of anthropogenic (human-made) activities. Thus, zeralanone, produced by a mold, is a toxin, whereas "dioxin" [2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)], produced during the production and/or combustion of certain chlorinated organic chemicals, is a toxicant. Some toxicants can be produced by both natural and anthropogenic activities. For example, polyaromatic hydrocarbons are produced by the combustion of organic matter, which may occur both through natural processes (e.g., forest fires) and through anthropogenic activities (e.g., combustion of coal for energy production; cigarette smoking). Arsenic, a toxic metalloid, may occur as a natural contaminant of groundwater or may contaminate groundwater secondary to indus-

trial activities. Generally, such toxic substances are referred to as toxicants, rather than toxins, because, although they are naturally produced, they are not produced by biological systems.

Toxic agents may also be classified in terms of their physical state (gas, dust, liquid), their chemical stability or reactivity (explosive, flammable, oxidizer), general chemical structure (aromatic amine, halogenated hydrocarbon, etc.), or poisoning potential (extremely toxic, very toxic, slightly toxic, etc.). Classification of toxic agents on the basis of their biochemical mechanisms of action (e.g., alkylating agent, cholinesterase inhibitor, methemoglobin producer) is usually more informative than classification by general terms such as irritants and corrosives. But more general classifications such as air pollutants, occupation-related agents, and acute and chronic poisons can provide a useful focus on a specific problem. It is evident from this discussion that no single classification is applicable to the entire spectrum of toxic agents and that combinations of classification systems or a classification based on other factors may be needed to provide the best rating system for a special purpose. Nevertheless, classification systems that take into consideration both the chemical and the biological properties of an agent and the exposure characteristics are most likely to be useful for regulatory or control purposes and for toxicology in general.

SPECTRUM OF UNDESIRED EFFECTS

The spectrum of undesired effects of chemicals is broad. Some effects are deleterious and others are not. In therapeutics, for example, each drug produces a number of effects, but usually only one effect is associated with the primary objective of the therapy; all the other effects are referred to as *undesirable* or *side effects* of that drug for that therapeutic indication. However, some of these side effects may be desired for another therapeutic indication. For example, the "first-generation" antihistamine diphenhydramine (Benadryl) is effective in reducing histamine responses associated with allergies, but it readily enters the brain and causes mild central nervous system (CNS) depression (drowsiness, delayed reaction time). With the advent of newer and selective histamine receptor antagonists that do not cross the blood–brain barrier and thus do not have this CNS-depressant side effect, diphenhydramine is used less commonly today as an antihistamine. However, it is widely used as an "over the counter" sleep remedy, often in combination with analgesics (e.g., Tylenol PM, Excedrin PM, etc), taking advantage of the CNS-depressant effects. Some side effects of drugs are never desirable and are always deleterious to the well-being of humans. These are referred to as the *adverse, deleterious,* or *toxic* effects of the drug.

Allergic Reactions

Chemical allergy is an immunologically mediated adverse reaction to a chemical resulting from previous sensitization to that chemical or to a structurally similar one. The term *hypersensitivity* is most often used to describe this allergic state, but *allergic reaction* and *sensitization reaction* are also used to describe this situation when pre-exposure of the chemical is required to produce the toxic effect (see Chap. 12). Once sensitization has occurred, allergic reactions may result from exposure to relatively very low doses of chemicals; therefore population-based dose–response curves for allergic reactions have seldom been obtained. Because of this omission, some people assumed that allergic reactions are not dose-related. Thus, they do not consider the allergic reaction to be a true toxic response. However, for a given allergic individual, allergic reactions are

dose-related. For example, it is well known that the allergic response to pollen in sensitized individuals is related to the concentration of pollen in the air. In addition, because the allergic response is an undesirable, adverse, deleterious effect, it obviously is also a toxic response. Sensitization reactions are sometimes very severe and may be fatal.

Most chemicals and their metabolic products are not sufficiently large to be recognized by the immune system as a foreign substance and thus must first combine with an endogenous protein to form an antigen (or immunogen). A molecule that must combine with an endogenous protein to elicit an allergic reaction is called a *hapten.* The hapten-protein complex (antigen) is then capable of eliciting the formation of antibodies, and usually at least 1 or 2 weeks is required for the synthesis of significant amounts of antibodies. Subsequent exposure to the chemical results in an antigen–antibody interaction, which provokes the typical manifestations of allergy. The manifestations of allergy are numerous. They may involve various organ systems and range in severity from minor skin disturbance to fatal anaphylactic shock. The pattern of allergic response differs in various species. In humans, involvement of the skin (e.g., dermatitis, urticaria, and itching) and involvement of the eyes (e.g., conjunctivitis) are most common, whereas in guinea pigs, bronchiolar constriction leading to asphyxia is the most common. However, chemically induced asthma (characterized by bronchiolar constriction) certainly does occur in some humans, and the incidence of allergic asthma has increased substantially in recent years. Hypersensitivity reactions are discussed in more detail in Chap. 12.

Idiosyncratic Reactions

Chemical idiosyncrasy refers to a genetically determined abnormal reactivity to a chemical (Goldstein *et al.*, 1974; Levine, 1978). The response observed is usually qualitatively similar to that observed in all individuals but may take the form of extreme sensitivity to low doses or extreme insensitivity to high doses of the chemical. However, while some people use the term *idiosyncratic* as a catchall to refer to all reactions that occur with low frequency, it should not be used in that manner (Goldstein *et al.*, 1974). A classic example of an idiosyncratic reaction is provided by patients who exhibit prolonged muscular relaxation and apnea (inability to breathe) lasting several hours after a standard dose of succinylcholine. Succinylcholine usually produces skeletal muscle relaxation of only short duration because of its very rapid metabolic degradation by an enzyme that is present normally in the bloodstream called plasma butyrylcholinesterase (also referred to as pseudocholinesterase). Patients exhibiting this idiosyncratic reaction have a genetic polymorphism in the gene for the enzyme butyrylcholinesterase, which is less active in breaking down succinylcholine. Family pedigree and molecular genetic analyses have demonstrated that the presence of low plasma butyrylcholinesterase activity is due to the presence of one or more single nucleotide polymorphisms in this gene (Bartels *et al.*, 1992). Similarly, there is a group of people who are abnormally sensitive to nitrites and certain other chemicals that have in common the ability to oxidize the iron in hemoglobin to produce *methemoglobin,* which is incapable of carrying oxygen to the tissues. The unusual phenotype is inherited as an autosomal recessive trait and is characterized by a deficiency in NADH-cytochrome b5 reductase activity. The genetic basis for this idiosyncratic response has been identified as a single nucleotide change in codon 127, which results in replacement of serine with proline (Kobayashi *et al.*, 1990). The consequence of this genetic deficiency is that these individuals may suffer from a serious lack of oxygen delivery to tissues after exposure to doses of methemoglobin-producing chemicals that would be harmless to individuals with normal NADH-cytochrome b5 reductase activity.

Immediate versus Delayed Toxicity

Immediate toxic effects can be defined as those that occur or develop rapidly after a single administration of a substance, whereas delayed toxic effects are those that occur after the lapse of some time. Carcinogenic effects of chemicals usually have a long latency period, often 20 to 30 years after the initial exposure, before tumors are observed in humans. For example, daughters of mothers who took diethylstilbestrol (DES) during pregnancy have a greatly increased risk of developing vaginal cancer, but not other types of cancer, in young adulthood, some 20 to 30 years after their in utero exposure to DES (Hatch *et al.*, 1998). Also, delayed neurotoxicity is observed after exposure to some organophosphorus insecticides that act by covalent modification of an enzyme referred to as *neuropathy target esterase* (NTE), a neuronal protein with serine esterase activity (Glynn *et al.*, 1999). Binding of certain organophosphates (OP) to this protein initiates degeneration of long axons in the peripheral and central nervous system. The most notorious of the compounds that produce this type of neurotoxic effect is triorthocresylphosphate (TOCP). The effect is not observed until at least several days after exposure to the toxic compound. In contrast, most substances produce immediate toxic effects but do not produce delayed effects.

Reversible versus Irreversible Toxic Effects

Some toxic effects of chemicals are reversible, and others are irreversible. If a chemical produces pathological injury to a tissue, the ability of that tissue to regenerate largely determines whether the effect is reversible or irreversible. Thus, for a tissue such as liver, which has a high ability to regenerate, most injuries are reversible, whereas injury to the CNS is largely irreversible because differentiated cells of the CNS cannot divide and be replaced. Carcinogenic and teratogenic effects of chemicals, once they occur, are usually considered irreversible toxic effects.

Local versus Systemic Toxicity

Another distinction between types of effects is made on the basis of the general site of action. Local effects are those that occur at the site of first contact between the biological system and the toxicant. Such effects are produced by the ingestion of caustic substances or the inhalation of irritant materials. For example, chlorine gas reacts with lung tissue at the site of contact, causing damage and swelling of the tissue, with possibly fatal consequences, even though very little of the chemical is absorbed into the bloodstream. The alternative to local effects is systemic effects. Systemic effects require absorption and distribution of a toxicant from its entry point to a distant site, at which deleterious effects are produced. Most substances except highly reactive materials produce systemic effects. For some materials, both effects can be demonstrated. For example, tetraethyl lead produces effects on skin at the site of absorption and then is transported systemically to produce its typical effects on the CNS and other organs. If the local effect is marked, there may also be indirect systemic effects. For example, kidney damage after a severe acid burn is an indirect systemic effect because the toxicant does not reach the kidney.

Most chemicals that produce systemic toxicity do not cause a similar degree of toxicity in all organs; instead, they usually elicit their major toxicity in only one or two organs. These sites are referred to as the *target organs* of toxicity of a particular chemical. The target organ of toxicity is often not the site of the highest concentration of the chemical. For example, lead is concentrated in bone, but its toxicity is due to its effects in soft tissues, particularly the brain. DDT is concentrated in adipose tissue but produces no known toxic effects in that tissue.

The target organ of toxicity most frequently involved in systemic toxicity is the CNS (brain and spinal cord). Even with many compounds having a prominent effect elsewhere, damage to the CNS can be demonstrated by the use of appropriate and sensitive methods. Next in order of frequency of involvement in systemic toxicity are the circulatory system; the blood and hematopoietic system; visceral organs such as the liver, kidney, and lung; and the skin. Muscle and bone are least often the target tissues for systemic effects. With substances that have a predominantly local effect, the frequency with which tissues react depends largely on the portal of entry (skin, gastrointestinal tract, or respiratory tract).

Interaction of Chemicals

Because of the large number of different chemicals an individual may come in contact with at any given time (workplace, drugs, diet, hobbies, etc.), it is necessary, in assessing the spectrum of responses, to consider how different chemicals may interact with each other. Interactions can occur in a variety of ways. Chemical interactions are known to occur by a number of mechanisms, such as alterations in absorption, protein binding, and the biotransformation and excretion of one or both of the interacting toxicants. In addition to these modes of interaction, the response of the organism to combinations of toxicants may be increased or decreased because of toxicologic responses at the site of action.

The effects of two chemicals given simultaneously produce a response that may simply be additive of their individual responses or may be greater or less than that expected by addition of their individual responses. The study of these interactions often leads to a better understanding of the mechanism of toxicity of the chemicals involved. A number of terms have been used to describe pharmacologic and toxicologic interactions. An *additive* effect occurs when the combined effect of two chemicals is equal to the sum of the effects of each agent given alone (example: $2 + 3 = 5$). The effect most commonly observed when two chemicals are given together is an additive effect. For example, when two organophosphate insecticides are given together, the cholinesterase inhibition is usually additive. A *synergistic* effect occurs when the combined effects of two chemicals are much greater than the sum of the effects of each agent given alone (example: $2 + 2 = 20$). For example, both carbon tetrachloride and ethanol are hepatotoxic compounds, but together they produce much more liver injury than the mathematical sum of their individual effects on liver at a given dose would suggest. *Potentiation* occurs when one substance does not have a toxic effect on a certain organ or system but when added to another chemical makes that chemical much more toxic (example: $0 + 2 = 10$). Isopropanol, for example, is not hepatotoxic, but when it is administered in addition to carbon tetrachloride, the hepatotoxicity of carbon tetrachloride is much greater than when it is given alone. *Antagonism* occurs when two chemicals administered together interfere with each other's actions or one interferes with the action of the other (example: $4 + 6 = 8$; $4 + (-4) = 0$; $4 + 0 = 1$). Antag-

onistic effects of chemicals are often very desirable in toxicology and are the basis of many antidotes. There are four major types of antagonism: functional, chemical, dispositional, and receptor. *Functional antagonism* occurs when two chemicals counterbalance each other by producing opposite effects on the same physiologic function. Advantage is taken of this principle in that the blood pressure can markedly fall during severe barbiturate intoxication, which can be effectively antagonized by the intravenous administration of a vasopressor agent such as norepinephrine or metaraminol. Similarly, many chemicals, when given at toxic dose levels, produce convulsions, and the convulsions often can be controlled by giving anticonvulsants such as the benzodiazepines (e.g., diazepam). *Chemical antagonism* or *inactivation* is simply a chemical reaction between two compounds that produces a less toxic product. For example, dimercaprol (British antilewisite, or BAL) chelates with metal ions such as arsenic, mercury, and lead and decreases their toxicity. The use of antitoxins in the treatment of various animal toxins is also an example of chemical antagonism. The use of the strongly basic low-molecular-weight protein protamine sulfate to form a stable complex with heparin, which abolishes its anticoagulant activity, is another example. *Dispositional antagonism* occurs when the disposition—that is, the absorption, distribution, biotransformation, or excretion of a chemical—is altered so that the concentration and/or duration of the chemical at the target organ are diminished. Thus, the prevention of absorption of a toxicant by ipecac or charcoal and the increased excretion of a chemical by administration of an osmotic diuretic or alteration of the pH of the urine are examples of dispositional antagonism. If the parent compound is responsible for the toxicity of the chemical (such as the anticoagulant warfarin) and its metabolic breakdown products are less toxic than the parent compound, increasing the compound's metabolism (biotransformation) by administering a drug that increases the activity of the metabolizing enzymes (e.g., a "microsomal enzyme inducer" such as phenobarbital) will decrease its toxicity. However, if the chemical's toxicity is largely due to a metabolic product (as in the case of the organophosphate insecticide parathion), inhibiting its biotransformation by an inhibitor of microsomal enzyme activity (SKF-525A or piperonyl butoxide) will decrease its toxicity. *Receptor antagonism* occurs when two chemicals that bind to the same receptor produce less of an effect when given together than the addition of their separate effects (example: $4 + 6 = 8$) or when one chemical antagonizes the effect of the second chemical (example: $0 + 4 = 1$). Receptor antagonists are often termed *blockers.* This concept is used to advantage in the clinical treatment of poisoning. For example, the receptor antagonist naloxone is used to treat the respiratory depressive effects of morphine and other morphine-like narcotics by competitive binding to the same receptor. Another example of receptor antagonism is the use of the antiestrogen drug tamoxifen to lower breast cancer risk among women at high risk for this estrogen-related cancer. Tamoxifen competitively block estradiol from binding to its receptor. Treatment of organophosphate insecticide poisoning with atropine is an example not of the antidote competing with the poison for the receptor (cholinesterase) but involves blocking the receptor (cholinergic receptor) for the excess acetylcholine that accumulates by poisoning of the cholinesterase by the organophosphate (see Chap. 22).

Tolerance

Tolerance is a state of decreased responsiveness to a toxic effect of a chemical resulting from prior exposure to that chemical or to a

structurally related chemical. Two major mechanisms are responsible for tolerance: one is due to a decreased amount of toxicant reaching the site where the toxic effect is produced (*dispositional tolerance*), and the other is due to a reduced responsiveness of a tissue to the chemical. Comparatively less is known about the cellular mechanisms responsible for altering the responsiveness of a tissue to a toxic chemical than is known about dispositional tolerance. Two chemicals known to produce dispositional tolerance are carbon tetrachloride and cadmium. Carbon tetrachloride produces tolerance to itself by decreasing the formation of the reactive metabolite (trichloromethyl radical) that produces liver injury (see Chap. 13). The mechanism of cadmium tolerance is explained by induction of metallothionein, a metal-binding protein. Subsequent binding of cadmium to metallothionein rather than to critical macromolecules decreases its toxicity.

CHARACTERISTICS OF EXPOSURE

Toxic effects in a biological system are not produced by a chemical agent unless that agent or its metabolic breakdown (biotransformation) products reach appropriate sites in the body at a concentration and for a length of time sufficient to produce a toxic manifestation. Many chemicals are of relatively low toxicity in the "native" form but, when acted on by enzymes in the body, are converted to intermediate forms that interfere with normal cellular biochemistry and physiology. Thus, whether a toxic response occurs is dependent on the chemical and physical properties of the agent, the exposure situation, how the agent is metabolized by the system, the concentration of the active form at the particular target site(s), and the overall susceptibility of the biological system or subject. Thus, to characterize fully the potential hazard of a specific chemical agent, we need to know not only what type of effect it produces and the dose required to produce that effect but also information about the agent, the exposure, and its disposition by the subject. Two major factors that influence toxicity as it relates to the exposure situation for a specific chemical are the route of exposure, and the duration, and frequency of exposure.

Route and Site of Exposure

The major routes (pathways) by which toxic agents gain access to the body are the gastrointestinal tract (ingestion), lungs (inhalation), skin (topical, percutaneous, or dermal), and other parenteral (other than intestinal canal) routes. Toxic agents generally produce the greatest effect and the most rapid response when given directly into the bloodstream (the intravenous route). An approximate descending order of effectiveness for the other routes would be inhalation, intraperitoneal, subcutaneous, intramuscular, intradermal, oral, and dermal. The "vehicle" (the material in which the chemical is dissolved) and other formulation factors can markedly alter absorption after ingestion, inhalation, or topical exposure. In addition, the route of administration can influence the toxicity of agents. For example, an agent that acts on the CNS, but is efficiently detoxified in the liver, would be expected to be less toxic when given orally than when given via inhalation, because the oral route requires that nearly all of the dose pass through the liver before reaching the systemic circulation and then the CNS.

Occupational exposure to toxic agents most frequently results from breathing contaminated air (inhalation) and/or direct and prolonged contact of the skin with the substance (dermal exposure), whereas accidental and suicidal poisoning occurs most frequently by oral ingestion. Comparison of the lethal dose of a toxic substance by different routes of exposure often provides useful information about its extent of absorption. In instances when the toxic dose after oral or dermal administration is similar to the toxic dose after intravenous administration, the assumption is that the toxic agent is absorbed readily and rapidly. Conversely, in cases where the toxic dose by the dermal route is several orders of magnitude higher than the oral toxic dose, it is likely that the skin provides an effective barrier to absorption of the agent. Toxic effects by any route of exposure can also be influenced by the concentration of the agent in its vehicle, the total volume of the vehicle and the properties of the vehicle to which the biological system is exposed, and the rate at which exposure occurs. Studies in which the concentration of a chemical in the blood is determined at various times after exposure are often needed to clarify the role of these and other factors in the toxicity of a compound. For more details on the absorption of toxicants, see Chap. 5.

Duration and Frequency of Exposure

Toxicologists usually divide the exposure of experimental animals to chemicals into four categories: acute, subacute, subchronic, and chronic. Acute exposure is defined as exposure to a chemical for less than 24 hours, and examples of exposure routes are intraperitoneal, intravenous, and subcutaneous injection; oral intubation; and dermal application. Whereas acute exposure usually refers to a single administration, repeated exposures may be given within a 24-hours period for some slightly toxic or practically nontoxic chemicals. Acute exposure by inhalation refers to continuous exposure for less than 24 hours, most frequently for 4 hours. Repeated exposure is divided into three categories: subacute, subchronic, and chronic. *Subacute exposure* refers to repeated exposure to a chemical for 1 month or less, *subchronic* for 1 to 3 months, and *chronic* for more than 3 months, although usually this refers to studies with at least 1 year of repeated dosing. These three categories of repeated exposure can be by any route, but most often they occur by the oral route, with the chemical added directly to the diet.

In human exposure situations, the frequency and duration of exposure are usually not as clearly defined as in controlled animal studies, but many of the same terms are used to describe general exposure situations. Thus, workplace or environmental exposures may be described as *acute* (occurring from a single incident or episode), *subchronic* (occurring repeatedly over several weeks or months), or *chronic* (occurring repeatedly for many months or years).

For many chemicals, the toxic effects that follow a single exposure are quite different from those produced by repeated exposure. For example, the primary acute toxic manifestation of benzene is central nervous system (CNS) depression, but repeated exposures can result in bone marrow toxicity and an increased risk for leukemia. Acute exposure to chemicals that are rapidly absorbed is likely to produce immediate toxic effects but also can produce delayed toxicity that may or may not be similar to the toxic effects of chronic exposure. Conversely, chronic exposure to a toxic chemical may produce some immediate (acute) effects after each administration in addition to the long-term, low-level, or chronic effects of the toxic substance. In characterizing the toxicity of a specific chemical, it is evident that information is needed not only for the single-dose (acute) and long-term (chronic) effects but also for exposures of intermediate duration. The other time-related factor that is important in the temporal characterization of repeated
Figure 2-2. *Diagrammatic view of the relationship between dose and concentration at the target site under different conditions of dose frequency and elimination rate.*

Line A. A chemical with very slow elimination (e.g., half-life of 1 year). *Line B.* A chemical with a rate of elimination equal to frequency of dosing (e.g., 1 day). *Line C.* Rate of elimination faster than the dosing frequency (e.g., 5 h). Blue-shaded area is representative of the concentration of chemical at the target site necessary to elicit a toxic response.

exposures is the frequency of exposure. The relationship between elimination rate and frequency of exposure is shown in Fig. 2-2. A chemical that produces severe effects with a single dose may have no effect if the same total dose is given in several intervals. For the chemical depicted by line B in Fig. 2-2, in which the half-life for elimination (time necessary for 50% of the chemical to be removed from the bloodstream) is approximately equal to the dosing frequency, a theoretical toxic concentration (shown conceptually as two Concentration Units in Fig. 2-2) is not reached until the fourth dose, whereas that concentration is reached with only two doses for chemical A, which has an elimination rate much slower than the dosing interval (time between each repeated dose). Conversely, for chemical C, where the elimination rate is much shorter than the dosing interval, a toxic concentration at the site of toxic effect will never be reached regardless of how many doses are administered. Of course, it is possible that residual cell or tissue damage occurs with each dose even though the chemical itself is not accumulating. The important consideration, then, is whether the interval between doses is sufficient to allow for complete repair of tissue damage. It is evident that with any type of repeated exposure, the production of a toxic effect is influenced not only by the frequency of exposure but may, in fact, be totally dependent on the frequency rather than the duration of exposure. Chronic toxic effects may occur, therefore, if the chemical accumulates in the biological system (rate of absorption exceeds the rate of biotransformation and/or excretion), if it produces irreversible toxic effects, or if there is insufficient time for the system to recover from the toxic damage within the exposure frequency interval. For additional discussion of these relationships, see Chaps. 5 and 7.

DOSE–RESPONSE RELATIONSHIP

The characteristics of exposure and the spectrum of toxic effects come together in a correlative relationship customarily referred to as the *dose–response relationship*. Whatever response is selected for measurement, the relationship between the degree of response of the biological system and the amount of toxicant administered assumes a form that occurs so consistently as to be considered the most fundamental and pervasive concept in toxicology.

From a practical perspective, there are two types of dose–response relationships: (1) the individual dose–response relationship, which describes the response of an *individual* organism to varying doses of a chemical, often referred to as a "graded" response because the measured effect is continuous over a range of doses, and (2) a quantal dose–response relationship, which characterizes the distribution of individual responses to different doses in a *population* of individual organisms.

Individual, or Graded, Dose–Response Relationships

Individual dose–response relationships are characterized by a dose-related increase in the severity of the response. The dose relatedness of the response often results from an alteration of a specific biochemical process. For example, Fig. 2-3 shows the dose–response relationship between different dietary doses of the organophosphate insecticide chlorpyrifos and the extent of inhibition of two
Figure 2-3. Dose–response relationship between different doses of the organophosphate insecticide chlorpyrifos and esterase enzyme inhibition in the brain.

Open circles and blue lines represent acetylcholinesterase activity and closed circles represent carboxylesterase activity in the brains of pregnant female Long-Evans rats given 5 daily doses of chlorpyrifos. *A.* Dose–response curve plotted on an arithmetic scale. *B.* Same data plotted on a semi-log scale. (From Lassiter *et al.*, Gestational exposure to chlorypyrifos: Dose response profiles for cholinesterase and carboxylesterase activity. *Toxicol Sci* 52:92–100, 1999, with permission.)

different enzymes in the brain and liver: acetylcholinesterase and carboxylesterase. In the brain, the degree of inhibition of both enzymes is clearly dose-related and spans a wide range, although the amount of inhibition per unit dose is different for the two enzymes. From the shapes of these two dose–response curves it is evident that, in the brain, cholinesterase is more easily inhibited than carboxylesterase. The toxicologic response that results is directly related to the degree of cholinesterase enzyme inhibition in the brain. Thus, clinical signs and symptoms for chlorpyrifos would follow a dose–response relationship similar to that for brain cholinesterase. However, for many chemicals, more than one effect may result because of multiple different target sites in different tissues. Thus, the observed response to varying doses of a chemical in the whole organism is often complicated by the fact that most toxic substances have multiple sites or mechanisms of toxicity, each with its own "dose–response" relationship and subsequent adverse effect. Note that when these dose–response data are plotted using the base 10 log of the dose on the abscissa (Fig. 2.3*B*), a better "fit" of the data to a straight line usually occurs. This is typical of many graded as well as quantal dose–response relationships.

Quantal Dose–Response Relationships

In contrast to the "graded" or continuous-scale dose–response relationship that occurs in individuals, the dose–response relationships in a *population* are by definition quantal—or "all or none"—in nature; that is, at any given dose, an individual in the population is classified as either a "responder" or a "nonresponder." Although these distinctions of "quantal population" and "graded individual" dose–response relationships are useful, the two types of responses are conceptually identical. The ordinate in both cases is simply labeled *the response,* which may be the degree of response in an individual or system or the fraction of a population responding, and the abscissa is the range in administered doses.

A widely used statistical approach for estimating the response of a population to a toxic exposure is the "Effective Dose" or ED. Generally, the mid-point, or 50%, response level is used, giving rise to the "ED_{50}" value. However, any response level, such as an ED_{01}, ED_{10} or ED_{30} could be chosen. A graphical representation of an approximate ED_{50} is shown in Fig. 2-4. Note that these data are
Figure 2-4. Diagram of quantal dose–response relationship.

The abscissa is a log dosage of the chemical. In the top panel the ordinate is response frequency, in the middle panel the ordinate is percent response, and in the bottom panel the response is in probit units (see text).

"quantal". Where death is the measured end-point, the ED_{50} would be referred to as the Lethal Dose 50 (LD_{50}). Historically, determination of the LD_{50} was often the first experiment performed with a new chemical. Today, it is widely recognized that the LD_{50} is of marginal value as a measure of hazard, although it does provide a useful "ball park" indication of the relative hazard of a compound to cause serious, life-threatening poisoning from a single exposure. Although death is an obvious quantal end-point to measure, it should be noted that any quantal response could be used. For example, the LD_{50} of lead or DDT is not a relevant endpoint when characterizing hazards of the agents to children or wildlife, respectively. Even continuous variables can be converted to quantal responses if desired. For example, an antihypertensive drug that lowers blood pressure might be evaluated in a population by assigning a "responder" as an individual who's blood pressure was lowered by 10 mm Hg or more. Note that, in this example, an individual that responded to a change in blood pressure of 50 mm Hg would classified the same as an individual with a change in only 10 mm Hg, yet an individual with a change in 8 mm Hg would be classified as a "non-responder". The top panel of Fig. 2-4 shows that quantal dose responses typically exhibit a normal or Gaussian distribution. The frequency histogram in this panel also shows the relationship between dose and effect. The bars represent the percentage of animals that responded at each dose minus the percentage that responded at the immediately lower dose. One can clearly see that only a few animals responded to the lowest dose and the highest dose. Larger numbers of animals responded to doses intermediate between these two extremes, and the maximum frequency of response occurred in the middle portion of the dose range. Thus, we have a bell-shaped curve known as a *normal frequency distribution.* The reason for this normal distribution is that there are differences in susceptibility to chemicals among individuals; this is known as biological variation. Animals responding at the left end of the curve are referred to as *hypersusceptible,* and those at the right end of the curve are called *resistant.* If the numbers of individuals responding at each consecutive dose are added together, a cumulative, quantal dose–response relationship is obtained. When a sufficiently large number of doses is used with a large number of animals per dose, a sigmoid dose–response curve is observed, as depicted in the middle panel of Fig. 2-4. With the lowest dose (6 mg/kg), 1% of the animals respond. A normally distributed sigmoid curve such as this one approaches a response of 0% as the dose is decreased and approaches 100% as the dose is increased; but—theoretically—it never passes through 0 and 100%. However, the minimally effective dose of any chemical that evokes a stated all-or-none response is called the *threshold dose* even though it cannot be determined experimentally.

For a normally distributed population response, the sigmoid curve has a relatively linear portion between 16 and 84%. These values represent the limits of 1 standard deviation (SD) of the mean (and the median) in a population with truly normal or Gaussian distribution. However, it is usually not practical to describe the dose–response curve from this type of plot because one does not usually have large enough sample sizes to define the sigmoid curve adequately. In a normally distributed population, the mean ± 1 SD represents 68.3% of the population, the mean ± 2 SD represents 95.5% of the population, and the mean ± 3 SD equals 99.7% of the population. Because quantal dose–response phenomena are usually normally distributed, one can convert the percent response to units of deviation from the mean or normal equivalent deviations (NEDs). Thus, the NED for a 50% response is 0; an NED of $+1$ is equated

with an 84.1% response. Traditionally, units of NED are converted by the addition of 5 to the value to avoid negative numbers; these converted units are called *probit units* (Bliss, 1957). The probit (from the contraction of *prob*ability un*it*), then, is an NED plus 5. In this transformation, a 50% response becomes a probit of 5, a $+1$ deviation becomes a probit of 6, and a -1 deviation is a probit of 4.

The data given in the top two panels of Fig. 2-4 are replotted in the bottom panel with the response plotted in probit units. The data in the middle panel (which was in the form of a sigmoid curve) and the top panel (a bell-shaped curve) form a straight line when transformed into probit units. In essence, what is accomplished in a probit transformation is an adjustment of quantal data to an assumed normal population distribution, resulting in a straight line. The ED_{50} is obtained by drawing a horizontal line from the probit unit 5, which is the 50% response point, to the dose–effect line. At the point of intersection, a vertical line is drawn, and this line intersects the abscissa at the ED_{50} point. It is evident from the line that information with respect to the effective dose for 90% or for 10% of the population also may be derived by a similar procedure. Mathematically, it can be demonstrated that the range of values encompassed by the confidence limits is narrowest at the midpoint of the line (ED_{50}) and widest at both extremes (ED_{10} and ED_{90}) of the dose–response curve (dotted lines in Fig. 2-5). In addition to the ED_{50}, the slope of the dose–response curve can also be obtained. Figure 2-5 demonstrates the dose–response curves for the response of two compounds. Compound A exhibits a "flat" dose–response curve, showing that a large change in dosage is required before a significant change in response will be observed. However, compound B exhibits a "steep" dose–response curve, where a relatively small change in dosage will cause a large change in response. It is evident that the ED_{50} for both compounds is the same (8 mg/kg). However, the slopes of the dose–response curves are quite different. At one-half of ED_{50} of the compounds (4 mg/kg), less than 1% of the animals exposed to compound B would respond but 20% of the animals given compound A would respond.

In Figs. 2-4 and 2-5 the dosage has been given on a log basis. Although the use of the log of the dosage is empiric, log-dosage plots for normally distributed quantal data provide a more nearly linear representation of the data. It must be remembered, however,

Figure 2-5. Comparison of dose–response relationship for two different chemicals, plotted on a log dose-probit scale.

Note that the slope of the dose–response is steeper for chemical *B* than chemical *A*. Dotted lines represents the confidence limits for chemical *A*.

Table 2.2
Allometric Scaling of Dose Across Different Species

SPECIES	WEIGHT (kg)	SURFACE AREA (cm²)*	FOLD DIFFERENCE, RELATIVE TO HUMANS, NORMALIZED BY BODY WEIGHT		
			mg/kg	$(BW)^{2/3}$	$(BW)^{3/4}$
Mouse	0.30	103	1	13.0	7.0
Rat	0.2	365	1	6.9	4.3
Guinea pig	0.4	582	1	5.5	3.6
Rabbit	1.5	1410	1	3.5	2.6
Cat	2	1710	1	3.2	2.4
Monkey	4	2720	1	2.6	2.0
Dog	12	5680	1	1.8	1.5
Human	70	18500	1	1.0	1.0

*Surface area of animals is closely approximated by the formula: $SA = 10.5 \times (Body\ wt,\ in\ grams)^{2/3}$.

that this is not universally the case. Some radiation effects, for example, give a better probit fit when the dose is expressed arithmetically rather than logarithmically. There are other situations in which other functions (e.g., exponentials) of dosage provide a better fit to the data than does the log function. It is also conventional to express the dosage in milligrams per kilogram. It might be argued that expression of dosage on a mole-per-kilogram basis would be better, particularly for making comparisons among a series of compounds. Although such an argument has considerable merit, dosage is usually expressed in milligrams per kilogram.

One might also view dosage on the basis of body weight as being less appropriate than other bases, such as surface area. The term *Allometry* refers to the field of study that examines the relationships between body weight and other biological and physical parameters such as rate of basal metabolism (caloric consumption), heart rate, blood flow, etc. Allometric studies revealed that the relationship between body weight and various other physiological parameters can be closely estimated by the formula, $Y = aW^b$, where Y is the biological parameter of interest, a and b are constants that relate Y to body weight (Rodricks *et al.*, 2001). In general, organ sizes between species seem to scale best when b is equal to 1, whereas metabolically derived parameters scale better when b is 0.67–0.75. The relationship between body surface area and body weight across most mammalian species is closely described by the formula $SA = 10.5 \times (body\ weight,\ in\ grams)^{0.67}$ (Harkness and Wagner, 1995). Empirical comparisons of toxicity data across species confirm that this relationship is appropriate for toxicological scaling. For example, Travis and White (1988) analyzed a number of toxicity testing data sets for 27 different chemotherapeutic drugs for which toxicity data were available in mouse, rat, hamster, dog, monkey, and human. They found that the exponent of body weight that gave the best correlation with toxicity was 0.73, with 95% confidence bounds of 0.69–0.77 (Rodricks *et al.*, 2001). Table 2-2 illustrates the differences in comparative doses when scaling is done by body weight (mg/kg) versus an allometric approach that uses an exponent of either 0.67 or 0.75. Thus, if a scaling factor of $(BW)^{2/3}$ is used, a mouse would need to receive a dose 13 times greater than humans for an equivalent toxic response, where as a it would be seven times greater if a scaling factor of $(BW)^{3/4}$ was used. However, not all toxic responses will necessarily scale across species in the same way. For example, acute lethality seemed to correlate better across species when body weight, rather than body surface area, was used (Rhomberg and Wolf, 1998).

Shape of the Dose–Response Curve

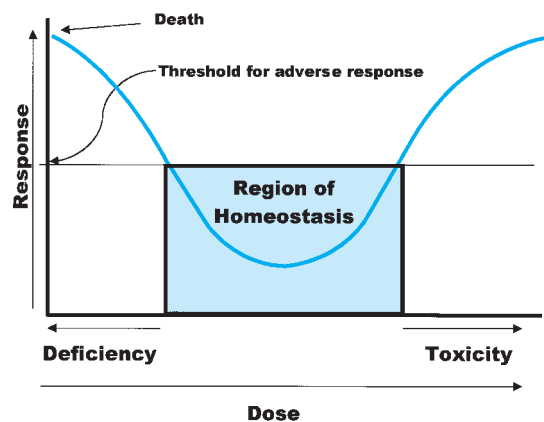
Essential Nutrients The shape of the dose–response relationship has many important implications in toxicity assessment. For example, for substances that are required for normal physiologic function and survival (e.g., vitamins and essential trace elements such as chromium, cobalt, and selenium), the shape of the "graded" dose–response relationship in an individual over the entire dose range is actually U-shaped (Fig. 2-6). That is, at very low doses, there is a high level of adverse effect, which decreases with an increasing dose. This region of the dose–response relationship for essential nutrients is commonly referred to as a *deficiency*. As the dose is increased to a point where the deficiency no longer exists, no adverse response is detected and the organism is in a state of homeostasis. However, as the dose is increased to abnormally high levels, an adverse response (usually qualitatively different from that observed at deficient doses) appears and increases in magnitude with increasing dose, just as with other toxic substances. Thus, it is recognized that high doses of vitamin A can cause liver toxicity and birth defects,


Figure 2-6. Individual dose–response relationship for an essential substance such as a vitamin or trace element.

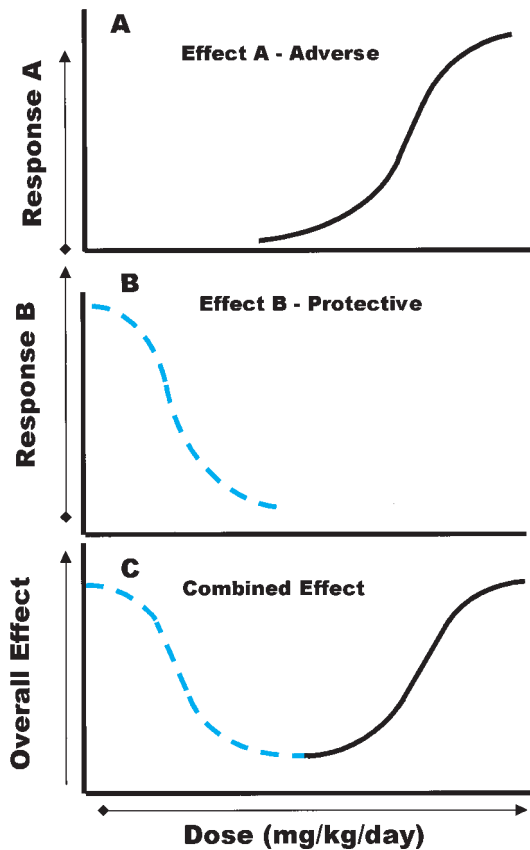
It is generally recognized that, for most types of toxic responses, a threshold exists such that at doses below the threshold, no toxicity is evident. For essential substances, doses below the minimum daily requirement, as well as those above the threshold for safety, may be associated with toxic effects. The blue-shaded region represents the "region of homeostasis"—the dose range that results in neither deficiency or toxicity.


Figure 2-7. Hypothetical dose–response relationship depicting characteristics of hormesis.

Hormetic effects of a substance are hypothesized to occur when relatively low doses result in the stimulation of a beneficial or protective response (*B*), such as induction of enzymatic pathways that protect against oxidative stress. Although low doses provide a potential beneficial effect, a threshold is exceeded as the dose increases and the net effects will be detrimental (*A*), resulting in a typical dose-related increase in toxicity. The complete dose–response curve (*C*) is conceptually similar to the individual dose–response relationship for essential nutrients shown in Fig. 2-6.

high doses of selenium can affect the brain, and high doses of estrogens may increase the risk of breast cancer, even though low doses of all these substances are essential for life.

Hormesis   There is considerable evidence to suggest that some nonnutritional toxic substances may also impart beneficial or stimulatory effects at low doses but that, at higher doses, they produce adverse effects. This concept of "hormesis" was first described for radiation effects but may also pertain to most chemical responses (Calabrese and Blaine, 2005). Thus, in plotting dose versus response over a wide range of doses, the effects of hormesis may also result in a "U-shaped" dose–response curve. In its original development, the concept of hormesis pertained to the ability of substances to stimulate biological systems at low doses but to inhibit them at high doses. The application of the concept of hormesis to whole-animal toxicologic dose–response relationships may also be relevant but requires that the "response" on the ordinate be variant with dose. For example, chronic alcohol consumption is well recognized to increase the risk of esophageal cancer, liver cancer, and cirrhosis of the liver at relatively high doses, and this response is dose-related

(curve A, Fig. 2-7). However, there is also substantial clinical and epidemiologic evidence that low to moderate consumption of alcohol reduces the incidence of coronary heart disease and stroke (curve B, Fig. 2-7) (Hanna *et al.*, 1997). Thus, when all responses are plotted on the ordinate, a "U-shaped" dose–response curve is obtained (curve C, Fig. 2-7). U-shaped dose–response relationships have obvious implications for the process of low dose extrapolation in risk assessment.

Threshold   Another important aspect of the dose–response relationship at low doses is the concept of the threshold. It has long been recognized that acute toxicologic responses are associated with thresholds; that is, there is some dose below which the probability of an individual responding is zero. Obviously, the identification of a threshold depends on the particular response that is measured, the sensitivity of the measurement, and the number of subjects studied. For the individual dose–response relationship, thresholds for most toxic effects certainly exist, although interindividual variability in response and qualitative changes in response pattern with dose make it difficult to establish a true "no effects" threshold for any chemical. The biological basis of thresholds for acute responses is well established and frequently can be demonstrated on the basis of mechanistic information (Aldridge, 1986). The traditional approaches to establishing acceptable levels of exposure to chemicals are inherently different for threshold versus nonthreshold responses. The existence of thresholds for chronic responses is less well defined, especially in the area of chemical carcinogenesis. It is, of course, impossible to scientifically prove the absence of a threshold, as one can never prove a negative. Nevertheless, for the identification of "safe" levels of exposure to a substance, the absence or presence of a threshold is important for practical reasons (see Chap. 4). A classic example of the difficulty of establishing thresholds experimentally is provided by the "ED01" study, where over 24,000 mice and 81 different treatment groups were used to determine the shape of the dose–response relationship for the prototypical carcinogen 2-acetylaminofluorene (2-AAF). The study was designed to identify a statistically significant response of 1% (0.01 probability). The mice were exposed to 2-AAF at one of seven different doses in the dose range of 30 to 150 ppm (plus 0 dose control) (Littlefield *et al.*, 1979). Eight "sacrifice intervals" were used to determine how quickly tumors developed. The dose–response relationship between 2-AAF exposure and liver and bladder cancer at 24 and 33 months of exposure are shown in Fig. 2-8. Both types of tumors demonstrated increasing incidence with increasing dose, but the shapes of the two curves are dramatically different. For liver tumors, no clear threshold was evident, whereas for bladder tumors, an apparent threshold was evident. However, the apparent threshold, or "no observable adverse effect level" (NOAEL), for bladder cancer was lower at 33 months (45 ppm) than at 24 months (75 ppm). Of course, the ability to detect a low incidence of tumors depends on the number of animals used in the study. Thus, although a threshold (a dose below which no response occurs) appears evident for bladder tumors in Fig. 2-8, one cannot say for certain that tumors would not occur if more animals had been included in the lower-dose groups. (See Chap. 4 for more discussion on statistical issues related to extrapolation of dose–response curves and the determination of NOAELs.)

     In evaluating the shape of the dose–response relationship in populations, it is realistic to consider inflections in the shape of the dose–response curve rather than absolute thresholds. That is, the slope of the dose–response relationship at high doses may be
Figure 2-8.   Dose–response relationship for carcinogens.

Eight groups of male mice were administered 2-acetylaminofluorine (2-AAF) in the diet from weaning. The percent of animals with liver (*blue line*) or bladder (*black line*) tumors at 24 months (*A*) or 33 months (*B*) are shown. Most of the animals in the high-dose group (150 ppm) did not survive to 33 months; thus, those data are not shown in *B*.

although the risk decreases proportionately with a decrease in the dose. The existence or lack of existence of a threshold dose for carcinogens has many regulatory implications and is a point of considerable controversy and research in the field of quantitative risk assessment for chemical carcinogens (see Chap. 4).

Assumptions in Deriving the Dose–Response Relationship

A number of assumptions must be considered before dose–response relationships can be used appropriately. The first is that the response is due to the chemical administered. To describe the relationship between a toxic material and an observed effect or response, one must know with reasonable certainty that the relationship is indeed a causal one. For some data, it is not always apparent that the response is a result of chemical exposure. For example, an epidemiologic study might result in the discovery of an "association" between a response (e.g., disease) and one or more variables. Frequently, the data are presented similarly to the presentation of "dose response" in pharmacology and toxicology. Use of the dose response in this context is suspect unless other convincing evidence supports a causal connection between the estimated dose and the measured endpoint (response). Unfortunately, in nearly all retrospective and case-control studies and even in many prospective studies, the dose, duration, frequency, and routes of exposure are seldom quantified, and other potential etiologic factors are frequently present. In its most strict usage, then, the dose–response relationship is based on the knowledge that the effect is a result of a known toxic agent or agents.

A second assumption seems simple and obvious: The magnitude of the response is in fact related to the dose. Perhaps because of its apparent simplicity, this assumption is often a source of misunderstanding. It is really a composite of three other assumptions that recur frequently:

1. There is a molecular target site (or sites) with which the chemical interacts to initiate the response.
2. The production of a response and the degree of response are related to the concentration of the chemical at the target site.
3. The concentration at the site is, in turn, related to the dose administered.

The third assumption in using the dose–response relationship is that there exists both a quantifiable method of measuring and a precise means of expressing the toxicity. For any given dose–response relationship, a great variety of criteria or endpoints of toxicity could be used. The ideal criterion would be one closely associated with the molecular events resulting from exposure to the toxicant. It follows from this that a given chemical may have a family of dose–response relationships, one for each toxic endpoint. For example, a chemical that produces cancer through genotoxic effects, liver damage through inhibition of a specific enzyme, and CNS effects via a different mechanism may have three distinct dose–response relationships, one for each endpoint. Early in the assessment of toxicity, little mechanistic information is usually available; thus establishing a dose–response relationship based on the molecular mechanism of action is usually impossible. Indeed, it might not be approachable even for well-known toxicants. In the absence of a mechanistic, molecular ideal criterion of toxicity, one looks to a measure of toxicity that is unequivocal and clearly relevant to the toxic effect. Such measures are often referred to as "effects-related biomarkers." For

substantially different from the slope at low doses, usually because of dispositional differences in the chemical. Saturation of biotransformation pathways, protein-binding sites or receptors, and depletion of intracellular cofactors represent some reasons why sharp inflections in the dose–response relationship may occur. For example, the widely used analgesic acetaminophen has a very low rate of liver toxicity at normal therapeutic doses. Even though a toxic metabolite [*N*-acetyl-*p*-benzoquinoneimine (NAPQI)] is produced in the liver at therapeutic doses, it is rapidly detoxified through conjugation with the intracellular antioxidant glutathione. However, at very high doses, the level of intracellular glutathione in the liver is depleted and NAPQI accumulates, causing serious and potentially fatal liver toxicity. This effect is analogous to the rapid change in pH of a buffered solution that occurs when the buffer capacity is exceeded. Some toxic responses, most notably the development of cancer after the administration of genotoxic carcinogens, are often considered to be linear at low doses and thus do not exhibit a threshold. In such circumstances, there is no dose with "zero" risk,

example, with a new compound chemically related to the class of organophosphate insecticides, one might approach the measurement of toxicity by measuring the inhibition of cholinesterase in blood. In this way, one would be measuring, in a readily accessible system and using a technique that is convenient and reasonably precise, a prominent effect of the chemical and one that is usually pertinent to the mechanism by which toxicity is produced.

The selection of a toxic endpoint for measurement is not always so straightforward. Even the example cited above may be misleading, as an organophosphate may produce a decrease in blood cholinesterase, but this change may not be directly related to its toxicity. As additional data are gathered to suggest a mechanism of toxicity for any substance, other measures of toxicity may be selected. Although many endpoints are quantitative and precise, they are often indirect measures of toxicity. Changes in enzyme levels in blood can be indicative of tissue damage. For example, alanine aminotransferase (ALT) and aspartate aminotransferase (AST) are used to detect liver damage. Use of these enzymes in serum is yet another example of an effects-related biomarker because the change in enzyme activity in the blood is directly related to damage to liver cells. Much of clinical diagnostic medicine relies on effects-related biomarkers, but to be useful the relationship between the biomarker and the disease must be carefully established. Patterns of isozymes and their alteration may provide insight into the organ or system that is the site of toxic effects. As discussed later in this chapter, the new tools of toxicogenomics provide an unprecedented opportunity to discover new "effects-related biomarkers" in toxicology.

Many direct measures of effects are also not necessarily related to the mechanism by which a substance produces harm to an organism but have the advantage of permitting a causal relation to be drawn between the chemical and its action. For example, measurement of the alteration of the tone of smooth or skeletal muscle for substances acting on muscles represents a fundamental approach to toxicological assessment. Similarly, measures of heart rate, blood pressure, and electrical activity of heart muscle, nerve, and brain are examples of the use of physiologic functions as indices of toxicity. Measurement can also take the form of a still higher level of integration, such as the degree of motor activity or behavioral change.

The measurements used as examples in the preceding discussion all assume prior information about the toxicant, such as its target organ or site of action or a fundamental effect. However, such information is usually available only after toxicological screening and testing based on other measures of toxicity. With a new substance, the customary starting point is a single dose acute toxicity test designed to provide preliminary identification of target organ toxicity. Studies specifically designed with lethality as an end-point are no longer recommended by United States or international agencies. Data from acute studies provides essential information for choosing doses for repeated dosing studies as well as choosing specific toxicological endpoints for further study. Key elements of the study design must be a careful, disciplined, detailed observation of the intact animal extending from the time of administration of the toxicant to any clinical signs of distress, which may include detailed behavioral observations or physiological measures. It is recommended that these observations be taken over a 14-day period. From properly conducted observations, immensely informative data can be gathered by a trained toxicologist. Second, an acute toxicity study ordinarily is supported by histological examination of major tissues and organs for abnormalities. From these observations, one can usually obtain more specific information about the events leading to the various
Figure 2-9. *Comparison of effective dose (ED), toxic dose (TD), and lethal dose (LD).*

The plot is of log dosage versus percentage of population responding in probit units.

endpoints, the target organs involved, and often a suggestion about the possible mechanism of toxicity at a relatively fundamental level.

Evaluating the Dose–Response Relationship

Comparison of Dose Responses   Figure 2-9 illustrates a hypothetical quantal dose–response curve for a desirable effect of a chemical effective dose (ED) such as anesthesia, a toxic dose (TD) effect such as liver injury, and the lethal dose (LD). As depicted in Fig. 2-9, a parallelism is apparent between the ED curve and the curve depicting mortality (LD). It is tempting to view the parallel dose–response curves as indicative of identity of mechanism—that is, to conclude that the lethality is a simple extension of the therapeutic effect. Whereas this conclusion may ultimately prove to be correct in any particular case, it is not warranted solely on the basis of the two parallel lines. The same admonition applies to any pair of parallel "effect" curves or any other pair of toxicity or lethality curves.

Therapeutic Index   The hypothetical curves in Fig. 2-9 illustrate two other interrelated points: the importance of the selection of the toxic criterion and the interpretation of comparative effect. The concept of the "therapeutic index," which was introduced by Paul Ehrlich in 1913, can be used to illustrate this relationship. Although the therapeutic index is directed toward a comparison of the therapeutically effective dose to the toxic dose of a chemical, it is equally applicable to considerations of comparative toxicity. The *therapeutic index* (TI) in its broadest sense is defined as the ratio of the dose required to produce a toxic effect and the dose needed to elicit the desired therapeutic response. Similarly, an index of comparative toxicity is obtained by the ratio of doses of two different materials to produce an identical response or the ratio of doses of the same material necessary to yield different toxic effects.

The most commonly used index of effect, whether beneficial or toxic, is the median effect dose (ED_{50}). The therapeutic index of a drug is an approximate statement about the relative safety of a drug expressed as the ratio of the adverse endpoint or toxic dose (historically the lethal dose) to the therapeutic dose:

$$\text{Therapeutic Index} = TD_{50}/ED_{50}$$
Figure 2-10. Schematic representation of the difference in the dose–response curves for four chemicals (A–D), illustrating the difference between potency and efficacy (see text).

From Fig. 2-9 one can approximate a therapeutic index by using these median doses. The larger the ratio, the greater the relative safety. The ED_{50} is approximately 20, and the TD_{50} is about 60; thus, the therapeutic index is 3, a number indicating that reasonable care in exposure to the drug is necessary to avoid toxicity. However, the use of the median effective and median toxic doses is not without disadvantages, because median doses tell nothing about the slopes of the dose–response curves for therapeutic and toxic effects.

Margins of Safety and Exposure   One way to overcome this deficiency is to use the ED_{99} for the desired effect and the TD_1 for the undesired effect. These parameters are used in the calculation of the margin of safety (MOS):

$$\text{Margin of safety} = TD_1/ED_{99}$$

The quantitative comparisons described above have been used mainly after a single administration of chemicals. However, for chemicals for which there is no beneficial or effective dose and exposures are likely to occur repeatedly, the ratio of TD_1 to ED_{99} has little relevance. Thus, for non-drug chemicals, the term *margin of safety* has found use in risk-assessment procedures as an indicator of the magnitude of the difference between an estimated "exposed dose" to a human population and the NOAEL or other benchmark dose determined in experimental animals.

A measure of the degree of accumulation of a chemical and/or its toxic effects can also be estimated from quantal toxicity data. The *chronicity index* of a chemical is a unitless value obtained by dividing its 1-dose TD_{50} by its 90-dose (90-day) TD_{50}, with both expressed in milligrams per kilogram per day. Theoretically, if no cumulative effect occurs over the doses, the chronicity index will be 1. If a compound were absolutely cumulative, the chronicity index would be 90.

Historically, statistical procedures similar to those used to calculate the LD_{50} can also be used to determine the lethal time 50 (LT_{50}), or the time required for half the animals to die (Litchfield, 1949). The LT_{50} value for a chemical indicates the time course of the toxic effects but does not indicate whether one chemical is more toxic than another.

Frequently, dose–response curves from repeated-dose experimental animal studies (subacute, subchronic, or chronic) are used

to estimate the NOAEL, or some other "benchmark" measure of minimal toxic response, such as the dose estimated to produce toxic effects in 10% of the population (TD_{10}) (see also Chap. 4). These estimates of minimal toxic dose, derived from quantal dose–response curves, can be used in risk assessment to derive a "margin of exposure" (MOE) index. This index compares the estimated daily exposure, in milligrams per kilogram per day, that might occur under a given set of circumstances to some estimated value from the quantal dose–response relationship (e.g., NOAEL or TD_{10}). Like the MOS, the MOE is often expressed as a ratio of these two values. Thus, for example, if an estimate of human exposure to a pesticide residue yielded a value of 0.001 mg/kg/day, and a TD_{10} of 1 mg/kg/day was determined for that same pesticide, the MOE would be 1000. This value indicates that the estimate of daily exposure under the described set of conditions is 1/1000 the estimated daily dose that would cause evident toxicity in 10% of exposed animals. (See Chap. 4 for a more complete discussion of benchmark doses, NOAELs, and MOE.)

Potency versus Efficacy   To compare the toxic effects of two or more chemicals, the dose response to the toxic effects of each chemical must be established. One can then compare the potency and maximal efficacy of the two chemicals to produce a toxic effect. These two important terms can be explained by reference to Fig. 2-10, which depicts dose–response curves to four different chemicals for the frequency of a particular toxic effect, such as the production of tumors. Chemical A is said to be more potent than chemical B because of their relative positions along the dosage axis. Potency thus refers to the range of doses over which a chemical produces increasing responses. Thus, A is more potent than B and C is more potent than D. Maximal efficacy reflects the limit of the dose–response relationship on the response axis to a certain chemical. Chemicals A and B have equal maximal efficacy, whereas the maximal efficacy of C is less than that of D.

VARIATION IN TOXIC RESPONSES

Selective Toxicity

Selective toxicity means that a chemical produces injury to one kind of living matter without harming another form of life even though

the two may exist in intimate contact (Albert, 1965, 1973). The living matter that is injured is termed the *uneconomic form* (or undesirable), and the matter protected is called the *economic form* (or desirable). They may be related to each other as parasite and host or may be two tissues in one organism. This biological diversity interferes with the ability of ecotoxicologists to predict the toxic effects of a chemical in one species (humans) from experiments performed in another species (laboratory animals). However, by taking advantage of the biological diversity, it is possible to develop chemicals that are lethal for an undesired species and harmless for other species. In agriculture, for example, there are fungi, insects, and even competitive plants that injure the crop, and thus selective pesticides are needed. Similarly, animal husbandry and human medicine require chemicals, such as antibiotics, that are selectively toxic to the undesirable form but do not produce damage to the desirable form.

Drugs and other chemicals used for selective toxic purposes are selective for one of two reasons. Either (1) the chemical is equally toxic to both economic and uneconomic cells but is accumulated mainly by uneconomic cells or (2) it reacts fairly specifically with a cytological or a biochemical feature that is absent from or does not play an important role in the economic form (Albert, 1965, 1973). Selectivity resulting from differences in distribution usually is caused by differences in the absorption, biotransformation, or excretion of the toxicant. The selective toxicity of an insecticide spray may be partly due to a larger surface area per unit weight that causes the insect to absorb a proportionally larger dose than does the mammal being sprayed. The effectiveness of radioactive iodine in the treatment of hyperthyroidism (as well as its thyroid carcinogenicity) is due to the selective ability of the thyroid gland to accumulate iodine. A major reason why chemicals are toxic to one, but not to another, type of tissue is that there are differences in accumulation of the ultimate toxic compound in various tissues. This, in turn, may be due to differences in the ability of various tissues to transport or biotransform the chemical into the ultimate toxic product.

Selective toxicity caused by differences in comparative cytology is exemplified by a comparison of plant and animal cells. Plants differ from animals in many ways—for example, absence of a nervous system, an efficient circulatory system, and muscles as well as the presence of a photosynthetic mechanism and cell walls. The fact that bacteria contain cell walls and humans do not has been utilized in developing selective toxic chemotherapeutic agents, such as penicillin and cephalosporins, that kill bacteria but are relatively nontoxic to mammalian cells.

Selective toxicity can also be a result of a difference in biochemistry in the two types of cells. For example, bacteria do not absorb folic acid but synthesize it from *p*-aminobenzoic acid, glutamic acid, and pteridine, whereas mammals cannot synthesize folic acid but have to absorb it from the diet. Thus, sulfonamide drugs are selectively toxic to bacteria because the sulfonamides, which resemble *p*-aminobenzoic acid in both charge and dimensions, antagonize the incorporation of *p*-aminobenzoic acid into the folic acid molecule—a reaction that humans do not carry out.

Species Differences

Although a basic tenet of toxicology is that "experimental results in animals, when properly qualified, are applicable to humans," it is important to recognize that both quantitative and qualitative differences in response to toxic substances may occur among different species. As discussed above, there are many reasons for selective toxicity among different species. Even among phylogenetically similar species (e.g., rats, mice, guinea pigs, and hamsters), large differences in response may occur. For example, the LD_{50} for the highly toxic dioxin, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), differs by more than 1000-fold between guinea pigs and hamsters. Not only does the lethal dose for TCDD vary widely among species, so do the particular target organs affected. Species differences in response to carcinogenic chemicals represent an important issue in regulatory risk assessment. As discussed in Chap. 4, extrapolation of laboratory animal data to infer human cancer risk is currently a key component of regulatory decision making. The validity of this approach of course depends on the relevance of the experimental animal model to humans. Large differences in carcinogenic response between experimental animal species are not unusual. For example, mice are highly resistant to the hepatocarcinogenic effects of the fungal toxin aflatoxin B_1. Dietary doses as high as 10,000 parts per billion (ppb) failed to produce liver cancer in mice, whereas in rats dietary doses as low as 15 ppb produced a significant increase in liver tumors (Wogan *et al.*, 1974). The mechanistic basis for this dramatic difference in response appears to be entirely related to species differences in the expression of a particular form of glutathione *S*-transferase (mGSTA3-3) that has unusually high catalytic activity toward the carcinogenic epoxide of aflatoxin (Eaton and Gallagher, 1994). Mice express this enzyme constitutively, whereas rats normally express a closely related form with much less detoxifying activity toward aflatoxin epoxide. Interestingly, rats do possess the gene for a form of glutathione *S*-transferase with high catalytic activity toward aflatoxin epoxide (rGSTA5-5) that is inducible by certain dietary antioxidants and drugs. Thus, dietary treatment can dramatically change the sensitivity of a species to a carcinogen.

Other examples in which large species differences in response to carcinogens have been observed include the development of renal tumors from 2,3,5-trimethylpentane and *d*-limonene in male rats (Lehman-McKeeman and Caudill, 1992), the production of liver tumors from "peroxisomal proliferators" such as the antilipidemic drug clofibrate and the common solvent trichloroethylene (Roberts, 1999), and the induction of nasal carcinomas in rats after inhalation exposure to formaldehyde (Monticello and Morgan, 1997).

Identifying the mechanistic basis for species differences in response to chemicals is an important part of toxicology because only through a thorough understanding of these differences can the relevance of animal data to human response be verified.

Individual Differences in Response

Even within a species, large interindividual differences in response to a chemical can occur because of subtle genetic differences. Hereditary differences in a single gene that occur in more than 1% of the population are referred to as *genetic polymorphism* and may be responsible for idiosyncratic reactions to chemicals, as discussed earlier in this chapter. However, genetic polymorphism may have other important but less dramatic effects than those described for acute idiosyncratic responses (such as that occurring in pseudocholinesterase-deficient individuals after succinylcholine exposure). For example, it is recognized that approximately 50% of the Caucasian population has a gene deletion for the enzyme glutathione S-transferase M1. This enzyme has no apparent significant physiologic function, and thus homozygotes for the gene deletion (e.g., those who lack both copies of the normal gene) are functionally and physiologically normal. However, epidemiologic studies have indicated that smokers who are homozygous for the null allele

may be at slightly increased risk of developing lung cancer compared with smokers who have one or both copies of the normal gene (Mohr *et al.*, 2003). Chapter 6 provides additional examples of genetic differences in biotransformation enzymes that may be important determinants of variability in individual susceptibility to chemical exposures.

Genetic polymorphism in physiologically important genes may also be responsible for interindividual differences in toxic responses. For example, studies in transgenic mice have shown that mice possessing one copy of a mutated *p*53 gene (a so-called tumor suppressor gene; see Chap. 8) are much more susceptible to some chemical carcinogens than are mice with two normal copies of the gene (Tennant *et al.*, 1999). In humans, there is evidence that possessing one mutated copy of a tumor suppressor gene greatly increases the risk of developing certain cancers. For example, retinoblastoma is a largely inherited form of cancer that arises because of the presence of two copies of a defective tumor suppressor gene (the Rb gene) (Wiman, 1993). Individuals with one mutated copy of the Rb gene and one normal copy are not destined to acquire the disease (as are those with two copies of the mutated gene), although their chance of acquiring it is much greater than that of persons with two normal Rb genes. This is the case because both copies of the gene must be nonfunctional for the disease to develop. With one mutated copy present genetically, the probability of acquiring a mutation of the second gene (potentially from exposure to environmental mutagens) is much greater than the probability of acquiring independent mutations in both copies of the gene as would be necessary in people with two normal Rb alleles. (See Chap. 8 for additional discussion of tumor suppressor genes.)

As our understanding of the human genome increases, more "susceptibility" genes will be discovered, and it is likely that the etiology of many chronic diseases will be shown to be related to a combination of genetics and environment. Simple blood tests may ultimately be developed that allow an individual to learn whether he or she may be particularly susceptible to specific drugs or environmental pollutants. Although the public health significance of this type of information could be immense, the disclosure of such information raises many important ethical and legal issues that must be addressed before wide use of such tests.

The study of "gene-environment" interactions, or "Ecogenetics" (Costa and Eaton, 2006) is a rapidly developing field of substantial relevance to toxicology. It is likely that the majority of chronic diseases develop as a result of the complex interplay between multiple genes and the myriad of environmental factors, including diet, lifestyle, and occupational and/or environmental exposures to toxic substances.

DESCRIPTIVE ANIMAL TOXICITY TESTS

Two main principles underlie all descriptive animal toxicity testing. The first is that the effects produced by a compound in laboratory animals, when properly qualified, are applicable to humans. This premise applies to all of experimental biology and medicine. On the basis of dose per unit of body surface, toxic effects in humans are usually in the same range as those in experimental animals. On a body weight basis, humans are generally more vulnerable than are experimental animals. When one has an awareness of these quantitative differences, appropriate safety factors can be applied to calculate relatively safe doses for humans. All known chemical carcinogens in humans, with the possible exception of arsenic, are carcinogenic in some species but not in all laboratory animals. It has become increas-

ingly evident that the converse—that all chemicals carcinogenic in animals are also carcinogenic in humans—is not true (Dybing and Sanner, 1999; Grisham, 1997; Hengstler *et al.*, 1999). However, for regulatory and risk assessment purposes, positive carcinogenicity tests in animals are usually interpreted as indicative of potential human carcinogenicity. If a clear understanding of the mechanism of action of the carcinogen indicates that a positive response in animals is not relevant to humans, a positive animal bioassay may be considered irrelevant for human risk assessment (see Chap. 4). This species variation in carcinogenic response appears to be due in many instances to differences in biotransformation of the procarcinogen to the ultimate carcinogen (see Chap. 6).

The second principle is that exposure of experimental animals to chemicals in high doses is a necessary and valid method of discovering possible hazards in humans. This principle is based on the quantal dose–response concept that the incidence of an effect in a population is greater as the dose or exposure increases. Practical considerations in the design of experimental model systems require that the number of animals used in toxicology experiments always be small compared with the size of human populations at risk. Obtaining statistically valid results from such small groups of animals requires the use of relatively large doses so that the effect will occur frequently enough to be detected. However, the use of high doses can create problems in interpretation if the response(s) obtained at high doses does not occur at low doses. Thus, for example, it has been shown that bladder tumors observed in rats fed very high doses of saccharin will not occur at the much lower doses of saccharin encountered in the human diet. At the high concentrations fed to rats, saccharin forms an insoluble precipitate in the bladder that subsequently results in chronic irritation of bladder epithelium, enhanced cell proliferation, and ultimately bladder tumors (Cohen, 1998, 1999). In vitro studies have shown that precipitation of saccharin in human urine will not occur at the concentrations that could be obtained from even extraordinary consumption of this artificial sweetener. Examples such as this illustrate the importance of considering the molecular, biochemical, and cellular mechanisms responsible for toxicological responses when extrapolating from high to low dose and across species.

Toxicity tests are not designed to demonstrate that a chemical is safe but to characterize the toxic effects a chemical can produce. Although there are no set toxicology tests that have to be performed on every chemical intended for commerce, a tiered approach typical of many hazard assessment programs is shown illustrated in Fig. 2-11. Depending on the eventual use of the chemical, the toxic effects produced by structural analogs of the chemical, as well as the toxic effects produced by the chemical itself, contribute to the determination of the toxicology tests that should be performed. The FDA, EPA, and Organization for Economic Cooperation and Development (OECD) have written good laboratory practice (GLP) standards that stipulate that procedure must be defined and accountability documented. These guidelines are expected to be followed when toxicity tests are conducted in support of the introduction of a chemical to the market.

The following sections provide an overview of basic toxicity testing procedures in use today. For a detailed description of these tests, the reader is referred to several authoritative texts on this subject (Williams and Hottendorf, 1999; Hayes, 2001; Jacobson-Kram and Keller, 2001).

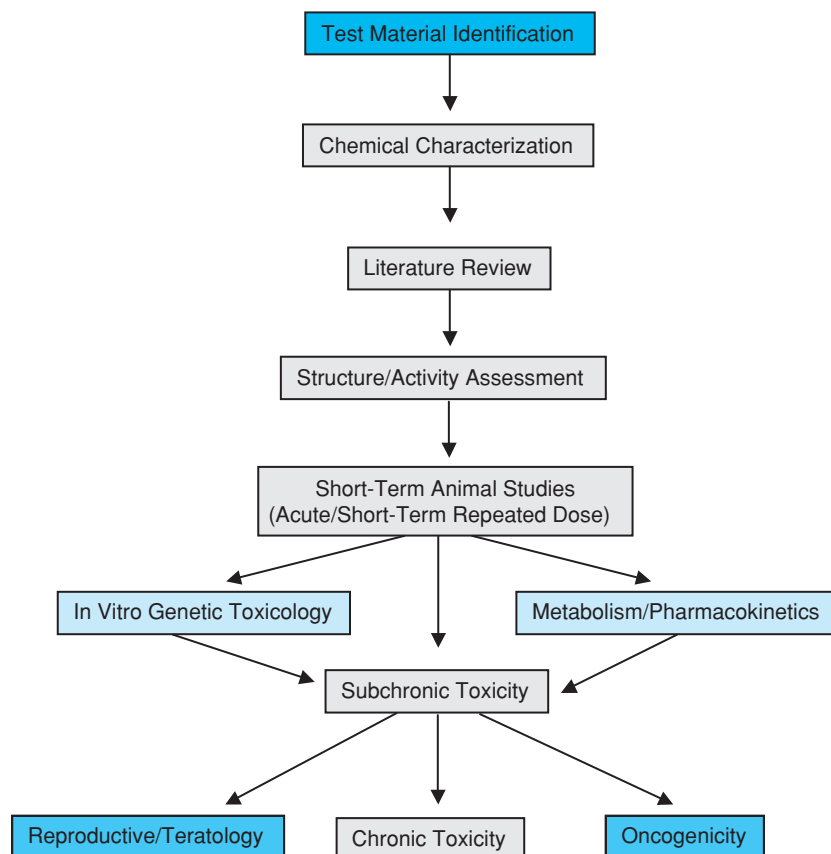
Although different countries have often had different testing requirements for toxicity testing/product safety evaluation, efforts to "harmonize" such testing protocols have resulted in more


Figure 2-11. Typical Tiered Testing Scheme for the Toxicological Evaluation of New Chemicals

(From: Wilson *et al.*, 2001. In: Hayes, 2001; *Principles and Methods in Toxicology*, 4th ed, Fig. 19-1, p. 918.)

standardized approaches. The International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (ICH) includes regulatory authorities from Europe, Japan, and the United States (primarily the FDA), as well as experts from the pharmaceutical industry in the three regions, who worked together to develop internationally recognized scientific and technical approaches to pharmaceutical product registration. ICH has adopted guidelines for most areas of toxicity testing (Table 2-3). In addition to safety assessment (ICH Guidelines designated with an "S"), ICH has also established guidelines on Quality (Q), Efficacy (E) and Multidisciplinary (M) topics. [see: http://www.ich.org/cache/compo/276-254-1.html for a description of current ICH guidelines and (Pugsley and Curtiss, 2006) for a detailed discussion of in vitro and in vivo pharmacological methods development that has been informed by the ICH regulatory guidance document for pre-clinical safety testing of drugs].

Typically, a tiered approach is used, with subsequent tests dependent on results of initial studies. A general framework for how new chemicals are evaluated for toxicity is shown in Fig 2-11. Early studies require careful chemical evaluation of the compound or mixture to assess purity, stability, solubility, and other physicochemical factors that could impact the ability of the test compound to be delivered effectively to animals. Once this information is obtained, the chemical structure of the test compound is compared with similar chemicals for which toxicological information is already available. Structure-activity relationships may be derived from a review of existing toxicological literature, and can provide additional guidance on design of acute and repeated dose experiments, and what specialized tests need to be completed. Once such basic information has been compiled and evaluated, the test compound is then administered to animals in acute and repeated dose studies.

Acute Toxicity Testing

Generally, the first toxicity test performed on a new chemical is acute toxicity, determined from the administration of a single exposure. The objectives of acute toxicity testing are to: (1) provide an estimate of the intrinsic toxicity of the substance, often times expressed as an approximate lethal dose (e.g., LD_{50}), (2) provide information on target organs and other clinical manifestations of toxicity, (3) identify species differences and susceptible species, (4) establish the reversibility of the toxic response, and (5) provide information that will assist in the design and dose selection for longer term (sub-chronic, chronic) studies. It should be noted that the ICH recommended in 1991 (D'Arcy and Harron, 1992) the elimination of LD_{50} determinations for pharmaceuticals, although other regulatory requirements, e.g., pesticide registration, may still require determinations of LD_{50}s.

The LD_{50} and other acute toxic effects are determined after one or more routes of administration (one route being oral or the intended route of exposure) in one or more species. The species most often used are the mouse and rat. Studies are performed in both adult

male and female animals. Food is often withheld the night before dosing. The number of animals that die in a 14-day period after a single dosage is tabulated. In addition to mortality and weight, daily examination of test animals should be conducted for signs of intoxication, lethargy, behavioral modifications, morbidity, food consumption, and so on.

Determination of the LD_{50} has become a public issue because of increasing concern for the welfare and protection of laboratory animals. The LD_{50} is not a biological constant. Many factors influence toxicity and thus may alter the estimation of the LD_{50} in any particular study. Factors such as animal strain, age, and weight, type of feed, caging, pretrial fasting time, method of administration, volume and type of suspension medium, and duration of observation have all been shown to influence adverse responses to toxic substances. These and other factors have been discussed in detail in earlier editions of this textbook (Doull, 1980). Because of this inherent variability in LD_{50} estimates, it is now recognized that for most purposes it is only necessary to characterize the LD_{50} within an order of magnitude range such as 5–50 mg/kg, 50–500 mg/kg, and so on.

There are several traditional approaches to determining the LD_{50} and its 95% confidence limit as well as the slope of the probit line. The reader is referred to the classic works of Litchfield and Wilcoxon (1949), Bliss (1957), and Finney (1971) for a description of the mechanics of these procedures. Other statistical tech-

niques that require fewer animals, such as the "moving averages" method of Thompson and Weill (Weil, 1952), are available but do not provide confidence limits for the LD_{50} and the slope of the probit line. Finney (1985) has succinctly summarized the advantages and deficiencies of many of the traditional methods. For most circumstances, an adequate estimate of the LD_{50} and an approximation of the 95% confidence intervals can be obtained with as few as 6 to 9 animals, using the "up-and-down" method as modified by Bruce (1985). When this method was compared with traditional methods that typically utilize 40 to 50 animals, excellent agreement was obtained for all 10 compounds tested (Bruce, 1987). In mice and rats the LD_{50} is usually determined as described above, but in the larger species only an approximation of the LD_{50} is obtained by increasing the dose in the same animal until serious toxic effects are evident.

If there is a reasonable likelihood of substantial exposure to the material by dermal or inhalation exposure, acute dermal and acute inhalation studies are performed. When animals are exposed acutely to chemicals in the air they breathe or the water they (fish) live in, the dose the animals receive is usually not known. For these situations, the lethal concentration 50 (LC_{50}) is usually determined; that is, the concentration of chemical in the air or water that causes death to 50% of the animals. In reporting an LC_{50}, it is imperative that the time of exposure be indicated. The acute dermal toxicity test is usually performed in rabbits. The site of application is shaved. The test substance is kept in contact with the skin for 24 hours by

wrapping the skin with an impervious plastic material. At the end of the exposure period, the wrapping is removed and the skin is wiped to remove any test substance still remaining. Animals are observed at various intervals for 14 days, and the LD_{50} is calculated. If no toxicity is evident at 2 g/kg, further acute dermal toxicity testing is usually not performed. Acute inhalation studies are performed that are similar to other acute toxicity studies except that the route of exposure is inhalation. Most often, the length of exposure is 4 hours.

Although by themselves LD_{50} and LC_{50} values are of limited significance given the growing sophistication of target organ toxicity endpoints and mechanistic analysis. The most meaningful scientific information derived from acute toxicity tests comes from clinical observations and postmortem examination of animals rather than from the specific LD_{50} value.

Skin and Eye Irritations

The ability of a chemical to irritate the skin and eye after an acute exposure is usually determined in rabbits. For the dermal irritation test (Draize test), rabbits are prepared by removal of fur on a section of the back by electric clippers. The chemical is applied to the skin (0.5 mL of liquid or 0.5 g of solid) under four covered gauze patches (1 in. square; one intact and two abraded skin sites on each animal) and usually kept in contact for 4 hours. The nature of the covering patches depends on whether occlusive, semiocclusive, or nonocclusive tests are desired. For occlusive testing, the test material is covered with an impervious plastic sheet; for semiocclusive tests, a gauze dressing may be used. Occasionally, studies may require that the material be applied to abraded skin. The degree of skin irritation is scored for erythema (redness), eschar (scab), and edema (swelling) formation, and corrosive action. These dermal irritation observations are repeated at various intervals after the covered patch has been removed. To determine the degree of ocular irritation, the chemical is instilled into one eye (0.1 mL of liquid or 100 mg of solid) of each test rabbit. The contralateral eye is used as the control. The eyes of the rabbits are then examined at various times after application.

Controversy over this test has led to the development of alternative in vitro models for evaluating cutaneous and ocular toxicity of substances. The various in vitro methods that have been evaluated for this purpose include epidermal keratinocyte and corneal epithelial cell culture models. These and other in vitro tests have been reviewed recently (Davila *et al.*, 1998).

Sensitization

Information about the potential of a chemical to sensitize skin is needed in addition to irritation testing for all materials that may repeatedly come into contact with the skin. Numerous procedures have been developed to determine the potential of substances to induce a sensitization reaction in humans (delayed hypersensitivity reaction), including the Draize test, the open epicutaneous test, the Buehler test, Freund's complete adjuvant test, the optimization test, the split adjuvant test, and the guinea pig maximization test (Maibach and Patrick, 2001; Rush *et al.*, 1995). Although they differ in regard to route and frequency of duration, they all utilize the guinea pig as the preferred test species. In general, the test chemical is administered to the shaved skin topically, intradermally, or both and may include the use of adjuvant to enhance the sensitivity of the assay. Multiple administrations of the test substance are generally given over a period of 2 to 4 weeks. Depending on the specific protocol, the treated

area may be occluded. Some 2 to 3 weeks after the last treatment, the animals are challenged with a nonirritating concentration of the test substance and the development of erythema is evaluated.

Subacute (Repeated-Dose Study)

Subacute toxicity tests are performed to obtain information on the toxicity of a chemical after repeated administration and as an aid to establish doses for subchronic studies. A typical protocol is to give three to four different dosages of the chemicals to the animals by mixing it in their feed. For rats, 10 animals per sex per dose are often used; for dogs, three dosages and 3 to 4 animals per sex are used. Clinical chemistry and histopathology are performed after 14 days of exposure, as described below in the section on subchronic toxicity testing.

Subchronic

The toxicity of a chemical after subchronic exposure is then determined. Subchronic exposure can last for different periods of time, but 90 days is the most common test duration. The principal goals of the subchronic study are to establish a NOAEL and to further identify and characterize the specific organ or organs affected by the test compound after repeated administration. One may also obtain a "lowest observed adverse effect level" (LOAEL) as well as the NOAEL for the species tested. The numbers obtained for NOAEL and LOAEL will depend on how closely the dosages are spaced and the number of animals examined. Determinations of NOAELs and LOAELs have numerous regulatory implications. For example, the EPA utilizes the NOAEL to calculate the *reference dose* (RfD), which may be used to establish regulatory values for "acceptable" pollutant levels (Barnes and Dourson, 1988) (see Chap. 4). An alternative to the NOAEL approach referred to as the *benchmark dose* uses all the experimental data to fit one or more dose–response curves (Crump, 1984). These curves are then used to estimate a benchmark dose that is defined as "the statistical lower bound on a dose corresponding to a specified level of risk" (Allen *et al.*, 1994a). Although subchronic studies are frequently the primary or sole source of experimental data to determine both the NOAEL and the benchmark dose, these concepts can be applied to other types of toxicity testing protocols, such as that for chronic toxicity or developmental toxicity (Allen *et al.*, 1994a, 1994b; Faustman *et al.*, 1994) (see also Chap. 4 for a complete discussion of the derivation and use of NOAELs, RfDs, and benchmark doses). If chronic studies have been completed, these data are generally used for NOAEL and LOAEL estimates in preference to data from subchronic studies.

A subchronic study is usually conducted in two species (usually rat and dog for FDA; and mouse for EPA) by the route of intended exposure (usually oral). At least three doses are employed (a high dose that produces toxicity but does not cause more than 10% fatalities, a low dose that produces no apparent toxic effects, and an intermediate dose) with 10 to 20 rodents and 4 to 6 dogs of each sex per dose. Each animal should be uniquely identified with permanent markings such as ear tags, tattoos, or electronically coded microchip implants. Only healthy animals should be used, and each animal should be housed individually in an adequately controlled environment. When the test compound is administered in the diet over a prolonged period of time (sub-chronic and chronic studies), the concentration in the diet should be adjusted periodically (weekly for the first 12–14 weeks) to maintain a constant intake of material based on food consumption and rate of change in body weight (Wilson *et al.*, 2001). Animals should be observed

once or twice daily for signs of toxicity, including changes in body weight, diet consumption, changes in fur color or texture, respiratory or cardiovascular distress, motor and behavioral abnormalities, and palpable masses. All premature deaths should be recorded and necropsied as soon as possible. Severely moribund animals should be terminated immediately to preserve tissues and reduce unnecessary suffering. At the end of the 90-day study, all the remaining animals should be terminated and blood and tissues should be collected for further analysis. The gross and microscopic condition of the organs and tissues (about 15 to 20) and the weight of the major organs (about 12) are recorded and evaluated. Hematology and blood chemistry measurements are usually done before, in the middle of, and at the termination of exposure. Hematology measurements usually include hemoglobin concentration, hematocrit, erythrocyte counts, total and differential leukocyte counts, platelet count, clotting time, and prothrombin time. Clinical chemistry determinations commonly made include glucose, calcium, potassium, urea nitrogen, alanine aminotransferase (ALT), serum aspartate aminotransferase (AST), gamma-glutamyltranspeptidase (GGT), sorbitol dehydrogenase, lactic dehydrogenase, alkaline phosphatase, creatinine, bilirubin, triglycerides, cholesterol, albumin, globulin, and total protein. Urinalysis is usually performed in the middle of and at the termination of the testing period and often includes determination of specific gravity or osmolarity, pH, proteins, glucose, ketones, bilirubin, and urobilinogen as well as microscopic examination of formed elements. If humans are likely to have significant exposure to the chemical by dermal contact or inhalation, subchronic dermal and/or inhalation experiments may also be required. Subchronic toxicity studies not only characterize the dose–response relationship of a test substance after repeated administration but also provide data for a more reasonable prediction of appropriate doses for chronic exposure studies.

For chemicals that are to be registered as drugs, acute and subchronic studies (and potentially additional special tests if a chemical has unusual toxic effects or therapeutic purposes) must be completed before the company can file an Investigational New Drug (IND) application with the FDA. If the application is approved, clinical trials can commence. At the same time phase I, phase II, and phase III clinical trials are performed, chronic exposure of the animals to the test compound can be carried out in laboratory animals, along with additional specialized tests.

Chronic

Long-term or chronic exposure studies are performed similarly to subchronic studies except that the period of exposure is longer than 3 months. In rodents, chronic exposures are usually for 6 months to 2 years. Chronic studies in nonrodent species are usually for 1 year but may be longer. The length of exposure is somewhat dependent on the intended period of exposure in humans. For example, for pharmaceuticals, the ICH S4 guidance calls for studies of 6 months in duration in rodents, and 9 months in non-rodents. However, if the chemical is a food additive with the potential for lifetime exposure in humans, a chronic study up to 2 years in duration is likely to be required.

Dose selection is critical in these studies to ensure that premature mortality from chronic toxicity does not limit the number of animals that survive to a normal life expectancy. Most regulatory guidelines require that the highest dose administered be the estimated maximum tolerable dose (MTD). This is generally derived from subchronic studies, but additional longer studies (e.g.,

6 months) may be necessary if delayed effects or extensive cumulative toxicity are indicated in the 90-day subchronic study. The MTD has had various definitions (Haseman, 1985). The MTD has been defined by some regulatory agencies as the dose that suppresses body weight gain slightly (i.e., 10%) in a 90-day subchronic study (Reno, 1997). However, regulatory agencies may also consider the use of parameters other than weight gain, such as physiological and pharmacokinetic considerations and urinary metabolite profiles, as indicators of an appropriate MTD (Reno, 1997). Generally, one or two additional doses, usually fractions of the MTD (e.g., one-half and one-quarter MTD), and a control group are tested.

Chronic toxicity tests may include a consideration of the carcinogenic potential of chemicals so that a separate lifetime feeding study that addresses carcinogenicity does not have to be performed. However, specific chronic studies designed to assess the carcinogenic potential of a substance may be required (see below).

Developmental and Reproductive Toxicity

The effects of chemicals on reproduction and development also need to be determined. *Developmental toxicology* is the study of adverse effects on the developing organism occurring anytime during the life span of the organism that may result from exposure to chemical or physical agents before conception (either parent), during prenatal development, or postnatally until the time of puberty. *Teratology* is the study of defects induced during development between conception and birth (see Chap. 10). *Reproductive toxicology* is the study of the occurrence of adverse effects on the male or female reproductive system that may result from exposure to chemical or physical agents (see Chap. 20).

Several types of animal tests are utilized to examine the potential of an agent to alter development and reproduction. General fertility and reproductive performance (segment I) tests are usually performed in rats with two or three doses (20 rats per sex per dose) of the test chemical (neither produces maternal toxicity). Males are given the chemical 60 days and females 14 days before mating. The animals are given the chemical throughout gestation and lactation. Typical observations made include the percentage of females that become pregnant, the number of stillborn and live offspring, and the weight, growth, survival, and general condition of the offspring during the first 3 weeks of life.

The potential of chemicals to disrupt normal embryonic and/or fetal development (teratogenic effects) is also determined in laboratory animals. Current guidelines for these segment II studies call for the use of two species, including one nonrodent species (usually rabbits). Teratogens are most effective when administered during the first trimester, the period of organogenesis. Thus, the animals (usually 12 rabbits and 24 rats or mice per group) are usually exposed to one of three dosages during organogenesis (day 7 to 17 in rodents and days 7 to 19 in rabbits), and the fetuses are removed by cesarean section a day before the estimated time of delivery (gestational days 29 for rabbit, 20 for rat, and 18 for mouse). The uterus is excised and weighed and then examined for the number of live, dead, and resorbed fetuses. Live fetuses are weighed; half of each litter is examined for skeletal abnormalities and the remaining half for soft tissue anomalies.

The perinatal and postnatal toxicities of chemicals also are often examined (segment III). This test is performed by administering the test compound to rats from the 15th day of gestation throughout delivery and lactation and determining its effect on the birthweight, survival, and growth of the offspring during the first 3 weeks of life.

In some instances a multigenerational study may be chosen, often in place of segment III studies, to determine the effects of chemicals on the reproductive system. At least three dosage levels are given to groups of 25 female and 25 male rats shortly after weaning (30 to 40 days of age). These rats are referred to as the F_0 generation. Dosing continues throughout breeding (about 140 days of age), gestation, and lactation. The offspring (F_1 generation) have thus been exposed to the chemical in utero, via lactation, and in the feed thereafter. When the F_1 generation is about 140 days old, about 25 females and 25 males are bred to produce the F_2 generation, and administration of the chemical is continued. The F_2 generation is thus also exposed to the chemical in utero and via lactation. The F_1 and F_2 litters are examined as soon as possible after delivery. The percentage of F_0 and F_1 females that get pregnant, the number of pregnancies that go to full term, the litter size, the number of stillborn, and the number of live births are recorded. Viability counts and pup weights are recorded at birth and at 4, 7, 14, and 21 days of age. The fertility index (percentage of mating resulting in pregnancy), gestation index (percentage of pregnancies resulting in live litters), viability index (percentage of animals that survive 4 days or longer), and lactation index (percentage of animals alive at 4 days that survived the 21-day lactation period) are then calculated. Gross necropsy and histopathology are performed on some of the parents (F_0 and F_1), with the greatest attention being paid to the reproductive organs, and gross necropsy is performed on all weanlings.

The International Commission on Harmonization (ICH) guidelines provide for flexible guidelines that address six "ICH stages" of development: premating and conception (stage A), conception to implantation (stage B), implantation to closure of the hard palate (stage C), closure of the hard palate to end of pregnancy (stage D), birth and weaning (stage E), and weaning to sexual maturity (stage F). All of these stages are covered in the segment I to segment III studies described above (Christian, 1997).

Numerous short-term tests for teratogenicity have been developed (Faustman, 1988). These tests utilize whole-embryo culture, organ culture, and primary and established cell cultures to examine developmental processes and estimate the potential teratogenic risks of chemicals. Many of these in utero test systems are under evaluation for use in screening new chemicals for teratogenic effects. These systems vary in their ability to identify specific teratogenic events and alterations in cell growth and differentiation. In general, the available assays cannot identify functional or behavioral teratogens (Faustman, 1988).

Mutagenicity

Mutagenesis is the ability of chemicals to cause changes in the genetic material in the nucleus of cells in ways that allow the changes to be transmitted during cell division. Mutations can occur in either of two cell types, with substantially different consequences. Germinal mutations damage DNA in sperm and ova, which can undergo meiotic division and therefore have the potential for transmission of the mutations to future generations. If mutations are present at the time of fertilization in either the egg or the sperm, the resulting combination of genetic material may not be viable, and the death may occur in the early stages of embryonic cell division. Alternatively, the mutation in the genetic material may not affect early embryogenesis but may result in the death of the fetus at a later developmental period, resulting in abortion. Congenital abnormalities may also result from mutations. Somatic mutations refer to mutations in all

other cell types and are not heritable but may result in cell death or transmission of a genetic defect to other cells in the same tissue through mitotic division. Because the initiating event of chemical carcinogenesis is thought to be a mutagenic one, mutagenic tests are often used to screen for potential carcinogens.

Numerous in vivo and in vitro procedures have been devised to test chemicals for their ability to cause mutations. Some genetic alterations are visible with the light microscope. In this case, cytogenetic analysis of bone marrow smears is used after the animals have been exposed to the test agent. Because some mutations are incompatible with normal development, the mutagenic potential of a chemical can also be evaluated by the dominant lethal test. This test is usually performed in rodents. The male is exposed to a single dose of the test compound and then is mated with two untreated females weekly for 8 weeks. The females are killed before term, and the number of live embryos and the number of corpora lutea are determined.

The test for mutagens that has received the widest attention is the *Salmonella*/microsome test developed by Ames and colleagues (Ames *et al.*, 1975). This test uses several mutant strains of *Salmonella typhimurium* that lack the enzyme phosphoribosyl ATP synthetase, which is required for histidine synthesis. These strains are unable to grow in a histidine-deficient medium unless a reverse or back-mutation to the wild type has occurred. Other mutations in these bacteria have been introduced to enhance the sensitivity of the strains to mutagenesis. The two most significant additional mutations enhance penetration of substances into the bacteria and decrease the ability of the bacteria to repair DNA damage. Because many chemicals are not mutagenic or carcinogenic unless they are biotransformed to a toxic product by enzymes in the endoplasmic reticulum (microsomes), rat liver microsomes are usually added to the medium containing the mutant strain and the test chemical. The number of reverse mutations is then quantified by the number of bacterial colonies that grow in a histidine-deficient medium.

Strains of yeast have recently been developed that detect genetic alterations arising during cell division after exposure to nongenotoxic carcinogens as well as mutations that arise directly from genotoxic carcinogens. This test identifies deletions of genetic material that occur during recombination events in cell division that may result from oxidative damage to DNA, direct mutagenic effects, alterations in fidelity of DNA repair, and/or changes in cell cycle regulation (Galli and Schiestl, 1999). Mutagenicity is discussed in detail in Chap. 9.

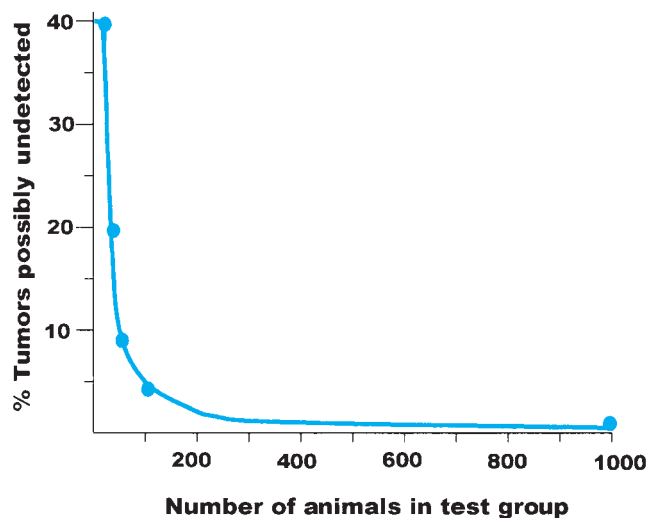
With the advent of techniques that readily allow manipulation of the mouse genome, transgenic animals have been developed that allow for in vivo assessment of mutagenicity of compounds. For example, two commercially available mouse strains, the "MutaMouse", and "BigBlue" contain the *lac* operon of *E. coli* that has been inserted into genomic DNA using a lambda phage to DNA to produce a recoverable shuttle vector. Stable, homozygous strains of these transgenic animals (both mice and rats have been engineered) can be exposed to potential mutagenic agents. Following in vivo exposure, the target *lac* genes can be recovered from virtually any cell type or organ and analyzed for mutations (Brusick, 2001).

Oncogenicity Bioassays

Oncogenicity studies are both time consuming and expensive, and are usually only done when there is reason to suspect that a chemcial may be carcinogenic, or when there may be wide spread, long term exposures to humans (e.g., widely used food additives, drinking

water contaminants, or pharmaceuticals that are likely to be administered repeatedly for long periods of time). Chemicals that test positive in several mutagenicity assays are likely to be carcinogenic, and thus are frequent candidates for oncogenicity bioassay assessment. In the United States, the National Toxicology Program (NTP) has the primary responsibility for evaluating non-drug chemicals for carcinogenic potential. For pharmaceuticals, the FDA may require the manufacturer to conduct oncogenicity studies as part of the preclinical assessment, depending on the intended use of the drug, and the results of mutagenicity assays and other toxicological data.

Studies to evaluate the oncogenic (carcinogenic) potential of chemicals are usually performed in rats and mice and extend over the average lifetime of the species (18 months to 2 years for mice; 2 to 2.5 years for rats). To ensure that 30 rats per dose survive the 2-year study, 60 rats per group per sex are often started in the study. Both gross and microscopic pathological examinations are made not only on animals that survive the chronic exposure but also on those that die prematurely. The use of the MTD in carcinogenicity has been the subject of controversy. The premise that high doses are necessary for testing the carcinogenic potential of chemicals is derived from the statistical and experimental design limitations of chronic bioassays. Consider that a 0.5% increase in cancer incidence in the United States would result in over 1 million additional cancer deaths each year—clearly an unacceptably high risk. However, identifying with statistical confidence a 0.5% incidence of cancer in a group of experimental animals would require a minimum of 1000 test animals, and this assumes that no tumors were present in the absence of exposure (zero background incidence).

Figure 2-12 shows the statistical relationship between minimum detectable tumor incidence and the number of test animals per group. This curve shows that in a chronic bioassay with 50 animals per test group, a tumor incidence of about 8% could exist even though no animals in the test group had tumors. This example assumes that there are no tumors in the control group. These statistical considerations illustrate why animals are tested at doses higher than those that occur in human exposure. Because it is impractical to use the large number of animals that would be required to test the potential carcinogenicity of a chemical at the doses usually encountered by people, the alternative is to assume that there is a relationship


between the administered dose and the tumorigenic response and give animals doses of the chemical that are high enough to produce a measurable tumor response in a reasonable size test group, such as 40 to 50 animals per dose. The limitations of this approach are discussed in Chap. 4. For non-mutagenic pharmaceutical agents, ICH S1C provides the following guidance on dose selection for oncogenicity studies: "The doses selected for rodent bioassays for non-genotoxic pharmaceuticals should provide an exposure to the agent that (1) allow an adequate margin of safety over the human therapeutic exposure, (2) are tolerated without significant chronic physiological dysfunction and are compatible with good survival, (3) are guided by a comprehensive set of animal and human data that focus broadly on the properties of the agent and the suitability of the animal (4) and permit data interpretation in the context of clinical use."

Another approach for establishing maximum doses for use in chronic animal toxicity testing of drugs is often used for substances for which basic human pharmacokinetic data are available (for example, new pharmaceutical agents which have completed phase I clinical trials). For chronic animal studies performed on drugs where single-dose human pharmacokinetic data are available, a daily dose that would provide an area under the curve (AUC) in laboratory animals equivalent to 25 times the AUC in humans given the highest (single) daily dose to be used therapeutically may be used, rather than the MTD. Based on a series of assumptions regarding allometric scaling between rodents and humans (Table 2-2), the ICH noted that it may not be necessary to exceed a dose of 1500 mg/kg/day where there is no evidence of genotoxicity, and where the maximum recommended human dose does not exceed 500 mg/day.

Most regulatory guidelines require that both benign and malignant tumors be reported in oncogenicity bioassays. Statistical increases above the control incidence of tumors (either all tumors or specific tumor types) in the treatment groups are considered indicative of carcinogenic potential of the chemical unless there are qualifying factors that suggest otherwise (lack of a dose response, unusually low incidence of tumors in the control group compared with "historic" controls, etc.; Huff, 1999). Thus, the conclusion as to whether a given chronic bioassay is positive or negative for carcinogenic potential of the test substance requires careful consideration of background tumor incidence. Properly designed chronic oncogenicity studies require that a concurrent control group matched for variables such as age, diet, housing conditions be used. For some tumor types, the "background" incidence of tumors is surprisingly high. Figure 2-13 shows the background tumor incidence for various tumors in male and female F-344 rats used in 27 National Toxicology Program 2-year rodent carcinogenicity studies. The data shown represent the percent of animals in control (nonexposed) groups that developed the specified tumor type by the end of the 2-year study. These studies involved more than 1300 rats of each sex. Figure 2-14 shows similar data for control (nonexposed) male and female B6C3F1 mice from 30 recent NTP 2-year carcinogenicity studies and includes data from over 1400 mice of each sex. There are several key points that can be derived from these summary data:

1. Tumors, both benign and malignant, are not uncommon events in animals even in the absence of exposure to any known carcinogen.
2. There are numerous different tumor types that develop "spontaneously" in both sexes of both rats and mice, but at different rates.

Figure 2-12. Statistical limitations in the power of experimental animal studies to detect tumorigenic effects.

Male F344 rats

- Testis Interstitial cell adenoma
- Mononuclear cell leukemia
- Adrenal gland pheochromocytoma
- Pituitary adenoma/carcinoma
- Thyroid c-cell adenoma/carcinoma
- Preputial gland adenoma/carcinoma
- Subcutaneous tissue neoplasms
- Mammary gland neoplasms
- Pancreatic islets adenoma/carcinoma
- Skin keratoacanthoma
- Liver adenoma/carcinoma
- Lung adenoma/carcinoma
- Mesothelioma
- Skin papilloma/carcinoma

% with tumors

Female F344 rats

- Pituitary gland adenoma/carcinoma
- Mammary gland neoplasms
- Mononuclear cell leukemia
- Uterus stromal polyp
- Thyroid c-cell adenoma/carcinoma
- Clitoral gland adenoma/carcinoma
- Adrenal gland pheochromocytoma
- Subcutaneous tissue neoplasms

% with tumors

Figure 2-13. Most frequently occurring tumors in untreated control rats from recent NTP 2-year rodent carcinogenicity studies.

The values shown represent the mean ±SD of the percentage of animals developing the specified tumor type at the end of the 2-year study. The values were obtained from 27 different studies involving a combined total of between 1319 and 1353 animals per tumor type.

3. Background tumors that are common in one species may be uncommon in another (for example, testicular interstitial cell adenomas are very common in male rats but rare in male mice; liver adenomas/carcinomas are about 10 times more prevalent in male mice than in male rats).

4. Even within the same species and strain, large gender differences in background tumor incidence are sometimes observed (for example, adrenal gland pheochromocytomas are about seven times more prevalent in male F344 rats than in female F344 rats; lung and liver tumors are twice as prevalent in male B6C3F1 mice as in female B6C3F1 mice).

5. Even when the general protocols, diets, environment, strain and source of animals, and other variables are relatively constant, background tumor incidence can vary widely, as shown by the relatively large standard deviations for some tumor types in the NTP bioassay program. For example, the range in liver adenoma/carcinoma incidence in 30 different groups of unexposed (control) male B6C3F1 mice went from a low of 10% to a high of 68%. Pituitary gland adenomas/carcinomas ranged from 12 to 60% and 30 to 76% in unexposed male and female F344 rats, respectively, and from 0 to 36% in unexposed female B6C3F1 mice.

Taken together, these data demonstrate the importance of including concurrent control animals in such studies. In addition, comparisons of the concurrent control results to "historic" controls accumulated over years of study may be important in identifying potentially spurious "false-positive" results. The relatively high variability in background tumor incidence among groups of healthy, highly inbred strains of animals maintained on nutritionally balanced and consistent diets in rather sterile environments highlights the dilemma in interpreting the significance of both positive and negative results in regard to the human population, which is genetically diverse, has tremendous variability in diet, nutritional status, and overall health; and lives in an environment full of potentially carcinogenic substances, both natural and human-made.

Finally, it should be noted that both inbred and outbred strains have distinct background tumor patterns and the NTP and most other testing programs select strains based on the particular needs of the agent under study. For example, the NTP used the Wistar rat for chemicals that may have the testis as a target organ, based on acute, sub-chronic or other bioassay results. Similarly, the NTP used the Sprague-Dawley strain of rat in studies of estrogenic agents such as genistein because its mammary tumors are responsive to estrogenic stimulation, as are humans.

Male B6C3F1 mice

- Liver adenoma/carcinoma
- Lung adenoma/carcinoma
- Subcutaneous tissue neoplasms
- Malignant lymphoma
- Hemangioma/hemangiosarcoma
- Harderian gland adenoma/carcinoma
- Adrenal cortical tumors

% with tumors

Female B6C3F1 mice

- Malignant lymphoma
- Liver adenoma/carcinoma
- Pituitary gland adenoma/carcinoma
- Lung adenoma/carcinoma
- Hemangioma/hemangiocarcinoma
- Harderian gland adenoma/carcinoma
- Uterus stromal polyps
- Thyroid gland follicular cell tumors
- Forestomach papilloma/carcinoma

% with tumors

Figure 2-14. Most frequently occurring tumors in untreated control mice from recent NTP 2-year rodent carcinogenicity studies.

The values shown represent the mean ±SD of the percentage of animals developing the specified tumor type at the end of the 2-year study. The values were obtained from 30 different studies involving a total of between 1447 and 1474 animals per tumor type.

Neurotoxicity Assessment

Neurotoxicity or a neurotoxic effect is defined as an adverse change in the chemistry, structure or function of the nervous system following exposure to a chemical or physical agent. The structure, function, and development of the nervous system and its vulnerability to chemicals, is examined in Chap. 16. When evaluating the potential neurological effects of a compound, effects may be on the central or peripheral nervous system or related to exposure that occurred during development or as an adult. The developing nervous system is particularly sensitive to chemical exposures (see Chap. 10).

In vitro systems often using cell culture techniques is a rapidly developing area of neurotoxicity assessment. Specific cell lines are available to examine effects on neuron or glial cells such as proliferation, migration, apoptosis, synpatogenesis and other endpoints. In vitro assays have a number of potential advantages including minimizing the use of animal, lower costs, and adaptable to high through put screening. It is also possible to use an in vitro model to examine the interaction of chemicals, such as food additives, on neuronal cells (Lau *et al.*, 2006). The principle and challenges on in vitro neurotoxicity testing are well described (Tiffany-Castiglioni, 2004).

Procedures for the neurobehavioral evaluation of animals were initially developed as part of the scientific investigation of behavioral motivation. Some of these procedures were then used to evaluate the neuropharmacological properties of new drugs. Now animals are commonly used to evaluate the neurotoxic properties of chemicals. A wide range of adult and developmental animal tests are used to access neurobehavioral function. In addition, neuropathological assessment is an important part of the neurotoxicity evaluation and best practices have been developed for developmental neurotoxicity (Bolon *et al.*, 2006). Irwin developed a basic screen for behavioral function in mice (Irwin, 1968), which was subsequently refined to the functional observational battery (FOB) (Moser, 2000). The FOB can also be used in the evaluation of drug safety (Redfern *et al.*, 2005).

The U.S. EPA established a protocol for the evaluation of developmental neurotoxicity (DNT) in laboratory animals (U.S. EPA 870.6300 and OECD 426) (EPA, 1998; OECD 2004). These protocols include tests of neurobehavioral function, such as auditory startle, learning and memory function, changes in motor activity, and neuropathologic examination and morphometric analysis. Methods and procedures for developmental neurotoxicity evaluation are well established (Claudio *et al.*, 2000; Cory-Slechta *et al.*, 2001; Dorman *et al.*, 2001; Garman *et al.*, 2001; Mileson and Ferenc, 2001). Recent studies examine the neurotoxicity of multiple chemical exposures in animals (Moser *et al.* 2006). Methods are also available to examine cognitive measures on weanling rodents in DNT studies (Ehman and Moser 2006). Non-human primates have been invaluable in evaluating the effects of neurotoxoicants and the risk assessment process (Burbacher and Grant 2000). Sophisticated assessment of operant behavior, and learning and memory assessment of rodents has been used to evaluate the effects of lead (Cory-Slechta, 1995, 1996, 2003). Monkeys can also be used to evaluate the low level effects of neurotoxicants such as mercury on vision, auditory function and vibration sensitivity (Burbacher *et al.*, 2005; Rice and Gilbert, 1982, 1992, 1995). There is remarkable concordance between human and animal neurotoxicity assessment, for example, in lead, mercury, and PCBs (Rice, 1995).

Human testing for the neurological effects of occupational exposures to chemicals is advancing rapidly (Anger, 2003; Farahat *et al.*, 2003; Kamel *et al.*, 2003; McCauley *et al.*, 2006) and even the neurotoxic effects of war (Binder *et al.*, 1999, 2001). These methods have also been applied to Hispanic workers (Rohlman *et al.*, 2001b) and populations with limited education or literacy (Rohlman *et al.*, 2003). The WHO has also recommended a test battery for humans (Anger *et al.*, 2000). There are also neurobehavioral test batteries for assessing children (Rohlman *et al.*, 2001a). Evaluation of the childhood neurological effects of lead (Lanphear *et al.*, 2005; Needleman and Bellinger, 1991) and mercury (Myers *et al.*, 2000) have added enormously to our understanding of the health effects of these chemicals and to the methodology of human neurobehavioral testing.

In summary, the neurontoxicological evaluation is an important aspect of developing a hazard and risk assessment of environmental chemicals and drugs.

Immunotoxicity Assessment

Under normal conditions, the immune system is responsible for host defense against pathogenic infections and certain cancers. However, environmental exposures can alter immune system development and/or function and lead to hypersensitivity, autoimmunity, or immunosuppression, the outcome of which may be expressed as a pathology in most any organ or tissue (see Chap. 12). Our understanding of the biological processes underlying immune system dysfunction remains incomplete. However, advances in molecular biology (including use of transgenic/knockout mice), analytical methods (including gene expression arrays and multiparameter flow cytometry), animal models (including adoptive transfers in immunocompromised mice and host resistance to viral, bacterial, or tumor cell challenge), and other methods are greatly advancing our knowledge.

From a toxicologist's perspective, evaluation of immune system toxicity represents special challenges. Development of hypersensitivity can take various forms, depending on the mechanism underlying the associated immune response, and standard assumptions regarding dose-response relationships may not necessarily apply. For example, a single or incidental exposure to beryllium has been associated with chronic beryllium disease in some individuals. We are only just beginning to understand the biological basis underlying such individual susceptibility. In the case of chronic beryllium disease, a genetic polymorphism in a gene involved in antigen recognition may be associated with increased susceptibility (see Bartell *et al.*, 2000). Although our ability to predict immunogenicity remains poor, research efforts are continuing to identify aspects of the chemical and the individual that confer immunogenicity and underlie hypersensitivity. For example, the increasing incidence of allergic asthma among preschool-age children in the United States since the 1980s, may be associated with exposure to allergens (e.g., dust mites, molds, and animal dander), genetic factors, and other factors in the *in utero* and post-natal environment (see Donovan and Finn, 1999; Armstrong *et al.*, 2005).

Immunosuppression is another form of immune system toxicity, which can result in a failure to respond to pathogenic infection, a prolonged infection period, or expression of a latent infection or cancer. Various chemicals have been associated with immunosuppression. Broad spectrum and targeted immunosuppressive chemicals are designed and used therapeutically to reduce organ transplant rejection or suppress inflammation. However, a large number of chemicals have been associated with immunosuppression, including organochlorine pesticides, diethylstilbesterol, lead, and halogenated aromatic hydrocarbons (including TCDD), and exposures that occur during critical stages may present special risk to development (Holladay, 2005).

Autoimmunity is a specific immune system disorder in which components of the immune system attack normal (self) tissues. Cases of autoimmunity have been reported for a wide range of chemicals including therapeutic drugs, metals, pesticides, and solvents. As with other forms of immune system toxicity, autoimmunity can present in most any tissue.

Finally, new forms of immunotoxicity are appearing based on novel forms of clinical therapy and immunomodulation. These include the variously classified "tumor lysis syndromes" and "cytokine storms" that arise from massive cytokine dysregulation. A recent example involved six healthy volunteers who had enrolled in a Phase 1 clinical trial in the UK who developed a severe cytokine response to an anti-CD28 monoclonal antibody leading to systemic organ failures (Bhogal and Combes, 2006). Such cases are stark reminders of the challenges we face in understanding how the immune system is regulated, developing reliable test systems for identifying such risks prior to human use, and safe means for testing these agents in humans.

As described in Chapter 12, current practice for evaluating potential toxic effects of xenobiotic exposures on the immune system involves a tiered approach to immunotoxicity screening (Luster *et al.*, 2003). This tiered approach is generally accepted world-wide in the registration of novel chemical and therapeutic products. Most recently, final guidance to the pharmaceutical industry was published in April, 2006 by the International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use (Table 2-3). This guidance, which applies to the nonclinical (animal) testing of human pharmaceuticals is the accepted standard in the U.S., EU, and Japan, and demonstrates the continued commitment by these regulatory bodies to understand the potential risks posed by novel therapeutics.

Tiered testing relies on the concept that standard toxicity studies can provide good evidence for immunotoxicity when considered with known biological properties of the chemical, including structural similarities to known immunomodulators, disposition, and other clinical information, such as increased occurrence of infections or tumors. Evaluation of hematological changes, including differential effects on white blood cells and immunoglobulin changes, and alterations in lymphoid organ weights or histology, can provide strong evidence of potential effects to the immune system. Should such evaluations indicate a potential effect on immune system function, more detailed evaluations may be considered, including the evaluation of functional effects (e.g., T-cell dependent antibody response or Natural Killer cell activity), flow cytometric immunophenotyping, or host resistance studies. Thus, as with other areas of toxicology, the evaluation of immune system toxicity requires the toxicologist to be vigilant in observing early indications from a variety of sources in developing a weight-of-evidence assessment regarding potential injury/dysfunction.

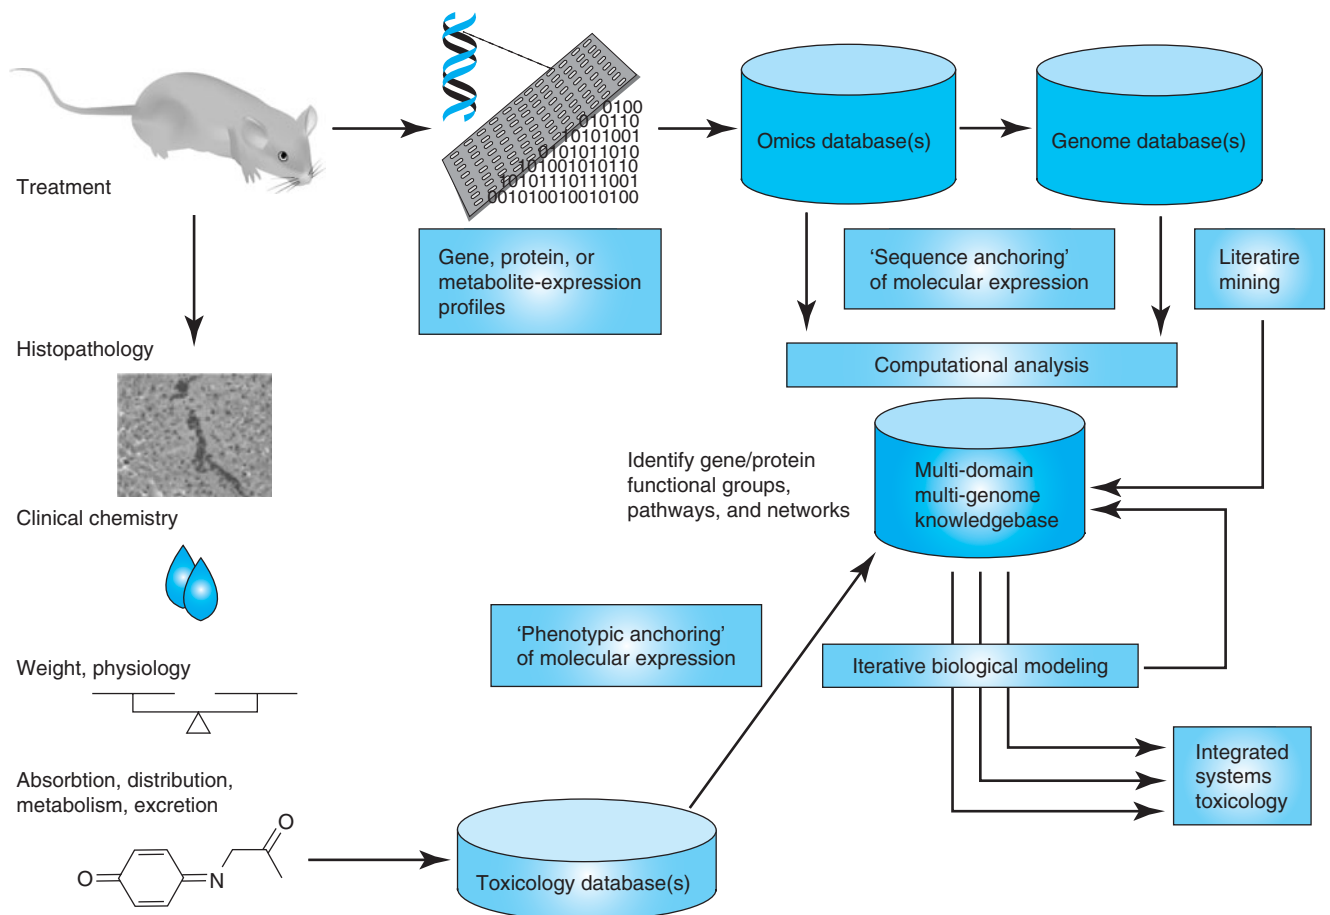
Other Descriptive Toxicity Tests

Most of the tests described above will be included in a "standard" toxicity testing protocol because they are required by the various regulatory agencies. Additional tests may be required or included in the protocol to provide information relating a special route of exposure, such as inhalation. Inhalation toxicity tests in animals usually are carried out in a dynamic (flowing) chamber rather than in static chambers to avoid particulate settling and exhaled gas complications. Such studies usually require special dispersing and analytic methodologies, depending on whether the agent to be tested is a gas, vapor, or aerosol; additional information on methods, concepts,

and problems associated with inhalation toxicology is provided in Chaps. 15 and 28. The duration of exposure for inhalation toxicity tests can be acute, subchronic, or chronic, but acute studies are more common with inhalation toxicology. Other special types of animal toxicity tests include toxicokinetics (absorption, distribution, biotransformation, and excretion), the development of appropriate antidotes and treatment regimens for poisoning, and the development of analytic techniques to detect residues of chemicals in tissues and other biological materials.

TOXICOGENOMICS

In the past decade, numerous new genome-based technologies have become available that allow for the large-scale analysis of biological responses to external stimuli. Traditional scientific approaches to elucidate the biochemical and molecular effects of toxic substances focused largely on examining biochemical pathways that were logically connected to observed responses identified through gross pathology, histology, blood chemistry, or behavioral observations. Such "hypothesis driven" research into understanding mechanism of action remains a mainstay of current scientific investigations in toxicology. However, technologies now available allow one to examine the entire "universe" of biological responses to a toxic substance (Fig. 2-15). These new "hypothesis generating" technologies include: genomics (characterization of much or all of the genome of an organism), transcriptomics (characterization of most or all of the mRNAs, or transcriptome, expressed in a given cell/tissue), proteomics (characterization of most or all of the proteins expressed in a given cell/tissue), and metabonomics (characterization of most or all of the small molecules in a cell or tissue, including substrates, products, and co-factors of enzyme reactions). Other "omics" approaches (e.g., "lipidomics", "nutrigenomics") are being devised to look broadly at the biological response of an organism to change. The integration of all of these levels of molecular function (genomics, transcriptomics, proteomics, metabonomics, etc.) to the understanding of how a living organism functions at the cellular level is sometimes referred to as "Systems Biology" (Weston and Hood, 2004). Because each level of analysis generates a very large quantity of data, the collection, organization, evaluation and statistical analysis is in itself an enormous undertaking. The field of "Bioinformatics" has been developed to address the many computational and statistical challenges of "omics" data. In the field of toxicology, the term "toxicogenomics" is used to define the area of research that "combines transcript, protein and metabolite profiling with conventional toxicology to investigate the interaction between genes and environmental stress in disease causation" (Waters and Fostel, 2004). A conceptual model for how the various new "omics" technologies can be incorporated into toxicological evaluation is shown in Fig. 2-15.

Genomics: The genome of an organism represents the full complement of genes that are determined at fertilization by the combination of the parental DNA. Thus, each cell of an organism has the same genome, characterized by the nucleotide sequences inherited from its parents. The human genome consists of approximately 3 billion base pairs of deoxyribonucleotides. Within the human genome, there is, on average, about 0.1% variability in DNA sequence between any two individuals, and it is these differences that contribute to the uniqueness of each person. Most of this variability exists as "single nucleotide polymorphism", or SNPs, although larger segments of DNA may be variable between individuals, including the duplication or loss of entire genes. The identification of particular genetic variants, such as the GSTM1 polymorphism, that might


Nature Reviews | Genetics

Figure 2-15. Conceptual approach for incorporating "omics" technologies and resulting large databases into toxicological evaluation.

Data from experiments that evaluate the effects of a chemical on global patterns of gene expression (transcriptomics), protein content (proteomics), and small molecules/metabolites (metabonomics/metabolomics), combined with genomic information from both the test species (e.g. rats, mice) and the target species of interest (e.g., humans), are analyzed by computational tools (bioinformatics) for unique or potentially predictive patterns of toxicity. Essential to the use of omics data for predictive toxicology/safety assessment is the ability to reliably tie observed omics patterns to traditional measures of toxicity, such as histopathology and clinical chemistry (phenotypic anchoring).
(From: Waters MD, Fostel JM: Toxicogenomics and systems toxicology: Aims and prospects. *Nat Rev Genet* 5(12):936–948, 2004, with permission.)

contribute to interindividual differences in susceptibility to chemicals or other environmental factors discussed previously, represents a relatively new and growing area of study that aims to understand the complex interactions between the human genome and the environment (Costa and Eaton, 2006).

Although the genome provides the blueprint for biological function, in order for the genomic information to be utilized in a cell, it must be expressed. Expression of the genome occurs when the coding sequence of DNA is converted to messenger RNA (mRNA). For any given cell, transcription of the genomic information contained in that cell is only partial. It is the differential expression of genes in a given cell that is largely responsible for the diverse function of the thousands of different cells, tissues, and organs that constitute an individual organism. Thus, understanding which genes are expressed

in a given tissue, at what level, and how toxicants perturb the "transcriptome" is of great relevance to toxicology. In addition to coding for mRNAs that provide the blueprint for protein synthesis, genomic DNA also generates small interfering RNAs (siRNA, microRNAs) which are biologically active and can participate in the regulation of gene expression. Furthermore, methylation of DNA is an important determinant of gene expression in cells and tissues, and exogenous chemicals can interfere with transcriptional function via alterating DNA methylation (Watson and Goodman, 2002). Importantly, although such epigenetic changes do not result in the alteration of the genomic sequence, they can result in heritable phenotypic changes. Thus, genomic analyses in toxicology may also include techniques to identify toxicant-induced changes in DNA methylation patterns (Watson and Goodman, 2002).

Transcriptomics: Among the first changes that a cell will exhibit following exposure to a toxic substance is a change in gene expression. The transcriptome (all of the mature mRNA species present in a cell at a given point in time) is dynamic, and represents the steady-state between the rate of synthesis (transcription) and degradation of mRNAs in a cell. Toxicologists have utilized the so-called "Northern blot" analysis to assess the level of expression of individual genes in cells or tissues for decades. The "Reverse Transcriptase Polymerase Chain Reaction" (RT-PCR) allows one to quantitatively measure the relative number of mRNA species in a sample for specific genes. Using general primers, it is also possible to amplify the entire transcriptome quantitatively to make many complete copies of the transcriptome in a test tube. Thus, large amounts of material for analysis can be obtained from a relatively small number of cells. Finally, using microarray technologies, where tens of thousands of unique oligonucleotides (or cDNAs) are anchored on a solid matrix, toxicologists can now quantitatively assess the expression of thousands of unique mRNAs in a single sample, thus capturing an "expression profile" of the entire transcriptome in one analysis.

There is great promise that gene expression profiles may be used to provide signatures of specific types of toxic responses, such as a cellular response to DNA damage or oxidative stress. There is also hope that such signature changes in gene expression could be used to facilitate more accurate cross-species extrapolation, allowing comparison of, for example, toxicant-induced changes in gene expression in rat hepatocytes with that of human hepatocytes under identical experimental conditions. However, one of the major challenges in toxicogenomics is the recognition that transcriptional regulation is highly dynamic, and that gene expression profiles can change dramatically with both dose and time. Because microarray experiments are relatively expensive and highly data intensive, it becomes both costly and challenging to conduct and analyze experiments with extensive dose and time course data (although costs are declining). Although changes in gene expression often contribute to, or are reflective of, phenotypic changes that occur in response to a toxic substance, the transcriptome is still somewhat far removed from the ultimate biochemical functions that dictate the actual biological function of the cell. Because the functional expression of a gene generally requires the translation of the mRNA to a protein, there is also great interest in looking at the "proteome"–the entire compliment of *proteins* that are present in a cell or tissue at a given point in time.

Proteomics: Analysis of the proteome of a cell or tissue is much more difficult than analysis of the transcriptome, primarily because it is not yet possible to "amplify" the number of copies of proteins in a cell. Furthermore, unambiguous identification of specific proteins is much more difficult than that for individual mRNAs. Identification of specific proteins is generally done using a combination of separation techniques (e.g., 2D-gel electrophoresis, high performance liquid chromatography), followed by tandem mass spectrometry for identification (Aebersold and Mann, 2003). Because of size limitations for accurate mass spectrometry, protein mixtures are usually digested to smaller peptide fragments. The mixture of peptide fragments is resolved into individual components, and the identity of the specific peptides is determined based on high resolution mass analysis and sequential degradation (sequential loss of single amino acids) of the peptides by various means (Aebersold and Mann, 2003). The large and complex set of peptide mass fragments is then analyzed by computers and compared with a large database of mass fragments of known peptides/proteins. Because as few as 5 amino acid

sequences may provide unique identification of a specific protein, the presence and relative abundance of specific proteins in a sample can then be reconstructed through bioinformatic analyses. As with transcriptomics, it is hoped that changes in protein expression can be used as specific biomarkers for particular types of toxic responses. Of course, such conceptual approaches have been used for years, e.g., use of serum transaminase proteins as indicators of liver damage, or the presence of prostate specific antigen (PSA) in serum as a potential biomarker of early stage prostate hyperplasia or cancer. The potential power of proteomics lies in the ability to identify unique patterns of protein expression, or identification of unique proteins or peptides, that are predictive of early toxic response or later development of disease.

Metabonomics/metabolomics: These two terms are often used interchangeably to describe the analysis of the "universe" of small molecules that serve as substrates, products, and co-factors of the milieu of enzymatic reactions and other metabolic processes that define living cells, and thus the organism. Metabonomics has been defined as "the comprehensive and simultaneous systematic profiling of metabolite levels and their systematic and temporal change through such effects on diet, lifestyle, environment, genetic and pharmaceuticals, both beneficial and adverse, in whole organisms" (Lindon *et al.*, 2003, 2006). The term "metabolomics" has been used principally in studies in plants and in vitro or single cell systems (Fiehn, 2002). Regardless of the specific term used (metabonomics will be used here), the concept of quantitatively analyzing toxicant-induced changes in the "metabolic profile" (the "metabonome") of a cell, tissue or body fluid in some ways represents the "Holy Grail" of toxicogenomics, because the changes in these small molecules must represent a biologically relevant integration of all of the molecular, biochemical and cellular perturbations that lead to the development of toxicity (Fig. 2-15). In other words, changes in the metabonome should reflect the biologically relevant changes in gene transcription, translation, protein function, and other cellular processes, including temporal and adaptive responses, while ignoring biologically irrelevant changes in these factors. Although conceptually superior to either transcriptomics or proteomics for predictive toxicology, metabonomics lags significantly in technological development of readily accessible tools for thorough analysis of the metabonome.

Two approaches for identifying and measuring hundreds, or even thousands, of small molecules in biological samples have emerged – Nuclear Magnetic Resonance (NMR), and mass spectrometry (Lindon *et al.*, 2003, 2006). Both have their advantages and limitations, and it is likely that the most successful approaches to applying metabonomics to toxicological problems will utilize both techniques.

Bioinformatics: One feature in common among all of the various "omics" technologies is the ability to generate very large volumes of data (literally millions of data points from a single experiment). Both the data management and statistical evaluation of toxicogenomics studies represents an enormous challenge. The emerging field of bioinformatics has developed to address these challenges. Numerous commercial platforms for conducting microarray analysis of the transcriptome are available, and sophisticated software is available for both data management and analysis. One of the major challenges in statistical analysis of large data sets is the large number of "false positives" that will result from multiple comparisons. In a typical gene array experiment, it is not uncommon for an investigator to make >20,000 different comparisons. At the typical "95%" statistical confidence limit, one would expect

more than 1000 of the noted differences to occur just by chance alone. Thus, more rigorous statistical methods have been developed to reduce the so-called "false discovery rate" in such experiments (Storey *et al.*, 2005; Gao, 2006).

Challenges in using "omics" technologies for predictive toxicology and risk assessment: A conceptual framework for incorporating these new technologies into toxicology, sometimes referred to as "Systems Toxicology" is shown in Fig. 2-15. Several key components of such an approach include: (1) large databases of treatment-specific information, such as results of transcriptomic, proteomic and metabonomic analyses from target tissues and/or body fluids derived from toxicant-treated animals, (2) genomic databases that describe the DNA sequence information from the species of interest, (3) computational tools that extract information from these and other databases and the published literature to identify critical pathways and networks that are altered by the toxicant treatment, and (4) comparison with traditional toxicological endpoints to ensure that the observed "omics responses are closely aligned with the toxicant-related pathophysiology in the animal (histopathology, clinical chemistry, etc) – a process called "phenotypic anchoring" (Waters and Fostel, 2004).

Toxicogenomics tools are becoming indespensible for research aimed at identifying the mechanisms and mode of action of toxic substances. However, the incorporation of such approaches into routine toxicity assessment presents numerous challenges. Numerous working group reports and publications have addressed the challenges of incorporating toxicogenomics data into predictive toxicology and risk assessment (Bammler, 2006; Maggioli *et al.*, 2006; Boverhof and Zacharewski, 2006).

One of the major challenges to incorporating toxicogenomic data into risk assessment is related to the highly dynamic processes that preceded an observed toxic response. Traditional measure of toxicity, such as histopathological changes in a tissue, tend to be stable or even irreversible, whereas the myriad of molecular, biochemical, and cellular changes that give rise to the toxic response(s) are highly dynamic, frequently changing by the hour. Thus, the profiles of mRNAs, proteins and/or metabolites captured at a single point in time may be dramatically different, depending on the specific point in time the sample was collected. Many of the observed changes may be the result of direct effects of the toxicant on specific targets, whereas others will be compensatory or feedback mechanisms invoked in response to the initial damage. Nevertheless, patterns of change in transcript, protein and/or metabolite profiles are likely to provide informative "signatures" of toxic response that will be of great value in predictive toxicology. Such approaches may be particularly useful in pharmaceutical development, where toxicogenomic profiles may help to accelerate preclinical evaluation of drug candidates by identifying "class prediction" profiles indicative of certain types of desirable (pharmacological efficacy) as well as adverse (e.g., DNA damage, oxidative stress) responses.

Finally, it is likely that the introduction of omics technologies to toxicity testing will eventually contribute to the reduction, refinement and replacement (the "3Rs") of animals in toxicity testing and product safety evaluations (Kroeger, 2006).

CHAPTER 3

MECHANISMS OF TOXICITY

Zoltán Gregus

Depending primarily on the degree and route of exposure, chemicals may adversely affect the function and/or structure of living organisms. The qualitative and quantitative characterization of these harmful or toxic effects is essential for an evaluation of the potential hazard posed by a particular chemical. It is also valuable to understand the mechanisms responsible for the manifestation of toxicity—that is, how a toxicant enters an organism, how it interacts with target molecules, and how the organism deals with the insult.

An understanding of the mechanisms of toxicity is of both practical and theoretical importance. Such information provides a rational basis for interpreting descriptive toxicity data, estimating the probability that a chemical will cause harmful effects, establishing procedures to prevent or antagonize the toxic effects, designing drugs and industrial chemicals that are less hazardous, and developing pesticides that are more selectively toxic for their target organisms. Elucidation of the mechanisms of chemical toxicity has led to a better understanding of fundamental physiologic and biochemical processes ranging from neurotransmission (e.g., curare-type arrow poisons) through deoxyribonucleic acid (DNA) repair (e.g., alkylating agents) to transcription, translation, and signal transduction pathways (e.g., chemicals acting through transcription factors, such as the aryl hydrocarbon receptor). Pathologic conditions such as cancer and Parkinson's disease are better understood because of studies on the mechanism of toxicity of chemical carcinogens and 1,2,3,6-tetrahydro-1-methyl-4-phenylpyridine (MPTP), respectively. Continued research on mechanisms of toxicity will undoubtedly continue to provide such insights.

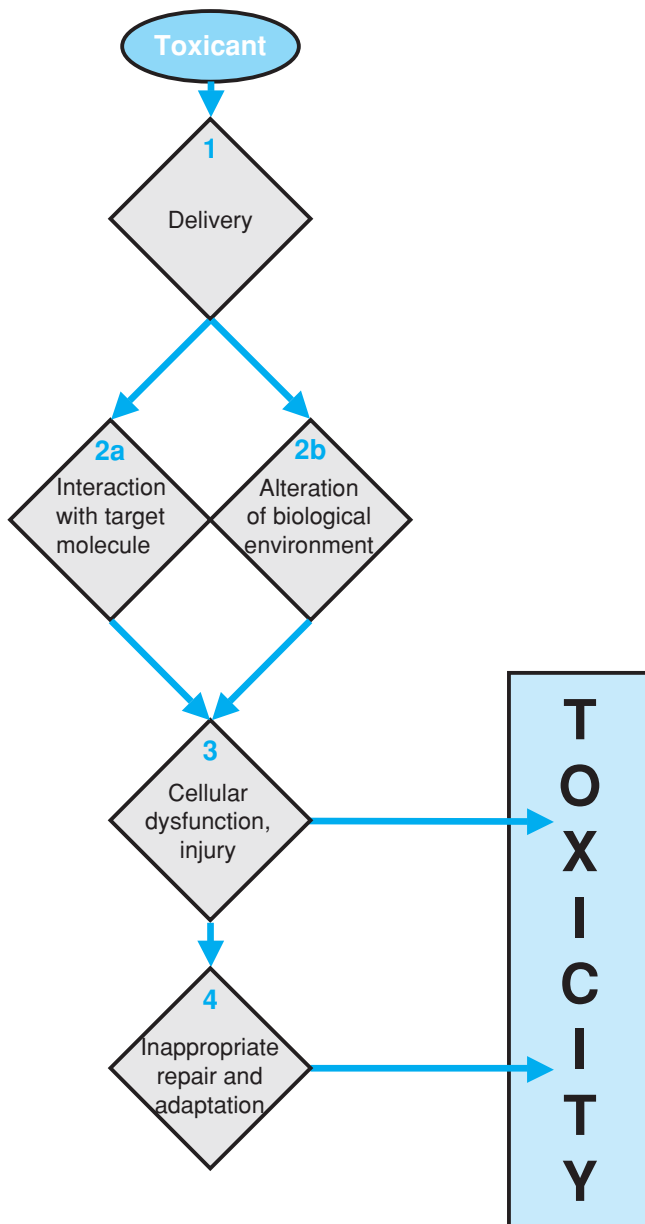
This chapter reviews the cellular mechanisms that contribute to the manifestation of toxicities. Although such mechanisms are dealt with elsewhere in this volume, they are discussed in detail in this chapter in an integrated and comprehensive manner. We provide an overview of the mechanisms of chemical toxicity by relating a


Figure 3-1. Potential stages in the development of toxicity after chemical exposure.

series of events that begins with exposure, involves a multitude of interactions between the invading toxicant and the organism, and culminates in a toxic effect. This chapter focuses on mechanisms that have been identified definitively or tentatively in humans or animals.

As a result of the huge number of potential toxicants and the multitude of biological structures and processes that can be impaired, there are a tremendous number of possible toxic effects. Correspondingly, there are various pathways that may lead to toxicity (Fig. 3-1). A common course is when a toxicant delivered to its target reacts with it, and the resultant cellular dysfunction manifests itself in toxicity. An example of this route to toxicity is that taken by the puffer fish poison, tetrodotoxin. After ingestion, this poison reaches the voltage-gated Na^+ channels of motoneurons (step 1). Interaction of tetrodotoxin with this target (step 2a) results in blockade

of Na^+ channels, inhibition of the activity of motor neurons (step 3), and ultimately skeletal muscle paralysis. No repair mechanisms can prevent the onset of such toxicity.

Sometimes a xenobiotic does not react with a specific target molecule but rather adversely influences the biological (micro) environment, causing molecular, organellar, cellular, or organ dysfunction leading to deleterious effects. For example, 2,4-dinitrophenol, after entering the mitochondrial matrix space (step 1), collapses the outwardly directed proton gradient across the inner membrane by its mere presence there (step 2b), causing mitochondrial dysfunction (step 3), which is manifest in toxic effects such as hyperthermia and seizures. Chemicals that precipitate in renal tubules and block urine formation represent another example for such a course (step 2b).

The most complex path to toxicity involves more steps (Fig. 3-1). First, the toxicant is delivered to its target or targets (step 1), after which the ultimate toxicant interacts with endogenous target molecules (step 2a), triggering perturbations in cell function and/or structure (step 3), which initiate repair mechanisms at the molecular, cellular, and/or tissue levels as well as adaptive mechanisms to diminish delivery, boost repair capacity and/or compensate for dysfunction (step 4). When the perturbations induced by the toxicant exceed repair and adaptive capacity or when repair and adaptation becomes malfunctional, toxicity occurs. Tissue necrosis, cancer, and fibrosis are examples of chemically induced toxicities whose development follow this four-step course.

STEP 1—DELIVERY: FROM THE SITE OF EXPOSURE TO THE TARGET

Theoretically, the intensity of a toxic effect depends primarily on the concentration and persistence of the ultimate toxicant at its site of action. The ultimate toxicant is the chemical species that reacts with the endogenous target molecule (e.g., receptor, enzyme, DNA, microfilamental protein, lipid) or critically alters the biological (micro) environment, initiating structural and/or functional alterations that result is toxicity. Often the ultimate toxicant is the original chemical to which the organism is exposed (parent compound). In other cases, the ultimate toxicant is a metabolite of the parent compound or a reactive oxygen or nitrogen species (ROS or RNS) generated during the biotransformation of the toxicant. Occasionally, the ultimate toxicant is an unchanged or altered endogenous molecule (Table 3-1).

The concentration of the ultimate toxicant at the target molecule depends on the relative effectiveness of the processes that increase or decrease it's concentration at the target site (Fig. 3-2). The accumulation of the ultimate toxicant at its target is facilitated by its absorption, distribution to the site of action, reabsorption, and toxication (metabolic activation). Conversely, presystemic elimination, distribution away from the site of action, excretion, and detoxication oppose these processes and work against the accumulation of the ultimate toxicant at the target molecule.

Absorption versus Presystemic Elimination

Absorption   Absorption is the transfer of a chemical from the site of exposure, usually an external or internal body surface (e.g., skin, mucosa of the alimentary and respiratory tracts), into the systemic circulation. Whereas transporters may contribute to the gastrointestinal absorption of some chemicals (e.g., salicylate and valproate by monocarboxylate transporters, some β-lactam antibiotics and ACE inhibitor drugs by peptide transporters, Fe^{2+}, Cd^{2+}, as well

Table 3.1
Types of Ultimate Toxicants and Their Sources

Parent xenobiotics as ultimate toxicants		
Pb ions		
Tetrodotoxin		
TCDD		
Methylisocyanate		
HCN		
CO		
Xenobiotic metabolites as ultimate toxicants		
Amygdalin	→	HCN
Arsenate	→	Arsenite
Fluoroacetate	→	Fluorocitrate
Ethylene glycol	→	Oxalic acid
Hexane	→	2,5-Hexanedione
Acetaminophen	→	N-Acetyl-p-benzoquinoneimine
CCl_4	→	$CCl_3OO^\bullet$
Benzo[a]pyrene (BP)	→	BP-7,8-diol-9,10-epoxide
Benzo[a]pyrene (BP)	→	BP-Radical cation
Reactive oxygen or nitrogen species as ultimate toxicants		
Hydrogen peroxide ⎫		
Diquat, doxorubicin, nitrofurantoin ⎬	→	Hydroxyl radical (HO$^\bullet$)
Cr(V), Fe(II), Mn(II), Ni(II) ⎭		
Paraquat → $O_2^{\bullet-}$ + NO$^\bullet$	→	Peroxynitrite (ONOO$^-$)
Endogenous compounds as ultimate toxicants		
Sulfonamides → albumin-bound bilirubin	→	Bilirubin
$CCl_3OO^\bullet$ → unsaturated fatty acids	→	Lipid peroxyl radicals
$CCl_3OO^\bullet$ → unsaturated fatty acids	→	Lipid alkoxyl radicals
$CCl_3OO^\bullet$ → unsaturated fatty acids	→	4-Hydroxynon-2-enal
HO$^\bullet$ → proteins	→	Protein carbonyls

as some other divalent metal ions by the divalent metal-ion transporter, and arsenate by phosphate transporters), the vast majority of toxicants traverse epithelial barriers and reach the blood capillaries by diffusing through cells. The rate of absorption is related to the concentration of the chemical at the absorbing surface, which depends on the rate of exposure and the dissolution of the chemical. It is also related to the area of the exposed site, the characteristics of the epithelial layer through which absorption takes place (e.g., the thickness of the stratum corneum in the skin), the intensity of the subepithelial microcirculation, and the physicochemical properties of the toxicant. Lipid solubility is usually the most important property influencing absorption. In general, lipid-soluble chemicals are absorbed more readily than are water-soluble substances.

Presystemic Elimination   During transfer from the site of exposure to the systemic circulation, toxicants may be eliminated. This is not unusual for chemicals absorbed from the gastrointestinal (GI) tract because they must first pass through the GI mucosal cells, liver, and lung before being distributed to the rest of the body by the systemic circulation. The GI mucosa and the liver may eliminate a significant fraction of a toxicant during its passage through these tissues, decreasing its systemic availability. For example, ethanol is oxidized by alcohol dehydrogenase in the gastric mucosa (Lim *et al.*, 1993), cyclosporine is returned from the enterocyte into the intestinal lumen by P-glycoprotein (an ATP-dependent xenobiotic transporter) and is also hydroxylated by cytochrome P450 (CYP3A4) in these cells (Lin *et al.*, 1999), morphine is glucuronidated in intestinal mucosa and liver, and manganese is taken up from the portal blood into liver and excreted into bile. Such processes may prevent a considerable quantity of chemicals from reaching the systemic blood. Thus, presystemic or first-pass elimination reduces the toxic effects of chemicals that reach their target sites by way of the systemic circulation. In contrast, the processes involved in presystemic elimination may contribute to injury of the digestive mucosa, liver, and lungs by chemicals such as ethanol, iron salts, α-amanitin, and paraquat because these processes promote their delivery to those sites.

Distribution to and Away from the Target

Toxicants exit the blood during the distribution phase, enter the extracellular space, and may penetrate into cells. Chemicals dissolved in plasma water may diffuse through the capillary endothelium via aqueous intercellular spaces and transcellular pores called fenestrae and/or across the cell membrane. Lipid-soluble compounds move readily into cells by diffusion. In contrast, highly ionized and hydrophilic xenobiotics (e.g., tubocurarine and aminoglycosides) are largely restricted to the extracellular space unless specialized membrane carrier systems are available to transport them.

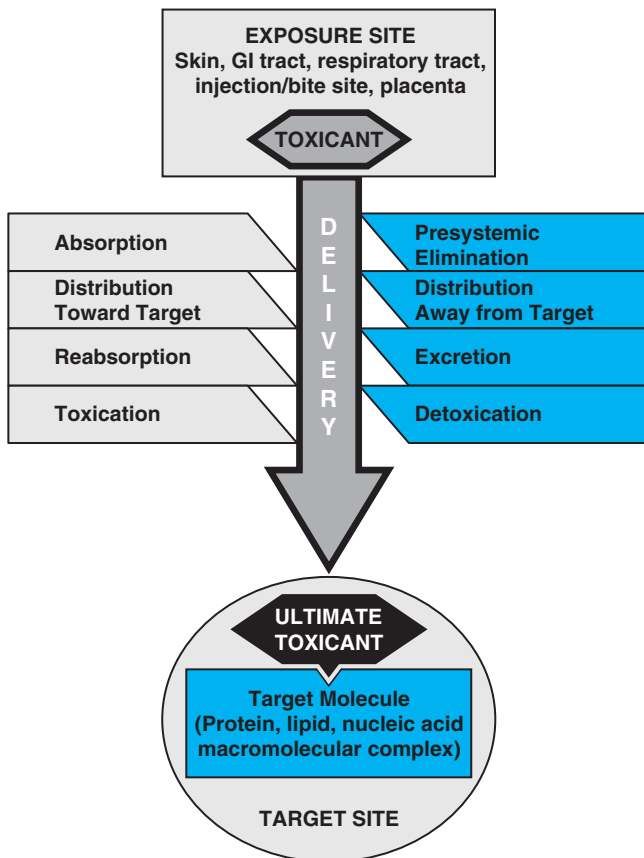
During distribution, toxicants reach their site or sites of action, usually a macromolecule on either the surface or the interior of a particular type of cell. Chemicals also may be distributed to the site or sites of toxication, usually an intracellular enzyme, where the ultimate toxicant is formed. Some mechanisms facilitate whereas others delay the distribution of toxicants to their targets.


Figure 3-2. The process of toxicant delivery is the first step in the development of toxicity.

Mechanisms Facilitating Distribution to a Target   Distribution of toxicants to specific target sites may be enhanced by (1) the porosity of the capillary endothelium, (2) specialized membrane transport, (3) accumulation in cell organelles, and (4) reversible intracellular binding.

Porosity of the Capillary Endothelium   Endothelial cells in the hepatic sinusoids and in the renal peritubular capillaries have larger fenestrae (50 to 150 nm in diameter) that permit passage of even protein-bound xenobiotics. This favors the accumulation of chemicals in the liver and kidneys.

Specialized Transport Across the Plasma Membrane   Specialized ion channels and membrane transporters can contribute to the delivery of toxicants to intracellular targets. For example, aquaglyceroporin channels may mediate influx of arsenite, which is present at physiological pH as uncharged $As(OH)_3$, voltage-gated Ca^{2+} channels permit the entry of cations such as lead or barium ions into excitable cells, and Na^+, K^+-ATPase promotes intracellular accumulation of thallous ion. Paraquat enters into pneumocytes via hitherto unspecified transporters, hepatocellular uptake of α-amanitin is mediated by the Na-dependent bile acid transporter (NTCP) and an organic anion transporting polypeptide (OATP1B3) and that of microcystin by OATP1B1 and OATP1B3, organic anion transporters such as human OAT1 and OAT3 mediate renal tubular uptake of ochratoxin and mercuric ion (the latter as the di-cysteine conjugate Cys-Hg-Cys), whereas both OAT1 and amino acid transporters can carry methylmercury as its cysteine conjugate CH_3-Hg-Cys, and an MPTP metabolite (MPP^+) enters into extrapyramidal dopamin-

ergic neurons by means of the dopamine transporter. Endocytosis of some toxicant-protein complexes, such as Cd-metallothionein or hydrocarbons bound to the male rat-specific α_{2u}-globulin, by renal proximal tubular cells can also occur. In addition, lipoprotein receptor–mediated endocytosis contributes to entry of lipoprotein-bound toxicants into cells equipped with such transporters. Membrane recycling can internalize cationic aminoglycosides associated with anionic phospholipids in the brush border membrane of renal tubular cells (Laurent *et al.*, 1990). This process may also contribute to cellular uptake of heavy metal ions. Such uptake mechanisms facilitate the entry of toxicants into specific cells, rendering those cells targets. Thus, carrier-mediated uptake of paraquat by pneumocytes and internalization of aminoglycosides by renal proximal tubular cells expose those cells to toxic concentrations of those chemicals.

Accumulation in Cell Organelles   Amphipathic xenobiotics with a protonable amine group and lipophilic character accumulate in lysosomes as well as mitochondria and cause adverse effects there. Lysosomal accumulation occurs by pH trapping, i.e., diffusion of the amine (e.g., amiodarone, amitriptyline, fluoxetine) in unprotonated form into the acidic interior of the organelle, where the amine is protonated, preventing its efflux. The entrapped amine inhibits lysosomal phospholipases, impairing degradation of lysosomal phospholipids, and causing phospholipidosis. Mitochondrial accumulation takes place electrophoretically. The amine is protonated in the intermembrane space (to where the mitochondria eject protons). The cation thus formed will then be sucked into the matrix space by the strong negative potential there (–220 mV), where it may impair β-oxidation and oxidative phosphorylation. By such mechanisms, the valued antiarrhytmic drug amiodarone is entrapped in the hepatic lysosomes and mitochondria, causing phospholipidosis (Kodavanti and Mehendale, 1990) and microvesiculas steatosis with other liver lesions (Fromenty and Pessayre, 1997), respectively. The cationic metabolite of MPTP (MPP^+) also electrophoretically accumulates in the mitochondria of dopaminergic neurons, causing mitochondrial dysfunction and cell death, whereas highly lipophilic local anesthetics (e.g., tetracaine, bupivacaine), when overdosed or inadvertently injected into a blood vessel, accumulate in cardiac mitochondria, compromising mitochondrial energy production and causing cardiac failure. Human equilibrative nucleoside transporter 1 (ENT1) in the mitochondrial inner membrane appears responsible for targeting fialuridine (an already withdrawn thymidine nucleoside analogue antiviral drug) into human mitochondria, where it inhibits mitochondrial DNA synthesis, thereby inducing hepatotoxicity. The fact that ENT1 is not localized in rodent mitochondria may account for the dramatic difference in mitochondrial toxicity of fialuridine between humans and rodents (Lee *et al.*, 2006).

Reversible Intracellular Binding   Binding to the pigment melanin, an intracellular polyanionic aromatic polymer, is a mechanism by which chemicals such as organic and inorganic cations and polycyclic aromatic hydrocarbons can accumulate in melanin-containing cells in the retina, the substantia nigra, and the skin (Larsson, 1993). The release of melanin-bound toxicants is thought to contribute to the retinal toxicity associated with chlorpromazine and chloroquine, injury to substantia nigra neurons by MPTP and manganese, and the induction of melanoma by polycyclic aromatics. Keratins are the major structural proteins in the epidermis and its appendages (nail and hair), constituting up to 85% of fully differentiated keratinocytes (skin cells). As keratins are abundant in cysteine residues, they can sequester thiol-reactive metal ions and metalloid compounds, whose nail and hair contents are indicative

of exposure. Release of keratin-bound arsenic in keratinocytes may adversely affect these cells, leading to dermal lesions common in arsenicism.

Mechanisms Opposing Distribution to a Target   Distribution of toxicants to specific sites may be hindered by several processes. The processes include (1) binding to plasma proteins, (2) specialized barriers, (3) distribution to storage sites such as adipose tissue, (4) association with intracellular binding proteins, and (5) export from cells.

Binding to Plasma Proteins   As long as xenobiotics such as DDT and TCDD are bound to high-molecular-weight proteins or lipoproteins in plasma, they cannot leave the capillaries by diffusion. Even if they exit the bloodstream through fenestrae, they have difficulty permeating cell membranes. Dissociation from proteins is required for most xenobiotics to leave the blood and enter cells. Therefore, strong binding to plasma proteins delays and prolongs the effects and elimination of toxicants.

Specialized Barriers   Brain capillaries have very low aqueous porosity because their endothelial cells lack fenestrae and are joined by extremely tight junctions. This blood–brain barrier prevents the access of hydrophilic chemicals to the brain except for those that can be actively transported. In the choroid plexus, where the capillaries are fenestrated, the choroidal epithelial cells are sealed together by tight junctions, forming the blood-cerebrospinal fluid barrier. Water-soluble toxicants also have restricted access to reproductive cells, which are separated from capillaries by other cells. The oocyte in the ovary is surrounded by multiple layers of granulosa cells, and the spermatogenic cells are supported by Sertoli cells that are tightly joined in the seminiferous tubules to form the blood-testis barrier (see Chap. 20). Transfer of hydrophilic toxicants across the placenta is also restricted. However, none of these barriers are effective against lipophilic substances.

Distribution to Storage Sites   Some chemicals accumulate in tissues (i.e., storage sites) where they do not exert significant effects. For example, highly lipophilic substances such as chlorinated hydrocarbon insecticides concentrate in adipocytes, whereas lead is deposited in bone by substituting for Ca^{2+} in hydroxyapatite. Such storage decreases the availability of these toxicants for their target sites and acts as a temporary protective mechanism. However, insecticides may return to the circulation and be distributed to their target site, the nervous tissue, when there is a rapid lipid loss as a result of fasting. This contributes to the lethality of pesticide-exposed birds during migration or during the winter months, when food is restricted. The possibility that lead is mobilized from the bone during pregnancy is of concern.

Association with Intracellular Binding Proteins   Binding to non-target intracellular sites also reduces the concentration of toxicants at the target site, at least temporarily. Metallothionein, a cysteine-rich cytoplasmic protein, serves such a function in acute cadmium intoxication (Klaassen *et al.*, 1999).

Export from Cells   Intracellular toxicants may be transported back into the extracellular space. This occurs in brain capillary endothelial cells. In their luminal membrane, these cells contain ATP-dependent membrane transporters (ATP-binding cassette or ABC transporters) such as the multidrug-resistance protein (MDR1), or P-glycoprotein, which extrudes chemicals and contributes to the blood-brain barrier (Schinkel, 1999). Compared to normal mice, mice with disrupted *mdr1a* gene exhibit 100-fold higher brain levels of and sensitivity to ivermectin, a neurotoxic pesticide and human antihelmintic drug

that is one of many P-glycoprotein substrates (Schinkel, 1999). The ooctye is also equipped with the P-glycoprotein that provides protection against chemicals that are substrates for this efflux pump (Elbling *et al.*, 1993). Hematopoietic stem cells (and perhaps other stem cells) are also protected by ABC transporters, such as MDR1, MRP1 and BCRP (breast cancer resistance protein), of which the latter confers these cells resistance to mitoxantrone. ABC transporters that export drugs were first identified in tumor cells which often overexpress them, thereby making these cells resistant to antitumor drugs these transporters pump out.

Excretion versus Reabsorption

Excretion   Excretion is the removal of xenobiotics from the blood and their return to the external environment. Excretion is a physical mechanism whereas biotransformation is a chemical mechanism for eliminating the toxicant.

For nonvolatile chemicals, the major excretory structures in the body are the renal glomeruli, which hydrostatically filter small molecules (<60 kDa) through their pores, and the proximal renal tubular cells and hepatocytes, which actively transport chemicals from the blood into the renal tubules and bile canaliculi, respectively. These cells are readily exposed to blood-borne chemicals through the large endothelial fenestrae; they have transporters of the solute carrier (SLC) family (e.g., OAT, OCT, and OATP type) that mediate the basolateral uptake of particular chemicals and transporters of the ATP-binding cassette (ABC) carrier family (e.g., MRP and MDR type) that mediate the luminal export of certain chemicals (see Chap. 5). Renal transporters have a preferential affinity for smaller (<300-Da), and hepatic transporters for larger (>400-Da), amphiphilic molecules. A less common "excretory" mechanism consists of diffusion and partition into the excreta on the basis of their lipid content (see below) or acidity. For example, morphine is transferred into milk and amphetamine is transferred into gastric juice by nonionic diffusion. This is facilitated by pH-trapping of those organic bases in those fluids, which are acidic relative to plasma (see Chap. 5).

The route and speed of excretion depend largely on the physico-chemical properties of the toxicant. The major excretory organs—kidney and liver—can efficiently remove only highly hydrophilic, usually ionized chemicals such as organic acids and bases. The reasons for this are as follows: (1) in the renal glomeruli, only compounds dissolved in plasma water can be filtered; (2) transporters in hepatocytes and renal proximal tubular cells are specialized for secretion of highly hydrophilic organic acids and bases; (3) only hydrophilic chemicals are freely soluble in the aqueous urine and bile; and (4) lipid-soluble compounds are readily reabsorbed by transcellular diffusion.

There are no efficient elimination mechanisms for nonvolatile, highly lipophilic chemicals such as polyhalogenated biphenyls and chlorinated hydrocarbon insecticides. If they are resistant to biotransformation, such chemicals are eliminated very slowly and tend to accumulate in the body upon repeated exposure. Three rather inefficient processes are available for the elimination of such chemicals: (1) excretion by the mammary gland after the chemical is dissolved in the milk lipids; (2) excretion in bile in association with biliary micelles and/or phospholipid vesicles; and (3) intestinal excretion, an incompletely understood transport from blood into the intestinal lumen. Volatile, nonreactive toxicants such as gases and volatile liquids diffuse from pulmonary capillaries into the alveoli and are exhaled.

Reabsorption   Toxicants delivered into the renal tubules may diffuse back across the tubular cells into the peritubular capillaries. This process is facilitated by tubular fluid reabsorption, which increases the intratubular concentration as well as the residence time of the chemical by slowing urine flow. Reabsorption by diffusion is dependent on the lipid solubility of the chemical. For organic acids and bases, diffusion is inversely related to the extent of ionization, because the nonionized molecule is more lipid-soluble. The ionization of weak organic acids, such as salicylic acid and phenobarbital, and bases, such as amphetamine, procainamide, and quinidine, is strongly pH-dependent in the physiologic range. Therefore their reabsorption is influenced significantly by the pH of the tubular fluid. Acidification of urine favors the excretion of weak organic bases, whereas alkalinization favors the elimination of weak organic acids. Some organic compounds may be reabsorbed from the renal tubules by transporters. For example, peptide transporters (PEPT) can move some β-lactam antibiotics and angiotensin converting enzyme inhibitor drugs across the brush border membrane. Carriers for the physiologic oxyanions mediate the reabsorption of some toxic metal oxyanions in the kidney. Chromate and molybdate are reabsorbed by the sulfate transporter, whereas arsenate is reabsorbed by the phosphate transporter.

Toxicants delivered to the GI tract by biliary, gastric, and intestinal excretion and secretion by salivary glands and the exocrine pancreas may be reabsorbed by diffusion across the intestinal mucosa. Because compounds secreted into bile are usually organic acids, their reabsorption is possible only if they are sufficiently lipophilic or are converted to more lipid-soluble forms in the intestinal lumen. For example, glucuronides of toxicants such as diethylstilbestrol, and glucuronides of the hydroxylated metabolites of polycyclic aromatic hydrocarbons, chlordecone, and halogenated biphenyls are hydrolyzed by the β-glucuronidase of intestinal microorganisms, and the released aglycones are reabsorbed (Gregus and Klaassen, 1986). Glutathione conjugates of hexachlorobutadiene and trichloroethylene are hydrolyzed by intestinal and pancreatic peptidases, yielding the cysteine conjugates, which are reabsorbed and serve as precursors of some nephrotoxic metabolites (Anders, 2004).

Toxication versus Detoxication

Toxication   A number of xenobiotics (e.g., strong acids and bases, nicotine, aminoglycosides, ethylene oxide, methylisocyanate, heavy-metal ions, HCN, CO) are directly toxic, whereas the toxicity of others is due largely to metabolites. Biotransformation to harmful products is called *toxication* or *metabolic activation.* With some xenobiotics, toxication confers physicochemical properties that adversely alter the microenvironment of biological processes or structures. For example, oxalic acid formed from ethylene glycol may cause acidosis and hypocalcaemia as well as obstruction of renal tubules by precipitation as calcium oxalate. Occasionally, chemicals acquire structural features and reactivity by biotransformation that allows for a more efficient interaction with specific receptors or enzymes. For example, the organophosphate insecticide parathion is biotransformed to paraoxon, an active cholinesterase inhibitor; the rodenticide fluoroacetate is converted in the citric acid cycle to fluorocitrate, a false substrate that inhibits aconitase; as a result of its CYP2E1-catalyzed oxidation, the general anesthetic methoxyflurane releases fluoride ion which inhibits several enzymes (including enolase in the glycolytic pathway) and which contributes to renal injury after prolonged anesthesia; some cephalosporin an-

tibiotics (e.g., cephoperazone) may cause hemorrhage because they undergo biotransformation with release of 1-methyltetrazole-5-thiol that inhibits vitamin K epoxide reductase and thus impairs activation clotting factors; and fialuridine, an antiviral drug withdrawn from development because it produced lethal hepatotoxicity in patients involved in the clinical trial, is phosphorylated to the triphosphate, which inhibits DNA polymerase-γ and thus impairs synthesis of mitochondrial DNA (Lewis *et al.*, 1996). Most often, however, toxication renders xenobiotics and occasionally other molecules in the body, such as oxygen and nitric oxide ($^\bullet$NO), indiscriminately reactive toward endogenous molecules with susceptible functional groups. This increased reactivity may be due to conversion into (1) electrophiles, (2) free radicals, (3) nucleophiles, or (4) redox-active reactants.

Formation of Electrophiles   Electrophiles are molecules containing an electron-deficient atom with a partial or full positive charge that allows it to react by sharing electron pairs with electron-rich atoms in nucleophiles. The formation of electrophiles is involved in the toxication of numerous chemicals (Table 3-2) (see Chap. 6). Such reactants are often produced by insertion of an oxygen atom, which withdraws electrons from the atom it is attached to, making that electrophilic. This is the case when aldehydes, ketones, epoxides, arene oxides, sulfoxides, nitroso compounds, phosphonates, and acyl halides are formed (Table 3-2). In other instances, conjugated double bonds are formed, which become polarized by the electron-withdrawing effect of an oxygen, making one of the double-bonded carbons electron-deficient (that is, electrophilic). This occurs when α, β-unsaturated aldehydes and ketones as well as quinones, quinoneimines, and quinonemethides are produced (Table 3-2). Formation of many of these electrophilic metabolites is catalyzed by cytochrome P450s.

Cationic electrophiles may be produced as a result of heterolytic bond cleavage. For example, methyl-substituted aromatics such as 7,12-dimethylbenzanthracene and aromatic amines (amides), such as 2-acetylaminofluorene, are hydroxylated to form benzylic alcohols and N-hydroxy arylamines (amides), respectively (Miller and Surh, 1994). These metabolites are then esterified, typically by sulfotransferases. Heterolytic cleavage of the C—O or N—O bonds of these esters results in a hydrosulfate anion and the concomitant formation of a benzylic carbonium ion or aryl-nitrenium ion, respectively (see Chap. 6). The antiestrogen tamoxifen undergoes similar activation by hydroxylation and sulfation to form a carbocationic metabolite (Kim *et al.*, 2004). After being C-hydroxylated by CYP2E1, the hepatocarcinogen dimethylnitrosamine undergoes spontaneous decomposition, finally a heterolytic cleavage of the C—N bond to form methyl carbonium cation ($^+$CH$_3$) (see Chap. 6). In a similar process, the tobacco-specific nicotine-derived nitrosamine ketone (NNK), the most potent carcinogen in tobacco, may generate either methyl carbonium cation or piridyloxobutyl carbonium cation, depending on the site of C-hydroxylation that initiates its decomposition. Formally, spontaneous heterolytic cleavage of the C—Cl bond results in formation of reactive epi- sulfonium ion from the vesicant chemical warfare agent sulfur mustard (2,2'-bis-chloroyethylsulfide). An episulfonium ion metabolite is also the ultimate toxicant produced from the fumigant 1,2-dibromoethane following its conjugation with glutathione to form S-(2-bromoethyl)glutathione conjugate, a so called half-sulfur mustard (Anders, 2004). The oxidation of mercury (Hg^0) to Hg^{2+} by catalase, reduction of CrO_4^{2-} to DNA-reactive Cr^{3+} by ascorbate (Quievryn *et al.*, 2002) and reduction of the phosphate-mimicking AsO_4^{3-} to thiol-reactive AsO_3^{2-}/As^{3+} by enzymes catalyzing

Table 3.2
Toxication by Formation of Electrophilic Metabolites

ELECTROPHILIC METABOLITE	PARENT TOXICANT	TOXICATION	TOXIC EFFECT
		ENZYMES CATALYZING	
Nonionic electrophiles			
Aldehydes, ketones			
Acetaldehyde	Ethanol	ADH	Hepatic fibrosis(?)
Zomepirac glucuronide	Zomepirac	GT→isomerization	Immune reaction(?)
2,5-Hexanedione	Hexane	CYP	Axonopathy
α, β-Unsaturated aldehydes, ketones			
Acrolein	Allyl alcohol	ADH	Hepatic necrosis
Acrolein	Allyl amine	MAO	Vascular injury
Muconic aldehyde	Benzene	Multiple	Bone marrow injury
4-Hydroxynon-2-enal	Fatty acids	Lipid peroxidation	Cellular injury(?)
Quinones, quinoneimines			
DES-4,4′-quinone	DES	Peroxidases	Carcinogenesis(?)
N-Acetyl-p-benzoquinoneimine	Acetaminophen	CYP, peroxidases	Hepatic necrosis
Epoxides, arene oxides			
Aflatoxin B$_1$ 8,9-epoxide	Aflatoxin B$_1$	CYP	Carcinogenesis
2-Chlorooxirane	Vinyl chloride	CYP	Carcinogenesis
Bromobenzene 3,4-oxide	Bromobenzene	CYP	Hepatic necrosis
Benzo[a]pyrene 7,8-diol 9,10-oxide	Benzo[a]pyrene	CYP	Carcinogenesis
Sulfoxides			
Thioacetamide S-oxide	Thioacetamide	FMO	Hepatic necrosis
Nitroso compounds			
Nitroso-sulfamethoxazole	Sulfamethoxazole	CYP	Immune reaction
Phosphonates			
Paraoxon	Parathion	CYP	ChE inhibition
Acyl halides			
Phosgene	Chloroform	CYP	Hepatic necrosis
Trifluoroacetyl chloride	Halothane	CYP	Immune hepatitis
Thionoacyl halides			
2,3,4,4-Tetrachlorothiobut-3-enoic acid chloride	HCBD	GST→GGT →DP→CβCL	Renal tubular necrosis
Thioketenes			
Chloro-1,2,2-trichlorovinyl-thioketene	HCBD	GST→GGT →DP→CCβL	Renal tubular necrosis
Cationic electrophiles			
Carbonium ions			
Benzylic carbocation	7,12-DMBA	CYP→ST	Carcinogenesis
Carbonium cation	DENA	CYP→s.r.	
Nitrenium ions			
Arylnitrenium ion	AAF, DMAB, HAPP	CYP→ST	Carcinogenesis
Sulfonium ions			
Episulfonium ion	1,2-dibromoethane	GST	Carcinogenesis
Metal ions			
Mercury(II) ion	Elemental Hg	Catalase	Brain injury
Diaquo-diamino platinate(II)	Cisplatinum	s.r.	Renal tubular necrosis

KEY: AAF = 2-acetylaminofluorene, ADH = alcohol dehydrogenase, CCβL = cysteine conjugate β-lyase; ChE = cholinesterase; CYP = cytochrome P450; DENA = diethylnitrosamine; DMAB N,N-dimethyl-4-aminoazobenzene; 7,12-DMBA = 7,12-dimethylbenzanthracene; DES = diethylstilbestrol; DP = dipeptidase; FMO = flavin-containing monooxygenase; GT = UDP-glucuronosyltransferase; GGT = gamma-glutamyltransferase; GST = glutathione S-transferase; HAPP = heterocyclic arylamine pyrolysis products; HCBD = hexachlorobutadiene; ST = sulfotransferase; s.r. = spontaneous rearrangement.

phosphorolytic reactions, such as glyceraldehyde-3-phosphate dehydrogenase (Gregus and Németi, 2005), are examples for formation of electrophilic toxicants from inorganic chemicals.

Formation of Free Radicals   A free radical is a molecule or molecular fragment that contains one or more unpaired electrons in its outer orbital. Radicals are formed by (1) accepting an electron or (2) losing an electron, or by (3) homolytic fission of a covalent bond.

1.   Xenobiotics such as paraquat, doxorubicin, and nitrofurantoin can accept an electron from reductases to give rise to radicals
Figure 3-3. Production of superoxide anion radical ($O_2^{\bullet-}$) by paraquat (PQ^{++}), doxorubicin (DR), and nitrofurantoin (NF).

Note that formation of ($O_2^{\bullet-}$) is not the final step in the toxication of these xenobiotics, because $O_2^{\bullet-}$ can yield the much more reactive hydroxyl radical, as depicted in Fig. 3-4.

(Fig. 3-3). These radicals typically transfer the extra electron to molecular oxygen, forming a superoxide anion radical ($O_2^{\bullet-}$) and regenerating the parent xenobiotic, which is ready to gain a new electron (Kappus, 1986). Through this "redox cycling," one electron acceptor xenobiotic molecule can generate many $O_2^{\bullet-}$ molecules. There are also endogenous sources of $O_2^{\bullet-}$. This radical is generated in large quantities by NADPH oxidase (Nox) in activated macrophages and granulocytes during "respiratory burst," and in smaller quantities by many other cells, such as endothelial cells and vascular smooth muscle cells, which also express Nox in the plasma membrane (Bokoch and Knaus, 2003). Growth factor receptor stimulation in these non-phagocytotic cells is coupled to Nox activation. $O_2^{\bullet-}$ is also produced by the mitochondrial electron transport chain, especially

by complexes I and III. The significance of $O_2^{\bullet-}$ stems to a large extent from the fact that $O_2^{\bullet-}$ is a starting compound in two toxication pathways (Fig. 3-4); one leading to formation of hydrogen peroxide (HOOH) and then hydroxyl radical (HO$^{\bullet}$), whereas the other produces peroxynitrite (ONOO$^-$) and ultimately nitrogen dioxide ($^{\bullet}$NO$_2$), and carbonate anion radical ($CO_3^{\bullet-}$).

2. Nucleophilic xenobiotics such as phenols, hydroquinones, aminophenols, aromatic amines (e.g., benzidine), hydrazines, phenothiazines (e.g., chlorpromazine; see Fig. 3-6), and thiols are prone to lose an electron and form free radicals in a reaction catalyzed by peroxidases (Aust *et al.*, 1993). Some of these chemicals, such as catechols and hydroquinones, may undergo two sequential one-electron oxidations, producing first semiquinone radicals and then quinones. Quinones are not only reactive electrophiles (Table 3-2) but also electron acceptors with the capacity to initiate redox cycling or oxidation of thiols and NAD(P)H. Polycyclic aromatic hydrocarbons with sufficiently low ionization potential, such as benzo[*a*]pyrene and 7,12-dimethylbenzanthracene, can be converted via one-electron oxidation by peroxidases or cytochrome P450 to radical cations, which may be the ultimate toxicants for these carcinogens (Cavalieri and Rogan, 1992). Like peroxidases, oxyhemoglobin (Hb-FeII-O$_2$) can catalyze the oxidation of aminophenols to semiquinone radicals and quinoneimines. This is another example of toxication, because these products, in turn, oxidize ferrohemoglobin (Hb-FeII) to methemoglobin (Hb-FeIII), which cannot carry oxygen.

3. Free radicals are also formed by homolytic bond fission, which can be induced by electron transfer to the molecule (reductive fission). This mechanism is involved in the conversion of CCl$_4$ to the trichloromethyl free radical (Cl$_3$C$^{\bullet}$) by an electron transfer from cytochrome P450 or the mitochondrial electron
Figure 3-4. Two pathways for toxication of superoxide anion radical ($O_2^{\bullet-}$) via nonradical products (ONOO$^-$ and HOOH) to radical products ($^{\bullet}$NO$_2$, $CO_3^{\bullet-}$ and HO$^{\bullet}$).

In one pathway, conversion of ($O_2^{\bullet-}$) to HOOH is spontaneous or is catalyzed by superoxide dismutase (SOD). Homolytic cleavage of HOOH to hydroxyl radical and hydroxyl ion is called the Fenton reaction and is catalyzed by the transition metal ions shown. Hydroxyl radical formation is the ultimate toxication for xenobiotics that form $O_2^{\bullet-}$ (see Fig. 3-3) or for HOOH, the transition metal ions listed, and some chemicals that form complexes with these transiton metal ions. In the other pathway, $O_2^{\bullet-}$ reacts avidly with nitric oxide ($^{\bullet}$NO), the product of $^{\bullet}$NO synthase (NOS), forming peroxynitrite (ONOO$^-$). Spontaneous reaction of ONOO$^-$ with carbon dioxide (CO$_2$) yields nitrosoperoxy carbonate (ONOOCO$_2^-$) that is homolytically cleaved to nitrogen dioxide ($^{\bullet}$NO$_2$) and carbonate anion radical ($CO_3^{\bullet-}$). All three radical products indicated in this figure are oxidants, whereas $^{\bullet}$NO$_2$ is also a nitrating agent.

transport chain (reductive dehalogenation) (Recknagel *et al.*, 1989). The $Cl_3C^{\bullet}$ reacts with O_2 to form the even more reactive trichloromethylperoxy radical ($Cl_3COO^{\bullet}$) (Hippeli and Elstner, 1999).

The hydroxyl radical ($HO^{\bullet}$), a free radical of paramount toxicological significance, is also generated by homolytic fission. Such a process yields large amounts of $HO^{\bullet}$ from water upon ionizing radiation. Reductive homolytic fission of hydrogen peroxide (HOOH) to $HO^{\bullet}$ and HO^- is called the *Fenton reaction* (Fig. 3-4). This is catalyzed by transition metal ions, typically Fe(II) or, Cu(I), Cr(V), Ni(II), or Mn(II), and is a major toxication mechanism for HOOH and its precursor $O_2^{\bullet-}$ as well as for transition metals. Moreover, the toxicity of chemicals, such as nitrilotriacetic acid, bleomycin, and orellanin (Hippeli and Elstner, 1999), which chelate transition metal ions is also based on Fenton chemistry because chelation increases the catalytic efficiency of some transition metal ions. Complexation with some endogenous oligopeptides also increases the catalytic efficiency of weakly Fenton-active metal ions, such as Ni(II). The pulmonary toxicity of inhaled mineral particles such as asbestos and silica is caused, at least in part, by the formation of $HO^{\bullet}$ triggered by Fe ions on the particle surface (Vallyathan *et al.*, 1998; Castranova, 2004). Hydrogen peroxide is a direct or indirect by-product of several enzymatic reactions, including monoamine oxidase, acyl-coenzyme A oxidase, xanthine oxidoreductase (Harrison, 2002) and CYP2E1 (Caro and Cederbaun, 2004). It is produced in large quantities by spontaneous or superoxide dismutase-catalyzed dismutation of $O_2^{\bullet-}$.

Homolytic cleavage is also involved in free radical generation from $ONOO^-$ (Squadrito and Pryor, 1998) (Fig. 3-4). The facile reaction of $ONOO^-$ with the ubiquitous CO_2 yields nitrosoperoxycarbonate ($ONOOCO_2^-$), which can spontaneously homolyze into two radicals, the oxidant and nitrating agent nitrogen dioxide ($^{\bullet}NO_2$) and the oxidant carbonate anion radical ($CO_3^{\bullet-}$). Thus, formation of $ONOO^-$ and the latter radicals represent a toxication mechanism for $O_2^{\bullet-}$ and $^{\bullet}NO$. As $^{\bullet}NO$ is the product of nitric oxide synthase (NOS), this mechanism is especially relevant in and around cells that express NOS constitutively (i.e., neurons and endothelial cells) as well as in and around cells that express the inducible form of NOS in response to cytokines. Inside the cell, a predominant site for formation of $ONOO^-$ as well as its products $CO_3^{\bullet-}$ and $^{\bullet}NO_2$ are the mitochondria, wherein the lipophilic $^{\bullet}NO$ can readily diffuse and where the electron transport chain and the citric acid cycle produces $O_2^{\bullet-}$ and CO_2, respectively (Denicola and Radi, 2005).

Formation of Nucleophiles The formation of nucleophiles is a relatively uncommon mechanism for activating toxicants. Examples include the formation of cyanide from amygdalin, which is catalyzed by bacterial β-glucosidase in the intestine; from acrylonitrile after epoxidation and subsequent glutathione conjugation; and from sodium mitroprusside by thiol-induced decomposition. Carbon monoxide is a toxic metabolite of dihalomethanes that undergo oxidative dehalogenation. Hydrogen selenide, a strong nucleophile and reductant, is formed from selenite by reaction with glutathione or other thiols.

Formation of Redox-Active Reactants There are specific mechanisms for the creation of redox-active reactants other than those already mentioned. Examples include the formation of the methemoglobin-producing nitrite from nitrate by bacterial reduction in the intestine or from esters of nitrous or nitric acids in reaction with glutathione. Dapsone hydroxylamine and 5-hydroxyprimaquine, hydroxylated metabolites of the respective drugs, produce methemoglobin by cooxidation (Fletcher *et al.*, 1988). Reductants such as ascorbic acid and reductases such as NADPH-dependent flavoenzymes reduce Cr(VI) to Cr(V) (Shi and Dalal, 1990). Xenobiotic radicals formed in redox cycling (e.g., those depicted in Fig. 3-3) as well as $O_2^{\bullet-}$ can reduce Fe(III) bound to ferritin and consequently release it as Fe(II). Cr(V) and Fe(II) thus formed catalyze $HO^{\bullet}$ formation (Fig. 3-4).

In summary, the most reactive metabolites are electron-deficient molecules and molecular fragments such as electrophiles and neutral or cationic free radicals. Although some nucleophiles are reactive (e.g., HCN, CO), many (e.g., hydroquinones) are activated by conversion to electrophiles. Similarly, free radicals with an extra electron (e.g., those shown in Fig. 3-3) cause damage by giving rise to the neutral $HO^{\bullet}$ radical after the formation and subsequent homolytic cleavage of HOOH.

Detoxication Biotransformation that eliminates an ultimate toxicant or prevents its formation is called *detoxication.* In some cases, detoxication may compete with toxication for a chemical. Detoxication can take several pathways, depending on the chemical nature of the toxic substance.

Detoxication of Toxicants with No Functional Groups In general, chemicals without functional groups, such as benzene and toluene, are detoxicated in two phases. Initially, a functional group such as hydroxyl or carboxyl is introduced into the molecule, most often by cytochrome-P450 enzymes. Subsequently, an endogenous acid, such as glucuronic acid, sulfuric acid, or an amino acid, is added to the functional group by a transferase. With some exceptions, the final products are inactive, highly hydrophilic organic acids that are readily excreted. Carbonyl reduction catalyzed by at least five enzymes (e.g., 11-β-hydroxysteroid dehydrogenase-1, carbonyl reductase and three members of aldo-keto reductase superfamily) initiates detoxication of the potent carcinogen nicotine-derived nitrosamine ketone [NNK; 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone]. The formed nicotine-derived nitrosamine alcohol is then readily glucuronidated at its hydroxyl moiety and is excreted into urine (Maser, 2004).

Detoxication of Nucleophiles Nucleophiles are generally detoxicated by conjugation at the nucleophilic functional group. Hydroxylated compounds are conjugated by sulfation, glucuronidation, or rarely by methylation, whereas thiols are methylated or glucuronidated and amines and hydrazines are acetylated. These reactions prevent peroxidase-catalyzed conversion of the nucleophiles to free radicals and biotransformation of phenols, aminophenols, catechols, and hydroquinones to electrophilic quinones and quinoneimines. An alternative mechanism for the elimination of thiols, amines, and hydrazines is oxidation by flavin-containing monooxygenases (Krueger and Williams, 2005). Some alcohols, such as ethanol, are detoxicated by oxidation to carboxylic acids by alcohol and aldehyde dehydrogenases. A specific detoxication mechanism is the biotransformation of cyanide to thiocyanate by rhodanese or mercaptopyruvate sulfurtransferase.

Detoxication of Electrophiles A general mechanism for the detoxication of electrophilic toxicants is conjugation with the thiol nucleophile glutathione (Ketterer, 1988). This reaction may occur spontaneously or can be facilitated by glutathione *S*-transferases. Metal ions—such as Ag^+, Cd^{2+}, Hg^{2+}, and CH_3Hg^+ ions—readily react with and are detoxicated by glutathione. Specific mechanisms
Figure 3-5. Detoxication of superoxide anion radical ($O_2^{\bullet-}$) by superoxide dismutase (SOD), and of HOOH by glutathione peroxidase (GPX), peroxiredoxin (Prx-$(SH)_2$), and catalase (CAT).

The byproducts are glutathione disulfide (GSSG) and peroxiredoxin disulfide ($PrxS_2$), from which glutathione (GSH) and Prx-$(SH)_2$ are regenerated by glutathione reductase and thioredoxin-reductase, respectively.

for the detoxication of electrophilic chemicals include epoxide hydrolase-catalyzed biotransformation of epoxides and arene oxides to diols and dihydrodiols, respectively, and carboxylesterase-catalyzed hydrolysis of organophosphate ester pesticides. Others are two-electron reduction of quinones to hydroquinones by NAD(P)H:quinone oxidoreductase (NQO1) and NRH:quinone oxidoreductase (NQO2), reduction of α, β-unsaturated aldehydes (e.g., the lipidperoxidation product 4-oxonon-2-enal) to alcohols or to their saturated derivative by carbonyl reductase (Maser, 2006), or oxidation of α, β-unsaturated aldehydes to acids by aldehyde dehydrogenases. Complex formation of thiol-reactive metal ions by metallothionein and the redox-active ferrous iron by ferritin are special types of detoxications. Covalent binding of electrophiles to proteins can also be regarded as detoxification provided that the protein has no critical function and does not become a neoantigen or otherwise harmful. Carboxylesterases, for example, inactivate organophosphates not only by hydrolysis but also by covalent binding.

Detoxication of Free Radicals   Because $O_2^{\bullet-}$ can be converted into much more reactive compounds (Fig. 3-4), its elimination is an important detoxication mechanism. This is carried out by superoxide dismutases (SOD), high-capacity enzymes located in the cytosol (Cu, Zn-SOD) and the mitochondria (Mn-SOD), which convert $O_2^{\bullet-}$ to HOOH (Fig. 3-5). Subsequently, HOOH is reduced to water by

catalase in the peroxisomes (also in the mitochondria in cardiac muscle), by the selenocysteine-containing glutathione peroxidases in the cytosol and mitochondria, and by peroxiredoxins in the cytosol, mitochondria and endoplasmic reticulum (Fig. 3-5) (Rhee *et al.*, 2005).

No enzyme eliminates HO$^\bullet$. Whereas some relatively stable radicals, such as peroxyl radicals (see Fig. 3-9), can readily abstract a hydrogen atom from glutathione, α-tocopherol (vitamin E), or ascorbic acid (vitamin C), thus becoming nonradicals, these antioxidants are generally ineffective in detoxifying HO$^\bullet$ (Sies, 1993). This is due to its extreme reactivity and thus short half-life (10^{-9}s), which provides little time for the HO$^\bullet$ to reach and react with antioxidants. Therefore the only effective protection against HO$^\bullet$ is to prevent its formation by elimination of its precursor, HOOH, via conversion to water (Fig. 3-5).

ONOO$^-$ (which is not a free radical oxidant) is significantly more stable than HO$^\bullet$ (half-life of about 1 second). Nevertheless, the small biological antioxidant molecules (glutathione, uric acid, ascorbic acid, α-tocopherol) are relatively inefficient in intercepting it, because ONOO$^-$ rapidly reacts with CO_2 (Squadrito and Pryor, 1998) to form reactive free radicals (Fig. 3-4). More efficient are the selenocysteine-containing glutathione peroxidase and peroxiredoxins, which can reduce ONOO$^-$ to nitrite (ONO$^-$) the same way they reduce HOOH to water (Fig. 3-5). Selenoprotein P, which contains 10 selenocysteine residues and coats the surface of endothelial cells, also reduces ONOO$^-$ and may serve as a protectant against this oxidant in blood. In addition, ONOO$^-$ reacts with oxyhemoglobin, heme-containing peroxidases and albumin, all of which could be important sinks for ONOO$^-$. Furthermore, elimination of the two ONOO$^-$ precursors—i.e., $^\bullet$NO by reaction with oxyhemoglobin (to yield methemoglobin and nitrate) and $O_2^{\bullet-}$ by SODs (see above)—is a significant mechanism in preventing ONOO$^-$ buildup (Squadrito and Pryor, 1998).

Peroxidase-generated free radicals are eliminated by electron transfer from glutathione. This results in the oxidation of glutathione, which is reversed by NADPH-dependent glutathione reductase (Fig. 3-6). Thus, glutathione plays an important role in the detoxication of both electrophiles and free radicals.

Detoxication of Protein Toxins   Presumably, extra- and intracellular proteases are involved in the inactivation of toxic polypeptides. Several toxins found in venoms, such as α- and β-bungaratoxin, erabutoxin, and phospholipase, contain intramolecular disulfide bonds that are required for their activity. These proteins are inactivated by thioredoxin, an endogenous dithiol protein that reduces the essential disulfide bond (Lozano *et al.*, 1994).

Figure 3-6. Detoxication of peroxidase (POD)–generated free radicals such as chlorpromazine free radical ($CPZ_\bullet^+$) by glutathione (GSH).

The by-products are glutathione thiyl radical (GS$^\bullet$) and glutathione disulfide (GSSG), from which GSH is regenerated by glutathione reductase (GR).

When Detoxication Fails   Detoxication may be insufficient for several reasons:

1. Toxicants may overwhelm detoxication processes, leading to saturation of the detoxication enzymes, consumption of the cosubtrates, or depletion of cellular antioxidants such as glutathione, ascorbic acid, and α-tocopherol. This results in the accumulation of the ultimate toxicant.
2. Occasionally, a reactive toxicant inactivates a detoxicating enzyme. For example, $ONOO^-$ incapacitates Mn-SOD, which normally would counteract $ONOO^-$ formation (Murphy, 1999) (see Fig. 3-4).
3. Some conjugation reactions can be reversed. For example, 2-naphthylamine, a bladder carcinogen, is *N*-hydroxylated and glucuronidated in liver, with the glucuronide excreted into urine. While in the bladder, the glucuronide is hydrolyzed, and the released arylhydroxylamine is converted by protonation and dehydration to the reactive electrophilic arylnitrenium ion (Bock and Lilienblum, 1994). Isocyanates and isothiocyanates form labile glutathione conjugates from which they can be released. Thus, methylisocyanate readily forms a glutathione conjugate in the lung after inhalation. From there, the conjugate is distributed to other tissues, where the reactive electrophilic parent compound may be regenerated (Baillie and Kassahun, 1994). Such conjugates are considered transport forms of toxicants.
4. Sometimes detoxication generates potentially harmful by-products, such as the glutathione thiyl radical and glutathione disulfide, which are produced during the detoxication of free radicals (Fig. 3-6). Glutathione disulfide can form mixed disulfides with protein thiols, whereas the thiyl radical ($GS^\bullet$), after reacting with thiolate (GS^-), forms a glutathione disulfide radical anion ($GSSG^{\bullet-}$), which can reduce O_2 to $O_2^{\bullet-}$. Conjugation with glutathione may lead to HCN generation in the course of acrylonitrile biotransformation, the first step of which is epoxidation of acrylonitrile ($H_2C=CH-CN$). Whereas glutathione conjugation detoxifies this epoxide if it takes place at the carbon adjacent to the nitrile group (-CN), it causes release of this group as HCN if glutathione conjugates with the epoxide at the carbon not linked to the nitrile moiety.

STEP 2—REACTION OF THE ULTIMATE TOXICANT WITH THE TARGET MOLECULE

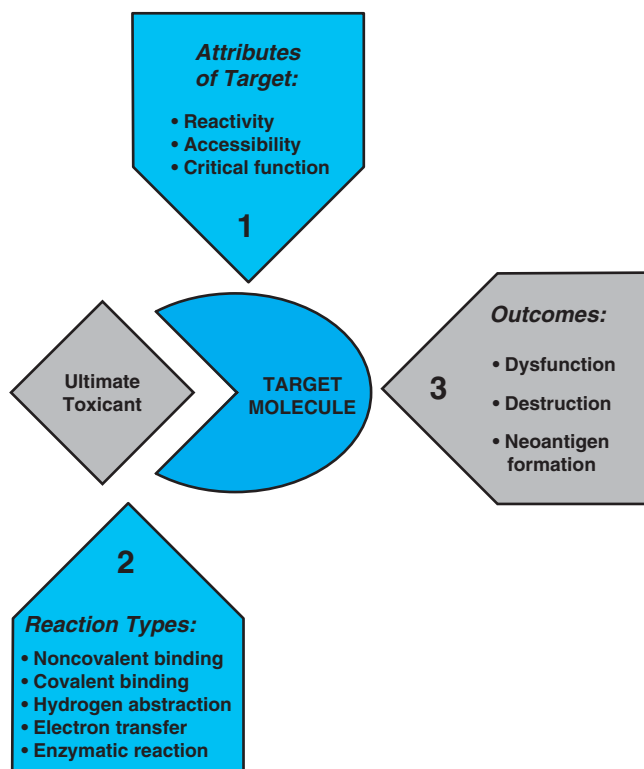
Toxicity is typically mediated by a reaction of the ultimate toxicant with a target molecule (step 2a in Fig. 3-1). Subsequently, a series of secondary biochemical events occur, leading to dysfunction or injury that is manifest at various levels of biological organization, such as at the target molecule itself, cell organelles, cells, tissues and organs, and even the whole organism. Because interaction of the ultimate toxicant with the target molecule triggers the toxic effect, consideration is given to (1) the attributes of target molecules, (2) the types of reactions between ultimate toxicants and target molecules, and (3) the effects of toxicants on the target molecules (Fig. 3-7). Finally, consideration is given to toxicities that are initiated not by reaction of the ultimate toxicant with target molecules, but rather by alteration of the biological (micro)environment (step 2b in Fig. 3-1) in which critical endogenous molecules, cell organelles, cells, and organs operate.


Figure 3-7. Reaction of the ultimate toxicant with the target molecule: the second step in the development of toxicity.

Attributes of Target Molecules

Practically all endogenous compounds are potential targets for toxicants. The identification and characteristics of the target molecules involved in toxicity constitute a major research priority, but a comprehensive inventory of potential target molecules is impossible. Nevertheless, the most prevalent and toxicologically relevant targets are macromolecules such as nucleic acids (especially DNA) and proteins. Among the small molecules, membrane lipids are frequently involved, whereas cofactors such as coenzyme A and pyridoxal rarely are involved.

   To be a target, an endogenous molecule must possess the appropriate reactivity and/or steric configuration to allow the ultimate toxicant to enter into covalent or noncovalent reactions. For these reactions to occur, the target molecule must be accessible to a sufficiently high concentration of the ultimate toxicant. Thus, endogenous molecules that are exposed to reactive chemicals or are adjacent to sites where reactive metabolites are formed are frequently targets. Technical advances in the field of proteonomics make it increasingly possible to identify potential protein targets of reactive chemicals as chemical-protein adducts. A compendium of proteins adducted by reactive toxicant metabolites has been established at the University of Kansas (http://tpdb.medchem.ku.edu:8080/ protein_database/search.jsp). The first target for reactive metabolites is often the enzyme that catalyzes their production or the adjacent intracellular structures. For example, thyroperoxidase, the enzyme involved in thyroid hormone synthesis, converts some nucleophilic xenobiotics (such as methimazole, amitrole, and resorcinol) into reactive free radicals that inactivate thyroperoxidase (Engler *et al.*, 1982). This is the basis for the antithyroid as well as the thyroid tumor–inducing effect of these chemicals. Carbon tetrachloride,

which is activated by cytochrome P450, destroys this enzyme as well as the neighboring microsomal membranes (Osawa *et al.*, 1995). Several mitochondrial enzymes are convenient targets for nephrotoxic cysteine conjugates such as dichlorovinyl cysteine, because these conjugates are converted to electrophiles by mitochondrial enzymes with cysteine conjugate β-lyase activity (e.g., aspartate aminotransferase and branched chain amino acid aminotransferase) that can readily channel their reactive products to neighboring enzymes such as α-ketoglutarate dehydrogenase (Anders, 2004). Reactive metabolites that are unable to find appropriate endogenous reaction partners in close proximity to their site of formation may diffuse until they encounter such reactants. For example, hard electrophiles such as the arylnitrenium ion metabolite of *N*-methyl-4-aminoazobenzene react readily with hard nucleophilic atoms in nucleic acids, and thus target DNA in the nucleus, even though the electrophiles are produced in the cytoplasm. Vinyl chloride epoxide formed in the hepatocytes from vinyl chloride reaches its DNA targets in the neighboring endothelial cells (that are more sensitive to this genotoxin than the liver cells), initiating hepatic hemangiosarcoma.

Not all targets for chemicals contribute to the harmful effects. Thus, while carbon monoxide causes toxicity by binding to ferrohemoglobin, it also associates with the iron in cytochrome P450 with little or no consequence. Covalent binding of toxicants to various intracellular proteins, including enzymes and structural proteins, has been demonstrated, yet it is often uncertain which protein(s) is/are involved in binding that is toxicologically relevant (Cohen *et al.*, 1997; Pumford and Halmes, 1997; Rombach and Hanzlik, 1999). Arylation of some hepatic mitochondrial proteins by acetaminophen (4'-hydroxyacetanilide) is thought to be causally related to the liver injury induced by this drug because the nonhepatotoxic regioisomer of acetaminophen (3'-hydroxyacetanilide) does not readily bind covalently to these proteins (Cohen *et al.*, 1997; Jaeschke and Bajt, 2006). In contrast, arylation of a number of hepatic cytoplasmic proteins by acetaminophen is likely to be inconsequential because the nonhepatotoxic regioisomer of this drug also arylates those proteins (Nelson and Pearson, 1990). Covalent binding to proteins without adverse consequences may even represent a form of detoxication by sparing toxicologically relevant targets. This principle is best exemplified by covalent binding of organophosphate insecticides to plasma cholinesterase, which is a significant protective mechanism, as it counteracts phosphorylation of acetylcholinesterase, the target

molecule. Thus, to conclusively identify a target molecule as being responsible for toxicity, it should be demonstrated that the ultimate toxicant (1) reacts with the target and adversely affects its function, (2) reaches an effective concentration at the target site, and (3) alters the target in a way that is mechanistically related to the observed toxicity.

Types of Reactions

The ultimate toxicant may bind to the target molecules noncovalently or covalently and may alter it by hydrogen abstraction, electron transfer, or enzymatically.

Noncovalent Binding   This type of binding can be due to apolar interactions or the formation of hydrogen and ionic bonds and is typically involved in the interaction of toxicants with targets such as membrane receptors, intracellular receptors, ion channels, and some enzymes. For example, such interactions are responsible for the binding of strychnine to the glycine receptor on motor neurons in the spinal cord, TCDD to the aryl hydrocarbon receptor, saxitoxin to sodium channels, phorbol esters to protein kinase C, and warfarin to vitamin K 2,3-epoxide reductase. Such forces also are responsible for the intercalation of chemicals such as acridine yellow and doxorubicin into the double helix of DNA. These chemicals are toxic because the steric arrangement of their atoms allows them to combine with complementary sites on the endogenous molecule more or less as a key fits into a lock. Noncovalent binding usually is reversible because of the comparatively low bonding energy.

Covalent Binding   Being practically irreversible, covalent binding is of great toxicologic importance because it permanently alters endogenous molecules (Boelsterli, 1993). Covalent adduct formation is common with electrophilic toxicants such as nonionic and cationic electrophiles and radical cations. These toxicants react with nucleophilic atoms that are abundant in biological macromolecules, such as proteins and nucleic acids. Electrophilic atoms exhibit some selectivity toward nucleophilic atoms, depending on their charge-to-radius ratio. In general, soft electrophiles prefer to react with soft nucleophiles (low charge-to-radius ratio in both), whereas hard electrophiles react more readily with hard nucleophiles (high charge-to-radius ratio in both). Examples are presented in Table 3-3. Metal ions such as silver and mercury are also classified as soft

Table 3.3

Examples of Soft and Hard Electrophiles and Nucleophiles

| ELECTROPHILES		NUCLEOPHILES
Carbon in polarized double bonds (e.g., quinones, α,β-unsaturated ketones)	Soft	Sulfur in thiols (e.g., cysteinyl residues in proteins and glutathione)
Carbon in epoxides, strained-ring lactones, aryl halides	↑	Sulfur in methionine
Aryl carbonium ions		Nitrogen in primary and secondary amino groups of proteins (e.g., lysine ε-amino group)
Benzylic carbonium ions, nitrenium ions		Nitrogen in amino groups in purine bases in nucleic acids
Alkyl carbonium ions	↓	Oxygen of purines and pyrimidines in nucleic acids
	Hard	Phosphate oxygen in nucleic acids

SOURCE: Based on Coles (1984).

electrophiles. These prefer to react covalently with soft nucleophiles (especially thiol groups). Conversely, hard electrophiles such as lithium, calcium, and barium, react preferentially as cations with hard nucleophiles (e.g., carboxylate and phosphate anions). Metals falling between these two extremes, such as chromium, zinc, and lead, exhibit universal reactivity with nucleophiles. The reactivity of an electrophile determines which endogenous nucleophiles can react with it and become a target.

A covalent reaction of special biological significance can take place between HOOH (a soft electrophile) and protein thiol groups, preferentially those with low pK_a value, i.e., with a propensity of being in the strongly nucleophilic thiolate anion form (Prot-S$^-$) at physiological pH. This reaction produces protein sulfenic acid (Prot-S-OH):

$$\text{Prot-SH} + \text{HOOH} \rightarrow \text{Prot-S-OH} + \text{HOH}$$

The S atom in a sulfenic acid is electrophilic as it is made electron deficient by the electron withdrawing effect of O. Therefore, a protein-sulfenic acid can react with another thiol group of the same or a different protein or of glutathione (GSH), resulting in, respectively, formation of an intramolecular disulfide, intermolecular disulfide or a mixed disulfide of the protein and glutathione (i.e., glutathionylation of the protein):

$$\text{Prot}_1\text{-S-OH} + \text{Prot}_2\text{-SH} \rightarrow \text{Prot}_1\text{-S-S-Prot}_2 + \text{HOH}$$

$$\text{Prot-S-OH} + \text{GSH} \rightarrow \text{Prot-S-SG} + \text{HOH}$$

Not only HOOH, but also hydroperoxides (e.g., lipid hydroperoxides, LOOH; see Fig. 3-9) may enter into such reactions, producing protein-sulfenic acids, protein-disulfides and glutathionylated proteins, which can be considered as posttranslational modifications with a role in redox signaling (Forman *et al.*, 2004).

Neutral free radicals such as HO$^\bullet$, $^\bullet$NO$_2$, and Cl$_3$C$^\bullet$ can also bind covalently to biomolecules. The addition of Cl$_3$C$^\bullet$ to double-bonded carbons in lipids or to lipid radicals yields lipids containing chloromethylated fatty acids. The addition of hydroxyl radicals to DNA bases results in the formation of numerous products, including 8-hydroxypurines, 5-hydroxymethylpyrimidines, and thymine and cytosine glycols (Breen and Murphy, 1995).

Nucleophilic toxicants are in principle reactive toward electrophilic endogenous compounds. Such reactions occur infrequently because electrophiles are rare among biomolecules. Examples include the covalent reactions of amines and hydrazides with the aldehyde pyridoxal, a cosubstrate for several enzymes, including glutamate decarboxylase. Carbon monoxide, cyanide, hydrogen sulfide, and azide form coordinate covalent bonds with iron in various hemeproteins. Other nucleophiles react with hemoglobin in an electron-transfer reaction (see below).

Hydrogen Abstraction   Neutral free radicals, such as those generated in reactions depicted in Fig. 3-4, can readily abstract H atoms from endogenous compounds, converting those compounds into radicals. Abstraction of hydrogen from thiols (R—SH) creates thiyl radicals (R—S$^\bullet$), which upon radical recombination with HO$^\bullet$ form sulfenic acids (R—S—OH) that are precursors of disulfides (R—S—S—R) (see above). Radicals can remove hydrogen from CH$_2$ groups of free amino acids or from amino acid residues in proteins and convert them to carbonyls. These carbonyls react covalently with amines, forming cross-links with DNA or other proteins. Hydrogen

Figure 3-8. Formation of 3-nitrotyrosine residues in proteins by reaction with nitrogen dioxide ($^\bullet$NO$_2$).

$^\bullet$NO$_2$ is an oxidizing and nitrating species generated from ONOO$^-$ (Fig. 3-4). In addition, $^\bullet$NO$_2$ is a contaminant in cigarette smoke, exhaust of gas engines and stoves, as well as the causative agent of "silo-filler's disease."

abstraction from deoxyribose in DNA yields the C-4$'$-radical, the first step to DNA cleavage (Breen and Murphy, 1995). Abstraction of hydrogen from fatty acids produces lipid radicals and initiates lipid peroxidation. As depicted in Fig. 3-8, nitration of tyrosine residues in proteins purportedly involves H abstraction followed by radical recombination, i.e., covalent binding between the resultant tyrosyl radical and $^\bullet$NO$_2$ (Squadrito and Pryor, 1998).

Electron Transfer   Chemicals can oxidize Fe(II) in hemoglobin to Fe(III), producing methemoglobinemia. Nitrite can oxidize hemoglobin, whereas N-hydroxyl arylamines (such as dapsone hydroxylamine), phenolic compounds (such as 5-hydroxy primaquine), and hydrazines (such as phenylhydrazine) are cooxidized with oxyhemoglobin, forming methemoglobin and hydrogen peroxide (Coleman and Jacobus, 1993).

Enzymatic Reactions   A few toxins act enzymatically on specific target proteins. For example, the plant toxins ricin and abrin are N-glycosidases; they hydrolyse a specific glycosidic bond in ribosomal RNS, blocking protein synthesis. Botulinum toxin acts as a Zn-protease; it hydrolyses the fusion proteins that assist in exocytosis of the neurotransmitter acetylcholine in cholinergic neurons, most importantly motoneurons, causing paralysis. The lethal factor component of anthrax toxin is also a Zn-protease, which inactivates mitogen-activated protein kinase kinase (MAPKK), inducing cell death. Other bacterial toxins catalyze the transfer for ADP-ribose from NAD$^+$ to specific proteins. Through such a mechanism, diphtheria toxin blocks the function of elongation factor 2 in protein synthesis and cholera toxin activates a G protein. Snake venoms contain hydrolytic enzymes that destroy biomolecules.

In summary, most ultimate toxicants act on endogenous molecules on the basis of their chemical reactivity. Those with more than one type of reactivity may react by different mechanisms with various target molecules. For example, quinones may act as electron acceptors and initiate thiol oxidation or free radical reactions that lead to lipid peroxidation, but they may also act as soft electrophiles

and bind covalently to protein thiols. The lead ion acts as a soft electrophile when it forms coordinate covalent bonds with critical thiol groups in δ-aminolevulinic acid dehydratase, its major target enzyme in heme synthesis (Goering, 1993). However, it behaves like a hard electrophile or an ion when it binds to protein kinase C or blocks calcium channels, substituting for the natural ligand Ca^{2+} at those target sites.

Effects of Toxicants on Target Molecules

Reaction of the ultimate toxicant with endogenous molecules may cause dysfunction or destruction; in the case of proteins, it may render them foreign (i.e., an antigen) to the immune system.

Dysfunction of Target Molecules   Some toxicants activate protein target molecules, mimicking endogenous ligands. For example, morphine activates opioid receptors, clofibrate is an agonist on the peroxisome proliferator–activated receptor, and phorbol esters and lead ions stimulate protein kinase C.

More commonly, chemicals inhibit the function of target molecules. Several xenobiotics—such as atropine, curare, and strychnine—block neurotransmitter receptors by attaching to the ligand-binding sites or by interfering with the function of ion channels. Tetrodotoxin and saxitoxin, for example, inhibit opening of the voltage-activated sodium channels in the neuronal membrane, whereas DDT and the pyrethroid insecticides inhibit their closure. Some toxicants block ion transporters, others inhibit mitochondrial electron transport complexes, and many inhibit enzymes. Chemicals that bind to tubulin (e.g., vinblastine, colchicine, paclitaxel, trivalent arsenic) or actin (e.g., cytochalasin B, phalloidin) impair the assembly (polymerization) and/or disassembly (depolymerization) of these cytoskeletal proteins.

Protein function is impaired when conformation or structure is altered by interaction with the toxicant. Many proteins possess critical moieties, especially thiol groups, which are essential for catalytic activity or assembly to macromolecular complexes. Proteins that are sensitive to covalent and/or oxidative modification of their thiol groups include the enzymes glyceraldehyde 3-phosphate dehydrogenase (see Table 3-6), and pyruvate dehydrogenase (see Fig. 3-13), the Ca^{2+} pumps (see Fig. 3-14, Table 3-7), the DNA repair enzyme O^6-methylguanine-DNA-methyltransferase, the DNA-methylating enzyme C^5-cytosine-DNA-methyltransferase, ubiquitin-conjugating enzymes, peroxiredoxins, protein tyrosine phosphatases (e.g., cdc25) the lipid phosphatase PTEN (phosphatase and tensin homologue) (Rhee et al., 2005), caspases (see Fig. 3-16), the transcription factor AP-1, and the electrophile-sensor protein Keap1 (see Fig. 3-23), just to name a few. These and many other proteins are inactivated by thiol-reactive chemicals, causing impaired maintenance of the cell's energy and metabolic homeostasis and/or altered signal transduction. As to the latter outcome, covalent and/or oxidative modification of thiol groups in Keap1 triggers the adaptive electrophile stress response, which is cytoprotective (see Fig. 3-23). Conversion of the catalytic thiol group (-SH) in protein tyrosine phosphatases (PTP) to sulfenic acid group (-S-OH) upon reaction with HOOH or lipid hydroperoxides (see reaction scheme above) inactivates these enzymes. As PTPs keep protein kinase-mediated signal transduction pathways under control (see Fig. 3-11), PTP inactivation permit such signaling to surge, thereby launching, for example, a mitogenic response. Formation of protein sulfenic acids by the oxidative stress product HOOH is thus considered as an initiating event of

redox signaling (Forman et al., 2004). It is important to note that protein sulfenic acid formation is readily reversed by reaction of the sulfenic acid with a thiol (e.g., glutathione), resulting in a protein disulfide (e.g., protein-S-SG; see the scheme above) which in turn is reduced by thioredoxin or glutaredoxin as shown in Fig. 3-19, thereby regenerating the active PTP in thiol form and terminating the signaling. Protein tyrosine nitration (see Fig. 3-8) may also alter protein function or may interfere with signaling pathways that involve tyrosine kinases and phosphatases.

Toxicants may interfere with the template function of DNA. The covalent binding of chemicals to DNA causes nucleotide mispairing during replication. For example, covalent binding of aflatoxin 8,9-oxide to N-7 of guanine results in pairing of the adduct-bearing guanine with adenine rather than cytosine, leading to the formation of an incorrect codon and the insertion of an incorrect amino acid into the protein. Such events are involved in the aflatoxin-induced mutation of the Ras proto-oncogene and the p53 tumor suppressor gene (Eaton and Gallagher, 1994). 8-Hydroxyguanine and 8-hydroxyadenine are mutagenic bases produced by $HO^{\bullet}$ that can cause mispairing with themselves as well as with neighboring pyrimidines, producing multiple amino acid substitutions (Breen and Murphy, 1995). Cr(III) produced from chromate (Cr(VI)) via reduction by ascorbate, alone or complexed to ascorbate, forms coordinate covalent bond with phosphate in DNA, thereby inducing a mutation (Quievryn et al., 2002). Chemicals such as doxorubicin, that intercalate between stacked bases in the double-helical DNA, push adjacent base pairs apart, causing an even greater error in the template function of DNA by shifting the reading frame.

Destruction of Target Molecules   In addition to adduct formation, toxicants alter the primary structure of endogenous molecules by means of cross-linking and fragmentation. Bifunctional electrophiles, such as 2,5-hexanedione, carbon disulfide, acrolein, 4-oxonon-2-enal, 4-hydroxynon-2-enal, and nitrogen mustard alkylating agents, cross-link cytoskeletal proteins, DNA, or DNA with proteins. HOOH and hydroxyl radicals can also induce cross-linking by converting proteins into either reactive electrophiles (e.g., protein sulfenic acids and protein carbonyls, respectively), which react with a nucleophilic group (e.g., thiol, amine) in another macromolecule. Radicals (e.g., those shown in Fig. 3-4) may induce cross-linking of macromolecules by converting them into radicals, which react with each other by radical recombination. Cross-linking imposes both structural and functional constraints on the linked molecules.

Some target molecules are susceptible to spontaneous degradation after chemical attack. Free radicals such as $Cl_3COO^{\bullet}$ and $HO^{\bullet}$ can initiate peroxidative degradation of lipids by hydrogen abstraction from fatty acids (Recknagel et al., 1989). The lipid radical ($L^{\bullet}$) formed is converted successively to lipid peroxyl radical ($LOO^{\bullet}$) by oxygen fixation, lipid hydroperoxide (LOOH) by hydrogen abstraction, and lipid alkoxyl radical ($LO^{\bullet}$) by the Fe(II)-catalyzed Fenton reaction. Subsequent fragmentation gives rise to hydrocarbons such as ethane and reactive aldehydes such as 4-hydroxynon-2-enal and malondialdehyde (Fig. 3-9). Thus, lipid peroxidation not only destroys lipids in cellular membranes but also generates endogenous toxicants, both free radicals (e.g., $LOO^{\bullet}$, $LO^{\bullet}$) and electrophiles (e.g., 4-oxonon-2-enal, 4-hydroxynon-2-enal). These substances can readily react with adjacent molecules, such as membrane proteins, or diffuse to more distant molecules such as DNA. F_2-isoprostanes are stable peroxidation products of arachidonic acid; these are not only sensitive markers of lipid
Figure 3-9. Lipid peroxidation initiated by the hydroxyl radical (HO•).

Many of the products, such as the radicals and the α,β-unsaturated alde-hydes, are reactive, whereas others, such as ethane, are nonreactive but are indicators of lipid peroxidation.

peroxidation, but also potent pulmonary and renal vasoconstrictors (Basu, 2004).

Apart from hydrolytic degradation by toxins and radiolysis, toxicant-induced fragmentation of proteins is not well documented. There are, however, examples for destruction of the prosthetic group in enzymes. For instance, cytochrome P450 converts allyl isopropyl acetamide into a reactive metabolite, which alkylates the heme moi-ety of the enzyme. This leads to loss of the altered heme and to porphyria (De Matteis, 1987). Arsine (AsH_3) acutely induces heme release from oxyhemoglobin, which may underlie its hemolytic ef-fect. Aconitase is attacked by $ONOO^-$ at its $[4Fe-4S]^{2+}$ cluster, whose one Fe atom is genuinely labile (as is complexed to inor-ganic sulfur and not to enzyme-bound cysteines like the others). As a result of the oxidant action of $ONOO^-$, the labile Fe is lost, inactivating the enzyme (Castro *et al.*, 1994) and compromising the citric acid cycle where aconitase functions.

Several forms of DNA fragmentation are caused by toxi-cants. For instance, attack of DNA bases by HO• can result in the formation of imidazole ring–opened purines or ring–contracted pyrimidines, which block DNA replication. Formation of a bulky adduct at guanine N-7 destabilizes the N-glycosylic bond, inducing depurination. Depurination results in apurinic sites that are muta-genic. Single-strand breaks typically are caused by hydroxyl rad-icals via abstraction of H from desoxyribose in DNA yielding the C-4′ radical, followed by $O_2^{\bullet}$ addition, Criegee rearrangement, and cleavage of the phosphodiester bond (Breen and Murphy, 1995). Multiple hydroxyl radical attacks on a short length of DNA, which occur after ionizing radiation, cause double-strand breaks that are typically lethal to the affected cell.

Neoantigen Formation   Whereas the covalent binding of xeno-biotics or their metabolites is often inconsequential with respect to the function of the immune system, in some individuals these altered proteins, which carry the xenobiotic adduct as a hapten, evoke an immune response. Some chemicals (e.g., dinitrochloroben-zene, penicillin, and nickel-ion) are sufficiently reactive to bind to proteins spontaneously. Others may obtain reactivity by autooxi-dation to quinones (e.g., urushiols, the allergens in poison ivy) or by enzymatic biotransformation (Park *et al.*, 2005). For example, cytochrome P450 biotransforms halothane to an electrophile, tri-fluoroacetyl chloride, which binds as a hapten to microsomal and cell surface proteins in the liver, inducing a hepatitis-like immune reaction in sensitive patients.

Haptenized proteins released from cells may evoke antibody-mediated (humoral) and/or T-cell-mediated (cellular) immune re-sponse. In the humoral response, B-cells play the leading role: they bind the complete antigen through their B-cell receptors and asso-ciate with T-helper cells (CD4$^+$). Antigen binding (as signal 1) and cell surface co-stimulatory molecules on T-helper cells (as signal 2) induce differentiation of B-cells into plasma B-cells that manufac-ture and secrete antibody. By binding to the antigen, the antibody as-sists in destruction of the antigen by phagocytosis, however, harmful consequences may also result. For example, when penicillin-bound proteins as antigens react with IgE-type antibodies on the surface of mast cells, the reaction triggers release of mast cell mediators (e.g., histamine, leukotrienes), which in turn may cause bronchoconstric-tion (asthma), vasodilatation, and plasma exudation (wheal, ana-phylactic shock).

In cellular immune response, T-cells are the main mediators. T-helper cells become activated by two signals coming from antigen-presenting cells (APC), such as macrophages in internal tissues and dendritic cells in tissues that are in contact with external en-vironment (i.e., skin and mucosal lining of the respiratory and gastrointestinal tract). The APC phagocytoses the haptenized pro-tein and migrates to the lymph nodes where most T-cells are lo-cated. Meanwhile, the APC processes the antigen into appropriate peptides, externalizes and transfers the processed antigen to the MHC (major histocompatibility complex) on its surface. On reach-ing the lymph node, the APC presents the MHC-bound peptide to the T-cell receptor (TCR) of T-helper cells (signal 1). In addi-tion, cell surface co-activator molecules (e.g., CD80 and CD86) on APC bind to their counterparts (e.g., CD28) on T-cells (sig-nal 2). Without signal 2 (which verifies that the antigen detected is foreign) the T-cell becomes functionally inert (anergic). On re-ceiving both signals, the helper T-cell becomes specific to one particular antigen, expresses the T-cell growth factor IL-2 and its

receptor, proliferate and differentiate. Using IL-2 and other cytokines, helper T-cells can activate cytotoxic T-cells (CD8$^+$) and induce expression of adhesion molecules at the site of allergen contact. Whereas this response is protective against virus-infected cells and tumor cells, it causes inflammation and cell injury in cells containing xenobiotic neoantigens. This model describes the response to contact allergens, such as nickel and urushiols, and is the basis of detecting contact allergens in mice with the local lymph node assay.

Besides the above-described classical mechanism of neoantigen-initiated APC-mediated T-cell activation, xenobiotics may cause T-cell activation by more direct ways. For example, Ni ions may not only form co-ordinate covalent bonds with proteins, making them neoantigens, but apparently crosslink MHC of APC with the TCR of T-cells, activating the latter. Moreover, some drugs (e.g., sulfamethoxazole), which can be biotransformed into adduct forming metabolites (e.g., nitroso-sulfamethoxazole) that triggers T-cell activation by the classical mechanism, purportedly may also stimulate the TCR of T-cells directly, without involvement of APC. Furthermore, the immune response may be facilitated by toxic and inflammatory cell injury because these "danger signals" upregulate the co-stimulatory molecules on T-cells.

Drug-induced lupus and possibly many cases of drug-induced agranulocytosis are thought to be mediated by immune reactions triggered by drug-protein adducts. The causative chemicals are typically nucleophiles, such as aromatic amines (e.g., aminopyrine, clozapine, procainamide, and sulfonamides), hydrazines (e.g., hydralazine and isoniazid), and thiols (e.g., propylthiouracil, methimazole, and captopril). These substances can be oxidized by myeloperoxidase of granulocytes and monocytes (the precursors of APC) or by the ROS/RNS such cells produce (HO$^\bullet$, ONOO$^-$, HOCl, see Fig. 3-22) to reactive metabolites that bind to the surface proteins of these cells, making them antigens (Uetrecht, 1992). The reactive metabolites may also activate monocytes and thus promote the immune reaction. Activation of CD4$^+$ T-cells by inhibition of promoter methylation of specific genes by procainamide and hydralazine as a possible lupus-inducing mechanism is discussed under dysregulation of transcription.

Toxicity Not Initiated by Reaction with Target Molecules

Some xenobiotics do not only interact with a specific endogenous target molecule to induce toxicity, but instead alter the biological microenvironment (see step 2b in Fig. 3-1). Included here are (1) chemicals that alter H$^+$ ion concentrations in the aqueous biophase, such as acids and substances biotransformed to acids, such as methanol and ethylene glycol, as well as protonophoric uncouplers such as 2,4-dinitrophenol and pentachlorophenol, which dissociate their phenolic protons in the mitochondrial matrix, thus dissipating the proton gradient that drives ATP synthesis; (2) solvents and detergents that physicochemically alter the lipid phase of cell membranes and destroy transmembrane solute gradients that are essential to cell functions; and (3) other xenobiotics that cause harm merely by occupying a site or space. For example, some chemicals (e.g., ethylene glycol, methotrexate, acyclovir) form water-insoluble precipitates in the renal tubules. By occupying bilirubin binding sites on albumin, compounds such as the sulfonamides induce bilirubin toxicity (kernicterus) in neonates. Carbon dioxide displaces oxygen in the pulmonary alveolar space and causes asphyxiation.

STEP 3—CELLULAR DYSFUNCTION AND RESULTANT TOXICITIES

The reaction of toxicants with a target molecule may result in impaired cellular function as the third step in the development of toxicity (Fig. 3-1). Each cell in a multicellular organism carries out defined programs. Certain programs determine the destiny of cells—that is, whether they undergo division, differentiation (i.e., express proteins for specialized functions), or apoptosis. Other programs control the ongoing (momentary) activity of differentiated cells, determining whether they secrete more or less of a substance, whether they contract or relax, and whether they transport and metabolize nutrients at higher or lower rates. For regulations of these cellular programs, cells possess signaling networks (such as those shown in Figs. 3-11 and 3-12) that can be activated and inactivated by external signaling molecules. To execute the programs, cells are equipped with synthetic, metabolic, kinetic, transport, and energy-producing systems as well as structural elements, organized into macromolecular complexes, cell membranes, and organelles, by which they maintain their own integrity (internal functions) and support the maintenance of other cells (external functions).

As outlined in Fig. 3-10, the nature of the primary cellular dysfunction caused by toxicants, but not necessarily the ultimate outcome, depends on the role of the target molecule affected. If the target molecule is involved in cellular regulation (signaling), dysregulation of gene expression, and/or dysregulation of momentary cellular function occurs primarily. However, if the target molecule is involved predominantly in the cell's internal maintenance, the resultant dysfunction can ultimately compromise the survival of the cell. The reaction of a toxicant with targets serving external functions can influence the operation of other cells and integrated organ systems. The following discussion deals with these consequences.

Toxicant-Induced Cellular Dysregulation

Cells are regulated by signaling molecules that activate specific cellular receptors linked to signal transducing networks that transmit the signals to the regulatory regions of genes and/or to functional proteins. Receptor activation may ultimately lead to (1) altered gene expression that increases or decreases the quantity of specific proteins and/or (2) a chemical modification of specific proteins, typically by phosphorylation, which activates or inhibits proteins. Programs controlling the destiny of cells primarily affect gene expression, whereas those regulating the ongoing activities primarily influence the activity of functional proteins; however, one signal often evokes both responses because of branching and interconnection of signaling networks.

Dysregulation of Gene Expression   Dysregulation of gene expression may occur at elements that are directly responsible for transcription, at components of the intracellular signal transduction pathway, and at the synthesis, storage, or release of the extracellular signaling molecules.

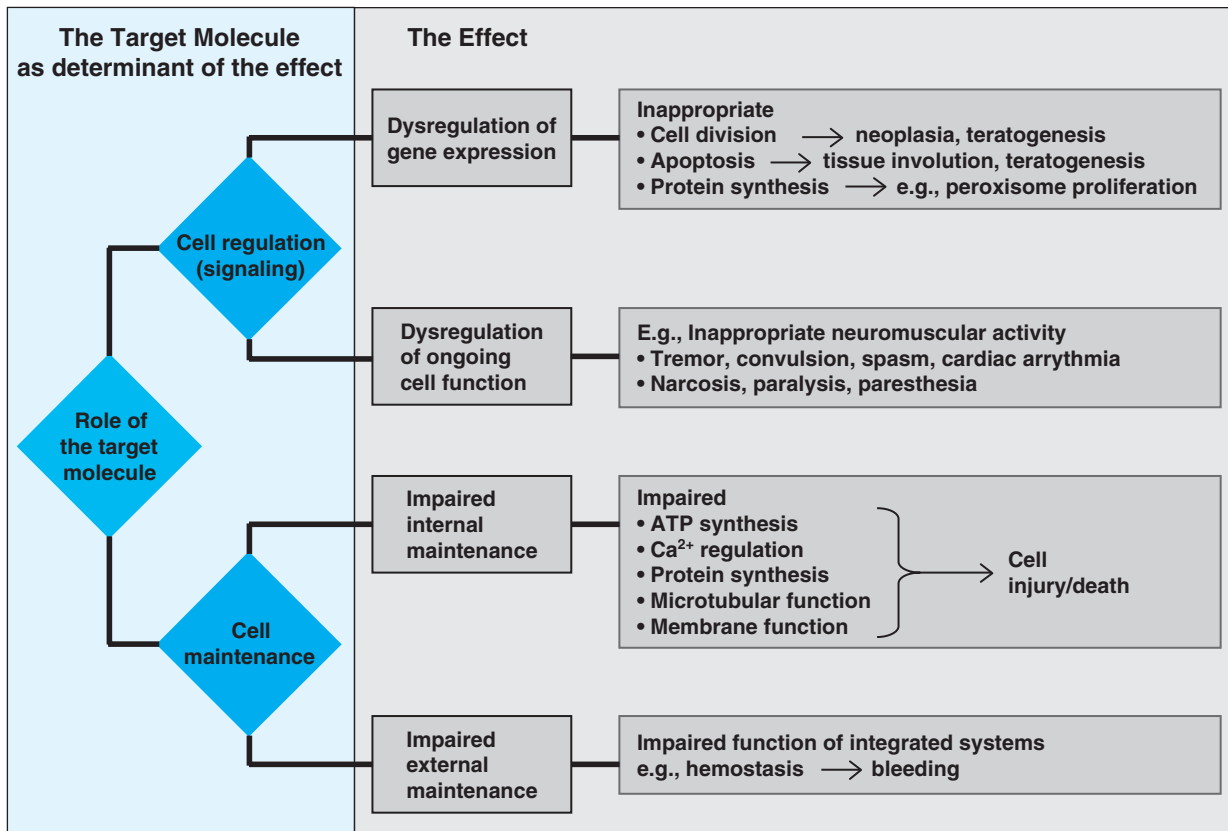
Dysregulation of Transcription   Transcription of genetic information from DNA to mRNA is controlled largely by interplay between transcription factors (TFs) and the regulatory or promoter region of genes. By binding to nucleotide sequences in this region, activated TFs facilitate the formation of the preinitiation complex, promoting transcription of the adjacent gene. Xenobiotics may interact with the


Figure 3-10. The third step in the development of toxicity: alteration of the regulatory or maintenance function of the cell.

TFs (or other components of the preinitiation complex) and with the promoter region of the gene.

Dysregulation of Transcription by Chemicals Acting Through Ligand-Activated Transcription Factors   Several endogenous compounds, such as hormones (e.g., steroids, thyroid hormones) and vitamins (retinoids and vitamin D), influence gene expression by binding to and activating TFs (Table 3-4). Xenobiotics may mimic the natural ligands. For example, fibric acid–type lipid-lowering drugs and phthalate esters substitute for polyunsaturated fatty acids as ligands for the peroxisome proliferator-activated receptor (PPARα) (Poellinger *et al.*, 1992), and xenoestrogens (e.g., diethylstilbestrol, DDT, methoxychlor) substitute estradiol, an endogenous ligand for estrogen receptors.

Acting through ligand-activated TFs, natural or xenobiotic ligands when administered at extreme doses or at critical periods during ontogenesis may cause toxicity by inappropriately influencing the fate of cells and inducing cell death or mitosis (Table 3-4). Glucocorticoids induce apoptosis of lymphoid cells. Whereas desirable in the treatment of lymphoid malignancies, this is an unwanted response in many other conditions. TCDD, a ligand of the aryl hydrocarbon receptor (AHR), produces thymic atrophy by causing apoptosis of thymocytes. Estrogens exert mitogenic effects in cells that express estrogen receptors (ER), such as those found in the female reproductive organs, the mammary gland, and the liver. ER-mediated proliferation appears to be responsible, at least in part, for formation of tumors in these organs during prolonged estrogen exposure (Green, 1992), as well as for induction of the rare vaginal adenocarcinoma in late puberty after transplacental exposure to the synthetic estrogen diethylstilbestrol (DES). Stimulation of these receptors during

a critical prenatal period of differentiation reprograms the estrogen target tissue (i.e., Mullerian duct), resulting in benign and malignant abnormalities in the reproductive tract later in life (Newbold, 2004). Mice exposed neonatally with DES served to model DES-induced late carcinogenesis in the reproductive tract. Compared to the wild-type animals, mice overexpressing ERα were exceedingly sensitive to DES-induced uterine adenocarcinoma, whereas ERα-knockout mice were resistant, indicating the role of ERα in tumorigenesis. It has been speculated that environmental xenoestrogens such as DDT, polychlorinated biphenyls, bisphenol A, and atrazine contribute to an increased incidence of breast cancer. Zearalenone, a mycoestrogen feed contaminant, causes vulval prolapse in swine, an example of an ER-mediated proliferative lesion. The mitogenic and hepatic tumor-promoting effects of peroxisome proliferators in rodents are also receptor-mediated, because it is not observed in PPARα-null mice (Peters *et al.*, 1998). Humans do not respond with hepatocellular and peroxisomal proliferation to fibrates and express PPARα at low levels and often in nonfunctional forms. Humanized mice (i.e., PPARα-null mice transfected with human PPARα) also fail to exhibit hepatocellular and peroxisomal proliferation after fibrate treatment (Gonzalez and Yu, 2006). Nevertheless, transfection of rat PPARα into human hepatocytes does not convey inducibility of peroxisomes by PPARα ligands, implying additional species differences in this signaling. Chemicals that act on ligand-activated TFs, such as glucocorticoids, TCDD, and retinoids, induce fetal malformations that may be regarded as inappropriate gene expression. Candidate target genes are the homeobox genes that determine the body plan during early ontogenesis.

Table 3.4

Toxicants Acting on Ligand-Activated Transcription Factors

LIGAND-ACTIVATED TRANSCRIPTION FACTOR	ENDOGENOUS LIGAND	EXOGENOUS LIGAND	EFFECT
Estrogen receptor (ER)	Estradiol	Ethynylestradiol Diethylstilbestrol DDT, Methoxychlor Zeralenone	Mammary and hepatic carcinogenesis Porcine vulval prolapse
Glucocorticoid receptor (GR)	Cortisol	Dexamethasone	Apoptosis of lymphocytes Teratogenesis (cleft palate)
Retinoic acid receptor (RAR, RXR)	All-*trans*-retinoic acid	13-*cis* retinoic acid	Teratogenesis (craniofacial, cardiac, thymic malformations)
Aryl hydrocarbon receptor (AHR)	Unknown	TCDD PCBs PAHs	Thymic atrophy Wasting syndrome Teratogenesis (cleft palate) Hepatocarcinogenesis in rats Enzyme induction (e.g., CYP1A1)
Peroxisome proliferator–activated receptor (PPARα)	Fatty acids	Fibrate esters (e.g., clofibrate) Phthalate esters (e.g., DEHP)	Hepatocarcinogenesis in mice Peroxisome proliferation Enzyme induction (e.g., CYP4A1, acyl-CoA oxidase)
Constitutive androstane receptor (CAR)	$3\alpha,5\alpha$-androstenol $3\alpha,5\alpha$-androstanol (inhibitors)	TCPOBOP, Phenobarbital* DDT, PCP Chlorpromazine	Enzyme induction (e.g., CYP2B, CYP3A) Hepatocarcinogenesis in mice
Pregnane X receptor (PXR)	Pregnenolone Progesterone	PCN, Dexamethasone Spironolactone, Cyproterone Rifampicin, Zearalenone Litocholic acid	Enzyme induction (e.g., CYP3A) Transporter induction (e.g., Oatp2, Mdr1, Mrp1, Mrp2, Mrp3)

TCPOBP = 1,2-bis[2-(3,5-dichloropyridyloxy)benzene, *Phenobarbital indirectly activates CAR not as a ligand.

Compounds that act on ligand-activated TFs can also change the pattern of cell differentiation by overexpressing various genes. For example, the PPARα-ligand fibric acid derivatives stimulate genes that encode peroxisomal enzymes and induce proliferation of peroxisomes in rodent liver (Green, 1992). TCDD, phenobarbital, and pregnenolone 16α-carbonitrile (PCN) activate AHR, the constitutive androstane receptor (CAR), and the pregnane X receptor (PXR), respectively (Table 3-4), thereby exerting their well known cytochrome P450–inducing effects. However, rodent, rabbit and human PXRs and CARs exhibit low degree of sequence conservation in their ligand-binding domains. This accounts for marked species differences in the induction potential of their ligands, such as PCN, rifampicin, and TCPOBOP (Gonzalez and Yu, 2006). Genes of several xenobiotic metabolizing enzymes may be activated by these chemicals. For example, TCDD increases the expression of cytochrome-P450 lAl, UDP-glucuronosyltransferase-1, and several subunits of mouse and rat glutathione *S*-transferase because the promoter region of their genes contains a dioxin (or xenobiotic) response element that is recognized by the TCDD-activated AHR complexed with its nuclear translocator protein ARNT (also called HIF-1β). In AHR-null mice, TCDD induces neither these enzymes nor the adverse effects listed in Table 3-4 (Gonzalez and Fernandez-Salguero, 1998).

Dysregulation of Transcription by Chemicals Altering the Regulatory Region of Genes   Xenobiotics may dysregulate transcription by also altering the regulatory gene regions through direct chemical interaction or by changing their methylation pattern. It has been hypothesized that thalidomide (or its hydrolysis product) exerts teratogenic effect in the embryo by intercalating to GGGCGG sequences (also called GC boxes) that are binding sites for Sp1, a transcription activator for RNA polymerase II (Stephens *et al.*, 2000). Thalidomide would thus impair insulin-like growth factor-1 (IGF-2) and fibroblast growth factor-2 (FGF-2) signaling pathways necessary for angiogenesis and limb formation, because both pathways encompass multiple proteins whose genes contain GC boxes in the regulatory region (but lack TATA and CCAAT boxes). Another chemical feature of thalidomide that may account for impaired Sp1-mediated transcriptional activation is that the hydrolysis product of this drug is a glutamine analogue and thus mimics the glutamine-rich activation domain of Sp1 protein.

As described in more detail in this chapter under carcinogenesis, methylation of cytosines in CpG islands located in the promoter of genes is a major epigenetic mechanism, which together with coupled histone modifications (e.g., acetylation, methylation) influences the transcriptional activity of the adjacent gene. Promoter methylation silences genes, whereas demethylation permits

their activation. Importantly, when DNA replication occurs, the methylation pattern is copied from the parent strand to the daughter strand by DNA methyltransferase-1 (Dnmt1), making the pattern heritable. Nevertheless, promoter methylation is subject to environmental influences, which can thus cause heritable changes in gene regulation. Altered promoter methylation has been implicated in chemically induced systemic lupus erythemathosus (SLE), in developmental deficiencies manifested postnatally or even in subsequent generations, and in cancer. The antiarrhytmic drug procainamide and the antihypertensive hydralazine often induce SLE, an autoimmune inflammatory disease. Both drugs inhibit DNA methylation and induce global DNA hypomethylation in CD4$^+$ T lymphocytes with concomitant overexpression of proteins important in inflammation, such as CD11a (an integrin subunit), CD70 (a B cell costimulatory molecule), and perforin (a cell killing molecule) (Ballestar *et al.*, 2006). Idiopathic lupus also involves global DNA hypomethylation in T cells with overexpression of these proinflammatory proteins. Therefore, promoter hypomethylation and overexpression of critical genes that convert T cells into aggressive inflammatory cells appears fundamental in the pathogenesis of both idiopathic and drug-induced SLE.

The so-called genomically imprinted genes are especially susceptible for epigenetic dysregulation. Normally, we carry equally expressed two copies (i.e., maternal and paternal alleles) of the vast majority of genes. However, for the relatively few (100–200) genomically imprinted genes, either the paternal or maternal copy is silenced by methylation, whereas the other allele is expressed. Dysregulation of imprinting can range from loss of imprinting, which results in bi-allelic expression and double amounts of the gene product, to silencing of both alleles. Dysregulation of the genomically imprinted insulin-like growth factor-2 gene (*Igf2*) has been implicated in the growth deficit observed in mouse embryos in response to TCDD exposure in the preimplantation stage (Wu *et al.*, 2004). The retarded growth is purportedly caused by decreased expression of *Igf2*, whose imprint control region becomes hypermethylated. TCDD also increased DNA methyltransferase activity in the embryos probably because *Dnmt1* gene expression is controlled by the transcription activator Sp1, which in turn is Ah-receptor inducible.

The genome is especially susceptible to epigenetic alterations during early development, as in the preimplantation mammalian embryo the genome (except for the imprinted genes) undergoes extensive demethylation, and appropriate patterns of cytosine methylation are reestablished after implantation. Developing mammalian germ cells are also subject to such changes: primordial germ cells undergo genomic demethylation while they migrate into the early gonad, and then they undergo remethylation during sex determination in the gonad, e.g., testis development. During this period (embryonic 11–15 day in the rat), the androgen receptor and estrogen receptor-β are expressed in the developing testis, and ligands of these nuclear receptors can influence the methylation process. Indeed, transient exposure of gestating female rats during the period of gonadal sex determination to vinclozolin (an agricultural fungicide with antiandrogenic activity) or methoxychlor (a DDT type insecticide with estrogenic activity) decreased the spermatogenic capacity (with reduced spermium number and viability) in the adult male offspring and increased the incidence of male infertility (Anway *et al.*, 2005). Importantly, these effects were transferred through the male germ line to nearly all males of the subsequent three generations. These adverse transgenerational effects on reproduction correlate with altered DNA methylation patterns in the germ line. Thus endocrine disruptors have the potency to epigenetically reprogram the germ line and promote transgenerational disease state, although the relevance of these findings under human exposure conditions is still uncertain.

Transcription is also severely dysregulated in cancer cells by altered promoter methylation (i.e., global DNA hypomethylation and tumor suppressor gene hypermethylation). DNA methylation, including its biochemistry, its influence on histone modifications (acetylation and methylation) and its role in chemical carcinogenesis, is discussed in this chapter under mechanisms of action of epigenetic carcinogenes.

Dysregulation of Signal Transduction   Extracellular signaling molecules, such as growth factors, cytokines, hormones, and neurotransmitters, can ultimately activate TFs utilizing cell surface receptors and intracellular signal transducing networks. Figure 3-11 depicts a simplified scheme for such networks and identifies some of the most important signal-activated TFs that control transcriptional activity of genes that influence cell cycle progression and thus determine the fate of cells. Among these TFs are the c-Fos and c-Jun proteins, which bind in dimeric combinations (called AP-1) to the tetradecanoylphorbol acetate (TPA) response element (TRE), for example, in the promoter of cyclin D gene whose product promotes the cell division cycle (see Figs. 3-21 and 3-27). Other signal-activated TFs that up regulate the transcription of cyclin D gene by binding to their cognate nucleotide sequences include c-Myc, E2F, NF-κB, CREB and STAT. Mitogenic signaling molecules thus induce cell proliferation. In contrast, TGF-β induces the expression of cyclin-dependent kinase inhibitor proteins (e.g., p15, p57) that mediates its antimitotic effect (Johnson and Walker, 1999) (see Fig. 3-27).

The signal from the cell surface receptors to the TFs is relayed mainly by successive protein-protein interactions and protein phosphorylations at specific serine, threonine, or tyrosine hydroxyl groups. Cell surface growth factor receptors (item 4 in Fig. 3-11) are in fact phosphorylating enzymes (i.e., receptor protein tyrosine kinases). Their ligands induce them to phosphorylate themselves, which, in turn, enable these receptors to bind adapter proteins. Through these, the growth factor receptors can initiate proliferative signaling via two important pathways: (1) by activating Ras, they set in motion the mitogen-activated kinase (MAPK) cascade (Qi and Elion, 2005), and (2) by activating phosphatidilinositol-3-kinase (PI3K), they start the PI3K-Akt pathway. A crucial step in the latter is the PI3K-catalyzed phosphorylation of a plasma membrane lipid to generate phosphatidylinositol-3,4,5-triphosphate (PIP$_3$) that recruits protein kinase Akt to the membrane for activation. Because Akt (also called protein kinase B) has numerous substrates, the PI3K-Akt pathway branches (Morgenszern and McLeod, 2005). For example, branches lead toward the transcription factor NF-κB and the protein kinase mTOR, whose phosphorylated products facilitate ribosomal translation of proteins (for the branch leading from Akt to mTOR, see Fig. 3-25).

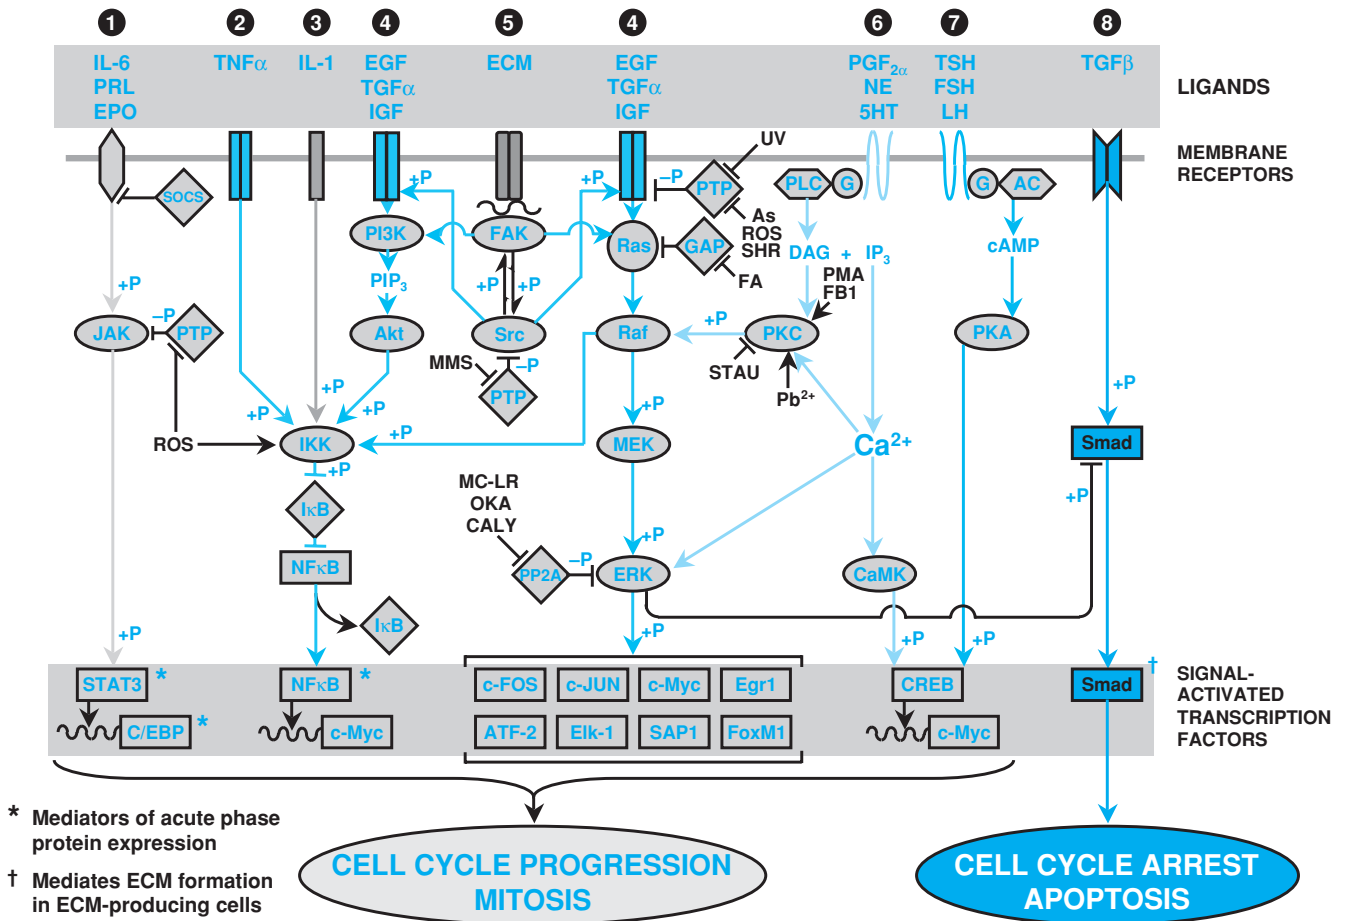
The intracellular signal transducer proteins are typically but not always activated by phosphorylation—that is catalyzed by protein kinases—and are usually inactivated by dephosphorylation, which is carried out by protein phosphatases. Interestingly, growth factor receptors can amplify their signals by inducing formation of HOOH. As discussed earlier, by attacking protein thiolate groups and converting them into sulfenic acid groups, HOOH reversibly inactivates protein tyrosine phosphatases and PTEN, a lipid phosphatase that eliminates PIP$_3$ (Rhee *et al.*, 2005). The source of HOOH is O$_2^{\bullet-}$ produced by the enzyme complex NADPH oxidase (Nox), which is activated by growth factor receptors via the PI3K $\rightarrow$ PIP$_3$ $\rightarrow$ Rac (a


Figure 3-11. Signal transduction pathways from cell membrane receptors to signal-activated nuclear transcription factors that influence transcription of genes involved in cell-cycle regulation.

The symbols of cell membrane receptors are numbered 1–8 and some of their activating ligands are indicated. Circles represent G proteins, oval symbols protein kinases, rectangles transcription factors, wavy lines genes, and diamond symbols inhibitory proteins, such as protein phosphatases (PTP, PP2A), the GTPase-activating protein GAP, and inhibitory binding proteins, such as IκB and SOCS (suppressor of cytokine signaling). Arrowheads indicate stimulation or formation of second messengers (e.g., DAG, IP$_3$, PIP$_3$, cAMP, Ca^{2+}), whereas blunt arrows indicate inhibition. Phosphorylation and dephosphorylation are indicated by $+$P and $-$P, respectively. Abbreviations for interfering chemicals are printed in black (As = arsenite; CALY = calyculin A; FA = fatty acids; FB1 = fumonisin B; MC-LR = microcystin-LR; OKA = okadaic acid; MMS = methylmethane sulfonate; PMA = phorbol miristate acetate; ROS = reactive oxygen species; SHR = SH-reactive chemicals, such as iodoacetamide; STAU = staurosporin).

Two important proliferative signaling can be evoked by growth factors, such as EGF, acting on their tyrosine kinase receptors (#4), which are duplicated in the figure for clarity. These receptors use adaptor proteins (Shc, Grb2, and SOS; not shown) to activate Ras by converting it from inactive GDP-bound form to active GTP-bound state, which in turn activates the MAP-kinase phosphorylation cascade built up from specific forms of MAPKKK, MAPKK and MAPK proteins (here Raf, MEK, and ERK, respectively). The phosphorylated MAPK (e.g., ERK) moves into the nucleus and phosphorylates transcription factors (e.g., c-FOS) thereby enabling them to bind to cognate sequences in the promoter regions of genes (e.g., cyclin genes) to facilitate transcription. The same growth factor receptors (#4) can signal through the phosphatidilinositol-3-kinase (PI3K) – Akt – IκB-kinase (IKK) – IκB – NF-κB pathway (see the text for more details). There are numerous interconnections between the signal transduction pathways. For example, the G-protein-coupled receptor (#6) can relay signal into the MAPK pathway via phospholipase C (PLC)-catalyzed formation of second messengers that activate protein-kinase C (PKC), whereas signals from TNFα and IL-1 receptors (#2 and 3) are channeled into the (PI3K) – Akt – NF-κB pathway by phosphorylating IKK. The integrin receptor (#5) whose ligands are constituents of the extracellular matrix (ECM), can also engage the growth factor receptors and Ras as well as PI3K via focal adhesion kinase (FAK) and the tyrosine kinase Src. The cell cycle acceleration induced by these and other signal transduction pathways is further enhanced by the ERK-catalyzed inhibitory phosphorylation of Smad that blocks the cell-cycle arrest signal from the TGF-β receptor (#9). Activation of protein kinases (PKC, CaMK, MAPK) by Ca^{2+} can also trigger mitogenic signaling. Several xenobiotics that are indicated in the figure may dysregulate the signaling network. Some may induce cell proliferation either by activating mitogenic protein kinases (e.g., PKC), or inhibiting inactivating proteins, such

G-protein that associates with Nox) pathway. Although once thought to be restricted to phagocytes, Nox occurs in the plasma membrane of many other cells, such as endothelial cells and vascular smooth muscle cells (Bokoch and Knaus, 2003). Although, Nox in these cells is much less efficient to produce $O_2^{\bullet}$ than Nox in the phagocytes, the non-phagocytotic Nox releases $O_2^{\bullet}$ into the cytoplasm, whereas the phagocytotic Nox delivers it to the external face of the plasma membrane (El-Benna *et al.*, 2005).

Chemicals may cause aberrant signal transduction in a number of ways, most often by altering protein phosphorylation, occasionally by interfering with the GTPase activity of G proteins (e.g., Ras), by disrupting normal protein-protein interactions or by establishing abnormal ones, or by altering the synthesis or degradation of signaling proteins. Such interventions may ultimately influence cell cycle progression.

Chemically Altered Signal Transduction with Proliferative Effect   Xenobiotics that facilitate phosphorylation of signal transducers often promote mitosis and tumor formation. Such are the phorbol esters and fumonisin B that activate protein kinase C (PKC). These chemicals mimic diacylglycerol (DAG), one of the physiologic activators of PKC (Fig. 3-11). The other physiologic PKC activator Ca^{2+} is mimicked by Pb^{2+}, whose effect on PKCα is concentration-dependent: stimulatory at picomolar concentration, when Pb^{2+} occupies only high-affinity binding sites on PKC, and inhibitory at micromolar concentration, where the low affinity sites are also occupied (Sun *et al.*, 1999). Lead acetate does induce marked hepatocellular proliferation in rats. The activated PKC promotes mitogenic signaling at least in two ways: (1) by phosphorylating Raf, the first protein kinase in the MAPK pathway (Fig. 3-11), and (2) by phosphorylating a protein phosphatase that dephosphorylates the transcription factor c-Jun at specific sites (Thr 231, Ser 234, and Ser 249), thereby permitting its binding to DNA. Protein kinases may also be activated by interacting proteins that had been altered by a xenobiotic. For example, the TCDD-liganded AhR binds to MAPK. This may contribute to the TCDD-induced overexpression of cyclins and cyclin-dependent kinases in guinea pig liver (Ma and Babish, 1999).

Aberrant phosphorylation of proteins may result not only from increased phosphorylation by kinases, but also from decreased dephosphorylation by phosphatases. Inhibition of phosphatases, including the lipid phosphatase PTEN, appears to be the underlying mechanism of the mitogenic effect of various chemicals, oxidative stress, and ultraviolet (UV) irradiation (Herrlich *et al.*, 1999). Protein tyrosine phosphatases and dual-specificity phosphatases (i.e., enzymes that remove phosphate from phosphorylated tyrosine as well as serine and threonine residues) as well as PTEN contain a catalytically active cysteine, and are susceptible to inactivation by HOOH via sulfenic acid formation and by covalent reaction with other SH-reactive chemicals (Forman *et al.*, 2004; Rhee *et al.*, 2005). Indeed, xenobiotics such as the SH-reactive iodoacetamide, the organometal compound tributyltin, arsenite, as well as HOOH cause phosphorylation of the epidermal growth factor (EGF) receptor (item 4 in Fig. 3-11) by interfering with the protein tyrosine phosphatase that would dephosphorylate and thus "silence" this receptor (Herrlich *et al.*, 1999; Chen *et al.*, 1998). Arsenite activates NADPH oxidase (Nox) in various cells, producing oxidative stress (Lynn *et al.*, 2000; Smith *et al.*, 2001). This may result from the arsenite-activated growth factor receptors that send an activating signal through the PI3K $\rightarrow$ PIP$_3$ $\rightarrow$ Rac path to the neighboring Nox, also localized in the plasma membrane. It is tempting to speculate that Nox activation and related $O_2^{\bullet}$ production in endothelial cells and vascular smooth muscle cells contributes to the vasculotoxic effects of arsenic. Arsenite may also inactivate the dual-specificity phosphatase that dephosphorylates and "silences" certain MAPKs (JNK, p38), whereas methylmethane sulfonate (MMS) appears to inhibit a protein phosphatase that inactivates Src, a protein tyrosine kinase (Herrlich *et al.*, 1999). The thiol oxidizing agent diamide (which increases phosphorylation of MAPKs) and phenolic antioxidants (which form phenoxyl radicals and increase c-Fos and c-Jun expression) (Dalton *et al.*, 1999) may also act by incapacitating protein tyrosine phosphatases. Protein phosphatase 2A (PP2A) is the major soluble ser/thr phosphatase in cells and is likely responsible, at least in part, for reversing the growth factor-induced stimulation of MAPK, thereby keeping the extent and duration of MAPK activity under control (Goldberg, 1999). PP2A also removes an activating phosphate from a mitosis-triggering protein kinase (p34^{cdc2}). Several natural toxins are extremely potent inhibitors of PP2A; including the blue–green algae poison microcystin-LR and the dinoflagellate-derived okadaic acid (Toivola and Eriksson, 1999), which are tumor promoters in experimental animals subjected to prolonged low-dose exposure. It is to be noted, however, that acute high-dose exposure to microcystin induces severe liver injury, whereas such exposure to okadaic acid is the underlying cause of the diarrhetic shellfish poisoning. In these conditions, hyperphosphorylation of proteins other than those involved in proliferative signaling (e.g., hepatocellular microfilaments in microcystin poisoning) may be primarily responsible for the pathogenesis.

Apart from phosphatases, there are also inhibitory binding proteins that can keep signaling under control. Such is IκB, which binds to NF-κB, preventing its transfer into the nucleus and its function as a TF. Upon phosphorylation by its designated IκB kinase (IKK), IκB is degraded by the proteosome and NF-κB is set free. IKK can be phosphorylated (activated) by other protein kinases, such as Raf, a member of the MAPK cascade, and by Akt a member of the PI3K-Akt pathway (Fig. 3-11). NF-κB is an important contributor to proliferative and pro-life signaling, because via the above pathways, growth factor receptor stimulation can cause IκB phosphorylation and thus the release of NF-κB, and because the released NF-κB transactivates genes whose products accelerate the cell division cycle (e.g., cyclin D1 and c-Myc) and inhibit apoptosis (e.g., antiapoptotic Bcl proteins and the caspase inhibitor IAP proteins) (Karin, 2006). NF-κB activation, via the Akt-mediated IKK phosphorylation, is involved in the proliferative (and possibly carcinogenic) effect of arsenite, nicotine, and the nicotine-derived

---

as protein phosphatases (PTP, PP2A), GAP or IκB. Others, e.g., inhibitors of PKC, oppose mitosis and facilitate apoptosis.

This scheme is oversimplified and tentative in several details. Virtually all components of the signaling network (e.g., G proteins, PKCs, MAPKs) are present in multiple, functionally different forms whose distribution may be cell specific. The pathways depicted are not equally relevant for all cells. In addition, these pathways regulating gene expression determine not only the fate of cells, but also control certain aspects of the ongoing cellular activity. For example, NF-κB induces synthesis of acute phase proteins.

nitrosamine ketone (NNK). In addition, because NF-κB also targets the genes of several cytokines (e.g., TNF-α, IL-1β) and acute phase proteins (e.g., C-reactive protein, α1-acid glycoprotein), and because such cytokines acting on their receptors (items 2 and 3 in Fig. 3-11) activate NF-κB, this TF plays a leading role also in inflammatory and acute phase reactions, as well as in cancer caused by chronic inflammation (Karin, 2006; Waddick and Uckun, 1999).

Another site from which aberrant mitogenic signals may originate is the GTP/GDP binding protein Ras, which is active in GTP-bound form but inactive in GDP-bound form. The activity of Ras is normally terminated via stimulation of its own GTPase activity by a GTPase-activating protein (GAP) (Fig. 3-11) that returns Ras into its inactive GDP-bound state. Fatty acids, which may accumulate, for example, in response to phospholipase A activation and exposure to peroxysome proliferators (Rose *et al.*, 1999), inhibit GAP and can delay the turning off of Ras. As discussed in more detail later in the chapter, genotoxic carcinogens may mutate Ras, and if the mutation leads to a loss of its GTPase activity, this would result in a permanent signaling for the MAPK pathway—a condition that contributes to malignant transformation of the affected cell population.

Chemically Altered Signal Transduction with Antiproliferative Effect   Downturning of increased proliferative signaling after cell injury may compromise replacement of injured cells. This prediction has been made from a study on cultured Hepa 1-6 cells that exhibited the following, seemingly consequential alterations upon exposure to acetaminophen (follow the path in Fig. 3-11): inhibition of Raf $\rightarrow$ diminished degradation of IκB $\rightarrow$ diminished binding of NF-κB to DNA $\rightarrow$ diminished expression of c-Myc mRNA (Boulares *et al.*, 1999). Down regulation of a normal mitogenic signal is a step away from survival and toward apoptosis. Indeed, inhibitors of PKC (staurosporin), PI3K (wortmannin), and of IκB degradation (gliotoxin) (Waddick and Uckun, 1999) are apoptosis inducers. TGF-β and glucocorticoids increase IκB synthesis and, in turn, decrease NF-κB activation and c-Myc expression (Waddick and Uckun, 1999). These mechanisms may contribute to the apoptotic effect of TGF-β and glucocorticoids, the latter in lymphoid cells.

Dysregulation of Extracellular Signal Production   Hormones of the anterior pituitary exert mitogenic effects on endocrine glands in the periphery by acting on cell surface receptors. Pituitary hormone production is under negative feedback control by hormones of the peripheral glands. Perturbation of this circuit adversely affects pituitary hormone secretion and, in turn, the peripheral gland. For example, xenobiotics that inhibit thyroid hormone production (e.g., the herbicide amitrole and the fungicide metabolite ethylenethiourea) or enhance thyroid hormone elimination (e.g., phenobarbital) reduce thyroid hormone levels and increase the secretion of thyroid-stimulating hormone (TSH) because of the reduced feedback inhibition. The increased TSH secretion stimulates cell division in the thyroid gland, which is responsible for the goiters or thyroid tumors caused by such toxicants (see Chap. 21). Decreased secretion of pituitary hormone produces the opposite adverse affect, with apoptosis followed by involution of the peripheral target gland. For example, estrogens produce testicular atrophy in males by means of feedback inhibition of gonadotropin secretion. The low sperm count in workers intoxicated with the xenoestrogen chlordecone probably results from such a mechanism.

Dysregulation of Ongoing Cellular Activity   Ongoing control of specialized cells is exerted by signaling molecules acting on membrane receptors that transduce the signal by regulating Ca^{2+} entry into the cytoplasm or stimulating the enzymatic formation of intracellular second messengers. The Ca^{2+} or other second messengers ultimately alter the phosphorylation of functional proteins, changing their activity and, in turn, cellular functions almost instantly. Toxicants can adversely affect ongoing cellular activity by disrupting any step in signal coupling.

Dysregulation of Electrically Excitable Cells   Many xenobiotics influence cellular activity in excitable cells, such as neurons, skeletal, cardiac, and smooth muscle cells. Cellular functions such as the release of neurotransmitters and muscle contraction are controlled by transmitters and modulators synthesized and released by adjacent neurons. The major mechanisms that control such cells are shown schematically in Fig. 3-12, and chemicals that interfere with these mechanisms are listed in Table 3-5.

Altered regulation of neural and/or muscle activity is the basic mechanism of action of many drugs and is responsible for toxicities associated with drug overdosage, pesticides, and microbial, plant, and animal toxins (Herken and Hucho, 1992). As neurons are signal-transducing cells, the influence of chemicals on neurons is seen not only on the neuron affected by the toxicant but also on downstream cells influenced by the primary target. Thus, tetrodotoxin, which blocks voltage-gated Na$^+$ channels (item 7 in Fig. 3-12) in motor neurons, causes skeletal muscle paralysis. In contrast, cyclodiene insecticides, which block GABA receptors (item 3 in Fig. 3-12) in the central nervous system, induce neuronal excitation and convulsions (Narahashi, 1991).

Perturbation of ongoing cellular activity by chemicals may be due to an alteration in (1) the concentration of neurotransmitters, (2) receptor function, (3) intracellular signal transduction, or (4) the signal-terminating processes.

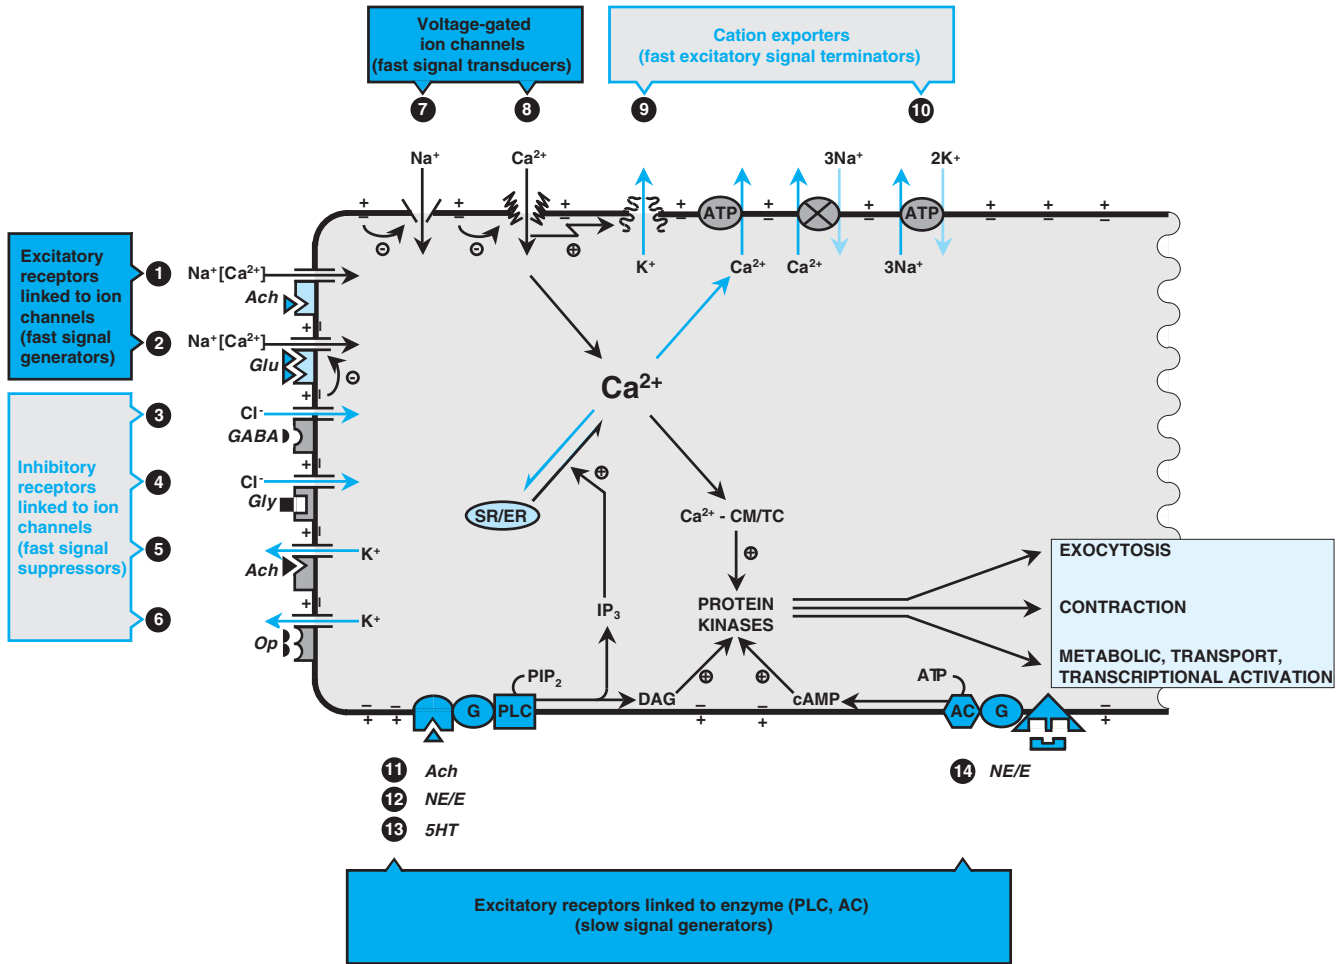
Alteration in Neurotransmitter Levels   Chemicals may alter synaptic levels of neurotransmitters by interfering with their synthesis, storage, release, or removal from the vicinity of the receptor. The convulsive effect of hydrazine and hydrazides (e.g., isoniazid) is due to their ability to decrease the synthesis of the inhibitory neurotransmitter GABA (Gale, 1992). Reserpine causes its several adverse effects by inhibiting the neuronal storage of norepinephrine, 5-hydroxytryptamine, and dopamine, thereby depleting these transmitters. Skeletal muscle paralysis caused by botulinum toxin is due to inhibition of acetylcholine release from motor neurons and the lacking stimulation of the acetylcholine receptors at the neuromuscular junction (receptor 1 in Fig. 3-12). In contrast, inhibition of acetylcholinesterase by organophosphate or carbamate insecticides or chemical warfare agents (e.g., soman) prevents the hydrolysis of acetylcholine, resulting in massive stimulation of cholinergic receptors (receptors 1, 5, and 11 in Fig. 3-12) and a cholinergic crisis (Table 3-5). Inhibition of the neuronal reuptake of norepinephrine by cocaine or tricyclic antidepressants is responsible for overexcitation of alpha$_1$-adrenergic receptors on vascular smooth muscles, resulting in nasal mucosal ulceration and myocardial infarction in heavy cocaine abusers, whereas overstimulation of beta$_1$-adrenergic receptors contributes to life-threatening arrhythmias. Similar cardiac complications may result from amphetamine abuse, because amphetamine enhances the release of norepinephrine from adrenergic neurons and competitively inhibits neuronal reuptake of this transmitter. A hypertensive crisis can occur with the combined use of tricyclic antidepressants and monoamine oxidase inhibitors, drugs that block different mechanisms of norepinephrine elimination (Hardman *et al.*, 1995). Concomitant use of drugs that increase the


Figure 3-12. Signaling mechanisms for neurotransmitters.

This simplified scheme depicts major cellular signaling mechanisms that are operational in many neurons and muscle and exocrine cells. Chemicals acting on the numbered elements are listed in Table 3-5. Fast signaling is initiated by the opening of ligand-gated Na^+/Ca^{2+} channels (1,2). The resultant cation influx decreases the inside negative potential (i.e., evokes depolarization) and thus triggers the opening of the voltage-gated Na^+ and Ca^{2+} channels (7,8). As a second messenger, the influxed Ca^{2+} activates intracellular Ca^{2+}-binding proteins such as calmodulin (CM) and troponin C (TC), which, in turn, enhance the phosphorylation of specific proteins, causing activation of specific cellular functions. The signal is terminated by channels and transporters (e.g., 9,10) that remove cations from the cells and thus reestablish the inside negative resting potential (i.e., cause repolarization) and restore the resting Ca^{2+} level. Fast signaling can be suppressed by opening the ligand-activated Cl^- or K^+ channels (3-6), which increases the inside negativity (i.e., induces hyperpolarization) and thus counteracts opening of the voltage-gated Na^+ and Ca^{2+} channels (7,8). Signal transduction from other receptors (11–14) that are coupled to G_s proteins involves enzymatic generation of second messengers: inositol 1,4,5-trisphosphate (IP_3) and diacylglycerol (DAG) by phospholipase C (PLC) and cyclic AMP (cAMP) by adenylyl cyclase (AC). These messengers influence cellular activities by activating protein kinases directly or by mobilizing Ca^{2+} from the sarcoplasmic or endoplasmic reticulum (SR and ER), as IP_3 does. For clarity, this figure does not depict that inhibitory receptors 5 and 6 are G_i protein-coupled and that besides opening K^+ channels, they also inhibit AC. Ach = acetylcholine; Glu = glutamate; GABA = γ-aminobutyric acid; Gly = glycine; Op = opioid peptides; NE = norepinephrine; E = epinephrine; 5HT = 5-hydroxytryptamine; G = G protein; PIP_2 = phosphatidylinositol 4,5-bisphosphate. Encircled positive and negative signs indicate activation and inhibition, respectively.

level of serotonin (5-HT) by enhancing its neuronal release, decreasing its neuronal reuptake (e.g., fluoxetine) or its biotransformation (e.g., monoamine oxidase inhibitors) induce the serotonin syndrome with cognitive and behavioral changes, autonomic dysfunction, and neuromuscular abnormalities. It is thought that cytotoxic antineoplastic drugs (e.g., cisplatin) and radiation cause nausea and emesis, a disturbing reaction to chemo- and radiotherapy, by inducing re-

lease of 5-HT from enterochromaffin cells of the intestinal mucosa, which stimulates the $5-HT_3$-receptors (5-HT-gated cation channel, functionally similar to item 1 in Fig. 3-12) on the adjacent vagal afferent neurons, thereby evoking the vomiting reflex (Endo *et al.*, 2000). Intestinal release of 5-HT and stimulation of vagal afferent neurons are also involved in the emetic effect of ipecac syrup and its alkaloids (cephaelin and emetine). The alpha$_2$-adrenergic receptor

Table 3.5
Agents Acting on Signaling Systems for Neurotransmitters and Causing Dysregulation of the Momentary Activity of Electrically Excitable Cells Such as Neurons and Muscle Cells*

Receptor/Channel/Pump		Agonist/Activator		Antagonist/Inhibitor	
NAME	LOCATION	AGENT	EFFECT	AGENT	EFFECT
1. Acetylcholine nicotinic receptor	Skeletal muscle	Nicotine Anatoxin-a Cytisine *Ind:* ChE inhibitors	Muscle fibrillation, then paralysis	Tubocurarine, lophotoxin α-Bungarotoxin α-Cobrotoxin α-Conotoxin Erabutoxin b *Ind:* botulinum toxin	Muscle paralysis
	Neurons	See above	Neuronal activation	Pb^{2+}, general anesthetics	Neuronal inhibition
2. Glutamate receptor	CNS neurons	*N*-Methyl-*D*-aspartate Kainate, domoate Quinolinate Quisqualate *Ind:* hypoxia, HCN $\rightarrow$ glutamate release	Neuronal activation $\rightarrow$ convulsion, neuronal injury ("excitotoxicity")	Phencyclidine Ketamine General anesthetics	Neuronal inhibition $\rightarrow$ anesthesia Protection against "excitotoxicity"
3. GABA$_A$ receptor	CNS neurons	Muscimol, avermectins sedatives (barbiturates, benzodiazepines) General anaesthetics (halothane) Alcohols (ethanol)	Neuronal inhibition $\rightarrow$ sedation, general anaesthesia, coma, depression of vital centers	Bicuculline Picrotoxin Pentylenetetrazole Cyclodiene insecticides Lindane, TCAD *Ind:* isoniazid	Neuronal activation $\rightarrow$ tremor, convulsion
4. Glycine receptor	CNS neurons, motor neurons	Avermectins (?) General anesthetics	Inhibition of motor neurons $\rightarrow$ paralysis	Strychnine *Ind:* tetanus toxin	Disinhibition of motor neurons $\rightarrow$ tetanic convulsion
5. Acetylcholine M$_2$ muscarinic receptor	Cardiac muscle	*Ind:* ChE inhibitors	Decreased heart rate and contractility	Belladonna alkaloids (e.g., atropine) atropinelike drugs (e.g., TCAD)	Increased heart rate
6. Opioid receptor	CNS neurons, visceral neurons	Morphine and congeners (e.g., heroin, meperidine) *Ind:* clonidine	Neuronal inhibition $\rightarrow$ analgesia, central respiratory depression, constipation, urine retention	Naloxone	Antidotal effects in opiate intoxication
7. Voltage-gated Na$^+$ channel	Neurons, muscle cells, etc.	Aconitine, veratridine Grayanotoxin Batrachotoxin Scorpion toxins Ciguatoxin DDT, pyrethroids	Neuronal activation $\rightarrow$ convulsion	Tetrodotoxin, saxitoxin μ-Conotoxin Local anaesthetics Phenytoin Quinidine	Neuronal inhibition $\rightarrow$ paralysis, anesthesia Anticonvulsive action
8. Voltage-gated Ca^{2+} channel	Neurons, muscle cell, etc.	Maitotoxin (?) Atrotoxin (?) Latrotoxin (?)	Neuronal/muscular activation, cell injury	ω-Conotoxin Pb^{2+}	Neuronal inhibition $\rightarrow$ paralysis

Receptor/Channel/Pump		Agonist/Activator		Antagonist/Inhibitor	
NAME	LOCATION	AGENT	EFFECT	AGENT	EFFECT
9. Voltage/Ca^{2+}-activated K^+ Channel	Neurons, smooth and skeletal muscle cardiac muscle	Pb^{2+}	Neuronal/muscular inhibition	Ba^{2+} Apamin (bee venom) Dendrotoxin 20-HETE hERG inhibitors (e.g., cisapride, terfenadine)	Neuronal/muscular activation → convulsion/spasm vasoconstriction PMV tachycardia (torsade de pointes)
10. Na^+,K^+-ATPase	Universal			Digitalis glycosides Oleandrin Chlordecone	Increased cardiac contractility, excitability Increased neuronal excitability → tremor
11. Acetylcholine M_3 muscarinic receptor	Smooth muscle, glands	*Ind:* ChE inhibitors	Smooth muscle spasm Salivation, lacrimation	Belladonna alkaloids (e.g., atropine) Atropinelike drugs (e.g., TCAD)	Smooth muscle relaxation → intestinal paralysis, decreased salivation, decreased perspiration
Acetylcholine M_1 muscarinic receptor	CNS neurons	Oxotremorine *Ind:* ChE inhibitors	Neuronal activation → convulsion	See above	
12. Adrenergic alpha$_1$ receptor	Vascular smooth muscle	(Nor)epinephrine *Ind:* cocaine, tyramine amphetamine, TCAD	Vasoconstriction → ischemia, hypertension	Prazosin	Antidotal effects in intoxication with alpha$_1$-receptor agonists
13. 5-HT$_2$ receptor	Smooth muscle	Ergot alkaloids (ergotamine, ergonovine)	Vasoconstriction → ischemia, hypertension	Ketanserine	Antidotal effects in ergot intoxication
14. Adrenergic beta$_1$ receptor	Cardiac muscle	(Nor)epinephrine *Ind:* cocaine, tyramine amphetamine, TCAD	Increased cardiac contractility and excitability	Atenolol, metoprolol	Antidotal effects in intoxication with beta$_1$-receptor agonists

*Numbering of the signaling elements in this table corresponds to the numbering of their symbols in Fig. 3-12. This tabulation is simplified and incomplete. Virtually all receptors and channels listed occur in multiple forms with different sensitivity to the agents. The reader should consult the pertinent literature for more detailed information. CNS = central nervous system; ChE = cholinesterase; *Ind* = indirectly acting (i.e., by altering neurotransmitter level); 20-HETE = 20-hydroxy 5,8,11,14-eicosatetraenoic acid; PMV = polymorphic ventricular; TCAD = tricyclic antidepressant.

agonist clonidine induces release in the brain of beta-endorphin, an endogenous peptide that stimulates opioid receptors (item 6 in Fig. 3-12). This explains why clonidine intoxication mimics several symptoms of morphine poisoning, including depressed respiration and pin-point pupils.

Toxicant–Neurotransmitter Receptor Interactions   Some chemicals interact directly with neurotransmitter receptors, including (1) agonists that associate with the ligand-binding site on the receptor and mimic the natural ligand, (2) antagonists that occupy the ligand-binding site but cannot activate the receptor, (3) activators, and (4) inhibitors that bind to a site on the receptor that is not directly involved in ligand binding. In the absence of other actions, agonists and activators mimic, whereas antagonists and inhibitors block, the physiologic responses characteristic of endogenous ligands. For example, muscimol, a mushroom poison, is an agonist at the inhibitory GABA$_A$ receptor (item 3 in Fig. 3-12), whereas barbiturates, benzodiazepines, general anesthetics, and alcohols are activators (Narahashi, 1991). Thus, all these chemicals cause inhibition of central nervous system activity, resulting in sedation, general anesthesia, coma, and ultimately blockade of the medullary respiratory center, depending on the dose administered. There are also similarities in the responses evoked by

agonist/activators on excitatory receptors and those elicited by antagonists/inhibitors on inhibitory sites. Thus, glutamate receptor agonists and muscarinic receptor agonists cause neuronal hyperactivity in the brain and ultimately convulsions, as do inhibitors of $GABA_A$ receptor. It is also apparent that chemicals acting as agonists/activators on inhibitory receptors and those acting as antagonists/inhibitors on excitatory receptors may exert similar effects. Moreover, general anesthetic solvents induce general anesthesia not only by activating the inhibitory ligand-gated chloride-ion channels (i.e., $GABA_A$ and glycine receptors; see items 3 and 4, respectively, in Fig. 3-12) but also by inhibiting the excitatory ligand-gated cation channels (i.e., neuronal nicotinic acetylcholine receptor and glutamate receptors; see items 1 and 2, respectively, in Fig. 3-12) (Franks and Lieb, 1998; Perouansky *et al.*, 1998). Because there are multiple types of receptors for each neurotransmitter, these receptors may be affected differentially by toxicants. For example, the neuronal nicotinic acetylcholine receptor is extremely sensitive to inhibition by lead ions, whereas the muscular nicotine receptor subtype is not (Oortgiesen *et al.*, 1993). Other chemicals that produce neurotransmitter receptor–mediated toxicity are listed in Table 3-5.

Some sensory neurons have receptors that are stimulated by chemicals, such as the capsaicin receptor, which is a ligand-gated cation channel (Herken and Hucho, 1992). This receptor mediates the burning sensation of the tongue and reflex stimulation of the lacrimal gland associated with exposure to red pepper and other irritants. Lacrimators in tear gas, which are typically thiol-reactive chemicals, also stimulate these neurons, though their precise mode of action is unclear.

Toxicant–Signal Transducer Interactions   Many chemicals alter neuronal and/or muscle activity by acting on signal-transduction processes. Voltage-gated Na^+ channels (item 7 in Fig. 3-12), which transduce and amplify excitatory signals generated by ligand-gated cation channels (receptors 1 and 2 in Fig. 3-12), are activated by a number of toxins derived from plants and animals (Table 3-5) as well as by synthetic chemicals such as DDT, resulting in overexcitation (Narahashi, 1992). In contrast, chemicals that block voltage-gated Na^+ channels (such as tetrodotoxin and saxitoxin) cause paralysis. The Na^+ channels are also important in signal transduction in sensory neurons; therefore, Na^+-channel activators evoke sensations and reflexes, whereas Na^+-channel inhibitors induce anesthesia. This explains the reflex bradycardia and burning sensation in the mouth that follow the ingestion of monkshood, which contains the Na^+-channel activator aconitine, as well as the use of Na^+-channel inhibitors such as procaine and lidocaine for local anesthesia.

Toxicant–Signal Terminator Interactions   The cellular signal generated by cation influx is terminated by removal of the cations through channels or by transporters (Fig. 3-12). Inhibition of cation efflux may prolong excitation, as occurs with the blockade of Ca^{2+}-activated K^+ channels (item 9 in Fig. 3-12) by Ba^{2+}, which is accompanied by potentially lethal neuroexcitatory and spasmogenic effects. The arachidonic acid metabolite 20-hydroxy 5,8,11,14-eicosatetraenoic acid (20-HETE) also blocks Ca^{2+}-activated K^+ channels, causing vasoconstriction. Induction by cyclosporine of 20-HETE production in renal proximal tubular cells and the resultant decrease in renal cortical blood flow may underlie the nephrotoxic effect of cyclosporine (Seki *et al.*, 2005). Blockade of specific voltage-gated K^+ channels (called hERG channels; item 9 in Fig. 3-12) in the heart delays cardiac repolarization (as indicated by prolonged QT time in ECG) and may evoke polymorphic ventricular

tachycardia (termed torsade de pointes), which may cause sudden death if degenerates into ventricular fibrillation (Sanguinetti and Mitcheson, 2005). Several drugs with such an effect (e.g., astemizole, cisapride, grepafloxacin, terfenadine) have been withdrawn from clinical use. Glycosides from digitalis and other plants inhibit Na^+,K^+-ATPase (item 10 in Fig. 3-12) and thus increase the intracellular Na^+ concentration, which, in turn, decreases Ca^{2+} export by Ca^{2+}/Na^+ exchange (Fig. 3-12). The resultant rise in the intracellular concentration of Ca^{2+} enhances the contractility and excitability of cardiac muscle. Inhibition of brain Na^+,K^+-ATPase by chlordecone may be responsible for the tremor observed in chlordecone-exposed workers (Desaiah, 1982). Lithium salts, although used therapeutically, have the potential to produce hyperreflexia, tremor, convulsions, diarrhea, and cardiac arrhythmias (Hardman *et al.*, 1995). Lithium also markedly potentiates cholinergically mediated seizures. Besides inhibition of Li^+-sensitive enzymes (e.g., inositol monophosphatase, bisphosphate 3′-nucleotidase), another possible reason for these toxic effects is inefficient repolarization of neurons and muscle cells in the presence of Li^+. Whereas Li^+ readily enters these cells through Na^+ channels, contributing to the signal-induced depolarization, it is not a substrate for the Na^+,K^+ pump. Therefore, the cells fail to repolarize properly if a fraction of intracellular Na^+ is replaced by Li^+.

Failure of the Na^+,K^+ pump is also believed to contribute to the neuronal damage resulting from hypoxia, hypoglycemia, and cyanide intoxication. Inasmuch as 70% of the ATP produced in neurons is used to drive the Na^+,K^+ pump; cessation of ATP synthesis causes a cell to become or remain depolarized. The depolarization-induced release of neurotransmitters such as glutamate from such neurons is thought to be responsible for the hypoxic seizures and further amplification of neuronal injury by the neurotoxic actions of glutamate (Patel *et al.*, 1993).

Dysregulation of the Activity of Other Cells   While many signaling mechanisms also operate in nonexcitable cells, disturbance of these processes is usually less consequential. For example, rat liver cells possess alpha$_1$-adrenergic receptors (item 12 in Fig. 3-12) whose activation evokes metabolic changes, such as increased glycogenolysis and glutathione export, through elevation of intracellular Ca^{2+}, which may have toxicologic significance.

Many exocrine secretory cells are controlled by muscarinic acetylcholine receptors (item 11 in Fig. 3-12). Salivation, lacrimation, and bronchial hypersecretion after organophosphate insecticide poisoning are due to stimulation of these receptors. In contrast, blockade of these receptors contributes to the hyperthermia characteristic of atropine poisoning. Kupffer cells, resident macrophages in the liver, secrete inflammatory mediators (see Fig. 3-22) that can harm the neighboring cells. Because Kupffer cells possess glycine receptors, i.e., glycine-gated Cl^- channels (item 4 in Fig. 3-12), the secretory function of these macrophages (e.g., secretion of inflammatory mediators) can be blocked by administration of glycine, which induces hyperpolarization via influx of Cl^-. Such intervention alleviates ethanol-induced liver injury (Yin *et al.*, 1998).

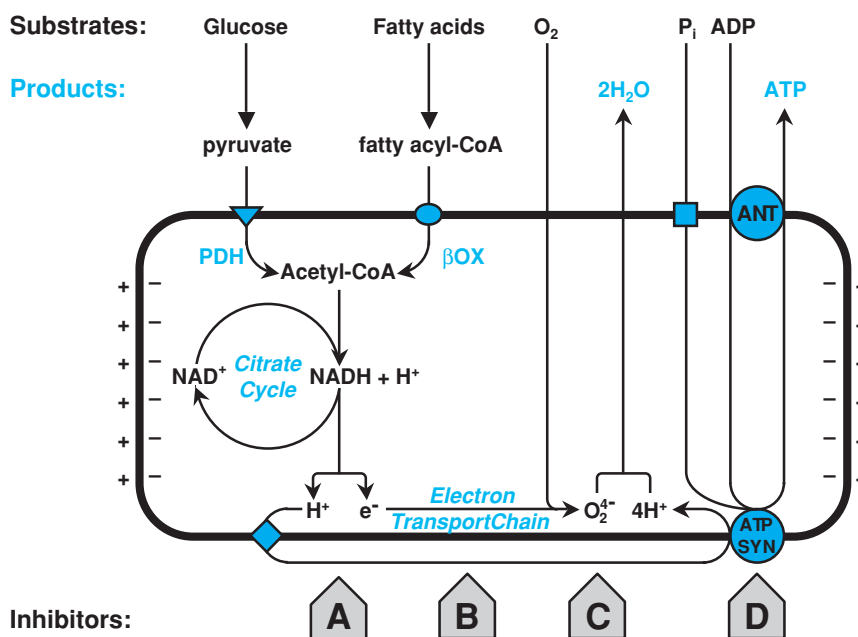
The discovery that some sulfonamides produce hypoglycemia in experimental animals led to the development of oral hypoglycemic agents for diabetic patients. These drugs inhibit K^+ channels in pancreatic beta cells, inducing sequentially depolarization, Ca^{2+} influx through voltage-gated Ca^{2+} channels, and exocytosis of insulin (Hardman *et al.*, 1995). The antihypertensive diazoxide acts in the opposite fashion on K^+ channels and impairs insulin secretion. Whereas this effect is generally undesirable, it is exploited in the treatment of inoperable insulin-secreting pancreatic tumors.


Figure 3-13. *ATP synthesis (oxidative phosphorylation) in mitochondria.*

Arrows with letters A to D point to the ultimate sites of action of four categories of agents that interfere with oxidative phosphorylation (Table 3-6). For simplicity, this scheme does not indicate the outer mitochondrial membrane and that protons are extruded from the matrix space along the electron transport chain at three sites. βOX = beta-oxidation of fatty acids; e^- = electron; P_i = inorganic phosphate; ANT = adenine nucleotide translocator; ATP SYN = ATP synthase (F_oF_1ATPase).

Toxic Alteration of Cellular Maintenance

Numerous toxicants interfere with cellular maintenance functions. In a multicellular organism, cells must maintain their own structural and functional integrity as well as provide supportive functions for other cells. Execution of these functions may be disrupted by chemicals, resulting in a toxic response.

Impairment of Internal Cellular Maintenance: Mechanisms of Toxic Cell Death   For survival, all cells must synthesize endogenous molecules; assemble macromolecular complexes, membranes, and cell organelles; maintain the intracellular environment; and produce energy for operation. Chemicals that disrupt these functions, especially the energy-producing function of mitochondria and protein synthesis controlling function of the genome, jeopardize survival and may cause toxic cell death.

There are three critical biochemical disorders that chemicals inflicting cell death may initiate, namely, ATP depletion, sustained rise in intracellular Ca^{2+}, and overproduction of ROS and RNS. In the following discussion, these events and the chemicals that may cause them are individually characterized. Then it is pointed out how their concerted action may induce a bioenergetic catastrophe, culminating in necrosis. Finally, there follows a discussion of the circumstances under which the cell can avoid this disordered decay and how it can execute death by activating catabolic processes that bring about an ordered disassembly and removal of the cell, called apoptosis.

Primary Metabolic Disorders Jeopardizing Cell Survival: ATP Depletion, Ca^{2+} Accumulation, ROS/RNS Generation Depletion of ATP   ATP plays a central role in cellular maintenance both as a chemical for biosynthesis and as the major source of energy. It is utilized in numerous biosynthetic reactions, activating endogenous compounds by phosphorylation and adenylation, and is incorpo-

rated into cofactors as well as nucleic acids. It is required for muscle contraction and polymerization of the cytoskeleton, fueling cellular motility, cell division, vesicular transport, and the maintenance of cell morphology. ATP drives ion transporters, such as the Na^+,K^+-ATPase in the plasma membrane, the Ca^{2+}-ATPase in the plasma and the endoplasmic reticulum membranes, and H^+-ATPase in the membrane of lysosomes and neurotransmitter-containing vesicles. These pumps maintain conditions essential for various cell functions. For example, the Na^+ concentration gradient across the plasma membrane generated by the Na^+,K^+ pump drives Na^+-glucose and Na^+-amino acid cotransporters as well as the Na^+/Ca^{2+} antiporter, facilitating the entry of these nutrients and the removal of Ca^{2+}.

Chemical energy is released by hydrolysis of ATP to ADP or AMP. The ADP is rephosphorylated in the mitochondria by ATP synthase (Fig. 3-13). Coupled to oxidation of hydrogen to water, this process is termed *oxidative phosphorylation.* In addition to ATP synthase, oxidative phosphorylation requires the (1) delivery of hydrogen in the form of NADH to the initial electron transport complex; (2) delivery of oxygen to the terminal electron transport complex; (3) delivery of ADP and inorganic phosphate to ATP synthase; (4) flux of electrons along the electron transport chain to O_2, accompanied by ejection of protons from the matrix space across the inner membrane; and (5) return of protons across the inner membrane into the matrix space down an electrochemical gradient to drive ATP synthase (Fig. 3-13).

Several chemicals impede these processes, interfering with mitochondrial ATP synthesis (Commandeur and Vermeuien, 1990; Wallace and Starkow, 2000). These chemicals are divided into five groups (Table 3-6). Substances in class A interfere with the delivery of hydrogen to the electron transport chain. For example, fluoroacetate inhibits the citric acid cycle and the production of reduced cofactors. Class B chemicals such as rotenone and cyanide

Table 3.6
Agents Impairing Mitochondrial ATP Synthesis*

A.   Inhibitors of hydrogen delivery to the electron transport chain acting on/as
   1.   Glycolysis (critical in neurons): hypoglycemia; iodoacetate and NO^+ at GAPDH
   2.   Gluconeogenesis (critical in renal tubular cells): coenzyme A depletors (see below)
   3.   Fatty acid oxidation (critical in cardiac muscle): hypoglycin, 4-pentenoic acid
   4.   Pyruvate dehydrogenase: arsenite, DCVC, p-benzoquinone
   5.   Citrate cycle
     (a)   Aconitase: fluoroacetate, $ONOO^-$
     (b)   Isocitrate dehydrogenase: DCVC
     (c)   Succinate dehydrogenase: malonate, DCVC, PCBD-cys, 2-bromohydroquinone, 3-nitropropionic acid, cis-crotonalide fungicides
   6.   Depletors of TPP (inhibit TPP-dependent PDH and α-KGDH): ethanol
   7.   Depletors of coenzyme A: 4-(dimethylamino)phenol, p-benzoquinone
   8.   Depletors of NADH
     (a)   See group A.V.1. in Table 3-7
     (b)   Activators of poly(ADP-ribose) polymerase: agents causing DNA damage (e.g., MNNG, hydrogen peroxide, $ONOO^-$)
B.   Inhibitors of electron transport acting on/as
   1.   Inhibitors of electron transport complexes
     (a)   NADH–coenzyme Q reductase (complex I): rotenone, amytal, MPP^+, paraquat
     (b)   Cycotochrome Q–cytochrome c reductase (complex III): antimycin-A, myxothiazole
     (c)   Cytochrome oxidase (complex IV): cyanide, hydrogen sulfide, azide, formate, $^•NO$, phosphine (PH_3)
     (d)   Multisite inhibitors: dinitroaniline and diphenylether herbicides, $ONOO^-$
   2.   Electron acceptors: CCl_4, doxorubicin, menadione, MPP^+
C.   Inhibitors of oxygen delivery to the electron transport chain
   1.   Chemicals causing respiratory paralysis: CNS depressants (e.g., opioids), convulsants
   2.   Chemicals impairing pulmonary gas exchange: CO_2, "deep pulmonary irritants" (e.g., NO_2, phosgene, perfluoroisobutene)
   3.   Chemicals inhibiting oxygenation of Hb: carbon monoxide, methemoglobin-forming chemicals
   4.   Chemicals causing ischemia: ergot alkaloids, cocaine
D.   Inhibitors of ADP phosphorylation acting on/as
   1.   ATP synthase: oligomycin, cyhexatin, DDT, chlordecone
   2.   Adenine nucleotide translocator: atractyloside, DDT, free fatty acids, lysophospholipids
   3.   Phosphate transporter: N-ethylmaleimide, mersalyl, p-benzoquinone
   4.   Chemicals dissipating the mitochondrial membrane potential (uncouplers)
     (a)   Cationophores: pentachlorophenol, dinitrophenol-, benzonitrile-, thiadiazole herbicides, salicylate, cationic amphiphilic drugs (amiodarone, perhexiline), valinomycin, gramicidin, calcimycin (A23187)
     (b)   Chemicals permeabilizing the mitochondrial inner membrane: PCBD-cys, chlordecone
E.   Chemicals causing mitochondrial DNA damage and/or impaired transcription of key mitochondrial proteins
   1.   Antiviral drugs: zidovudine, zalcitabine, didanosine, fialuridine
   2.   Chloramphenicol (when overdosed)
   3.   Ethanol (when chronically consumed)

*The ultimate sites of action of these agents are indicated in Fig. 3-13. DCVC = dichlorovinyl-cysteine; GAPDH = glyceraldehyde 3-phosphate dehydrogenase; α-KGDH = α-ketoglutarate dehydrogenase; MNNG = N-methyl-N'-nitro-N-nitrosoguanidine; MPP^+ = 1-methyl-4-phenylpyridinium; PCBD-cys = pentachlorobutadienyl-cysteine; PDH = pyruvate dehydrogenase; TPP = thyamine pyrophosphate

inhibit the transfer of electrons along the electron transport chain to oxygen. Class C agents interfere with oxygen delivery to the terminal electron transporter, cytochrome oxidase. All chemicals that cause hypoxia ultimately act at this site. Chemicals in class D inhibit the activity of ATP synthase, the key enzyme for oxidative phosphorylation. At this site, the synthesis of ATP may be inhibited in one of four ways: (1) direct inhibition of ATP synthase, (2) interference with ADP delivery, (3) interference with inorganic phosphate delivery, and (4) deprivation of ATP synthase from its driving force, the controlled influx of protons into the matrix space. Protonophoric chemicals (uncouplers) such as 2,4-dinitrophenol and pentachlorophenol import protons into the mitochondrial matrix, dissipating the proton gradient that drives the controlled influx of protons into the matrix, which, in turn, drives ATP synthase. Finally, chemicals causing mi-

tochondrial DNA injury, and thereby impairing synthesis of specific proteins encoded by the mitochondrial genome (e.g., subunits of complex I and ATP synthase), are listed in group E. These include the dideoxynucleoside antiviral drugs used against AIDS, such as zidovudine. Table 3-6 lists other chemicals that impair ATP synthesis.

Impairment of oxidative phosphorylation is detrimental to cells because failure of ADP rephosphorylation results in the accumulation of ADP and its breakdown products as well as depletion of ATP. Accordingly, hepatocytes exposed to KCN and iodoacetate exhibit a rapid rise in cytosolic H^+ and Mg^{2+} as a result of the hydrolysis of adenosine di- and triphosphates (existing as Mg salts) and the release of phosphoric acid and Mg^{2+} (Herman *et al.*, 1990). The increased conversion of pyruvate to lactate also may contribute to the acidosis. The lack of ATP compromises the operation of ATP-requiring ion
Figure 3-14. **Four mechanisms for the elimination of Ca^{2+} from the cytoplasm: Ca^{2+}-ATPase-mediated pumping into (1) the extracellular space as well as (2) the endoplasmic reticulum (ER) and ion-gradient–driven transport into (3) the extracellular space (by the Ca^{2+}/Na^+ exchanger) as well as (4) the mitochondria (M; by the Ca^{2+} uniporter).**

Some chemicals that inhibit these mechanisms are listed in Table 3-7, group B.

pumps, leading to the loss of ionic and volume-regulatory controls (Buja *et al.*, 1993). Shortly after intracellular acidosis and hypermagnesemia, liver cells exposed to KCN and iodoacetate exhibit a rise in intracellular Na^+, probably as a result of failure of the Na^+ pump, after which plasma membrane blebs appear. The intracellular phosphoric acidosis is beneficial for the cells presumably because the released phosphoric acid forms insoluble calcium phosphate, preventing the rise of cytosolic Ca^{2+}, with its deleterious conse-

quences (see below). In addition, a low pH also directly decreases the activity of phospholipases and inhibits mitochondrial permeability transition (see later). Terminally, the intracellular pH rises, increasing phospholipase activity, and this contributes to irreversible membrane damage (i.e., rupture of the blebs) not only by degrading phospholipids but also by generating endogenous detergents such as lysophospholipids and free fatty acids. The lack of ATP aggravates this condition because the reacylation of lysophospholipids with fatty acids is impaired.

Sustained Rise of Intracellular Ca^{2+} Intracellular Ca^{2+} levels are highly regulated (Fig. 3-14). The 10,000-fold difference between extracellular and cytosolic Ca^{2+} concentration is maintained by the impermeability of the plasma membrane to Ca^{2+} and by transport mechanisms that remove Ca^{2+} from the cytoplasm (Richter and Kass, 1991). Ca^{2+} is actively pumped from the cytosol across the plasma membrane and is sequestered in the endoplasmic reticulum and mitochondria (Fig. 3-14). Because mitochondria are equipped with a low-affinity Ca^{2+} transporter, they play a significant role in Ca^{2+} sequestration only when the cytoplasmic levels rise into the micromolar range. Under such conditions, a large amount of Ca^{2+} accumulates in the mitochondria, where it is deposited as calcium phosphate.

Toxicants induce elevation of cytoplasmic Ca^{2+} levels by promoting Ca^{2+} influx into or inhibiting Ca^{2+} efflux from the cytoplasm (Table 3-7). Opening of the ligand- or voltage-gated Ca^{2+} channels or damage to the plasma membrane causes Ca^{2+} to move down its concentration gradient from extracellular fluid to the cytoplasm. Toxicants also may increase cytosolic Ca^{2+} by inducing its leakage from the mitochondria or the endoplasmic reticulum. They also may diminish Ca^{2+} efflux through inhibition of Ca^{2+} transporters or depletion of their driving forces. Several chemicals that can cause a sustained rise in cytoplasmic Ca^{2+} levels are listed in Table 3-7.

Table 3.7
Agents Causing Sustained Elevation of Cytosolic Ca^{2+}

A. **Chemicals inducing Ca^{2+} influx into the cytoplasm**
   I.   Via ligand-gated channels in neurons:
       1.   Glutamate receptor agonists ("excitotoxins"): glutamate, kainate, domoate
       2.   TRPV1 receptor (capsaicin receptor) agonists: capsaicin, resiniferatoxin
   II.   Via voltage-gated channels: maitotoxin (?), $HO^\bullet$
   III.   Via "newly formed pores": maitotoxin, amphotericin B, chlordecone, methylmercury, alkyltins
   IV.   Across disrupted cell membrane:
       1.   Detergents: exogenous detergents, lysophospholipids, free fatty acids
       2.   Hydrolytic enzymes: phospholipases in snake venoms, endogenous phospholipase A_2
       3.   Lipid peroxidants: carbon tetrachloride
       4.   Cytoskeletal toxins (by inducing membrane blebbing): cytochalasins, phalloidin
   V.   From mitochondria:
       1.   Oxidants of intramitochondrial NADH: alloxan, *t*-BHP, NAPBQI, divicine, fatty acid hydroperoxides, menadione, MPP^+
       2.   Others: phenylarsine oxide, gliotoxin, $^\bullet NO$, $ONOO^-$
   VI.   From the endoplasmic reticulum:
       1. IP_3 receptor activators: γ-HCH (lindan), IP_3 formed during "excitotoxicity"
       2.   Ryanodine receptor activators: δ-HCH
B. **Chemicals inhibiting Ca^{2+} export from the cytoplasm** (inhibitors of Ca^{2+}-ATPase in cell membrane and/or endoplasmic reticulum)
   I.   Covalent binders: acetaminophen, bromobenzene, CCl_4, chloroform, DCE
   II.   Thiol oxidants: cystamine (mixed disulfide formation), diamide, *t*-BHP, $O_2^\bullet$ and HOOH generators (e.g., menadione, diquat)
   III.   Others: vanadate, Cd^{2+}
   IV.   Chemicals impairing mitochondrial ATP synthesis (see Table 3-6)

KEY: DCE = 1,1-dichloroethylene; *t*-BHP = *t*-butyl hydroperoxide; HCH = hexachlorocyclohexane; MPP^+ = 1-methyl-4-phenylpyridinium; NAPBQI = *N*-acetyl-*p*-benzoquinoneimine.

Sustained elevation of intracellular Ca^{2+} is harmful because it can result in (1) depletion of energy reserves, (2) dysfunction of microfilaments, (3) activation of hydrolytic enzymes, and (4) generation of ROS and RNS. There are at least three mechanisms by which sustained elevations in intracellular Ca^{2+} unfavorably influence the cellular energy balance. First, high cytoplasmic Ca^{2+} concentrations cause increased mitochondrial Ca^{2+} uptake by the Ca^{2+} "uniporter," which, like ATP synthase, utilizes the inside negative mitochondrial membrane potential ($\Delta\Psi m$) as the driving force. Consequently, mitochondrial Ca^{2+} uptake dissipates $\Delta\Psi m$ and inhibits the synthesis of ATP. Moreover, chemicals that oxidize mitochondrial NADH activate a transporter that extrudes Ca^{2+} from the matrix space (Richter and Kass, 1991). The ensuing continuous Ca^{2+} uptake and export ("Ca^{2+} cycling") by the mitochondria further compromise oxidative phosphorylation. Second, Ca^{2+} may also impair ATP synthesis by causing oxidative injury to the inner membrane by mechanisms described later. Third, a sustained rise in cytoplasmic Ca^{2+} not only impairs ATP synthesis but also increases ATP consumption by the Ca^{2+}-ATPases working to eliminate the excess Ca^{2+}.

A second mechanism by which an uncontrolled rise in cytoplasmic Ca^{2+} causes cell injury is microfilamental dissociation (Nicotera *et al.*, 1992; Leist and Nicotera, 1997). The cellwide network of actin filaments maintains cellular morphology by attachment of the filaments to actin-binding proteins in the plasma membrane. An increase of cytoplasmic Ca^{2+} causes dissociation of actin filaments from α-actinin and fodrin, proteins that promote anchoring of the filament to the plasma membrane. This represents a mechanism leading to plasma membrane blebbing, a condition that predisposes the membrane to rupture.

A third event whereby high Ca^{2+} concentrations are deleterious to cells is activation of hydrolytic enzymes that degrade proteins, phospholipids, and nucleic acids (Nicotera *et al.*, 1992; Leist and Nicotera, 1997). Many integral membrane proteins are targets for Ca^{2+}-activated neutral proteases, or calpains (Liu *et al.*, 2004). Calpain-mediated hydrolysis of actin-binding proteins also may cause membrane blebbing. Indiscriminate activation of phospholipases by Ca^{2+} causes membrane breakdown directly and by the generation of detergents. Activation of a Ca^{2+}-Mg^{2+}-dependent endonuclease causes fragmentation of chromatin. Elevated levels of Ca^{2+} can lock topoisomerase II in a form that cleaves but does not religate DNA. In summary, intracellular hypercalcaemia activates several processes that interfere with the ability of cells to maintain their structural and functional integrity. The relative importance of these processes in vivo requires further definition.

Overproduction of ROS and RNS   There are a number of xenobiotics that can directly generate ROS and RNS, such as the redox cyclers (Fig. 3-3) and the transition metals (Fig. 3-4). In addition, overproduction of ROS and RNS can be secondary to the intracellular hypercalcaemia, as Ca^{2+} activates enzymes that generate ROS and/or RNS in the following ways:

1. Activation of the dehydrogenases in the citric acid cycle by Ca^{2+} accelerates the hydrogen output from the citrate cycle and, in turn, the flux of electrons along the electron transport chain (see Fig. 3-13). This, together with the suppressed ATP-synthase activity (owing to the Ca^{2+}-induced uncoupling), increases the formation of $O_2^{\bullet}$ by the mitochondrial electron transport chain.
2. Ca^{2+}-activated proteases proteolytically convert xanthine dehydrogenase into xanthine oxidase, whose byproducts are $O_2^{\bullet}$ and HOOH (Harrison, 2002).

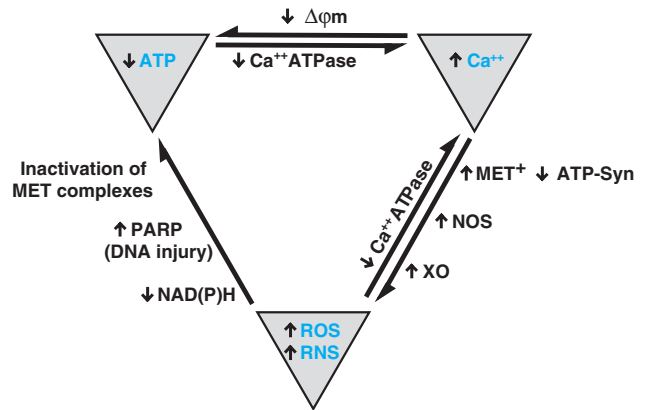

Figure 3-15. Interrelationship between the primary metabolic disorders (ATP depletion, intracellular hypercalcemia, and overproduction of ROS/RNS) that ultimately cause necrosis or apoptosis.

See text for details. ATP-Syn = ATP synthase, MET = mitochondrial electron transport; NOS = nitric oxide synthase; PARP = poly(ADP-ribose) polymerase; ROS = reactive oxygen species; RNS = reactive nitrogen species; XO = xanthine oxidase; $\Delta\psi m$ = mitochondrial membrane potential.

3. Neurons and endothelial cells constitutively express NOS that is activated by Ca^{2+}. Given the extremely high reactivity of $^{\bullet}NO$ with $O_2^{\bullet}$, co-production of these radicals will inevitably lead to formation of $ONOO^-$, a highly reactive oxidant (Murphy, 1999) (Fig. 3-4). Moreover, $ONOO^-$ can increase its own formation by incapacitating the highly sensitive Mn-SOD, which would eliminate $O_2^{\bullet}$, a precursor of $ONOO^-$.

Interplay between the Primary Metabolic Disorders Spells Cellular Disaster   The primary derailments in cellular biochemistry discussed above do not remain isolated but interact and amplify each other in a number of ways (Fig. 3-15):

1. Depletion of cellular ATP reserves deprives the endoplasmic and plasma membrane Ca^{2+} pumps of fuel, causing elevation of Ca^{2+} in the cytoplasm. With the influx of Ca^{2+} into the mitochondria, $\Delta\Psi m$ declines, hindering ATP synthase.
2. As stated above, intracellular hypercalcaemia facilitates formation of ROS and RNS, which oxidatively inactivate the thiol-dependent Ca^{2+} pump, which in turn, aggravates the hypercalcaemia.
3. The ROS and RNS can also drain the ATP reserves. $^{\bullet}NO$ is a reversible inhibitor of cytochrome oxidase, NO^+ (nitrosonium cation, a product of $^{\bullet}NO$) S-nitrosylates and thus inactivates glyceraldehyde 3-phosphate dehydrogenase, impairing glycolysis, whereas $ONOO^-$ irreversibly inactivates respiratory chain complexes I, II, III, and aconitase (by reacting with their Fe-S center) (Murphy, 1999). Therefore, $^{\bullet}NO$ and $ONOO^-$ inhibit cellular ATP synthesis.
4. Furthermore, $ONOO^-$ can induce DNA single-strand breaks, which activate poly(ADP-ribose) polymerase (PARP) (Szabó, 1996). As part of the repair strategy, activated PARP transfers multiple ADP-ribose moieties from NAD^+ to nuclear proteins and PARP itself (D'Amours *et al.*, 1999). Consumption of NAD^+ severely compromises ATP synthesis (see Fig. 3-13), whereas resynthesis of NAD^+ consumes ATP. Hence a major

consequence of DNA damage by ONOO$^-$ is a cellular energy deficit (Murphy, 1999).

The chain of events and their contribution to the worsening metabolic conditions are somewhat cell- and toxicant-specific. For example, cyanide toxicity in neurons is associated with depolarization and glutamate release (Patel *et al.*, 1993), followed by Ca^{2+} influx through voltage-gated as well as glutamate-gated channels (see items 8 and 12, respectively, in Fig. 3-12). As they express Ca^{2+}-activated NOS, neurons are also prone to generate "nitrosative stress," which affects not only themselves but perhaps more significantly the neighboring astrocytes (Szabó, 1996). In contrast, in cyanide- and iodoacetate-poisoned liver cells, the increase in cytoplasmic Ca^{2+} is not an early event (Herman *et al.*, 1990). A nitrosative stress critically contributes to propagation of acetaminophen-induced hepatocellular injury, in which the initiating event is covalent binding of *N*-acetyl-*p*-benzoquinoneimine (NAPBQI) to mitochondrial proteins (Jaeschke and Bajt, 2006). This purportedly causes a surge in mitochondrial O$_2^\bullet$ generation, followed by in situ formation of ONOO$^-$. Owing to depletion of the protective glutathione by NAPBQI, ONOO$^-$ readily nitrates mitochondrial proteins. Concomitantly, covalent binding incapacitates the plasma membrane Ca^{2+} pump and the resultant hypercalcemia further deteriorates mitochondrial function and ATP production. It appears that in this and many other cytotoxicities the interplay of ATP depletion, intracellular hypercalcemia, and overproduction of ROS and RNS, involving multiple vicious cycles (Fig. 3-15), can progressively aggravate the biochemical disorder until it becomes a disaster.

Mitochondrial Permeability Transition (MPT) and the Worst Outcome: Necrosis   Mitochondrial Ca^{2+} uptake, decreased $\Delta\Psi$m, generation of ROS and RNS, depletion of ATP, and consequences of the primary metabolic disorders (e.g., accumulation of inorganic phosphate, free fatty acids, and lysophosphatides) are all considered as causative factors of an abrupt increase in the mitochondrial inner-membrane permeability, termed MPT. This is thought to be caused by misfolded proteins from the inner and outer membrane, which aggregate and open a proteinaceous pore ("megachannel") that spans both mitochondrial membranes (Kroemer *et al.*, 1998; Kim *et al.*, 2003; Rodriguez-Enriquez *et al.*, 2004). As this pore is permeable to solutes of size <1500 Da, its opening permits free influx into the matrix space of protons, causing rapid and complete dissipation of $\Delta\Psi$m and cessation of ATP synthesis as well as osmotic influx of water, resulting in mitochondrial swelling. Ca^{2+} that accumulates in the matrix space effluxes through the pore, flooding the cytoplasm. Such mitochondria are not only incapable of synthesizing ATP but even waste the remaining resources because depolarization of the inner membrane forces the ATP synthase to operate in the reverse mode, as an ATPase, hydrolyzing ATP. Then even glycolysis may become compromised by the insufficient ATP supply to the ATP-requiring glycolytic enzymes (hexokinase, phosphofructokinase). A complete bioenergetic catastrophe ensues in the cell if the metabolic disorders evoked by the toxic chemical (such as one listed in Tables 3-6 and 3-7) is so extensive that most or all mitochondria in the cell undergo MPT, causing depletion of cellular ATP (see Fig. 3-17). Degradative processes already outlined (e.g., oxidative and hydrolytic degradation of macromolecules and membranes as well as disintegration of intracellular solute and volume homeostasis) will go to completion, causing a complete failure in maintenance of cellular structure and functions and culminating in cell lysis or necrosis.

An Alternative Outcome of MPT: Apoptosis   Chemicals that adversely affect cellular energy metabolism, Ca^{2+} homeostasis, and redox state and ultimately cause necrosis, may also induce apoptosis, another form of cell demise. Whereas the necrotic cell swells and lyses, the apoptotic cell shrinks; its nuclear and cytoplasmic materials condense, and then it breaks into membrane-bound fragments (apoptotic bodies) that are phagocytosed (Wyllie, 1997).

As discussed above, the multiple metabolic defects that a cell suffers in its way to necrosis are causal yet rather random in sequence. In contrast, the routes to apoptosis are ordered, involving cascade-like activation of catabolic processes that finally disassemble the cell. A scheme of the apoptotic pathways is presented in Fig. 3-16.

It appears that most if not all chemical-induced cell deaths will involve the mitochondria, and the resulting mitochondrial dysfunction (such as Ca^{2+} accumulation, dissipation of $\Delta\Psi$m, and overproduction of ROS/RNS) may ultimately trigger either necrosis or apoptosis, and that MPT can be a crucial event in both. A related event is release into the cytoplasm of cytochrome *c* (cyt *c*), a small positively charged hemeprotein that normally resides in the mitochondrial intermembrane space attached electrostatically to cardiolipin, a specific inner membrane phospholipid with excess negative charge. Peroxidation of cardiolipin results in detachment of cyt *c* from the lipid, which may be a critical first step of cyt *c* release into the cytoplasm (Orrenius, 2004).

The significance of cyt *c* release is twofold (Cai *et al.*, 1998): (1) As cyt *c* is the penultimate link in the mitochondrial electron transport chain, its loss will block ATP synthesis, increase formation of O$_2^\bullet$ (instead of O$_2^{4-}$ as shown in Fig. 3-13), and potentially thrust the cell toward necrosis. (2) Simultaneously, the unleashed cyt *c* (and some other proteins set free from the mitochondria) represents a signal or an initial link in the chain of events directing the cell to the apoptotic path (Cain, 2003) (Fig. 3-16). Cyt *c* together with dATP/ATP induces the cytoplasmic adapter protein Apaf-1 to oligomerize and bind the latent procaspase-9 (forming a complex called apoptosome), facilitating its conversion to active caspase-9.

Caspases are cysteine proteases (that is, they possess a catalytically active cysteine) that cleave proteins after specific aspartate residues. They reside mostly in the cytoplasm in inactive forms, as procaspases, which are activated either by dimerization (initiators) or proteolytic cleavage (effectors) (Boatright *et al.*, 2003). Perhaps in order to guarantee that inadvertent activation of caspases should not occur, inhibitor of apoptosis proteins (IAP), such as XIAP and cIAP, reside in the cytoplasm and physically capture caspases that might have become activated (Cain, 2003). Therefore, cyt *c* alone probably could not induce sufficiently strong caspase activation if it were not for a gang of proteins that physically remove the IAPs from the caspases just being activated. These proteins, named Smac and Omi (or Diablo and HtrA2, respectively), are not only the helpers of cyt *c*, but also residents of the mitochondrial intermembrane space, from where they are jointly mobilized to promote the caspase cascade. Some caspases on the "top" of the cascade, (e.g., 8 and 9) cleave and activate procaspases. Thereby these initiator caspases carry the activation wave to the so-called effector caspases (e.g., 3, 6, and 7), which cleave specific cellular proteins, activating or inactivating them. It is the hydrolysis of these specific proteins that accounts directly or indirectly for the morphologic and biochemical alterations in apoptotic cells. For example, proteolytic inactivation of PARP prevents futile DNA repair and wasting of ATP; hydrolysis of the inhibitor of caspase-activated DNase (ICAD) permits caspase-activated DNase (CAD) to translocate to the nucleus and
Figure 3-16. Apoptotic pathways initiated by mitochondrial insult, nuclear DNA insult, and Fas or TNF receptor-1 stimulation.

The figure is a simplified scheme of three pathways to apoptosis. (1) Mitochondrial insult (see text) ultimately opens the permeability transition pore spanning both mitochondrial membranes and/or causes release of cytochrome c (Cyt c) and other pro- and antiapoptotic proteins (not shown) from the mitochondria. Cyt c release is facilitated by Bax or truncated Bid (tBid) proteins and opposed by Bcl-2 protein. (2) DNA insult, especially double-strand breaks, activates p53 protein which increases the expression of Bax (that mediates Cyt c release) and the membrane receptor protein Fas. (3) Fas ligand or tumor necrosis factor (TNF) binds to and activates their respective receptor, Fas and TNF1 receptor. These ligand-bound receptors and the released Cyt c interact with specific adapter proteins (i.e., FADD, TRADD and Apaf-1) through which they activate initiator procaspases (PC; e.g., PC-8 and PC-9) to active caspases (C). The latter in turn cleave and activate other proteins e.g., Bid and the main effector procaspase PC-3. The active effector caspase-3 activates other effector procaspases (PC-6, PC-7). Finally, C-3, C-6, and C-7 cleave specific cellular proteins, leading to morphological and biochemical features of apoptosis. These pathways are not equally relevant in all types of cells and other pathways, such as those employing TGF-β as an extracellular signaling molecule, and ceramide as an intracellular signaling molecule, also exist. FAK = focal adhesion kinase; ICAD = inhibitor of caspase-activated DNase; PARP = poly(ADP-ribose) polymerase; SREBP = sterol regulatory element binding protein.

cleave internucleosomal DNA; cleavage of structural proteins (α-fodrin, actin, lamins) aids in disassembly of the cell; incapacitation of focal adhesion kinase (see Fig. 3-11) permits detachment of the cell from the extracellular matrix; and hydrolytic activation of sterol regulatory element-binding proteins may contribute to accumulation of sterols and externalization of phosphatidylserine in the plasma membrane that identify the apoptotic cell to phagocytes. Besides caspases, DNA fragmentation can be induced by apoptosis-inducing factor (AIF) and endonuclease G that are also released from the mitochondrial intermembrane space and may contribute to DNA fragmentation during apoptosis and acetaminophen-induced caspase-independent hepatocellular necrosis (Jaeschke and Bajt, 2006).

The decisive mitochondrial event of cell death, i.e., release of cyt c and other pro-apoptotic proteins (e.g., Smac, AIF), are controlled by the Bcl-2 family of proteins, which includes members that facilitate (e.g., Bax, Bak, Bad, Bid, Puma, Noxa) and those that inhibit (e.g., Bcl-2, Bcl-XL) these processes. The death-promoting members can oligomerize and form pores in the mitochondrial outer membrane. By doing so, they may facilitate release of cyt c and other intermembrane proapoptotic proteins via MPT induced by toxic insult of the mitochondria; however, mitochondrial outer membrane permeabilization (MOMP) alone by Bax and its congeners is sufficient to evoke egress of cyt c from the mitochondria. MOMP induced by Bax, Bak, and/or Bid is responsible for cyt c release in apoptosis initiated at extramitochondrial targets, including death receptors and the nuclear DNA (see below). The death-suppressor Bcl-2 and Bcl-XL can dimerize with the death-inducing counterparts and neutralize them. Thus, the relative amount of these antagonistic proteins functions as a regulatory switch between cell survival and death (Reed et al., 1998).

The proapoptotic Bax and Bid proteins, which can induce MOMP, represent links whereby death programs initiated extramitochondrially, e.g., by DNA damage in the nucleus or by stimulation of the so-called death receptors (Fas receptor and TNF receptor-1) at the cell surface, can engage the mitochondria into the apoptotic process (Green, 1998) (Fig. 3-16). DNA damage (evoked by ionizing and UV radiations, alkylating chemicals, and topoisomerase II inhibitors, such as doxorubicin (Adriamycin)) induces stabilization and activation of p53 protein, a transcription factor, which increases expression of proapoptotic members of the Bcl-family of proteins, such as Bax, Puma and Noxa (Liu and Chen, 2006) (see also Fig. 3-28). As discussed further on, DNA damage is potentially mutagenic and carcinogenic; therefore, apoptosis of cells with damaged DNA is an important self-defense of the body against oncogenesis. Furthermore, the antitumor drugs targeting the nuclear DNA exert their desirable toxic effects against tumor cells (and also their undesirable cytotoxic effects against rapidly dividing normal cells such as hematopoietic cells and small intestinal mucosal cells) by inducing apoptosis primarily via a p53-dependent mechanism.

Stimulation of TNF receptor-1 or Fas receptor by their ligands induces receptor oligomerization and recruitment of adapter proteins to activate the caspase cascade through their initiator procaspase, caspase-8 (Fig. 3-16). Nevertheless, death receptor activation can also engage the mitochondria into the apoptosis program via caspase-8-mediated cleavage of Bid. The Fas system is involved in cell-mediated cytotoxicity, as cytotoxic T lymphocytes express the Fas ligand that activates the Fas receptor in the membrane of potential target cells, such as those of the liver, heart, and lung. Cholestatic liver injury involves apoptosis induced by the retained hydrophobic bile acids mediated partly through their mitochondrial effect (i.e., MPT) and through the death receptors

(Higuchi and Gores, 2003). By activating PKC, toxic bile acids promote trafficking of Fas receptor and TRAIL-receptor-2 (another death receptor) from the Golgi complex into the plasma membrane of liver cells, where the increased receptor density induces spontaneous (i.e., ligand-independent) receptor oligomerization and caspase activation. Increased expression of soluble FasL and Fas receptor is thought to play a causative role in the apoptosis of pulmonary alveolar epithelial cells underlying acute lung injury (or acute respiratory distress syndrome) (Martin et al., 2005), a potentially lethal outcome of various pathologies and heroin intoxication. The Fas system also mediates germ cell apoptosis in the testes of rodents exposed to mono-(2-ethylhexyl)phthalate or 2,5-hexanedione, the ultimate toxicant formed from hexane. These chemicals damage the microtubules in the Sertoli cells that normally nurse the germ cells. Unable to support the germ cells, Sertoli cells overexpress the Fas ligand to limit the number of germ cells (which up-regulate their Fas receptor) by deleting them via apoptosis (Cohen et al., 1997; Lee et al., 1997).

Thus, apoptosis can be executed via multiple pathways, most involving caspase activation. The route preferred will depend, among others, on the initial insult (Fig. 3-16) as well as on the type and state of the cell. For example, T lymphocytes lacking the Bax gene can still undergo p53-dependent death in response to ionizing radiation, probably by increasing Fas expression (Fig. 3-16), whereas Bax-null fibroblasts cannot.

What Determines the Form of Cell Death?   For reasons discussed later, it is not inconsequential for the surrounding tissue whether a cell dies by apoptosis or necrosis. Therefore considerable research has focused on what determines the form of cell death. Interestingly, there are some common features in the process of apoptosis and necrosis. Both forms of cell death caused by cytotoxic agents may involve similar metabolic disturbances and MPT (Kim et al., 2003; Kroemer et al., 1998; Quian et al., 1999), and blockers of the latter (e.g., cyclosporin A, Bcl-2 overexpression) prevent both apoptosis and necrosis in different settings. Furthermore, many xenobiotics—such as the hepatotoxicant 1,1-dichloroethylene, thioacetamide, and cadmium as well as the nephrotoxicant ochratoxin—can cause both apoptosis and necrosis (Corcoran et al., 1994). However, toxicants tend to induce apoptosis at low exposure levels or early after exposure at high levels, whereas they cause necrosis later at high exposure levels. This indicates that the severity of the insult determines the mode of cell death. Based on experimental evidence it appears that larger toxic insults cause necrotic cell death rather than apoptosis because it incapacitates the cell to undergo apoptosis. This incapacitation may result from three causatively related cellular events, i.e., increasing number of mitochondria undergoing MPT, depletion of ATP, and failed activation of caspases or their inactivation.

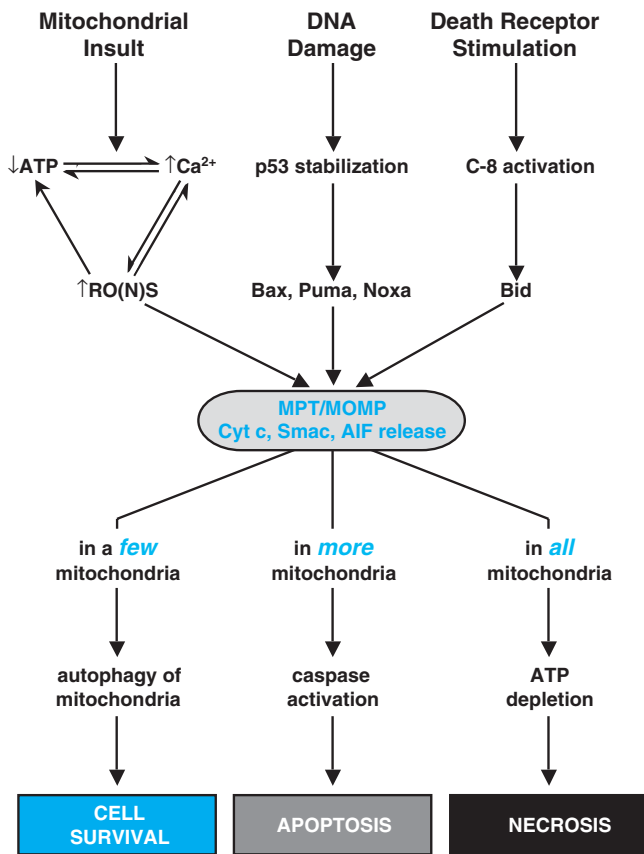
Lemasters and coworkers (Kim et al., 2003; Rodriguez-Enriquez et al., 2004) used confocal microscopy to visualize mitochondria in cells exposed to an apoptogenic stimulus and found that MPT does not occur uniformly in all mitochondria. They proposed a model in which the number of mitochondria undergoing MPT (which probably depends on the degree of chemical exposure) determines the fate of the cell. According to this model, when only a few mitochondria develop MPT, they are removed by lysosomal autophagy and the cell survives. When more mitochondria suffer MPT, the autophagic mechanism becomes overwhelmed, and the released proapoptotic factors (e.g., cyt c, Smac, AIF) initiate caspase activation and apoptosis (Fig. 3-16). When MPT involves virtually all mitochondria, cytolysis occurs. Figure 3-17 illustrates an expanded version of this model.


Figure 3-17. "Decision plan" on the fate of injured cell.

See the text for details. MOMP = mitochondrial outer membrane permeabilization; MPT = mitochondrial permeability transition; Puma = p53-up-regulated modulator of apoptosis; RO(N)S = reactive oxygen or nitrogen species.

For reasons discussed above, ATP is bound to become severely depleted in cells in which most mitochondria suffer MPT. The degree of ATP depletion may decide the fate of the cell. In experimental models as distinct as Ca^{2+}-exposed hepatocytes, Fas-stimulated T lymphocytes, and HOOH-exposed endothelial cells, necrosis occurs instead of apoptosis when cells are depleted of ATP, whereas apoptosis takes place rather than necrosis when ATP depletion is alleviated by providing substrates for ATP generation (Leist *et al.*, 1997; Kim *et al.*, 2003; Lelli *et al.*, 1998). Lack of ATP can prevent execution of the apoptotic program, because apoptosis involves ATP-requiring steps, such as activation of procaspase-9 in the apoptosome complex (Fig. 3-16).

Failure of caspase activation can also result from direct action of reactive toxicants on these enzymes. The active site of caspases is composed of a pentapeptide (QACXG) with a reactive cysteine in it. At high concentrations, soft electrophiles, disulfides (e.g., glutathione disulfide) and oxidants (e.g., ROS), can react with this cysteine, causing caspase inactivation and ablation of the apoptotic program, with necrosis rather than apoptosis as the final outcome. Such a scenario has been demonstrated for cell death evoked by tributyltin, pyrrolidine dithiocarbamate, and arsenic trioxide (Orrenius, 2004) and might also underlie the acetaminophen-induced hepatocellular necrosis, which involves cyt *c* release with no caspase activation or apoptosis (Jaeschke and Bajt, 2006).

Induction of Cell Death by Unknown Mechanisms   In addition to chemicals that ultimately injure mitochondria by disrupting oxidative phosphorylation and/or control of intracellular Ca^{2+}, there are toxicants that cause cell death by affecting other functions or structures primarily. Included here are (1) chemicals that directly damage the plasma membrane, such as lipid solvents, detergents, and venom-derived hydrolytic enzymes; (2) xenobiotics that damage the lysosomal membrane, such as aminoglycoside antibiotics and hydrocarbons binding to α_{2u}-globulin; (3) toxins that destroy the cytoskeleton, such as the microfilamental toxins phalloidin and cytochalasins, and the microtubular toxins colchicine and 2,5-hexanedione; (4) the protein phosphatase inhibitor hepatotoxicant microcystin, which causes hyperphosphorylation of microfilaments and other cellular proteins (Toivola and Eriksson, 1999); (5) toxins that disrupt protein synthesis, such as α-amanitin and ricin; and (6) cholesterol lowering drugs (statins) that inhibit HMG-coenzyme A reductase, the rate limiting enzyme in the mevalonate pathway, and rarely cause myotoxicity.

The events leading to cell death after exposure to these chemicals are generally unknown. It is likely that cell death caused by these chemicals is ultimately mediated by impairment of oxidative phosphorylation, sustained elevation of intracellular Ca^{2+}, and/or overproduction of ROS/RNS, and that it takes the form of necrosis if these processes are abrupt, but apoptosis if they are protracted. For example, direct injury of the plasma membrane would lead rapidly to increased intracellular Ca^{2+} levels. Neurofilamental toxins that block axonal transport cause energy depletion in the distal axonal segment. HMG-coenzyme A reductase inhibitors diminish not only the synthesis of cholesterol, but may also compromise formation of other products of the mevalonate pathway. Such are the mitochondrial electron transporting molecule ubiquinone (also called coenzyme Q) and isopentenyl pyrophosphate, which is utilized for isopentenylation of selenocysteinyl-tRNA, an obligatory step for synthesis of selenoproteins, including the antioxidant glutathione peroxidase (see Fig. 3-5) and thioredoxin reductase (see Fig. 3-19). These alterations may contribute to statin-induced myopathy and rhabdomyolysis.

Impairment of External Cellular Maintenance   Toxicants also may interfere with cells that are specialized to provide support to other cells, tissues, or the whole organism. Chemicals acting on the liver illustrate this type of toxicity. Hepatocytes produce and release into the circulation a number of proteins and nutrients. They remove cholesterol and bilirubin from the circulation, converting them into bile acids and bilirubin glucuronides, respectively, for subsequent excretion into bile. Interruption of these processes may be harmful to the organism, the liver, or both. For example, inhibition of hepatic synthesis of coagulation factors by coumarins does not harm the liver, but may cause death by hemorrhage (Hardman *et al.*, 1995). This is the mechanism of the rodenticidal action of warfarin. In the fasting state, inhibitors of hepatic gluconeogenesis, such as hypoglycin, may be lethal by limiting the supply of glucose to the brain. Similarly, Reye's syndrome, which is viewed as a hepatic mitochondrial injury caused by a combination of a viral disease (which may induce hepatic NOS) and intake of salicylate (which provokes MPT) (Fromenty and Pessayre, 1997; Kim *et al.*, 2003), causes not only hepatocellular injury but also severe metabolic disturbances (hypoglycemia, hyperammonemia) that affect other organs as well. Chemical interference with the β-oxidation of fatty acids or the synthesis, assembly, and secretion of lipoproteins overloads the hepatocytes

with lipids, causing hepatic dysfunction (Fromenty and Pessayre, 1997). α-Naphthylisothiocyanate causes separation of the intercellular tight junctions that seal bile canaliculi (Krell *et al.*, 1987), impairing biliary secretion and leading to the retention of bile acids and bilirubin; this adversely affects the liver as well as the entire organism.

STEP 4—INAPPROPRIATE REPAIR AND ADAPTATION

The fourth step in the development of toxicity is inappropriate repair and adaptation (Fig. 3-1). As noted previously, many toxicants alter macromolecules, which eventually cause damage at higher levels of the biological hierarchy in the organism. Progression of toxic lesions can be intercepted by repair mechanisms operating at molecular, cellular, and tissue levels (Fig. 3-18). Another strategy whereby the organism can resist the noxious chemical is by increasing its own readiness to cope with it and with its harmful effects. This phenomenon is called adaptation. Because the capacity of the organism to repair itself and adapt to the toxic exposure and effects is so important in determining the outcome of chemical exposure, the mechanisms of repair and adaptation will be discussed below.

Mechanisms of Repair

Molecular Repair   Damaged molecules may be repaired in different ways. Some chemical alterations, such as oxidation of protein thiols and methylation of DNA, are simply reversed. Hydrolytic removal of the molecule's damaged unit or units and insertion of a newly synthesized unit or units often occur with chemically altered DNA and peroxidized lipids. In some instances, the damaged molecule is totally degraded and resynthesized. This process is time-consuming but unavoidable in cases such as the regeneration of cholinesterase after organophosphate intoxication.

Repair of Proteins   Thiol groups are essential for the function of numerous proteins, such as receptors, enzymes, cytoskeletal proteins, and TFs. Oxidation of protein thiols (Prot-SHs) to protein disulfides (Prot-SS, Prot$_1$-SS-Prot$_2$), protein-glutathione mixed disulfides (Prot-SSG), and protein sulfenic acids (Prot-SOH) as well

as oxidation of methionine in proteins to methionine sulfoxide can be reversed by enzymatic reduction (Watson *et al.*, 2004; Gravina and Mieyal, 1993; Moskovitz, 2005) (Fig. 3-19). The endogenous reductants are thioredoxins and glutaredoxins, small, ubiquitous proteins with two redox-active cysteines in their active centers (Holmgren *et al.*, 2006). These proteins as well as thioredoxin-reductase have two isoenzymes; those labeled 1 are located in the cytosol, whereas 2 are mitochondrial. Because the catalytic thiol groups in these proteins become oxidized, they are reduced by NADPH, which is generated by NADP$^+$-dependent isocitrate dehydrogenase localized in various cell compartments (cytosol, mitochondria, peroxysomes), as well as by the cytosolic glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase in the pentose phosphate pathway. Repair of oxidized hemoglobin (methemoglobin) occurs by means of electron transfer from cytochrome b_5, which is then regenerated by a NADH-dependent cytochrome b_5 reductase (also called methemoglobin reductase).

Soluble intracellular proteins are susceptible to denaturation (misfolding) and aggregation by physical or chemical insults. Molecular chaperones such as the heat-shock proteins can rescue denatured proteins by ATP-dependent disaggregation and refolding, or by engaging the chaperone-dependent ubiquitin ligase CHIP, assist in their degradation by proteasomes (Lee and Tsai, 2005). Proteasomes are large ATP-consuming protease complexes in the cytosol that not only control the level of regulatory proteins (e.g., p53, IκB, Nrf2, cyclins), but also have a predominant role in eliminating oxidized, misfolded, or otherwise damaged intracellular proteins (Poppek and Grune, 2006). For example, CYP2E1, in which the heme becomes cross-linked to the protein as a consequence of reductive dechlorination of CCl$_4$ to the trichloromethyl free radical by this enzyme, is eliminated by proteosomal degradation. Damaged proteins are first conjugated with ubiquitin in an ATP-dependent manner, allowing their recognition by the proteosome that degrades them. Damaged proteins can be eliminated also by proteolysis in lysosomes. For example, lysosomal proteases degrade the immunogenic trifluoroacetylated proteins that are formed in the liver during halothane anesthesia (Cohen *et al.*, 1997). Damaged proteins enter lysosomes by autophagy, i.e., ATP-demanding enclosure into membrane vesicles (autophagosomes) that fuse with lysosomes (Meijer and Codogno, 2004). Erythrocytes have

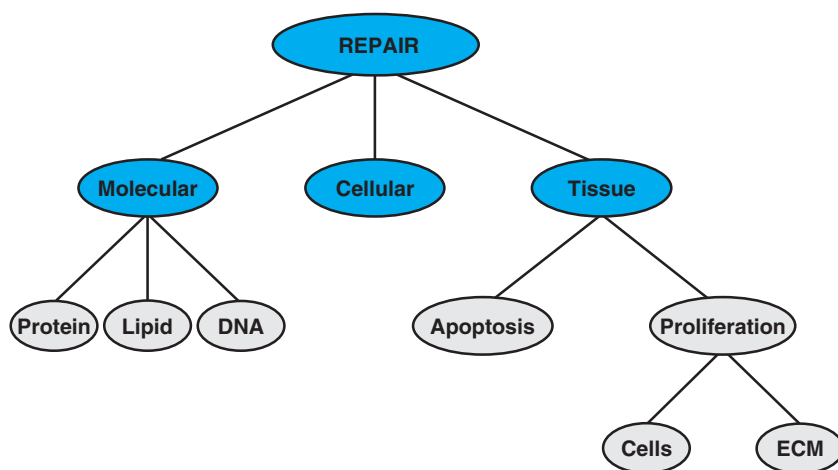

Figure 3-18. Repair mechanisms.

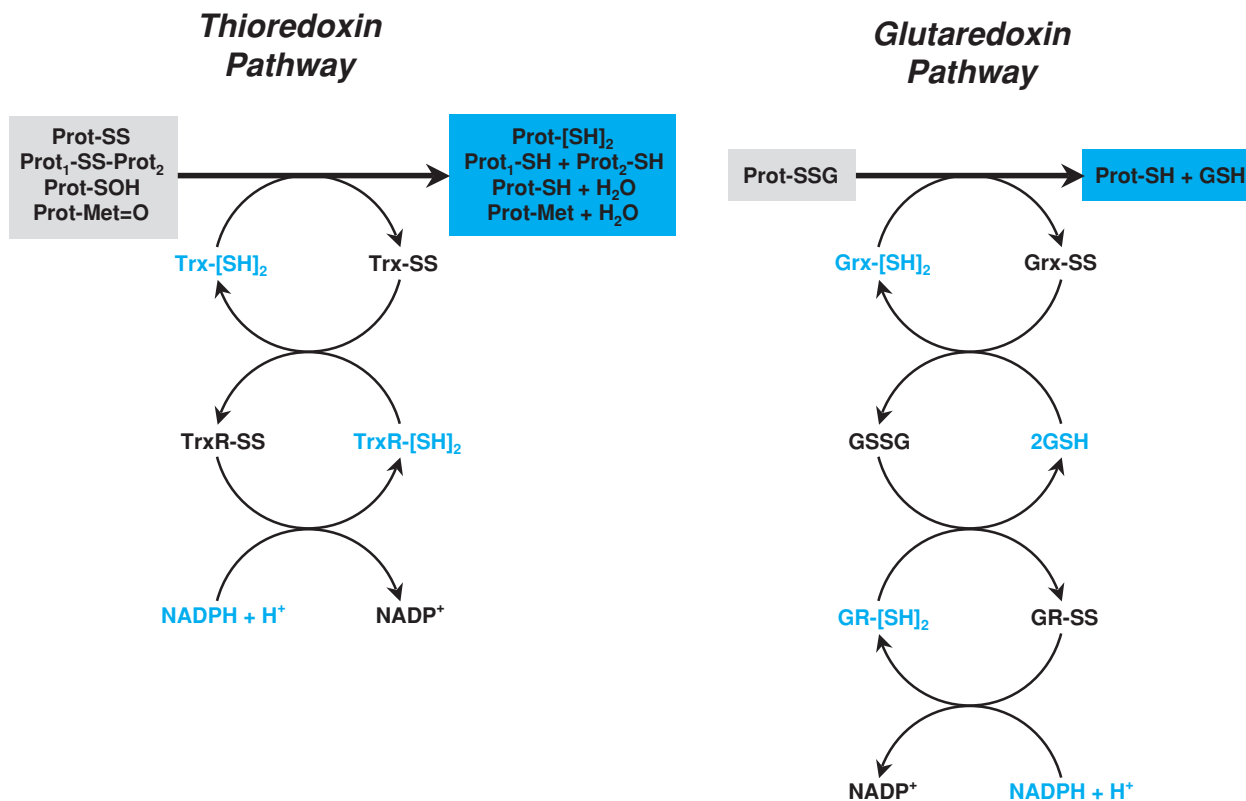
Dysfunction of these mechanisms results in dysrepair, the fourth step in the development of numerous toxic injuries. ECM = extracellular matrix.


Figure 3-19. Repair of proteins oxidized at their thiol groups.

Protein disulfides (Prot-SS, $Prot_1$-SS-$Prot_2$), protein sulfenic acids (Prot-SOH) and protein methionine sulfoxides (Prot-Met=O) are reduced by thioredoxin (Trx-[SH]$_2$) with methionine sulfoxide reductases catalyzing the latter process. Protein-glutathione mixed disulfides (Prot-SSG) are reduced by glutaredoxin (Grx-[SH]$_2$), which is also called thioltransferase. The figure also indicates how Trx-[SH]$_2$ and Grx-[SH]$_2$ are regenerated from their disulfides (Trx-SS and Grx-SS, respectively). In the mitochondria, Trx-SS also can be regenerated by the dithiol dihydrolipoic acid, a component of the pyruvate- and α-ketoglutarate dehydrogenase complexes. GSH = glutathione; GSSG = glutathione disulfide; GR-[SH]$_2$ and GR-SS = glutathione reductase (dithiol and disulfide forms, respectively); TrxR-[SH]$_2$ and Trx-SS = thioredoxin-reductase (dithiol and disulfide forms, respectively).

ATP-independent, nonlysosomal proteolytic enzymes that rapidly and selectively degrade proteins denatured by HO$^\bullet$ (Davies, 1987). Removal of damaged and aggregated proteins is especially critical in the eye lens for maintenance of its transparency.

Repair of Lipids   Peroxidized lipids are repaired by a complex process that operates in concert with a series of reductants as well as with glutathione peroxidase and reductase (Fig. 3-20). Phospholipids containing fatty acid hydroperoxides are preferentially hydrolyzed by phospholipase A2, with the peroxidized fatty acids replaced by normal fatty acids (van Kuijk *et al.*, 1987). Again, NADPH is needed to "repair" the reductants that are oxidized in the process.

Repair of DNA   Despite its high reactivity with electrophiles and free radicals, nuclear DNA is remarkably stable, in part because it is packaged in chromatin and because several repair mechanisms are available to correct alterations. The mitochondrial DNA, however, lacks histones and efficient repair mechanisms and therefore is more prone to damage. Different types of damages are corrected by specialized mechanisms, each employing a different set of repair proteins (Christmann *et al.*, 2003).

Direct Repair   Certain covalent DNA modifications are directly reversed by enzymes such as DNA photolyase, which cleaves adjacent pyrimidines dimerized by UV light. Inasmuch as this chromophore-equipped enzyme uses the energy of visible light to correct damage, its use is restricted to light-exposed cells.

Minor adducts, such as methyl groups, attached to DNA bases by alkylating agents (e.g., methylmethane sulfonate) may be removed by special enzymes (Christmann *et al.*, 2003). Such groups attached to the O^6 position of guanine are cleaved off by O^6-methyguanine-DNA-methyltransferase (MGMT). While repairing the DNA, this alkyltransferase sacrifices itself, transferring the adduct onto one of its cysteine residues. This results in its inactivation, ubiquitination, and proteosomal degradation. Thus, like glutathione, which is depleted during detoxication of electrophiles, MGMT is consumed during the repair of DNA. Methyl groups attached to N^1 of adenine and guanine, and N^3 of thymine and cytosine are removed by oxidative demethylation catalyzed by DNA dioxygenases (ABH2 and ABH3). These peculiar O_2, Fe^{2+}, ascorbate, and 2-oxoglutarate dependent enzymes oxygenate the methyl group adduct, which in turn leaves as formaldehyde, while 2-oxoglutarate is oxidatively decarboxylated to succinate.

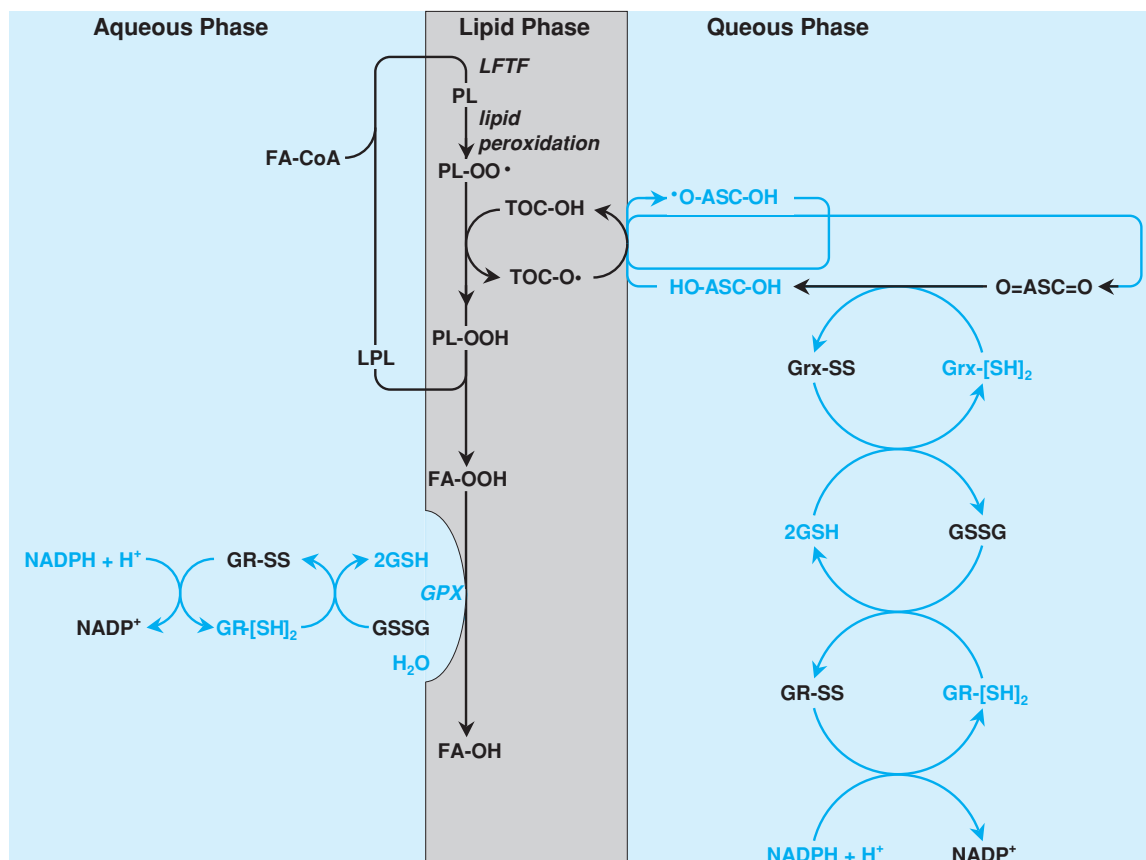
Excision Repair   Base excision and nucleotide excision are two mechanisms for removing damaged bases from DNA (see


Figure 3-20. Repair of peroxidized lipids.

Phospholipid peroxyl radicals (PL-OO$^\bullet$) formed as a result of lipid peroxidation (Fig. 3-9) may abstract hydrogen from alpha-tocopherol (TOC-OH) and yield phospholipid hydroperoxide (PL-OOH). From the latter, the fatty acid carrying the hydroperoxide group is eliminated via hydrolysis catalyzed by phospholipase (PLase), yielding a fatty acid hydroperoxide (FA-OOH) and a lysophospholipid (LPL). The former is reduced to a hydroxy-fatty acid (FA-OH) by glutathione peroxidase (GPX), utilizing glutathione (GSH), or by peroxiredoxins (not shown), whereas the latter is reacylated to phospholipid (PL) by lysophosphatide fatty acyl-coenzyme A transferase (LFTF), utilizing long-chain fatty acid-coenzyme A (FA-CoA). The figure also indicates regeneration of TOC-OH by ascorbic acid (HO-ASC-OH), regeneration of ascorbic acid from dehydroascorbic acid (O=ASC=O) by glutaredoxin (Grx-[SH]$_2$), and reduction of the oxidized glutaredoxin (Grx-SS) by GSH. Oxidized glutathione (GSSG) is reduced by glutathione reductase (GR-[SH]$_2$), which is regenerated from its oxidized form (GR-SS) by NADPH, the ultimate reductant. NADPH is produced by NADP$^+$-dependent isocitrate dehydrogenases and during metabolism of glucose via the pentose phosphate shunt. TOC-O$^\bullet$= tocopheroxyl radical; $^\bullet$O-ASC-OH = ascorbyl radical.

Chaps. 8 and 9). Lesions that do not cause major distortion of the helix typically are removed by base excision, in which the altered base is recognized by a relatively substrate-specific DNA-glycosylase that hydrolyzes the N-glycosidic bond, releasing the modified base and creating an apurinic or apyrimidinic (AP) site in the DNA. For example, 8-hydroxyguanine (8-OH-Gua), a major mutagenic product of oxidative stress, is removed from the DNA by specific 8-OH-Gua DNA glycosylase. The AP site is recognized by the AP endonuclease, which hydrolyzes the phosphodiester bond adjacent to the abasic site. After its removal, the abasic sugar is replaced with the correct nucleotide by a DNA polymerase and is sealed in place by a DNA ligase. Interestingly, AP endonuclease is a bifunctional protein and is also called redox factor-1 (Ref-1). In concert with thioredoxin and thioredoxin-reductase, it maintains transcription factors with sensitive thiol groups in their DNA-binding do-

main (Fos, Jun, NF-κB) in an active reduced state (Hansen *et al.*, 2006).

Bulky lesions such as adducts produced by aflatoxins or aminofluorene derivatives and dimers caused by UV radiation are removed by nucleotide-excision repair, which employs approximately 30 proteins (Christmann *et al.*, 2003). Lesions in the non-transcribed strands or the non-transcribed regions of the genome are corrected by the global genomic repair system. This involves proteins that recognize the distorted double helix at the lesion, unwind the DNA, excise a number of intact nucleotides on both sides of the lesion together with the one containing the adduct. The excised section of the strand is restored by insertion of nucleotides into the gap by DNA polymerase and ligase, using the complementary strand as a template. Lesions in the transcribed DNA strand blocking the RNA polymerase in the actively transcribed genes are removed by another

variation of nucleotide excision repair, the transcription-coupled repair system. This involves assembly of repair proteins to remove the stalled RNA polymerase before excision of the damage and filling the gap. Resynthesis of the removed section of the strand is designated "unscheduled DNA synthesis" and can be detected by the appearance of altered deoxynucleosides in urine. Excision repair has a remarkably low error rate of less than 1 mistake in 10^9 bases repaired.

Poly(ADP-ribose)polymerase (PARP) appears to be an important contributor in excision repair. Upon base damage or single-strand break, PARP binds to the injured DNA and becomes activated. The active PARP cleaves NAD^+ to use the ADP-ribose moiety of this cofactor for attaching long chains of polymeric ADP-ribose to nuclear proteins, such as histones. Because one ADP-ribose unit contains two negative charges, the poly(ADPribosyl)ated proteins accrue negativity and the resultant electrorepulsive force between the negatively charged proteins and DNA causes decondensation of the chromatin structure. It is hypothesized that PARP-mediated opening of the tightly packed chromatin allows the repair enzymes to access the broken DNA and fix it. Thereafter, poly(ADP-ribose) glycohydrolase gains access to the nucleus from its perinuclear localization and reverses the PARP-mediated modification of nuclear proteins (D'Amours *et al.*, 1999). Other features of PARP that are relevant in toxicity—such as destruction of PARP by caspases during apoptosis as well as the significance of NAD^+ (and consequently ATP) wasting by PARP in necrosis—have been discussed earlier in this chapter.

Recombinational (or Postreplication) Repair   Recombinational repair occurs when the excision of a bulky adduct or an intrastrand pyrimidine dimer fails to occur before DNA replication begins. At replication, such a lesion prevents DNA polymerase from polymerizing a daughter strand along a sizable stretch of the parent strand that carries the damage. The replication results in two homologous ("sister") yet dissimilar DNA duplexes; one has a large postreplication gap in its daughter strand and an intact duplex synthesized at the opposite leg of the replication fork. This intact sister duplex is utilized to complete the postreplication gap in the damaged sister duplex. This is accomplished by recombination ("crossover") of the appropriate strands of the two homologous duplexes. After separation, the sister duplex that originally contained the gap carries in its daughter strand a section originating from the parent strand of the intact sister, which in turn carries in its parent strand a section originating from the daughter strand of the damaged sister. This strand recombination explains the phenomenon of "sister chromatid exchange," which is indicative of DNA damage corrected by recombinational repair. This process also repairs double breaks, which can also be repaired by the so-called DNA nonhomologous end-joining system that ligates DNA ends and employs several proteins including DNA-dependent protein kinase. A combination of excision and recombinational repairs occurs in restoration of DNA with interstrand cross-links.

Cellular Repair: A Strategy in Peripheral Neurons   Repair of damaged cells is not a widely applied strategy in overcoming cellular injuries. In most tissues, injured cells die, with the survivors dividing to replace the lost cells. A notable exception is nerve tissue, because mature neurons have lost their ability to multiply. In peripheral neurons with axonal damage, repair does occur and requires macrophages and Schwann cells. Macrophages remove debris by phagocytosis and produce cytokines and growth factors, which activate Schwann cells to proliferate and transdifferentiate from myelinating operation mode into a growth-supporting mode. Schwann cells play an indispensable role in promoting axonal regeneration by increasing their synthesis of cell adhesion molecules (e.g., N-CAM), by elaborating extracellular matrix proteins for base membrane construction, and by producing an array of neurotrophic factors (e.g., nerve growth factor, glial–cell line–derived growth factor) and their receptors (Fu and Gordon, 1997). While comigrating with the regrowing axon, Schwann cells physically guide as well as chemically lure the axon to reinnervate the target cell.

In the mammalian central nervous system, axonal regrowth is prevented by growth inhibitory glycoproteins (e.g., NI 35, myelin-associated glycoprotein) and chondroitin sulfate proteoglycans produced by the oligodendrocytes and by the scar produced by astrocytes (Johnson, 1993). Thus, damage to central neurons is irreversible but is compensated for in part by the large number of reserve nerve cells that can take over the functions of lost neurons. For example, in Parkinson's disease, symptoms are not observed until there is at least an 80% loss of nigrostriatal neurons.

Tissue Repair   In tissues with cells capable of multiplying, damage is reversed by deletion of the injured cells and regeneration of the tissue by proliferation. The damaged cells are eliminated by apoptosis or necrosis.

Apoptosis: An Active Deletion of Damaged Cells   Apoptosis initiated by cell injury can be regarded as tissue repair for two reasons, the first of which is that it may intercept the process leading to necrosis, as discussed earlier (see Fig. 3-17). Necrosis is a more harmful sequel than apoptosis for the tissue in which the injured cell resides. A cell destined for apoptosis shrinks; its nuclear and cytoplasmic materials condense, and then it breaks into membrane-bound fragments (apoptotic bodies) that are phagocytosed (Bursch *et al.*, 1992). During necrosis, cells and intracellular organelles swell and disintegrate with membrane lysis. Whereas apoptosis is orderly, necrosis is a disorderly process that ends with cell debris in the extracellular environment. The constituents of the necrotic cells attract aggressive inflammatory cells, and the ensuing inflammation amplifies cell injury (see further on). With apoptosis, dead cells are removed without inflammation. Second, apoptosis may intercept the process leading to neoplasia by eliminating the cells with potentially mutagenic DNA damage. This function of apoptosis is discussed in more detail in the final section of this chapter.

It must be emphasized, however, that apoptosis of damaged cells has a full value as a tissue repair process only for tissues that are made up of constantly renewing cells (e.g., the bone marrow, the respiratory and gastrointestinal epithelium, and the epidermis of the skin), or of conditionally dividing cells (e.g., hepatic and renal parenchymal cells), because in these tissues the apoptotic cells are readily replaced. The value of apoptosis as a tissue repair strategy is markedly lessened in organs containing nonreplicating and nonreplaceable cells, such as the neurons, cardiac muscle cells, and female germ cells, because deletion of such cells, if extensive, can cause a deficit in the organ's function. Apoptosis in the pulmonary alveolar epithelium, an extremely tight barrier, could cause flooding of the alveolar space with interstitial fluid, a potentially lethal outcome.

Proliferation: Regeneration of Tissue   Tissues are composed of various cells and the extracellular matrix. Tissue elements are anchored to each other by transmembrane proteins. Cadherins allow

adjacent cells to adhere to one another, whereas connexins connect neighboring cells internally by associating these proteins into tubular structures (gap junctions). Integrins link cells to the extracellular matrix. Therefore, repair of injured tissues involves not only regeneration of lost cells and the extracellular matrix but also reintegration of the newly formed elements. In parenchymal organs such as liver, kidney, and lung, various types of cells are involved in the process of tissue restoration. Nonparenchymal cells of mesenchymal origin residing in the tissue, such as resident macrophages and endothelial cells, and those migrating to the site of injury, such as blood monocytes, produce factors that stimulate parenchymal cells to divide and stimulate some specialized cells (e.g., the stellate cells in the liver) to synthesize extracellular matrix molecules.

Replacement of Lost Cells by Mitosis   Soon after injury, cells adjacent to the damaged area enter the cell division cycle (Fig. 3-21). Enhanced DNA synthesis is detected experimentally as an increase in the labeling index, which is the proportion of cells that incorporate administered ^{3}H-thymidine or bromodeoxyuridine into their nuclear DNA during the S phase of the cycle. Also, mitotic cells can be observed microscopically. As early as 2 to 4 hours after administration of a low dose of carbon tetrachloride to rats, the mitotic index in the liver increases dramatically, indicating that cells already in the G_2 phase progress rapidly to the M phase. The mitotic activity of the hepatocytes culminates at 36 to 48 hours, after a full transit through the cycle, indicating that quiescent cells residing in G_0 enter and progress to mitosis (M). Peak mitosis of nonparenchymal cells occurs later, after activation and replication of parenchymal cells. In some tissues, such as intestinal mucosa and bone marrow, stem cells first divide to provide self-renewal and then differentiate to replace more mature cells lost through injury. Stem cell-derived cells, called oval cells, are also located in the liver, in the bile ductules. In severe toxic liver injury, when hepatocyte replication is impaired (e.g., in rats dosed with galactosamine or acetylaminofluorene, and in humans intoxicated with acetaminophen), the oval cells proliferate and differentiate into both hepatocytes and biliary epithelial cells (Fausto *et al.*, 2006; Vessey and Hall, 2001). As these cells produce α-fetoprotein, the level of serum α-fetoprotein correlates with improved outcome of acetaminophen-induced injury. In an ozone-exposed lung, the nonciliated Clara cells and type II pneumocytes undergo mitosis and terminal differentiation to replace, respectively, the damaged ciliated bronchial epithelial cells and type I pneumocytes (Mustafa, 1990).

Sequential changes in gene expression occur in the cells that are destined to divide. In rats subjected to partial hepatectomy to study the regeneration of the liver, oligonucleotide microarray analysis revealed that more than 150 genes involved in the early gene response with up or down-regulation (Su *et al.*, 2002). The overexpressed genes include those that code for transcription factors important in proliferative signaling, such as c-*fos*, c-*jun, Egr1,* and c-*myc* (see Fig. 3-11), the genes of the antiapoptotic protein Bcl-X$_L$ (see Fig. 3-16), and that of the cell cycle accelerator protein mdm2 (see Fig. 3-27). Interestingly, some genes whose products decelerate the cell cycle also become temporarily overexpressed (e.g., the cyclin dependent kinase inhibitor p21 and gadd45; see Fig. 3-27), suggesting that this duality keeps tissue regeneration precisely regulated. Nevertheless, the genetic expression is apparently reprogrammed so that DNA synthesis and mitosis gain priority over specialized cellular activities. For example, as a result of dedifferentiation, regenerating hepatocytes underexpress cytochrome P450, N-acetyltransferase-2 as well as PPARα, and hepatic stellate cells cease to accumulate fat and vitamin A.

Figure 3-21. *The cell division cycle and the participating cyclins and cyclin-dependent protein kinases.*

Areas representing phases of the cycle are meant to be proportional to the number of cells in each phase. Normally, most cells are in G_0 phase, a differentiated and quiescent state. After receiving signals to divide, they progress into the G_1 phase of the cell division cycle. G_0/G_1 transition involves activation of immediate early genes so that cells acquire replicative competence. Now increasingly responsive to growth factors, these cells progress to the phase of DNA synthesis (S). If this progression is blocked (e.g., by the accumulated p53 protein), the cells may undergo apoptosis (A). After DNA replication, the cells prepare further for mitosis in the G_2 phase. Mitosis (M) is the shortest phase of the cell cycle (approximately 40 min out of the 40-h-long cycle of hepatocytes) and most likely requires the largest energy expenditure per unit of time. The daughter cells produced may differentiate and enter into the pool of quiescent cells (G_0), substituting for those which had been lost. During the cycle, the levels of various cyclins temporarily surge by synthesis and degradation (see figure). These proteins bind to and activate specific cyclin-dependent protein kinases (Cdk, see figure), which, in turn, phosphorylate and thus activate enzymes and other proteins required for DNA replication and cell division (Johnson and Walker, 1999) (see Fig. 3-27). In addition to cyclines, phosphorylation also regulate the activity of Cdks: phosphorylation by Wee1 protein kinase inactivates Cdk 1 and Cdk 2, whereas dephosphorylation by cdc25 phosphatases activates them. After tissue necrosis, the number of cells entering the cell division cycle markedly increases at areas adjacent to the injury. The proportion of cells that are in S phase in a given period is reflected by the labeling index, whereas the percentage of cells under going mitosis is the mitotic index (see text).

It has been speculated that the regenerative process is initiated by the release of chemical mediators from damaged cells. The nonparenchymal cells, such as resident macrophages and endothelial cells, are receptive to these chemical signals and produce a host of secondary signaling molecules, cytokines, and growth factors that promote and propagate the regenerative process (Fig. 3-22). In rodents subjected to partial hepatectomy the initial or priming phase of liver regeneration is controlled by the cytokines TNF-α and IL-6, whose hepatic mRNA and serum levels increase. TNF-α originates
Figure 3-22. Mediators of tissue repair and side reactions to tissue injury in liver: (1) growth factors promoting replacement of cells and the extracellular matrix; (2) mediators of inflammation, acute-phase protein AAP synthesis, and fever; and (3) cytotoxic mediators of inflammatory cells.

HGF = hepatocyte growth factor; PDGR = platelet-derived growth factor; TGF-α = transforming growth factor-alpha, TGF-β = transforming growth factor-beta; NO$^\bullet$ = nitric oxide; PGI$_2$ = prostacyclin; LTC$_4$ = leukotriene C$_4$; IL = interleukin; LTB$_4$ = leukotriene B$_4$; PAF = platelet-activating factor; CINC (the rat homolog of IL-8) = cytokine-induced neutrophil chemoattractant; MCP-1 = monocyte chemotactic protein; TNF = tumor necrosis factor. Cells presented are E = endothelial cells; G = granulocyte; H = hepatocyte; M = macrophage (Kupffer cell); S = stellate cell (also called perisinusoidal, Ito or fat-storing cell). *Rather than the endothelial cells, other stromal cells are the main sources of chemokines (e.g., stellate cells for MCP-1). Solid arrows represent effects of growth factors on cell division, whereas the dashed arrow shows the effect on extracellular matrix formation. Positive and negative signs indicate stimulation and inhibition, respectively. See text for further details.

from the Kupffer cells. This cytokine acts on these macrophages in an autocrine manner, activating its receptor (item 2 in Fig. 3-11) and the coupled signal transducing network. This in turn causes activation of NF-κB, which increases IL-6 expression. The secreted IL-6 then acts on the hepatocytes and through its receptor (item 1 in Fig. 3-11) activates JAK (Janus kinase) and induces transcription factors (e.g., Stat3, C/EBPβ), which activate several target genes. This cytokine network promotes transition of the quiescent liver cells (G$_0$) into cell cycle (G$_1$) and makes them receptive to growth factors ("priming"). Growth factors, especially the hepatocyte growth factor (HGF), transforming growth factor-α (TGF-α), and heparin-binding epidermal growth factor-like growth factor

(HB-EGF), initiate the progression of the "primed" cells in the cycle toward mitosis (Costa *et al.*, 2003; Fausto *et al.*, 2006). Despite its name, neither the formation nor the action of HGF is restricted to the liver. It is produced by resident macrophages and endothelial cells of various organs—including liver, lung, and kidney—and in a paracrine manner activates receptors on neighboring parenchymal cells (Fig. 3-22). In rats intoxicated with carbon tetrachloride, the synthesis of HGF in hepatic and renal nonparenchymal cells increases markedly (Noji *et al.*, 1990) and HGF levels in blood rise rapidly (Lindroos *et al.*, 1991). The communication between parenchymal and nonparenchymal cells during tissue repair is mutual. For example, TGF-α, a potent mitogen produced by regenerating hepatocytes, acts both as an autocrine and a paracrine mediator on liver cells as well as on adjacent nonparenchymal cells (Fig. 3-22). By activating their receptors (item 4 in Fig. 3-11), these growth factors initiate signaling through the MAPK pathway and the PI3K – Akt pathway (Fig. 3-11), thereby mediate activation of transcription factors (c-Jun, c-Fos, c-Myc, FoxM1B, NF-κB, Stat3). These among others, induce cyclins and the protein phosphatase cdc25, two groups of short-lived regulatory proteins. Then cyclins activate Cdks by associating with them (Figs. 3-21), whereas cdc25 activates Cdk1 and Cdk2 by dephosphorylating their two amino-acid residues (Thr14 and Tyr15). The activated Cdks accelerate the cell cycle mainly by phosphorylation of pRb. This in turn releases the transcription factor E2F, which induces enzymes and regulatory proteins needed for cell cycle progression (Fig. 3-27). The growth factor signaling also activates mTOR (mammalian target of rapamycin) which up-regulates mRNA translation, thereby meeting the demand for increased protein synthesis (see Fig. 3-25). Similar signaling appears to mediate regeneration of the *S*-(1,2-dichlorovinyl)-L-cysteine-injured kidney that exhibits increased expression of the cytokine IL-6, the growth factors TGF-α and HB-EGF, the growth factor receptors EGFR (also receptor for TGF-α) and IGF-1R, and the MAP kinase isoform Erk1 (Vaidya *et al.*, 2003).

Although the cytotokine- and growth factor-controlled mitotic cell replacement is likely an essential part in the repair of most tissues built up of cells with proliferative capacity, there are also tissue specific features of tissue repair. For example in the liver, bile acids also stimulate hepatocyte proliferation through their nuclear receptor, FXR (Huang *et al.*, 2006). In mice subjected to partial hepatectomy, liver regrowth is hastened by bile acid feeding, but is markedly delayed when FXR is deleted or recirculation of bile acids from the intestine to the liver is prevented. Epithelia composed of a single cell layer form important barriers; therefore replacement of mortally injured epithelial cells, which become detached from the basement membrane, is an urgent need. This can be achieved more rapidly by cell migration than by mitotic cell replacement. For example, in the damaged mucosa of the gastrointestinal tract, cells of the residual epithelium rapidly migrate to the site of injury as well as elongate and thin to reestablish the continuity of the surface even before this could be achieved by cell replication. Cell movement involves orderly dissociation of cadherin-mediated cell-cell contacts (involving β-catenin phosphorylation) and integrin-mediated cell-ECM contacts at focal adhesions (involving FAK phosphorylation), assembly of actin stress fibers, and formation of lamellopodia (cell projection filled with F-actin meshwork). Mucosal repair is dictated not only by growth factors and cytokines operative in tissue repair elsewhere but also by trefoil factors (TFF). TFFs are small (7–12 kDa) protease-resistant proteins that are abundantly secreted from specific mucosal cells (e.g., intestinal goblet cells) and are associated with the mucous layer of the gastrointestinal tract (Taupin

and Podolsky, 2003). TFF expression is rapidly up-regulated at the margins of mucosal injury by cytokine and growth factor signaling. Whereas growth factors (e.g., HGF and EGF) exert both motogenic (motility-increasing) and mitogenic effects on enterocytes, TFFs are potent motogens, but are not mitogens. Although TFFs do not act alone, they are the only peptides shown to be essential for restitution of the injured intestinal mucosa. Normal mice exposed to dextran sodium sulfate in the drinking water develop diffuse colonic mucosal injury some exhibiting bloody diarrhea. In contrast, the majority of TFF3-null mice develop frank bloody diarrhea and die in response to dextran sodium sulfate. The immediate target molecule (e.g., receptor) for TFFs remains unknown. Migration of the surviving cells also precedes mitotic cell replacement in the tubular epithelium of the injured kidney. It appears that extracellular matrix components, such as collagen IV, beneath the tubular epithelial cells aid in the restitution of the injured epithelium and reestablishment of its polarity (Nony and Schnellmann, 2003).

Replacement of the Extracellular Matrix   The extracellular matrix is composed of proteins, glycosaminoglycans, and the glycoprotein and proteoglycan glycoconjugates (Gressner, 1992). In liver, these molecules are synthesized by stellate or fat storing cells located in the space of Disse, between the hepatic sinusoid and the hepatocytes (Fig. 3-22). The stellate cells become activated during liver regeneration, undergoing mitosis and major phenotypic changes. The latter changes include not only increased synthesis and secretion of extracellular matrix constituents, but also expression of α-smooth muscle actin and loss of fat, vitamin A and PPARγ content. Thus, resting stellate cells become transdifferentiated into myofibroblast-like contractile and secretory cells. Activation of stellate cells is mediated chiefly by two growth factors—platelet-derived growth factor (PDGF) and transforming growth factor-β (TGF-β) (Fig. 3-22). Both may be released from platelets (that accumulate and degranulate at sites of injury) and later from the activated stellate cells themselves. The main sources of TGF-β, however, are the neighboring tissue macrophages residing in the hepatic sinusoids (Gressner, 1992). A dramatic increase in TGF-β mRNA levels in Kupffer cells is observed with in situ hybridization after carbon tetrachloride-induced hepatic necrosis. Proliferation of stellate cells is induced by the potent mitogen PDGF, whereas TGF-β acts on the stellate cells to induce their transdifferentiation and to stimulate the synthesis of extracellular matrix components, including collagens, fibronectin, tenascin, and proteoglycans. TGF-β acts through its Ser/Thr kinase receptor (item 8 in Fig. 3-11), which phosphorylates the transcription factors Smad2 and 3 (Flanders, 2004). TGF-β also plays a central role in extracellular matrix formation in other tissues. In kidney and lung, for example, TGF-β targets the mesangial cells and the septal fibroblasts, respectively. Remodeling of the extracellular matrix is aided by matrix metalloproteinases, which hydrolyse specific components of the matrix, as well as by tissue inhibitors of matrix metalloproteinases. The former group of these proteins originates from various types of nonparenchymal cells, including inflammatory cells; however, their inhibitors are mainly produced by stellate cells (Arthur *et al.*, 1999).

The way in which tissue regeneration is terminated after repair is unclear, but the gradual dominance of TGF-β, which is a potent antimitogen and apoptogen, over mitogens is a contributing factor in the termination of cell proliferation. Extracellular matrix production may be halted by an intracellular negative feedback mechanism in the ECM producing cells, i.e., by induction of Smad7 (an inhibitory Smad), which competitively inhibits phosphorylation of the receptor-activated Smads (Smad2 and 3). In addition, extracel-

lular products of the proliferative response, such as the proteoglycan decorin and the positive acute phase protein alpha$_2$-macroglobulin, can bind and inactivate TGF-β, thereby they may contribute to its silencing (Gressner, 1992).

Side Reactions to Tissue Injury   In addition to mediators that aid in the replacement of lost cells and the extracellular matrix, resident macrophages and endothelial cells activated by cell injury also produce other mediators that induce ancillary reactions with uncertain benefit or harm to tissues (Fig. 3-22). Such reactions include inflammation, altered production of acute-phase proteins, and generalized reactions such as fever.

Inflammation-Leukocyte Invasion Alteration of the microcirculation and accumulation of inflammatory cells are the hallmarks of inflammation. These processes are largely initiated by resident macrophages secreting cytokines, such as TNF-α and interleukin-1 (IL-1), in response to tissue damage (Baumann and Gauldie, 1994) (Fig. 3-22). These cytokines, in turn, stimulate neighboring stromal cells, such as the endothelial cells and fibroblasts, to release mediators that induce dilation of the local microvasculature and cause permeabilization of capillaries. Activated endothelial cells also facilitate the egress of circulating leukocytes into the injured tissue by releasing chemoattractants and expressing cell-adhesion molecules, which are cell surface glycoproteins (Jaeschke, 1997). One group of cell-adhesion molecules, called selectins, located on the membrane of endothelial cells, interact with their ligands on the surface of leukocytes, thereby slowing down the flow of these cells and causing them to "roll" on the capillary surface. Subsequently a stronger interaction (adhesion) is established between the endothelial cells and leukocytes with participation of intercellular adhesion molecules (e.g., ICAM-1) expressed on the endothelial cell membrane and integrins expressed on the membrane of leukocytes. This interaction is also essential for the subsequent transendothelial migration of leukocytes. This is facilitated by gradients of chemoattractants that induce expression of leukocyte integrins. Chemoattractants originate from various stromal cells and include chemotactic cytokines (or chemokines), such as the monocyte chemotactic protein-1 (MCP-1) and IL-8 (whose rat homolog is the cytokine-induced neutrophil chemoattractant or CINC), as well as lipid-derived compounds, such as platelet-activating factor (PAF) and leukotriene B$_4$ (LTB$_4$). Ultimately all types of cells in the vicinity of injury express ICAM-1, thus promoting leukocyte invasion; the invading leukocytes also synthesize mediators, thus propagating the inflammatory response. Production of most inflammatory mediators is induced by signaling, turned on by TNF-α and IL-1, which results in activation of transcription factors, notably NF-κB and C/EBP (Poli, 1998) (see Fig. 3-11). Genes of many of the proteins mentioned above (e.g., selectins, ICAM-1, MCP-1, IL-8) and below (e.g., inducible nitric oxide synthase, acute phase proteins) as well as the genes of TNF-α and IL-1 themselves contain binding sites for the NF-κB (Lee and Burckart, 1998).

Inflammation-ROS and RNS Production   Macrophages, as well as leukocytes, recruited to the site of injury undergo a respiratory burst, discharging free radicals and enzymes (Weiss and LoBuglio, 1982) (Fig. 3-22). Free radicals are produced in the inflamed tissue in three ways, each of which involves a specific enzyme: NADPH oxidase (Nox), nitric oxide synthase, or myeloperoxidase.

Nox is an electron-transporting protein complex composed of two transmembrane proteins (one of them the FAD- and heme-containing catalytic subunit) and four cytoplasmic proteins (including the G-protein Rac) (El-Benna *et al.*, 2005). In resting

cells Nox is dormant, however, in activated cells the cytoplasmic subunits become extensively phosphorylated and move to the membrane to assemble the Nox complex. Constituents of microorganisms, such as the bacterial lipopolysaccharide (LPS; the active endotoxin component of Gram negative bacteria), acting through the cell surface Toll-like receptors (TLR), and PKC activators, such phorbol miristate acetate (PMA), may evoke Nox activation. Unlike in nonphagocytic cells, in macrophages and granulocytes activation causes a sudden and rapid electron transfer from NADPH through the FAD and heme in Nox to the molecular oxygen, releasing the thus formed superoxide anion radical ($O_2^{\bar{\bullet}}$) in a burst ("respiratory burst") at the external membrane surface into the phagocytic vacuole:
$$NADPH + 2O_2 \rightarrow NADP^+ + H^+ + 2O_2^{\bar{\bullet}}$$

The $O_2^{\bar{\bullet}}$ can give rise to the hydroxyl radical ($HO^\bullet$) in two sequential steps: The first is spontaneous or is catalyzed by superoxide dismutase, and the second, the Fenton reaction, is catalyzed by transition metal ions (see also Fig. 3-4):

$$2O_2^{\bar{\bullet}} + 2H^+ \rightarrow O_2 + HOOH$$

$$HOOH + Fe^{2+} \rightarrow Fe^{3+} + HO^- + HO^\bullet$$
Macrophages, but not granulocytes, generate another cytotoxic free radical, nitric oxide ($^\bullet NO$). This radical is produced from arginine by nitric oxide synthase (Wang *et al.*, 1993), which is inducible in macrophages by bacterial endotoxin and the cytokines IL-1 and TNF:

$$\text{L-arginine} + O_2 \rightarrow \text{L-citrulline} + {}^\bullet NO$$
Subsequently, $O_2^{\bar{\bullet}}$ and $^\bullet NO$, both of which are products of activated macrophages, can react with each other, yielding peroxynitrite anion; upon reaction with carbon dioxide, this decays into two radicals, nitrogen dioxide and carbonate anion radical (Fig. 3-4):

$$O_2^{\bar{\bullet}} + {}^\bullet NO \rightarrow ONOO^-$$

$$ONOO^- + CO_2 \rightarrow ONOOCO_2^-$$

$$ONOOCO_2^- \rightarrow {}^\bullet NO_2 + CO_3^{\bar{\bullet}}$$

Granulocytes, but not macrophages, discharge the lysosomal enzyme myeloperoxidase into engulfed extracellular spaces, the phagocytic vacuoles (Wang *et al.*, 1993). Myeloperoxidase catalyzes the formation of hypochlorous acid (HOCl), a powerful oxidizing agent, from hydrogen peroxide (HOOH) and chloride ion:

$$HOOH + H^+ + Cl^- \rightarrow HOH + HOCl$$

Like HOOH, HOCl can form $HO^\bullet$ as a result of electron transfer from Fe^{2+} or from $O_2^\bullet$ to HOCl:

$$HOCl + O_2^{\bar{\bullet}} \rightarrow O_2 + Cl^- + HO^\bullet$$
All these reactive chemicals, as well as the discharged lysosomal proteases, are destructive products of inflammatory cells. Although these chemicals exert antimicrobial activity at the site of microbial invasion, at the site of toxic injury they can damage the adjacent healthy tissues and thus contribute to propagation of tissue injury (see "Tissue Necrosis," below). Moreover, in some chemically induced injuries, inflammation plays the leading role. For example, α-naphthyl-isothiocyanate (ANIT), a cholestatic chemical, causes neutrophil-dependent hepatocellular damage. ANIT apparently acts on bile duct epithelial cells, causing them to release chemoattractants for neutrophil cells, which upon invading the liver, injure hepatocytes (Hill *et al.*, 1999). Kupffer cell activation, TNF-α release, and subsequent inflammation are also prominent and causative events in galactosamine-induced liver injury in rats (Stachlewitz *et al.*, 1999).

Whereas it is well recognized that chemical-inflicted tissue injury can induce inflammation as a side reaction of tissue repair, it is becoming clear that inflammation (even if harmless alone) can precipitate an overt tissue injury upon chemical exposure that is noninjurious alone. For example, a small harmless dose of the macrophage activator LPS converts nontoxic doses of monocrotaline, aflatoxin B_1 and allyl alcohol into ones that are markedly hepatotoxic (Roth *et al.*, 2003). Moreover, in rats pretreated with LPS, unlike in untreated animals, chlorpromazine, ranitidine and trovafloxacin caused liver injury. These drugs (and many others) when given to patients can induce rare, unexpected and not obviously dose-related liver injury. Therefore, it is hypothesized that such idiosyncratic drug reactions develop when some endotoxin exposure decreases the threshold for drug toxicity by priming the Kupffer cells that produce ROS and inflammatory mediators discussed above. Manifest or subclinical infection, gastrointestinal disturbance or alcohol consumption (which greatly increases the intestinal permeability for endotoxin) may be the source of endotoxin. It is not surprising that most idiosyncratic drug reactions affect the liver, because this organ contains 80–90% of the body's fixed macrophages (i.e., Kupffer cells), because the liver is the first organ to be exposed to LPS translocating from the intestinal lumen, and because the Kupffer cells are not only activated by LPS but also remove it from the circulation, thereby protecting other organs from its inflammatory effects (Roth *et al.*, 2003). However, the causative relationship between inflammation and idiosyncrasy needs further substantiation.

Altered Protein Synthesis: Acute-Phase Proteins   Cytokines released from macrophages and endothelial cells of injured tissues also alter protein synthesis, predominantly in the liver (Baumann and Gauldie, 1994) (Fig. 3-18). Mainly IL-6 but also IL-1 and TNF act on cell surface receptors and increase or decrease the transcriptional activity of genes encoding certain proteins called positive and negative acute-phase proteins, respectively, utilizing primarily the transcription factors NF-κB, C/EBP, and STAT (Poli, 1998; see Fig. 3-12). Many of the hepatic acute-phase proteins, such as C-reactive protein, are secreted into the circulation, and their elevated levels in serum are diagnostic of tissue injury, inflammation, or neoplasm. Increased sedimentation of red blood cells, which is also indicative of these conditions, is due to enrichment of blood plasma with positive acute-phase proteins such as fibrinogen.

Apart from their diagnostic value, positive acute-phase proteins may play roles in minimizing tissue injury and facilitating repair. For example, many of them, such as alpha$_2$-macroglobulin and alpha$_1$-antiprotease, inhibit lysosomal proteases released from the injured cells and recruited leukocytes. Haptoglobin binds hemoglobin in blood, metallothionein complexes metals in the cells, heme oxygenase oxidizes heme to biliverdin, and opsonins facilitate phagocytosis. Thus, these positive acute-phase proteins may be involved in the clearance of substances released upon tissue injury.

Negative acute-phase proteins include some plasma proteins, such as albumin, transthyretin, and transferrin, as well as hepatic enzymes (e.g., several forms cytochrome P450 and glutathione *S*-transferase), ligand-activated transcription factors (e.g., PPARα and the bile acid receptor FXR), and transporters, such as bile acid

transporters at the sinusoidal and canalicular membrane of hepatocytes (Ntcp and Bsep, respectively) and the bile canalicular export pump Mrp2. Because the latter enzymes and transporters play important roles in the toxication, detoxication and excretion of endo- and xenobiotics, the disposition and toxicity of bile acids and toxicants may be altered markedly during the acute phase of tissue injury.

Although the acute-phase response is phylogenetically preserved, some of the acute-phase proteins are somewhat species-specific. For example, during the acute phase of tissue injury or inflammation, C-reactive protein and serum amyloid A levels dramatically increase in humans but not in rats, whereas the concentrations of alpha$_1$-acid glycoprotein and alpha$_2$-macroglobulin increase markedly in rats but only moderately in humans.

Generalized Reactions   Cytokines released from activated macrophages and endothelial cells at the site of injury also may evoke neurohumoral responses. Thus IL-1, TNF, and IL-6 alter the temperature set point of the hypothalamus, triggering fever. IL-1 possibly also mediates other generalized reactions to tissue injury, such as hypophagia, sleep, and "sickness behavior" (Rothwell, 1991). In addition, IL-1 and IL-6 act on the pituitary to induce the release of ACTH, which in turn stimulates the secretion of cortisol from the adrenals. This represents a negative feedback loop because corticosteroids inhibit cytokine gene expression.

Mechanisms of Adaptation

Adaptation may be defined as a noxa-induced capability of the organism for increased tolerance to the noxa itself. It involves responses acting to preserve or regain the biological homeostasis in the face of increased harm. Theoretically, adaptation to toxicity may result from biological changes causing (1) diminished delivery of the causative chemical(s) to the target, (2) decreased size or susceptibility of the target, (3) increased capacity of the organism to repair itself, and (4) strengthened mechanisms to compensate the toxicant-inflicted dysfunction. Mechanistically, adaptation involves sensing the noxious chemical and/or the initial damage or dysfunction, and a response that typically occurs through altered gene expression. Such mechanisms will be briefly overviewed below.

Adaptation by Decreasing Delivery to the Target   The first step in the development of toxicity is delivery of the ultimate toxicant (a xenobiotic, its metabolite or xenobiotic-generated ROS and RNS) to the target (Fig. 3-2). Certain chemicals induce adaptive changes that lessen their delivery by diminishing the absorption, increasing their sequestration by intracellular binding proteins, enhancing their detoxication, or promoting their cellular export.

Repression of Iron Absorption   An adaptive mechanism affecting absorption is induced by iron whose uptake from the intestinal lumen into the enterocyte is mediated by the divalent metal transporter 1 (DMT1). High iron intake diminishes the expression of DMT1 in the apical membrane of enterocytes, whereas low intake has the opposite effect. This regulation occurs at the translational level by the intracellular iron-regulatory proteins (IRP). IRP1 contains a [4Fe-4S] cluster that, when in this form, prevents its binding to mRNA. Iron deficiency causes loss of Fe from the cluster, allowing the thus formed IRP1 apoprotein to bind to the DMT1 mRNA. This protects the mRNA from enzymatic degradation, thereby increasing its level and allowing more DMT1 protein to be translated. Conversely, iron overload saturates IRP1 with Fe, making it incapable of binding to and stabilizing the DMT1 mRNA. The conse-

quential loss of DMT1 mRNA and protein then markedly limits Fe^{2+} absorption. This adaptive mechanism has utmost physiological importance in maintenance of iron homeostasis. Its toxicological relevance is that DMT1 also mediates the transport of Cd^{2+}, therefore DMT1 overexpression in iron deficiency increases intestinal absorption of this highly toxic metal ion (Park *et al.*, 2002).

Induction of Ferritin and Metallothionein   Adaptive cellular accumulation of the binding proteins ferritin and metallothionein (MT) is protective against their respective ligands, iron and cadmium ions. Interestingly, up-regulation of ferritin by iron overload, like down-regulation of DMT1, is also translationally mediated by IRP1. However, the apoIRP1 (that is formed in iron deficiency) acts oppositely on ferritin mRNA and blocks its translation. Iron overload relieves this blockade, as it yields IPR1 with the [4Fe-4S] cluster, which does not bind to the ferritin mRNA, thus causing a surge in ferritin translation. Ferritin is protective as it removes iron from the Fenton reaction (Fig. 3-4).

MT is greatly induced by cadmium and elevated levels of MT protect the liver by restricting distribution of this toxic metal ion to sensitive intracellular targets (Klaassen *et al.*, 1999). Induction of MT by Cd^{2+} is likely indirect; mediated by Zn (displaced from intracellular binding sites), which activates the metal-responsive transcription factor 1 (MTF-1) that in turn augments transcription of the MT gene by binding to the metal-responsive elements in its promoter (Lichtlen and Schaffner, 2001).

Induction of Detoxication—The Electrophile Response, Part 1   Adaptive increases in detoxication (i.e., elimination of xenobiotics, their reactive metabolites, harmful endobiotics, or ROS and RNS by biotransformation) and cellular export have a major role in limiting toxicity. Such adaptation is typically induced by compounds with thiol reactivity (i.e., soft electrophiles, oxidants and those generating oxidative stress), which are sensed by the cytosolic Keap1-Nrf2 protein complex. The response is initiated by the transcription factor Nrf2, which activates genes with electrophile-response element (EpRE) in their regulatory region (Fig. 3-23; Dinkova-Kostova *et al.*, 2005). Normally Nrf2 is retained in the cytoplasm by Keap1, a homodimeric protein with ubiquitin ligase activity. Keap1 keeps Nrf2 inactive and at low intracellular levels by targeting it for proteosomal degradation by ubiquitination. Upon disruption of the Keap1-Nrf2 complex, the active Nrf2 escapes rapid degradation and accumulates in the cell. Electrophiles, such as quinones (e.g., *t*-butylquinone), qinoneimines (e.g., derived from acetaminophen), quinone methides (e.g., metabolite of butylated hydroxytoluene), α, β-unsaturated aldehydes and ketones (e.g., the lipid peroxidation products 4-oxonon-2-enal, 4-hydroxynon-2-enal and 15-A$_{2t}$-isoprostane), isothiocyanates (e.g., α-naphthylisothiocyanate), thiol-reactive metal ions (e.g., Cd^{2+}), and trivalent arsenicals, as well as direct and indirect oxidants (e.g., HOOH, diquat, quinones) may attack Keap1 at its reactive cysteine thiol groups by binding to them covalently or oxidizing them, thereby forcing Keap1 to release Nrf2. Alternatively, Nrf2 release may be induced via phosphorylation of Keap1 by kinases, such as PKC and those in the MAPK and the PI3K-Akt signaling pathways (Fig. 3-11) that may be turned on by chemical stresses (Jaiswal, 2004). After being released from Keap1, Nrf2 translocates into the nucleus, forms a heterodimer with small Maf proteins, and activates genes through binding to EpREs.

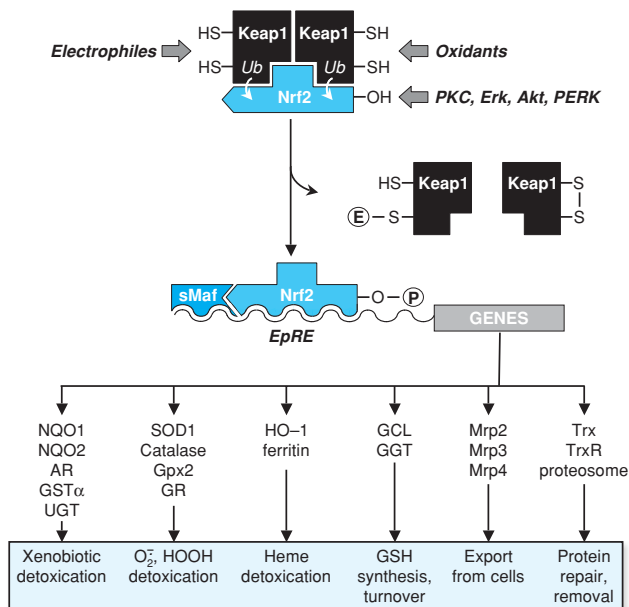
There are many genes with EpRE motifs that encode proteins known to be important in detoxication and export (Fig. 3-23). These include genes that code for (1) enzymes that detoxify xenobiotics (e.g., NQO1, NQO2, AR, GST, UGT), (2) enzymes that eliminate O$_2^{\bullet-}$ and HOOH (e.g., SOD1, GPX2, catalase), (3) proteins that detoxify


Figure 3-23. Signaling by Keap1/Nrf2 mediates the electrophile response.

Normally Nrf2 (NF-E2-related factor 2) is kept inactive and at a low intracellular level by interacting with Keap1 which promotes its proteosomal degradation by ubiquitination. Electrophiles covalently bind to, whereas oxidants oxidize the reactive thiol groups of Keap1, causing Keap1 to release Nrf2. Alternatively, Nrf2 release may follow phosphorylation of Keap1 by protein kinases. After being released from Keap1, the active Nrf2 accumulates in the cell, translocates into the nucleus and forms a heterodimer with small Maf proteins to activate genes that contain electrophile response element (EpRE) in their promoter region. These include enzymes, binding proteins, and transporters functioning in detoxication and elimination of xenobiotics, ROS, and endogenous reactive chemicals, as well as some proteins that can repair or eliminate oxidized proteins. Induction of such proteins represents an electrophile-stress response that provides protection against a wide range of toxicants. Abbreviations: AR, aldose reductase; G6PDH, glucose 6-phosphate dehydrogenase; GCL, glutamate-cysteine ligase; GGT, gamma-glutamyl transpeptidase; GPX2, glutathione peroxidase 2; GR, glutathione reductase; GSTα, glutathione S-transferase α subunit; HO-1, heme oxygenase 1; NQO1, NAD(P)H:quinone oxidoreductase; NQO2, NRH:quinone oxidoreductase; 2; Mrp2, Mrp3 and Mrp4, multidrug-resistance protein 2, 3 and 4; SOD1, superoxide dismutase 1; UGT, UDP-glucuronosyltransferase; SOD1, superoxide dismutase 1; Trx, thioredoxin; TrxR, thioredoxin reductase.

heme (e.g., HO-1, ferritin), (4) enzymes involved in the synthesis and regeneration of GSH (e.g., GCL and the NADPH-forming G6PDH), and (5) transporters (e.g., Mrp2, 3 and 4) that pump xenobiotics and their metabolites out of cells. Other Nrf2-induced proteins of known toxicological relevance will be mentioned later.

As demonstrated in Fig. 3-24, these Nrf2-mediated adaptive changes facilitate elimination and detoxication of electrophilic chemicals, as well as ROS that may be generated by them, and assist in repairing or removing damaged proteins (to be discussed later); therefore Nrf2 conveys protection against a wide range of toxicants. Indeed, Nrf2 knockout mice are more sensitive to the hepatotoxicity of acetaminophen, the pulmonary toxicity of butylated hydroxytoluene, hyperoxia, or cigarette smoke, the neurotoxicity of 3-nitropropionic acid, and the carcinogenicity of benzo[a]pyrene (Dinkova-Kostova *et al.*, 2005). Conversely, liver specific deletion of Keap1 constitutively activates Nrf2 in hepatocytes, causing

Figure 3-24. Adaptive changes in response to the t-butylhydroquinone (tBHQ)-induced electrophile stress that influence the metabolic fate and some effects of (tBHQ) and of superoxide anion radical generated in the course of tBHQ biotransformation.

This figure illustrates the numerous proteins (i.e., enzymes, exporters, repair proteins), which when induced in response to the tBHQ-induced electrophile stress, facilitates the detoxication and export of tBHQ and/or its metabolites, the detoxication of ROS formed during the biotransformation of tBHQ, and repair or removal of proteins damaged by the reactive metabolites. Proteins induced by Nrf2 as a result of adaptation to the electrophile stress are marked with an asterisk.

tBHQ (1) can be detoxified by UDP-glucuronosyltransferase to form tBHQ-glucuronide (2) and toxified by cytochrome P450-catalyzed dehydrogenation to t-butylquinone (tBQ; 3), which contains electrophilic carbon atoms (+), and is believed to be the actual inducer of electrophile stress response. tBQ can undergo three biotransformations. First, it can be detoxified by conjugation with glutathione (GSH) to form tBHQ-SG (4), which together with tBHQ-glucuronide, are exported from the cell by Mrp 2, 3 and 4. Secondly, tBQ can covalently bind to SH groups in proteins (5), including Keap1. Thirdly, by accepting an electron (e), tBQ can form t-butylsemiquinone radical (6), which can pass the electron to molecular oxygen to form superoxide anion radical ($O_2^{\bullet-}$), completing a redox cycle. In a process catalyzed by superoxide dismutase (SOD), $O_2^{\bullet-}$ can form HOOH, which is detoxified by GSH-peroxidase (GPX), using GSH (whose synthesis is rate-limited by GCL), or toxified by Fe^{2+}-catalyzed Fenton reaction to form hydroxyl radical ($HO^{\bullet}$). $HO^{\bullet}$ can react with proteins to form oxidized proteins (Prot-C=O, Prot-S-S), which can be degraded in the proteosome, or Prot-S-S can also be repaired through reduction by the thioredoxin (Trx) – thioredoxin reductase (TrxR) system. $HO^{\bullet}$ can also react with lipid (L) and form lipid hydroperoxide (LOOH), which can be reduced to lipid alcohol (LOH) by GPX at the expense of GSH. This results in formation of glutathione disulfide (GSSG), which can be reduced back to GSH by glutathione reductase (GR) at the expense of NADPH generated by glucose-6-phosphate dehydrogenase (G6PDH). Virtually all of these processes become more effective after the electrophile stress response.

them to overexpress many detoxifying enzymes and become resistant to acetaminophen-induced hepatotoxicity. Nrf2 can be activated by treatment with several chemicals of low toxicity, such as *t*-butyl hydroquinone (*t*BHQ), butylated hydroxyanisole (BHA), sulforaphane (an isothiocyanate in broccoli) and oltipraz (a dithiolenethione compound whose metabolites can form mixed disulfides with thiols, probably also with those on Keap1). These chemicals induce Nrf2 target genes and protect from toxicant-induced tissue injury and cancer. Of these chemopreventive agents, some (e.g., *t*BHQ and BHA) are antioxidants. Hence the inappropriate names "antioxidant response" and "antioxidant-response element" or ARE for the Nrf2-mediated adaptive alterations and the cognate DNA-binding site for Nrf2, respectively. It became apparent only later that the electrophilic quinone metabolites of these chemicals are the inducers and not the antioxidants.

Adaptation by Decreasing the Target Density or Responsiveness
Decreasing the density and sensitivity of the xenobiotic target is an adaptation mechanism for several cell surface receptors. Such alterations underlie the tolerance induced by opioids, abused drugs of considerable clinical toxicological interests.

Induction of Opioid Tolerance   The main target of opioids (e.g., morphine, heroine, methadone) is the μ-opioid receptor. Stimulation of this G_i-protein-coupled inhibitory receptor by an agonist results in adenyl-cyclase inhibition (causing decline in cyclic AMP levels and PKA activity) and K^+ channel opening (causing hyperpolarization) (Fig. 3-12) in neurons with opioid receptors, such as those in the midbrain periaqueductal gray. Even brief stimulation induces adaptive alterations: the receptor is desensitized by G-protein receptor kinase-mediated phosphorylation and β-arrestin binding, then becomes uncoupled from the G protein and internalized via a clathrin-dependent pathway. Whereas some receptors are recycled to the cell membrane, others are degraded in the lysosomes, causing receptor down regulation (Bailey and Connor, 2005). Upon prolonged stimulation, adenyl-cyclase signaling undergoes a compensatory increase. Tolerance to opioids, though far from being clarified mechanistically, may result from down-regulation of the receptors and up-regulation of adenyl-cyclase signaling. These changes would require increasing doses of agonist to produce an effect (i.e., inhibition of adenyl-cyclase signaling) as intensive as after its first application. These adaptive changes could also explain the withdrawal reaction, i.e., appearance of clinical symptoms (dysphoria, excitement, pain sensation), contrasting with the pharmacologic effects of opioids (euphoria, sedation, analgesia), upon abrupt termination of drug treatment, because withdrawal of the opioid would disinhibit the reinforced signaling it had inhibited. Nevertheless, mechanistic relationships between tolerance and the withdrawal reaction remain controversial (Bailey and Connor, 2005). An important clinical feature of opioid tolerance is that the tolerance to the respiratory depressive effect is short-lived and sensitivity returns after some abstinence. Therefore abusers then often kill themselves with a dose tolerated earlier.

Adaptation by Increasing Repair   There are several repair mechanisms that can be induced after toxicant exposure. Some of these may aid in repairing damaged molecules, proteins and DNA, others in regenerating the injured tissue.

Induction of Enzymes Repairing Oxidized Proteins—The Electrophile Response, Part 2   After sublethal exposure to chemicals, such as *t*BHQ, 4-hydroxynon-2-enal, and Cd^{2+}, not only

enzymes functioning in xenobiotic detoxication, but also some of those mediating protein repair become overexpressed as part of the above-described electrophile response. The induced proteins include thioredoxin 1 (Trx1) and thioredoxin-reductase 1 (TR1), which can reduce oxidized proteins (protein disulfides, -sulfenic acids, and -methionine sulfoxides) (Fig. 3-19), and several subunits of the proteosome complex, which hydrolyses damaged proteins. These repair proteins are transcribed from genes containing EpRE, and their transcription is controlled by Nrf2 (Fig. 3-23). As Trx1 and TR1 are reduction partners for ribonucleotide reductase, they support this enzyme in forming deoxyribonucleotides for DNA synthesis. Thus induction of Trx1 and TR1 also assists DNA repair.

Induction of Chaperones Repairing Misfolded Proteins—The Heat-shock Response   The cellular abundance of many molecular chaperones, which can disaggregate and refold denatured proteins, also increases after physical and chemical stresses (e.g., heat, ionizing radiation, oxidants, metal ions). Two adaptive reactions involving overexpression of chaperones are known; they are the heat-shock response and the endoplasmic reticulum (ER) stress response.

Although first observed as a result of hyperthermia, the heat-shock response is an adaptive mechanism also triggered by various pathologic conditions (e.g., trauma, tissue ischemia) and by virtually all reactive chemicals and/or their metabolites (e.g., electrophiles, oxidants, lipid peroxidation products, metal ions, arsenite) that denature proteins. Thus it takes place simultaneously with the electrophile response discussed above. This reaction, however, is governed by heat-shock transcription factors (HSF), mainly HSF1, which transactivate genes that encode heat-shock proteins (Hsp) through heat-shock response elements (HSE) within the promoter region. HSF1, like Nrf2, normally resides in the cytoplasm, where it associates with Hsp90, Hsp70, and Hsp40. Upon heat- or chemical-induced protein damage, these Hsps are purportedly sequestered by damaged proteins, allowing HSF1 to be released. HSF1 then migrates into the nucleus, trimerizes, undergoes phosphorylation and stimulates the transcription of Hsp genes. The chaperones Hsp90 and Hsp70, together with co-chaperone proteins, are especially important in maintaining the integrity of hundreds of proteins. The client proteins include not only those carrying out house-keeping functions, but also those involved in signaling and apoptosis. Therefore, induction of Hsps has pleiotropic effects besides increased protection from cytotoxicity.

Induction of Chaperones Repairing Misfolded Proteins—The Endoplasmic-Reticulum Stress Response   All proteins that are destined for export or insertion into cellular membranes pass through the ER where disulfide bonds are formed and the proteins are correctly folded. This process is catalyzed by ER-resident chaperones, such as glucose-regulated proteins Grp78, Grp94, and protein disulfide isomerase. Damage of proteins being processed in the ER by reactive intermediates (e.g., free radicals formed from CCl_4) or depletion of Ca^{2+} in the ER lumen (e.g., by inactivation of the ER Ca^{2+}-ATPase; see Fig. 3-14) causes accumulation of unfolded proteins in the ER that evokes the ER stress response (also called unfolded protein response) (Cribb *et al.*, 2005). This is initiated by removal of Grp78 by the damaged proteins from IRE1-α, an endoribonuclease. This in turn splices the mRNA for XBP1 into mature XBP1, allowing its translation into XBP1 protein, a transcription factor activating transcription of the ER-resident chaperones, such as Grp78 and Grp94, whose genes contain unfolded protein response elements (UPRE) in their promoter. Concomitantly, another transcription factor, ATF6 (activating transcription factor 6), becomes activated by proteolytic cleavage of its precursor in the

Golgi complex. Through binding to the ER stress response element (ERSE), ATF6 also promotes the transcription of the chaperones Grp78 and Grp94, as well as that of XBP1. Indeed, cells exposed to CCl_4, exhibit rapid induction of Grp78. This response fails to occur in cells that lack CYP2E1, indicating that the ER stress response is mediated by $Cl_3C^\bullet$ and $Cl_3COO^\bullet$ formed by CYP2E1 and/or by the CYP2E1-generated ROS (Lewis and Roberts, 2005). In addition to enrolling new ER-associated molecular chaperones to cope with the increase in damaged proteins, other measures are also taken by this complex adaptive program, such as temporary attenuation of mRNA translation (by engaging the ER-resident kinase PERK which catalyzes inactivating phosphorylation of $eIF2\alpha$, a translation initiation factor) and increased removal of unfolded and misfolded proteins from the ER through translocon pores and their delivery to the cytoplasmic proteosome.

Induction of Enzymes Repairing DNA—The DNA Damage Response   Upon DNA damage an adaptive response is initiated in which the protagonist is p53, a protein that can play the role of a transcription factor regulating gene expression and the role of an associate protein affecting the function of its interacting protein partner. Normally, p53 is kept inactive and at low levels by its binding protein mdm2 (see Fig. 3-28), which ubiquitinates p53, facilitating its proteosomal degradation. DNA damage activates kinases, such as ATM (ataxia telangiectasia mutated), ATR (ataxia telangiectasia related) and DNA-PK (DNA-dependent protein kinase), which through checkpoint kinases (Chk1, Chk2) phosphorylate p53 (Christmann *et al.*, 2003; McGowan and Russel, 2004). Upon phosphorylation, p53 escapes from mdm2, allowing its activation and stabilization. Indeed, the levels of p53 protein in cells increase dramatically in response to DNA damage caused by UV or gamma irradiation or genotoxic chemicals. p53 then facilitates DNA repair by a number of mechanisms. For example, mainly by transcriptionally up-regulating the cyclin-dependent kinase inhibitor protein p21, p53 arrests cells in G1 phase of the cell cycle (see Fig. 3-28), allowing more time for DNA repair. As a transcription factor, p53 also increases expression of proteins directly involved in DNA repair (Harms *et al.*, 2004). Such proteins include (a) GADD45 (growth arrest and DNA damage inducible), that interacts with histones and facilitates access of proteins (e.g., topoisomerase) to DNA, (b) XPE and XPC, members of the xeroderma pigmentosum group of proteins important in UV-induced DNA damage recognition before nucleotide excision repair, (c) MSH2 and PCNA (proliferating cell nuclear antigen) operating in mismatch repair, and (d) a form of ribonucleotide reductase that provides deoxyribonucleotides for filling in DNA gaps. As a partner protein, p53 supports the function of several proteins of the nucleotide excision machinery (e.g., TFIH, XPB, XPD). Other roles p53 plays in apoptosis and in carcinogenesis as a tumor suppressor protein are illustrated in Figs. 3-16 and 3-28 and discussed elsewhere in this chapter.

Adaptive Increase in Tissue Repair—A Proliferative Response   Many toxicants potentially injurious to cells, e.g., electrophiles, oxidants and those inducing oxidative stress, can initiate a mitogenic signaling as a prelude to tissue repair via cell replacement. It appears that the need for mitogenesis is sensed by protein tyrosine phosphatases (PTP, e.g., PTP1B) and the lipid phosphatase PTEN, which contain reactive cysteine-thiols at their active site (Rhee *et al.*, 2005). These phosphatases serve as brakes on the growth factor receptor-initiated mitogenic signaling, as PTPs dephosphorylate (and inactivate) the receptors themselves (e.g., EGFR, PDGFR, IGFR) as well as some protein kinases (e.g., Src and JAK), whereas PTEN dephosphorylates PIP_3, an important second messenger in the PI3K–Akt–IKK–NF-κB pathway (Fig. 3-11). Electrophiles covalently bind to essential cysteine-SH groups in these phosphatases. HOOH can oxidize the critical –SH group in PTEN to an intramolecular disulfide, whereas it oxidizes the -SH group of PTP1B, through sulfenic acid (-S-OH), to a five-membered cyclic sulfenyl amide species in which the sulfur atom is covalently linked to the nitrogen of the neighboring serine (Rhee *et al.*, 2005). Inactivation of PTPs and PTEN, which decrease the proliferative signal transduction, amplifies intracellular signaling for mitosis and survival.

It has been known for some time that oxidative stress, if not severe, activates the transcription factor NF-κB (Dalton *et al.*, 1999). For example, silica, which can produce ROS on its surface, activates NF-κB as well as PI3K when added to various cells (Castranova, 2004). In light of new information discussed above, NF-κB activation is now attributed to the fact that this transcription factor is situated downstream of growth factor receptors (which are negatively controlled by the ROS-sensitive PTP) and PIP_3 (which is eliminated by ROS-sensitive PTEN) (Fig. 3-11). Furthermore, NF-κB is at the focal point of proliferative and pro-life signaling, as it transactivates genes producing cell cycle accelerators (e.g., cyclin D1 and c-Myc) and apoptosis inhibitors (e.g., antiapoptotic Bcl proteins and the caspase inhibitor IAP proteins) (Karin, 2006). In addition, NF-κB also transactivates the genes of ferritin, GST, SOD1, HO-1, a proteosome subunit, and GADD45, facilitating detoxication and molecular repair. All these roles of NF-κB explain its involvement in tolerance to chemically induced tissue injury, resistance against cholestatic liver injury caused by bile acids, in adaptation to ionizing radiation, as well as in the phenomenon termed preconditioning. This is a tolerance to ischemic tissue injury (e.g., myocardial infarction); a tolerance induced by temporarily enhanced ROS formation evoked by hyperoxia or brief periods of ischemia-reperfusion.

In addition to signaling for cell replacement in damaged tissue–in which NF-κB plays a leading role–the growing cells need to boost protein synthesis. This is done under the control of the protein kinase mTOR (mammalian target of rapamycin). As shown in Fig. 3-25, mTOR activation results from signaling through both pathways coupled to growth factor receptors, i.e., the MAPK-pathway leading to phosphorylation of the MAPK isoform Erk, and the PI3K-pathway leading to phosphorylation of Akt (see Fig. 3-11). Importantly, these pathways are subject to activation in response to oxidant or electrophile exposure as they are controlled by PTPs and PTEN. Erk and Akt protein kinases activate mTOR through a complex mechanism (Fig. 3-25), and mTOR in turn phosphorylates and regulates effectors of protein synthesis, such as the translation repressor protein 4EBP1 and the protein kinase S6K, which modifies ribosomes increasing their translational efficiency (Shaw and Cantley, 2006). As described under hypoxia response and energy stress response, mTOR signaling is switched off in the cell to save energy as a measure to adapt to the energy shortage caused by hypoxia or toxic impairment of ATP synthesis.

Adaptation by Compensating Dysfunction   Dysfunctions caused by toxicants or drug overdose manifested at the level of organism (e.g., hypoxia), organ system (e.g., hypo- and hypertension), or organ (e.g., renal tubular dysfunction) may evoke compensatory mechanisms.

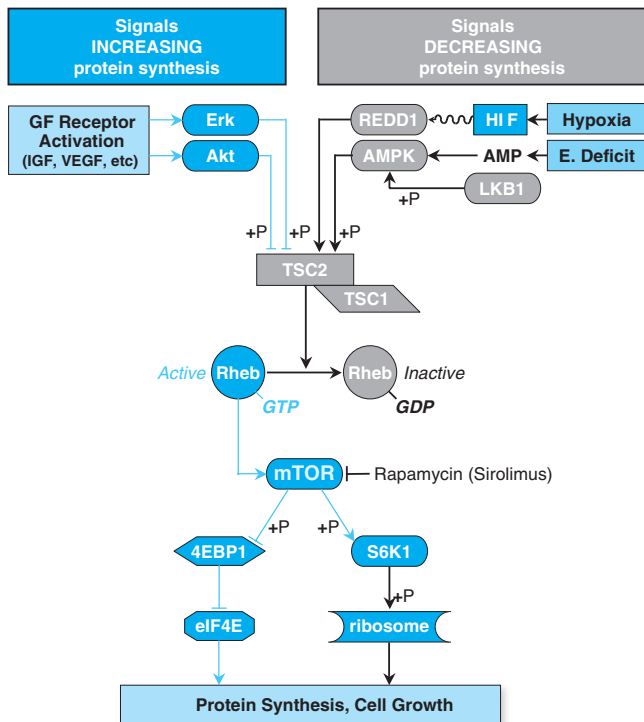
Adaptation to Hypoxia—The Hypoxia Response   When O_2 delivery is impaired and hypoxia persists for more than a few minutes, a response involving gene expression alteration is initiated.


Figure 3-25. Modulation of protein synthesis at translational level by signaling through the mTOR pathway as a means for cellular adaptation – increased signaling via mTOR supports cell growth and proliferation, whereas attenuated signaling permits energy conservation when hypoxia or toxic injury cause energy deficit.

Growth factor receptors signaling via either the MAPK-pathway, leading to phosphorylation of Erk, or via the PI3K-pathway, leading to phosphorylation of Akt (see Fig. 3-11), activate the serine/threonine kinase, mTOR (mammalian target of rapamycin; rapamycin is also called sirolimus), by an indirect mechanism. The protein kinases Erk and Akt catalyze inactivating phosphorylation of TSC2, a member of TSC1/2 complex. TSC2 is a GTPase-activating protein whose substrate is Rheb, a small G protein (ras homologue), which is active in the GTP-bound form and inactive in the GDP-bound form. With its GTPase activity inactivated by Erk or Akt, TSC2 cannot convert Rheb-GTP into inactive Rheb-GDP, and thus Rheb-GTP activates mTOR. In turn, mTOR phosphorylates two substrates which are necessary to initiate translation of mRNA into proteins, i.e., (1) 4EBP1 (eukaryotic initiation factor 4E-binding protein-1), which thus releases the translational initiation factor eIF4E, and (2) S6K1 (ribosomal protein S6 kinase-1), which phosphorylates ribosomal protein S6, thereby increasing translational efficiency of mRNAs that encode ribosomal proteins ("ribosomal biogenesis"). Regulation of protein synthesis by mTOR controls cell size and proliferation.

Protein synthesis for cell growth and proliferation, however, is halted in times of energy deficit resulting from hypoxia or toxic impairment of ATP production. Then AMP levels increase and AMP binds to the AMP-activated protein kinase (AMPK), facilitating its phosphorylation by protein kinase LKB1. Activated AMPK phosphorylates TSC2 (at a site different from that targeted by Akt and Erk), thereby increasing the GTPase-activating capacity of TSC2. This in turn switches Rheb off, making mTOR inactive and bringing mRNA translation to a halt. Hypoxia can initiate this process in a more specific way as well, i.e., via stabilization of the hypoxia inducible factor (HIF). This transcription factor induces the synthesis of REDD1, by a mechanism that is not completely understood, activates TSC2. See text for further details on cellular responses to hypoxia and energy deficit.

This reaction is mainly orchestrated by hypoxia inducible factor-1α (HIF-1α), a ubiquitous transcription factor whose activity and cellular abundance is greatly increased in response to hypoxia (Maxwell and Salnikow, 2004; Pouyssegur *et al.*, 2006). HIF-1α is maintained at very low intracellular levels because of its continuous hydroxylation of two proline residues by HIF-prolyl hydroxylases. This permits a ubiquitin ligase subunit (called von Hippel Lindau protein or VHL) to capture HIF-1α and initiate its destruction by proteosomal degradation. Indeed, HIF-1α is one of the shortest lived proteins with a half-life of less than 5 minutes. In addition, HIF-1α is kept transcriptionally inactive by hydroxylation at one of its asparagine residues by HIF-asparagine hydroxylases, which prevents interaction of HIF-1α with transcriptional co-activators, such as p300 and CBP. These two types of HIF hydroxylases are O_2 sensors: they use O_2 as a substrate to carry out proline/asparagine hydroxylations with concomitant oxidative decarboxylation of 2-oxoglutarate to succinate, with the K_M of O_2 being close to the ambient O_2 concentration. As the O_2 concentration falls, decreases in the hydroxylation rate of HIF-1α as well as its VHL-mediated ubiquitination and proteosomal degradation occur, and this increases its abundance and transcriptional activity. HIF hydroxylases belong to the Fe^{2+} and ascorbate-dependent dioxygenases (the largest group of non-heme oxidases), therefore not only hypoxia, but also Fe^{2+} deficiency impairs their activity. This latter feature explains why iron chelators (e.g., deferoxamine) or Fe^{2+}-mimicking metal ions (e.g., Co^{2+} and Ni^{2+}) also induce and activate HIF-1α (Maxwell and Salnikow, 2004). When induced after hypoxic conditions, HIF-1α dimerizes with HIF-1β (also called Arnt, which coincidentally, is the dimerization partner for the Ah receptor as well). The HIF complex transactivates a vast array of genes with hypoxia response element (HRE) in their promoter. Many of the gene products assist in acclimatization to hypoxia (Pouyssegur *et al.*, 2006). These include (1) erythropoietin (EPO) that is produced largely in kidney and activates erythropoiesis in bone marrow, (2) vascular endothelial growth factor (VEGF) and angiopoietin-2 that stimulate blood vessel growth (i.e., angiogenesis), (3) proteins facilitating anaerobic ATP synthesis from glucose (i.e., glycolysis), such as the glucose transporter GLUT1 and some glycolytic enzymes, (4) proteins that correct acidosis caused by glycolytic overproduction of lactate (e.g., a monocarboxylate transporter and a Na^+/H^+ exchanger for export of lactate and H^+, respectively), (5) the REDD1 signal transducer protein that initiates a complex signaling pathway that leads to suspension of the ATP-consuming protein synthesis via inactivation of the protein kinase mTOR (Fig. 3-25), and (6) many other proteins, such as those that promote extracellular matrix remodeling (e.g., matrix metalloproteinase-2) and cell migration (perhaps to facilitate access of the cells to the blood vessel), as well as BNIP3, a pro-apoptotic member of Bcl-2 family (perhaps to induce apoptosis upon extreme hypoxia). Experiments on mice kept in low O_2 environment (hypoxic preconditioning) demonstrated that HIF-1α became stabilized in the retina of these animals, hypoxia-responsive genes (EPO, VEGF) were induced, and the retina became resistant to light toxicity (Grimm *et al.*, 2005). Adaptation to hypoxia also occurs, for example, in response to high altitude hypoxia, chronic cardiorespiratory dysfunction, ischemic preconditioning, along with other adaptive responses discussed above. The hypoxia response is also expected to develop as a result of toxicities causing hypoxia acutely or subacutely (e.g., respiratory muscle weakness after organophosphate intoxication, diquat-induced pulmonary injury) or as a delayed sequel (e.g., respiratory surface restriction in hard metal disease).

Adaptation to Energy Depletion—The Energy Stress Response
Cells try to maintain their adenosine nucleotide pool in triphosphorylated, energized state, which is in the form of ATP. When the re-phosphorylation rate of AMP and ADP to ATP does not keep up with the rate of ATP use, because, for example, oxidative phosphorylation is impaired or ATP use for muscle contraction or ion pumping is excessive, the ratio of AMP to ATP increases. A cellular mechanism has evolved to sense this menacing energy deficit and, in order to compensate, boosts ATP production and curtails ATP consumption (Hardie *et al.*, 2006). The sensor is a ubiquitous heterotrimeric intracellular protein complex called AMP-activated protein kinase (AMPK). AMP strongly activates AMPK allosterically, and also by making it susceptible for phosphorylation by protein kinase LKB1 (or by the calmodulin dependent protein kinase kinase, CaMKK, in neurons). The phosphorylated, and thus activated AMPK, targets two sets of proteins. One set includes those whose activation facilitates ATP production from catabolism of glucose and fatty acids as well as by promoting the biogenesis of mitochondria. For example, AMPK activation increases (a) glucose uptake (via recruiting to the cell membrane or activating glucose transporters GLUT4 and GLUT1), (b) glycolysis (via phosphorylation and activation of 6-phosphofructo-2-kinase (PFK-2) whose product, fructose-2,6-bisphosphate is a glycolytic activator), and (c) fatty acid oxidation in mitochondria (via phosphorylation and inactivation of acetyl-CoA-carboxylase, whose product, malonyl-CoA, is an allosteric inhibitor of carnitine palmitoyltransferase-1, or CPT-1, which mediates uptake of long-chain fatty acid CoA esters into mitochondria). Another set of proteins, which are inactivated by AMPK (directly or indirectly), include those that are involved in biosynthetic ATP consuming reactions. Thus, AMPK inhibits (a) glycogen synthesis via phosphorylation and inactivation of glycogen synthase, (b) lipid synthesis by phosphorylating and inactivating acetyl-CoA-carboxylase, whose product, malonyl-CoA, is an essential substrate for fatty acid synthesis, (c) cholesterol synthesis by phosphorylating and inactivating HMG-CoA reductase, (d) glucose synthesis via inactivating phosphorylation of a transcriptional coactivator, TORC2, which then decreases expression of key gluconeogenetic enzymes, such as phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase, and (e) protein synthesis, and thus cell growth, by inhibiting the protein kinase mTOR (Fig. 3-25). AMPK-mediated modulation of cellular energy supply and consumption involves mainly kinase reactions rather than new protein synthesis. Therefore, this adaptation is a rapid process. It can be a response to any harmful condition that compromises oxidative phosphorylation, such as hypoxia, hypoglycemia (especially in neurons) and chemically induced mitochondrial toxicity. For example, cells exposed to arsenite exhibit rapid increases in the AMP/ATP ratio and AMPK activity, with concomitant declines in HMG-CoA reductase activity as well as fatty acid and cholesterol synthesis (Corton *et al.*, 1994).

After surveying the major cellular adaptation mechanisms to toxicants, it is easy to recognize that one noxa may initiate several adaptive responses. For example, cells exposed to a hypoxic environment can rapidly respond with both AMPK-mediated program of energy stabilization, and HIF-1α-directed adaptation to oxygen shortage. Theoretically, an electrophile toxicant that can bind covalently to cellular macromolecules and can also generate oxidative stress, such as a redox cycling quinone, would be expected to induce a number of adaptive processes, including the electrophile response, the heat-shock response, the endoplasmic-reticulum stress response, the DNA-damage response, and the proliferative response, and if it

compromises ATP synthesis as well, it even induces the energy-stress response.

Adaptation by Neurohumoral Mechanisms   There are numerous adaptive responses to dysfunctions of organs or organ systems that are mediated by humoral or neuronal signals between cells located in the same or different organs. For example, the rapid hyperventilation evoked by acute hypoxia or HCN inhalation, mediated by a neural reflex initiated by glomus cells in the carotid body. These chemosensitive cells generate a Ca^{2+} signal via the above-described AMP-sensor, AMPK, which becomes activated by hypoxia or CN^- through impairment of oxidative phosphorylation in these cells, causing rise in the AMP/ATP ratio (Evans *et al.*, 2005). Besides CN^-, mitochondrial electron transport inhibitors (e.g., rotenone, antimycin A, myxothiazole), uncouplers (e.g., 2,4-dinitrophenol) or ATP-synthase inhibitors (e.g., oligomycin) (see Table 3-6 and Fig. 3-13) as well as AMPK activators mimic the response to hypoxia in these cells. There are numerous other neurohumoral adaptive mechanisms in the body, such as the sympathetic reflex as well as activation of the renin-angiotensin-aldosterone system in response to hypotension, and the feedback systems between endocrine glands and the hypothalamus-hypophysis, which correct abnormal hormone levels. For information on these and other mechanisms, the reader is referred to textbooks of physiology.

When Repair and Adaptation Fail

When Repair Fails   Although repair mechanisms operate at molecular, cellular, and tissue levels, for various reasons they often fail to provide protection against injury. First, the fidelity of the repair mechanisms is not absolute, making it possible for some lesions to be overlooked. However, repair fails most typically when the damage overwhelms the repair mechanisms, as when protein thiols are oxidized faster than they can be reduced. In other instances, the capacity of repair may become exhausted when necessary enzymes or cofactors are consumed. For example, alkylation of DNA may lead to consumption of O^6-methyguanine-DNA-methyltransferase, and lipid peroxidation can deplete alpha-tocopherol. Sometimes the toxicant-induced injury adversely affects the repair process itself. For example, ethanol generates ROS via CYP2E1 which impairs proteosomal removal of damaged proteins. After exposure to necrogenic chemicals, mitosis of surviving cells may be blocked and restoration of the tissue becomes impossible (Mehendale, 2005). Finally, some types of toxic injuries cannot be repaired effectively, as occurs when xenobiotics are covalently bound to proteins. Thus, toxicity is manifested when repair of the initial injury fails because the repair mechanisms become overwhelmed, exhausted, or impaired or are genuinely inefficient.

It is also possible that repair contributes to toxicity. This may occur in a passive manner, for example, if excessive amounts of NAD^+ are cleaved by PARP when this enzyme assists in repairing broken DNA strands, or when too much NAD(P)H is consumed for the repair of oxidized proteins and endogenous reductants. Either event can compromise oxidative phosphorylation, which is also dependent on the supply of reduced cofactors (see Fig. 3-13), thus causing or aggravating ATP depletion that contributes to cell injury. Excision repair of DNA and reacylation of lipids also contribute to cellular deenergization and injury by consuming significant amounts of ATP. However, repair also may play an active role in toxicity. This is observed after chronic tissue injury, when the repair process goes astray and leads to uncontrolled proliferation instead of tissue

remodeling. Such proliferation of cells may yield neoplasia whereas overproduction of extracellular matrix results in fibrosis.

When Adaptation Fails   Although adaptation mechanisms, such as the Nrf2-mediated electrophile response and the NF-κB-induced proliferative reaction, boost the capacity of the organism to withstand toxicant exposure and damage, excessive exposure can overwhelm this protective response. Moreover, toxicants may impair the adaptive process. For example, moderate oxidative stress activates NF-κB, AP-1, and Nrf2 to initiate adaptive protection. However, extensive oxidant exposure, aborts this program because it leads to oxidation of thiol groups in the DNA-binding domain of these transcription factors (Hansen *et al.*, 2006). Similarly, Hg^{2+} can incapacitate NF-κB, thus inhibiting the pro-life program activated by this transcription factor. This promotes Hg^{2+}-induced renal tubular cell injury (Dieguez-Acuna *et al.*, 2004).

Some adaptive mechanisms may be harmful under extreme conditions. For example, acute tubular injury, which impairs tubular reabsorption and causes polyuria, triggers a tubuloglomerular feedback mechanism that reduces glomerular blood flow and filtration. Ultimately, this may precipitate anuric renal failure. It is possible that an adaptive mechanism that is beneficial in the short term, may become harmful when forced to operate for a prolonged period of time. As discussed earlier, NF-κB activation is indispensable for repair via proliferation of the acutely injured tissue. However, NF-κB also targets cytokine genes, and the cytokines (e.g., TNF-α, IL-1β) in turn activate NF-κB through their receptors (see Fig. 3-11). This vicious cycle may lead to chronic inflammation and cancer when repetitive tissue injury maintains NF-κB signaling (Karin, 2006). This occurs after occupational exposure to silica (Castranova, 2004). Sustained activation of HIF-1α in tumors facilitates invasiveness, in part by increasing VEGF expression and angiogenesis. In the kidney HIF-1α may be involved in fibrogenesis, as it targets critical genes, like tissue inhibitor of metalloproteinase-1.

Toxicity Resulting from Inappropriate Repair and Adaptation

Like repair, dysrepair occurs at the molecular, cellular, and tissue levels. Some toxicities involve dysrepair at an isolated level. For example, hypoxemia develops after exposure to methemoglobin-forming chemicals if the amount of methemoglobin produced overwhelms the capacity of methemoglobin reductase. Because this repair enzyme is deficient at early ages, neonates are especially sensitive to chemicals that cause methemoglobinemia. Formation of cataracts purportedly involves inefficiency or impairment of lenticular repair enzymes, such as the endo- and exopeptidases, which normally reduce oxidized crystalline and hydrolyze damaged proteins to their constituent amino acids. Dysrepair also is thought to contribute to the formation of Heinz bodies, which are protein aggregates formed in oxidatively stressed and aged red blood cells. Defective proteolytic degradation of the immunogenic trifluoroacetylated proteins may make halothane-anesthetized patients victims of halothane hepatitis.

Several types of toxicity involve failed and/or derailed repairs at different levels before they become apparent. This is true for the most severe toxic injuries, such as tissue necrosis, fibrosis, and chemical carcinogenesis.

Tissue Necrosis   As discussed above, several mechanisms may lead to cell death. Most or all involve molecular damage that is potentially reversible by repair mechanisms. If repair mechanisms operate effectively, they may prevent cell injury or at least retard its progression. For example, prooxidant toxicants cause no lipid fragmentation in microsomal membranes until alpha-tocopherol is depleted in those membranes. Membrane damage ensues when this endogenous antioxidant, which can repair lipids containing peroxyl radical groups (Fig. 3-20), becomes unavailable (Scheschonka *et al.*, 1990). This suggests that cell injury progresses toward cell necrosis if molecular repair mechanisms are inefficient or the molecular damage is not readily reversible.

Progression of cell injury to tissue necrosis can be intercepted by two repair mechanisms working in concert: apoptosis and cell proliferation. As discussed above, injured cells can initiate apoptosis, which counteracts the progression of the toxic injury. Apoptosis does this by preventing necrosis of injured cells and the consequent inflammatory response, which may cause injury by releasing cytotoxic mediators. Indeed, the activation of Kupffer cells, the source of such mediators in the liver, by the administration of bacterial lipopolysaccharide (endotoxin) greatly aggravates the hepatotoxicity of galactosamine. In contrast, when the Kupffer cells are selectively eliminated by pretreatment of rats with gadolinium chloride, the necrotic effect of carbon tetrachloride is markedly alleviated (Edwards *et al.*, 1993). Blockade of Kupffer cell function with glycine (via the inhibitory glycine receptor; see item 4 in Fig. 3-12) also protects the liver from alcohol-induced injury (Yin *et al.*, 1998).

Another important repair process that can halt the propagation of toxic injury is proliferation of cells adjacent to the injured cells. This response is initiated soon after cellular injury. A surge in mitosis in the liver of rats administered a low (nonnecrogenic) dose of carbon tetrachloride is detectable within a few hours. This early cell division is thought to be instrumental in the rapid and complete restoration of the injured tissue and the prevention of necrosis. This hypothesis is corroborated by the finding that in rats pretreated with chlordecone, which blocks the early cell proliferation in response to carbon tetrachloride, a normally nonnecrogenic dose of carbon tetrachloride causes hepatic necrosis (Mehendale, 2005). The sensitivity of a tissue to injury and the capacity of the tissue for repair are apparently two independent variables, both influencing the final outcome of the effect of injurious chemical—that is, whether tissue restitution ensues with survival or tissue necrosis occurs with death. For example, variations in tissue repair capacity among species and strains of animals appear to be responsible for certain variations in the lethality of hepatotoxicants (Soni and Mehandale, 1998).

It appears that the efficiency of repair is an important determinant of the dose-response relationship for toxicants that cause tissue necrosis. Following chemically induced liver or kidney injury, the intensity of tissue repair increases up to a threshold dose, restraining injury, whereupon it is inhibited, allowing unrestrained progression of injury (Mehendale, 2005). Impaired signaling to mitosis (see Fig. 3-11), caused by high tissue concentrations of toxicants (e.g., acetaminophen in the liver or *S*-(1,2-dichlorovinyl)-L-cysteine in the kidney) and their reactive metabolites may account for lagging tissue repair (Boulares *et al.*, 1999; Vaidya *et al.*, 2003), but maintenance of DNA and protein synthesis, mitotic machinery, and energy supply may also be impaired at high-dose chemical exposures. That is, tissue necrosis is caused by a certain dose of a toxicant not only because that dose ensures sufficient concentration of the

ultimate toxicant at the target site to initiate injury but also because that quantity of toxicant causes a degree of damage sufficient to compromise repair, allowing for progression of the injury. Experimental observations with hepatotoxicants indicate that apoptosis and cell proliferation are operative with latent tissue injury caused by low (nonnecrogenic) doses of toxicants, but are inhibited with severe injury induced by high (necrogenic) doses. For example, 1,1-dichloroethylene, carbon tetrachloride, and thioacetamide all induce apoptosis in the liver at low doses, but cause hepatic necrosis after high-dose exposure (Corcoran *et al.*, 1994). Similarly, there is an early mitotic response in the liver to low-dose carbon tetrachloride, but this response is absent after administration of the solvent at necrogenic doses (Mehendale, 2005). This suggests that tissue necrosis occurs because the injury overwhelms and disables the repair mechanisms, including (1) repair of damaged molecules, (2) elimination of damaged cells by apoptosis, and (3) replacement of lost cells by cell division.

Fibrosis Fibrosis is a pathologic condition characterized by excessive deposition of an extracellular matrix of abnormal composition. Hepatic fibrosis, or cirrhosis, results from chronic consumption of ethanol or high dose retinol (vitamin A), treatment with methotrexate, and intoxication with hepatic necrogens such as carbon tetrachloride and iron. Pulmonary fibrosis is induced by drugs such as bleomycin and amiodarone and prolonged inhalation of oxygen or mineral particles. Doxorubicin may cause cardiac fibrosis, whereas exposure to ionizing radiation induces fibrosis in many organs. Most of these agents generate free radicals and cause chronic cell injury.

Fibrosis is a specific manifestation of dysrepair of the chronically injured tissue. As discussed above, cellular injury initiates a surge in cellular proliferation and extracellular matrix production, which normally ceases when the injured tissue is remodeled. If increased production of extracellular matrix is not halted, fibrosis develops.

The cells that manufacture the extracellular matrix during tissue repair (e.g., stellate cells and myofibroblasts in liver, mesangial cells in the kidney, fibroblasts-like cells in lungs and skin) are the ones that overproduce the matrix in fibrosis. These cells are controlled and phenotypically altered ("activated") by cytokines and growth factors secreted by nonparenchymal cells, including themselves (see Fig. 3-22). TGF-β appears to be the major mediator of fibrogenesis, although other factors are also involved. These include growth factors, such as connective tissue growth factor (CTGF; a TGF-β-induced growth factor) and platelet-derived growth factor, vasoactive peptides, such as endothelin-1 and angiotensin-II, and the adipocyte-derived hormone leptin (Lotersztajn *et al.*, 2005). The evidence is compelling to indicate that TGF-β, acting through its receptor (item 8 in Fig. 3-11), and receptor activated transcription factors (Smad2 and 3), is a highly relevant causative factor of fibrosis. For example, subcutaneous injection of TGF-β induces local fibrosis, whereas overexpression of TGF-β in transgenic mice produces hepatic fibrosis. Smad3-null mice are relatively resistant to radiation-nduced cutaneous fibrosis, bleomycin-induced pulmonary fibrosis and CCl$_4$-induced hepatic fibrosis. TGF-β antagonists, such as anti-TGF-β immunoglobulin and decorin, as well as Smad3 antagonists, such as halofuginone and overexpressed Smad7 protein (that is antagonistic to Smad 2 and 3), ameliorate chemically induced fibrogenesis (Flanders, 2004). In several types of experimental fibrosis and in patients with active liver cirrhosis, overexpression of TGF-β in affected tissues has been demonstrated.

The increased expression of TGF-β is a common response mediating regeneration of the extracellular matrix after an acute injury. However, whereas TGF-β production ceases when repair is complete, this does not occur when tissue injury leads to fibrosis. Failure to halt TGF-β overproduction could be caused by continuous injury or a defect in the regulation of TGF-β. Indeed, after acute CCL$_4$-induced liver injury hepatic stellate cells exhibit a TGF-β-mediated induction of Smad7 (which purportedly terminates the fibrotic signal by inhibiting activation of Smad2 and Smad3 by TGF-β receptor), however, after chronic injury, Smad7 induction fails to occur (Flanders, 2004).

The fibrotic action of TGF-β is due to (1) stimulation of the synthesis of individual matrix components by specific target cells and (2) inhibition of matrix degradation by decreasing expression of matrix metalloproteinase-1 and increasing the expression of matrix degrading enzyme inhibitors, such as tissue inhibitor of metalloproteinase-1 (TIMP-1) and plasminogen activator inhibitor-1 (PAI-1) (Arthur *et al.*, 1999; Flanders, 2004). Interestingly, TGF-β induces transcription of its own gene in target cells (Flanders, 2004), suggesting that the TGF-β produced by these cells can amplify in an autocrine manner the production of the extracellular matrix. This positive feedback (autoinduction) may facilitate fibrogenesis.

Fibrosis involves not only excessive accumulation of the extracellular matrix but also changes in its composition. The basement membrane components, such as collagen IV and laminin, as well as the fibrillar type collagens (collagen I and III), which confer rigidity to tissues, increase disproportionately, during fibrogenesis (Gressner, 1992).

Fibrosis is detrimental in a number of ways:

1. The scar compresses and may ultimately obliterate the parenchymal cells and blood vessels.
2. Deposition of basement membrane components between the capillary endothelial cells and the parenchymal cells presents a diffusional barrier which contributes to malnutrition of the tissue cells.
3. An increased amount and rigidity of the extracellular matrix unfavorably affect the elasticity and flexibility of the whole tissue, compromising the mechanical function of organs such as the heart and lungs.
4. Furthermore, the altered extracellular environment is sensed by integrins. Through these transmembrane proteins and the coupled intracellular signal transducing networks (see Fig. 3-11), fibrosis may modulate several aspects of cell behavior, including polarity, motility, and gene expression (Raghow, 1994).

Carcinogenesis Chemical carcinogenesis involves inappropriate function of various repair and adaptive mechanisms, including (1a) insufficient adaptive response to DNA damage with failure of DNA repair that leads to mutation of critical genes, (1b) inappropriate control at regulatory gene regions over expression of critical genes, (2) failure to induce apoptosis, and (3) failure to terminate cell proliferation.

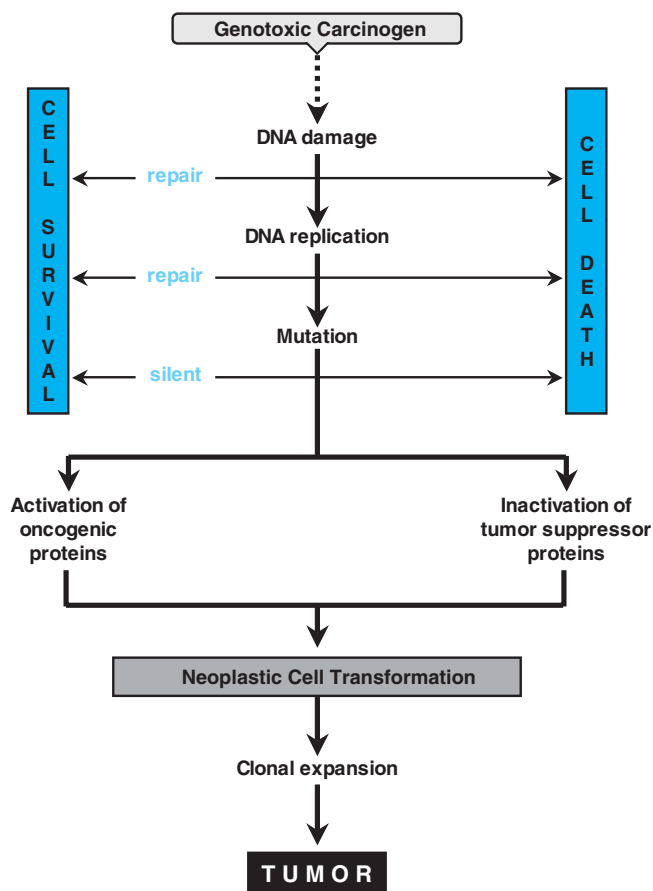
As to be described in more detail later, carcinogenesis entails gene expression alterations initiated by two fundamentally distinct types of mechanisms that often work simultaneously and in concert, i.e., genetic and epigenetic mechanisms. Genetic mechanisms bring about *qualitative* change in gene expression, i.e., expression of an altered gene product, a mutant protein, with gain or loss in activity. In contrast, epigenetic mechanisms cause *quantitative* change in


Figure 3-26. *The process of carcinogenesis initiated by genotoxic carcinogens.*

The figure indicates that activating mutation of proto-oncogenes that encode permanently active oncoproteins and inactivating mutation of tumor suppressor genes that encode permanently inactive tumor suppressor proteins can cooperate in neoplastic transformation of cells. It is important to realize that overexpression of normal proto-oncogenes (e.g., by hypomethylation of their promoter) and under-expression (silencing) of normal tumor suppressor genes (e.g., by hypermethylation of their promoter) may also contribute to such transformation (see text for explanation).

gene expression resulting in more or less protein product. Whereas genetic mechanisms affect the coding sequences of critical genes, causing DNA damage, epigenetic mechanisms influence the regulatory (promoter) region of genes, causing increased or decreased transcriptional activity of the gene. Thus, chemical and physical insults may induce neoplastic transformation of cells by affecting critical genes through genotoxic and nongenotoxic (i.e., epigenetic) mechanisms. However, either mechanism ultimately induces cancer by causing cellular failures in initiating apoptosis and/or terminating cell proliferation.

Inappropriate Repair of the Coding Region of Critical Genes: Mutation, an Initiating Event in Carcinogenesis   Chemicals that react with DNA may cause damage such as adduct formation, oxidative alteration, and strand breakage (Fig. 3-26). In most cases, these lesions are repaired or injured cells are eliminated. If neither event occurs, a lesion in the parental DNA strand may induce a heritable alteration, or mutation, in the daughter strand during replication. The mutation may remain silent if it does not alter the protein encoded

by the mutant gene or if the mutation causes an amino acid substitution that does not affect the function of the protein. Alternatively, the genetic alteration may be incompatible with cell survival. The most unfortunate scenario for the organism occurs when the altered genes express mutant proteins that reprogram cells for multiplication and avoidance of apoptosis (i.e., immortalization). When such cells undergo mitosis, their descendants also have a similar propensity for proliferation. Moreover, because enhanced DNA replication and cell division increases the likelihood of mutations, these cells eventually acquire additional mutations that may further increase their growth advantage over their normal counterparts. The final outcome of this process is a nodule, followed by a tumor consisting of transformed, rapidly proliferating cells (Fig. 3-26).

The critical role of DNA repair in preventing carcinogenesis is attested by the human heritable disease xeroderma pigmentosum. Affected individuals lack excision repair proteins of the XP series and exhibit a greatly increased incidence of sunlight-induced skin cancers. Cells from these patients are also hypersensitive to DNA-reactive chemicals, including aflatoxin B_l, aromatic amines, polycyclic hydrocarbons, and 4-nitroquinoline-1-oxide (Lehmann and Dean, 1990). Also, mice with ablated PARP gene are extremely sensitive to γ-rays and N-methylnitrosourea and show genomic instability, as indicated by increases in the levels of both sister chromatid exchanges and chromatid breaks following genotoxic insult (D'Amours *et al.*, 1999).

A small set of cellular genes are the targets for genetic alterations that initiate neoplastic transformations. Included are proto-oncogenes and tumor-suppressor genes (Barrett, 1992).

Mutation of Proto-oncogenes   Proto-oncogenes are highly conserved genes encoding proteins that stimulate the progression of cells through the cell cycle (Smith *et al.*, 1993). The products of proto-oncogenes include (1) growth factors; (2) growth factor receptors; (3) intracellular signal transducers such as G proteins, protein kinases, cyclins, and cyclin-dependent protein kinases; and (4) nuclear transcription factors. Figure 3-27 depicts several proto-oncogene products that are closely involved in initiating the cell-division cycle. The legend of that figure outlines some important details on the function of these proteins and their interaction with tumor suppressor proteins (to be discussed below). Transient increases in the production or activity of proto-oncogene proteins are required for regulated growth, as during embryogenesis, tissue regeneration, and stimulation of cells by growth factors or hormones. In contrast, permanent activation and/or overexpression of these proteins favor neoplastic transformation. One mechanism whereby genotoxic carcinogens induce neoplastic cell transformation is by producing an activating mutation of a proto-oncogene. Such a mutation is so named because the altered gene (then called an *oncogene*) encodes a permanently active protein that forces the cell into the division cycle. An example of mutational activation of an oncogene protein is that of the Ras proteins.

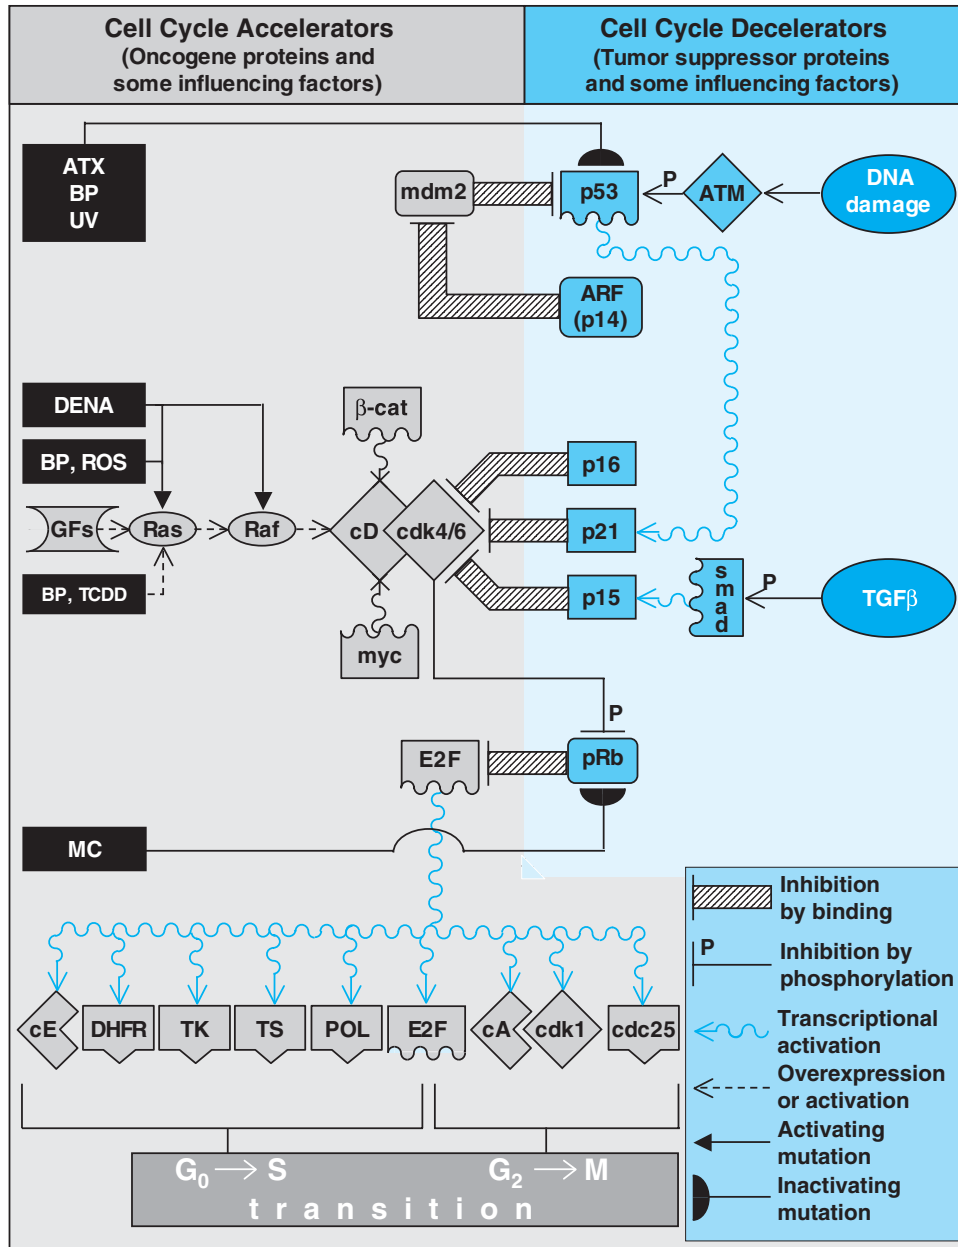
Ras proteins are G-proteins with GTP/GDP binding capacity as well as GTPase activity (Anderson *et al.*, 1992). They are localized on the inner surface of the plasma membrane and function as crucial mediators in responses initiated by growth factors (see Figs. 3-11 and 3-27). Ras is located downstream from growth factor receptors and nonreceptor protein tyrosine kinases and upstream from mitogen-activated protein kinase (MAPK) cascade whose activation finally up-regulates the expression of cyclin D and initiates the mitotic cycle (Fig. 3-27). In this pathway, Ras serves as a molecular switch, being active in the GTP-bound form and inactive in the GDP-bound form. Some mutations of the *Ras* gene (e.g., a


Figure 3-27. Key regulatory proteins controlling the cell division cycle with some signaling pathways and xenobiotics affecting them.

Proteins on the left, represented by gray symbols, accelerate the cell cycle and are oncogenic if permanently active or expressed at high level. In contrast, proteins on the right, represented by blue symbols, decelerate or arrest the cell cycle and thus suppress oncogenesis, unless they are inactivated (e.g., by mutation).

Accumulation of cyclin D (cD) is a crucial event in initiating the cell division cycle. cD activates cyclin-dependent protein kinases 4 and 6 (cdk4/6), which in turn phosphorylate the retinoblastoma protein (pRb) causing dissociation of pRb from transcription factor E2F (Johnson and Walker, 1999). Then the unleashed E2F is able to bind to and transactivate genes whose products are essential for DNA synthesis, such as dihydrofolate reductase (DHFR), thymidine kinase (TK), thymidylate synthetase (TS), and DNA polymerase (POL), or are regulatory proteins, such as cyclin E (cE), cyclin A (cA) and cyclin-dependent protein kinase 1 (cdk1), that promote further progression of the cell cycle. Expression of cD is increased, for example, by signals evoked by growth factors (GFs) via Ras proteins and by transcription factors, such as myc and β-catenin (β-cat). Some carcinogens, e.g., benzpyrene (BP) and reactive oxygen species (ROS), and diethylnitrosamine (DENA) may cause mutation of the *Ras* or *Raf* gene that results in permanently active mutant Ras protein, but BP as well as TCDD may also induce simple overexpression of normal Ras protein.

Cell cycle progression is counteracted, for example, by pRb (which inhibits the function of E2F), by cyclin-dependent protein kinase inhibitors (such as p15, p16, and p21), by p53 (that transactivates the *p21* gene), and by ARF (also called p14 that binds to mdm2, thereby neutralizing the antagonistic effect of mdm2 on p53). Signals

point mutation in codon 12) dramatically lower the GTPase activity of the protein. This in turn locks Ras in the permanently active GTP-bound form. Continual rather than signal-dependent activation of Ras can lead eventually to uncontrolled proliferation and transformation. Indeed, microinjection of Ras-neutralizing monoclonal antibodies into cells blocks the mitogenic action of growth factors as well as cell transformation by several oncogenes. Numerous carcinogenic chemicals induce mutations of Ras proto-oncogenes that lead to constitutive activation of Ras proteins (Anderson *et al.*, 1992). These include *N*-methyl-*N*-nitrosourea, polycyclic aromatic hydrocarbons, benzidine, aflatoxin B$_l$, and ionizing radiation. Most of these chemicals induce point mutations by transversion of G$_{35}$ to T in codon 12.

Another example for activating mutation of a proto-oncogene is *B-Raf* mutation, although *Ras* and *Raf* mutations are mutually exclusive (Shaw and Cantley, 2006). Raf proteins are protein kinases; lying just downstream from Ras and being the first signal transducers in the MAP kinase pathway (see Fig. 3-11). After recruitment by Ras to the cell membrane, Raf is activated by the growth factor receptor (see item 4 in Fig. 3-11) through phosphorylation in its activating segment. B-Raf mutations occur in mouse liver tumors induced by diethylnitrosamine (Jaworski *et al.*, 2005) in 66% of malignant melanomas and a wide range of human cancers. All mutations are within the activation segment of B-Raf, with a single amino acid substitution (V599E) accounting for the majority. The mutant B-Raf protein has elevated kinase activity probably because substitution of the non-polar valine with the negatively charged glutamate mimics an activating phosphorylation. Thus, the constitutively active B-Raf continually sends Ras-independent proliferative signal down the MAPK pathway. Indeed, transfection of the mutant *B-Raf* gene into cells induced neoplastic transformation even in the absence of Ras proteins (Davies *et al.*, 2002). Another proto-oncogene product that often undergoes activating mutation in breast and colon tumors is p110α, the catalytic subunit of PI3K (Shaw and Cantley, 2006). This can cause permanent proliferative signaling via the GF receptor–PI3K–Akt pathway (see Fig. 3-11).

Whereas constitutive activation of oncogene proteins, as a result of point-mutation, is a common initiator of chemical carcinogenesis, permanent overexpression of such proteins also can contribute to neoplastic cell transformation. Overexpression of proto-oncogene proteins may result from amplification of the proto-oncogene (i.e., the formation more than one copy) (Anderson *et al.*, 1992). Such event may be initiated by DNA strand breaks, and therefore often observed after exposure to ionizing radiation; however, proto-oncogene amplification also occurs in spontaneous human cancer. Overexpression of proto-oncogene proteins as a result of nongenotoxic, epigenetic mechanisms will be discussed later.

Mutation of Tumor-Suppressor Genes   Tumor-suppressor genes encode proteins that inhibit the progression of cells in the division cycle, or promote apoptosis upon DNA damage. Figure 3-27 depicts such proteins, which include, for example, cyclin-dependent protein kinase inhibitors (e.g., p15, p16, and p21), transcription factors (e.g., p53 and Smad) that activate genes encoding cyclin-dependent protein kinase inhibitors, proteins (e.g., pRb) that block transcription factors involved in DNA synthesis and cell division, and proteins (e.g., ARF) that block inhibitors of tumor suppressor proteins. Other notable tumor suppressor gene products include, for example, the protein kinases (e.g., ATM, ATR) that sense the DNA damage and signal for the p53-controlled response shown in Fig. 3-28, proapoptic proteins (e.g., Bax, Puma, Noxa) induced after DNA damage (Fig. 3-28), the phosphatase PTEN (that dephosphorylates the membrane lipid phosphatidylinositol-3,4,5-triphosphate, an essential intermediate in the PI3K-Akt pathway) that turns off the PI3K-Akt pathway-mediated proliferative signaling (Fig. 3-11), and the GTPase activating protein TSC2 (tuberous sclerosis complex-2) that prevents activation of mTOR (Fig. 3-25). Uncontrolled proliferation can occur when the mutant tumor-suppressor gene encodes a protein that cannot suppress cell division. Inactivating mutations of specific tumor suppressor genes in germ cells are responsible for the inherited predisposition to cancer, as in familial retinoblastoma (pRb), Wilms' tumor (WT1), familial polyposis (Smad4), and Li-Fraumeni syndrome (p53). Mutations of tumor-suppressor genes in somatic cells contribute to nonhereditary cancers. The genes of p16, PTEN, pRb are frequently mutated in human cancer. The best-known tumor suppressor gene involved in both spontaneous and chemically induced carcinogenesis is p53.

The p53 tumor suppressor gene encodes a 53 kDa protein with multiple functions (Fig. 3-28). Acting as a transcriptional modulator, the p53 protein (1) transactivates genes whose products arrest the cell cycle (e.g., p21 and gadd45), repair damaged DNA (e.g., XPE, MSH2), or promote apoptosis (e.g., Bax, Puma, and Fas receptor) and (2) represses genes that encode cell cycle accelerators (e.g., cyclin B1, Cdk1), or antiapoptotic proteins (e.g., bcl-2 and IGF-1 receptor) (Bennett *et al.*, 1999; Liu and Chen, 2006). DNA damage activates protein kinases to phosphorylate and stabilize the p53 protein, causing its accumulation (Fig. 3-28). The accumulated p53 may induce cell cycle arrest, DNA repair and apoptosis of the affected cells. Thus, p53 eliminates cancer-prone cells from the replicative pool, counteracting neoplastic transformation (Fig. 3-26); therefore it is commonly designated as guardian of the genome.

Indeed, cells that have no p53 are a million times more likely to permit DNA amplification than are cells with a normal level of the suppressor gene. Furthermore, mice with the p53 gene deleted develop cancer by 6 to 9 months of age, attesting to the crucial role of the p53 tumor-suppressor gene in preventing carcinogenesis.

Mutations in the p53 gene are found in 50 percent of human tumors and in a variety of induced cancers. The majority are "missense mutations" that change an amino acid and result in a faulty or altered protein (Bennett *et al.*, 1999). The faulty p53 protein forms a complex with endogenous wild-type p53 protein and inactivates it. Thus, the mutant p53 not only is unable to function as a tumor suppressor protein but also prevents tumor suppression by the wild-type p53.

Carcinogens may cause characteristic pattern of mutations in the p53 tumor-suppressor gene. An example is the point mutation in codon 249 from AGG to AGT, which changes amino acid 249 in the p53 protein from arginine to serine. This mutation predominates

---

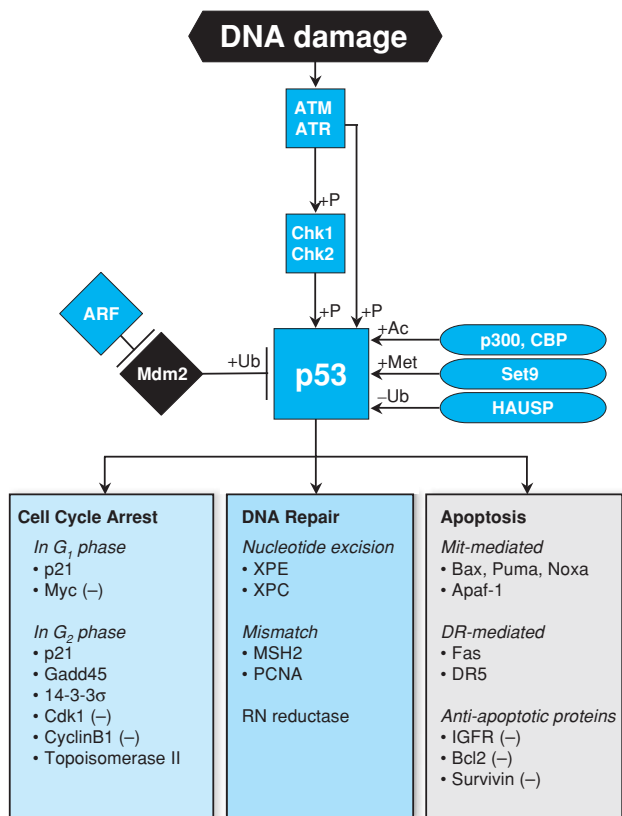
evoked by DNA damage and TGF-β will ultimately result in accumulation of p53 and p15 proteins, respectively, and deceleration of the cell cycle. In contrast, mutations that disable the tumor suppressor proteins facilitate cell cycle progression and neoplastic conversion and are common in human tumors. Aflatoxin B$_1$ (ATX), BP and UV light cause such mutations of the *p53* gene (Bennet *et al.*, 1999), whereas *pRb* mutations occur invariably in methylcholanthrene (MC)-induced transplacental lung tumors in mice (Miller, 1999).


Figure 3-28. The guardian of the genome: p53 tumor suppressor protein—its role and regulation.

When activated upon DNA damage, the p53 protein may mediate cell cycle arrest, DNA repair and apoptosis. p53 can induce these effects by acting chiefly as a transcription factor that can activate the transcription of most target genes, while repressing some of others, such as those marked with (-) in the figure (Liu and Chen, 2006). For example, p53 transactivates *p21* and *gadd45* genes (whose products are inhibitors of cyclin–cyclin-dependent protein kinase complexes) and arrest the cell cycle in G_1 and G_2 phases, respectively, but p53 represses the *Cdk1* and *cyclin B1* genes (whose products are indispensable for the cells to transit from G_2 phase to M) (see Fig. 3-21). p53 also transactivates the genes of some DNA repair proteins and pro-apoptotic proteins (e.g., bax and fas; see Fig. 3-16) and represses the genes of anti-apoptotic proteins (e.g., bcl-2 and insulin-like growth factor-1 [IGF-1] receptor), whereby it promotes apoptosis. These (and other) p53-induced pro-apoptotic mechanisms may be cell specific, i.e., all are not necessarily occurring in the same cell at the same time.

The intracellular level and activity of p53 depends primarily on the presence of mdm2 protein, which inactivates p53 by ubiquitinating it; monoubiquitination causes export of p53 from the nucleus, whereas polyubiquitination promotes its proteosomal degradation. The influence of mdm2 on p53 may be disrupted by overexpression of the ARF (or p14) protein (which binds to mdm2 and removes it from p53) or by posttranslational modification of p53 through phosphorylation by protein kinases (see below), acetylation by acetyltransferases (e.g., p300 and CBP), and methylation by methyltransferases (e.g., Set9) (Liu and Chen, 2006). These mechanisms release p53 from mdm2, stabilize the p53 protein, thereby greatly increasing its abundance and activity. Phosphorylation of p53 is induced by DNA damage. This is sensed by kinases, such as ATM (ataxia telangiectasia mutated) and ATR (ataxia telangiectasia related), which directly or through checkpoint kinases (Chk1, Chk2) phosphorylate p53 to induce cell cycle arrest, DNA repair or apoptosis (McGowan and Russel, 2004).

It is important to emphasize that there is also a p53-independent mechanism to arrest the cells suffering DNA damage before mitosis. Like induction of p53, this is also initiated by the activated Chk1, which phosphorylates and

in hepatocellular carcinomas in individuals living where food is contaminated with aflatoxin B_1 (Bennett *et al.*, 1999). Because aflatoxin B_1 induces the transversion of G to T in codon 249 of the p53 tumor-suppressor gene in human hepatocytes (Aguilar *et al.*, 1993), it appears likely that this mutation is indeed induced by this mycotoxin. Although the detected mutation in patients presumably contributes to the hepatocarcinogenicity of aflatoxin B_1 in humans, it is not required for aflatoxin B_1–induced hepatocarcinogenesis in rats, as rats do not show this aberration in the transformed liver cells. ***Inappropriate Activation or Responsiveness of the Regulatory Region of Critical Genes: Epigenetic Mechanisms in Carcinogenesis*** Whereas some chemicals cause cancer by reacting with DNA and inducing a mutation, others do not damage DNA, yet induce cancer after prolonged exposure (Barrett, 1992). These chemicals are designated *nongenotoxic* or *epigenetic carcinogens* and include (1) xenobiotic mitogens, such as the PKC activator phorbol esters and fumonisin B_1, as well as some other chemicals that promote mitogenic signaling, such as the protein phosphatase inhibitor okadaic acid (see Fig. 3-11); (2) endogenous mitogens, such as growth factors (e.g., TGF-α) and hormones with mitogenic action on specific cells [e.g., estrogens on mammary gland or liver cells, TSH on the follicular cells of the thyroid gland, and luteinizing hormone (LH) on Leydig cells in testes]; (3) toxicants that, when given chronically, cause sustained cell injury (such as chloroform and *d*-limonene); (4) xenobiotics that are nongenotoxic carcinogens in rodents but not in humans, such as phenobarbital, DDT, TCDD and peroxisomal proliferators (e.g., fibrates, WI-14643, di- and trihalogenated acetic acids); and (5) ethionine and diethanolamine, which interfere with formation of endogenous methyl donors (Poirier, 1994). Because several of the listed chemicals promote the development of tumors after neoplastic transformation has been initiated by a genotoxic carcinogen, they are referred to as *tumor promoters*. Despite the initial belief that promoters are unable to induce tumors by themselves, studies suggest that they can do so after prolonged exposure.

It is apparent that nongenotoxic chemicals, like the genotoxic ones, ultimately also influence proto-oncogenes and/or tumor suppressor genes, but in a different manner: they increase the transcriptional activity of proto-oncogenes and/or decrease the transcription rate of tumor suppressor genes. Therefore, nongenotoxic carcinogens, when continuously present, can permanently induce the synthesis of normal proto-oncogene proteins and/or repress the synthesis of normal tumor suppressor proteins, rather than inducing the synthesis of permanently active mutant proto-oncogene proteins or permanently inactive mutant tumor suppressor proteins, as the mutagenic genotoxic carcinogens do.

---

inactivates cdc25A, a protein phosphatase, which normally would dephosphorylate Cdk1 and activate the Cdk1-cyclin B complex (see Fig. 3-21). Thus when cdc25A is inactivated Cdk1 stalls and mitosis is delayed. Interestingly, p53 assists in keeping Cdk1, this mitosis-driving molecular motor, off track as it induces 14-3-3σ, a cytoplasmic binding protein, which associates with both cdc25A and the Cdk1-cyclin B complex and sequesters them in the cytoplasm.

By arresting division of cells with potentially mutagenic DNA damage, facilitating the DNA repair or eliminating such cells, p53 protein counteracts neoplastic development. *p53*-null mice, like *ARF*-null mice, develop tumors with high incidence. Mutational inactivation of the p53 protein is thought to contribute to the carcinogenic effect of aflatoxin B_1, sunlight and cigarette smoke in humans. Overexpression of mdm2 can lead to constitutive inhibition of p53 and thereby promotes oncogenesis even if the *p53* gene is unaltered. See the text for more details.

The ultimate target of epigenetic carcinogens is the promoter region of critical genes where they can act via two distinct modes. First, they may alter the abundance and/or activity of transcription factors, typically by influencing upstream signaling elements ranging from extracellular signaling molecules (e.g., TSH) to intracellular transducer proteins (e.g., PKC). Obviously both xenobiotic and endogenous mitogens mentioned above can thus activate proliferative pathways (see Fig. 3-11) that descend to transcription factors (e.g., Myc) that act on the promoter of proto-oncogenes (e.g., cyclins). It is easy to recognize that even epigenetic carcinogens of the cytotoxic type act in this manner. As discussed under tissue repair, cell injury evokes the release of mitogenic growth factors such as HGF and TGF-α from tissue macrophages and endothelial cells. Thus, cells in chronically injured tissues are exposed continuously to endogenous mitogens. Although these growth factors are instrumental in tissue repair after acute cell injury, their continuous presence is potentially harmful because they may ultimately transform the affected cells into neoplastic cells. Indeed, transgenic mice that overexpress TGF-α develop hepatomegaly at a young age and tumors by 12 months (Fausto *et al.*, 2006). Mitogenic cytokines secreted by Kupffer cells are apparently involved in hepatocyte proliferation and, possibly, tumor formation induced by peroxysome proliferators in rats (Rose *et al.*, 1999) and in the formation of the endothelial cell-derived hepatic hemangiosarcoma in mice exposed to 2-butoxyethanol (Corthals *et al.*, 2006).

Epigenetic carcinogens can alter expression of critical genes also by a second major mechanism, i.e., by altering the responsiveness of the promoter region of these genes to transcription factors. Promoter responsiveness is typically controlled by methylation at C_5 of specific cytosine residues located in CpG islands (i.e., clusters of CpG dinucleotides) in the promoter. It is well known that promoter methylation decreases the transcriptional activity of genes. For example, tissue specific genes (e.g., the genes of gastrointestinal trefoil factors) are fully methylated in tissues where they are not expressed, but are typically demethylated in tissues where they are expressed.

Promoter methylation by DNA cytosine methyltransferases (e.g., DNMT1, DNMT3a, and DNMT3b) can silence genes because it weakens binding of transcription factors to the promoter and because it can reduce accessibility of the promoter for transcription factors (Esteller, 2005). This latter mechanism involves modification of core histone proteins at their protruding amino-terminal tails by deacetylation and methylation of lysine residues. This makes the histone more compact, thereby diminishing access to the gene promoter of transcription factors and other proteins involved in transcription initiation. Histone deacetylases that remove the acetyl group from histone tails may be recruited by DNMTs directly, or through proteins that recognize and bind to the methylated CpG dinucleotides (e.g., MeCP1, MeCP2, MBD2, MBD3). Some of these methyl-CpG binding domain containing proteins (e.g., MBD2, MBD3) also have histone deacetylase activity. Finally, both DNMTs and MBDs can recruit histone methyltransferases (HMT) to methylate histone tail lysines.

While methylation of CpG dinucleotides codes for gene silencing via histone deacetylation and methylation ("histone code"), unmethylated genes are alert. In fact, CpG islands in the 5′-end region (promoter, untranslated region, exon 1) of genes are relatively unmethylated in normal tissues, except for tissue-specific or germline-specific genes, and genomically imprinted genes (see earlier). Thus, if the appropriate transcription factors are available for a particular gene, and if the CpG island remains unmethylated, the histones acetylated and unmethylated, then the gene will be transcribed

(Esteller, 2005). Histones are acetylated by histone acetyltransferases, such as p300 and CBP, which also acetylate other proteins, including p53 (see Fig. 3-28), and are also transcriptional coactivators.

It is well documented that the normal methylation pattern of DNA is disrupted in cancer cells. Such cells are characterized by global (average) hypomethylation, i.e., decreased content of genomic 5′-methylcytosine. Paradoxically, DNA hypomethylation occurs in the face of hypermethylation of the CpG islands in the promoter region tumor suppressor genes, which are normally demethylated (Esteller, 2005). Among the frequently hypermethylated tumor suppressor genes in human cancers are, for example, the Cdk inhibitor p15 and p16, the mdm2-binding protein ARF, pRb that tethers E2F (see Fig. 3-30), the DNA repair enzyme O^6-methyguanine-DNA-methyltransferase (MGMT) and the lipid phosphatase PTEN. Importantly, both the global hypomethylation and tumor suppressor gene hypermethylation intensify with increased malignancy of the tumor. Relevance of hypermethylation-induced silencing of tumor suppressor genes in carcinogenesis is supported by the finding that inhibitors of DNMTs (such as 5-aza-2′-deoxycytidine) can stop the growth of cancer cells and induce their differentiation by demethylating the dormant tumor suppressor genes, thereby restoring their expression (Esteller, 2005). The consequence of global hypomethylation of DNA is less clear. Nevertheless, demethylation of proto-oncogenes and increased expression of their products is a plausible mechanism (Goodman and Watson, 2002), although others have also been proposed (e.g., chromosomal instability, reactivation of transposable DNA elements and loss of genomic imprinting). On comparing mouse strains, it has been suggested that their sensitivity to chemical carcinogens may be related inversely to their capacity to maintain normal patterns of DNA methylation. It is worth noting that DNA methylation is more stable in human cells than in rodent cells (Goodman and Watson, 2002).

It appears that some of the epigenetic carcinogens alter DNA methylation. Inhibition of DNA methylation is a plausible mechanism that underlies tumorigenesis induced by ethionine, which depletes *S*-adenosyl-methionine (the methyl donor for DNMTs), and diethanolamine, which inhibits cellular uptake of choline, a dietary methyl group source for methylation of homocysteine to methionine. Upon prolonged administration, virtually all nongenotoxic rodent liver carcinogens listed above decrease DNA methylation. In addition to global DNA hypomethylation, promoter hypomethylation of the following proto-oncogenes have been observed in mouse or rat liver: *Ras* or *Raf*, following phenobarbital treatment, *c-Jun*, *c-Myc*, and *IGF-2*, after treatment with dichloro-, dibromo-, or trichloroacetic acid, and *c-Myc* after WY-14643 dosing. Long-term arsenic exposure of mice also induces hypomethylation of hepatic DNA globally and in the promoter of estrogen receptor-α (ERα), a hormone-activated transcription factor. This is associated with an increase of cyclin D, a potentially ERα-linked gene (Chen *et al.*, 2004). In contrast, in human keratinocytes TCDD induces promoter hypermethylation in the tumor suppressor genes p16 and p53 as well as immortalization of these cells (Ray and Swanson, 2004). Although the mechanisms that initiate altered promoter methylation are currently unknown, it is possible that that altered promoter methylation plays a role in tumor promotion by these nongenotoxic carcinogens.

Cooperation of Genotoxic and Epigenetic Mechanisms in Carcinogenesis   Genotoxic and epigenetic mechanisms most likely complement and amplify each other in chemical carcinogenesis. For example, tumor suppressor genes are often silenced by promoter methylation in tumors induced by genotoxic carcinogens (like

in spontaneous human tumors). In aflatoxin B_1-induced mouse lung tumor and in skin tumor induced by 7,12-dimethylbenzanthracene, tumor suppressor genes such as *p16*, *ARF* and *MGMT* exhibit increased methylation. Conversely, global DNA hypomethylation and tumor suppressor gene hypermethylation may increase the occurrence of mutations in cells exposed to epigenetic carcinogens. In this sense, epigenetic mechanisms may also initiate carcinogenesis (Goodman and Watson, 2002). Furthermore, one chemical may exert both genotoxic and epigenetic effects. This has been proposed for estrogens that may produce mutagenic free radicals via redox cycling of their quinone and hydroquinone metabolites and also induce receptor-mediated proliferative effect (Newbold, 2004). The antiestrogen tamoxifen, a hepatocarcinogen in rats (but not in humans), exerts genotoxic effect and induces global hypomethylation of DNA and histones in rat liver (Tryndyak *et al.*, 2006).

Cooperation of Proto-oncogenes and Tumor-Suppressor Genes in Carcinogenesis   The accumulation of genetic damage in the form of mutant proto-oncogenes (which encode activated proteins) and mutant tumor-suppressor genes (which encode inactivated proteins) as well as increased activation of normal proto-oncogenes (causing expression of more cell cycle accelerator proteins) and silencing of normal tumor suppressor genes (causing expression of less cell cycle decelerator proteins) are the forces that drive transformation of normal cells with controlled proliferative activity to malignant cells with uncontrolled proliferative activity. Because the number of cells in a tissue is regulated by a balance between mitosis and apoptosis, the uncontrolled proliferation results from perturbation of this balance (Fig. 3-29).

Failure of Apoptosis: Promotion of Mutation and Clonal Growth
As discussed earlier, in cells suffering DNA damage, the stabilized p53 protein may induce cell death by apoptosis (Fig. 3-28). Apoptosis thus eliminates cells with DNA damage, preventing mutations to initiate carcinogenesis. Initiated preneoplastic cells have much higher apoptotic activity than do normal cells (Bursch *et al.*, 1992) and this can counteract their clonal expansion. In fact, facilitation of apoptosis can induce tumor regression. This occurs when hormone dependent tumors are deprived of the hormone that promotes growth and suppresses apoptosis. This is the rationale for the use of tamoxifen, an antiestrogen, and gonadotropin-releasing hormone analogs to combat hormone-dependent tumors of the mammary gland and the prostate gland, respectively (Bursch *et al.*, 1992).

Thus, the inhibition of apoptosis is detrimental because it facilitates both mutations and clonal expansion of preneoplastic cells. Indeed, apoptosis inhibition plays a role in the pathogenesis of human B-cell lymphomas, in which a chromosomal translocation, results in aberrantly increased expression of Bcl-2 protein, which overrides programmed cell death after binding to and inactivating the proapoptotic Bax protein (see Fig. 3-16). Increased levels of Bcl-2 are also detected in other types of cancer, and a high Bcl-2/Bax ratio in a tumor is a marker for poor prognosis (Jäättelä, 1999). Other antiapoptotic proteins, such as Hsp 27, 70, and 90 (Sreedhar and Csermely, 2004) and IAP family members, may also contribute to progression of neoplasia. Survivin, a member of the IAP family, is expressed in all cancer cells but not in adult differentiated cells (Jäättelä, 1999).

Inhibition of apoptosis is one mechanism by which the rodent tumor promoter phenobarbital promotes clonal expansion of preneoplastic cells. This has been demonstrated in rats given a single dose of *N*-nitrosomorpholine followed by daily treatments with phenobarbital for 12 months to initiate and promote, respectively,

neoplastic transformation in liver (Schulte-Hermann *et al.*, 1990). From 6 months onward, phenobarbital did not increase DNA synthesis and cell division in the preneoplastic foci, yet it accelerated foci enlargement. The foci grow because phenobarbital lowers apoptotic activity, allowing the high cell replicative activity to manifest itself. The peroxisome proliferator nafenopin, a nongenotoxic hepatocarcinogen, also suppresses apoptosis in primary rat hepatocyte cultures (Bayly *et al.*, 1994), supporting the hypothesis that this mechanism may play a role in the hepatocarcinogenicity of peroxisome proliferators in rodents.

Failure to Terminate Proliferation: Promotion of Mutation, Proto-Oncogene Expression, and Clonal Growth   Enhanced mitotic activity, whether it is induced by oncogenes inside the cell or by external factors such as xenobiotic or endogenous mitogens, promotes carcinogenesis for a number of reasons.

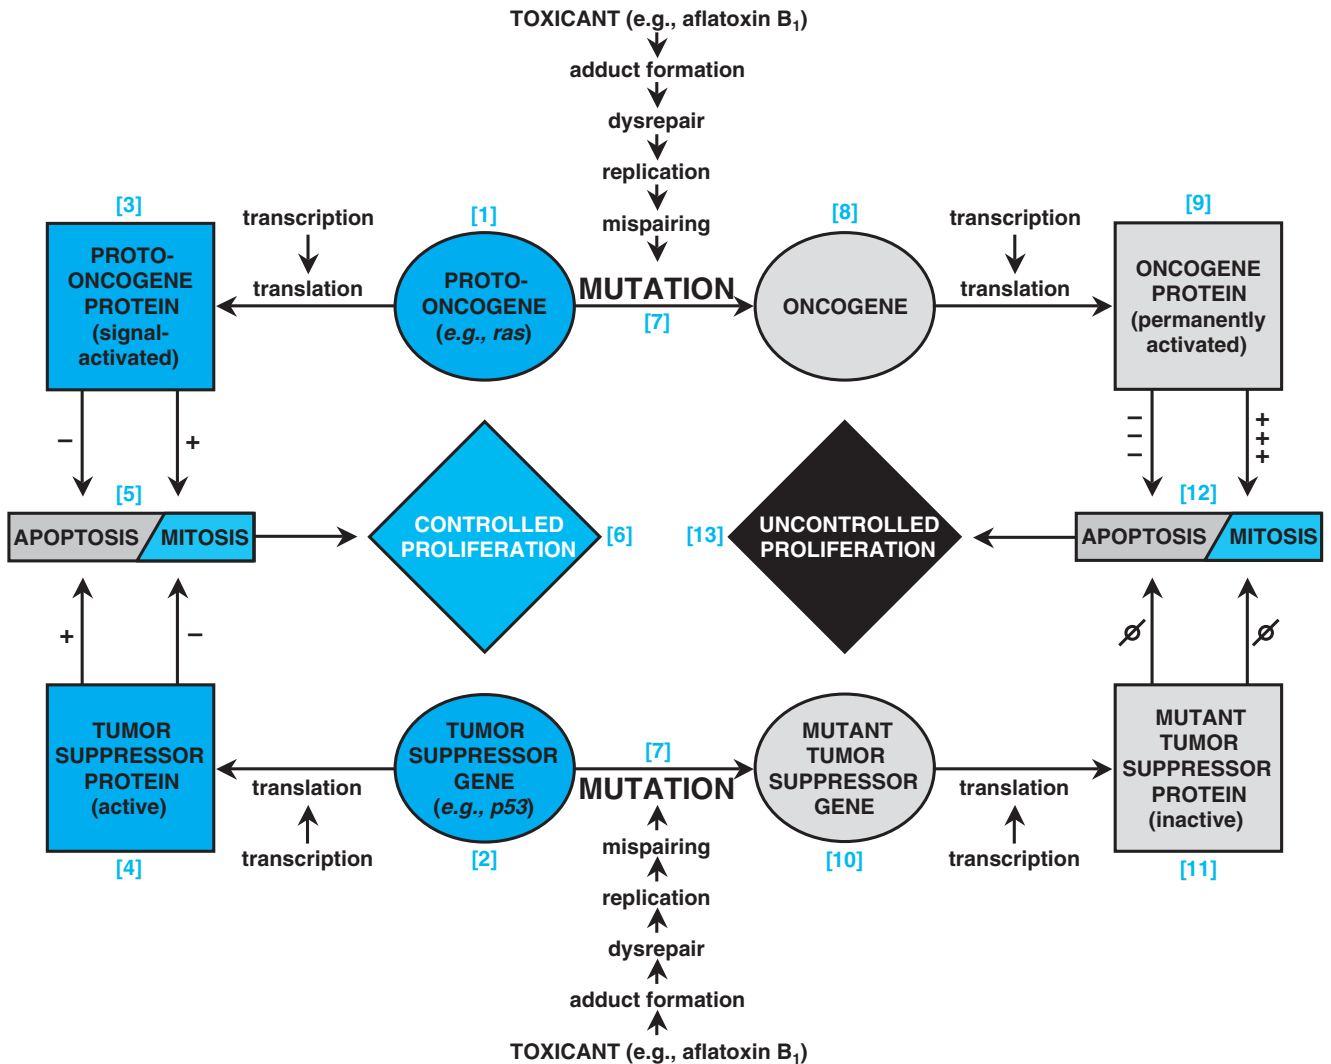
1. First, the enhanced mitotic activity increases the probability of mutations. This is due to activation of the cell-division cycle, which invokes a substantial shortening of the G_l phase. Thus, less time is available for the repair of injured DNA before replication, increasing the chance that the damage will yield a mutation. Although repair still may be feasible after replication, postreplication repair is error-prone. In addition, activation of the cell-division cycle increases the proportion of cells that replicate their DNA at any given time. During replication, the amount of DNA doubles and the DNA becomes unpacked, greatly increasing the effective target size for DNA-reactive mutagenic chemicals, including ROS.

2. Enhanced mitotic activity may compromise DNA methylation, which occurs in the early postreplication period and carried out by DNMTs that copy the methylation pattern of the parental DNA strand to the daughter strand (maintenance methylation). Limitation of DNMTs by shortened G_2 phase or by presence of other transacting factors might impair methylation and may contribute to overexpression of proto-oncogens, starting a vicious cycle.

3. Another mechanism by which proliferation promotes the carcinogenic process is through clonal expansion of the initiated cells to form nodules (foci) and tumors.

4. Finally, cell-to-cell communication through gap junctions (constructed from connexins) and intercellular adhesion through cadherins are temporarily disrupted during proliferation. Lack of these junctions contributes to the invasiveness of tumor cells. Several tumor promoters, such as phenobarbital, phorbol esters, and peroxisome proliferators, decrease gap junctional intercellular communication. It has been hypothesized that this contributes to neoplastic transformation. Increased susceptibility of connexin-knockout mice to spontaneous and chemically induced liver tumors supports this hypothesis (Chipman *et al.*, 2003).

It appears that genotoxic carcinogens induce cancer *primarily* by causing mutations in critical genes whose aberrant products promote mitosis and inhibit apoptosis, and *secondarily* by causing aberrant methylation of critical genes whose normal products produced in abnormal quantities, there by further tilting the balance of mitosis and apoptosis to the favor of the former. In contrast, nongenotoxic carcinogens cause cancer by promoting carcinogenesis initiated by genotoxic agents or spontaneous DNA damage (Fig. 3-30). Spontaneous DNA damage, which occasionally gives rise to mutation, commonly occurs in normal cells (Barrett, 1992). It is estimated



TOXICANT (e.g., aflatoxin B_1)

Figure 3-29. _A model of cooperation between a proto-oncogene (1) and a tumor suppressor gene (2) before and after mutation._

The model shows that the normal proteins encoded by the cellular proto-oncogenes and the tumor suppressor genes [(3) and (4), respectively] reciprocally influence mitosis and apoptosis (5) and thus ensure controlled cell proliferation (6). However, the balance between the effects of these two types of proteins is offset by a toxicant-induced mutation of their genes (7) if the mutant proto-oncogene (oncogene) (8) encodes a constitutively (i.e., permanently) active oncogene protein (9) and the mutant tumor suppressor gene (10) encodes an inactive tumor suppressor protein (11). Under this condition, the effect of the oncogene protein on mitosis and apoptosis is unopposed (12), resulting in uncontrolled proliferation. Such a scenario may underlie the carcinogenicity of aflatoxin B_1, which can induce mutations in _Ras_ proto-oncogene and the _p53_ tumor suppressor gene (see text for details). Positive and negative signs represent stimulation and inhibition, respectively; Ø means "no effect." It is important to realize that in addition to activating mutation of proto-oncogenes and inactivating mutation of tumor suppressor genes overexpression of normal proto-oncogenes (e.g., by hypomethylation of their promoter) and under-expression (silencing) of normal tumor suppressor genes (e.g., by hypermethylation of their promoter) may also contribute to and cooperate in neoplastic transformation of cells (see text for explanation).

that in human cells, 1 out of 10^8 to 10^{10} base pairs suffers spontaneous mutation. Genotoxic carcinogens increase the frequency 10- to 1000-fold. Nongenotoxic carcinogens also increase the frequency of spontaneous mutations through a mitogenic effect and by the mechanisms discussed earlier. In addition, nongenotoxic carcinogens, by inhibiting apoptosis, increase the number of cells with DNA damage and mutations. Both enhanced mitotic activity and decreased apoptotic activity brought about by nongenotoxic carcino-

gens expand the population of transformed cells, promoting cancer development. In summary, nongenotoxic carcinogens appear to act by enhancing cell division and/or inhibiting apoptosis.

CONCLUSIONS

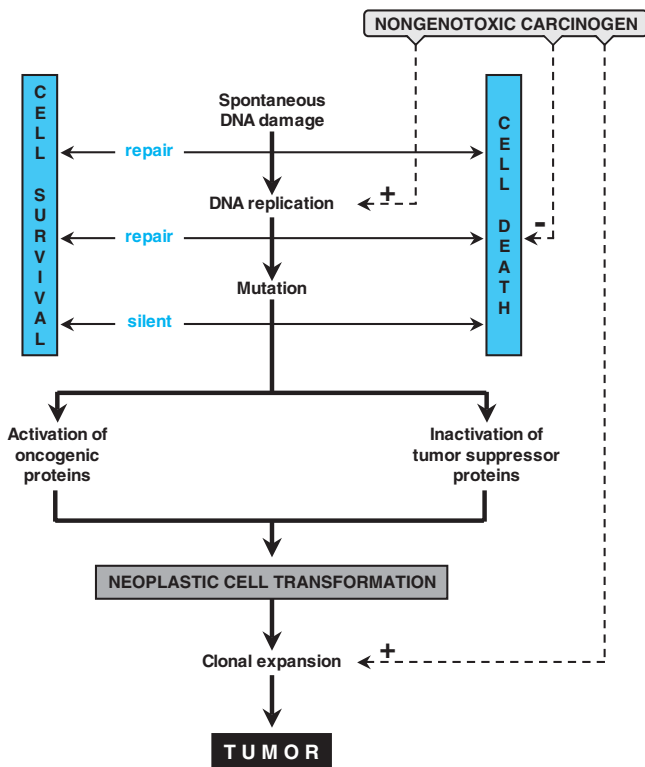
This overview systematically surveys the mechanisms of the potential events that follow toxicant exposure and contribute to toxicity.


Figure 3-30. The process of carcinogenesis promoted by nongenotoxic carcinogens.

Positive and negative signs represent stimulation and inhibition, respectively. See text for explanation.

This approach is also useful in the search for mechanisms responsible for (1) selective toxicity, that is, differences in the sensitivity to toxicants of various organisms, such as different species and strains of animals, organs, and cells, and (2) alteration of toxicity by exogenous factors such as chemicals and food and physiologic or pathologic conditions such as aging and disease. To identify the mechanisms that underlie selective toxicity or alterations in toxicity, all steps where variations might occur must be considered systematically. Selective or altered toxicity may be due to different or altered (1) exposure; (2) delivery, thus resulting in a different concentration of the ultimate toxicant at the target site; (3) target molecules; (4) biochemical processes triggered by the reaction of the chemical with the target molecules; (5) repair at the molecular, cellular, or tissue level; or (6) altered gene expression-based stress responses as well as circulatory and thermoregulatory reflexes by which the affected organism can adapt to some of the toxic effects.

In this chapter, a simplified scheme has been used to give an overview of the development of toxicity (Fig. 3-1). In reality, the route to toxicity can be considerably more diverse and complicated. For example, one chemical may yield several ultimate toxicants, one ultimate toxicant may react with several types of target molecules, and reaction with one type of target molecule may have a number of consequences. Thus, the toxicity of one chemical may involve several mechanisms which can interact with and influence each other in an intricate manner.

This chapter has emphasized the significance of the chemistry of a toxicant in governing its delivery to and reaction with the target molecule as well as the importance of the biochemistry, molecular and cell biology, immunology, and physiology of the affected organism in its response to the action of the toxicant. An organism has mechanisms that (1) counteract the delivery of toxicants, such as detoxication; (2) reverse the toxic injury, such as repair mechanisms; and (3) offset some dysfunctions, such as adaptive responses. Thus, toxicity is not an inevitable consequence of toxicant exposure because it may be prevented, reversed, or compensated for by such mechanisms. Toxicity develops if the toxicant exhausts or impairs the protective mechanisms and/or overrides the adaptability of biological systems.

CHAPTER 4

RISK ASSESSMENT

Elaine M. Faustman and Gilbert S. Omenn

INTRODUCTION AND HISTORICAL CONTEXT

Toxicologic research and toxicity testing constitute the scientific core of an important activity known as risk assessment, which is used for the evaluation of potential adverse health impacts from chemical exposures. Risk evaluation is not new since for decades the American Conference of Governmental Industrial Hygienists (ACGIH) has set threshold limit values for occupational exposures and the U.S. Food and Drug Administration (FDA) has established acceptable daily intakes for pesticide residues and food additives. In 1958, the U.S. Congress instructed the FDA in the Delaney Clause to prohibit the addition to the food supply of all substances found to cause cancer in animals or humans. Pragmatically, this policy allowed food sources that had nondetectable levels of these additives to be declared "safe." As advances in analytic chemistry revealed that "nondetects" were not equivalent to "not present," regulatory agencies were forced to develop "tolerance levels" and "acceptable risk levels." Risk assessment methodologies blossomed in the 1970s with the rising need to address these issues and statues (Albert, 1994).

In *Risk Assessment in the Federal Government: Managing the Process* (The Red Book), the National Research Council (NRC) detailed steps for hazard identification, dose–response assessment, exposure analysis, and characterization of risks (NRC, 1983). This framework has evolved into the scheme shown in Fig. 4-1, and provides a consistent risk assessment framework across agencies. The figure illustrates a framework with bidirectional arrows demonstrating an ideal situation where mechanistic research feeds directly into risk assessments and critical data uncertainty drives research. Initially, attention was focused on cancer risks; in subsequent years, noncancer endpoints were examined with similar methods. Continuing advances in toxicology, epidemiology, exposure assessment, biologically-based modeling of adverse responses, the modeling of variability and uncertainty, and the rapidly growing area of genomics have contributed to improvements in risk assessment. Nevertheless, public policy objectives often require extrapolations that go far beyond the observation of actual effects and reflect different approaches for addressing risks, generating controversy.

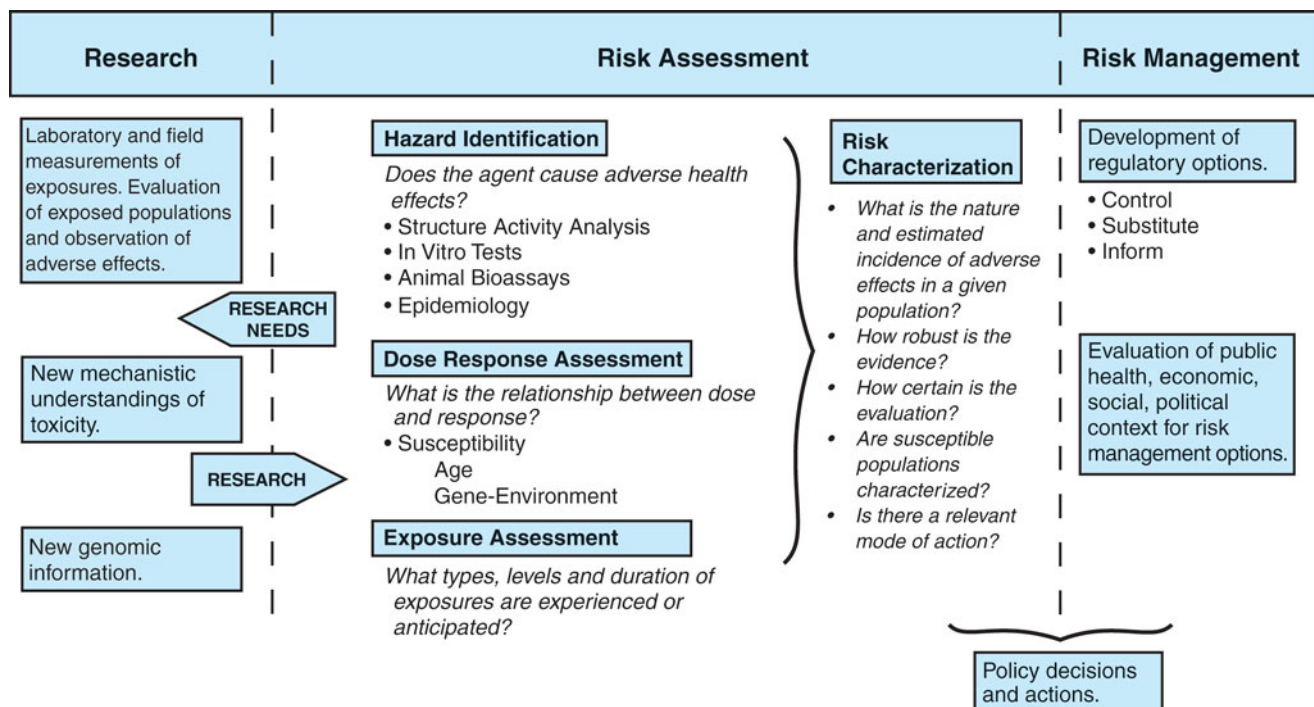
The National Academy of Sciences (NAS) 1994 report entitled *Science and Judgment in Risk Assessment* captured in its title the combination of qualitative and quantitative approaches essential for effective assessment of risks (NRC, 1994). The report discussed in detail the challenges and provided approaches for incorporating new scientific findings into the risk assessment process. It also highlighted approaches to deal with uncertainty when insufficient scientific information was available. To address these challenges, the Presidential/Congressional Commission on Risk Assessment and Risk Management (Risk Commission, 1997) formulated a comprehensive framework that (1) put each environmental problem or issue into public health and/or ecological context and (2) proactively called for engaging relevant stakeholders, often affected or potentially affected community groups, from the very beginning of the six-stage process shown in Fig. 4-2. This report emphasized that particular exposures and potential health effects must be evaluated across sources and exposure pathways and in light of multiple endpoints, not just one chemical, in one environmental medium (air, water, soil, food, products), for one health effect at a time. This has been the general approach up to the present. The importance of defining the risk problem is critical to risk assessment, a process that has been outlined by the U.S. Environmental Protection Agency (EPA) (www.epa.gov/pesticides/ecosystem/ecorisk.htm). Similar frameworks have been used by the Health and Safety Executive Risk Assessment Policy Unit of the United Kingdom (Health and Safety Executive, 2000) and by the World Health Organization (WHO).


Figure 4-1. Risk assessment/risk management framework.

This framework shows in blue the four key steps of risk assessment: hazard identification, dose–response assessment, exposure assessment, and risk characterization. It shows an interactive, two-way process where research needs from the risk assessment process drive new research, and new research findings modify risk assessment outcomes. (Adapted from NRC, 1983, 1994; Calkins, 1980; Faustman, 1996; Gargas, 1999, reprinted with permission from the National Academic Press, National Academy of Sciences.)
Figure 4-2. Risk management framework for environmental health from the U.S. Commission on Risk Assessment and Risk Management.

The framework comprises six stages: (1) formulating the problem in a broad public health context; (2) analyzing the risks; (3) defining the options; (4) making risk-reduction decisions; (5) implementing those actions; and (6) evaluating the effectiveness of the actions taken. Interactions with stakeholders are critical and thus have been put at the center of the framework. (Charnley and Omenn, 1997; Risk Commission, 1997).

DEFINITIONS

Risk assessment is the systematic scientific evaluation of potential adverse health effects resulting from human exposures to hazardous agents or situations (NRC, 1983, 1994; Omenn, 2000). *Risk* is defined as the probability of an adverse outcome based upon the exposure and potency of the hazardous agent(s). Although historically there have been differences in how the term *hazard* has been used, international risk harmonization activities have allowed for current consensus on hazard as reference to intrinsic toxic properties. Risk assessment requires an integration of both qualitative as well as quantitative scientific information. For example, qualitative information about the overall evidence and nature of the endpoints and hazards are integrated with quantitative assessment of the exposures, host susceptibility factors, and the magnitude of the hazard. A description of the uncertainties and variability in the estimates is a significant part of risk characterization and an essential component of risk assessment. Analogous approaches are applied to ecologic risks, as demonstrated by EPA's ecological risk assessment guidelines (http://www.epa.gov/pesticides/ecosystem/ecorisk.htm). The objectives of risk assessment are outlined in Table 4-1.

The phrase *characterization of risk* reflects the combination of qualitative and quantitative analysis. Increasingly, the use of the term "hazard characterization" versus "hazard identification" has been seen in both the EPA (2005a) and WHO (World Health Organization, 2004) documents. This shift recognizes the difficulties in evaluating only hazard information without dose–response information. Unfortunately, many users equate risk assessment with quantitative risk assessment, generating a number for an overly precise risk estimate, while ignoring crucial information about the

Table 4.1

Objectives of Risk Assessment

1. Balance risks and benefits.
   Drugs
   Pesticides
2. Set target levels of risk.
   Food contaminants
   Water pollutants
3. Set priorities for program activities.
   Regulatory agencies
   Manufacturers
   Environmental/consumer organizations
4. Estimate residual risks and extent of risk reduction after steps are taken to reduce risks.

uncertainties of the risk assessment, mechanism, and type of effect across species. In January 2006, the Office of Management and Budget (OMB) in collaboration with the Office of Science and Technology Policy (OSTP) proposed standards and guidelines for agency risk assessments with the aim of improving the technical quality and transparency of information used in risk assessment and subsequent public policy and regulation. In part, the draft guidelines have emphasized the need to provide uncertainty and variability characterization in the estimate of risk. The NAS reviewed the OMB proposal in 2007.

Risk management refers to the process by which policy actions are chosen to control hazards identified in the risk assessment stage of the framework (Fig. 4-2). Risk managers consider scientific evidence and risk estimates—along with statutory, engineering, economic, social, and political factors—in evaluating alternative options and choosing among those options (Risk Commission, 1997).

Risk communication is the challenging process of making risk assessment and risk management information comprehensible to community groups, lawyers, local elected officials, judges, busi-

ness people, labor, and environmentalists (Morgan, 1993; Sandman, 1993; Fischhoff *et al.*, 1996; NRC, 1996). Part of this analytic-deliberative process is the crucial, too-often neglected requirement of considering the fears, perceptions, priorities, and proposed remedies of these "stakeholders" (Risk Commission, 1997; Drew *et al.*, 2003; Judd *et al.*, 2005). Sometimes the decision makers and stakeholders simply want to know the "bottom line": is a substance or a situation "safe" or not? Others will be keenly interested in knowing why the risk estimates are uncertain and may be well prepared to challenge underlying assumptions about context and methodology. The *perception of risk* is further discussed at the end of this chapter.

DECISION MAKING

Risk management decisions are reached under diverse statutes in the United States. Table 4-2 lists examples of major environmental statutes and the year of initial enactment. Some statutes specify reliance on risk alone, whereas others require a balancing of risks and benefits of the product or activity. Risk assessments provide a valuable framework for priority setting within regulatory and health agencies, in the chemical development process within companies, and in resource allocation by environmental organizations. Similar approaches for risk assessment have been developed in many other countries and through such international organizations as the International Programme for Chemical Safety (IPCS) within the WHO. Currently within the IPCS, there are significant efforts toward a global harmonization of risk assessment methodology. The goal is to develop confidence and acceptance of different assessment approaches through a common understanding and agreement on basic principles of testing and assessment.

A major challenge for risk assessment, risk communication, and risk management is to work across disciplines to demonstrate the biological plausibility and clinical significance of the conclusions from epidemiologic, lifetime animal, short-term in vitro and in vivo, and structure–activity studies of chemicals thought to have

Table 4.2

Examples of Major Toxic Chemical Laws in the United States by Responsible Agency and Year of Initial Enactment

potential adverse effects. Biomarkers of exposure, effect, or individual susceptibility can link the presence of a chemical in various environmental compartments to specific sites of action in target organs and to host responses (NRC, 1989a,b, 1992a,b). Mechanistic investigations of the actions of specific chemicals can help us penetrate the "black box" approach of simply counting tumors, for example, in exposed animals in routine bioassays. Greater appreciation of the mechanisms and extent of individual variation in susceptibility among humans can improve protection of subgroups of susceptible populations and better relate findings in animals to the characterization of risk for humans. Individual behavioral and social risk factors may be critically important both to the risk and to the reduction of risk. Finally, public and media attitudes toward local polluters, other responsible parties, and relevant government agencies may lead to what has been labeled "the outrage factor" (Sandman, 1993), greatly influencing the communication process and the choices for risk management.

HAZARD IDENTIFICATION

Assessing Toxicity of Chemicals—Introduction

In order to assess the toxicity of chemicals, information from four types of studies is used: structure–activity relationships (SAR), in vitro or short-term studies, in vivo animal bioassays, and information from human epidemiological studies. In many cases, toxicity information for chemicals is limited. For example, in 1998, the EPA evaluated high production volume (HPV) chemicals (those produced in excess of 1 million lb/y) to ascertain the availability of chemical hazard data. Their study found that for 43% of these HPV chemicals, there were no publicly available studies for any of the basic toxicity endpoints (EPA, 1998a). In response, EPA established a voluntary program called the HPV Challenge Program (www.epa.gov/hpv/). Industry participants in this program committed to filling the data gaps for HPV chemicals. Since its inception, there have been over 2,200 chemicals sponsored for additional testing. International efforts such as the Organization for Economic Cooperation and Development's screening information data set (OECD/SIDS) program are also addressing data needs related to HPV, highlighted by the publication of their Manual for Investigation of HPV Chemicals (www.oecd.org).

Data requirements for specific chemicals can vary greatly by compound type and applicable regulatory statutes. Introduced in 2003 and approved in 2006, the European Union released a regulatory framework for Registration, Evaluation and Authorisation of Chemicals (REACH) (http://ec.europa.eu/environment/chemicals/reach/reach_intro.htm). Under the REACH framework, starting in 2007, all stakeholders must submit physical, chemical, and toxicological data as well as risk assessment studies for all chemicals in use. Table 4-3 shows requirements and costs during 1997 for one example class of agents, pesticides (Stevens, 1997); 40 CFR 158.340 (EPA, 1998b, 2000a). It also illustrates current international efforts to harmonize these testing guidelines by listing examples of the new harmonized 870 test guidelines (EPA, 2000b).

Assessing Toxicity of Chemicals—Methods

Structure–Activity Relationships   Given the cost of $2 to $4 million and the 3–5 years required for testing a single chemical in a lifetime rodent carcinogenicity bioassay, initial decisions on whether to continue development of a chemical, to submit pre-manufacturing

notice (PMN), or to require additional testing may be based largely on results from structure–activity relationships (SARs) and limited short-term assays.

A chemical's structure, solubility, stability, pH sensitivity, electrophilicity, volatility, and chemical reactivity can be important information for hazard identification. Historically, certain key molecular structures have provided regulators with some of the most readily available information on the basis of which to assess hazard potential. For example, 8 of the first 14 occupational carcinogens were regulated together by the Occupational Safety and Health Administration (OSHA) as belonging to the aromatic amine chemical class. The EPA Office of Toxic Substances relies on SARs to meet deadlines to respond to pre-manufacturing notice for new chemical manufacture under the Toxic Substances Control Act (TSCA). Structural alerts such as *N*-nitroso or aromatic amine groups, amino azo dye structures, or phenanthrene nuclei are clues to prioritize chemicals for additional evaluation as potential carcinogens. The database of known developmental toxicants limits SARs to a few chemical classes, including chemicals with structures related to those of valproic acid, retinoic acid, phthalate esters, and glycol ethers (NRC, 2000). More recently, omic technologies have been used to supplement SAR relationship databases, as seen with the creation of the National Cancer Institute's (NCI) gene expression database (http://dtp.nci.nih.gov/).

SARs have been used for assessment of complex mixtures of structurally related compounds. A prominent application has been the assessment of risks associated with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), related chlorinated and brominated dibenzo-*p*-dioxins, dibenzofurans, and planar biphenyls, and chemicals generally present as mixtures in the environment. The use of toxicity equivalence factors (TEFs) is used to evaluate health risks associated with closely related chemicals. For the TCDD class, this is based on a common mechanism of aryl-hydrocarbon (Ah) receptor induction (EPA, 1994b). The estimated toxicity of environmental mixtures containing these chemicals is calculated as the sum of the product of the concentration of each chemical multiplied by its TEF value. The World Health Organization has organized efforts to reach international consensus on the TEFs used for polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), and polychlorinated dibenzofurans (PCDFs) for both humans and wildlife, and has recently updated its values and published the supporting database (Van den Berg *et al*., 1998, 2006; Haws *et al*., 2006). Under the auspices of WHO, the dioxin-like PCB congeners have been assigned TEFs reflecting their toxicity relative to TCDD, which itself has been assigned a TEF of 1.0.

Computerized SAR methods have, in general, given disappointing results in the National Toxicology Program (NTP) 44-chemical rodent carcinogenicity prediction challenge (Ashby and Tennant, 1994; Omenn *et al*., 1995; Benigni and Zito, 2004). More focused efforts are those of pharmaceutical companies successfully using combinatorial chemistry and three-dimensional (3D) molecular modeling approaches to design ligands (new drugs) that can sterically fit into the "receptors of interest." However, for environmental pollutants where selective binding to specific receptors is rare, these applications of SAR has had limited applications within risk assessment.

In Vitro and Short-Term Tests   The next level of biological information obtained within the hazard identification process includes assessment of the test chemical in in vitro or short-term tests, ranging from bacterial mutation assays performed entirely in vitro to more elaborate short-term tests, such as skin-painting studies in mice or

Table 4.3
EPA/FIFRA Requirement for Hazard Evaluation of Pesticides

GUIDE-ELINE NO.	REVISED 870 GUIDELINE	TYPE OF TOXICITY STUDY	TEST SYSTEM	OBJECTIVE	APPROXIMATE COST/STUDY (US$)
81-1	1100	Acute oral	Rats	Define toxic dose by ingestion	2000
81-2	1200	Acute dermal	Rabbits	Define toxic dose by absorption through skin	1500
81-3	1300	Acute inhalation	Rats	Define toxic dose by inhalation	5000
81-4	2400	Ocular	Rabbits	Assess eye irritation/injury	1500
81-5	2500	Skin irritation	Rabbits	Assess skin irritation/injury	100
81-6	2600	Sensitization	Guinea pigs	Assess allergic potential	3000
81-7	6100–6855	Neurotoxicity*[†]	Hens/rats	Assess nervous system injury	25,000[†]
84-2	5100–5915	Mutagenicity[‡]	In vivo/in vitro	Determine genotoxic potential; screen for carcinogenicity	5,000[§]
82-1	3050–3465	Range-finding[‡] Subacute (28- to 90-day§)	Rats	Determine effects following repeated doses; set dose level	70,000
			Mice		70,000
			Dogs	for longer studies	100,000
			Rabbits		75,000
			Tats	Identify target organs; set dose	190,000
			Mice levels for chronic studies		190,000
83-5	4200–4300	Carcinogenicity/ Chronic toxicity	Rats	Determine potential to induce	1,400,000
83-2			Mice	tumors; define dose-response relationships (lifetime)	800,000
83-1			Dogs	Determine long-term toxic effects (1 year)	400,000
83-3	3550–3800	Reproduction and teratogenicity	Rats	Determine potential to cause fetal	505,000
83-4			Rabbits	abnormalities and effects on development, fertility, pregnancy, and development of offspring over at least two generations	
85-1	7485	Toxicokinetics	Rats Mice	Determine and quantitate the metabolic fate of a pesticide	100,000

*Required for organophosphate insecticides only.

[†]Additional neurotoxicity tests 81-7, 81-8, 82-6, 82-7, and 83-6 have been added to requirements for certain materials and can include tests such as functional observational battery, motor activity, developmental landmarks, and learning and memory assessments (Sette, 1991). Costs listed for this type of study are only those for the initial study, not additional testing.

[‡]Range-finding studies are not required, but provide justification for setting dose levels in required studies. EPA-required studies can include reverse mutation assays in *Salmonella*, forward mutation assays in mammalian cells—e.g., Chinese hamster ovary cells, mouse lymphoma L5178Y (the locus cells)—and in vivo cytogenetics (Dearfield, 1990).

[§]Indicates per assay cost and represent 1997 estimates using guideline 81 series.

SOURCE: Adapted from Stevens, (1997), and updated with newly revised EPA 870 guideline information (EPA, 2000b). For details on changes in the Health Effects test guidelines reflective of the harmonization of the toxicology guidelines between the Office of Pollution Prevention and Toxics (OPPT) and the Office of Pesticide Programs (OPP), within the EPA and with the Organization for Economic Cooperation and Development (OECD) guidelines, see EPA (2000b) (http://www.epa.gov/OPPTS_Harmonized/870_Health_Effects_Test_Guidelines).

altered rat liver–foci assays conducted in vivo. For example, EPA mutagenicity guidelines call for assessment of reverse mutations using the Ames *Salmonella typhimurium* assay; forward mutations using mammalian cells, mouse lymphoma L5178Y, Chinese hamster ovary, or Chinese hamster lung fibroblasts; and in vivo cytogenetics assessment (bone marrow metaphase analysis or micronucleus tests). Chapter 8 discusses uses of these assays for identifying chemical carcinogens and Chap. 9 describes in detail various assays of genetic and mutagenic endpoints. Other assays evaluate developmental toxicity (Faustman, 1988; Schwetz, 1993; Whittaker and Faustman, 1994; Brown et al., 1995; Lewandowski et al., 2000; NRC, 2000), reproductive toxicity (Gray, 1988; Harris et al., 1992; Shelby et al., 1993), neurotoxicity (Atterwill et al., 1992; Costa, 2000), and immunotoxicity (Chap. 12). Less information is available on the extrapolation of these test results for noncancer risk assessment than for the mutagenicity or carcinogenicity endpoints;

however, mechanistic information obtained in these systems has been applied to risk assessment (Abbott *et al.*, 1992; EPA, 1994a; Leroux *et al.*, 1996; NRC, 2000).

Overall, progress in developing new in vitro assays has been slow and frustrating. The 2005 EPA guidelines for carcinogen risk assessment lists standard tests for gene mutations in bacteria and mammalian cells and for structural chromosomal aberrations as relevant in vitro methods. In addition, they highlight the option of newer methods including mouse mutations and cancer transgenic models.

The Interagency Coordinating Committee on the Validation of Alternative Methods (ICCVAM) of NTP has reinvigorated the validation process in the United States as a result of Public Law 103-43 and coordinates cross-agency issues relating to development, validation, acceptance, and national/international harmonization of toxicological test methods for use in risk assessments. The committee has put forth recommendations for various short-term/in vitro assays, such as the cell-free corrosivity test, and for the mouse local lymph node assay for assessing chemical potential to elicit allergic contact dermatitis (NIEHS, 1999a,b). In addition, in 2006 the committee released a draft document that extensively reviews in vitro acute toxicity methods (http://ntp-apps.niehs.nih.gov/iccvampb/SearchDoc.cfm). The European Centre on the Validation of Alternative Methods (ECVAM) was also formed to "support the development, validation, and acceptance of methods that could reduce, refine, or replace the use of laboratory animals" (http://ecvam.jrc.cec.eu.int/index.htm). Recent successes of EC-VAM are described in Hartung *et al.* (2003).

The validation and application of short-term assays is particularly important to risk assessment because such assays can be designed to provide information about mechanisms of effects, moreover, they are fast and inexpensive compared with lifetime bioassays (McGregor *et al.*, 1999). Validation of in vitro assays, like other kinds of tests, requires determination of their sensitivity (ability to identify true carcinogens), specificity (ability to recognize noncarcinogens as noncarcinogens), and predictive value for the toxic endpoint under evaluation. The societal costs of relying on such tests, with false positives (noncarcinogens classified as carcinogens) and false negatives (true carcinogens not detected) are the subject of a value-of-information model for testing in risk assessment and risk management (Lave and Omenn, 1986; Omenn and Lampen, 1988).

Efforts to improve our ability to utilize short-term tests for carcinogenicity prediction include increased attention to improving the mechanistic basis of short-term testing. Examples of this approach include the development and application of several knockout transgenic mouse models as shorter-term in vivo assays to identify carcinogens and currently under evaluation by NTP (Nebert and Duffy, 1997; Tennant *et al.*, 1999). The primary use of short-term tests continues to be for mechanistic evaluations. In that context, results from short-term assays have impacted risk assessments. For example, evidence of nonmutagenicity in both in vitro and in vivo short-term assays play an essential role, allowing regulators to consider nonlinear cancer risk assessment paradigms for nongenotoxic carcinogens (EPA, 1999b). Mechanistic information from short-term in vitro assays can also be used to extend the range of biological observations available for dose–response assessment. In addition, assay methods building on new knowledge from molecular and developmental biology for developmental toxicity risk assessment that acknowledge the highly conserved nature of developmental pathways across species should accelerate use of a broader range of model organisms and assay approaches for noncancer risk assessments (NRC, 2000).

Animal Bioassays   Animal bioassays are a key component of the hazard identification process. A basic premise of risk assessment is that chemicals that cause tumors in animals can cause tumors in humans. All human carcinogens that have been adequately tested in animals produce positive results in at least one animal model. Thus, "although this association cannot establish that all agents and mixtures that cause cancer in experimental animals also cause cancer in humans, nevertheless, in the absence of adequate data on humans, it is biologically plausible and prudent to regard agents and mixtures for which there is sufficient evidence of carcinogenicity in experimental animals as if they presented a carcinogenic risk to humans" (IARC, 2000)—a reflection of the "precautionary principle." The USEPA Cancer Guidelines (EPA, 2005b) also assume relevance of animal bioassays unless lack of relevance for human assessment is specifically determined. In general, the most appropriate rodent bioassays are those that test exposure pathways of most relevance to predicted or known human exposure pathways. Bioassays for reproductive and developmental toxicity and other noncancer endpoints have a similar rationale. The National Toxicology Program Center for the Evaluation of Risks to Human Reproduction (CERHR) serves as a resource to the public and regulatory agencies regarding the interpretation and assessment of adverse effects of chemicals on reproduction and development (http://cerhr.niehs.nih.gov/).

Consistent features in the design of standard cancer bioassays include testing in two species and both sexes, with 50 animals per dose group and near lifetime exposure. Important choices include the strains of rats and mice, the number of doses, and dose levels [typically 90, 50, and 10–25% of the maximally tolerated dose (MTD)], and the details of the required histopathology (number of organs to be examined, choice of interim sacrifice pathology, etc.). The NTP website lists details on study designs and protocols (http://ntp-server.niehs.nih.gov/). Positive evidence of chemical carcinogenicity can include increases in number of tumors at a particular organ site, induction of rare tumors, earlier induction (shorter latency) of commonly observed tumors, and/or increases in the total number of observed tumors.

The cancer bioassay, designed for hazard identification, is frequently used to evaluate dose–response. The relatively limited number of evaluated doses and the use of high doses have caused issues for low-dose extrapolations and has limited the use of cancer bioassays as a "gold standard" for prediction of human carcinogenicity risk (McClain, 1994; Cohen, 1995; Risk Commission, 1997; Rodericks *et al.*, 1997; Capen *et al.*, 1999; Rice *et al.*, 1999). Tumors may be increased only at the highest dose tested, which is usually at or near a dose that causes systemic toxicity (Ames and Gold, 1990). Second, even without toxicity, the high dose may trigger different events than do low-dose exposures.

Rats and mice give concordant positive or negative results in only 70% of bioassays, so it is unlikely that rodent/human concordance would be higher (Lave *et al.*, 1988). Haseman and Lockhart (1993) concluded that most target sites in cancer bioassays showed a strong correlation (65%) between males and females—especially for forestomach, liver, and thyroid tumors—so they suggested, for efficiency, that bioassays could rely on a combination of male rats and female mice. Even when concordant, positive results are observed, there can still be large differences in potency, as observed in aflatoxin-induced tumors in rats and mice. In this example, an almost 100,000-fold difference in susceptibility to aflatoxin B_1 (AFB_1)-induced liver tumors is seen between the sensitive rat and trout species versus the more resistant mouse strains. Genetic differences in the expression of cytochrome P450 and

glutathione-S-transferases explain most of these species differences and suggest that humans may be as sensitive to AFB_1-induced liver tumors as rats (Eaton and Gallagher, 1994; Eaton *et al.*, 1995, 2001). These species differences have been supported by research results (Groopman and Kensler, 1999) and have been extended within epidemiological studies to demonstrate the interaction of hepatitis C infection with AFB_1 exposure to fully explain elevated human liver cancer risks.

Lifetime bioassays have been enhanced with the collection of additional mechanistic data and with the assessment of multiple noncancer endpoints. It is feasible and desirable to integrate such information together with data from mechanistically oriented short-term tests and biomarker and genetic studies in epidemiology (Perera and Weinstein, 2000). In the example of AFB_1 induced liver tumors, AFB_1-DNA adducts have proved to be an extremely useful biomarker. A highly linear relationship was observed between liver tumor incidence (in rats, mice, and trout) and AFB_1-DNA adduct formation over a dose range of five orders of magnitude (Eaton and Gallagher, 1994). Such approaches may allow for an extension of biologically observable phenomena to doses lower than those leading to frank tumor development and help to address the issues of extrapolation over multiple orders of magnitude to predict response at environmentally relevant doses.

Table 4-4 presents some mechanistic details about rodent tumor responses that are no longer thought to be directly predictive of cancer risk for humans. This table lists examples of both qualitative and quantitative considerations useful for determining relevance of rodent tumor responses for human risk evaluations. An example of qualitative considerations is the male rat kidney tumor observed following exposure to chemicals that bind to a_{2u}-globulin (e.g., unleaded gasoline, 1,4-dichlorobenzene, D-limonene). The a_{2u}-globulin is a male-rat-specific low-molecular-weight protein not found in female rats, humans, or other species, including mice and monkeys (McClain, 1994; Neumann and Olinn, 1995; Oberdorster, 1995; Omenn *et al.*, 1995; Risk Commission, 1997; Rodericks *et al.*, 1997).

Table 4-4 also illustrates quantitative considerations important for determining human relevance of animal bioassay information. For example, doses of compounds so high as to exceed solubility in the urinary tract outflow lead to tumors of the urinary bladder in male rats following crystal precipitation and local irritation leading to hyperplasia. Such precipitates are known to occur following saccharin or nitriloacetic acid exposure (Cohen *et al.*, 2000). The decision to exclude saccharin from the NTP list of suspected human carcinogens reaffirms the nonrelevance of such high-dose responses for likely human exposure considerations (Neumann and Olinn, 1995; National Toxicology Program, 2005). A gross overloading of the particle clearance mechanism of rat lungs via directly administered particles, as was seen in titanium dioxide (TDO) exposures, resulted in EPA's delisting TDO as a reportable toxicant for the Clean Air Act Toxic Release Inventory (EPA, 1988c; Oberdorster, 1995).

Table 4.4

Examples of Mechanistic Considerations for Carcinogens: Explanation for Special Cases of Rodent Bioassay Data Lacking Relevance for Human Risk Evaluation

SYSTEM	TARGET ORGAN	MECHANISM FOR SUSCEPTIBLE SPECIES	SPECIES DIFFERENCES	ILLUSTRATIVE CHEMICAL AGENTS
Urinary tract	Renal tumors in male rats	Chemicals bind to a_{2U}-globulin Accumulation in target kidney cells Increased necrosis Increased regenerative hyperplasia Renal tubular calcification neoplasia	a_{2U}-globulin male rat specific low-molecular weight protein not found in female rats, humans, mice, monkeys	Unleaded gasoline 1,4-Dichlorobenzene D-limonene Isophorons Dimethyl-methylphosphonate Perchloroethylene Pentachloroethane Hexachloroethane
	Bladder	Reactive hyperplasia from cytotoxic precipitated chemicals	Rodent exposure levels exceed solubility, not relevant for human exposure	Saccharin, melamine, nitrilotriacetic acid, fosetyl-A2
Gastric	Forestomach	Direct oral gavage Local cytotoxicity Hyperplasia	Rodent gavage treatment, exposure conditions not relevant for human exposure	BHA, propionic acid, ethyl acrylate
Endocrine	Thyroid gland tumors	Alteration in thyroid homeostasis Decreased thyroid hormone production Sustained increase in thyroid stimulating hormone (TSH) Thyroid tumors	Lack of thyroid-binding protein in rodents versus humans Decreased $t_{1/2}$ for T_4; increased TSH levels in rodents	Ethylene bisdithio-carbamate, fungicides, amitrol, goitrogens, sulfamethazine
Respiratory	Rat lung	Overwhelming clearance mechanisms	High dose effects seen with rodent models	Various particles, titanium dioxide

Table 4.5

Example of Three Types of Epidemiological Study Designs

METHODOLOGICAL ATTRIBUTES	TYPE OF STUDY		
	COHORT	CASE-CONTROL	CROSS-SECTIONAL
Initial classification	Exposure–nonexposure	Disease–nondisease	Either one
Time sequence	Prospective	Retrospective	Present time
Sample composition	Nondiseased individuals	Cases and controls	Survivors
Comparison	Proportion of exposed with disease	Proportion of cases with exposure	Either one
Rates	Incidence	Fractional (%)	Prevalence
Risk index	Relative risk-attributable risk	Relative odds	Prevalence
Advantages	Lack of bias in exposure; yields incidence and risk rates	Inexpensive, small number of subjects, rapid results, suitable for rare diseases, no attrition	Quick results
Disadvantages	Large number of subjects required, long follow-up, attrition, change in time of criteria and methods, costly, inadequate for rare diseases	Incomplete information, biased recall, problem in selecting control and matching, yields only relative risk—cannot establish causation, population of survivors	Cannot establish establish causation (antecedent consequence); population of survivors; inadequate for rare diseases

SOURCES: Gamble and Battigelli, 1978, 1991.

Other rodent responses not likely to be predictive for humans include localized forestomach tumors after gavage. Ethyl acrylate, which produces such tumors, was delisted on the basis of extensive mechanistic studies (National Toxicology Program, 2005). In general, for risk assessment, it is desirable to use the same route of administration as the likely exposure pathway in humans to avoid such extrapolation issues. Despite the example of forestomach tumors, tumors in unusual sites—like the pituitary gland, the eighth cranial nerve, or the Zymbal gland—should not be immediately dismissed as irrelevant, since organ-to-organ correlation is often lacking (NRC, 1994). The EPA cancer guidelines provide a good list of considerations for evaluating relevance in the sections on evaluating weight of evidence (EPA, 2005b).

In an attempt to improve the prediction of cancer risk to humans, transgenic mouse models have been developed as possible alternative to the standard two-year cancer bioassay. Transgenic models use knockout or transgenic mice that incorporate or eliminate a gene that has been linked to human cancer. NTP evaluated some of these models and found the p53 deficient (p53+/− heterozygous) and Tg.AC (v-Ha-ras transgene) models to be particularly useful in identifying carcinogens and mechanisms of action (Bucher, 1998; Chhabra et al., 2003). The use of transgenic models has the power to improve the characterization of key cellular and mode of action of toxicological responses (Mendoza et al., 2002; Gribble et al., 2005). However, these studies have been used primarily for mechanistic characterization than for hazard identification. Transgenic models have been shown to reduce cost and time as compared to the standard 2-year assay but also have been shown to be somewhat limited in their sensitivity (Cohen, 2001). As stated in the current EPA Cancer Guidelines, transgenic models should not be used to replace the standard 2-year assay, but should be used in conjunction with other types of data to assist in the interpretation of additional toxicological and mechanistic evidence (EPA, 2005b).

Use of Epidemiologic Data in Risk Assessment   The most convincing line of evidence for human risk is a well-conducted epidemiologic study in which a positive association between exposure and disease has been observed (NRC, 1983). Epidemiologic studies are essentially opportunistic. Studies begin with known or presumed exposures, comparing exposed versus nonexposed individuals, or with known cases, compared with persons lacking the particular diagnosis.

Table 4-5 shows examples of epidemiologic study designs and provides clues on types of outcomes and exposures evaluated. Although convincing, there are important limitations inherent in epidemiologic studies. When the study is exploratory, hypotheses are often weak. Robust exposure estimates are often difficult to obtain as they are frequently done retrospectively and have a long latency before clinical manifestations appear. Another challenge for interpretation is that there are often exposures to multiple chemicals, especially when a lifetime exposure period is considered. There is always a trade-off between detailed information on relatively few persons and very limited information on large numbers of persons. Contributions from lifestyle factors, such as smoking and diet, are important to assess as they can have a significant impact on cancer development. Human epidemiology studies provide very useful information for hazard assessment and can provide quantitative information for data characterization. Several good illustrations of epidemiological studies and their interpretation for toxicological evaluation are available (Gamble and Battigelli, 1991; Checkoway, 1997; Lippmann and Schlesinger, 2000).

There are three major types of epidemiology study designs: cross-sectional studies, cohort studies, and case-control studies, as detailed in Table 4-5. Cross-sectional studies survey groups of humans to identify risk factors (exposure) and disease but are not useful for establishing cause and effect. Cohort studies evaluate individuals selected on the basis of their exposure to a chemical under study. Thus, based on exposure status, these individuals are

monitored for development of disease. These prospective studies monitor over time individuals who initially are disease-free to determine the rates at which they develop disease. In case-control studies subjects are selected on the basis of disease status: disease cases and matched cases of disease-free individuals. Exposure histories of the two groups are compared to determine key consistent features in their exposure histories. All case-control studies are retrospective studies.

In risk assessment, epidemiologic findings are judged by the following criteria: strength of association, consistency of observations (reproducibility in time and space), specificity (uniqueness in quality or quantity of response), appropriateness of temporal relationship (did the exposure precede responses?), dose–responsiveness, biological plausibility and coherence, verification, and analogy (biological extrapolation) (Hill, 1965). In addition, epidemiologic study designs should be evaluated for their power of detection, appropriateness of outcomes, verification of exposure assessments, completeness of assessing confounding factors, and general applicability of the outcomes to other populations at risk. Power of detection is calculated using study size, variability, accepted detection limits for endpoints under study, and a specified significance level (Healey, 1987; Dean, 1995; EGRET, 1994).

Recent advances from the human genome project, increased sophistication and molecular biomarkers, and improved mechanistic bases for epidemiologic hypotheses, have allowed epidemiologists to get within the "black box" of statistical associations and move forward our understanding of biological plausibility and clinical relevance. "Molecular epidemiology," the integration of molecular biology into traditional epidemiologic research, is a new focus of human studies where improved molecular biomarkers of exposure, effect, and susceptibility have allowed investigators to more effectively link molecular events in the causative disease pathway. Epidemiologists can now include the contribution of potential genetic factors with environmental risk factors to the determination of the etiology, distribution, and prevention of disease. Highlighting the potential power of genetic information to epidemiological studies, the Human Genome Epidemiology Network (HuGE) was launched in 2001, providing a literature database of published, population-based epidemiologic studies of human genes (Lin *et al*., 2006).

With the advance of genomics, the range of biomarkers has grown dramatically and includes identification of single nucleotide polymorphisms (SNPs), genomic profiling, transcriptome analysis, and proteomic analysis (Simon and Wang, 2006). Implications of these improvements for risk assessment are tremendous, as they provide an improved biological basis for extrapolation across the diversity of human populations and allow for improved cross-species comparisons with rodent bioassay information. In addition, genomics allows for "systems-based" understanding of disease and response, moving risk assessment away from a linear, single-event-based concept and improving the biological plausibility of epidemiologic associations (Toscano and Oehlke, 2005).

Integrating Qualitative Aspects of Risk Assessment

Qualitative assessment of hazard information should include a consideration of the consistency and concordance of findings, including a determination of the consistency of the toxicological findings across species and target organs, an evaluation of consistency across duplicate experimental conditions, and a determination of the adequacy of the experiments to detect the adverse endpoints of interest.

NTP uses several categories to classify bioassay results, with the category *clear evidence of carcinogenicity* describing bioassays where dose-related increases in malignant or combined malignant and benign neoplasms are seen across doses including at least a significant increase in two of the four species/sex test groups. NTP's evaluation guidelines specify the additional categories of *some, equivocal, no evidence,* and *inadequate study.*

Qualitative assessment of animal or human evidence is done by many agencies, including the EPA and International Agency for Research on Cancer (IARC). Similar evidence classifications have been used for both the animal and human evidence categories by both agencies. These evidence classifications have included levels of sufficient, limited, inadequate, and no evidence (EPA, 1994a, 2005b) or *evidence suggesting lack of carcinogenicity* (IARC, 2000). For both agencies, these classifications are used for overall weight-of-evidence approach for carcinogenicity classification.

Weight-of-evidence is an integrative step used by the EPA to "characterize the extent to which the available data support the hypothesis that an agent causes cancer in humans" (EPA, 2005b). It is the process of "weighing" all of the evidence to reach a conclusion about carcinogenicity. With this method, the likelihood of human carcinogenic effect is evaluated in addition to an understanding of the conditions under which such effects may be expressed. Weight of evidence can consider both the quality and quantity of data as well as any underlying assumptions. The evidence includes data from all of the hazard assessment and characterization studies such as SAR data, in vivo and/or in vitro studies and epidemiological data. Using this type of information and weight-of-evidence approach, the EPA includes hazard descriptors to define carcinogenic potential and to provide a measure of clarity and consistency in the characterization narrative: "carcinogenic to humans," "likely to be carcinogenic to humans," "suggestive evidence of carcinogenic potential," "inadequate information to assess carcinogenic potential," and "not likely to be carcinogenic to humans." In this section, approaches for evaluating cancer endpoints are discussed. Similar weight-of-evidence approaches have been proposed for reproductive risk assessment (refer to *sufficient* and *insufficient evidence* categories in EPA's guidelines for reproductive risk (EPA, 1996b)).

The Institute for Evaluating Health Risks defined an "evaluation process" by which reproductive and developmental toxicity data can be consistently evaluated and integrated to ascertain their relevance for human health risk assessment (Moore *et al*., 1995). This evaluation process now serves as the basis for NTP's Center for the Evaluation of Risks to Human Reproduction (CERHR) (http://cerhr.niehs.nih.gov/). Application of such carefully deliberated approaches for assessing noncancer endpoints should help avoid the tendency to list chemicals as yes or no (positive or negative) without human relevancy information.

Mode of Action The EPA has emphasized in their revised cancer guidelines, the importance of using "weight of evidence" to arrive at insights to possible "mode(s) of action" (MOA) (EPA, 2005b). MOA information describes key events and processes leading to molecular and functional effects that would in general explain the overall process of cancer development. In many cases these could be plausible hypothesized MOAs for both specific toxicity endpoints, but the detailed mechanistic nuances of the pathway might not yet be fully known. EPA has proposed using such MOA information to suggest nondefault approaches for cancer risk assessments and for

evaluating toxicity of compounds with common MOAs in cumulative risk assessments (EPA, 1996b, 1998a).

Within the EPA's new Carcinogenic Risk Assessment Guidelines, the MOA framework considers evidence from animal studies, relevance to humans, and life stage or population susceptibility (EPA, 2005b). Chemical-specific adjustment factors for interspecies differences and human variability have been proposed and build upon guidance developed by the WHO's International Programme on Chemical Safety Harmonization Project (World Health Organization, 2000). Critical to the MOA development is the use of "criteria of causality" considerations, which build on Hill criteria used in epidemiology (Hill, 1965; Faustman *et al.*, 1996; EPA, 1999b; Klaunig *et al.*, 2003), and consider dose–response relationships and temporal associations, as well as the biological plausibility, coherence, strength, consistency, and specificity of the postulated MOA.

DOSE–RESPONSE ASSESSMENT

Integrating Quantitative Aspects of Risk Assessment

Quantitative considerations in risk assessment include dose–response assessment, exposure assessment, variation in susceptibility, and characterization of uncertainty. For dose–response assessment, varying approaches have been proposed for threshold versus nonthreshold endpoints. Traditionally, in the United States, threshold approaches have been applied for assessment of noncancer endpoints, and nonthreshold approaches have been used for cancer endpoints. As we have learned more about nongenotoxic mechanisms of carcinogenicity, these processes have been evaluated using threshold approaches. Each approach and its inherent assumptions are discussed below, as are recent efforts to include more detailed mechanistic considerations to harmonize these approaches (Bogdanffy *et al.*, 2001).

In general, human exposure data for prediction of human response to environmental chemicals are quite limited; thus, animal bioassay data have primarily served as the basis for most quantitative risk assessments and have required extrapolation for human health evaluation. The risk assessor, however, is normally interested in low environmental exposures when considering human risk, exposures which are well below the experimentally observable range of responses in most animal assays. Thus, methods for extrapolating from high dose to low dose as well as extrapolating from animal risk to human risk are required and comprise a major portion of dose–response assessment.

The fundamental basis of the quantitative relationships between exposure to a chemical and the incidence of an adverse response is the dose–response assessment. Analysis of dose–response relationships must start with the determination of the critical effects to be quantitatively evaluated. It is usual practice to choose the most robust data sets with adverse effects occurring at the lowest levels of exposure from studies using the most relevant exposure routes. The "critical" adverse effect is defined as the significant adverse biological effect that occurs at the lowest exposure level (Barnes and Dourson, 1988). EPA has issued toxicity-specific guidelines that are useful in identifying such critical effects (for developmental toxicity (EPA, 1991b); reproductive toxicity (EPA, 1996b); neurotoxicity (EPA, 1995); cancer (EPA, 1994a, 1996a, 1999b, 2005b). IPCS has recently compiled a document cited as the Principles for Modeling Dose–Responses for the Risk Assessments of Chemicals (World Health Organization, 2004). It outlines key concepts and consid-

erations for dose–response evaluations within the context of a risk assessment.

Threshold Approaches Approaches for characterizing threshold dose–response relationships include identification of "no observed adverse effect level" (NOAELs) or "lowest observed adverse effect levels" (LOAELs). On the dose–response curve illustrated in Fig. 4-3, the doses tested in the bioassay are given as E, F, G, H, and I. The statistical significance of points G, H, and I is indicated using an asterisk (*). The threshold (T) represents the dose below which no additional increase in response is observed. The NOAEL (F) is identified as the highest nonstatistically significant dose tested; in this example the NOAEL occurs at approximately 2 mg/kg body weight. Point G is the LOAEL ($\sim$2.3 mg/kg body weight), as it is the lowest dose tested with a statistically significant effect. Lines A–D represent possible extrapolations below the point of departure (POD), which is represented on this figure as an (*) and is labeled as point E. The POD is used to specify the estimated dose near the lower end of the observed dose range, below which, extrapolation to lower exposures is necessary (EPA, 2005b). In Fig. 4-3, the POD occurs at 10% effective dose or ED_{10}. The type of extrapolation below the POD is depending on the type of data available. The importance of choosing an appropriate POD and extrapolation type is discussed further in the following sections of the chapter.

In general, most animal bioassays are constructed with sufficient numbers of test animals to detect biological responses at the 10% response range; however, this is dependent upon endpoint and

Figure 4-3. Dose–response curve.

This figure is designed to illustrate a typical dose–response curve with points E to I indicating the biologically determined responses. Statistical significance of these responses is indicated with a "*" symbol. The threshold dose is shown by T, a dose below which no change in biological response occurs. Point E represents the point of departure (POD), the dose near the lower end of the observed dose–response range, below which, extrapolation to lower doses is necessary (EPA, 2005b). Point F is the highest nonstatistically significant response point, hence it is the "no observed adverse effect level" (NOAEL) for this example. Point G is the "lowest observed adverse response level" (LOAEL). Curves A–D show some options for extrapolating the dose–response relationship below the range of biologically observed data points, POD, point E.

the background rate of the endpoint in control animals. The risk assessor should always understand the biological significance of the responses being evaluated in order to put statistical observations in context. *Significance* thus usually refers to both biological and statistical criteria (Faustman *et al.*, 1994) and is dependent upon the number of dose levels tested, the number of animals tested at each dose, and background incidence of the adverse response in the nonexposed control groups. The NOAEL should not be perceived as risk-free, as several reports have shown that the response of NOAELs for continuous endpoints averages 5% risk, and NOAELs based on quantal endpoints can be associated with risk of greater than 10% (Allen *et al.*, 1994; Faustman *et al.*, 1994).

As described in Chap. 2, approaches for characterizing dose–response relationships include identification of effect levels such as LD_{50} (dose producing 50% lethality), LC_{50} (concentration producing 50% lethality), ED_{10} (dose producing 10% response), as well as NOAELs.

NOAELs have traditionally served as the basis for risk assessment calculations, such as reference doses or acceptable daily intake (ADI) values. Reference doses (RfDs) or concentrations (RfCs) are estimates of a daily exposure to an agent that is assumed to be without adverse health impact in humans. The ADIs are used by WHO for pesticides and food additives to define "the daily intake of chemical, which during an entire lifetime appears to be without appreciable risk on the basis of all known facts at that time" (World Health Organization, 1962; Dourson *et al.*, 1985). Reference doses (first introduced in Chap. 2) and ADI values typically are calculated from NOAEL values by dividing by uncertainty (UF) and/or modifying factors (MF) (Dourson and Stara, 1983; Dourson and DeRosa, 1991; EPA, 1991b).

$$RfD = NOAEL/(UF * MF)$$
$$ADI = NOAEL/(UF * MF)$$

Tolerable daily intakes (TDI) can be used to describe intakes for chemicals that are not "acceptable" but are "tolerable" as they are below levels thought to cause adverse health effects. These are calculated in a manner similar to ADI. In principle, dividing by the uncertainty factors allows for interspecies (animal-to-human) and intraspecies (human-to-human) variability with default values of 10

each. An additional uncertainty factor is used to account for experimental inadequacies—for example, to extrapolate from short-exposure-duration studies to a situation more relevant for chronic study or to account for inadequate numbers of animals or other experimental limitations. If only a LOAEL value is available, then an additional 10-fold factor commonly is used to arrive at a value more comparable to a NOAEL. For developmental toxicity endpoints, it has been demonstrated that the application of the 10-fold factor for LOAEL-to-NOAEL conversion is too large (Allen *et al.*, 1994). Traditionally, a safety factor of 100 would be used for RfD calculations to extrapolate from a well-conducted animal bioassay (10-fold factor animal to human) and to account for human variability in response (10-fold factor human-to-human variability).

Modifying factors can be used to adjust the uncertainty factors if data on mechanisms, pharmacokinetics, or relevance of the animal response to human risk is available. For example, if there is kinetic information suggesting that rat and human metabolism are very similar for a particular compound, producing the same active target metabolite, then—rather than using a 10-fold uncertainty factor to divide the NOAEL from the animal toxicity study to obtain a human relevant RfD—a factor of 3 for that uncertainty factor might be used. Of particular interest is the recent addition of an extra 10-fold factor through the Food Quality and Protection Act (FQPA) to ensure protection of infants and children (EPA, 1996a). Under this law an additional uncertainty factor is added to ensure protection of children's health; it is currently being used for determining allowable pesticide chemical residues. This factor is designed to take into account potential pre- and postnatal toxicity and to overcome the incompleteness of toxicity and exposure data (FQPA; PL 104-170). Illustrative discussions on how such a legislatively mandated uncertainty factor might be applied are available for chlorpyrifos (EPA, 1999a; Schardein and Scialli, 1999). In this case, this factor was reduced due to the availability of specific animal experiments assessing developmental toxicity at sensitive life stages (Zhao *et al.*, 2006) (www.epa.gov/iris/subst/0026.htm).

To reduce uncertainty in calculating RfDs and ADIs, there has been a transition from the use of traditional 10-fold uncertainty factors to the use of data-derived and chemical-specific adjustment factors. Such efforts have included reviewing the human pharmacologic literature from published clinical trials (Silverman
Figure 4-4. Toxicokinetic (TK) and toxicodynamic (TD) considerations inherent in interspecies and interindividual extrapolations.

Toxicokinetics refers to the processes of absorption, distribution, elimination, and metabolism of a toxicant. *Toxicodynamics* refers to the actions and interactions of the toxicant within the organism and describes processes at organ, tissue, cellular, and molecular levels. This figure shows how uncertainty in extrapolation both across and within species can be considered as being due to two key factors: a kinetic component and a dynamic component. Refer to the text for detailed explanations.
Figure 4-5. Illustration of benchmark dose (BMD) approach.

This figure shows the $BMDL_{10}$ and BMD_{10}, the lower confidence limit and dose (ED_{10}) associated with a 10% incidence of adverse response, respectively (Kavlock, 1995; EPA, 2005).

et al., 1999) and developing human variability databases for a large range of exposures and clinical conditions (Renwick, 1991, 1999; Johnson *et al.*, 1997). Toward this goal, Renwick has separated the intra- and interspecies uncertainty factors into two components: toxicokinetic (TK) and toxicodynamic (TD) aspects (Renwick, 1991, 1999; Johnson *et al.*, 1997). Figure 4-4 shows these distinctions. A key advantage of this approach is that it provides a structure for incorporating scientific information on specific aspects of the overall toxicologic process into the reference dose calculations; thus, relevant data can replace a portion of the overall "uncertainty" surrounding these extrapolations. Current WHO guidance uses a 4.0- and 2.5-fold factor for the TK and TD interspecies components, respectively (World Health Organization, 2005), and inter-individual TK and TD factors of 3.16 (Renwick and Lazarus, 1998).

NOAEL values have also been utilized for risk assessment by evaluating a "margin of exposure" (MOE), where the ratio of the NOAEL determined in animals and expressed as mg/kg/day is compared with the level to which a human may be exposed. For example, human exposures to a specific chemical are calculated to be solely via drinking water, and the total daily intake of the compound is 0.04 mg/kg/day. If the NOAEL for neurotoxicity is 100 mg/kg/day, then the MOE would be 2,500 for the oral exposure route for neurotoxicity. Such a large value is reassuring to public health officials. Low values of MOE indicate that the human levels

of exposure are close to levels for the NOAEL in animals. There is usually no factor included in this calculation for differences in human or animal susceptibility or animal-to-human extrapolation; thus, MOE values of less than 100 have been used by regulatory agencies as flags for requiring further evaluation.

The NOAEL approach has been criticized on several points, including that (1) the NOAEL must, by definition, be one of the experimental doses tested and (2) once this is identified, the rest of the dose–response curve is ignored. Because of these limitations, an alternative to the NOAEL approach, the benchmark dose (BMD) method, was proposed (Crump, 1984). In this approach, the dose–response is modeled and the lower confidence bound for a dose at a specified response level [benchmark response (BMR)] is calculated. The BMR is usually specified at 1, 5, or 10%. Figure 4-5 shows the BMD using a 10% benchmark response (BMD_{10}) and a 95% lower confidence bound on dose ($BMDL_{10}$). The BMDx (with x representing the percent benchmark response) is used as an alternative to the NOAEL value for reference dose calculations. Thus, the RfD would be

$$RfD = BMDx/UF * MF$$

EPA has developed software for the application of benchmark dose methods and developed a technical guidance document

to provide guidelines for application of BMDs for both cancer and noncancer endpoints (EPA, 2000a). The 2004 WHO guidelines for dose–response modeling for risk assessment also discuss BMD approaches (World Health Organization, 2004). Both the EPA and WHO guidelines distinguish NOAEL versus BMD based approaches. Harmonization of approaches available for assessments is discussed in these documents.

The benchmark dose approach has been applied to study several noncancer endpoints, including developmental (Allen *et al.*, 1994) and reproductive toxicity (Auton, 1994). The most extensive studies with developmental toxicity have shown that BMD_{05} values were similar to a statistically derived NOAEL for a wide range of developmental toxicity endpoints and that results from using generalized dose–response models were similar to statistical models designed specifically to represent unique features of developmental toxicity testing.

Advantages of the benchmark dose approach can include (1) the ability to take into account the dose–response curve; (2) the inclusion of a measure of variability (confidence limit); and (3) the use of a consistent benchmark response level for RfD calculations across studies. Obviously, limitations in the animal bioassays in regard to minimal test doses for evaluation, shallow dose responses, and use of study designs with widely spaced test doses will limit the utility of these assays for any type of quantitative assessments, whether NOAEL- or BMD-based approaches.

Nonthreshold Approaches As Fig. 4-3 shows, numerous dose–response curves can be proposed in the low-dose region of the dose–response curve if a threshold assumption is not made. Because the risk assessor generally needs to extrapolate beyond the region of the dose–response curve for which experimentally observed data are available; the choice of models to generate curves in this region has received lots of attention. For nonthreshold responses, methods for dose–response assessments have also utilized models for extrapolation to de minimus (10^{-4} to 10^{-6}) risk levels at very low doses, far below the biologically observed response range and far below the effect levels evaluated for threshold responses.

EPA guidelines define the dose–response methods as requiring two steps: (1) defining the "point of departure" (POD) or the lowest dose associated with adverse effects within the range of the experimental data and (2) the extrapolation from the POD to low environmentally relevant exposure levels based on experimental data. The extrapolation can be done with a linear model or a nonlinear model with this choice dependent on the amount and type of experimental data available. Risk estimates using the linear model (biological response increases proportionally with level of exposure) are higher that nonlinear models where the biological response does not vary proportionally with the dose. For example, in 2003, the EPA released a Dioxin Reassessment and used the BMD dose–response method. The reassessment used a POD based on a 1% response with a linear extrapolation model based on the position that the scientific data were inadequate to rule out the EPA's standard default linear assumption. The EPA dioxin reassessment was evaluated in a National Academies Report in 2006 (NAS, 2006) and this review discusses remaining extrapolation issues.

Two general types of dose–response models exist for extrapolation: statistical (or probability distribution models) and mechanistic models (Krewski and Van Ryzin, 1981). The distribution models are based on the assumption that each individual has a tolerance level for a test chemical and that this response level is a variable following a specific probability distribution function. These responses can be modeled using a cumulative dose–response function. Chapter 2 discusses the common normal distribution pattern (see Fig. 2-3). A log probit model estimates the probability of response at a specified dose (d); thus, $P(d) = \phi[a + \beta \log d]$, where ϕ is the cumulative function for a standard normal distribution of the log tolerances with standard deviations σ and mean μ, a equals μ/σ, and β equals the slope of the probit line ($-1/\sigma$). The probit curve at low doses usually assumes an S-shape. Chapter 2 discusses determination of the LD_{50} value from such a curve. However, extrapolation of the experimental data from 50% response levels to a "safe," "acceptable," or "de minimus" level of exposure—e.g., one in a million risk above background—illustrates the huge gap between scientific observations and highly protective risk limits (sometimes called *virtually safe doses* or those corresponding to a 95% upper confidence limit on adverse response rates).

The log logistic model was derived from chemical kinetic theory. The probability of response at dose d is defined as $P(d) = [1 - \exp(a + \beta \log d)]^{-1}$. Like the probit model, this model defines sigmoidal curves that are symmetrical around the 50% response level; however, the log logistic curves approach the 0 and 100% response levels with a shallow curve shape. The logit and probit curves are indistinguishable in fitting the data in the region of the response curve where experimentally derived data are present (Brown, 1984; Hartung, 1987).

Models Derived from Mechanistic Assumptions This modeling approach designs a mathematical equation to describe dose–response relationships that are consistent with postulated biological mechanisms of response. These models are based on the idea that a response (toxic effect) in a particular biological unit (animal, human, pup, etc.) is the result of the random occurrence of one or more biological events (stochastic events).

Radiation research has spawned a series of such "hit models" for cancer modeling, where a hit is defined as a critical cellular event that must occur before a toxic effect is produced. The simplest mechanistic model is the one-hit (one-stage) linear model in which only one hit or critical cellular interaction is required for a cell to be altered. For example, based on somatic mutation theory, a single mutational change would be sufficient for a cell to become cancerous through a transformational event and dose-independent clonal expansion. The probability statement for these models is $P(d) = 1 - \exp^{(-\lambda d)}$, where λd equals the number of hits occurring during a time period. A single molecule of a genotoxic carcinogen would have a minute but finite chance of causing a mutational event.

As theories of cancer have grown in complexity, so too have these hit-based mechanistic models. Multihit models have been developed that can describe hypothesized single-target multihit events, as well as multitarget, multihit events in carcinogenesis. The probability statements for these models is $P(d) = \int^{\lambda d} \chi^{k-1} \exp(-x)/\Gamma(k)dx$, where $\Gamma(k)$ denotes the gamma function with $k =$ critical number of hits for the adverse response. The Weibull model has a dose–response function with characteristics similar to those of the multihit models, where the response equation is $P(d) = 1 - \exp[-\lambda d^k]$. Here again, $k =$ critical number of hits for the toxic cellular response.

Armitage and Doll (1957) developed a multistage model for carcinogenesis that was based on these equations and on the hypothesis that a series of ordered stages was required before a cell could undergo mutation, initiation, transformation, and progression to form a tumor. This relationship was generalized by Crump (1980) by maximizing the likelihood function over polynomials, so that the
Figure 4-6. Exposure pathway schematic.

Within the risk assessment process, a critical early step is the identification of the exposure pathway(s). To fully characterize exposure, the site-specific and chemical-specific exposure pathways must be identified. This hypothetical exposure pathway schematic illustrated the various ways in which contaminants can move from the source through media to points of exposure. (http://www.atsdr.cdc.gov/HAC/PHAManual/images/figure6_2.jpg).

probability statement is:

$$P(d) = 1 - \exp\left[- \left(\lambda_0 + \lambda_1 d^1 + \lambda_2 d^2 + \cdots \lambda_k d^k \right) \right]$$

If the true value of λ_1 is replaced with λ_1^* (the upper confidence limit of λ_1), then a linearized multistage model can be derived where the expression is dominated by $(\lambda d^*)d$ at low doses. The slope on this confidence interval, q_1^*, has been used by EPA for quantitative cancer assessment. To obtain an upper 95% confidence interval on risk, the q_1^* value (risk/Δ dose in mg/kg/day) is multiplied by the amount of exposure (mg/kg/day). Thus, the upper-bound estimate on risk (R) is calculated as:

$$R = q_1^*[\text{risk}(\text{mg/kg/day})^{-1}] \times \text{exposure (mg/kg/day)}$$

This relationship has been used to calculate a "virtually safe dose" (VSD), which represents the lower 95% confidence limit on a dose that gives an "acceptable level" of risk (e.g., upper confidence limit for 10^{-6} excess risk). The integrated risk information system (IRIS) (www.epa.gov/iriswebp/iris) developed by EPA gives q^* values for many environmental carcinogens (EPA, 2000c). Because both the q_1^* and VSD values are calculated using 95% confidence intervals, the values are believed to represent conservative, protective estimates.

The EPA has utilized the LMS model to calculate "unit risk estimates" in which the upper confidence limit on increased individual lifetime risk of cancer for a 70-kg human breathing 1 μg/m^3 of contaminated air or drinking 2 L/day of water containing 1 ppm (1 mg/L) is estimated over a 70-year life span. The example given in Fig. 4-7 shows the calculation of incremental lifetime cancer risk (ILCR) of skin cancer using soil exposure and q^* values for inorganic arsenic. If a POD-based approach is used for low dose extrapolation, the model would be used to extrapolate from the POD or upper confidence limit and these slopes would be considered for the q^* values.

Toxicologic Enhancements of the Models   Three exemplary areas of research that have improved the models used in risk extrapolation are time to tumor information, physiologically based toxicokinetic modeling, and biologically based dose–response modeling (Albert, 1994). Chapter 7 discusses in detail improvements in our estimation of exposure and offers approaches on how to model "target internal effective dose" in risk assessment rather than just using single-value "external exposure doses." In this chapter we discuss the biologically based dose–response (BBDR) modeling.

BBDR modeling aims to make the generalized mechanistic models discussed in the previous section more clearly reflect specific biological processes. Measured rates are incorporated into the mechanistic equations to replace default or computer-generated values. For example, the Moolgavkar–Venson–Knudson (MVK) model

A. Ingestion of Arsenic from Soil—Point Estimation Method

$$\frac{\text{Soil concentration} \times \text{Ingestion rate} \times \text{Exposure duration} \times \text{Exposure frequency}}{\text{Body weight} \times \text{Averaging time}} \times \quad \text{Bioavailability} \times q^* \quad = \text{Incremental Lifetime Cancer Risk(ILCR) from Skin Cancer}$$

$$\frac{2{,}300 \text{ mg/kg} \times 100 \text{ mg/d} \times 30 \text{ yr} \times 350 \text{ d/yr}}{70 \text{ kg} \times 25{,}550 \text{ d}} \times \quad 0.09 \times 1.50 \text{ (mg/kg-d)}^{-1} \quad = 1.8 \times 10^{-4}$$

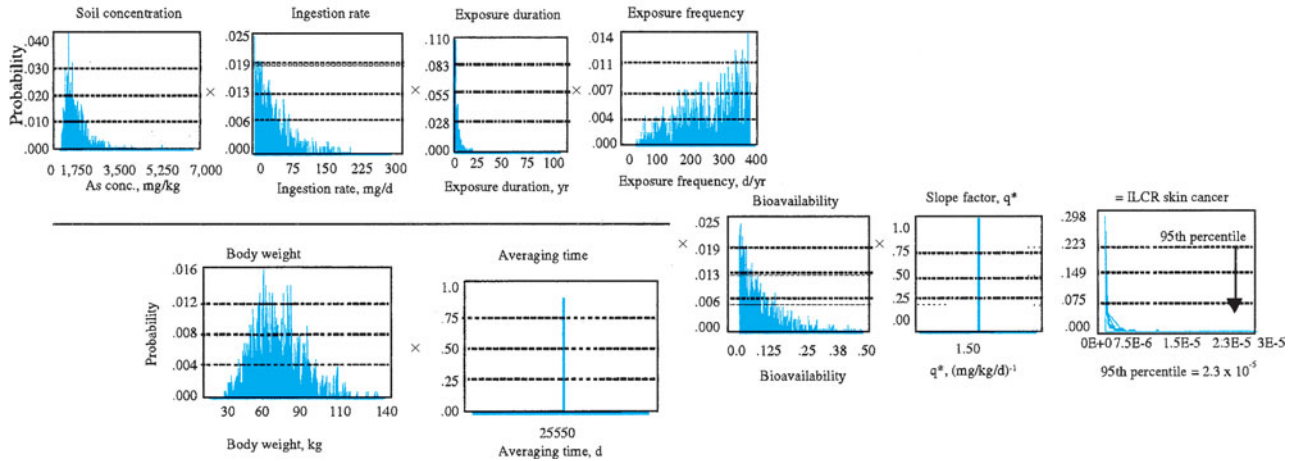
B. Ingestion of Arsenic from Soil—Probabilistic Methods


Figure 4-7. Example of risk calculations for incremental lifetime cancer risk (ILCR) of skin cancer due to ingestion of arsenic in soil.

A. Point exposure estimation method for calculation of ILCR. Point estimates for arsenic exposure input parameters are used in this example to calculate the ILCR. This exposure estimate is multiplied by the bioavailability of arsenic in soil to calculate the dose. Multiplication of the dose by the slope factor (q^*) yields the lifetime risk. *B.* Probabilistic exposure methods for calculating the incremental lifetime cancer risk (ILCR) from arsenic ingestion. In this example, the soil concentration, ingestion rate, exposure duration and frequency, body weight, and bioavailability are modeled as distributions. Note that q^* and averaging time (years) are given as single-point estimations. This method yields a distribution of ILCR, with a 95th percentile upper confidence interval of 2.3×10^{-5}. (Data from Calabrese, 1989; Davis, 1990; EPA, 1989a,b, 1992, 1999b; Israeli, 1992; Brorby, 1993; ATSDR, 1998.)

is based on a two-stage model for carcinogenesis, where two mutations are required for carcinogenesis and birth and death rates of cells are modeled through clonal expansion and tumor formation. This model has been applied effectively to human epidemiologic data on retinoblastoma. In animal studies, kidney and liver tumors in the 2-acetylaminofluorene (2-AAF) "mega mouse" study, rat lung tumors following radiation exposure, rat liver tumors following *N*-nitrosomorpholine exposure, respiratory tract tumors following benzo[a]pyrene exposure, and mouse liver tumors following chlordane exposure have been modeled (Cohen and Ellwein, 1990; Moolgavkar and Luebeck, 1990). EPA relied primarily on the receptor binding theory in its dioxin risk reassessments (EPA, 1994a, 2003). Kohn *et al*. (1993) and Anderson *et al*. (1993) have used physiologically based toxicokinetics (PBTK) and BBDR information to improve dioxin risk assessment.

Development of biologically based dose–response models for endpoints other than cancer are limited; however, several approaches have been explored in developmental toxicity, utilizing mode of action information on cell cycle kinetics, enzyme activity, and cytotoxicity as critical endpoints (Faustman *et al*., 1989, 2005; Shuey *et al*., 1994; Leroux *et al*., 1996; Gohlke *et al*., 2002, 2004, 2005, 2007). Approaches have been proposed that link pregnancy-specific toxicokinetic models with temporally sensitive toxicodynamic models

for developmental impacts (Faustman *et al*., 1999, 2006). Unfortunately, there is a lack of specific, quantitative biological information on kinetics and dynamics for most toxicants and endpoints (NRC, 2000; EPA, 2004).

RISK CHARACTERIZATION

Risk characterization is a summary of the risk assessment components and serves to outline the key findings and inform the risk manager in public health decisions. It is an analysis and integration of the conclusions from the hazard assessment, the dose–response, and the exposure assessment. EPA outlines the science policy and elements for completing a risk characterization in their *Risk Characterization Handbook* (EPA, 2000d).

For many years there has been an information-sharing process aimed at harmonization of chemical testing regimes and clinical trials methodologies, so that data might be accepted in multiple countries. Recent efforts by WHO and IPCS have included the Harmonization of Approaches to the Assessment of Risk from Exposure to Chemicals Project (www.who.int/ipcs/methods/harmonization/en/). This project has the goal of globally harmonizing but not standardizing the approaches to risk assessment by increasing understanding and developing basic principles and

guidance on specific chemical risk assessment issues. The WHO has worked to harmonize dose–response methodologies (DRM) and released a report providing a descriptive guidance for risk assessors in using DRM in hazard characterization (World Health Organization, 2004).

Variation in Susceptibility

Risk assessment methodologies incorporating human variability have been slow to develop. Generally, assay results utilize means and standard deviations to measure variation, or even standard errors of the mean. This ignores variability in response due to differences in age, sex, health status, and genetics. Default factors of 10X are overutilized to describe cross- and between-species differences and toxicokinetic and dynamic data are rare. Nevertheless, EPA and OSHA are expected under the Clean Air Act and the Occupational Safety and Health Act to promulgate standards that protect the most susceptible subgroups or individuals in the population (Omenn *et al*., 1990; Faustman and Omenn, 2006; Kramer *et al*., 2006; Cullen *et al*., in revision).

Ecogenetics has been defined as the study of critical genetic determinants that define susceptibility to environmentally influenced adverse health effects (Costa and Eaton, 2006). Ecogenetic variation can affect biotransformation systems that activate and detoxify chemicals or alter the response in target tissues. With the completion of the Human Genome Project in April 2003, the identification of human polymorphisms has greatly expanded our potential for understanding how genetic variability can impact biological response and susceptibility. There have been numerous activities initiated with the goal of understanding the linkage between genes and the environment and the following databases and initiatives are designed to identify polymorphisms, including single-nucleotide polymorphisms (SNP). These include the SNP consortium (http://snp.cshl.org/), the DNA Polymorphism Discovery Resource (www.genome.gov/10001552), the National Center for Biotechnology Information (NCBI) SNP databases (www.ncbi.nlm.nih.gov/SNP/) (www.ncbi.nlm.nih.gov/ -entrez/?db=snp), and the NIH GAIN program (www.genome.gov/ 19518664). Using the information from such databases, researchers hope to identify genetic similarities and differences in human beings with the goal of identifying genes that affect health, disease, and individual responses to medications and environmental factors. It should be noted that this type of information raises ethical, social, and legal concerns regarding protections of individual donors (Hsieh, 2004).

One of the key challenges for toxicologists doing risk assessments will be the interpretation and linking of observations from highly sensitive molecular and genome-based methods with the overall process of toxicity (Eisen *et al*., 1998; Limbird and Taylor, 1998; Andersen and Barton, 1999; NRC, 2000). The basic need for linkage of observations was highlighted in early biomarker work. NRC reports on biomarkers (NRC, 1989a,b, 1992a,b) drew distinctions for biomarkers of effect, exposure, and susceptibility across a continuum of exposure, effect, and disease/toxicity. Biomarkers of early effects, like frank clinical pathology, arise as a function of exposure, response, and time. Early, subtle, and possibly reversible effects can generally be distinguished from irreversible disease states. Chemical-specific biomarkers have the potential to provide critical information, but there is an inherent complexity in pulling the information together. If biomarkers are considered a reflection of exposure or disease state, then considerations have to be made regarding the interactions between genes and the environ-

ment and the difference between a population-based assessment and individual assessment (Groopman and Kensler, 1999).

Nowhere is the challenge for interpretation of early and highly sensitive response biomarkers clearer than in the complicated data from gene expression arrays (toxicogenomics). Because our relatively routine ability to monitor gene responses—up to tens of thousands of them simultaneously—has grown exponentially in the last decade, the need for toxicologists to interpret such observations for risk assessment and for the overall process of toxicity has been magnified with equal or greater intensity. Recent papers from several toxicogenomics projects have confirmed the repeatability and cross-platform concordance of microarray data (Bammler *et al*., 2005; Guo *et al*., 2006; Nature Biotechnology Editorial, 2006; Patterson *et al*., 2006).

Microarray analysis for risk assessment requires sophisticated analyses beyond the basic cluster analysis (Eisen *et al*., 1998b) to arrive at a functional interpretation and linkage to conventional toxicological endpoints. Because of the vast number of measured responses with gene expression arrays, pattern analysis techniques are being used through pathway mapping platforms such as MAPPfinder and GenMAPP (Moggs *et al*., 2004; Currie *et al*., 2005). The Gene Ontology Consortium has developed a controlled vocabulary (ontology) for sharing biological information. Database users can then annotate their gene products with gene ontology (GO) terms, establishing a consistent description and definition across databases and studies. Through the power of GO terms, new analysis methods are being developed to allow for a quantitative time- and dose-dependent interpretation of genomic response at the biological and cellular level (Yu *et al*., 2006).

Both the EPA and FDA have formally recognized the power of genomic information as well as its potential limitations. Both agencies have issued interim policies guiding how to include genomic information into risk assessments and state to use genomic information in conjunction with standard risk assessment data (www.epa.gov/osa/genomics.htm, www.fda.gov/oc/initiatives/ criticalpath/whitepaper.html).

EXPOSURE ASSESSMENT

The primary objectives of exposure assessment are to determine source, type, magnitude, and duration of contact with the chemical of interest. Obviously, this is a key element of the risk assessment process, as hazard does not occur in the absence of exposure. However, it is also frequently identified as the key area of uncertainty in the overall risk determination. Here, the primary focus is on uses of exposure information in quantitative risk assessment.

Obviously, the primary goal of such calculations is to determine not only the type and amount of total exposure, but also to find out specifically how much may be reaching target tissues. A key step in making an exposure assessment is determining what exposure pathways are relevant for the risk scenario under development. Figure 4-6 shows an example exposure diagram used to illustrate possible exposure pathways from a hazardous waste site release. The subsequent steps entail quantitation of each pathway identified as a potentially relevant exposure and then summarizing these pathway-specific exposures for calculation of overall exposure. Such calculations can include an estimation of total exposures for a specified population as well as calculation of exposure for highly exposed individuals. The EPA has published numerous documents which provide guidelines for determining such exposures (EPA, 1989a, 1992, 1997), with the recognition that special

considerations need to be adopted when assessing childhood exposures (EPA, 2006).

Conceptually, calculations are designed to represent "a plausible estimate" of exposure of individuals in the upper 90th percentile of the exposure distribution. Upper-bound estimations would be "bounding calculations" designed to represent exposures at levels that exceed the exposures experienced by all individuals in the exposure distribution and are calculated by assuming limits for all exposure variables. A calculation for individuals exposed at levels near the middle of the exposure distribution is a central estimate. Figure 4-7 gives example risk calculations using two types of exposure estimation procedures (EPA, 1989a,b, 1992). Part A shows a point estimation method for the calculation of arsenic (As) exposure via a soil ingestion route. In this hypothetical scenario, As exposure is calculated using point estimates, and a lifetime average daily dose (LADD) is calculated as follows:

$$LADD = \frac{\begin{array}{c} \text{Concentration of} \times \text{Contact} \times \text{Contact} \times \text{Exposure} \\ \text{the toxicant in the} \quad \text{rate} \quad \text{fraction} \quad \text{duration} \\ \text{exposure media} \end{array}}{\text{(body weight) (lifetime)}}$$

Many exposures are now estimated using exposure factors probability distributions rather than single-point estimates for the factors within the LADD equation (Finley *et al*., 1994; Cullen and Frey, 1999). Such approaches can provide a reality check and can be useful for generating more realistic exposure profiles. Part B of Fig. 4-7 shows how this is done using an example arsenic risk scenario with soil As concentration, ingestion rate, exposure duration, frequency, body weight, and bioavailability modeled as distributed variables. Using Monte Carlo simulation techniques, an overall incremental lifetime cancer risk (ILCR) distribution can be generated and a 95th percentile for population risk obtained. The *EPA Exposure Factors Handbook,* which is online (www.epa.gov/ncea/efh/pdfs/efh-chapter01.pdf), provides useful information about exposure distributions (EPA, 1997). In 2006, the EPA released a supplemental document with child-specific exposure factors to address the special considerations necessary when evaluating childhood exposures (EPA, 2006).

Additional considerations for exposure assessments include how time and duration of exposure are evaluated in risk assessments. In general, estimates for cancer risk use average exposure over a lifetime (see LADD example above). In a few cases, short-term exposure limits (STELs) are required (e.g., ethylene oxide) and characterization of brief but high levels of exposure is required. In these cases exposures are not averaged over the lifetime and the effects of high, short-term doses are estimated. With developmental toxicity, a single exposure can be sufficient to produce an adverse developmental effect; thus, daily doses are used, rather than lifetime weighted averages (EPA, 1991b; Weller *et al*., 1999).

The Food Quality Protection Act of 1996 has highlighted the need for several additional exposure and risk considerations (EPA, 1996c). These include the need to evaluate total exposures by determining aggregate exposure measures for all exposures to a single substance. Cross-media exposure analyses, such as those conducted for lead and mercury, are good examples of the value of looking at such total exposures in evaluating human risks and complex models are available [see EPA's integrated exposure uptake biokinetic model for lead in children (IEUBK)]. *Cumulative exposures* and *cumulative risk* refer to the total exposure to a group of compounds with similar modes of toxicity. For example, EPA is identifying and categorizing pesticides that act by a common mode of action, and such discussions of cumulative exposures to classes of organophosphates with similar modes of toxic action have been used as examples of classes of pesticides for which cumulative exposure and cumulative risk estimates are needed (ILSI, 1999).

INFORMATION RESOURCES

There are numerous information resources available for toxicology including the Toxicology Data Network (http://toxnet.nlm.nih.gov/) from the U.S. National Library of Medicine, the U.S. National Toxicology Program (http://ntp-server.niehs.nih.gov/), the WHO International Programme on Chemical Safety (www.who.int/pcs/IPCS/index.htm), and the International Agency for Research on Cancer (www.iarc.fr/).

RISK PERCEPTION AND COMPARATIVE ANALYSES OF RISK

Individuals respond differently to information about hazardous situations and products, as do communities and whole societies (Fischhoff, 1981; Fischhoff *et al*., 1993, 1996; Sandman, 1993; NRC, 1996; Risk Commission, 1997; Institute of Medicine, 1999). Understanding these behavioral responses is critical in stimulating constructive risk communication and evaluating potential risk management options. In a classic study, students, League of Women Voters members, active club members, and scientific experts were asked to rank 30 activities or agents in order of their annual contribution to deaths (Slovic *et al*., 1979, 2005). Club members ranked pesticides, spray cans, and nuclear power as safer than did other lay persons. Students ranked contraceptives and food preservatives as riskier and mountain climbing as safer than did others. Experts ranked electric power, surgery, swimming, and X-rays as

Table 4.6
Example Exposure Factor Handbook Information: Drinking Water Intake

AGE GROUP	INTAKE (mL/day) MEAN	INTAKE (mL/day) 10th–90th PERCENTILES	INTAKE (mL/day) MEAN	INTAKE (mL/day) 10th–90th PERCENTILES
Infants (<1 year)	302	0–649	43.5	0–101.8
Children (1–10 years)	736	286–1,294	35.5	12.5–64.4
Teens (11–19 years)	965	353–1,701	18.2	6.5–32.3
Adults (20–64 years)	1,366	559–2,268	19.9	8.0–33.7
Adults (64+ years)	1,459	751–2,287	21.8	10.9–34.7
All ages	1,193	423–2,092	22.6	8.2–39.8

SOURCE: US EPA, 1997; Ershow and Cantor, 1989.

Figure 4-8. Perceptions of risk illustrated using a "risk space" axis diagram.

Risk space has axes that correspond roughly to a hazard's perceived "dreadedness" and to the degree to which it is familiar or observable. Risks in the upper right quadrant of this space are most likely to provoke calls for government regulation.

more risky, but nuclear power and police work as less risky than did lay persons. There are also group differences in perceptions of risk from chemicals among toxicologists, correlated with their employment in industry, academia, or government (Neal *et al*., 1994).

Psychological factors such as dread, perceived uncontrollability, and involuntary exposure interact with factors that represent the extent to which a hazard is familiar, observable, and "essential" for daily living (Lowrance, 1976; Morgan, 1993). Figure 4-8 presents a grid on the parameters controllable/uncontrollable and observable/not observable for a large number of risky activities; for each of the two-paired main factors, highly correlated factors are described in the boxes.

Public demand for government regulations often focuses on involuntary exposures (especially in the food supply, drinking water, and air) and unfamiliar hazards, such as radioactive waste, electromagnetic fields, asbestos insulation, and genetically modified crops and foods. The public can respond negatively when they perceive that information about hazards or new technologies has been withheld or underrated. This can explain some of the very strong responses to genetically modified foods, HIV-contaminated blood transfusions in the 1980s, or hazardous chemical and radioactive wastes.

Perceptions of risk led to the addition of an extra safety factor (default value 10) for children in the Food Quality Protection Act of 1996. Engineering based "as low as reasonably achievable"

(ALARA) approaches also reflect the general "precautionary principle," which is strongly favored by those who, justifiably, believe we are far from knowing all risks given the limited toxicity testing (Roe *et al*., 1997).

SUMMARY

The NRC and Risk Commission frameworks for risk assessment and risk management provide a consistent framework-based approach for evaluating risks and taking action to reduce risks. The objectives of risk assessments vary with the issues, risk management needs, and statutory requirements. Hence, setting the context and problem formation for risk evaluation is essential. The frameworks are sufficiently flexible to address various objectives and to accommodate new knowledge while also providing guidance for priority setting in industry, environmental organizations, and government regulatory and public health agencies. Toxicology, epidemiology, exposure assessment, and clinical observations can be linked with biomarkers, cross-species investigations of mechanisms of effects, and systematic approaches to risk assessment, risk communication, and risk management. Advances in toxicology are certain to improve the quality of risk assessments for a broad array of health endpoints as scientific findings substitute data for assumptions and help to describe and model uncertainty more credibly.

UNIT 2

DISPOSITION OF TOXICANTS

This page intentionally left blank

ABSORPTION, DISTRIBUTION, AND EXCRETION OF TOXICANTS

Lois D. Lehman-McKeeman

INTRODUCTION

The disposition of a chemical or *xenobiotic* is defined as the composite actions of its *absorption*, *distribution*, *biotransformation*, and *elimination*. This chapter will focus on the contribution of absorption, distribution, and elimination to xenobiotic toxicity, whereas Chap. 6 is dedicated to biotransformation. The quantitative characterization of xenobiotic disposition is termed *pharmacokinetics* or *toxicokinetics* and is reviewed in Chap. 7.

The various factors and organs involved in affecting disposition of a toxicant are depicted in Fig. 5-1. The complexity of this diagram is intended to illustrate that, although they will be discussed separately, all processes related to disposition are likely to occur simultaneously. Fundamentally, the disposition of any compound is a major contributor to its potential for toxicity. Specifically, as discussed previously (see Chaps. 2 and 3), the toxicity of a substance is directly dependent on the dose, where "dose" is defined as the amount that ultimately reaches the site or sites of action (tissue, cell, or molecular target). Therefore, because the disposition of a chemical determines its concentration at the site of action, the concerted action of absorption, distribution, and elimination dictates the potential for adverse events to occur.

The skin, lungs, and alimentary canal are the main barriers that separate higher organisms from an environment containing a large number of chemicals. Toxicants must cross one or several of these incomplete barriers to exert deleterious effects, and only chemicals that are caustic and corrosive (acids, bases, salts, oxidizers), which act directly at the point of contact, are exceptions to this generalization. A chemical absorbed into the bloodstream or lymphatics through any of the major barriers is distributed, at least to some extent, throughout the body, including the site where it produces damage. This site is called the *target organ* or *target tissue.* A chemical may have one or several target organs, and, in turn, several chemicals may have the same target organ or organs. However, target organ concentration is not the only factor that can influence the susceptibility of organs to toxicants, and the organ or tissue with the highest concentration of a toxicant is not necessarily the site where toxicity is observed. A classical example of this distinction is dichlorodiphenyltrichloroethane (DDT), a chlorinated hydrocarbon insecticide that achieves high concentrations in fat depots but is not toxic to that tissue.

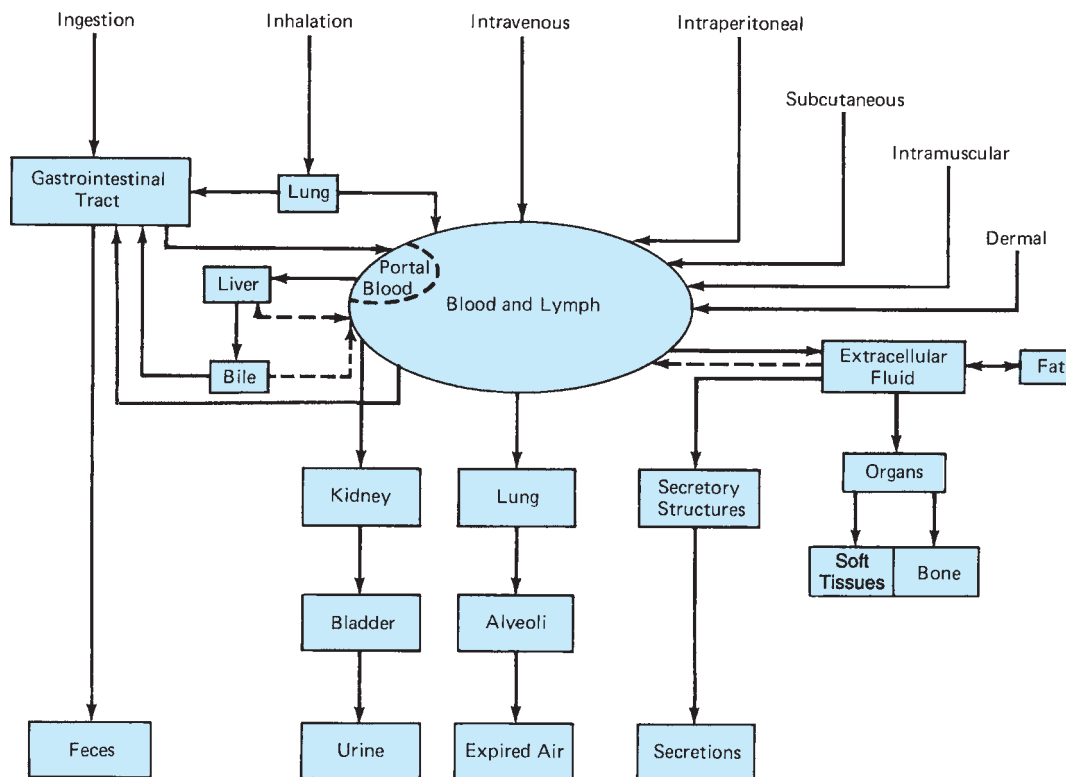
Poor absorption of a toxicant, resulting from a low amount absorbed or a low rate of absorption, limits or prevents toxicity because a chemical may never attain a sufficiently high concentration at a potential site of action to cause toxicity. Similarly, if a chemical is well absorbed but rapidly biotransformed or eliminated from an organism, it is less likely to be toxic because the rapid excretion prevents it from reaching a sufficiently high concentration at a potential site of action to cause toxicity. These are examples of how the disposition of toxicants contributes to the fundamental concept (see Chap. 1) that the "dose makes the poison."


Figure 5-1. Summary of the disposition of toxicants as determined by absorption, distribution, and excretion in the body.

Collectively, all the processes comprising xenobiotic disposition are interrelated and influence each other. The integrated relationship of these processes is illustrated in Fig. 5-1. In this chapter, the qualitative aspects of absorption, distribution, and excretion are presented with emphasis on the functional features and molecular determinants of these processes. As all these processes involve passage across biological membranes, we begin with a discussion of this important and ubiquitous barrier.

at physiologic temperatures. The fluid character of membranes is determined largely by the structure and relative abundance of unsaturated fatty acids. The more unsaturated fatty acids the membranes contain, the more fluid-like they are, facilitating more rapid active or passive transport.

Toxicants cross membranes either by passive processes in which the cell expends no energy or by mechanisms in which the cell provides energy to translocate the toxicant across its membrane.

CELL MEMBRANES

Toxicants usually pass through a number of cells, such as the stratified epithelium of the skin, the thin cell layers of the lungs or the gastrointestinal (GI) tract, capillary endothelium, and ultimately the cells of the target organ. The plasma membranes surrounding all these cells are remarkably similar. The basic unit of the cell membrane is a phospholipid bilayer composed primarily of phosphatidylcholine and phosphatidylethanolamine. Phospholipids are amphiphilic, consisting of a hydrophilic polar head and a hydrophobic lipid tail. In membranes, polar head groups are oriented toward the outer and inner surfaces of the membrane, whereas the hydrophobic tails are oriented inward and face each other to form a continuous hydrophobic inner space. The thickness of the cell membrane is about 7–9 nm. Numerous proteins are inserted or embedded in the bilayer, and some *transmembrane* proteins traverse the entire lipid bilayer, functioning as important biological receptors or allowing the formation of aqueous pores and ion channels (Fig. 5-2). Some cell membranes (eukaryotic) have an outer coat or glycocalyx consisting of glycoproteins and glycolipids. The fatty acids of the membrane do not have a rigid crystalline structure but are semifluid

Figure 5-2. Schematic model of a biological membrane. (www.bioeng. auckland.ac.nz/images/database/bioinformatics/cell_membrane/gif; with permission).

Passive Transport

Simple Diffusion   Most toxicants cross membranes by simple diffusion, following the principles of Fick's law which establishes that chemicals traverse from regions of higher concentration to regions of lower concentration without any energy expenditure. Small hydrophilic molecules (up to about 600 Da) permeate membranes through aqueous pores (Benz *et al.*, 1980), in a process termed paracellular diffusion, whereas hydrophobic molecules diffuse across the lipid domain of membranes (transcellular diffusion). The smaller a hydrophilic molecule is, the more readily it traverses membranes by simple diffusion through aqueous pores. Consequently, a small, water-soluble compound such as ethanol is rapidly absorbed into the blood from the GI tract and is distributed just as rapidly throughout the body by simple diffusion from blood into all tissues.

Many toxicants are larger organic molecules with differing degrees of lipid solubility. For such compounds, the rate of transport across membranes correlates with lipid solubility, which is frequently expressed as octanol/water partition coefficients of the uncharged molecules, or log P as listed in Table 5-1. The log P is an extremely informative physicochemical parameter relative to assessing potential membrane permeability, with positive values as-sociated with high lipid solubility. Thus, the amino acids such as glycine are water soluble and have a negative log P, whereas the environmental contaminants DDT and TCDD are very lipid soluble and have a high, positive log P.

Many chemicals are weak organic acids or bases which in solution are ionized according to Arrhenius' theory. The ionized form usually has low lipid solubility and thus does not permeate readily through the lipid domain of a membrane. There may be some transport of organic anions and cations (depending on their molecular weight) through the aqueous pores, but this is a slow and inefficient process. In contrast, the nonionized form of weak organic acids and bases is to some extent lipid soluble, resulting in diffusion across the lipid domain of a membrane. The rate of transport of the nonionized form is proportional to its lipid solubility. The molar ratio of ionized to nonionized molecules of a weak organic acid or base in solution depends on the ionization constant. The ionization constant provides a measure for the weakness of organic acids and bases. The pH at which a weak organic acid or base is 50% ionized is called its pK_a or pK_b. Like pH, both pK_a and pK_b are defined as the negative logarithm of the ionization constant of a weak organic acid or base. With the equation $pK_a = 14 - pK_b$, pK_a can also be calculated for weak organic bases. An organic acid with a low pK_a is relatively a strong acid, and one with a high pK_a is a weak acid. The opposite is true for bases. The numerical value of pK_a does not indicate whether a chemical is an organic acid or a base. Knowledge of the chemical structure is required to distinguish between organic acids and bases.

The degree of ionization of a chemical depends on its pK_a and on the pH of the solution. The relationship between pK_a and pH is described by the Henderson–Hasselbalch equations.

$$\text{For acids: } pK_a - pH = \log \frac{[\text{nonionized}]}{[\text{ionized}]}$$

$$\text{For bases: } pK_a - pH = \log \frac{[\text{ionized}]}{[\text{nonionized}]}$$

The effect of pH on the degree of ionization of an organic acid (benzoic acid) and an organic base (aniline) is shown in Fig. 5-3. According to the Brönsted–Lowry acid–base theory, an acid is a proton (H$^+$) donor and a base is a proton acceptor. Thus, the ionized and nonionized forms of an organic acid represent an acid–base pair, with the nonionized moiety being the acid and the ionized moiety being the base. At a low pH, a weak organic acid such as benzoic acid is largely nonionized. At pH 4, exactly 50% of benzoic acid is ionized and 50% is nonionized because this is the pK_a of the compound. As the pH increases, more and more protons are neutralized by hydroxyl groups, and benzoic acid continues to dissociate until almost all of it is in the ionized form. For an organic

base such as aniline, the inverse is true. At a low pH, when protons are abundant, almost all of aniline is protonated, i.e., ionized. This form of aniline is an acid because it can donate protons. As the pH increases, ions from aniline continue to dissociate until almost all the aniline is in the nonionized form, which is the aniline base. As transmembrane passage is largely restricted to the nonionized form, benzoic acid is more readily translocated through a membrane from an acidic environment, whereas more aniline is transferred from an alkaline environment.

Filtration   When water flows in bulk across a porous membrane, any solute small enough to pass through the pores flows with it. Passage through these channels is called *filtration*, as it involves bulk flow of water caused by hydrostatic or osmotic force. One of the main differences between various membranes is the size of these channels. In renal glomeruli, a primary site of filtration, these pores are relatively large (about 70 nm) allowing molecules smaller than albumin (approximately 60 kDa) to pass through. In contrast, there are no aqueous pores at cellular tight junctions, and channels in most cells are much smaller (3–6 Å), thereby only permitting substantial passage of molecules with molecular weights of no more than a few hundred daltons (Schanker, 1962; Lin, 2006).

Special Transport

There are numerous compounds whose movement across membranes cannot be explained by simple diffusion or filtration. Some compounds are too large to pass through aqueous pores or too insoluble in lipids to diffuse across the lipid domains of membranes. Nevertheless, they are often transported very rapidly across membranes, even against concentration gradients. To explain these phenomena, specialized transport systems have been identified. These systems are responsible for the transport (both influx and efflux) across cell membranes of many nutrients, such as sugars and amino and nucleic acids, along with some foreign compounds. Based on the sequencing of the human genome, there are at least 500 genes whose putative function involves membrane transport (Venter *et al.*, 2001). However, not all of these genes contribute to the disposition of toxicants. Throughout this chapter, transporters known to contribute to the disposition and subsequent effects of xenobiotics will be emphasized. Importantly, the role of xenobiotic transporters in chemical disposition is an emerging research field, and new information regarding their function, molecular regulation, and genetic polymorphisms is likely to modify traditional concepts in toxicology.

Active Transport   Active transport is characterized by: (1) movement of chemicals against electrochemical or concentration gradients, (2) saturability at high substrate concentrations, (3) selectivity for certain structural features of chemicals, (4) competitive inhibition by chemical cogeners or compounds that are carried by the same transporter, and (5) requirement for expenditure of energy, so that metabolic inhibitors block the transport process.

Substances actively transported across cell membranes presumably form a complex with a membrane-bound macromolecular carrier on one side of the membrane. The complex subsequently traverses to the other side of the membrane, where the substance is released. Afterward, the carrier returns to the original surface to repeat the transport cycle.

Xenobiotic Transporters   Significant advances in identifying and understanding the carrier-mediated transport systems for xenobiotics have been made in the recent years. In total, it is estimated that at least 5% of all human genes are transporter related, indicative of the importance of the transport function in normal biological and toxicological outcomes (Hediger *et al.*, 2004). Transporters mediate the influx (uptake) or efflux of xenobiotics and can be divided into two categories, determined by whether they mediate active or facilitated transfer of compounds. The first active, energy-dependent xenobiotic transporter identified was a phosphoglycoprotein overexpressed in tumor cells that showed resistance to anticancer drugs. The gene conferred multidrug resistance (MDR) to the cells, and was also called P-glycoprotein (P-gp). This transporter functions as an efflux pump, which in cancerous cells, exudes cytotoxic drugs out of the tumor cells, and thus contributes to their resistance (Ambudkar *et al.*, 1999). In humans, the major form of P-gp involved in xenobiotic transport is a single protein (MDR1), whereas in rodents there are two drug-transporting P-gp homologs identified as Mdr1a and Mdr1b. There is an additional member of the MDR family (Mdr2) that is involved in phospholipid transport but does not play an important role in xenobiotic disposition. Similarly, the bile salt export pump (BSEP) functions specifically to transport bile acids.

P-gp was the first member of a large superfamily of transport proteins known as ATP-binding cassette (ABC) transporters. There are now seven subfamilies of ABC transporters identified, with 48 genes in humans (Dean *et al.*, 2001). The second important ABC transport subfamily is the multiresistant drug protein (MRP) family for which MRP1 was also originally isolated from multidrug resistant cells (see Box 5-1). Members of this family excrete chemicals from cells, and MRP2 and MRP3 are particularly important in the efflux of xenobiotic metabolites, particularly those conjugated with UDP-glucuronic acid or glutathione. Breast cancer resistance protein (BCRP), which was originally isolated from a breast cancer cell line, is expressed in normal and malignant tissue and appears to play a role in the efflux transport of numerous endogenous and xenobiotic sulfate conjugates (Mao and Unadkat, 2005).

ABC transporters exhibit all the characteristics of the active transport outlined above, and most notably, they require the expenditure of energy to function. For most ABC transporters, the binding and hydrolysis of ATP provides the energy required to move their substrates across membranes. The typical structure of most ABC transporters consists of two types of structural domains including hydrophobic membrane spanning domain (MSD) and the hydrophilic, intracellular nucleotide binding domain (NBD) where ATP binds and is hydrolyzed (Fig. 5-4). The typical structural organization of the ABC transporter, as exemplified by P-gp, is a tandem repeat of two domains (1 MSD followed by 1 NBD). The two repeated halves are joined by a polypeptide linker sequence. MRPs are distinguished from P-gp in that they comprise five domains, with an extra MSD that comprises five transmembrane segments and an extracytosolic amino terminus, whereas BCRP is a "half-transporter" that comprises a single MSD with six transmembrane segments preceded by a single NBD. Recent evidence suggests that BCRP forms a homodimer or a homotetramer to function as an efflux pump (Leslie *et al.*, 2005). These differences in structure account for differences in molecular weight (approximately 170, 190, and 70 kDa for P-gp, MRP1, and BCRP, respectively), but there remains considerable overlap in many of the xenobiotics that are transported by these proteins.

Box 5-1

Major ABC Transporters Involved in Xenobiotic Disposition

ABBREVIATION	NAME	GENE SYMBOL	FUNCTION
MDR1/P-gp	Multidrug resistant protein/P-glycoprotein	*ABCB1*	Efflux from gut, brain, and placenta; biliary excretion
MDR2	Multidrug resistant protein 2	*ABCB4*	Phospholipid transport
BSEP	Bile salt export pump	*ABCB11*	Bile salt transport
MRP1	Multidrug resistance associated protein 1	*ABCC1*	Multidrug resistance in many tissues
MRP2	Multidrug resistance associated protein 2	*ABCC2*	Organic anion efflux, glucuronide, and glutathione conjugates
MRP3	Multidrug resistance associated protein 3	*ABCC3*	Organic anion efflux, glucuronide, and glutathione conjugates
MRP4	Multidrug resistance associated protein 4	*ABCC4*	Nucleoside transport
MRP5	Multidrug resistance associated protein 5	*ABCC5*	Nucleoside transport
MRP6	Multidrug resistance associated protein 6	*ABCC6*	Unknown
BCRP	Breast cancer resistance protein	*ABCG2*	Organic anion efflux, mainly sulfate conjugates

NOTE: Gene nomenclature denotes those genes identified in humans.

Members of the ABC transport family are expressed constitutively in many cells, and collectively they play important roles in absorption from the GI tract and elimination into bile or into urine for a diverse array of xenobiotics. They are also critical to maintaining the barrier function of numerous tissues sites including the blood–brain barrier, the blood–testis barrier, and the maternal–fetal barrier or placenta. Hence, they play a central role in the disposition and toxicity of xenobiotics. Their function in absorption, distribution, and excretion will be discussed throughout the remaining sections of this chapter.

The second major type of xenobiotic transporters is that which function predominantly as facilitative transporters. A major family of such transporters is known as solute carriers (SLCs), for which there are now 43 gene families known. Many of the nearly 300 genes comprising the 43 distinct SLC families play important roles in the disposition of endogenous compounds, including glucose, neurotransmitters, nucleotides, essential metals, and peptides. Additionally, there are several families that are vital to xenobiotic disposition, regulating the movement of many diverse organic anions and cations across cell membranes (Hediger *et al.*, 2004).

Genes in families SLC21 and SLC22 are extremely important in xenobiotic disposition (see Box 5-2). The organic-anion transporting peptides (OATP, SLCO family) are important membrane transport proteins that mediate the sodium-independent transport of a wide range of compounds, including organic acids, bases, and neutral compounds. Although they are largely regarded as influx pumps, solutes can move bidirectionally, and these proteins appear to be especially important in the hepatic uptake of xenobiotics. In human liver, three OATPs (OATP1B1, OATP1B3, and OATP2B1) have been identified, whereas the major Oatps in rat liver are Oatp1a1, Oatp1a4, and Oatp1b2. For Oatps, the mechanism of transport is anion exchange such that the cellular influx of an organic compound is thought to be coupled to the efflux of bicarbonate, glutathione, or glutathione conjugates.

The organic-anion transporter (OAT; SLC22) family is particularly important in the renal uptake of anions, and four human proteins (OAT1, 2, 3, and 4) have been identified in the kidney, whereas Oat1 and Oat3 are the major transporters identified in the rat kidney. The organic-cation transporter (OCT; also SLC22) family is important in both the renal and hepatic uptake of xenobiotics. In this family, OCT1 is expressed in human liver, whereas only OCT2 has been detected in human kidney. In rats, Oct1 is found in liver, whereas both Oct1 and Oct2 are expressed in rat kidney. Novel organic-cation transporters (OCTNs; also SLC22) have also been identified which transport exogenous cations along with important endogenous compounds such as carnitine. OATs transport substrates against an electrochemical gradient in exchange for intracellular dicarboxylates, such as α-ketoglutarate, whereas the driving force for Oct-mediated transport is the electrochemical gradient of the transported cation, typical of faciliated diffusion (described below). Peptide transporters (PEPT1 and PEPT2) are responsible for the transport of di- and tri-peptides as well as drugs and toxicants such as the β-lactam antibiotics.

Facilitated Diffusion   Facilitated diffusion applies to carrier-mediated transport that exhibits the properties of active transport except that the substrate is not moved against an electrochemical or concentration gradient, and the transport process does not require the input of energy; that is, metabolic poisons do not interfere with this transport. The transport of glucose from the GI tract across the basolateral membrane of the intestinal epithelium, from plasma into red blood cells, and from blood into the central nervous system (CNS) occurs by facilitated diffusion. As noted earlier, OCTs, which function in the uptake of organic cations particularly

in the liver and kidney, mediate cation movement by faciliated diffusion.

Additional Transport Processes   Other forms of specialized transport have been proposed, but their overall importance is not as well established as that of active transport and facilitated diffusion. Phagocytosis and pinocytosis are proposed mechanisms for cell membranes flowing around and engulfing particles. This type of transfer has been shown to be important for the removal of particulate matter from the alveoli by phagocytes and from blood by the reticuloendothelial system of the liver and spleen.

ABSORPTION

The process by which toxicants cross body membranes and enter the bloodstream is referred to as *absorption.* There are no specific systems or pathways for the sole purpose of absorbing toxicants. Xenobiotics penetrate membranes during absorption by the same processes as do biologically essential substances such as oxygen, foodstuffs, and other nutrients. The main sites of absorption are the GI tract, lungs, and skin. However, absorption may also occur from other sites, such as the subcutis, peritoneum, or muscle, if a chemical is administered by special routes. Experimentalists and medical professionals often distinguish between parenteral and enteral administration of drugs and other xenobiotics. Enteral administration includes all routes pertaining to the alimentary canal (sublingual, oral, and rectal), whereas parenteral administration involves all other routes (intravenous, intraperitoneal, intramuscular, subcutaneous, etc.).

Absorption of Toxicants by the Gastrointestinal Tract

The GI tract is one of the most important sites where toxicants are absorbed. Many environmental toxicants enter the food chain and are absorbed together with food from the GI tract. This site of absorption is also particularly relevant to toxicologists because accidental ingestion is the most common route of unintentional exposure to a toxicant (especially for children) and intentional overdoses most frequently occur via the oral route.

The GI tract may be viewed as a tube traversing the body. Although it is within the body, its contents can be considered exterior to the body. Therefore, unless a noxious agent has caustic or irritating properties, poisons in the GI tract usually do not produce systemic injury to an individual until they are absorbed.

Absorption of toxicants can take place along the entire GI tract, even in the mouth and the rectum. Therefore, although the majority of drugs are given orally, drugs such as nitroglycerin are administered sublingually whereas others are administered as rectal suppositories. If a toxicant is an organic acid or base, it tends to be absorbed by simple diffusion in the part of the GI tract where it exists in its most lipid-soluble (nonionized) form. Because gastric juice is acidic (pH about 2) and the intestinal contents are nearly neutral, the lipid solubility of weak organic acids or bases can differ markedly in these two areas of the GI tract. One can determine by the Henderson–Hasselbalch equations the fraction of a toxicant that is in the nonionized (lipid-soluble) form and estimate the rate of absorption from the stomach or intestine. According to this equation, a weak organic acid is present mainly in the nonionized (lipid-soluble) form in the stomach and predominantly in the ionized form in the intestine. Therefore, weak organic acids are absorbed more

readily from the stomach than from the intestine. In contrast, organic bases (except very weak organic bases) are likely to be ionized and not lipid soluble in the stomach, but are more likely to be in the nonionized form in the intestine, suggesting that the absorption of such compounds occurs predominantly in the intestine rather than in the stomach. However, the Henderson–Hasselbalch equations have to be interpreted with some qualifications because other factors—including the mass action law, surface area, and blood flow rate—have to be taken into consideration in examining the absorption of weak organic acids or bases. For example, only 1% of benzoic acid is present in the lipid-soluble form in the intestine. Therefore, one might conclude that the intestine has little capacity to absorb this organic acid. However, absorption is a dynamic process. The

---

blood keeps removing benzoic acid from the lamina propria of the intestine, and according to the mass action law, the equilibrium will always be maintained at 1% in the nonionized form, providing continuous availability of benzoic acid for absorption. Moreover, absorption by simple diffusion is also proportional to the surface area. The small intestine has a very large surface because the villi and microvilli increase the surface area approximately 600-fold, such that the overall capacity of the intestine for absorption of benzoic acid is quite large. Similar considerations are valid for the absorption of all weak organic acids from the intestine (Box 5-3).

The mammalian GI tract has numerous specialized transport systems (carrier-mediated) for the absorption of nutrients and electrolytes (Table 5-2). The absorption of some of these substances is complex and depends on a number of factors. The absorption of iron, for example, depends on the need for iron and takes place in two steps: Iron first enters the mucosal cells and then moves into the blood. The first step is relatively rapid, whereas the second is slow. Consequently, iron accumulates within the mucosal cells as a protein–iron complex termed *ferritin*. When the concentration of iron in blood drops below normal values, some iron is liberated from the mucosal stores of ferritin and transported into the blood. As a consequence, the absorption of more iron from the intestine is triggered to replenish these stores. Calcium is also absorbed by a two-step process: absorption from the lumen followed by exudation into the interstitial fluid. The first step is faster than the second, and therefore intracellular calcium rises in mucosal cells during absorption. Vitamin D is required for both steps of calcium transport.

Some xenobiotics are absorbed by the same specialized transport systems, thereby leading to potential competition or interaction. For example, 5-fluorouracil is absorbed by the pyrimidine transport system (Yuasa *et al.*, 1996), thallium utilizes the system that normally absorbs iron (Leopold *et al.*, 1969), lead can be absorbed by the calcium transporter (Fullmer *et al.*, 1992), and cobalt and manganese compete for the iron transport system (Flanagan *et al.*, 1980).

Numerous xenobiotic transporters are expressed in the GI tract where they function to increase or decrease absorption of xenobiotics (Fig. 5-5). Several proteins in the SLC families are expressed in the intestine where they are predominantly localized on the apical brush border membranes of the enterocytes and increase uptake from the lumen into the enterocytes. In humans OATP2B1, 3A1, and 4A1 have been identified, whereas in rodents Oatp1a5 is the predominant uptake transporter. OCTs, particularly OCT1 and 2, have also been identified in the human intestine. There are also peptide transporters (PEPT1) in the GI tract that mediate the transport of peptide-like drugs such as antibiotics, particularly those containing a β-lactam structure (Tsuji *et al.*, 1993; Dantzig *et al.*, 1994). Transepithelial absorption of dipeptides (e.g., glycylsarcosine) and β-lactam antibiotics at low concentrations occurs predominantly by active carrier-mediated mechanisms at both apical and basolateral membranes (Thwaites *et al.*, 1993).

The primary active efflux transporters such as P-gp, MRP2, and BCRP are also expressed on enterocyte brush border membranes where they function to excrete their subsrates into the lumen, thereby decreasing the net absorption of xenobiotics. MRP3 is also found in the intestine, but is localized to the basolateral membrane. P-gp expression in the intestine increases from the duodenum to colon, whereas MRP2 expression is highest in the duodenum and decreases to undetectable levels in the terminal ileum and colon, and BCRP is found throughout the small intestine and colon. There will be a net reduction in the absorption of chemicals that are substrates for these transporters, and this is a desirable outcome for toxic chemicals. For example, the dietary

carcinogen, 2-amino-1-methyl-6-phenylimidazo(4,5-b)pyridine (PhIP), a heterocyclic amine produced during the cooking of meat, is a substrate for MRP2. Studies comparing the disposition of PhIP in wild-type and Mrp2-deficient rats showed that MRP is very important in limiting the oral absorption of this harmful compound (Dietrich *et al.*, 2001). However, whereas limiting absorption of toxicants and carcinogens is beneficial, these transporters can also function to limit the oral absorption of drugs. For example, the immunosuppressive drug cyclosporine and the chemotherapeutic anticancer drugs paclitaxel (taxol), colchicine, and vincristine

Figure 5-5. Schematic model showing the important xenobiotic transport systems present in the gastrointestinal tract. Oatp1a5 is expressed in rat intestine whereas in humans, OATP2B1, 3A1, 4A1 are found.

are not readily absorbed from the GI tract because they are good substrates for P-gp.

The number of toxicants actively absorbed by the GI tract is low; most enter the body by simple diffusion. Although lipid-soluble substances are absorbed by this process more rapidly and extensively than are water-soluble substances, the latter may also be absorbed to some degree. After oral ingestion, about 10% of lead, 4% of manganese, 1.5% of cadmium, and 1% of chromium salts are absorbed. If a compound is very toxic, even small amounts of absorbed material produce serious systemic effects. An organic compound that would not be expected to be absorbed on the basis of the pH-partition hypothesis is the fully ionized quaternary ammonium compound pralidoxime chloride (2-PAM; molecular weight 137), yet it is absorbed almost entirely from the GI tract. The mechanism by which some lipid-insoluble compounds are absorbed is not entirely clear. It appears that organic ions of low molecular weight (<200) can be transported across the mucosal barrier by paracellular transport, that is, passive penetration through aqueous pores at the tight junctions (Aungst and Shen, 1986), or by active transport as discussed above.

Particles and particulate matter can also be absorbed by the GI epithelium. In this case, particle size determines absorption and factors such as the lipid solubility or ionization characteristics are less important. For particles, size is inversely related to absorption such that absorption increases with decreasing particle diameter (Florence *et al.*, 1995). This explains why metallic mercury is relatively nontoxic when ingested orally and why powdered arsenic was found to be significantly more toxic than its coarse granular form (Schwartze, 1923). Emulsions of polystyrene latex particles 22 μm in diameter enter intestinal cells by pinocytosis, a process that is much more prominent in newborns than in adults (Williams and Beck, 1969), after which they are carried through the intestinal epithelium in intact vesicles and discharged into the interstices of the lamina propria. Absorption into gut-associated lymphoid tissue (such as Peyer's patches) and the mesenteric lymph supply play a key role in systemic absorption of particles (Jani *et al.*, 1990; Florence *et al.*, 1995).

There is recent interest in particles of very small diameter that may be used in a variety of chemical and biological processes. *Nanoparticles* or nanomaterials are typically less than 100 nm in
size, and numerous issues have been raised regarding the toxic potential of these entities. Although the absorption of large particles is typically limited, absorption of nanoparticles by the GI tract in rats is as high as 30% for particles that are 50 nm in diameter (Jani *et al.*, 1990), and nonionized particles showed higher absorption than those modified to possess an ionized surface (Florence *et al.*, 1995).

It is clear that the absorption of a toxicant from the GI tract depends on its physical properties, including lipid solubility and its dissolution rate. Although it is often generalized that an increase in lipid solubility increases the absorption of chemicals, an extremely lipid-soluble chemical is unlikely to dissolve in the aqueous fluids within the GI tract, and thus, absorption of a highly lipid soluble compound from the GI tract is likely to be very low (Houston *et al.*, 1974). Similarly, if the toxicant is a solid and is relatively insoluble in GI fluids, it will again have limited contact with the GI mucosa and its rate of absorption will be low.

In addition to the characteristics of the compounds themselves, there are numerous additional factors relating to the GI tract itself that influence the absorption of xenobiotics. These factors include pH, the presence of food, digestive enzymes, bile acids, and bacterial microflora in the GI tract, and the motility and permeability of the GI tract. Chemical resistance or lack of resistance to alteration by the acidic pH of the stomach, enzymes of the stomach or intestine, or the intestinal flora are extremely important. A toxicant may be hydrolyzed by stomach acid or biotransformed by enzymes in the GI tract or the microflora to new compounds with a toxicity greatly different from that of the parent compound. For example, snake venoms, which are proteinaceous, are much less toxic by the oral route relative to intravenous exposure because they are broken down by digestive enzymes of the GI tract. In direct contrast, a variety of nitroaromatic compounds are reduced by intestinal microflora to potentially toxic and carcinogenic aromatic amines. For example, 2,6-dinitrotoluene requires nitroreduction to 2,6-diaminotoluene in the GI tract to produce long-term adverse effects, and these effects including mutagenicity and carcinogenicity, are not seen in germ-free animals (Rickert *et al.*, 1984). Similarly, the nitroaromatic perfume, musk xylene, can inhibit the activity of cytochrome P450 enzymes in the liver only after it is reduced to an amine derivative by resident microflora in the GI tract and subsequently absorbed (Lehman-McKeeman *et al.*, 1997). It has also been shown that ingestion of well water with a high nitrate content produces methemoglobinemia much more frequently in infants than in adults. In this case, bacteria in the GI tract convert nitrate to nitrite, increasing the likelihood of methemoglobinemia (Mensinga *et al.*, 2003). Infants are more susceptible to methemoglobinemia because the higher pH of the neonatal GI tract is permissive for the growth of bacteria (such as *Escherichia coli*) that convert nitrate to nitrite. The contribution of bacteria in the GI tract to other aspects of xenobiotic disposition, particularly enterohepatic circulation, is discussed in greater detail later in this chapter.

Agents such as the chelator, ethylenediaminetetraacetic acid (EDTA), increase absorption of some toxicants by increasing intestinal permeability. An increase in permeability is thought to result from the chelation of calcium that is involved in the formation and maintenance of tight intercellular junctions (Ballard *et al.*, 1995) such that binding of calcium reduces the integrity of the cell junctions, allowing more paracellular absorption. Furthermore, simple diffusion is proportional not only to the surface area and the permeability but also to the residency time within various segments of the GI tract. Therefore, the rate of absorption of a toxicant remaining for longer periods in the intestine increases, whereas that with a shorter

residency time decreases. Experiments have shown that the oral toxicity of some chemicals is increased by diluting the dose (Borowitz *et al.*, 1971). This phenomenon may be explained by more rapid stomach emptying induced by increased dosage volume, which in turn leads to greater absorption in the duodenum because of the larger surface area there. Furthermore, some agents used as laxatives alter absorption of xenobiotics by increasing intestinal motility (Levine, 1970), whereas agents used as antidiarrheals may increase absorption by slowing intestinal motility.

The amount of a chemical that enters the systemic circulation after oral administration depends on several factors. The amount absorbed into the cells of the GI tract is important, and transporters can influence this amount by affecting the uptake or efflux from the cells. Further, before a chemical enters the systemic circulation, it can be biotransformed by the cells in the GI tract or extracted by the liver and excreted into bile with or without prior biotransformation. This phenomenon of the removal of chemicals before entrance into the systemic circulation is referred to as *presystemic elimination* or *first-pass effect.* The lung can also contribute to the biotransformation or elimination of chemicals before their entrance into the systemic circulation, although its role is less well-defined than that of the intestine and the liver. Chemicals that have a high first-pass effect will appear to have a lower absorption because they are eliminated as quickly as they are absorbed. For toxicants, a high first-pass effect will serve to limit exposure and typically minimizes toxic potential.

A number of other factors have been shown to alter absorption. For example, although lead and many other heavy metal ions are not absorbed readily from the GI tract, EDTA and other chelators increase the lipid solubility and thus the absorption of complexed ions. Thus, it is important not to give a chelator orally when excess metal is still present in the GI tract after oral ingestion. Furthermore, metal ions can affect absorption of other ions. For example, cadmium decreases the absorption of zinc and copper, calcium decreases cadmium absorption, and magnesium decreases absorption of fluoride (Pfeiffer, 1977). Consumption of grapefruit juice can also influence GI absorption through the actions of naringin, a flavonoid, that inhibits intestinal cytochrome P450 3A activity (see Chap. 6) and alters the function of P-gp (Evans, 2000). Grapefruit juice increases the GI absorption of numerous pharmaceutical agents (such as calcium-channel blockers and cholesterol-lowering agents) and in some cases, this effect leads to toxic or adverse reactions resulting from increased exposure to the drugs.

Species differences in absorption across the GI tract are widely recognized. As one example, absorption of nadolol after intraperitoneal and oral dosing was compared across species by calculating the plasma area-under-the-curve (AUC) and was found to be essentially complete in dogs, substantially less in humans, and quite limited in rats (Table 5-3). Urinary and fecal excretion of nadolol support the bioavailability data, as the low oral absorption of nadolol in rats is consistent with the large amount of drug recovered in feces. However, excretory data further indicate that in addition to the nonabsorbed portion of this compound, biliary and possibly nonbiliary sources also contribute to the fecal excretion of this compound. Similar comparisons across species provide further evidence for species differences in the absorption of numerous compounds, indicating that nadolol is not an exceptional case (Calabrese, 1984).

The factors that contribute to species differences in absorption are not fully understood. Anatomical considerations are likely to contribute to species differences in intestinal absorption, and substantial functional differences exist between species. Because most

xenobiotics are transported across the GI mucosa by passive diffusion, and because this transport is surface area- and site-dependent, it can be expected that these factors will be responsible for species differences in some instances. Furthermore, species differences in the pH along the GI tract exist (Table 5-4), varying by as much as 2 pH units. The magnitude of this diversity can translate into differences up to two orders of magnitude in the concentration of the nonionized versus ionized moiety of a weak organic acid or base available for absorption. In addition, the GI absorption is often higher in dogs compared to other species because paracellular absorption is thought to occur to a greater extent in dogs.

Another factor that may result in species-dependent absorption of xenobiotics is the presence and function of the GI microflora. Bacteria in the GI tract are highly abundant, with strict anaerobes (oxygen intolerant) being the most prevalent. More than 400 species of bacteria have been found in the GI tract. In general, the intestinal

microflora in animals is remarkably similar, although qualitative and quantitative differences have been reported (Rowland *et al.*, 1985). For example, rabbit and humans are distinguished from other species in that the number of microbes found in the upper regions of the GI tract is relatively low (Table 5-5). The lower pH of the stomach in rabbits and humans contributes to the lower number of microbes found in this region. Importantly, bacterial metabolism is a prerequisite for absorption of some xenobiotics, and species differences in absorption may result from differences in the type and number of microbes in the GI tract.

Absorption of Toxicants by the Lungs

Toxic responses to chemicals can occur from absorption following inhalation exposure. A frequent cause of death from poisoning—carbon monoxide—and an important occupational disease—silicosis—both result from absorption or deposition of airborne poisons in the lungs.

A major group of toxicants that are absorbed by the lungs are gases (e.g., carbon monoxide, nitrogen dioxide, and sulfur dioxide), vapors of volatile or volatilizable liquids (e.g., benzene and carbon tetrachloride), and aerosols. Because the absorption of inhaled gases and vapor differs from that of aerosols, aerosols are discussed separately below. However, the absorption of gases and vapors is governed by the same principles, and therefore the word *gas* is used to represent both in this section.

Gases and Vapors   The absorption of inhaled gases takes place mainly in the lungs. However, when inhaled, gases first pass through the nose, filtering through delicately scrolled, simple epithelial-lined turbinates, which serve to increase the surface area of exposure. Because the mucosa of the nose is covered by a film of fluid, gas molecules can be retained by the nose and not reach the lungs if they are very water soluble or react with cell surface components. Therefore, the nose acts as a "scrubber" for water-soluble gases and highly reactive gases, partially protecting the lungs from potentially injurious insults. Although these actions may serve to reduce systemic exposure or to protect the lungs, they also increase the risk that the nose could be adversely affected. Such is the case with formaldehyde (Kerns *et al.*, 1983) and vinyl acetate (Bogdanffy *et al.*, 1999), which cause tumors of the nasal turbinates in rats.

Absorption of gases in the lungs differs from intestinal and percutaneous absorption of compounds in that the dissociation of acids and bases and the lipid solubility of molecules are less important factors in pulmonary absorption because diffusion through cell membranes is not rate-limiting in the pulmonary absorption of gases. There are at least three reasons for this. First, ionized molecules are of very low volatility, so that they do not achieve significant concentrations in normal ambient air. Second, the epithelial cells lining the alveoli—that is, type I pneumocytes—are very thin and the capillaries are in close contact with the pneumocytes, so that the distance for a chemical to diffuse is very short. Third, chemicals absorbed by the lungs are removed rapidly by the blood, and blood moves very quickly through the extensive capillary network in the lungs.

When a gas is inhaled into the lungs, gas molecules diffuse from the alveolar space into the blood and then dissolve. Except for some gases with a special affinity for certain body components (e.g., the binding of carbon monoxide to hemoglobin), the uptake of a gas by a tissue usually involves the simple physical process of dissolving. The end result is that gas molecules partition between the two media: air and blood during the absorptive phase and blood

and other tissues during the distributive phase. As the contact of the inspired gas with blood continues in the alveoli, more molecules dissolve in blood until gas molecules in blood are in equilibrium with gas molecules in the alveolar space. At equilibrium, the ratio of the concentration of chemical in the blood and chemical in the gas phase is constant. This solubility ratio is called the *blood-to-gas partition coefficient*, and it is unique for each gas. Note that whereas the ratio is constant, the concentrations achieved vary in accordance with Henry's law, which dictates that the amount of gas dissolved in a liquid is proportional to the partial pressure of the gas in the gas phase at any given concentration before or at saturation. Thus, the higher the inhaled concentration of a gas (i.e., the higher the partial pressure), the higher the gas concentration in blood, but the blood:gas ratio does not change unless saturation has occurred. When equilibrium is reached, the rate of transfer of gas molecules from the alveolar space to blood equals the rate of removal by blood from the alveolar space. For example, chloroform has a relatively high blood-to-gas partition coefficient (approximately 20), whereas ethylene has a low coefficient (0.14). By comparison, a smaller percentage of the total ethylene in the lungs is removed into the blood during each circulation because the low blood-to-gas partition coefficient dictates that blood is quickly saturated with this gas. Therefore, an increase in the respiratory rate or minute volume does not change the transfer of such a gas to blood. In contrast, an increase in the rate of blood flow increases the rate of uptake of a compound with a low solubility ratio because of more rapid removal from the site of equilibrium, that is, the alveolar membranes. It has been calculated that the time to equilibrate between the blood and the gas phase for a relatively insoluble gas is about 10–20 minutes.

A gas with a high blood-to-gas partition coefficient, such as chloroform, is readily transferred to blood during each respiratory cycle so that little if any remains in the alveoli just before the next inhalation. The more soluble a toxic agent is in blood, the more of it will be dissolved in blood by the time equilibrium is reached. Consequently, the time required to equilibrate with blood is much longer for a gas with a high blood-to-gas partition coefficient than for a gas with a low ratio. This has been calculated to take a minimum of 1 hour for compounds with a high solubility ratio, although it may take even longer if the gas also has high tissue affinity (i.e., high fat solubility). With highly soluble gases, the principal factor limiting the rate of absorption is respiration. Because the blood is already removing virtually all gases with a high solubility ratio from the lungs, increasing the blood flow rate does not substantially increase the rate of absorption. However, the rate can be accelerated greatly by increasing the rate of respiration.

The blood carries the dissolved gas molecules to the rest of the body. In each tissue, the gas molecules are transferred from the blood to the tissue until equilibrium is reached at a tissue concentration dictated by the tissue-to-blood partition coefficient. After releasing part of the gas to tissues, blood returns to the lungs to take up more of the gas. The process continues until a gas reaches equilibrium between blood and each tissue according to the tissue-to-blood partition coefficients characteristic of each tissue. This equilibrium is referred to as *steady state*, and at this time, no net absorption of gas takes place as long as the exposure concentration remains constant.

Aerosols and Particles   Absorption of aerosol and particles is distinguished from gases and vapors by the factors that determine absorption from the inhalation route of exposure. The absorption of gases and vapors by inhalation is determined by the partitioning of the compound between the blood and the gas phase along with its solubility and tissue reactivity. In contrast, the important characteristics that affect absorption after exposure to aerosols are the aerosol size and water solubility of any chemical present in the aerosol.

The site of deposition of aerosols and particulates depends largely on the size of the particles. This relationship is discussed in detail in Chap. 15. In general, the smaller the particle, the further into the respiratory tree the particle will deposit (Fig. 5-6). Particles ranging from 5 μm or larger, described as "course particles" usually are deposited in the nasopharyngeal region. Those deposited on the unciliated anterior or rostral portion of the nose tend to remain at the site of deposition until they are removed by nose wiping, blowing, or sneezing. The mucous blanket of the ciliated nasal surface propels insoluble particles by the movement of the cilia. These particles and particles inhaled through the mouth are swallowed within minutes. Soluble particles may dissolve in the mucus and be carried to the pharynx or may be absorbed through the nasal epithelium into the blood.

Particulate matter with diameters of approximately 2.5 μm, referred to as "fine particles" are deposited mainly in the tracheobronchiolar regions of the lungs, from which they may be cleared by retrograde movement of the mucus layer in the ciliated portions of the respiratory tract (also known as the mucociliary escalator). The rate of cilia-propelled movement of mucus varies in different parts of the respiratory tract, although in general it is a rapid and efficient transport mechanism. Toxicants or viral infections that damage cilia may impair the efficiency of this process. Measurements have shown transport rates between 0.1 and 1 mm per minute, resulting in removal half-lives between 30 and 300 minutes. Coughing and sneezing greatly increase the movement of mucus and particulate matter toward the mouth. Particles eventually may be swallowed and absorbed from the GI tract or expectorated.

Particles 1 μm and smaller penetrate to the alveolar sacs of the lungs. Ultrafine or nanoparticles are those that are less than 0.1 μm (100 nM) in diameter. Those particles that are approximately 10–20 nm in size have the greatest likelihood of depositing in the alveolar region. These extremely small particles may be absorbed into blood or cleared through the lymphatics after being scavenged by alveolar macrophages (Oberdorster *et al.*, 2005).

In addition to being a major determinant of lung deposition, as particle size decreases, the number of particles in a unit of space increases along with the total surface area of the particles. This relationship, illustrated in Table 5-6, indicates that nanoparticles have the propensity to deliver high amounts of particulates to the lung. The contribution of nanoparticles to toxic responses, with special emphasis on their disposition (and factors that influence disposition including size, composition, surface structure, surface group modification, solubility, and aggregation) are major areas of toxicological and human health effects research (Nel *et al.*, 2006).

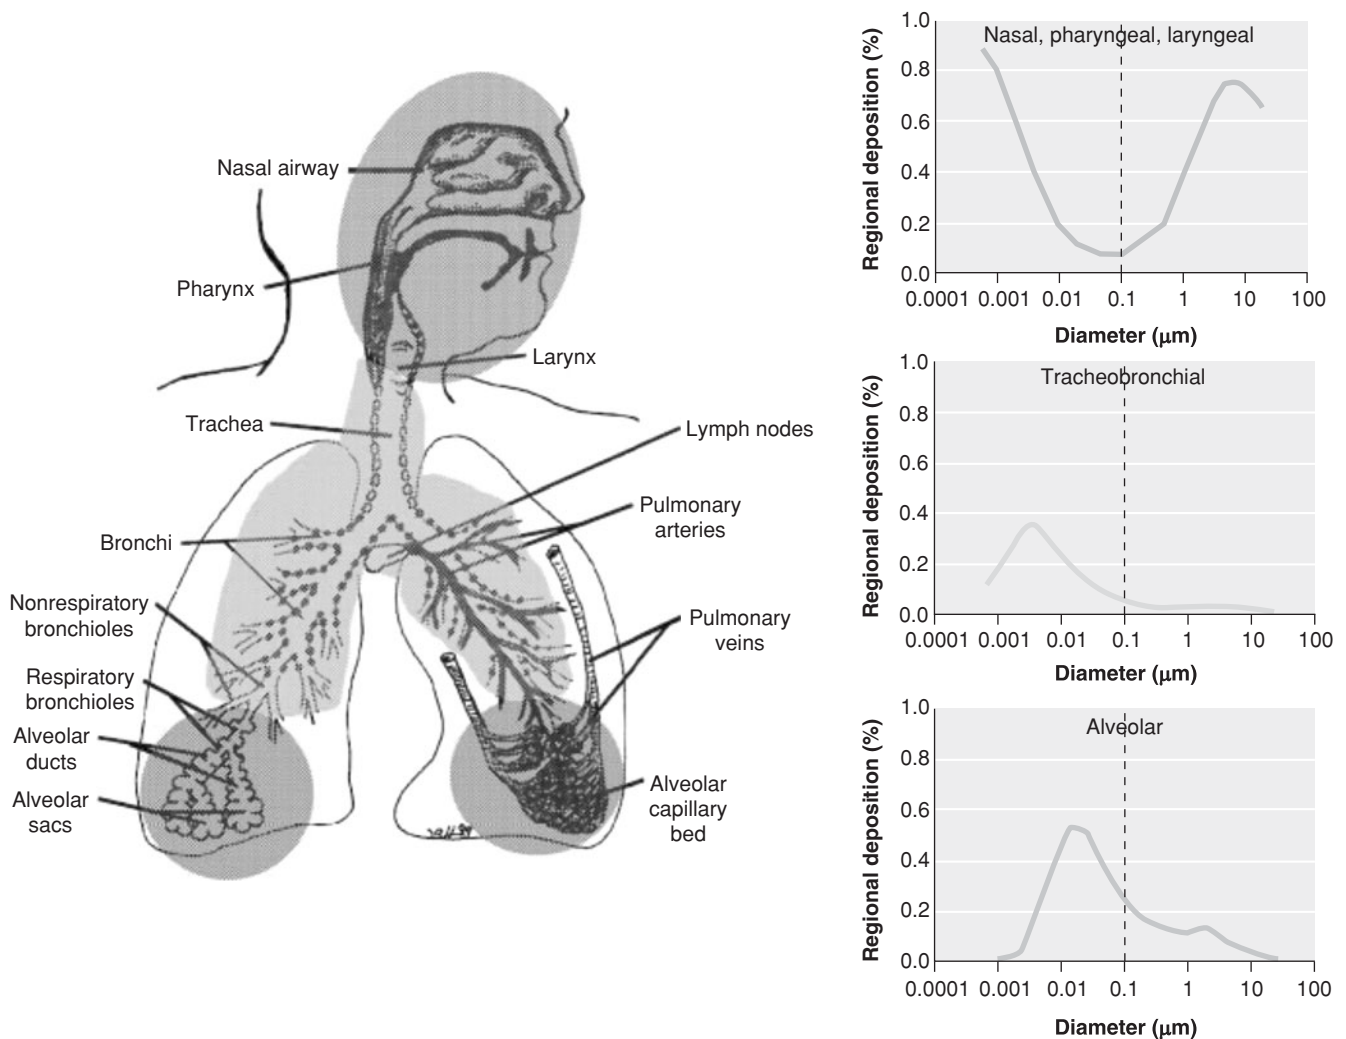
The mechanisms responsible for the removal or absorption of particulate matter from the alveoli are less clear than those responsible for the removal of particles deposited in the tracheobronchial tree. Removal appears to occur by three major mechanisms. First, particles may be removed from the alveoli by a physical process. As described earlier, it is thought that particles deposited on the fluid layer of the alveoli are aspirated onto the mucociliary escalator of the tracheobronchial region. From there, they are transported to the mouth and may be swallowed. The origin of the thin fluid layer in the alveoli is probably a transudation of lymph and secretions of lipids and other components by the alveolar epithelium. The alveolar fluid flows by an unknown mechanism to the terminal


Figure 5-6. *Representation of particle distribution in the lungs relative to size. (Oberdorster et al., 2005, with permission).*

bronchioles. This flow seems to depend on lymph flow, capillary action, the respiratory motion of the alveolar walls, the cohesive nature of the respiratory tract's fluid blanket, the propelling power of the ciliated bronchioles, and the surface tension within the fluid layer. Second, particles from the alveoli may be removed by phagocytosis. The principal cells responsible for engulfing alveolar debris are the resident alveolar macrophages. These phagocytic cells are found in large numbers in normal lungs and contain many phago-

0.05	153,000,000	12,000

SOURCE: Modified from Oberdorster *et al.* (2005) and Nel *et al.* (2006).

cytized particles of both exogenous and endogenous origin. They apparently migrate to the distal end of the mucociliary escalator and are cleared and eventually swallowed. Third, removal may occur via the lymphatics. The endothelial cells lining lymphatic capillaries are permeable to very large molecules (molecular weight $>10^6$) and for particles, although the rate of penetration is low above a molecular weight of 10,000. Nevertheless, the lymphatic system plays a prominent role in collecting high-molecular-weight proteins leaked from cells or blood capillaries and particulate matter from the interstitium and the alveolar spaces. Particulate matter may remain in lymphatic tissue for long periods, and this explains the phenomenon of "dust store of the lungs."

In general, the overall removal of particles from the alveoli is relatively inefficient. The rate of clearance by the lungs can be predicted by a compound's solubility in lung fluids. The lower the solubility, the lower the removal rate. Thus, it appears that removal of particles that enter the alveoli is largely due to the dissolution and vascular transport. Some particles may remain in the alveoli indefinitely. This may occur when long-lived alveolar macrophages phagocytose indigestible dust particles and secrete cytokines that stimulate the development of a local network of type I and III collagen fibers to form an alveolar dust plaque or nodule.

Absorption of Toxicants Through the Skin

Skin is the largest body organ and provides a relatively good barrier for separating organisms from their environment. Overall, human skin comes into contact with many toxic chemicals, but exposure is usually limited by its relatively impermeable nature. However, some chemicals can be absorbed by the skin in sufficient quantities to produce systemic effects. For example, there are several insecticides for which fatal exposures have occurred in agricultural workers after absorption through intact skin (see Chap. 22). In addition, there are numerous chemicals that increase tumor development in other organs after dermal application.

The skin comprises two major layers, the epidermis and dermis (Fig. 5-7). The epidermis is the outermost layer and comprises keratinocytes that are metabolically competent and able to divide. Dividing keratinocytes in the stratum germinativum displace maturing keratinocyte layers upward until they reach the outermost layer, the stratum corneum. The stratum corneum comprises densely packed keratinized cells that have lost their nuclei and are biologically inactive. The stratum corneum is replaced approximately every 3 to 4 weeks in human adults. This complex process involves dehydration and polymerization of intracellular matrix forming keratin-filled dried cell layers. During the process, the cell walls apparently double in thickness and transform to a dry, keratinous semisolid state with much lower permeability for diffusion of toxicants. The stratum corneum is unique anatomically and represents the single most important barrier to preventing fluid loss from the body while also serving as the major barrier to prevent the absorption of xenobiotics into the body.

The dermis is situated beneath the epidermis and comprises primarily of fibroblasts. This region also contains the vascular network that provides the dermis and epidermis with blood supply and serves to carry absorbed compounds into the body. Although the major anatomical area that controls absorption across the skin is the stratum corneum, compounds may also be absorbed through dermal appendages, including sweat and sebaceous glands and hair follicles found in the dermis. Sweat glands and hair follicles are scattered in varying densities on skin. These appendages account for no more than 1% of the total cross-sectional area of the total skin surface, and in general, passage through these areas is much more rapid than

passage through the stratum corneum. Ultimately, to be absorbed a chemical must pass the barrier of the stratum corneum and then traverse the other six layers of the skin (Dugard, 1983; Poet and McDougal, 2002).

In contrast to the complexity of the GI tract, the skin is a simpler penetration barrier for chemicals because passage through the stratum corneum is the rate-determining step. All toxicants move across the stratum corneum by passive diffusion. In general, lipophilic (fat-soluble) compounds are absorbed more readily across the stratum corneum, whereas the penetration of hydrophilic (water-soluble) compounds is more limited. Nonpolar toxicants diffuse through the skin in a manner that is proportional to their lipid solubility and inversely related to molecular weight. However, although lipophilic compounds may pass more readily through the stratum corneum, their passage through the dermis may become rate-limiting. Hydrophilic compounds are more likely to penetrate the skin through appendages such as hair follicles.

Human stratum corneum displays significant differences in structure and chemistry from one region of the body to another, and these differences affect the permeability of the skin to chemicals. Skin from the plantar and palmar regions is much different from skin from other areas of the body in that the stratum corneum of the palms and soles is adapted for weight bearing and friction and there are no hair follicles present. The stratum corneum of the rest of the body surface is adapted for flexibility and fine sensory discrimination. The permeability of the skin also depends on both the diffusivity and the thickness of the stratum corneum. Whereas the stratum corneum is much thicker on the palms and soles (400–600 μm in callous areas) than on the arms, back, legs, and abdomen (8–15 μm), it has much higher diffusivity per unit thickness. In contrast, the skin of the scrotum is characterized by a thin stratum corneum and a high diffusivity. Consequently, as illustrated by the comparative absorption of malathion across different human skin sites (Table 5-7), toxicants are likely to readily cross scrotal skin, whereas absorption across forehead skin is less extensive, and penetration across the palm is lowest because of the thickness of the stratum corneum and the lack of dermal appendages.

The second phase of percutaneous absorption consists of diffusion of the toxicant through the lower layers of the epidermis (stratum granulosum, spinosum, and germinativum) and the dermis. Despite possessing tight intercellular junctions, these cell layers are far inferior to the stratum corneum as diffusion barriers. In contrast to the stratum corneum, they contain a porous, nonselective, aqueous diffusion medium. Toxicants pass through this area by diffusion and enter the systemic circulation through the numerous venous and lymphatic capillaries in the dermis. The rate of diffusion depends on

blood flow, interstitial fluid movement, and perhaps other factors, including interactions with dermal constituents.

There are several factors that can influence the absorption of toxicants through the skin, including: (1) the integrity of the stratum corneum, (2) the hydration state of the stratum corneum, (3) temperature, (4) solvents as carriers, and (5) molecular size. Because the stratum corneum plays a critical role in determining cutaneous permeability, removal of this layer causes a dramatic increase in the permeability of the epidermis for a variety of large or small molecules, both lipid-soluble and water-soluble (Poet and McDougal, 2002). Caustic agents such as acids and alkalis that damage the stratum corneum increase its permeability. The most frequently encountered penetration-enhancing damage to the skin results from burns and various skin diseases. Water also plays an extremely important role in skin permeability. Under normal conditions, the stratum corneum is partially hydrated, containing about 7% water by weight. This amount of water increases the permeability of the stratum corneum approximately 10-fold over the permeability that exists when it is completely dry. On contact with water, the stratum corneum can increase its weight of tightly bound water up to fivefold, and this can increase permeability an additional two- to threefold. In many studies, the site of application will be covered with plastic wrap (occlusive application), as originally described by Draize *et al.* (1944), which hydrates the stratum corneum and enhances the absorption of some toxicants. Similarly, an increase in temperature will increase dermal penetration by increasing dermal blood flow. This is particularly important for occupational exposures to agents such as insecticides in which agricultural workers are likely to be working strenuously at relatively high temperatures. Such environmental conditions increase dermal penetration and may increase the risk of systemic toxicity.

Solvents used to dissolve compounds of interest can also influence dermal penetration. In general, lower absorption will be observed if a toxicant is highly soluble in the vehicle, whereas low solubility of the toxicant in the vehicle will tend to increase dermal penetration. In addition, solvents such as dimethyl sulfoxide (DMSO) facilitate the penetration of toxicants through the skin by increasing the permeability of the stratum corneum. Although the mechanism by which DMSO enhances skin permeability is not fully understood, it has been suggested that DMSO: (1) removes much of the lipid matrix of the stratum corneum, making holes on artificial shunts in the penetration barrier; (2) produces reversible configurational changes in protein structure brought about by the substitution of integral water molecules; and (3) functions as a swelling agent (Dugard and Embery, 1969). Finally, it is generally recognized that compounds with molecular weights greater than 400 Da will exhibit poor dermal penetration. As described earlier, nanomaterials represent a unique new area in which the small size of the particles is likely to increase penetration and systemic exposures to these small molecules.

Dermal absorption has been studied in most laboratory animals including rats, mice, rabbits, guinea pigs, primates, and pig, and dermal absorption varies widely across these species. As a general rule, dermal absorption across rodent skin is much greater than human skin, whereas the cutaneous permeability characteristics of guinea pigs, pigs, and monkeys are often similar to those observed in humans (Wester and Maibach, 1993). Species differences in percutaneous absorption account for the differential toxicity of insecticides in insects and humans. For example, the LD_{50} of injected DDT is approximately equal in insects and mammals, but DDT is much less toxic to mammals than to insects when it is applied to the skin. This

appears to be due to the fact that DDT is poorly absorbed through the skin of mammals but passes readily through the chitinous exoskeleton of insects. Furthermore, insects have a much greater body surface area relative to weight than do mammals.

Species differences in dermal absorption of xenobiotics result from several anatomic, physiologic, and biochemical factors (Dugard, 1983; Poet and McDougal, 2002). First, the composition and thickness of the stratum corneum along with the nature of the the the dermal appendages are highly variable across species. The stratum corneum is much thicker in humans than in most laboratory animals, making human skin typically less permeable than animal skin. However, the thinner stratum corneum in animals is often compensated for by a relatively thick hair cover, diminishing direct contact of the skin with a xenobiotic. Sweat and pilosebaceous ducts also reveal great species variability. Eccrine sweat glands are located in the pads of the extremities of all mammals. However, the general body surface of humans contains 100 to 600/m^2 of coiled tubular sweat glands, whereas rodents, rabbits, cats, and dogs have none. The number of pilosebaceous ducts in humans and pigs is similar (about 40/cm^2), but rodents may have up to 100 times more. Another important potential rate-limiting step in the dermal absorption of chemicals is the cutaneous blood flow. Owing to an important thermoregulatory function of the skin in humans as opposed to furred animals, there is a much more extensive vasculature in humans than in most mammals (Calabrese, 1984). Biotransformation reactions in skin can also facilitate absorption, and the presence of metabolizing enzymes is highly variable across species. Xenobiotic transporters, including Mrp1, 3, 4, 5, and 6, have been identifed in skin keratinocytes and may also contribute to species differences in dermal absorption of toxicants (Kao *et al.*, 1985; Baron *et al.*, 2001).

Overall, commonly-used laboratory animals are typically not good models of human absorption of toxicants. An example of the species differences and lack of concordance with human data for dermal absorption of the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D) is illustrated in Table 5-8. In general, absorption through primate or pig skin is considered to most closely predict human dermal absorption (Wester and Maibach, 1993). Additionally, in vitro methods using human skin may provide reasonable alternatives to the use of laboratory animals for evaluating dermal absorption of toxicants (Bronaugh *et al.*, 1982).

Absorption of Toxicants after Special Routes of Administration

Toxicants usually enter the bloodstream after absorption through the skin, lungs, or GI tract. However, in studying the effects of chemicals in laboratory animals, other routes of administration may also be used. The most common routes are: (1) intravenous, (2) intraperitoneal, (3) subcutaneous, and (4) intramuscular. The intravenous route introduces the toxicant directly into the bloodstream, eliminating the process of absorption. Intraperitoneal injection results in rapid absorption of xenobiotics because of the rich peritoneal and mesenteric blood supply and the relatively large surface area of the peritoneal cavity. In addition, this route of administration circumvents the delay and variability of gastric emptying. Intraperitoneally administered compounds are absorbed primarily through the portal circulation and therefore must pass through the liver before reaching other organ. Subcutaneously and intramuscularly administered toxicants are usually absorbed at slower rates but enter directly into the general circulation. The rate of absorption by these two routes can be altered by changing the blood flow to the injection site. For

Table 5-8

Comparison of Dermal Absorption of 2,4-D Across Species

SPECIES	WASH TIME (hour)	COLLECTION TIME (hour)	% ABSORBED
Rat	24	336	20
Rabbit	24	336	12
Monkey	24	336	6
Human	4	120	3.7

NOTE: Data modified from Ross *et al*. (2005) and represent application of the dimethyl-lamine salt of 2,4-D. In all cases, the dose applied was 4 μg/cm^2. For rats, rabbits, and monkeys, the application site was washed after 24 hours, whereas human skin was washed after 4 hours. The collection time denotes the interval over which data were collected to determine absorption.

example, epinephrine causes vasoconstriction and will decrease the rate of absorption if it is coinjected intramuscularly with a toxicant. The formulation of a xenobiotic may also affect the rate of absorption, as toxicants are typically absorbed more slowly from suspensions than from solutions.

The toxicity of a chemical may or may not depend on the route of administration. If a toxicant is injected intraperitoneally, most of the chemical enters the liver via the portal circulation before reaching the general circulation. Therefore, an intraperitoneally administered compound may be completely extracted and biotransformed by the liver with subsequent excretion into bile without gaining access to the systemic circulation. Propranolol (Shand and Rangno, 1972) and lidocaine (Boyes *et al*., 1970) are two drugs with efficient extraction during the first pass through the liver. A chemical with a high first-pass effect that is toxic in an organ other than the liver and GI tract is likely to be less toxic when administered intraperitoneally than when administered by other routes (intravenously, intramuscularly, or subcutaneously) because the intraperitoneal route favors extraction in the liver to reduce what is available systemically. In contrast, compounds with no appreciable biotransformation in the liver are likely to show similar toxicity independent of the route of administration if the rates of absorption are equal. Therefore, preliminary information on the contribution of biotransformation and excretion of xenobiotics to toxic outcome can be derived by comparing toxic responses after administration by different routes.

DISTRIBUTION

After entering the blood by absorption or intravenous administration, a toxicant is distributed to tissues throughout the body. Distribution usually occurs rapidly. The rate of distribution to organs or tissues is determined primarily by blood flow and the rate of diffusion out of the capillary bed into the cells of a particular organ or tissue. The final distribution depends largely on the affinity of a xenobiotic for various tissues. In general, the initial phase of distribution is dominated by blood flow, whereas the eventual distribution is determined largely by affinity. The penetration of toxicants into cells occurs by passive diffusion or special transport processes, as was discussed previously. Small water-soluble molecules and ions apparently diffuse through aqueous channels or pores in the cell membrane. Lipid-soluble molecules readily permeate the membrane itself. Very polar molecules and ions of even moderate size (molecular weight of 50 or more) cannot enter cells easily except by special transport mechanisms because they are surrounded by a hydration shell, making their actual size much larger.

Volume of Distribution

Total body water is derived from that which is either extracellular or intracellular and represents three distinct compartments: plasma water and interstitial water comprise the extracellular compartment and are distinguished from intracellular water. The concentration of a toxicant in blood depends largely on its volume of distribution. The volume of distribution (Vd) is used to quantify the distribution of a xenobiotic throughout the body. It is defined as *the volume in which the amount of drug would need to be uniformly dissolved in order to produce the observed blood concentration*. Illustrated below are examples of observed plasma concentrations after absorption of 1 g of a compound in a 70-kg human, which are determined by the Vd. For example, a high concentration would be observed in the plasma if the chemical were distributed into plasma water only (a low Vd), and a much lower concentration would be reached if it were distributed into a large pool, such as total body water (a high Vd). However, the distribution of toxicants is complex and under most circumstances cannot be equated with distribution into one of the water compartments of the body. Binding to and/or dissolution in various storage sites of the body, such as fat, liver, and bone, are usually more important factors in determining the distribution of chemicals (Box 5-4).

Some toxicants do not readily cross cell membranes and therefore have restricted distribution, whereas other toxicants rapidly pass through cell membranes and are distributed throughout the body. Some toxicants selectively accumulate in certain parts of the body as a result of protein binding, active transport, or high solubility in fat. The target organ for toxicity may be the site of accumulation, but this is not always the case. If a toxicant accumulates at a site other than the target organ or tissue, the accumulation is likely to be protective because plasma levels and consequently its concentration at the site of action is reduced. In this case, it is assumed that the chemical in the storage depot is toxicologically inactive. However, a chemical in a storage depot is also in equilibrium with the free fraction of the toxicant in plasma, so that it is released into the circulation as the unbound fraction of toxicant is eliminated.

Box 5-4

COMPARTMENT	% OF TOTAL	LITERS IN 70-kg HUMAN	PLASMA CONCENTRATION AFTER 1 g OF CHEMICAL
Plasma water	4.5	3	333 mg/L
Total extracellular water	20	14	71 mg/L
Total body water	55	38	26 mg/L
Tissue binding	—	—	0–25 mg/L

Storage of Toxicants in Tissues

Because only the free fraction of a chemical is in equilibrium throughout the body, binding to or dissolving in certain body constituents greatly alters the distribution of a xenobiotic. Some xenobiotics attain their highest concentrations at the site of toxic action, such as carbon monoxide, which has a very high affinity for hemoglobin, and paraquat, which accumulates in the lungs. Other chemicals concentrate at sites other than the target organ. For example, lead is stored in bone, but manifestations of lead poisoning appear in soft tissues. The compartment where a toxicant is concentrated is described as a storage depot. Toxicants in these depots are always in equilibrium with the free fraction in plasma, so that as a chemical is biotransformed or excreted from the body, more is released from the storage site. As a result, the biological half-life of stored compounds can be very long. The following discussion deals with the major storage sites for xenobiotics in the body.

Plasma Proteins as Storage Depot   Binding to plasma proteins is the major site of protein binding, and several different plasma proteins bind xenobiotics and some endogenous constituents of the body. As depicted in Fig. 5-8, albumin is the major protein in plasma and it binds many different compounds. α_1-Acid glycoprotein, although present at a much lower concentration than albumin, is also an important protein in plasma, and compounds with basic characteristics tend to bind to it. Transferrin, a beta globulin, is important for the transport of iron in the body. The other major metal-binding protein in plasma is ceruloplasmin, which carries copper. The alpha- and beta-lipoproteins are very important in the transport of lipid-soluble compounds such as vitamins, cholesterol, and steroid hormones as well as xenobiotics. Plasma gamma globulins are antibodies that function specifically in immunological reactions. (Wilkinson, 1983). Overall, plasma proteins bind acidic compounds such as phenylbutazone, basic compounds such as imipramine, and neutral compounds such as digitoxin.

Albumin, present in the plasma at a concentration of 500–600 μM, is the most abundant protein in plasma and serves as both a depot and multivalent transport protein for many endogenous and exogenous compounds. Protein–ligand interactions occur primarily as a result of hydrophobic forces, hydrogen bonding, and Van der Waals forces. Because of their high molecular weight, plasma proteins and the toxicants bound to them cannot cross capillary walls.
Consequently, the fraction of a toxicant bound to plasma proteins is not immediately available for distribution into the extravascular space or filtration by the kidneys. However, the interaction of a chemical with plasma proteins is a reversible process, and as unbound chemical diffuses out of capillaries, bound chemical dissociates from the protein until the free fraction reaches equilibrium between the vascular space and the extravascular space. In turn, diffusion in the extravascular space to sites more distant from the capillaries continues, and the resulting concentration gradient provides the thermodynamic force for continued dissociation of the bound fraction in plasma. Active transport processes are not limited by the binding of chemicals to plasma proteins.

The binding of toxicants to plasma proteins is usually determined by equilibrium dialysis or ultrafiltration. The total amount in plasma is determined prior to these separation methods, and the fraction that passes through a dialysis membrane or appears in the ultrafiltrate is the unbound (or free) fraction. The bound fraction is determined as the difference between the total and unbound fractions. Binding of toxicants to plasma proteins can be assessed through the use of Scatchard analysis (Scatchard, 1949) in which the ratio of bound to free ligand (toxicant) is plotted on the ordinate and the concentration of bound ligand is plotted on the abscissa, depicted in Fig. 5-9. From this analysis, the number of ligand binding sites (N) per molecule of protein and the affinity constant of the protein–ligand complex can be determined. Although Fig. 5-9 shows a linear relationship, Scatchard plots frequently exhibits nonlinearity, indicating the presence of two or more classes of binding sites with different affinities and capacity characteristics. The extent of plasma protein binding varies considerably among xenobiotics. Some, such as antipyrine, are not bound; others, such as secobarbital, are bound to about 50%; and some, like warfarin, are 99% bound.

The binding of chemicals to plasma proteins is an important concept in toxicology for two reasons. Toxicity is typically manifested by the amount of a xenobiotic that is unbound. Therefore, a compound with a high degree of plasma protein binding may not show toxicity when compared to one that is less extensively bound to plasma proteins. Ironically, a high degree of protein binding also tends to increase the risk of adverse effects resulting from

Figure 5-8. Ligand interactions with plasma proteins.

SOURCE: Modified from Cayen (1980).

interactions with other highly bound compounds. In particular, severe toxic reactions can occur if a toxicant with a high degree of protein binding is displaced from plasma proteins by another agent, increasing the free fraction of the toxicant in plasma. This interaction increases the equilibrium concentration of the toxicant in a target organ, thereby increasing the potential for toxicity. Most research on the adverse interactions associated with binding of xenobiotics to plasma proteins has been conducted with drugs. For example, if a strongly bound sulfonamide is given concurrently with an antidiabetic drug, the sulfonamide may displace the antidiabetic drug and induce a hypoglycemic coma. Similarly, interactions resulting from displacement of warfarin can lead to inappropriate blood clotting and possible deleterious effects. Xenobiotics can also compete with and displace endogenous compounds that are bound to plasma proteins. The importance of this phenomenon was demonstrated in a clinical trial comparing the efficacy of tetracycline with that of a penicillin–sulfonamide mixture in the management of bacterial infections in premature infants (Silverman *et al*., 1956). The penicillin–sulfonamide mixture led to much higher mortality than did the tetracycline, because the sulfonamide displaced a considerable amount of bilirubin from albumin. Free bilirubin then diffused into the brain of the newborns (because the blood–brain barrier is not fully developed), causing a severe form of brain damage termed *kernicterus*. In addition to drugs, some chemicals, such as the insecticide dieldrin, also bind avidly to plasma proteins (99%). Therefore, it is to be expected that chemical–chemical interactions that alter plasma protein binding occur with many different xenobiotics.

Plasma protein binding can also give rise to species differences in the disposition of xenobiotics. For example, plasma protein binding of clofibric acid is considerably different between mice, rats, and humans and correlates with the half-lives of this compound in these species (Table 5-9). Because clofibric acid is primarily eliminated in all three species by glomerular filtration without tubular reabsorption, differences in the free fraction of this compound in plasma across the species contribute to the observed species differences in drug half-life. Additional factors that influence plasma protein binding across species include differences in the concentration of albumin, in binding affinity, and/or in competitive binding of endogenous substances.

Liver and Kidney as Storage Depots   The liver and kidney have a high capacity for binding many chemicals. These two organs probably concentrate more toxicants than do all the other organs combined, and in most cases, active transport or binding to tissue components are likely to be involved.

Hepatic uptake of lead illustrates how rapidly liver binds foreign compounds: just 30 minutes after a single dose, the concentration of lead in liver is 50 times higher than the concentration in plasma (Klaassen and Shoeman, 1974). In addition, some proteins serve to sequester xenobiotics in the liver or kidney. For example, metallothionein (MT), a specialized metal-binding protein, sequesters both essential and toxic metals including zinc and cadmium (Cd) with high affinities in the kidney and liver. In liver, Cd bound to MT serves to concentrate and sequester the heavy metal while preventing its excretion into bile. In the kidney, however, the Cd–MT complex is very toxic and is mechanistically involved in the chronic toxicity of Cd (Klaassen and Liu, 1997). Another protein that sequesters certain toxicants in the kidney is α2u-globulin. This protein, which is synthesized in large quantities only in male rats, binds to a diverse array of xenobiotics including metabolites of D-limonene (a major constituent of orange juice and 2,4,4-trimethylpentane (found in unleaded gasoline). The chemical-α2u-globulin complex is taken up by the kidney, where it accumulates within the lysosomal compartment and damages the proximal tubule cells. Ultimately, the accumulation of this complex in the kidney is responsible for male-rat-specific nephrotoxicity and carcinogenicity (Lehman-McKeeman, 1997).

Fat as Storage Depot   There are many organic compounds that are highly stable and lipophilic, leading to their accumulation in the environment. The lipophilic nature of these compounds also permits rapid penetration of cell membranes and uptake by tissues, and it is not surprising that highly lipophilic toxicants are distributed and concentrated in body fat. The environmental accumulation and potential toxicological significance of long-term storage of numerous compounds including the pesticides aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, mirex, and toxaphene, along with polychlorinated and polybrominated biphenyls, dioxins, and furans has led to international treaties controlling the use of these persistent organic pollutants. The potential for these compounds to produce toxicity, including carcinogenic, developmental, and endocrine effects is related to their accumulation and storage in body fat (Jandacek and Tso, 2001).

Toxicants appear to accumulate in fat by dissolution in neutral fats, which constitute about 50% and 20% of the body weight of obese individuals and lean athletic individuals, respectively. Thus, toxicants with a high lipid/water partition coefficient may be stored in body fat, and higher amounts are likely to be retained in obese individuals. Storage lowers the concentration of the toxicant in the target organ such that toxicity is likely to be less severe in an obese person than in a lean individual. However, of more practical toxicological concern is the possibility that a sudden increase in the concentration of a chemical in blood and the target organ of toxicity may occur if rapid mobilization from fat occurs. Several studies have shown that signs of intoxication can be produced by short-term starvation of experimental animals that were previously exposed to persistent organochlorine insecticides.

There have been numerous attempts to alter storage of lipophilic toxins in adipose tissues in animal models and humans. Changes in body fat composition appear to be the most effective in reducing body burdens, and interventions designed to reduce the absorption of these compounds from the GI tract appear to be somewhat helpful in reducing storage depots of persistent organic pollutants in fat (Jandacek and Tso, 2001).

Bone as Storage Depot   Compounds such as fluoride, lead, and strontium may be incorporated and stored in the bone matrix. For example, 90% of the lead in the body is eventually found in the skeleton. Skeletal uptake of xenobiotics is essentially a surface chemistry phenomenon, with exchange taking place between the bone surface

and the fluid in contact with it. The fluid is the extracellular fluid, and the surface is that of the hydroxyapatite crystals of bone mineral. Many of those crystals are very small, resulting in a large surface area relative to the mass of the bone. The extracellular fluid brings the toxicant into contact with the hydration shell of the hydroxyapatite, allowing diffusion through it and penetration of the crystal surface. As a result of similarities in size and charge, F^- may readily displace OH^-, whereas lead or strontium may substitute for calcium in the hydroxyapatite lattice matrix through an exchange–absorption reaction.

Foreign compounds deposited in bone are not sequestered irreversibly by that tissue. Toxicants can be released from the bone by ionic exchange at the crystal surface and dissolution of bone crystals through osteoclastic activity. An increase in osteolytic activity such as that seen after parathyroid hormone administration leads to enhanced mobilization of hydroxyapatite lattice, which can be reflected in an increased plasma concentration of toxicants. Ultimately, deposition and storage of toxicants in bone may or may not be detrimental. Lead is not toxic to bone, but the chronic effects of fluoride deposition (skeletal fluorosis) and radioactive strontium (osteosarcoma and other neoplasms) are well documented.

Blood–Brain Barrier

Access to the brain is restricted by the presence of two barriers: the blood–brain barrier (BBB) and the blood–cerebral spinal fluid barrier (BCSFB). Although neither represents an absolute barrier to the passage of toxic agents into the CNS, many toxicants do not enter the brain in appreciable quantities because of these barriers.

The BBB is formed primarily by the endothelial cells of blood capillaries in the brain (Fig. 5-10). Each endothelial cell forms a tight junction with adjacent cells, essentially forming a tight seal between the cells and preventing diffusion of polar compounds through paracellular pathways. Diffusion of more lipophilic compounds through endothelial cell membranes is counteracted by xenobiotic efflux transporters present in the endothelial cells. Glial cells, particularly astrocytes, contribute to the BBB by secreting chemical factors that modulate endothelial cell permeability, and astrocytes and perivascular microglial cells extend processes that support the integrity of the BBB. For small- to medium-sized water-soluble molecules, the tighter junctions of the capillary endothelium and the lipid membranes of the glial cell processes represent the major barrier. Although the absorption of lipid-soluble compounds is favored in the brain, such compounds must traverse the membranes of the endothelial cells, not be substrates for xenobiotic transporters, and then traverse the glial cell processes to enter the brain.

The BCSFB is found between the circulating blood and the circulating cerebral spinal fluid in the brain (Fig. 5-11). It comprises
Figure 5-11. Schematic model showing the xenobiotic transporting systems that contribute to the blood–cerebral spinal fluid barrier.

elements of the choroid plexus, the arachnoid membrane, and certain periventricular locations (including the area postrema). The choroid plexus has highly permeable endothelial cells on the blood side but is lined by epithelial cells on the CSF side that form the barrier. Xenobiotic transporters also contribute to removing compounds that may enter the endothelial cells. Furthermore, the protein concentration in CSF is much lower than that in other body fluids. The low protein content of the CSF also limits the movement of water-insoluble compounds by paracellular transport, which is possible in a largely aqueous medium only when such compounds are bound to proteins. Furthermore, in most cases, toxicants achieve concentrations in the CSF that are no higher than the concentration of the unbound toxicant in the plasma. The BCSFB is more of an anatomical entity than a true barrier, but it does provide some protection against the distribution of toxicants to the CNS, thereby affording some protection against toxicity.

Active transport processes represent a key mechanism that decreases the concentration of xenobiotics in the brain. Four ATP-dependent transporters have been identified as part of the BBB including P-gp, Mrp2, Mrp4, and BCRP (deLange, 2004; Leslie et al., 2005). These transporters are located on the luminal (blood side) plasma membrane and function to move xenobiotics absorbed into the capillary endothelial cells out into the blood (Fig. 5-10). Oatp1a4 is also found on the luminal side and could drive a concentrative efflux if coupled energetically to the electrical potential difference across the endothelial cell membrane. Collectively, these transporters can efficiently efflux a wide range of anionic (Mrp2, Mrp4), cationic (P-gp, BCRP), uncharged (all four), and numerous drug conjugates (Oatp1a4, Mrp2) from the brain.

Xenobiotic transporters are also expressed in the choroid plexus, but within the BSCFB, P-gp and Mrp1 are thought to play the most important roles (Fig. 5-10). In this barrier, P-gp is expressed on the luminal side, with efflux from the choroidal epithelial cells into the CSF. In contrast, Mrp1 is expressed on the basolateral side of the choroidal epithelium, catalyzing the transport of xenobiotics out of the cells and into the vascular compartment (deLange, 2004). Members of the Oatp, Oat, Oct, and peptide transporters are also expressed at the choriod plexus. Oatp3, Oat3, and Pept2 are particularly important in regulating xenobiotic concentrations in the CSF (deLange, 2004).

The importance of transport processes to the maintenance of the BBB has been demonstrated in genetically modified mouse models. Compounds that are substrates for P-gp achieve much higher brain levels in P-gp null ($Mdr1a^{-/-}/Mdr1b^{-/-}$) mice relative to wild-type

Figure 5-10. Schematic model showing the xenobiotic transporting systems that contribute to the blood–brain barrier.

mice, and are likely to show increased toxicity as well. Seminal studies demonstrated that P-gp null mice were far more sensitive to the insecticide, ivermectin, and the anticancer agent, vinblastine. The brain uptake of these compounds was increased 26- and 80-fold, respectively, and the sensitivity to neurotoxicity or lethality was increased up to 100-fold (Schinkel *et al.*, 1994; Lankas *et al.*, 1997). Expression of Mrp1 in the choroid plexus has been shown to modulate the concentrations of toxicants in the cerebral spinal fluid, but no studies have yet shown a correlation to neurotoxic potential relative to Mrp1 function.

The effectiveness of the blood–brain barrier varies from one area of the brain to another. For example, the cortex, the lateral nuclei of the hypothalamus, the area postrema, the pineal body, and the posterior lobe of the hypophysis are more permeable than are other areas of the brain. It is not clear whether this is due to the increased blood supply to those areas, or because the BSCFB represents a more permeable barrier, or both. In general, the entrance of toxicants into the brain follows the same principle that applies to transfer across other cells in the body. Only the free fraction of a toxicant (i.e., not bound to plasma proteins) equilibrates rapidly with the brain. Lipid solubility plays an important role in determining the rate of entry of a compound into the CNS, as does the degree of ionization, as discussed earlier. Lipid solubility enhances the rate of penetration of toxicants into the CNS, whereas ionization greatly diminishes it. Pralidoxime (2-PAM), a quaternary nitrogen derivative, does not readily penetrate the brain and is ineffective in reversing the inhibition of brain cholinesterase caused by organophosphate insecticides. Some very lipophilic compounds may enter the brain but are so efficiently removed by xenobiotic transporters that they do not reach appreciable concentrations. This is particularly true for agents like cyclosporin. TCDD, which is highly lipophilic, is also not readily distributed into the brain, but it is not known whether transporters influence its distribution to the brain or not. It is likely that strong binding to plasma proteins or lipoproteins, as well as the composition of the brain (mainly phospholipids), limits the entry of very lipophilic compounds into the brain. Some xenobiotics, although very few, appear to enter the brain by carrier-mediated processes. For example, methylmercury combines with cysteine, forming a structure similar to methionine (see Box 5-5), and the complex is then accepted by the large neutral amino acid carrier of the capillary endothelial cells (Clarkson, 1987).

The blood–brain barrier is not fully developed at birth, and this is one reason why some chemicals are more toxic in newborns than adults. The example of kernicterus resulting from increased brain

levels of bilirubin in infants was noted earlier. In addition, morphine is 3–10 times more toxic to newborn than to adult rats because of the higher permeability of the brain of a newborn to morphine. Similarly, lead produces encephalomyelopathy in newborn rats but not in adults, apparently because of differences in the stages of development of the blood–brain barrier.

Passage of Toxicants Across the Placenta

The term *placental barrier* has been associated with the concept that the main function of the placenta is to protect the fetus against the passage of noxious substances from the mother. However, the placenta is a multifunctional organ that also provides nutrition for the conceptus, exchanges maternal and fetal blood gases, disposes of fetal excretory material, and maintains pregnancy through complex hormonal regulation. Placental structure and function show more species differences than any other mammalian organ. Anatomically, the placental barrier consists of a number of cell layers interposed between the fetal and maternal circulations, but the number of cell layers varies across species and with the stage of gestation. Placentas in which the maximum number of cell layers are present (all six layers) are called *epitheliochorial* (Table 5-10). Those in which the maternal epithelium is absent are referred to as *syndesmochorial.* When only the endothelial layer of the maternal tissue remains, the tissue is termed *endotheliochorial*; when even the endothelium is gone (as in humans), the chorionic villi bathe in the maternal blood, and the tissue is called *hemochorial*. In some species, some of the fetal layers are absent and are called *hemoendothelial*. Within the same species, the placenta may also change its histologic classification during gestation. For example, at the beginning of gestation, the placenta of a rabbit has six major layers (epitheliochorial), and at the end it has only one (hemoendothelial). Overall, there are marked species differences in placental structure. The animal models that are most similar to the organization of the human placenta based on its hemochorial histological organization are rodents and primates, but the decidual nature of the rodent placenta still differs markedly from that of humans (Myllynen *et al.*, 2005; Leiser and Kauffman, 1994).

Most of the vital nutrients necessary for the development of the fetus are transported by active transport systems. For example, vitamins, amino acids, essential sugars, and ions such as calcium and iron are transported from mother to fetus against a concentration gradient (Ganapathy *et al.*, 2000; Ginsburg, 1971). In contrast, most toxic chemicals pass the placenta by simple diffusion. The only exceptions are a few antimetabolites that are structurally similar to endogenous purines and pyrimidines, which are the physiologic substrates for active transport from the maternal to the fetal circulation. The placenta also has biotransformation capabilities that may prevent some toxic substances from reaching the fetus (Syme *et al.*, 2004). Among the substances that cross the placenta by passive diffusion, more lipid-soluble substances rapidly attain a maternal-fetal equilibrium. Under steady-state conditions, the concentrations of a toxic compound in the plasma of the mother and fetus are usually the same.

Many foreign substances can cross the placenta, and the same factors that dictate the passage of xenobiotics across biological membranes are important determinants of the placental transfer. In addition to chemicals, viruses (e.g., rubella virus), cellular pathogens (e.g., syphilis spirochetes), and globulin antibodies can traverse the placenta. In this regard, the placental barrier is not as precise an anatomical unit like the BBB. The human placenta

SOURCE: Modified from Morris *et al*. (1994).

comprises the syncytiotrophoblast and cytotrophoblast layers. The apical membrane of the syncytiotrophoblast, which forms a continuous epithelial layer, is bathed in maternal blood and the basolateral surface is in contact with either the discontinuous cytotrophoblast layer, the stromal tissue or the fetal vasculature (Fig. 5-12). To reach the fetus, toxins must traverse the apical and basolateral membranes of the syncytiotrophoblast as well as the endothelium of the fetal capillaries. Xenobiotic transporters are differentially expressed in these various cells and contribute to the barrier function that restricts distribution of toxicants to the fetus. In particular, P-gp, Mrp2, and BCRP are expressed on the apical border of the syncytiotrophoblast, whereas Mrp1 is localized to the basolateral membranes of syncytiotrophoblasts and the fetal capillary endothelial cells. These transporters play important roles in protecting the fetus while regulating the movement of essential nutrients. There are numerous other transporters in the placenta, many of which are critical to the transfer of nutrients to or the removal of waste products from the fetus. In addition, transporters from the OAT, OCT, and OCTN families have been identified in the placenta, but the precise function and/or membrane location has not been fully established (Ganapathy *et al*., 2000). For example, the homozygous offspring of female P-gp null mice ($Mdr1a^{-/-}/Mdr1b^{-/-}$) develop cleft palate when treated with a photoisomer of avermectin, whereas heterozygous littermates showed intermediate susceptibility and wild-type mice were resistant to this adverse effect (Lankas *et al*., 1998).

BCRP, whose expression is highest in the human placenta relative to any other organ, has also been shown to protect the fetus from exposure to toxicants, and Mrp2 is likely to be particularly important for preventing the passage of conjugated metabolites of toxicants from the maternal to fetal circulation. Finally, Mrp1, lo-

cated on the fetal capillary endothelium is proposed to prevent or limit the entry of organic anions into the fetal circulation.

Despite the presence of biotransformation systems and xenobiotic transporters designed to nourish and protect the fetus, the transfer of xenobiotics across the placenta can still occur. One important consequence of placental transfer is that of transplacental carcinogenesis. In this case exposing the mother during gestation increases the likelihood of tumor development in the offspring later in life (see Chap. 8). The most well-known transplacental carcinogen in humans is diethylstilbestrol (Newbold and McLachlan, 1996), but other compounds such as the anti-viral drug zidovudine (Diwan *et al*., 1999) and inorganic arsenic (Waalkes *et al*., 2003) induce tumors in mice when exposed to these chemicals only during gestation.

Redistribution of Toxicants

The most critical factors that affect the distribution of xenobiotics are the organ blood flow and its affinity for a xenobiotic. The initial phase of distribution is determined primarily by blood flow to the various parts of the body. Therefore, a well-perfused organ such as the liver may attain high initial concentrations of a xenobiotic. However, chemicals may have a high affinity for a binding site (e.g., intracellular protein or bone matrix) or to a cellular constituent (e.g., fat), and with time, will redistribute to these high affinity sites. For example, although 50% of a dose of lead is found in the liver 2 hours after administration, 1 month later, 90% of the lead remaining in the body is associated with the crystal lattice of bone. Similarly, persistent organic pollutants do not distribute rapidly to fat, but accumulate selectively in adipose tissue over time.

EXCRETION

Toxicants are eliminated from the body by several routes. The kidney is perhaps the most important organ for the excretion of xenobiotics because more chemicals are eliminated from the body by this route than by any other (see Chap. 14). Biotransformation to more water-soluble products is usually a prerequisite to the excretion of xenobiotics through urine (see Chap. 6). The second important route of elimination of many xenobiotics is through feces, and the third, primarily for gases, is through the lungs. Biliary excretion of xenobiotics and/or their metabolites is most often the major source of fecal excretion, but a number of other sources can be significant for some compounds. All body secretions appear to have the ability to excrete chemicals; toxicants have been found in sweat, saliva, tears, and milk.
Figure 5-12. Schematic model showing the transport systems that contribute to the barrier function of the placenta.

Urinary Excretion

The kidney is a very efficient organ for the elimination of toxicants from the body. The functional unit of the kidney is the nephron, comprising the glomerulus, a capillary tuft that initiates the process of filtration of the blood, and tubular elements within the renal cortex and medulla that function to produce and concentrate urine. Toxic compounds are excreted in urine by the same mechanisms the kidney uses to remove the endproducts of intermediary metabolism from the body including glomerular filtration, tubular excretion by passive diffusion, and active tubular secretion. In general, the excretion of small molecular weight (<350 Da), water-soluble compounds is favored in urine.

The kidney receives about 25% of the cardiac output, about 20% of which is filtered at the glomeruli. The glomerular capillaries have large pores (approximately 70 nm) which filter compounds up to a molecular weight of about 60 kDa (smaller than albumin). The degree of plasma protein binding affects the rate of filtration because protein-xenobiotic complexes, particularly those bound to albumin, will not be filtered by the glomerulus. Glomerular filtration rates vary considerably across species, ranging from a high of approximately 10 mL/min/kg in mice to about 1.8 mL/min/kg in humans. This difference appears to be determined by the relative number of nephrons per kilogram of body weight, with mice being the highest (Lin, 1995).

A toxicant filtered at the glomerulus may remain in the tubular lumen and be excreted with urine. Depending on the physicochemical properties of a compound, it may be reabsorbed across the tubular cells of the nephron back into the bloodstream. The principles governing the reabsorption of toxicants across the kidney tubules are the same as those discussed earlier in this chapter for passive diffusion across cell membranes. Thus, toxicants with a high lipid/water partition coefficient are reabsorbed efficiently, whereas polar compounds and ions are excreted with urine. The pH of urine may vary but it is usually slightly acidic (approximately 6–6.5). Just as the Henderson–Hasselbach calculations determine the absorption of nonionized compounds from the GI tract, they also determine urinary excretion. In this case, urinary excretion (i.e., not reabsorbed) of the ionized moiety is favored, such that bases are excreted to a greater extent at lower pH whereas

excretion of acids predominates at higher urinary pH. A practical application of this knowledge is illustrated by the treatment of phenobarbital poisoning with sodium bicarbonate. The percentage of ionization can be increased markedly within physiologically attainable pH ranges for a weak organic acid such as phenobarbital (pK_a 7.2). Consequently, alkalinization of urine by the administration of sodium bicarbonate results in a significant increase in the excretion of phenobarbital. Acceleration of salicylate loss via the kidney can be achieved through the administration of sodium bicarbonate. In a similar manner, urinary acidification can be used to increase the excretion of a weak base like phencyclidine (PCP) in drug abusers.

Toxic agents can also be excreted from plasma into urine by passive diffusion through the tubule. This process is probably of minor significance because filtration is much faster than excretion by passive diffusion through the tubules, providing a favorable concentration gradient for reabsorption rather than excretion. Exceptions to this generalization may be some organic acids ($pK_a \approx 3$–5) and bases ($pK_a \approx 7-9$) that would be largely ionized and thus trapped at the pH of urine (pH ≈ 6). For renal excretion of such compounds, the flow of urine is likely to be important for the maintenance of a concentration gradient, favoring excretion. Thus, diuretics can hasten the elimination of weak organic acids and bases.

Xenobiotics can also be excreted into urine by active secretion. This process involves the uptake of toxicants from the blood into the cells of the renal proximal tubule, with subsequent efflux from the cell into the tubular fluid from which urine is formed. Figure 5-13 illustrates the various families of transporters expressed in the rodent kidney that are directly involved in xenobiotic disposition. There are numerous other transporters such as specific glucose transporters or nucleotide transporters that play a role predominantly in the flux of endogenous substances which are not presented here. Transporters may be expressed on the lumenal side of the cell where they contribute to tubular secretion and reabsorption, whereas other transporters are localized to the basolateral membranes, serving to transport xenobiotics to and from the circulation and the renal tubular cells. Renal functional activity, as may be altered by toxicant exposure, can also be evaluated by determining the renal clearance of transporter substrates such as the widely used organic anion, *p*-aminohippurate (PAH).

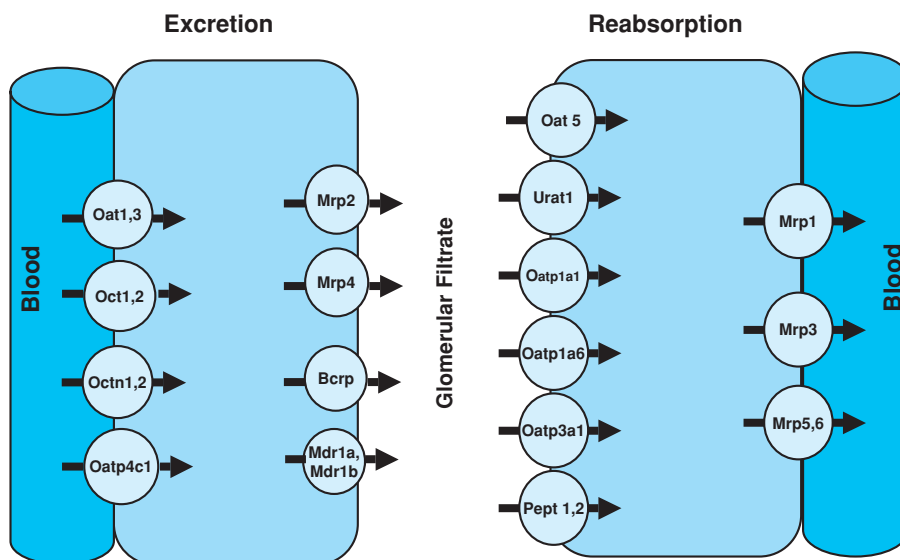
Excretion   **Reabsorption**


Figure 5-13. Schematic model showing the transport systems in the proximal tubule of the kidney.

Transporters expressed on the basolateral side of the renal tubules include OATs, OCTs, and selected members of the organic anion transporting polypeptides (OATP). The OAT family mediates the renal uptake of organic acids such as PAH and is important in the renal exchange of dicarboxylates. In humans, OAT1, 2, 3 are expressed on the basolateral membrane, whereas OAT4 is localized to the brush border membrane. In rodents, Oat1 and 3 are localized to the basolateral membranes. Although the OATs play an important role in the physiological exchange of metabolites in the kidney, they can also contribute to the development of renal toxicity. In particular, the clinical use of antiviral drugs cidofovir and adefovir is limited by nephrotoxicity that is mediated by the accumulation of these drugs in the proximal tubule by OAT1 (Ho *et al.*, 2000). Oat5 is reported to transport ochratoxin A, and may play a role in the nephrotoxicity associated with exposure to this naturally occurring mycotoxin.

The OCT family is responsible for the renal uptake of some cations, particularly those of low molecular weight. Substrates for OCTs include endogenous compounds such as choline, tetraethylammonium (TEA), and certain cationic drugs including cimetidine and acyclovir. OCT2 is highly expressed in human kidney, whereas Oct1 and 2 are expressed on the basolateral membranes of the rodent kidney (Shitara *et al.*, 2005). A second cation transporter is OCTN, and two isoforms, OCTN1 and 2 are localized to the brush border membranes in human and rodent kidney. Substrates include cations like TEA, and OCTN2 is particularly important in the renal reabsorption of carnitine, which is an essential cofactor for fatty acid β-oxidation.

In kidney, peptide transporters, localized to the brush border membrane of the proximal tubule are important for the reuptake of di- and tripeptides. Two transporters, Pept1 and 2 have been identified in the human and rodent kidney, with Pept1 localized in the upper region of the proximal tubule (pars convoluta) and Pept2 expressed in the lower region (pars recta) of the convoluted tubule.

P-gp, MRP2, and MRP4 are also found on the luminal brush border of the proximal tubule, where they contribute to the efflux of xenobiotics out of the cells and into the tubular fluid, thereby enhancing excretion. Mrp1 is also expressed in the rodent kidney, but it is primarily found in the epithelial cells of the loop of Henle and the collecting ducts, whereas in humans, MRP1 has been detected in the glomerulus. In Mrp1$^{(-/-)}$ null mice, the anticancer drug VP-16 causes polyuria indicative of damage to the collecting duct, suggesting that Mrp1 is likely to be involved in the clearance of the compound from the kidney (Wijnholds *et al.*, 1998). Finally, Bcrp is expressed at high levels in the rat and mouse kidney, where it is localized to the apical brush border of the proximal tubule epithelium. This transporter appears to play an important role in the efflux of certain sulfate conjugates of xenobiotics. In contrast, BCRP has not been detected in the human kidney, suggesting that species differences in the urinary excretion of sulfated compounds could occur.

As in all active transport systems, there is competition for renal secretion of xenobiotics. This fact was taken advantage of during World War II, when penicillin was in short supply. Penicillin is actively secreted by the organic acid systems (OATs) of the kidney. To lengthen its half-life and duration of action, another acid was sought to compete with penicillin for renal secretion, and probenecid was successfully introduced for this purpose. Uric acid is also secreted actively by renal tubules, and a unique member of the OAT family, the urate transporter (URAT1) is expressed only in the kidney where it functions specifically as a mechanism for reabsorption of urate.

Various uricosuric agents, including probenecid and phenylbutazone inhibit URAT1 to facilitate the excretion of uric acid from the body.

Because many functions of the kidney are incompletely developed at birth, some xenobiotics are eliminated more slowly in newborns than in adults, and therefore may be more toxic to newborns. For example, the clearance of penicillin by premature infants is only about 20% of that observed in older children. In general, the OATs is not fully developed at birth, but its development can be stimulated by the administration of substances normally excreted by this system (Hirsch and Hook, 1970). Some compounds, such as cephaloridine, are known to be nephrotoxic in adult animals but not in newborns. Because active uptake of cephaloridine by the kidneys is not well developed in newborns, this chemical is not concentrated in the tubules and consequently is not nephrotoxic. If the development of active transport in newborns is stimulated, the kidneys take up cephaloridine more readily and nephrotoxicity is observed (Wold *et al.*, 1977).

The renal proximal tubule reabsorbs small plasma proteins that are filtered at the glomerulus. This largely occurs by pinocytosis at the brush border membrane of the proximal tubule epithelium. If a toxicant binds to those small proteins, it can be carried into the proximal tubule cells and exert toxicity. As discussed previously, cadmium bound to metallothionein is readily taken up by the kidney and is the major cause of Cd-induced nephrotoxicity (Klaassen and Liu, 1997). Similarly, chemicals such as limonene and 2,4,4-trimethyl pentane bind to the male-rat-specific protein, α_{2u}-globulin, and are taken up by the proximal tubule to produce hyaline droplet nephropathy and eventually renal tumors in male rats (Lehman-McKeeman, 1997).

Species differences in regard to the urinary excretion of weak organic acids and bases are observed frequently, as the pH of urine varies widely among species. Differences in renal clearance also can occur for compounds filtered at the glomeruli because of differences in plasma protein binding. Similarly, differences in xenobiotic transporter expression, regulation, and function can contribute to differences in the renal excretion of toxicants.

Additional factors affecting the excretion of xenobiotics are exemplified by the disposition of griseofulvin in rats and rabbits (Table 5-11). Rabbits metabolize griseofulvin to 6-demethylgriseofulvin (a phase-I metabolite), a low-molecular weight species that is predominantly excreted in urine. In contrast, rats metabolize griseofulvin to many conjugates (phase-II metabolites) which are higher molecular weight species (>350) that are preferentially excreted in bile. In this example, species differences

Table 5-11

in biotransformation ultimately determine the route of excretion of griseofulvin.

Fecal Excretion

Fecal excretion is the other major pathway for the elimination of xenobiotics from the body. Fecal excretion of chemicals is a complex process that is not as well understood as urinary excretion. Several important sources and many more minor sources contribute to the excretion of toxicants via the feces.

Nonabsorbed Ingesta   In addition to undigested material, varying proportions of nutrients and xenobiotics that are present in food or are ingested voluntarily (drugs) pass through the alimentary canal unabsorbed, contributing to fecal excretion. The physicochemical properties of xenobiotics and the biological characteristics that facilitate absorption were discussed earlier in this chapter. Although most chemicals are lipophilic to some extent and thereby available for absorption, it is rare for 100% of a compound to be absorbed. At the same time, some macromolecules and some essentially completely ionized compounds of higher molecular weight are not absorbed at all. For example, the absorption of polymers or quaternary ammonium bases is quite limited in the intestine. Consequently, most of a dose of orally administered sucrose polyester, cholestyramine, or paraquat can be found in feces. Therefore, the nonabsorbed portion of xenobiotics contributes to the fecal excretion of most chemicals to some extent. One other factor contributing to fecal excretion is intestinal secretion, which likely occurs by passive diffusion out of enterocytes or via exfoliation of intestinal cells during the normal turnover of this epithelium.

Biliary Excretion   The biliary route of elimination is perhaps the most significant source contributing to the fecal excretion of xenobiotics and is even more important for the excretion of metabolites. The liver plays an important role in removing toxic chemicals from blood after absorption from the GI tract, because blood from the GI tract passes via the portal circulation through the liver before reaching the general circulation. A compound can be extracted by the liver, thereby preventing its distribution to other parts of the body. The liver is also the main site for biotransformation of toxicants, and metabolites may be excreted directly into bile. In this manner, the liver can remove xenobiotics and their metabolites before entering the general circulation (Fig. 5-14). Furthermore, xenobiotics and/or their metabolites excreted into bile enter the intestine and may be excreted with feces. However, if the physicochemical properties favor reabsorption, an enterohepatic circulation may ensue (discussed below).

The biliary excretion of two organic acids, sulfobromophthalein (BSP) and indocyanine green (ICG), is used to evaluate liver function. This diagnostic test is performed by injecting either BSP or ICG intravenously and determining its disappearance from plasma. A lack of proper plasma clearance of BSP or ICG indicates reduced biliary excretion, suggesting liver dysfunction or injury.

Toxic chemicals bound to plasma proteins are fully available for active biliary excretion. The factors that determine whether a chemical will be excreted into bile or into urine are not fully understood. However, as a general rule, low-molecular-weight compounds (<325) are poorly excreted into bile whereas compounds or their conjugates with molecular weights exceeding about 325 can be excreted in appreciable quantities. Glutathione and glucuronide conjugates have a high predilection for excretion into bile, but there are marked species differences in the biliary excretion of foreign compounds with consequences for the biological half-life of a compound and its toxicity (Klaassen *et al.*, 1981). Table 5-12 provides examples of species differences in biliary excretion, and demonstrates that species variation in biliary excretion is also compound specific. It is therefore difficult to categorize species into "good" or "poor" biliary excretors but, in general, rats and mice tend to be better biliary excretors than are other species (Klaassen and Watkins, 1984).

Foreign compounds excreted into bile are often divided into three classes on the basis of the ratio of their concentration in bile versus that in plasma. Class A substances have a ratio of nearly 1

and include sodium, potassium, glucose, mercury, thallium, cesium, and cobalt. Class B substances have a ratio of bile to plasma greater than 1 (usually between 10 and 1000). Class B substances include bile acids, bilirubin, SBP, lead, arsenic, manganese, and many other xenobiotics. Class C substances have a ratio below 1 (e.g., inulin, albumin, zinc, iron, gold, and chromium). Compounds rapidly excreted into bile are usually class B substances. However, a compound does not have to be highly concentrated in bile for biliary excretion to be of quantitative importance. For example, mercury is not concentrated in bile, yet bile is the main route of excretion for this slowly eliminated substance.

Biliary excretion is regulated predominantly by xenobiotic transporters present on the canalicular membrane. Transporters present on the sinusoidal membranes of hepatocytes also contribute to hepatic uptake and efflux, and thereby contribute to hepatobiliary clearance of xenobiotics. There are four known transporters expressed on the canalicular membrane that are directly involved in biliary excretion. These include P-gp, Mrp2, BCRp, and BSEP. P-gp, Mrp2, and Bcrp are important in the biliary excretion of many xenobiotics, whereas BS is critical for the secretion of bile and the regulation of bile flow. Mrp2 is extremely important in biliary excretion because it is largely responsible for the transport of organic anions including the glucuronide and glutathione conjugates of many xenobiotics. BCRP has particular affinity for sulfated conjugates of toxicants, whereas P-gp primarily transports cationic substrates into bile.

The important contribution of Mrp2 to biliary excretion of toxicants was established in part by the characterization of two naturally occurring mutant strains of rat, the Groningen/Yellow transport deficient (TR$^-$) and the Eisai hyperbilirubinemic rat (EHBR), both of which lack functional Mrp2 protein. These rats are phenotypically similar to humans suffering from Dubin–Johnson syndrome, a rare inherited disorder associated with mutations in MRP2 and characterized by chronic conjugated hyperbilirubinemia. The mutant rats also present with conjugated hyperbilirubinemia, show reduced biliary excretion of glutathione, and are defective in the normal biliary excretion of glucuronide and glutathione conjugates of many xenobiotics. An Mrp2$^{-/-}$ null mouse has been developed, and like its mutant rat counterparts, shows marked reductions in bile flow, biliary glutathione concentrations, and reduced ability to eliminate xenobiotics. For example, plasma levels of the food-derived carcinogen, PhIp, was increased 1.9-fold in Mrp2$^{-/-}$ null mice compared to wild-type controls, demonstrating that functional Mrp2 plays a role in reducing exposure to toxic chemicals (Vlaming et al., 2006). Finally, species differences in Mrp2 function may contribute to the qualitative differences observed across species in biliary excretion. In a direct comparison of the transport of 2,4-dinitrophenyl-S-glutathione (DNP-SG) across canalicular membrane vesicles from various species, clearance (μL/min/mg protein) ranged from a high rate of 64.2 in rats to a low of 3.8 in humans, with intermediate values for other species including mouse, guinea pig, rabbit, and dog (Ishizuka et al., 1999). Such differences are likely to contribute to the observed species differences in biliary excretion illustrated in Table 5-12.

Although the highest levels of Bcrp are found in the placenta, the transporter is expressed on the bile canalicular membrane of hepatocytes where it preferentially transports sulfate conjugates of xenobiotics. Known substrates for BCRP include estrone 3-sulfate and 4-methylembelliferone sulfate and methotrexate. P-gp is important in the biliary elimination of compounds such as doxorubicin and vinblastine.

The biliary excretion of xenobiotics mediated by Mrp2, Bcrp, and P-gp usually results in increased excretion of toxicants out of hepatocytes and into bile. In doing so, these transporters increase excretion of xenobiotics and generally limit the likelihood of toxicity in the liver. However, adverse reactions can occur if the function of these transporters is inhibited, as evidenced by the examples illustrated above for the genetic mutant or knockout models. Furthermore, although BSEP does not appear to play a major role in the excretion of xenobiotics, some compounds can inhibit the function of this transporter, thereby decreasing the biliary excretion of bile acids and leading to cholestasis (defined as a decrease in bile flow with increased serum bilirubin) and cholestatic liver injury (Arrese and Ananthanarayanan, 2004). For example, inhibition of BSEP by the pharmaceutical agent, troglitazone, and to a much greater extent, troglitazone sulfate, competitively inhibits BSEP function, leading to intrahepatic cholestasis, which may contribute to the hepatotoxicity of troglitazone. Furthermore, inhibition of BSEP contributes to the cholestasis observed with steroids such as estradiol.

Although the transporters located on the canalicular membrane are directly responsible for biliary excretion of xenobiotics, other xenobiotic transporters localized to the sinusoidal membranes are also important in determining hepatic concentrations of toxicants and thereby contribute to hepatic disposition and biliary elimination. Transporters present on rat sinusoidal membranes include the ABC transport family members, Mrp3, Mrp4, and Mrp6, along with Oatps, Oats, and Oct. The Na$^+$/taurocholate cotransporting polypeptide (NCTP) is also found on the sinusoidal membrane where it functions in the uptake of bile acids into the liver.

Mrp3 transports many of the same organic anions that are substrates for Mrp2 from the liver into the blood circulation. It has recently been shown to be important in the excretion of acetaminophen- and morphine glucuronide conjugates from liver

into blood (Borst *et al*., 2006). In humans, it is upregulated during cholestasis and in patients with Dubin–Johnson syndrome, and in a similar manner, it is increased in TR⁻ and EHBR rats. The increase in Mrp3 is recognized as a compensatory response that helps to protect hepatocytes from toxic chemicals for cells deficient in Mrp2. Mrp4 is specifically involved in the cellular efflux of purine analogs, nucleoside antiviral drugs, and cyclic nucleotides, including cAMP and cGMP. It has also been shown to be a carrier for some xenobiotics including conjugated and unconjugated compounds (Borst *et al*., 2006). A major role for Mrp6 in xenobiotic disposition has not been established, but mutations in human MRP6 are associated with pseudoxanthoma elasticum, a hereditary disease affecting the elasticity of connective tissues (Bergen *et al*., 2007).

Several Oatps are located on the basolateral membrane of hepatocytes where they contribute to the uptake of many organic anions. The Oatps exhibit broad substrate specificity and play an important role in the hepatic uptake of numerous drugs and xenobiotics along with a variety of hormones, including thyroxin, and hormone conjugates. Oat2 is expressed in liver and transports small organic anions such as indomethacin and salicylate along with prostaglandins (Anzai *et al*., 2006). Oct1 is also expressed in human and rodent liver, and contributes to the uptake of organic cations. This includes numerous endogenous compounds such as choline and dopamine as well as cationic xenobiotics. It has recently been shown that the biguanide compound, metformin, which is used to treat type 2 diabetes, is a substrate for OCT1. Metformin can cause lactic acidosis through alterations in mitochondrial function, and Oct1$^{-/-}$ knockout mice are generally resistant to lactic acidosis compared to wild-type mice (Wang *et al*., 2003), suggesting an important role for this transporter in the elimination and toxic potential of this compound. In concert, the Oatps, OAT, and OCT family of transporters are important in the uptake of toxicants into the liver, a step that can contribute to metabolism in the liver or efflux into the bile, or back into the circulation. Overall, these uptake transporters are important in determining the distribution to and excretion from the liver.

An important concept relating to biliary excretion is the phenomenon of enterohepatic circulation. After a compound is excreted into bile, it enters the intestine where it can be reabsorbed or eliminated with feces. Many organic compounds are conjugated with UDP-glucuronic acid, sulfate, or glutathione (see Chap. 6) before excretion into bile, and these polar metabolites are not sufficiently lipid-soluble to be reabsorbed. However, enzymes found in the intestinal microflora may hydrolyze glucuronide and sulfate conjugates, liberating a more lipophilic moiety and increasing the likelihood of reabsorption. Reabsorption of the liberated xenobiotic completes a cycle in which the compound can return to the liver, where it can again be metabolized and excreted back into bile. Repeated enterohepatic cycling may lead to very long half-lives of xenobiotics in the body. Therefore, it is often desirable to interrupt this cycle to hasten the elimination of a toxicant from the body. This principle has been utilized in the treatment of dimethylmercury poisoning; ingestion of a polythiol resin binds the mercury and thus prevents its reabsorption (Magos and Clarkson, 1976).

An increase in hepatic excretory function also has been observed after pretreatment with some drugs (Klaassen and Watkins, 1984). For example, it has been demonstrated that phenobarbital increases plasma disappearance of BSP by enhancing its biliary excretion. The increase in bile flow caused by phenobarbital is an important factor in increasing the biliary excretion of BSP. However, other factors, including induction of phase-II enzymes (see Chap. 6) and xenobiotic transporters may also enhance biliary elimination. Induction of metabolizing enzymes and transporters work in concert to increase the clearance of a toxicant from the plasma. In particular, induction of these processes increases the capacity for a xenobiotic to be: (1) taken up into the liver; (2) metabolized to conjugates that are likely to be excreted into bile; and (3) excreted into bile and removed from the general circulation. However, not all microsomal enzyme inducers increase bile flow and excretion, as agents such as 3-methylcholanthrene and benzo[a]pyrene are relatively ineffective in this regard.

An increase in biliary excretion often decreases the toxicity of xenobiotics. For example, in laboratory animals, phenobarbital treatment enhances the biliary excretion and elimination of methylmercury from the body (Magos and Clarkson, 1976). Two steroidal agents, spironolactone and pregnenolone-16α-carbonitrile, which also increase bile production and enhance biliary excretion of BSP, decrease the toxicity of cardiac glycosides at least in part by increasing their biliary excretion. This in turn decreases the concentration of cardiac glycosides in the heart, their target organ of toxicity (Castle and Lage, 1973; Klaassen, 1974).

The toxicity of some compounds can also be directly related to their biliary excretion. For example, the intestinal toxicity of several xenobiotics and drugs is increased by their excretion into bile. This is the case for nonsteroidal anti-inflammatory drugs which cause intestinal ulcerations that can be abolished by bile-duct ligation (Duggan *et al*., 1975). More recently, irinotecan, an anticancer drug, was found to induce severe GI toxicity (severe diarrhea) in humans and rats. The mechanism for the effect of this drug involved metabolism to an active metabolite that was a good substrate for Mrp2. The excretion into bile mediated by Mrp2 results in high concentrations of the toxic metabolite in the intestinal lumen and

Table 5-13

Urinary, Biliary, and Fecal Excretion of Indomethacin and/or its Metabolites in Dogs and Monkeys after Intravenous Dosage

	URINE		BILE		FECES	
COMPOUND	DOG	MONKEY	DOG	MONKEY	DOG	MONKEY
Indomethacin	0.6*	10.5	3.8	33.6	68.7	4

toxicity ensues. The toxicity of irinotecan can be modulated by inhibiting Mrp2 function (Chu *et al.*, 1997).

Many xenobiotic transporters are not expressed early in development, and the hepatic excretory system is not fully developed in newborns. As a result, there are numerous examples of compounds that are more toxic to newborns than to adults (Klaassen and Slitt, 2005). For example, ouabain is about 40 times more toxic in newborn than in adult rats. This is due to an almost complete inability of the newborn rat liver to remove ouabain from plasma. The development of hepatic excretory function can be promoted in newborns by administering microsomal enzyme inducers.

Often the elimination of a compound occurs by different routes in different species, as shown in the case of indomethacin in the dog and the rhesus monkey (Table 5-13). Dogs excrete most of a dose in feces, whereas monkeys excrete the majority of a dose in urine. Both species excrete similarly large quantities of a dose in bile. Because dogs excrete most of a dose in bile as conjugates (MW > 500 Da), it is to be expected that these hydrophilic indomethacin derivatives will not be reabsorbed unless they are hydrolyzed by intestinal bacteria to the reabsorbable parent compound, or to phase-I metabolites (which do have good bioavailability). Based on available experimental data, it is not possible to determine whether this occurs in dogs. It appears that indomethacin undergoes enterohepatic circulation with repeated conjugation in the liver and deconjugation in the small intestine, with a gradual "loss" of conjugates into the large intestine. However, because almost all of fecal excretion consists of indomethacin, it is apparent that the large intestinal flora hydrolyzes the indomethacin conjugates. Limited reabsorption of indomethacin is not surprising ($pK_a \approx 4.5$, colon pH $\approx$ 8), because more than 99.7% of indomethacin is ionized in the large intestine, which has a small surface area (compared to the small intestine). This does not allow for a sufficiently rapid shift in the mass balance to result in substantial reabsorption.

Monkeys also have extensive enterohepatic recycling of indomethacin (51.7% of dose excreted in bile within 2 hours). However, most of the biliary excretion consists of parent compound, which is readily reabsorbed in the small intestine, as indicated by the small amount lost into feces (about 10% of dose). In contrast to dogs, monkeys excrete most of a dose as phase-I metabolites (24.2% of dose) and indomethacin (10.5% of dose). Because indomethacin has a molecular weight of 358 and phase-I metabolites have molecular weights of 220–345, these compounds are more readily excreted in urine.

Exhalation

Substances that exist predominantly in the gas phase at body temperature are eliminated mainly by the lungs. Because volatile liquids are in equilibrium with their gas phase in the alveoli, they may also be excreted via the lungs. The amount of a liquid eliminated via the lungs is proportional to its vapor pressure. A practical application of this principle is seen in the breath analyzer test for determining the amount of ethanol in the body. Highly volatile liquids such as diethyl ether and certain volatile anesthetics (nitrous oxide) are excreted almost exclusively by the lungs.

No specialized transport systems have been described for the excretion of toxic substances by the lungs. Some xenobiotic transporters, including Mrp1 and P-gp, have been identified in the lung, but overall, compounds excreted via exhalation in the lung are most likely to be eliminated by simple diffusion. Elimination of gases is roughly inversely proportional to the rate of their absorption. Therefore, gases with low solubility in blood, such as ethy-

lene, are rapidly excreted, whereas chloroform, which has a much higher solubility in blood, is eliminated very slowly by the lungs. Trace concentrations of highly lipid-soluble anesthetic gases such as halothane and methoxyflurane may be present in expired air for as long as 2–3 weeks after a few hours of anesthesia. Undoubtedly, this prolonged retention is due to deposition in and slow mobilization from adipose tissue of these very lipid-soluble agents. The rate of elimination of a gas with low solubility in blood is perfusion-limited, whereas that of a gas with high solubility in blood is ventilation-limited.

Other Routes of Elimination

Cerebrospinal Fluid A specialized route of removal of toxic agents from a specific organ is represented by the cerebrospinal fluid (CSF). All compounds can leave the CNS with the bulk flow of CSF through the arachnoid villi. In addition, lipid-soluble toxicants also can exit at the site of the blood–brain barrier. As discussed earlier, toxicants also can be removed from the CSF by active transport, using the transport systems present in the BCSFB.

Milk The secretion of toxic compounds into milk is extremely important because (1) a toxic material may be passed with milk from the mother to the nursing offspring and (2) compounds can be passed from cows to people via dairy products. Toxic agents are excreted into milk by simple diffusion. Because milk has an acidic pH (about 6.5), basic compounds may be concentrated in milk, whereas acidic compounds may attain lower concentrations in milk than in plasma (Findlay, 1983; Wilson, 1983). More important, about 3–4% of milk consists of lipids, and the lipid content of colostrum after parturition is even higher. Lipid-soluble xenobiotics diffuse along with fats from plasma into the mammary glands and are excreted with milk during lactation. Many of the same compounds that can accumulate in fat such as aldrin, chlordane, DDT, and polychlorinated and polybrominated biphenyls, dibenzo-*p*-dioxins, and furans (Van den Berg *et al.*, 1987; Li *et al.*, 1995) have been found in human breast milk, and milk can be a major route of their excretion. More recently, other persistent compounds such as nitromusk perfume ingredients have been identified in milk, but it is unclear as to whether the presence of these compounds is directly responsible for possible adverse effects (Leibl *et al.*, 2000). Species differences in the excretion of xenobiotics with milk are to be expected, as the proportion of milk fat derived from the circulation versus that synthesized de novo in the mammary gland differs widely among species. Metals chemically similar to calcium, such as lead, and chelating agents that form complexes with calcium also can be excreted into milk to a considerable extent.

Sweat and Saliva The excretion of toxic agents in sweat and saliva is quantitatively of minor importance. Again, excretion depends on the diffusion of the nonionized, lipid-soluble form of an agent. Toxic compounds excreted into sweat may produce dermatitis. Substances excreted in saliva enter the mouth, where they are usually swallowed to become available for GI absorption.

CONCLUSION

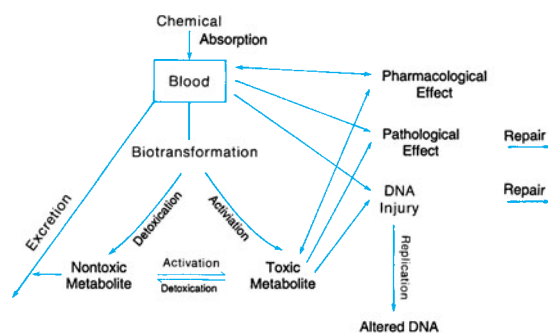
Humans are in continuous contact with toxic chemicals. Toxicants are in the food we eat, the water we drink, and the air we breathe. Depending on their physical and chemical properties, toxic chemicals may be absorbed by the GI tract, the lungs, and/or the skin. Fortunately, the body has the ability to biotransform and excrete these


Figure 5-15. *Schematic representation of the disposition and toxic effects of chemicals.*

compounds into urine, feces, and air. However, when the rate of absorption exceeds the rate of elimination, toxic compounds may accumulate and reach a critical concentration at a certain target site, and toxicity may ensue (Fig. 5-15). Whether a chemical elicits toxicity depends not only on its inherent potency and site specificity but also on whether, and if so how, it is absorbed, distributed, and eliminated.

Therefore, knowledge of the disposition of chemicals is of great importance in judging the toxicity of xenobiotics. For example, for a potent CNS suppressant that displays a strong hepatic first-pass effect, oral exposure is of less concern than is exposure by inhalation. Also, two equipotent gases, with the absorption of one being perfusion rate-limited and that of the other being ventilation rate-limited, will exhibit completely different toxicity profiles at a distant site because of differences in the concentrations attained in the target organ.

Many chemicals have very low inherent toxicity but can be metabolically activated into toxic metabolites, and toxicity may be determined by the rate of formation of toxic metabolites. Alternatively, a very potent toxicant may be detoxified rapidly by biotransformation. The fundamental and overarching concept is that adverse effects are related to the unbound concentration of the "toxic chemical" at the site of action (in the target organ), whether a chemical is administered or generated by biotransformation in the target tissue or at a distant site. Accordingly, the toxic response exerted by chemicals is critically influenced by the rates of absorption, distribution, biotransformation, and excretion.

BIOTRANSFORMATION OF XENOBIOTICS

Andrew Parkinson and Brian W. Ogilvie

INTRODUCTION

In 2003, my father, Edward William Parkinson, died of Lou Gehrig disease, otherwise known as ALS in America and as MND in Britain. He died beeping. The beeping came from a portable, electronic syringe that periodically injected my father with glycopyrrolate, an anticholinergic drug that blocks the production of saliva that many ALS patients have difficulty swallowing. Glycopyrrolate is a quaternary ammonium salt, hence, it is positively charged at physiological pH. As such, glycopyrrolate does not readily cross lipid bilayers, which is why it is injected intravenously or intramuscularly, it has fewer CNS effects (it does not readily cross the blood–brain barrier), and a relatively small volume of distribution at steady state ($V_{ss} = 0.42$ L/kg). Glycopyrrolate is rapidly eliminated in the urine. The mean elimination half-life increases from 19 minutes in patients with normal kidney function to 47 minutes in patients with severe kidney impairment, indicating that renal disease impairs the elimination of glycopyrrolate. Although it is excreted in the urine largely as unchanged drug, glycopyrrolate reinforces a number of principles about xenobiotic biotransformation, the most important of which is: xenobiotic biotransformation is the process—actually a series of enzyme-catalyzed processes—that alters the physiochemical

properties of foreign chemicals (xenobiotics) from those that favor absorption across biological membranes (namely, lipophilicity) to those favoring elimination in urine or bile (namely, hydrophilicity). Without xenobiotic biotransformation, the numerous foreign chemicals to which we are exposed (which includes both man-made and natural chemicals such as drugs, industrial chemicals, pesticides, pollutants, pyrolysis products in cooked food, alkaloids, secondary plant metabolites, and toxins produced by molds, plants, etc.) either unintentionally or, in the case of drugs, intentionally would—if they are sufficiently lipophilic to be absorbed from the gastrointestinal tract and other sites of exposure—eventually accumulate to toxic levels. Furthermore, absent xenobiotic biotransformation, many of the drugs in use today would have an unacceptably long duration of action. In contrast, drugs that are not lipophilic, like glycopyrrolate, are not absorbed from the gastrointestinal tract (hence they are not orally active), and if they are administered parenterally they are not biotransformed (because they are already hydrophilic), and they are rapidly eliminated from the body.

The enzymes that catalyze xenobiotic biotransformation are often called drug-metabolizing enzymes. The acronym ADME stands for **a**bsorption, **d**istribution, **m**etabolism, and **e**limination. This acronym is used widely in the pharmaceutical industry to

describe the four main processes governing drug disposition. This chapter describes some fundamental principles of xenobiotic biotransformation, and describes the major enzyme systems involved in the biotransformation (or metabolism) of drugs and other xenobiotics. The examples given are biased toward drugs and human enzyme systems for two reasons. First, many of the fundamental principles of xenobiotic biotransformation stem from such studies. This is especially true of drugs with a narrow therapeutic index (where the toxic dose is not much greater than the therapeutic dose), which have revealed a large number of genetic and environmental factors that affect xenobiotic biotransformation and, hence, drug toxicity. Second, adverse drug reactions are one of the leading causes of death in the United States. Lazarou *et al.* (1998) estimated that in 1994 over 2 million hospitalized patients had serious adverse drug events (ADEs) and 106,000 had fatal outcomes, placing ADEs only behind heart disease, cancer, stroke, and pulmonary disease as a leading cause of death. Furthermore, of the 548 new chemical entities approved by the FDA between 1974 and 1999, ~10% (56 drugs) required black box warnings or were withdrawn from the market because of ADEs that included hepatotoxicity, cardiotoxicity (several as a result of drug–drug interactions), myelotoxicity, immunotoxicity, and warnings to pregnant women (Lasser *et al.*, 2002; Thomas, 2002). In many cases, xenobiotic biotransformation is central to understanding these ADEs.

PRINCIPLES OF XENOBIOTIC BIOTRANSFORMATION

It is difficult to make categorical statements about xenobiotic biotransformation because there is an exception to every rule. Nevertheless, the following points, which might be considered principles or rules, apply in the majority of cases:

Point 1   Xenobiotic biotransformation or drug metabolism is the process of converting lipophilic (fat soluble) chemicals, which are readily absorbed from the gastrointestinal tract and other sites, into hydrophilic (water soluble) chemicals, which are readily excreted in urine or bile. There are exceptions even to this most basic rule. For example, acetylation and methylation are biotransformation reactions that can actually decrease the water solubility of certain xenobiotics. As a general rule, xenobiotics with a log $D_{7.4} > 0$ require biotransformation to facilitate their elimination (Williams *et al.*, 2003b).

Point 2   The biotransformation of xenobiotics is catalyzed by various enzyme systems that can be divided into four categories based on the reaction they catalyze:

1. Hydrolysis (e.g., carboxylesterase)
2. Reduction (e.g., carbonyl reductase)
3. Oxidation (e.g., cytochrome P450)
4. Conjugation (e.g., UDP-glucuronosyltransferase)

The mammalian enzymes involved in the hydrolysis, reduction, oxidation, and conjugation of xenobiotics are listed in Table 6-1, together with their principal subcellular location. The conjugation reactions include glucuronidation, sulfonation (often called sulfation), acetylation, methylation, conjugation with glutathione (mercapturic acid synthesis) and conjugation with amino acids (such as glycine, taurine, and glutamic acid). Examples of the major chemical groups that undergo biotransformation together with the enzymes that commonly mediate their biotransformation are given in Table 6-2 (Williams *et al.*, 2003b).

Xenobiotic biotransformation is generally catalyzed by enzymes, but there are exceptions. For example, hydrolysis of certain carboxylic and phosphoric acid esters, reduction of sulfoxides to sulfides (e.g., rabeprazole), isomerization involving enol–keto tautomerization (e.g., thalidomide), and the conjugation of certain xenobiotics with glutathione can occur nonenzymatically at an appreciable rate. Certain reactions are catalyzed by gastric acid, such as the hydrolysis of esters and the conversion of indole-3-carbinol to a dimer that is a potent agonist of the aryl hydrocarbon receptor (AhR) and, consequently, an inducer of various enzymes including certain cytochrome P450 enzymes (CYP1A1, 1A2, 1B1, and 2S1).

Point 3   In general, individual xenobiotic-biotransforming enzymes are located in a single organelle. In Table 6-1, some enzymes are listed with two or more subcellular locations. However, in such cases, the enzyme name generally refers to two or more enzymes, each with its own distinct subcellular location. For example, the epoxide hydrolase located in microsomes is a different enzyme from the epoxide hydrolase located in cytosol (i.e., they are distinct gene products). From a practical perspective, it is noteworthy that during the homogenization of tissue and the preparation of subcellular fractions, a certain degree of cross-contamination of organelles occurs. For example, microsomes contain detectable levels of monoamine oxidase due to their contamination with the outer mitochondrial membrane.

Point 4   In general, xenobiotic biotransformation is accomplished by a limited number of enzymes with broad substrate specificities. In humans, for example, two cytochrome P450 enzymes— namely, CYP2D6 and CYP3A4—metabolize over half the orally effective drugs in current use (Gonzalez and Tukey, 2006). The broad and sometimes overlapping substrate specificities of xenobiotic-biotransforming enzymes preclude the possibility of naming the individual enzymes after the reactions they catalyze (which is how most other enzymes are named). Many of the enzymes involved in xenobiotic biotransformation are named according to nomenclature systems based on the primary amino acid sequence of the individual enzymes. Some enzymes are given the same name across all mammalian species, whereas others are named in a species-specific manner. For example, some cytochrome P450 enzymes, such as CYP1A1, CYP1A2, and CYP1B1, are so named in all mammalian species, whereas cytochrome P450 enzymes in the CYP2, CYP3, and CYP4 families (with certain exceptions such as CYP2E1) are named in a species-specific manner. The convention of using italic and normal letters to distinguish between the gene and gene products (mRNA and protein), respectively, and the convention of using lower case letters to designate mouse genes and gene products will not be followed in this chapter.

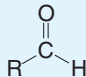
The structure (i.e., amino acid sequence) of a given xenobiotic-biotransforming enzyme may differ among individuals, which can give rise to differences in rates of drug metabolism. In general, a variant form of a xenobiotic-biotransforming enzyme (known as an *allelic variant* or an *allelozyme*) has diminished enzymatic activity compared with that of the wild-type enzyme, although this is not always the case (see section "Alcohol Dehydrogenase"). The impact of amino acid substitution(s) on the catalytic activity of a xenobiotic-biotransforming enzyme may be substrate dependent, such that an allelic variant may interact normally with some substrates (and inhibitors) but interact atypically with others.

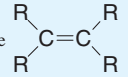
Point 5   Hydrolysis, reduction, and oxidation expose or introduce a functional group (such as –OH, –NH$_2$, –SH, or –COOH) that can be converted to a water-soluble conjugate (see Table 6-2).

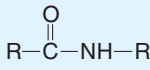
Table 6-1

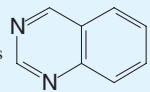
General Pathways of Xenobiotic Biotransformation and Their Major Subcellular Location

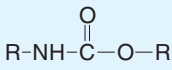
REACTION	ENZYME OR SPECIFIC REACTION	LOCALIZATION
Hydrolysis	Carboxylesterase	Microsomes, cytosol, lysosomes, blood
	Alkaline phosphatase	Plasma membrane
	Peptidase	Blood, lysosomes
	Epoxide hydrolase	Microsomes, cytosol
Reduction	Azo- and nitro-reduction	Microflora
	Carbonyl (aldo-keto) reduction	Cytosol, microsomes, blood
	Disulfide reduction	Cytosol
	Sulfoxide reduction	Cytosol
	Quinone reduction	Cytosol, microsomes
	Dihydropyrimidine dehydrogenase	Cytosol
	Reductive dehalogenation	Microsomes
	Dehydroxylation (cytochrome b_5)	Microsomes
	Dehydroxylation (aldehyde oxidase)	Cytosol
Oxidation	Alcohol dehydrogenase	Cytosol
	Aldehyde dehydrogenase	Mitochondria, cytosol
	Aldehyde oxidase	Cytosol
	Xanthine oxidase	Cytosol
	Monoamine oxidase	Mitochondria
	Diamine oxidase	Cytosol
	Peroxidase	Microsomes, lysosomes, saliva
	Flavin-monooxygenases	Microsomes
	Cytochrome P450	Microsomes
Conjugation	UDP-Glucuronosyltransferase	Microsomes
	Sulfotransferase	Cytosol
	Glutathione transferase	Cytosol, microsomes, mitochondria
	Amino acid transferase	Mitochondria, microsomes
	N-Acetytransferase	Mitochondria, cytosol
	Methytransferase	Cytosol, microsomes, blood

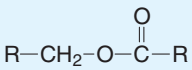
The first three reactions (hydrolysis, reduction, and oxidation) are often called Phase 1 reactions, and the conjugation reactions are often called Phase 2 reactions. The classification of xenobiotic-biotransforming enzymes into Phase 1 and Phase 2 (and the extension of this system to classify xenobiotic transporters as Phase 3) has been criticized lately by Josephy *et al*. (2005), as being both misleading and contrary to the original principles of Williams (1959), the drug metabolism pioneer who coined the phrases to distinguish reactions that resulted in either a decrease or increase in xenobiotic toxicity (Phase 1) from reactions that resulted in only a decrease in toxicity (Phase 2). The arguments against the Phase 1–Phase 2 classification are as follows.


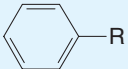


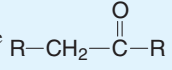


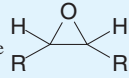


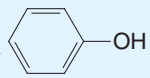


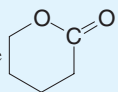












First, although the conjugation of many xenobiotics is preceded by hydrolysis, reduction, or oxidation (such that xenobiotics can be said to undergo Phase 1 before Phase 2 metabolism), there are several cases where a xenobiotic undergoes oxidation after it has been conjugated (such that Phase 2 precedes Phase 1 metabolism). For example, gemfibrozil is conjugated with glucuronic acid before it undergoes oxidation by cytochrome P450 (Ogilvie *et al*., 2006). Second, there are numerous xenobiotics that are conjugated directly. For example, the majority of acetaminophen (Tylenol) is conjugated directly with glucuronic acid and, to a lesser extent, sulfonic acid. Third, the original idea that Phase 2 metabolism results in only detoxication is incorrect. Indeed, all xenobiotic-metabolizing enzymes are capable of increasing the toxicity of one or more xenobiotics, including the conjugating enzymes that R.T. Williams clas-

sified as Phase 2 (detoxifying) enzymes. For example, conjugation of carboxylic acid-containing drugs with glucuronic acid to form acyl glucuronides is thought to be responsible for the hepatotoxicity observed with numerous NSAIDs (nonsteroidal anti-inflammatory drugs). In fact, in the United States, NSAIDs and other carboxylic acid-containing drugs represent the largest category of drugs whose clinical development was halted or whose regulatory approval was subsequently withdrawn because of liver toxicity in humans (Fung *et al*., 2001). Finally, some enzymes do not fit neatly into the Phase 1 or Phase 2 category. Epoxide hydrolase, for example, might be considered a Phase 1 enzyme because it introduces a functional group (-OH) for subsequent conjugation reactions, but it might also be considered a Phase 2 enzyme because it catalyzes the addition of water to aliphatic epoxides and arene oxides that are often formed by cytochrome P450. In this chapter, the terms Phase 1 and Phase 2 metabolism will not be used; instead the pathways of xenobiotic biotransformation will be divided into four categories: hydrolysis, reduction, oxidation, and conjugation.

Point 6 Not all biotransformation reactions are catalyzed by the mammalian enzymes listed in Table 6-1. Some biotransformation reactions are catalyzed by enzymes in the gut microflora (largely anaerobic bacteria in the colon), whereas the biotransformation of still other xenobiotics is catalyzed by enzymes that participate in intermediary (endobiotic) metabolism. This principle is illustrated in Fig. 6-1 for three xenobiotics that are all converted to benzoic acid and then hippuric acid. The conversion of toluene to hippuric acid

Table 6-2

Common Chemical Groups and Enzymes Possibly Involved in Their Metabolism

CHEMICAL GROUP	ENZYME(S)	REACTION(S)	CHEMICAL GROUP	ENZYME(S)	REACTION(S)
Alkane $R—CH_2—R$	CYP	Hydroxylation, dehydrogenation	Aldehyde (structure)	CYP, ALDH	Oxidative de-formylation, oxidation to carboxylic acid
Alkene (structure)	CYP, GST	Epoxidation, glutathione adduct formation	Amide (structure)	Amidase (esterase)	Hydrolysis
Alkyne $R—C≡C—R$	CYP	Oxidation to carboxylic acid	Aniline (structure) $—NH_2$	CYP, NAT, UGT, peroxidase, SULT	N-Hydroxylation, N-acetylation, N-glucuronidation, N-oxidation, N-sulfonation
Aliphatic alcohol $R—CH_2—OH$	CYP, ADH, catalase, UGT, SULT	Oxidation, glucuronidation, sulfonation	Aromatic azaheterocycles (structure)	UGT, CYP, aldehyde oxidase	N-Glucuronidation, hydroxylation, N-oxidation, ring cleavage, oxidation
Aliphatic amine $R—NH_2$	CYP, FMO, MAO, UGT, SULT, MT, NAT, peroxidase	N-Dealkylation, N-oxidation, deamination, N-glucuronidation, N-carbamoyl glucuronidation, N-sulfonation, N-methylation, N-acetylation	Carbamate (structure) $R-NH-C-O-R$	CYP, esterase	Oxidative cleavage, hydrolysis
Amidine $HN=CR—NH_2$	CYP	N-Oxidation	Ester (structure) $R—CH_2—O—C—R$	CYP, esterase	Oxidative cleavage, hydrolysis
Arene (structure) $—R$	CYP	Hydroxylation and epoxidation	Ether $R—CH_2-O—CH_2-R$	CYP	O-Dealkylation
Carboxylic acid $R—COOH$	UGT, amino acid transferases	Glucuronidation, amino acylation	Ketone (structure) $R—CH_2—C—R$	CYP, SDR, AKR	Baeyer–Villiger oxidation, reduction
Epoxide (structure)	Epoxide hydrolase, GST	Hydrolysis, glutathione adduct formation	Phenol (structure) $—OH$	CYP, UGT, SULT, MT	Ipso-substitution, glucuronidation, sulfonation, methylation
Lactone (structure)	Lactonase (paraoxonase)	Hydrolysis (ring opening)	Thioether $R—CH_2-S—CH_2-R$	CYP, FMO	S-Dealkylation, S-oxidation

ADH, alcohol dehydrogenase; ALDH, aldehyde dehydrogenase; AKR, aldo-keto reductases; FMO, flavin monoxygenase; GST, glutathione transferase; MAO, monoamine oxidase; MT, methyltransferase; SDR, short-chain dehydrogenases/reductases; NAT, N-acetyltransferase; SULT, sulfotransferase; UGT, UDP-glucuronosyltransferase.

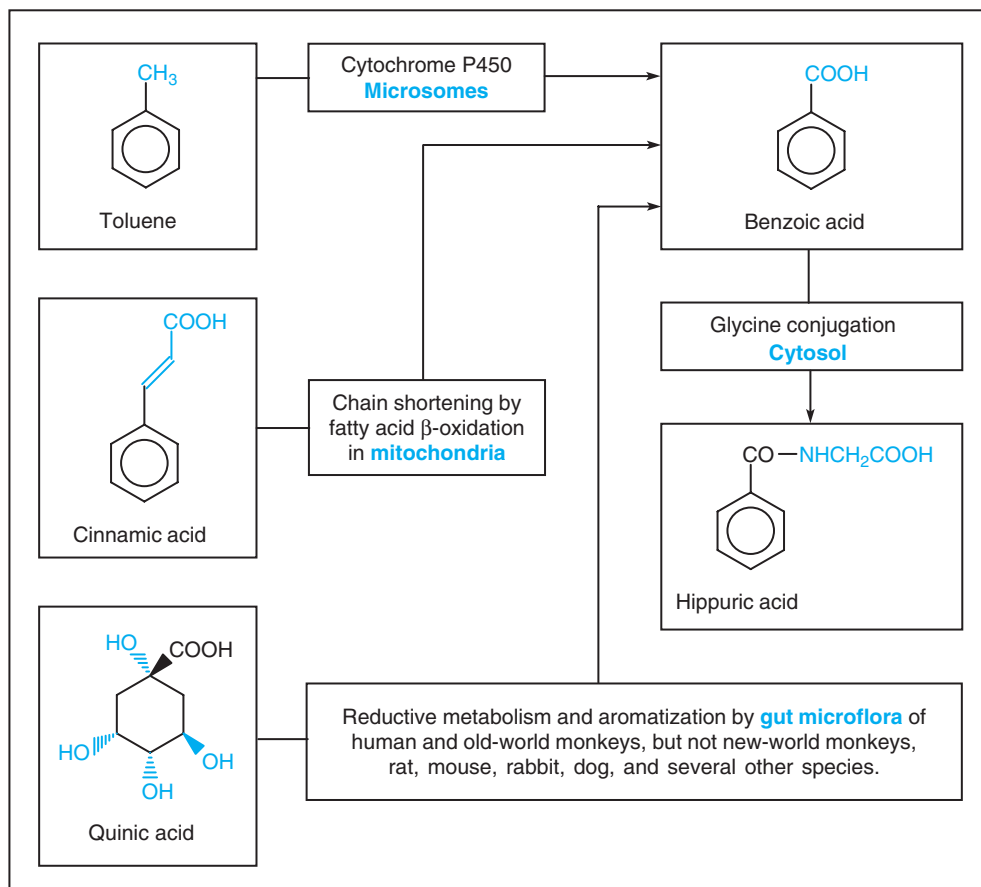
SOURCE: Data adapted from Williams JA, Hurst SI, Bauman J, *et al.*: Reaction phenotyping in drug discovery: moving forward with confidence? *Curr Drug Metab* 4:527–534, 2003b.


Figure 6-1. Examples of xenobiotic biotransformation by different enzyme systems: a xenobiotic-biotransforming enzyme (cytochrome P450), an endobiotic-metabolizing enzyme, and gut microflora.

is catalyzed by some of the xenobiotic biotransforming enzymes listed in Table 6-1: Microsomal cytochrome P450 converts toluene to benzoic acid in three oxidative steps ($R\text{-}CH_3 \rightarrow R\text{-}CH_2OH \rightarrow RCHO \rightarrow RCOOH$), which introduces a functional group (namely, –COOH) that is conjugated with glycine to produce hippuric acid, which is excreted in urine. Cinnamic acid is also converted to benzoic acid but, in this case, the reaction is catalyzed by the mitochondrial enzymes involved in the β-oxidation of fatty acids. Quinic acid is also converted to benzoic acid, but this reductive, multistep reaction is catalyzed by gut microflora. Incidentally, the conversion of benzoic acid to hippuric acid is of historical interest because it is generally recognized as the first xenobiotic biotransformation reaction to be discovered (in dogs by Woehler in 1828, and in humans by Ure in 1841).

Some drugs are intentionally designed to be biotransformed by endobiotic-metabolizing enzymes. For example, the anti-HIV drug zidovudine (AZT) is converted to a triphosphate nucleoside by enzymes in the salvage pathway (nucleoside kinase, nucleoside monophosphate kinase or NMK, and nucleoside diphosphate kinase or NDK). HIV reverse transcriptase inhibitors, like zidovudine, are administered as nonphosphorylated analogs to facilitate their absorption and cellular uptake. Conversely, some drugs are administered as a phosphorylated prodrug (e.g., fosamprenavir) to promote their water solubility and rate of dissolution. The luminal surface of the small intestine contains high levels of alkaline phosphatase, which hydrolyzes prodrugs like fosamprenavir and thereby releases

the active drug at the surface of the enterocyte, where it is readily absorbed. Generally speaking, kinase and alkaline phosphatase are not usually considered to be xenobiotic-biotransforming enzymes.

Point 7   Just as some xenobiotics are biotransformed by the so-called endobiotic-metabolizing enzymes (Point 6), certain endobiotics are biotransformed by the so-called xenobiotic-metabolizing enzymes. For example, the same cytochrome P450 enzymes implicated in xenobiotic biotransformation also contribute to the hepatic catabolism of steroid hormones, and the same UDP-glucuronosyltransferases that conjugate xenobiotics also glucuronidate bilirubin, thyroid hormones, and steroid hormones. Benzoic acid, a xenobiotic, is conjugated with glycine (as shown in Fig. 6-1), and so are bile acids (endobiotics). Certain leukotrienes are glutathione conjugates. From the few examples in Points 6 and 7, it is apparent that, on a case-by-case basis, there is no clear-cut distinction between endobiotic- and xenobiotic-biotransforming enzymes.

The human genome project has helped to establish that what were once thought to be two distinct enzymes, one involved in the metabolism of endobiotics and one involved in the metabolism of xenobiotics, are in fact one and the same enzyme. For example, the microsomal enzyme known as 11β-hydroxysteroid dehydrogenase is identical to the xenobiotic-metabolizing enzyme known as microsomal carbonyl reductase.

Point 8   Several xenobiotic-biotransforming enzymes are inducible, meaning their expression can be increased (upregulated) usually in response to exposure to high concentrations of

xenobiotics. Induction is mediated by ligand-activated receptors (so-called xenosensors) that are activated by xenobiotics (ligands) to DNA-binding proteins that upregulate the transcription of various genes encoding xenobiotic-biotransforming enzymes, especially cytochrome P450 (CYP) enzymes, which are usually induced to the greatest extent (in terms of fold increase). The major xenosensors are the aryl hydrocarbon receptor (AhR), which induces CYP1 enzymes, the constitutive androstane receptor (CAR), which induces CYP2B, 2C, and 3A enzymes, the pregnane X receptor (PXR), which also induces CYP2B, 2C, and 3A enzymes, and the peroxisome proliferator activated receptor alpha (PPARα), which induces CYP4 enzymes. CAR and PXR are closely related, and they tend to be activated by the same ligands and bind to the same DNA-response elements (i.e., the same discrete regions of DNA that control gene expression), for which reason there is said to be considerable *cross-talk* between these two xenosensors. There is also considerable cross-talk between xenosensors and several other nuclear receptors including nuclear factor kappa-B (NF-κB), the receptor activated during infectious and inflammatory diseases, which suppress CYP expression and induction because NF-κB represses all four xenosensors (and several other nuclear receptors). Certain xenosensors are activated by endogenous ligands (e.g. bilirubin, bile acids, and fatty acids activate CAR, PXR, and PPARα, respectively), and certain nuclear receptors, such as the vitamin D receptor (VDR) can mimic PXR and induce CYP3A4, which inactivates the active metabolite of vitamin D. These examples illustrate how xenosensors are not just involved in xenobiotic disposition but also play a role in endobiotic homeostasis. Two proteins called KEAP-1 (Kelch-like ECH-related protein) and Nrf2 (nuclear factor E2 p45-related factor-2) function as xenosensors in as much as they induce enzymes in response to oxidative stress, which is often associated with xenobiotic biotransformation. Binding of the transcription factor Nrf2 to the region of DNA known as the antioxidant response element (also known as the electrophilic response element) induces enzymes that detoxify electrophiles and metabolites that generate reactive oxygen species (ROS), including glutathione transferase (GSTA1), microsomal epoxide hydrolase, aldo-keto reductase (AKR7A, also known as aflatoxin aldehyde reductase), NAD(P)H-quinone oxidoreductase (NQO1, also known as DT-diaphorase), and glutamate-cysteine ligase (GCL), which catalyzes the rate-limiting step in glutathione synthesis. Induction of GCL increases the rate of glutathione synthesis under conditions of oxidative stress and a decrease in glutathione concentration (Lee and Johnson, 2004).

Induction is a reversible, adaptive response to xenobiotic exposure. The induced enzymes (and transporters) usually accelerate the elimination of the xenobiotic that triggered the induction process, in which case the xenobiotic is said to be an auto-inducer (one that induces its own metabolism). However, xenobiotics often induce enzymes that are not capable of metabolizing them, in which case the induction is said to be gratuitous. Induction is a pleiotropic response: Activation of AhR, CAR, PXR, PPARα, and Nrf2 all result in alterations in the expression of numerous genes, some of which are upregulated (or induced) and some of which are downregulated (or suppressed).

Point 9   The ability of certain xenobiotic-biotransforming enzymes to metabolize hormones and other endobiotics (Point 7) and the ability of certain xenobiotics to induce xenobiotic-biotransforming enzymes (Point 8) have implications for understanding an important mechanism by which certain xenobiotics can alter homeostasis or cause toxicity. Persistent exposure to xenobiotics that are enzyme inducers can increase the rate of steroid hor-

mone oxidation by cytochrome P450 and increase the rate of thyroid hormone glucuronidation and sulfonation which, in rodents, can lead to the development of Leydig cell tumors (due to elevated levels of LH and FSH) and thyroid follicular tumors (due to elevated levels of TSH), respectively (Grasso *et al.*, 1991). Persistent exposure to enzyme inducers can also cause liver tumors, although the mechanism is not fully understood. Activation of certain xenosensors is critical to liver tumor development, although upregulation of xenobiotic-biotransforming enzymes appears to be less important than other xenosensor-dependent events, such as the down-regulation of gap junctional proteins, which diminishes cell–cell communication.

Phenobarbital, Wy-14,643, methapyrilene, and Ponceau S are representatives of four classes of nongenotoxic rodent tumorigens (epigenetic tumor promoters) that cause hepatocellular hyperplasia and hypertrophy in association with proliferation of the endoplasmic reticulum, peroxisomes, mitochondria, and lysosomes, respectively (Grasso *et al.*, 1991). In the first two cases, the hepatocellular changes depend on activation of CAR (in the case of phenobarbital) and PPARα (in the case of Wy-14,643). Prolonged activation of these receptors in rodents results in the development of liver and/or thyroid tumors. However, this is thought to be a rodent-specific phenomenon because, in the case of phenobarbital and other enzyme-inducing antiepileptic drugs (EIAEDs), there is compelling epidemiological evidence that these chemicals do not cause liver tumors in humans even after 30+ years of treatment (Parkinson *et al.*, 2006).

The major UDP–glucuronosyltransferase responsible for conjugating bilirubin is UGT1A1, which is inducible by CAR agonists such as phenobarbital and scoparone (6,7-dimethylesculetin). At one time, the management of neonatal jaundice included treatment with phenobarbital to induce bilirubin conjugation, but this practice has been discontinued. However, the Chinese herbal Yin Zhi Wuang (active ingredient scoparone) is still used to treat neonatal jaundice. Bilirubin is also a CAR agonist, and high levels of bilirubin induce UGT1A1 and bilirubin/bilirubin glucuronide transporters to increase the rate of bilirubin elimination when bilirubin levels are elevated (e.g., during hemolytic anemia).

Point 10   Xenobiotic biotransformation can alter the biological properties of a xenobiotic. It can make the xenobiotic less toxic (detoxication), but in some cases it can make it more toxic (activation). The oxidation of ethanol (alcohol) to acetaldehyde is an example of xenobiotic activation, and the subsequent oxidation of acetaldehyde to acetic acid is an example of detoxication. The biotransformation of drugs can result in (1) a loss of pharmacological activity (e.g., the conversion of acetaminophen to acetaminophen glucuronide and the conversion of morphine to morphine 3-glucuronide), (2) no change in pharmacological activity (e.g., the conversion of fluoxetine to its N-demethylated metabolite norfluoxetine), or (3) an increase in pharmacological activity (e.g., the conversion of codeine to morphine, as well as the conversion of morphine to morphine 6-glucuronide).

Point 11   In many cases, the toxicity of a xenobiotic is due to the parent compound (the compound that was absorbed), in which case xenobiotic biotransformation serves as a detoxication mechanism. This is illustrated by the clinical observation that the incidence of adverse drug events is often higher in individuals with a poor metabolizer phenotype (discussed later in Point 23). However, xenobiotic-biotransforming enzymes can convert certain xenobiotics to reactive (electrophilic) metabolites, and this activation process plays an important role in chemical toxicity and chemical mutagenicity/carcinogenicity; the former often involves the covalent

binding of electrophilic metabolites to critical cellular nucleophiles like proteins, whereas the latter involves covalent binding to one or more purine or pyrimidine bases in DNA. Cytochrome P450 is particularly effective at converting proximate carcinogens to ultimate carcinogens by converting the former to electrophilic metabolites that bind to and mutate DNA, thereby leading to mutations and tumor initiation. The Ames' bacterial mutagenicity assay, which is representative of several mutagenicity tests, is performed in the absence and presence of cytochrome P450 (i.e., liver microsomes) to evaluate the mutagenic potential of both the parent compound and any electrophilic metabolites, respectively. Polycyclic aromatic hydrocarbons (combustion pollutants and components of tobacco smoke), aromatic amines (industrial chemicals), aflatoxin (a mycotoxin), cooked-food pyrolysis products, and tobacco-specific nitrosamines are all examples of proximate carcinogens that require metabolic activation to form electrophilic, DNA-binding metabolites (ultimate carcinogens).

Certain anticancer drugs require activation by xenobiotic-metabolizing enzymes in order to exert their antineoplastic effects. For example, cyclophosphamide is activated by CYP2B6 and several other cytochrome P450 enzymes, and TLK286 is activated by glutathione transferase, which is often over-expressed in tumors thereby conferring resistance against certain anticancer drugs (see section "Glutathione Conjugation") (Gonzalez and Tukey, 2006).

Point 12 The toxicity and potential carcinogenicity of electrophilic metabolites produced by cytochrome P450 and other xenobiotic-biotransforming enzymes is reduced and often altogether eliminated by their conjugation with glutathione, which is often described as a noncritical cellular nucleophile. In the majority of cases, conjugation with glutathione represents a detoxication reaction; one that protects critical cellular nucleophiles, such as protein and DNA, from covalent modification. However, there are cases (e.g., dibromoethane) where conjugation with glutathione actually produces a DNA-reactive (mutagenic) metabolite. Conjugation with glutathione can occur both enzymatically (by glutathione *S*-transferase) and nonenzymatically.

Point 13 The biotransformation of some xenobiotics results in the production of reactive oxygen species (ROS), which can cause cell toxicity (including DNA damage) through oxidative stress and lipid peroxidation. Glutathione, glutathione transferases, and glutathione peroxidases all limit the toxic effects of ROS just as they limit the toxicity of reactive metabolites formed directly from xenobiotics. Oxidative stress and the formation of electrophilic metabolites reduce glutathione levels and thus result in the concurrent oxidation of KEAP-1, which then releases Nrf2, which in turn upregulates the expression of enzymes that detoxify electrophilic metabolites (e.g., epoxides) and those metabolites that generate ROS (e.g., quinones) (see Point 8).

Point 14 The balance between activation and detoxication by xenobiotic-biotransforming enzymes is often a key determinant of chemical toxicity, and is often the basis for organ or species differences in toxicity. For example, aflatoxin is converted by liver microsomal cytochrome P450 to a reactive epoxide that is thought to be responsible for the hepatotoxic and hepatocarcinogenic effect of this mycotoxin. The fact that this reaction occurs in the liver explains why aflatoxin causes liver toxicity and liver tumors. On this basis, mice would be expected to be more sensitive than rats to the hepatotoxic effects of aflatoxin because mice catalyze the epoxidation of aflatoxin faster than rats. However, through glutathione conjugation, mice also detoxify aflatoxin epoxide faster than rats. Consequently, despite their slower rate of activation, rats are more

susceptible than mice to the toxic effects of aflatoxin. Coumarin is hepatotoxic to rats, but not to humans. This species difference is attributable to differences in the metabolites formed by cytochrome P450. Rats convert coumarin to a reactive epoxide that rearranges to a reactive aldehyde, whereas humans convert coumarin to the relatively nontoxic metabolite 7-hydroxycoumarin (umbelliferone).

The enzymes involved in xenobiotic activation and detoxication play important roles in determining the susceptibility of mammals to the hepatotoxic effects of acetaminophen, which is the leading cause of acute liver failure in humans (Kaplowitz, 2005). Acetaminophen is activated to a reactive metabolite by cytochrome P450, including CYP2E1, which is detoxified by conjugation with glutathione (see section "Glutathione Conjugation"). Experiments with so-called knockout mice have established that gene deletion of CYP2E1 protects mice from acetaminophen hepatotoxicity, whereas depletion of glutathione (by chemical, not genetic means) potentiates it. However, gene deletion experiments have identified a host of factors that increase the susceptibility of mice to acetaminophen hepatotoxicity, including deletion of CAR, glutathione transferase-Pi, Jun Kinase-2 (JNK2), DNAse 1, interferon-γ (IFN-γ), lipopolysaccharide-binding protein (LPS-BP), Toll-like receptor-4 (TRL4), and osteopontin, as well as depletion of neutrophil and NK/NKT cells. Conversely, other gene deletions have been shown to protect mice from the hepatotoxic effects of acetaminophen, including Nrf2, interleukin-6 (IL-6), interleukin-10 (IL-10), cyclooxygenase-2 (Cox-2), chemokine receptor-2 (CCR2), and chemokine receptor-5 (CCR5), as well as depletion of Kupffer cells (Kaplowitz, 2005). The important point here is that the factors that determine whether a xenobiotic will or will not cause cellular toxicity go far beyond the enzymes involved in xenobiotic activation and detoxication, and these additional factors can also play a role in determining organ and species differences in xenobiotic toxicity. This principle is illustrated by the anti-HIV drug abacavir, hypersensitivity to which is determined not by an individual's enzymatic capacity to activate or detoxify the drug but by an individual's human leukocyte antigen (HLA) subtype (Mallal *et al.*, 2002).

Point 15 Exposure to xenobiotics (especially drugs) is largely through oral ingestion, and the small intestine and liver are highly developed to limit systemic exposure to orally ingested xenobiotics, a process known as *first-pass elimination* (*or presystemic elimination*). The enterocytes at the tips of the small intestinal villi express the efflux transporter *P*-glycoprotein (also known as MDR1 or ABCB1), which serves to limit xenobiotic absorption. The enterocytes express high levels of certain cytochrome P450 and UDP-glucuronosyltransferase enzymes, which biotransform a wide variety of xenobiotics. The liver expresses a number of uptake transporters that actively remove xenobiotics from the blood. They also express a number of efflux transporters that actively discharge xenobiotics or their metabolites (especially conjugates) into the bile canaliculus for biliary excretion, or that actively discharge xenobiotic metabolites (especially conjugates) across the sinusoidal membrane back into the blood for urinary excretion. The liver expresses the largest number and, with few exceptions, the highest concentrations of xenobiotic-biotransforming enzymes.

Although the liver contains higher concentrations of most xenobiotic-biotransforming enzymes, and because the number of hepatocytes in the liver exceeds the number of enterocytes in the small intestine, it might be assumed that, compared with the liver, the small intestine would make only a small contribution to first-pass metabolism, but this is not the case. Furanocoumarins in grapefruit juice inhibit intestinal but not hepatic CYP3A4 and yet grapefruit

juice increases systemic exposure to felodipine and other drugs that undergo first-pass metabolism by CYP3A4 (Paine *et al*., 2006). The impact of the CYP3A4 inhibitor ketoconazole on the disposition of the CYP3A4 substrate midazolam depends on whether midazolam is given orally or intravenously. When midazolam is given intravenously, such that its clearance is dependent only on hepatic metabolism, ketoconazole causes a three- to fivefold increase in the area-under-the-plasma-concentration-time curve (AUC). However, when midazolam is given orally, ketoconazole causes a 10- to 15-fold increase in AUC, the difference reflecting the significant role of intestinal metabolism to the presystemic clearance of midazolam. In rats, administration of the general cytochrome P450 inhibitor 1-aminobenzotriazole (ABT) by the intravenous route (which inhibits only hepatic CYP enzymes) and the oral route (which inhibits both intestinal and hepatic CYP enzymes) can be used to assess the relative role of the intestine and liver to the first-pass metabolism of a drug or other xenobiotic (Strelevitz *et al*., 2006).

The small intestine and liver are exposed to high concentrations of xenobiotics, and they possess high levels of the enzymes that potentially convert xenobiotics to reactive or toxic metabolites. It is perhaps not surprising, therefore, that both tissues possess protective mechanisms to minimize the risk of xenobiotic toxicity and carcinogenicity. As already mentioned, both tissues have enzymes and transporters that facilitate the elimination of xenobiotics and their metabolites. In both tissues, several of the xenobiotic-biotransforming enzymes and transporters are inducible, enabling the liver and the small intestine to respond to high levels of xenobiotics by enhancing the rate of xenobiotic biotransformation and elimination. In the small intestine, the enterocytes at the villus tips undergo extensive turnover, such that the mature cells that are exposed to high levels of xenobiotics and/or reactive metabolites are quickly lost (exfoliated) and replaced in a matter of days. In liver, high levels of glutathione (5–10 mM), a large proportion of diploid (binucleated) cells, and a high regenerative capacity all protect the liver from xenobiotic toxicity or help the liver to repair chemical-mediated toxicity. In addition, severely damaged hepatocytes can undergo apoptosis (cell-programmed death) to eliminate precancerous cells (i.e., cells with extensive DNA damage).

Point 16   Some of the same mechanisms that protect the small intestine and liver from xenobiotic toxicity also protect certain organs such as the brain and reproductive organs. Xenobiotics that enter the systemic circulation are often excluded from the brain by the blood–brain barrier, which poses a physical barrier to xenobiotic transport (in the form of tight junctions) and a biochemical barrier notably in the form of the efflux transporter *P*-glycoprotein (MDR1 or ABCB1). Germ cells in the testis are protected in part by a blood–testis barrier, by high levels of glutathione (and glutathione transferase and glutathione peroxidase), and by high cell turnover (as in the case of enterocytes). The ovum, with virtually no cell turnover, possesses high levels of glutathione (8 mM and more), which protects it from DNA-reactive electrophiles and from the oxidative stress that accompanies both xenobiotic exposure and fertilization. Efflux transporters and glutathione transferases are often over-expressed in tumor cells as a result of chromosomal rearrangements that place the genes encoding these proteins under the control of a strong promoter. The over-expression of a transporter and/or glutathione transferase can confer resistance to certain cancer chemotherapeutic agents (many of which are intended to be converted to reactive metabolites that damage DNA and kill tumor cells).

Point 17   In view of the important role of cytochrome P450 in the metabolic activation of proximate carcinogens to ultimate carcinogens, it may seem paradoxical to list cytochrome P450 induction among the defense mechanisms that protect organisms from the carcinogenic effects of xenobiotics. Activation by cytochrome P450 is definitely required for certain xenobiotics to exert their carcinogenic effects, and induction of cytochrome P450 is associated with an increase in the toxicity of certain xenobiotics. However, contrary to expectation, treatment of rodents with a cytochrome P450 inducer prior to treatment with a known proximate carcinogen (such as aflatoxin, various nitrosamines, or polycyclic aromatic hydrocarbons) is generally associated with a decrease, not an increase, in tumor incidence (Parkinson and Hurwitz, 1991). The route of exposure to the carcinogen can affect the impact of enzyme induction; it protects against orally administered drugs but may increase the tumorigenicity of carcinogens applied directly to their site of action (Nebert *et al*., 2004), and prolonged treatment of rodents with an enzyme inducer *after* application of the initiating carcinogen can lead to an increase in tumor incidence because many enzyme inducers act as tumor promoters (see Point 9). Nevertheless, enzyme induction appears, for the most part, to provide protection against chemical carcinogenesis.

Point 18   Although the small intestine and liver contain the highest concentrations, xenobiotic-biotransforming enzymes are nevertheless widely distributed throughout the body. In terms of specific content (i.e., the amount of enzyme on a per-mg-protein basis), some of the highest concentrations of xenobiotic-metabolizing enzymes are to be found in nasal epithelium, a portal of entry for many volatile xenobiotics. Xenobiotic-biotransforming enzymes in the lung, eye, and skin can be especially important for the metabolism of drugs delivered by inhalation, eye drop, or topical application, respectively. The kidney expresses several xenobiotic-biotransforming enzymes, in addition to numerous transporters that actively secrete xenobiotics (especially acidic metabolites) into urine. The kidney also metabolizes glutathione conjugates formed in the liver.

Point 19   Species differences in xenobiotic-biotransforming enzymes are often the basis for species differences in both the qualitative and quantitative aspects of xenobiotic biotransformation and toxicity. As mentioned in Point 14, species difference in coumarin metabolism and toxicity (activation by epoxidation in rats, detoxication by aromatic hydroxylation in humans) reflects a species difference in hepatic microsomal cytochrome P450, whereas species differences in glutathione transferase activity account for the difference between rats and mice in terms of their susceptibility to aflatoxin-induced liver toxicity. Species differences in the fetal expression of xenobiotic-biotransforming enzymes have raised questions about the suitability of laboratory animals to assess the risk of human teratogenicity because human fetal liver expresses CYP3A7, an enzyme capable of activating aflatoxin to reactive metabolites, whereas no such enzyme is expressed in the fetus of rodents (Li *et al*., 1997).

Biotransformation, inhibition, and induction can occur in a species-specific manner. For example, furafylline and omeprazole are inhibitors and inducers of human CYP1A2, respectively, but they do not inhibit or induce CYP1A2 in rodents. Such species differences are the impetus for the development of so-called humanized mice, which involves substituting the murine genes that encode xenobiotic-metabolizing enzymes (and the receptors that regulate their expression) with their human counterparts (Gonzalez, 2003; Gonzalez and Yu, 2006).

In some species, entire pathways of xenobiotic biotransformation are low or absent. For example, cats and dogs are considered poor glucuronidators and poor acetylators of xenobiotics, respectively. Metabolism by gut microflora can occur in a species-dependent manner. For example, as shown in Fig. 6-1, quinic acid is converted to benzoic acid in humans and old-world monkeys but not in new-world monkeys, mice, rats, and most other laboratory animals (Adamson *et al.*, 1970).

Point 20   In sexually mature rats and, to a lesser extent, mice there are marked gender differences in the expression of certain xenobiotic-biotransforming enzymes (both oxidative and conjugating enzymes). In other species, including humans, gender differences either do not exist or they generally represent less than a twofold difference, whereas the differences in rodents can be an order of magnitude or greater. Against a large background of interindividual variation in each gender, it is often difficult to discern gender differences in xenobiotic biotransformation in humans although, in general, women appear to have lower CYP1A2 and higher CYP3A4 activity than men (reviewed in Parkinson *et al.*, 2004). It is particularly interesting that, compared with men, women appear to have a higher incidence of idiosyncratic drug toxicity (Walgren *et al.*, 2005), which has been the cause of a number of drug withdrawals and black box warnings (see Point 21).

Point 21   Idiosyncratic drug reactions (IDRs) are rare adverse events ($<0.1\%$) that do not involve an exaggerated pharmacological response, do not occur in most patients at any dose, and typically do not occur immediately after exposure but do so after weeks or months of repeated administration (Walgren *et al.*, 2005). IDRs are also known as Type B reactions, and they can be divided into allergic and nonallergic IDRs. The former tend to develop relatively quickly (in days or weeks) and, after the drug is discontinued, patients respond robustly when rechallenged with the same or a closely related drug, whereas the latter tend to develop relatively slowly (with symptoms sometimes appearing after 6 months or more of drug treatment) and patients may or may not respond to rechallenge with the drug. Evidence for an immune component to allergic IDRs is often circumstantial or lacking, as is the evidence for the lack of an immune component to nonallergic IDRs. Hepatotoxicity is a prevalent IDR. Drugs that were withdrawn from the U.S. market or carry a black box warning for idiosyncratic hepatotoxicity are listed in Table 6-3. The drugs are structurally diverse and fall into numerous therapeutic classes. In many cases there is evidence implicating a reactive metabolite in the idiosyncratic hepatotoxicity, although such metabolites tend to be formed in all individuals, leaving unanswered the critical question of what factor or factors predispose a small proportion of the population to the hepatotoxic effects of certain drugs, many of which cause little or no discernible liver toxicity in laboratory animals. In several cases, the drugs listed in Table 6-3 have closely related structures that do not cause idiosyncratic hepatotoxicity. For example, rosiglitazone and pioglitazone contain the same thiazolidinedione ring that in troglitazone is converted to a reactive metabolite, and yet only troglitazone has been withdrawn from the market because of idiosyncratic hepatotoxicity. This difference may be due to the much larger daily dose of troglitazone (300 mg) compared with rosiglitazone (4–8 mg) and pioglitazone (15–45 mg). Uetrecht (2001) has proposed the general rule that drugs administered at a daily dose of 10 mg or less do not cause idiosyncratic toxicity, and this rule is consistent with the dosing information shown in Table 6-3. Other examples of closely related drugs where one does and one does not cause hepatotoxicity include tolcapone/entacapone, ticlopidine/clopidogrel, amineptine/tianeptine,

tamoxifen/toremifene, ibufenac/ibuprofen, ebrotidine/famotidine, and niperotidine/ranitidine (Walgren *et al.*, 2005). Labetrol has two chiral centers and is a racemic mixture of four enantiomers, one of which is dilevalol. Although labetrol carries a black box warming for hepatotoxicity, dilevalol was not approved by the FDA because it caused a high incidence of liver toxicity during clinical trials. In some cases the difference is thought to be due to differences in dose (which is invariably higher for the drug partner that causes hepatotoxicity), but in other cases the basis for the difference is not known.

Point 22   The same dose of drug (or any other xenobiotic) administered to humans often results in large interindividual differences in exposure to the parent compound (typically measured as the area under the plasma concentration–time curve or AUC). This variation can reflect genetically determined differences in the activity of xenobiotic-biotransforming enzymes or transporters (genetic polymorphisms) or environmental differences, such as drug–drug interactions.

Point 23   The study of the causes, prevalence, and impact of heritable differences in xenobiotic-biotransforming enzymes is known as *pharmacogenetics*. It is the basis for the concept of individualized medicine, whereby the dosage of drugs with a narrow therapeutic index (such as anticancer drugs) is adjusted in accordance with an individual's genotype (i.e., drug-metabolizing potential).

Genetic variation in a xenobiotic-metabolizing enzyme produces four discernable phenotypes: poor metabolizers (PMs), intermediate metabolizers (IMs), extensive metabolizers (EMs), and ultrarapid metabolizers (UM), which arise from the expression of no functional alleles ($-/-$) for PMs, one nonfunctional allele and one partially functional allele or two partially active alleles ($-/*$ or $*/*$) for IMs, one or two functional alleles ($+/-$, $+/*$, or $+/+$) for EMs, and gene duplication ($[+/+]n$) for UMs. This traditional classification scheme has been revised recently on the basis of an activity score, which assigns to each allelic variant a functional activity value from 1 (for the wild type or *1 allele) to zero (for any completely nonfunctional allele), as shown in Table 6-4 (Zineh *et al.*, 2004).

For those enzymes that are polymorphically expressed, such as CYP2D6, the incidence of the PM (and UM) genotype can vary widely from one ethnic group to the next. For example, the CYP2D6 PM genotype is common among Caucasians but not Asians, whereas the converse is true of the CYP2C19 PM genotype.

When the clearance of a drug is largely determined by a polymorphically expressed enzyme, such as CYP2D6, exposure follows the rank order: poor metabolizers (PMs) > intermediate metabolizers (IMs) > extensive metabolizers (EMs) > ultrarapid metabolizers (UMs). Exposure to metabolites (especially the maximum concentration, C_{max}) follows the opposite rank order. The difference in exposure between PMs and EMs (i.e., the fold increase in AUC associated with the PM phenotype versus the EM phenotype) depends on fractional metabolism (*fm*), a measure of how much of the drug's clearance is determined by CYP2D6 (or whatever enzyme is responsible for metabolizing the drug in question). The fold increase in AUC (AUC_{PM}/AUC_{EM}) is equal to $1/(1 - fm)$; hence, the impact of the polymorphism increases dramatically as *fm* approaches unity. If CYP2D6 accounted for half of a drug's clearance ($fm = 0.5$), exposure to that drug would increase twofold in CYP2D6 PMs. However, if CYP2D6 accounted for 90% of a drug's clearance ($fm = 0.9$), then exposure to that drug would increase tenfold in CYP2D6 PMs. This is why PMs are often at increased risk of adverse drug events either due to an exaggerated

Table 6-3
Drugs That Have Been Withdrawn or Carry a Black Box Warning for Idiosyncratic Hepatotoxicity[a]

DRUG NAME	TYPICAL DOSE (mg)	INDICATION	REACTIVE METABOLITE AND EVIDENCE OF MECHANISM-BASED ENZYME INHIBITION	INDUCTION[b], IMMUNOLOGICAL AND OTHER MECHANISTIC ASPECTS
Drugs withdrawn				
Benoxaprofen	300–600	NSAID	Acyl glucuronide	Inducer (rat AhR and PPARα agonist)
Bromfenac	25–50	NSAID	Acyl glucuronide	
Iproniazid	25–150	Depression	Multiple. MBI of MAO-B	Anti-MAO-B and antimitochondria
Nefazodone	200	Depression	Quinoneimine. MBI of CYP3A4	
Tienilic acid	250–500	Diuretic	Thiophene epoxide, sulfoxide. MBI of CYP2C9	Anti-LKM$_2$ (anti-CYP2C9)
Troglitazone	400	Diabetes	Quinone methide, sulfenic acid, α-ketoisocyanate	Inducer (CAR/PXR agonist)
Black box warnings				
Acitretin	25–50	Psoriasis	No. Acitretin, a retinoid, is esterified to etretinate	Etretinate was withdrawn in 2002
Bosentan	125–250	PAH	No	Inhibits BSEP. Inducer (PXR agonist)
Dacarbazine	140–315	Melanoma, lymphoma	Methyl diazohydroxide and methyl cation (CH_3^+)	Hepatotoxic to laboratory animals
Dantrolene	300–400	Muscle relaxant	Nitro-reduction intermediates bind to GSH	Inducer (AhR agonist)
Felbamate	1200	Epilepsy	2-Phenylpropenal (atropaldehyde)	Inducer (PXR agonist)
Flutamide	750	Prostate cancer	Unknown metabolites bind to protein and GSH	Inhibits mitochondrial respiration
Gemtuzumab	9 mg/m^2	AML	Reductive activation to a di-radical	Designed to intercalate and bind DNA
Isoniazid	300	Tuberculosis	Multiple. MBI of CYP1A1, 2A6, 2C19, and 3A4.	Radicals formed by myeloperoxidase
Ketoconazole	200	Fungal infections	Di-aldehyde	Auto-inhibitor (inhibits CYP3A4)
Naltrexone	50	Alcoholism, addiction	No	
Nevirapine	200–400	AIDS	No	Inducer (PXR agonist)
Pemoline	37.5–112.5	Hyperactivity	No	
Tolcapone	300	Parkinsonism	Nitro reduction and then quinoneimine formation	Uncouples mitochondrial respiration
Trovafloxacin	100–500	Antibiotic	No, but it has a lipophilic difluorinated side chain present in a toxic fluoroquinolone—now withdrawn	Eosinophilia suggests an immune-mediated hepatitis
Valproic acid (VPA)	1000–4200	Epilepsy	CoA esterification and epoxidation of 4-ene-VPA	Disrupts mitochondrial β-oxidation

[a] Data Adapted from Walgren JL, Mitchell MD, Thompson DC: Role of metabolism in drug-induced idiosyncratic hepatotoxicity. *Crit Rev Toxicol* 35:325–361, 2005.
[b] The receptor agonist assignment is based on the CYP-induced enzyme (CYP1A for AhR; CYP2B, CYP2C, and/or CYP3A for CAR/PXR; CYP4A for PPARα).
AhR, aryl hydrocarbon receptor; AIDS, acquired immunodeficiency syndrome; AML, acute myeloid leukemia; anti-LKM$_2$, auto-antibodies against liver and kidney microsomes (anti-LKM$_1$ contains antibodies against CYP2D6, whereas anti-LKM$_2$ contains antibodies against CYP2C9); BSEP, bile salt export pump (a bile canalicular transporter); CYP, cytochrome P450; GSH, glutathione; MAO, monoamine oxidase; MBI, mechanism-based inhibitor (a.k.a. suicide inactivator); NSAID, nonsteroidal anti-inflammatory drug; PAH, pulmonary arterial hypertension; PPARα, peroxisome proliferator activated receptor-alpha; PXR, pregnane X receptor; VPA, valproic acid.

Table 6-4

The Relationship Between Genotype and Phenotype for a Polymorphically Expressed Enzyme with Active (wt), Partially Active (*x), and Inactive (*y) Alleles

GENOTYPE	ALLELES	CONVENTIONAL PHENOTYPE[a]	ACTIVITY SCORE[b]	ACTIVITY SCORE PHENOTYPE[c]
Duplication of active alleles ($n = 2$ or more)	(wt/wt)n	UM	$2 \times n$	UM
Two fully active wild-type (wt) alleles	wt/wt	EM	$1 + 1 = 2$	High EM
One fully active + one partially active allele	wt/*x	EM	$1 + 0.5 = 1.5$	Medium EM
One fully active + one inactive allele	wt/*y	EM	$1 + 0 = 1$	Low EM
Two partially active alleles	*x/*x	EM or IM	$0.5 + 0.5 = 1$	Low EM
One partially active + one inactive allele	*x/*y	IM	$0.5 + 0 = 0.5$	IM
Two inactive alleles	*y/*y	PM	$0 + 0 = $ zero	PM

[a]The phenotypes are ultrarapid metabolizer (UM), extensive metabolizer (EM), intermediate metabolizer (IM), and poor metabolizer (PM), based on the particular combination of alleles that are fully active (wt), partially active (*x), or inactive (*y).

[b]In the case of CYP2D6 (Data from Zineh et al., 2004), various activity scores have been determined experimentally as follows:

Activity score = 1.0 for each *1 (wt), *2, *35, and *41 [2988G].

Activity score = 0.75 for each *9, *29, *45, and *46.

Activity score = 0.5 for each *10, *17, and *41 [2988A].

Activity score = 0 for each *3, *4, *5, *6, *7, *8, *11, *12, *15, *36, *40, and *42.

[c]Activity scores are classified as follows (from Zineh et al., 2004):

UM activity score => 2.0 (e.g., [*1/*1]n where n is 2 or more gene duplications).

High EM activity score = 1.75 to 2.0 (e.g., *1/*1).

Medium EM activity score = 1.5 (e.g., *1/*17 or *9/*9).

Low EM activity score = 1.0 to 1.25 (e.g., *1/*4, *17/*17, or *9/*17).

IM activity score = 0.5 to 0.75 (e.g., *4/*9 or *4/*17).

PM activity score = 0 (e.g., *4/*4).

pharmacological response to the drug or due to its toxic side effects. An exception is omeprazole and other proton pump inhibitors, which actually provide improved control over gastroesophageal reflux disease (GERD) in CYP2C19 PMs compared with EMs (Furuta et al., 2005).

There are a minority of cases where the UMs, not the PMs, are at increased risk, especially in cases where the polymorphic enzyme catalyzes the formation of a pharmacologically active or toxic metabolite. For example, CYP2D6 converts the prodrug codeine into the active metabolite morphine, and there are reports of morphine intoxication in CYP2D6 UMs; one case being the death of a baby being breast fed by a CYP2D6 UM mother who was prescribed codeine (Gasche et al., 2004; Koren et al., 2006).

Many cases have now been described where the PM phenotype requires dosage adjustment to prevent drug toxicity or an exaggerated pharmacological response. For example, CYP2D6 PMs are at increased risk for perhexiline hepatotoxicity and at increased risk for an exaggerated pharmacological response to debrisoquine and sparteine, three drugs that were not approved in the USA because of the high incidence of adverse events in the PMs. On the other hand, when drugs are converted to active metabolites by CYP2D6, then PMs derive inadequate therapeutic effect. For example, CYP2D6 converts codeine to morphine; hence, codeine is a less-effective analgesic in PMs. Similarly, CYP2D6 converts the breast cancer drug tamoxifen to endoxifen (which is 30- to 100-fold more potent than tamoxifen in suppressing estrogen-dependent cell proliferation), hence, CYP2D6 PMs are at increased risk for breast cancer recurrence following tamoxifen adjuvant therapy (Goetz et al., 2005). Other examples of genetic polymorphisms that affect drug disposition in humans include CYP2C9 (warfarin), CYP2C19 (omeprazole), CYP3A4 (clopidogrel, irinotecan, thioridazine), CYP3A5 (tacrolimus), UGT1A1 (irinotecan), UGT2B7 (morphine), TPMT (6-mercaptopurine), NAT2 (isoniazid), COMT (levodopa), DPD (5-

fluorouracil), and the efflux transporter P-glycoprotein (digoxin) (Robert et al., 2005; Relling and Giacomini, 2006). Most of these drugs identified in parentheses all have a narrow therapeutic target. Details of these genetic polymorphisms are given later in the chapter.

Genetic polymorphisms in xenobiotic-biotransforming enzymes have an impact on the incidence of certain environmental diseases. For example, ethnic differences in the incidence of polymorphisms in alcohol dehydrogenase and aldehdye dehydrogenase impact the incidence of alcoholism (Li, 2000). Genetic polymorphisms in CYP2A6 impact the incidence of cigarette-smoking-induced lung cancer. Individuals lacking CYP2A6 are PMs of nicotine (so they tend to smoke less than CYP2A6 EMs) and are poor activators of tobacco-specific mutagens (so they form fewer DNA-reactive metabolites than do CYP2A6 EMs) (Kamataki et al., 2005).

Genetic polymorphisms can be the underlying cause of a disease. For example, the severe and mild hyperbilirubinemia associated with Crigler–Najjar syndrome and Gilbert's syndrome, respectively, reflect a complete and partial loss of the UDP-glucuronosyltransferase responsible for conjugating bilirubin, namely, UGT1A1. The hyperbilirubinemic Gunn rat is the rodent equivalent of Crigler–Najjar syndrome.

Genetic polymorphisms have been described in laboratory animals. For example, laboratory-bred rabbits have about 50:50 chance of being a poor or rapid acetylator of certain drugs a (such as isoniazid) because N-acetyltransferase 2 (NAT2) is polymorphically expressed in rabbits.

Point 24   Environmental factors can introduce as much variation in drug metabolism as can genetic factors, and this is especially true of drug–drug interactions. To take CYP3A4 as an example, PMs can be created pharmacologically with inhibitors (such as ketoconazole and erythromycin), whereas UMs can be created pharmacologically with inducers (such as rifampin and the herbal agent

St. John's wort). Whereas the impact of genetic polymorphisms on drug disposition and safety is often identified during clinical trials, the impact of drug–drug interactions may not be identified until after the drug has been approved and is under postmarketing surveillance.

Drugs (and other xenobiotics) can be viewed from a *victim* and *perpetrator* perspective. A drug whose clearance is largely determined by a single route of elimination, such as metabolism by a single CYP enzyme, is considered a victim drug (also known as a sensitive or object drug). Such drugs have a high victim potential because a diminution or loss of that elimination pathway, either due to a genetic deficiency in the relevant CYP enzyme or due to its inhibition by another, concomitantly administered drug, will result in a large decrease in victim drug clearance and a correspondingly large increase in exposure (the magnitude of which will depend on fractional metabolism, as indicated in Point 23). Some victim drugs have a high therapeutic index, hence, they are therapeutically effective in PMs to UMs and cause roughly the same incidence of adverse effects regardless of genotype. However, in the case of victim drugs with a narrow therapeutic index, dosage must be increased in UMs to achieve a therapeutic effect and/or it must be decreased in PMs to prevent adverse drug events.

Perpetrators are those drugs (or other environmental factors) that inhibit or induce the enzyme that is otherwise responsible for clearing a victim drug. In other words, perpetrators are drugs that cause drug–drug interactions. Perpetrators are also known as precipitants. Genetic polymorphisms that result in the partial or complete loss of enzyme activity can also be viewed as perpetrators inasmuch they cause a decrease in the clearance of—and an increase in exposure to—victim drugs.

Terfenadine (Seldane), cisapride (Propulsid), astemizole (Hismanal), and cerivastatin (Baycol) are all victim drugs, so much so that they have all been withdrawn from the market (Fung *et al.*, 2001). The first three are all victim drugs because they are extensively metabolized by CYP3A4. Inhibition of CYP3A4 by various antimycotic drugs, such as ketoconazole, and antibiotic drugs, such as erythromycin, decrease the clearance of terfenadine, cisapride, and astemizole and increase their plasma concentrations to levels that, in some individuals, cause ventricular arrhythmias (QT prolongation) which can result in fatal heart attacks. Cerivastatin is extensively metabolized by CYP2C8. Its metabolism is inhibited by gemfibrozil (actually by gemfibrozil glucuronide), and the combination of cerivastatin (Baycol) and gemfibrozil (Lopid) was associated with a high incidence of fatal, cerivastatin-induced rhabdomyolysis (Ogilvie *et al.*, 2006).

Mibefradil (Posicor) is the only drug withdrawn from the U.S. market largely because of its perpetrator potential. This calcium channel blocker not only causes extensive inhibition of CYP3A4, it causes prolonged inhibition of the enzyme by virtue of being a metabolism-dependent inhibitor of CYP3A4. By inactivating CYP3A4 in an irreversible manner—such that restoration of normal CYP3A4 activity required the synthesis of new enzyme—mibefradil inhibits CYP3A4 long after treatment with the drug is discontinued.

The in vitro technique of reaction phenotyping (also known as enzyme mapping) is the process of identifying which enzyme or enzymes are largely responsible for metabolizing a drug candidate (Williams *et al.*, 2003b; Ogilvie *et al.*, 2007). Reaction phenotyping allows an assessment of the victim potential of a drug candidate or other xenobiotic. Drug candidates can also be evaluated in vitro for their potential to inhibit or induce cytochrome P450, which allows an assessment of their perpetrator potential (Tucker *et al.*, 2001; Bjornsson *et al.*, 2003; U.S. Food and Drug Administration, 2006).

Herbal remedies can also interact with drugs. For example, St. John's wort contains hyperforin, which is a potent PXR agonist and, as such, is an inducer of CYP3A4 (along with several other xenobiotic-metabolizing enzymes) and *P*-glycoprotein (MDR1 or ABCB1). To prevent a loss of therapeutic efficacy, the use of St. John's wort is not recommended for patients on antirejection drugs (such as cyclosporine and tacrolimus), anti-HIV drugs (such as indinavir and nevirapine), anticoagulants (such as warfarin and phenprocoumon), or oral contraceptive steroids (Pal and Mitra, 2006). Food can affect drug disposition in a number of ways. It can affect absorption, which is why some drugs are taken with meals and others are taken between meals. Large quantities of cruciferous vegetables (e.g., broccoli and Brussels sprouts) can induce hepatic CYP1A2 (Conney, 1982), whereas grapefruit juice can inhibit intestinal CYP3A4 (Paine *et al.*, 2006).

Point 25   Although drug–drug interactions can cause an increase in the incidence of adverse events or, in the case of induction, a loss of therapeutic efficacy, not all drug–drug interactions are undesirable. For example, some anti-HIV drugs, like ritonavir, inhibit CYP3A4 and thereby improve the pharmacokinetic profile of other anti-HIV drugs, like saquinavir and lopinavir. Tumors often over-express various transporters and glutathione transferases, which limit the effectiveness of several anticancer drugs. Drugs that inhibit transporters and glutathione transferase are being developed to enhance the efficacy of anticancer drugs.

Point 26   Although the amount of functional enzyme determines whether an individual is a poor or rapid metabolizer, there are other factors that can impact the rate of xenobiotic metabolism. Not surprisingly, severe liver disease decreases the rate of metabolism of a large number of drugs whose clearance is determined by hepatic metabolism. For certain xenobiotic-metabolizing enzymes, particularly the conjugating enzymes, cofactor availability can impact the rate of xenobiotic biotransformation. The liver usually has sufficient NADPH to saturate reactions catalyzed by cytochrome P450, but it does not have sufficient levels of UDP-glucuronic acid (UDPGA) or 3′-phosphoadenosine-5′-phosphosulfate (PAPS) to saturate the enzymes responsible for glucuronidating or sulfonating xenobiotics. Consequently, alterations in the levels of these cofactors can impact the rate or extent of glucuronidation and sulfonation. For example, fasting lowers hepatic levels of these cofactors, and fasting decreases the extent to which acetaminophen is conjugated. Consequently, fasting increases the extent to which acetaminophen is metabolized to a toxic metabolite by cytochrome P450 (including CYP2E1, which is induced by fasting), for which reason fasting is suspected of being one of the risk factors for acetaminophen hepatotoxicity (Whitcomb, 1994).

Point 27   Stereochemical aspects can play an important role in the interaction between a xenobiotic and its biotransforming enzyme (both from a substrate and inhibitor perspective), and xenobiotic-biotransforming enzymes can play a key role in converting one stereoisomer to another, a process known as *mutarotation* or *inversion of configuration*.

A xenobiotic that contains a chiral center can exist in two mirror-image forms called stereoisomers or enantiomers. The biotransformation of some chiral xenobiotics occurs stereoselectively; meaning that one enantiomer (stereoisomer) is biotransformed faster than its antipode. For example, the antiepileptic drug Mesantoin®, which is a racemic mixture of *R*- and *S*-mephenytoin, is biotransformed stereoselectively in humans, such that the *S*-enantiomer

is rapidly hydroxylated (by CYP2C19) and eliminated faster than the *R*-enantiomer. The ability of some chiral xenobiotics to inhibit xenobiotic-biotransforming enzymes can also occur stereoselectively. For example, quinidine is a potent inhibitor of CYP2D6, where as quinine, its antipode, has relatively little inhibitory effect on this enzyme. In some cases, achiral molecules (or achiral centers) are converted to a mixture of enantiomeric metabolites, and this conversion may proceed stereoselectively such that one enantiomer is formed preferentially over its antipode. For example, several cytochrome P450 enzymes catalyze the 6-hydroxylation of steroid hormones. Some P450 enzymes (such as the rat enzyme CYP2A1) preferentially catalyze the 6α-hydroxylation reaction, whereas other P450 enzymes (such as the CYP3A enzymes in all mammalian species) preferentially catalyze the 6β-hydroxylation reaction (which is a major route of hepatic steroid biotransformation).

Inversion of configuration is the process whereby one enantiomer is converted to its antipode via an achiral intermediate. This interconversion can occur nonenzymatically, as in the case of thalidomide, or it can be catalyzed by a xenobiotic-metabolizing enzyme, as in the case of lisofylline, or by an endobiotic-metabolizing enzyme, as in the case of simvastatin (Fig. 6-2).

In the case of thalidomide, inversion of configuration (as shown in Fig. 6-2) occurs spontaneously, although the process is facilitated by albumin (Eriksson *et al.*, 1998). In the mid-to-late 1950s, mainly in Europe, thalidomide was prescribed to pregnant women in the first trimester to treat morning sickness. Unfortunately, whereas (*R*)-thalidomide is an effective sedative, the (*S*)-enantiomer is a teratogen that produces phocomelia (limb shortening) and other congenital defects in the offspring largely as a result of its ability to inhibit angiogenesis (vasculogenesis). The teratogenic effect of thalidomide cannot be circumvented by administering only the (*R*)-enantiomer because spontaneous or albumin-facilitated racemization quickly produces the teratogenic (*S*)-enantiomer. Thalidomide blocks the release of tissue necrosis factor alpha (TNFα) and it has been approved for the treatment of erythema nodosum leprosum (an acute inflammatory reaction associated with lepromatous leprosy), and is useful in the treatment of several other inflammatory conditions and immune-mediated diseases. Because of its ability to inhibit angiogenesis (the process that supplies tumors with new blood vessels), thalidomide is also under investigation as an anticancer drug. It is ironic that a drug with antivascular side effects that was originally prescribed as a sedative is now in clinical trials for vascular diseases with sedation as a side effect (Franks *et al.*, 2004).

Ketones can be reduced by carbonyl reductases to a mixture of enantiomeric secondary alcohols, and this can occur with a high degree of stereoselectivity. For example, pentoxifylline is reduced by carbonyl reductases in blood and liver to a mixture of secondary alcohols with the major metabolite having an *S*-configuration, as shown in Fig. 6-2. Interestingly, the minor metabolite, a secondary alcohol with the *R*-configuration, has pharmacological properties distinct from those of its *S*-antipode and its ketone precursor, pentoxifylline. This minor metabolite is known as lisofylline, which is under clinical investigation for the treatment of various diseases. Through the action of carbonyl reductase, lisofylline is oxidized to pentoxifylline and then reduced to its antipode (i.e., *R*-alcohol → ketone → *S*-alcohol), the net result being an inversion of configuration (Lillibridge *et al.*, 1996). The same type of interconversion explains why the administration of pure *R*-albuterol to human volunteers results in the formation of *S*-albuterol, just as the admin-

istration of pure *S*-albuterol leads to the formation of *R*-albuterol (Boulton and Fawcett, 1997).

In the case of simvastatin (which contains a β-hydroxy-lactone), the interconversion of two secondary alcohols (β-hydroxy-lactone ↔ α-hydroxy-lactone) involves hydrolysis of the lactone ring (by paraoxonase 3 [hPON3] in humans) followed by formation of a thioether with coenzyme A, the first step in the β-oxidation of fatty acids, followed by dehydration to an achiral intermediate. Reversal of the steps by a combination of hydrolysis and lactonization (condensation) restores the lactone ring with the hydroxyl group in the original β-configuration or in the opposing α-configuration. In humans, the initial hydrolysis of the lactone ring and the final lactonization (condensation) reaction are both catalyzed by paraoxonase-3 (hPON3) (Draganov and La Du, 2004).

Point 28   Mass spectrometry is widely used to characterize the structure of metabolites, and many instruments now come equipped with software to assist in this process, based on the fact that certain xenobiotic reactions are associated with discrete changes in mass. For example, the loss of 2 atomic mass units (amu) signifies dehydrogenation, whereas the loss of 14 amu usually signifies demethylation (–CH_2). Several reactions result in an increase in mass, including reduction (+2 amu = 2H), methylation (+14 amu = CH_2), oxidation (+16 amu = O), hydration (+18 amu = H_2O), acetylation (+42 amu = C_2H_2O), glucosylation (+162 = $C_6H_{10}O_5$), sulfonation (+80 amu = SO_3), glucuronidation (+176 amu = $C_6H_8O_6$), and conjugation with glutathione (+305 amu = $C_{10}H_{15}N_3O_6S$), glycine (+74 amu = $C_2H_4NO_2$), and taurine (+42 amu = $C_2H_6NO_3S$).

Occasionally, routine changes in mass can arise from unexpected reactions. For example, ziprasidone is converted to two metabolites, each of which involves an increase of 16 amu, which normally indicates addition of oxygen (e.g., hydroxylation, sulfoxidation, N-oxygenation). One of the metabolites is indeed formed by addition of oxygen to ziprasidone (sulfoxidation), as shown in Fig. 6-3 (Beedham *et al.*, 2003). However, the other metabolite is formed by a combination of reduction (+2 amu) and methylation (+14). Therefore, care must be exercised in interpreting routes of metabolism based on changes in mass.

Mass spectrometry can typically provide information on which region of a molecule has undergone biotransformation, but it can seldom distinguish between several closely related possibilities. For example, based on mass spectrometry alone, it might be possible to ascertain that a certain phenyl group has been hydroxylated. However, analysis by nuclear magnetic resonance (NMR) is required to ascertain whether the hydroxylation occurred at the ortho, meta, or para position.

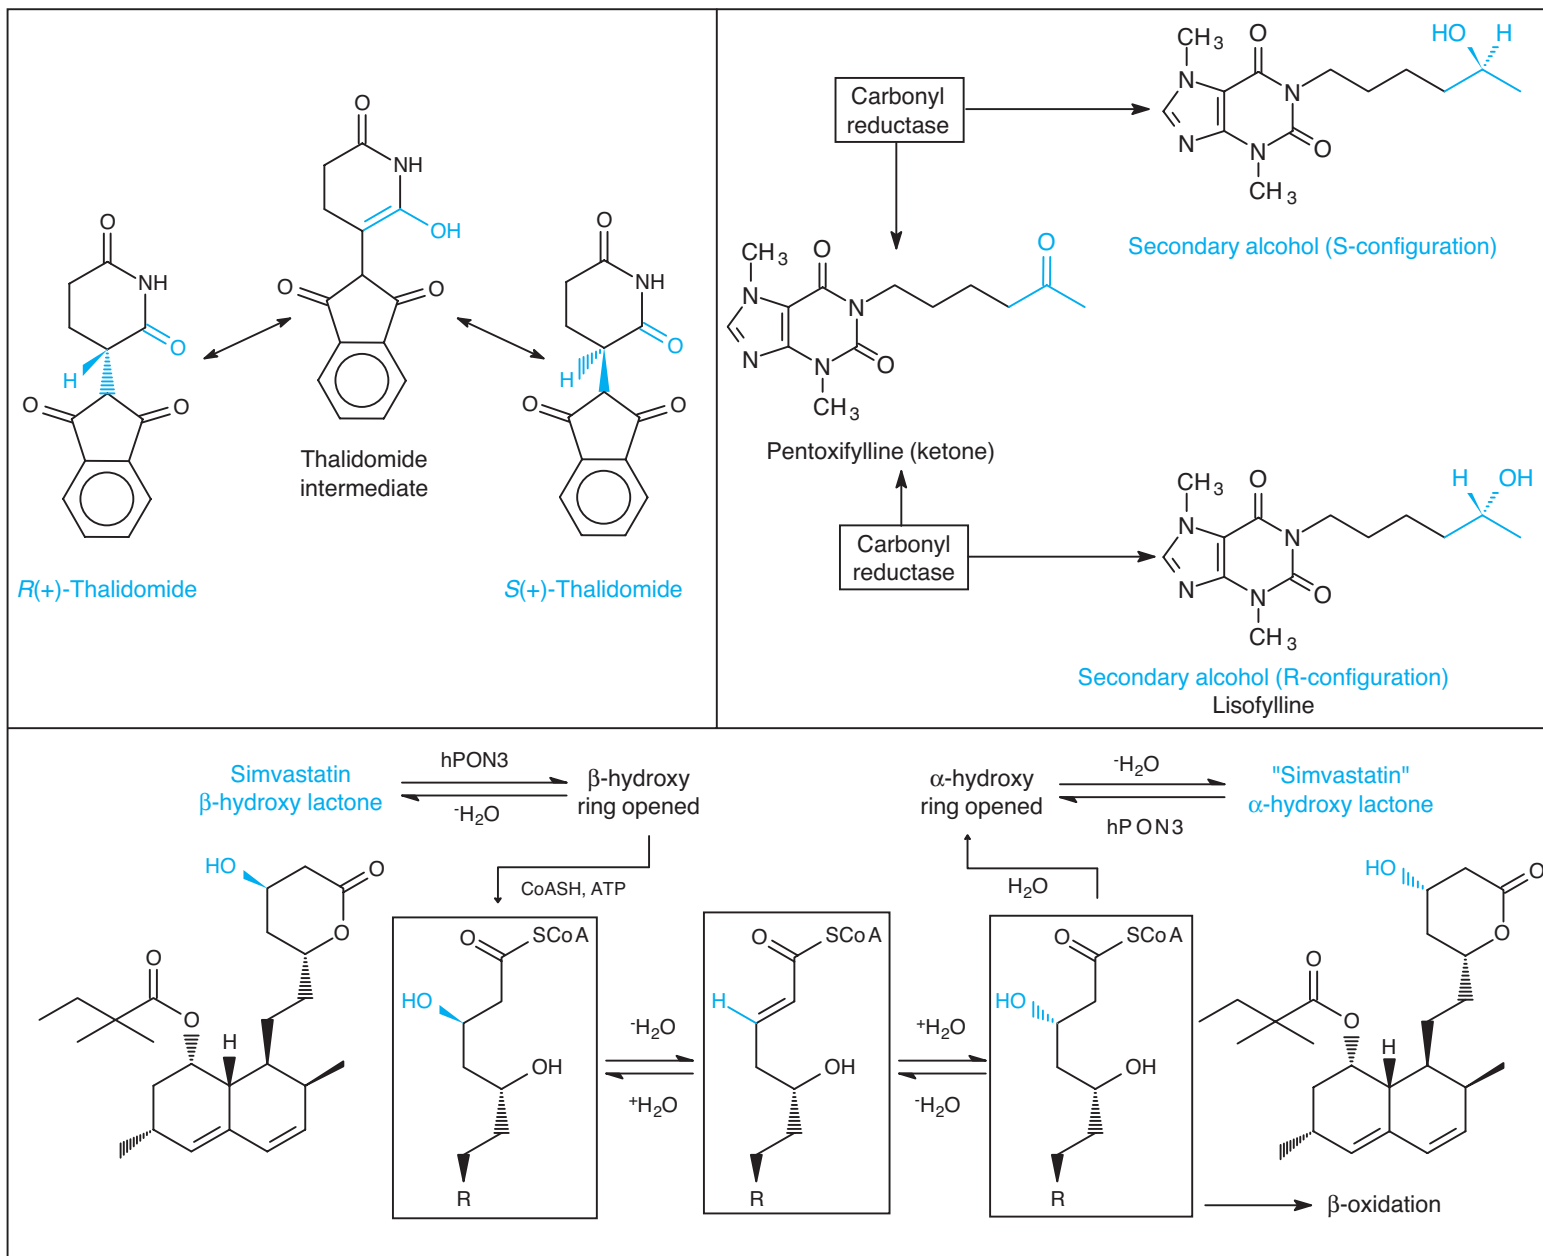
Point 29   As mentioned in Point 18, xenobiotic-biotransforming enzymes are widely distributed throughout the body. The advent of high-throughput assays based on quantitative real-time reverse-transcription polymerase chain reaction (QPCR) has facilitated comprehensive measurements of the levels of mRNA encoding numerous xenobiotic-biotransforming enzymes, transporters, and xenosensors in a wide range of human tissues (Nishimura *et al.*, 2003, 2004; Furukawa *et al.*, 2004; Nishimura and Naito, 2005, 2006). These data are very informative as far as mRNA expression is concerned, but it can be difficult to draw conclusions about the activity of a given enzyme in a given tissue based on mRNA levels alone. For instance, based on mRNA levels in human liver, the levels of the top-ten CYP enzymes follow the rank order: CYP2E1 ≫ 2A6 > 2C8 > 2C18 ≈ 1A2 ≈ 4A11 ≈ 8B1 ≈ 2C9 ≈ 3A4 > CYP51A1 (Nishimura *et al.*, 2003). This contrasts substantially from the levels of CYP


Figure 6-2. Stereochemical aspects of xenobiotic biotransformation: Inversion of configuration by nonenzymatic means (thalidomide), by carbonyl reductase (liso-fylline), and by hydrolysis and condensation (lactonization) of a lactone ring (simvastatin).
Figure 6-3. Conversion of ziprasidone to two different metabolites both involving a mass increase of 16 amu (relative to ziprasidone).

protein, which follow the rank order: CYP3A4 > 2C9 ≈ 3A5 ≈ 2E1 > 1A2 > 2A6 > 2C8 > 2C19 > 2B6 > 2D6 (Rowland-Yeo *et al.*, 2004; Howgate *et al.*, 2006). In the case of CYP2E1, hepatic mRNA levels are more than 17 times higher than the levels of CYP3A4 mRNA, but CYP2E1 protein levels are less than half those of CYP3A4. This discrepancy is due to the fact that, under normal conditions, most of the mRNA encoding CYP2E1 is sequestered in the cytoplasm and is not available for translation (Gonzalez, 2007). The mRNA for FMO2 is present at very high levels in human lung, but is not translated into functional enzyme due to the presence of a truncation mutation in Caucasians and Asians. However, about 26% of African Americans, 7% of Puerto Ricans, and 2% of Mexicans have one normal allele and express a functional protein (Cashman and Zhang, 2006).

HYDROLYSIS, REDUCTION, AND OXIDATION

Hydrolysis

Mammals contain a variety of enzymes that hydrolyze xenobiotics containing such functional groups as a carboxylic acid ester (delapril and procaine), amide (procainamide), thioester (spironolactone), phosphoric acid ester (paraoxon), acid anhydride (diisopropyl-fluorophosphate [DFP]), and lactone (spironolactone), as shown in Fig. 6-4. The major hydrolytic enzymes are the carboxylesterases, cholinesterases, and paraoxonases (for which lactonase is a more encompassing name), but they are by no means the only hydrolytic enzymes involved in xenobiotic biotransformation. The first two classes of hydrolytic enzymes, the carboxylesterases and cholinesterases, are known as serine esterases because their catalytic site contains a nucleophilic serine residue that participates in the hydrolysis of various xenobiotic and endobiotic substrates. This serine residue becomes phosphorylated by organophosphorus (OP) compounds, such as those used as insecticides, herbicides, fungi-

cides, nematicides, and plant growth regulators. However, following completion of the human genome project, it was determined that, of the estimated 22,500 human genes, about 5% (1227 genes) can be classified as serine hydrolases based on structural features (motifs) predicted from their DNA sequence, of which about 150 can be classified as serine proteases (Casida and Quistad, 2005).

Based on the large number of potential serine hydrolases, it is not surprising that enzymes other than those described in this chapter (namely, the carboxylesterases, cholinesterases, and paraoxonases) may participate in xenobiotic metabolism. Aldehyde dehydrogenases, carbonic anhydrases, carboxypeptidases, lipases, proteases, and even albumin have all been shown to have hydrolytic (esteratic) activity toward various xenobiotics. Cytochrome P450 can catalyze the cleavage of certain xenobiotics containing a carboxylic acid ester (see section "Cytochrome P450" for examples).

Based on the large number of potential serine hydrolases, it is not surprising that enzymes other than carboxylesterases and cholinesterases represent additional targets for phosphorylation and inactivation by OP compounds. Some of these OP targets have been identified; they include enzymes involved in the hydrolysis of endobiotics and certain receptors (reviewed in Casida and Quistad, 2005). Differential binding to these numerous sites may account for some of the differences observed among OP compounds. However, in insects, nematodes, and mammals, the critical site is acetylcholinesterase, the cholinesterase that hydrolyzes acetylcholine and thereby terminates its neurotransmitter activity. Phosphorylation of acetylcholinesterase is the principal mechanism of OP toxicity, with 70–90% inhibition usually proving lethal, and reversal of this phosphorylation event is one of the strategies to treat OP poisoning (e.g., with pralidoxime).

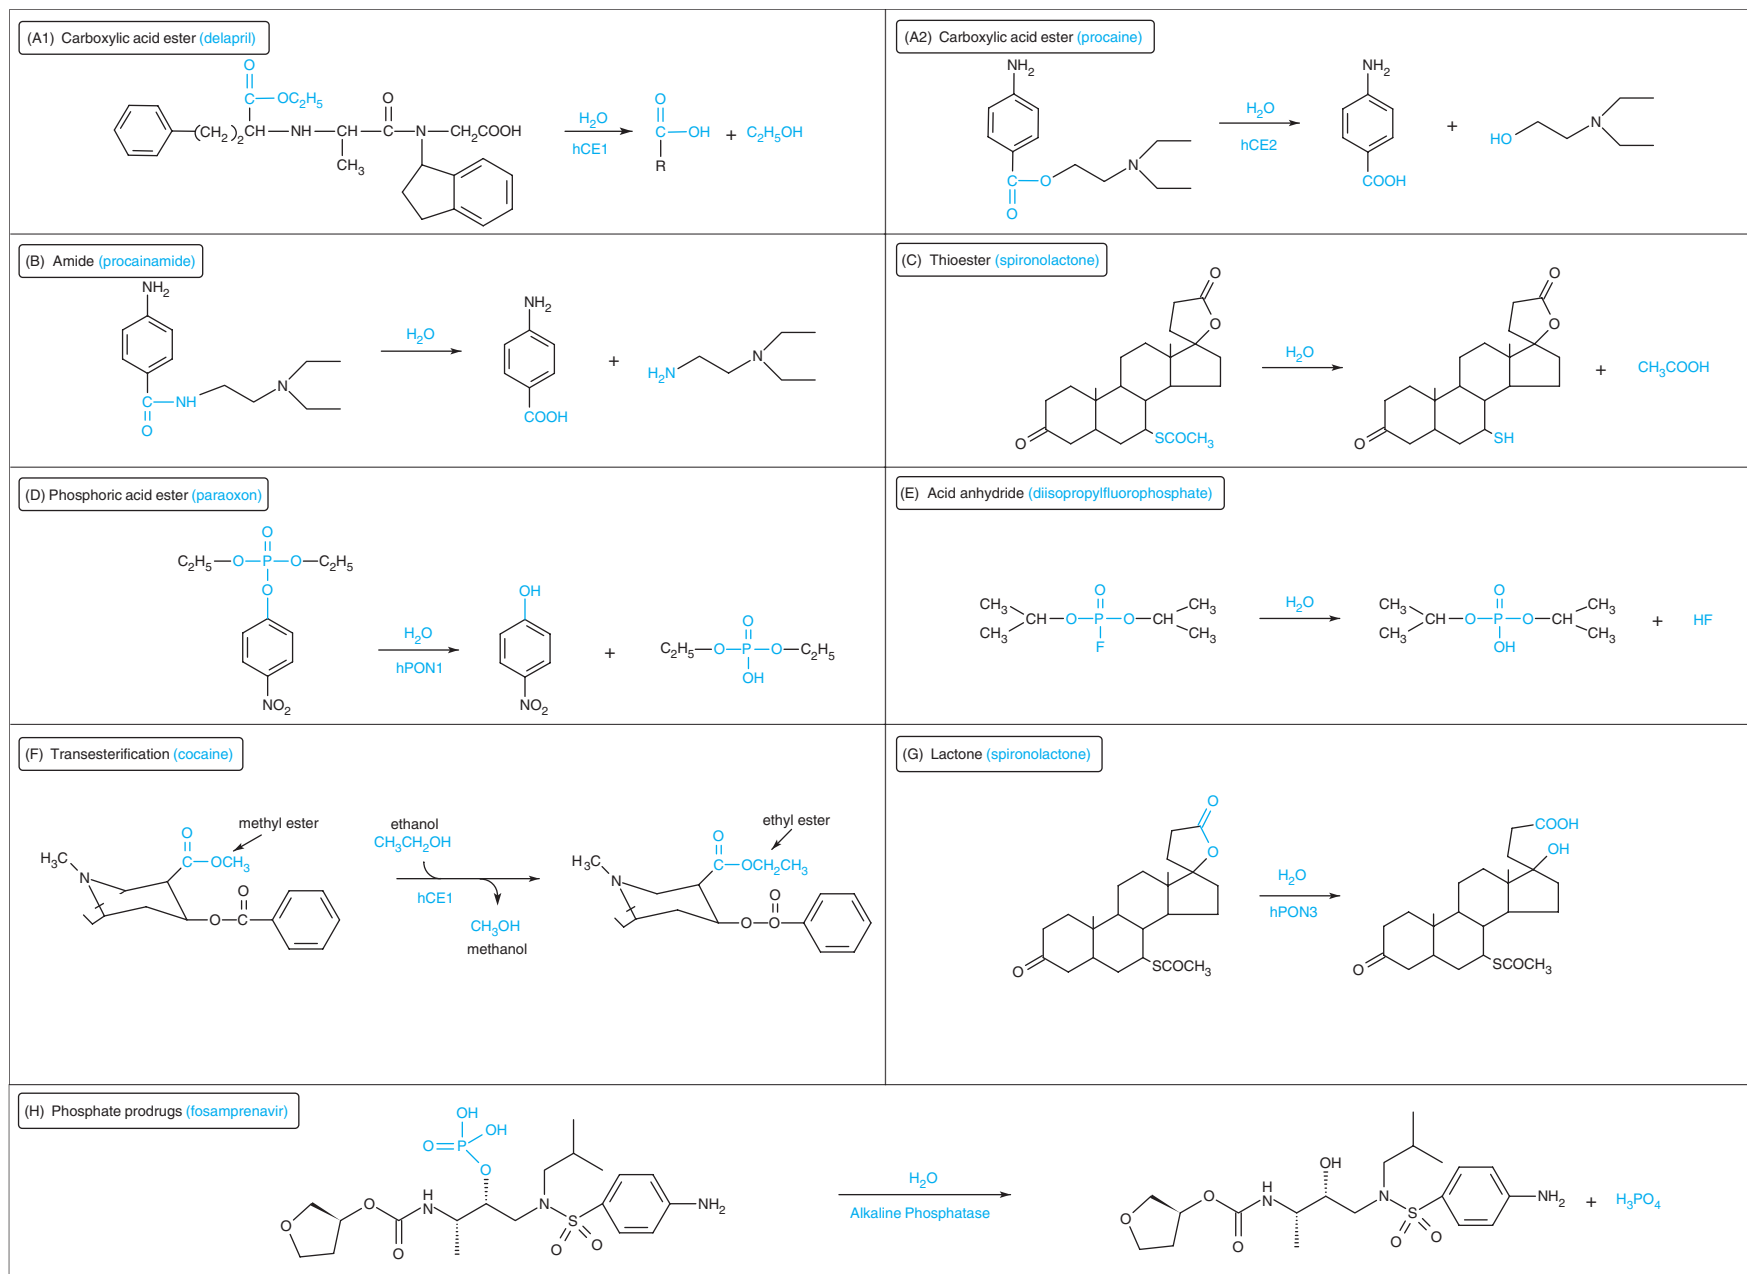
In the presence of an alcohol, carboxylesterases and certain other hydrolytic enzymes can catalyze the transesterification of xenobiotics, which accounts for the conversion of cocaine (a methyl ester) to ethylcocaine (the corresponding ethyl ester) (Fig. 6-4).


Figure 6-4. Examples of reactions catalyzed by carboxylesterases, cholinesterases, organophosphatases, and alkaline phosphatase. hCE1 and hCE2, human carboxylesterases 1 and 2; hPON1 and hPON3 (human) paraoxonase 1 and 3.

Transesterification occurs when ethanol, not water, cleaves the catalytic transition state, i.e., the esteratic bond between the active serine residue on the enzyme and the carbonyl group on the xenobiotic:

$$\text{Enzyme}-\text{O}-\text{CO}-\text{R} + \text{CH}_3\text{CH}_2\text{OH}$$
$$\rightarrow \text{Enzyme}-\text{OH} + \text{CH}_3\text{CH}_2-\text{O}-\text{CO}-\text{R}$$
Carboxylesterases in serum, liver, intestine, and other tissues and the cholinesterases in blood (and muscles depending on the route of xenobiotic exposure) collectively determine the duration and site of action of certain drugs. For example, procaine—a carboxylic acid ester—is rapidly hydrolyzed, which is why this drug is used mainly as a local anesthetic. In contrast, procainamide, the amide analog of procaine, is hydrolyzed much more slowly; hence, this drug reaches the systematic circulation, where it is useful in the treatment of cardiac arrhythmia. In general, enzymatic hydrolysis of amides occurs more slowly than esters, although electronic factors can influence the rate of hydrolysis. The presence of electron-withdrawing substituents weakens an amide bond, making it more susceptible to enzymatic hydrolysis.

The hydrolysis of xenobiotics by carboxylesterases and other hydrolytic enzymes is not always a detoxication process. Figure 6-5 shows some examples in which carboxylesterases convert xenobiotics to toxic and tumorigenic metabolites.

In 1953, Aldridge classified hydrolytic enzymes on the basis of their interaction with OP compounds, classifying those that hydrolyze OP compounds as A-esterases, those that are inhibited by OP compounds as B-esterases, and those that do not interact with OP compounds as C-esterases. Although the terms are still widely used, the classification system of Aldridge can be somewhat confusing because it divides the paraoxonases into the A- and C-esterase class (the human paraoxonase hPNO1 hydrolyzes OP compounds and so can be classified as an A-esterase, whereas hPON2 and hPON3 can be classified as C-esterases because they do not hydrolyze OP compounds, nor are they inhibited by them). Furthermore, carboxylesterases and cholinesterases, two distinct classes of hydrolytic enzymes, are both B-esterases according to Aldridge because both are inhibited by OP compounds.

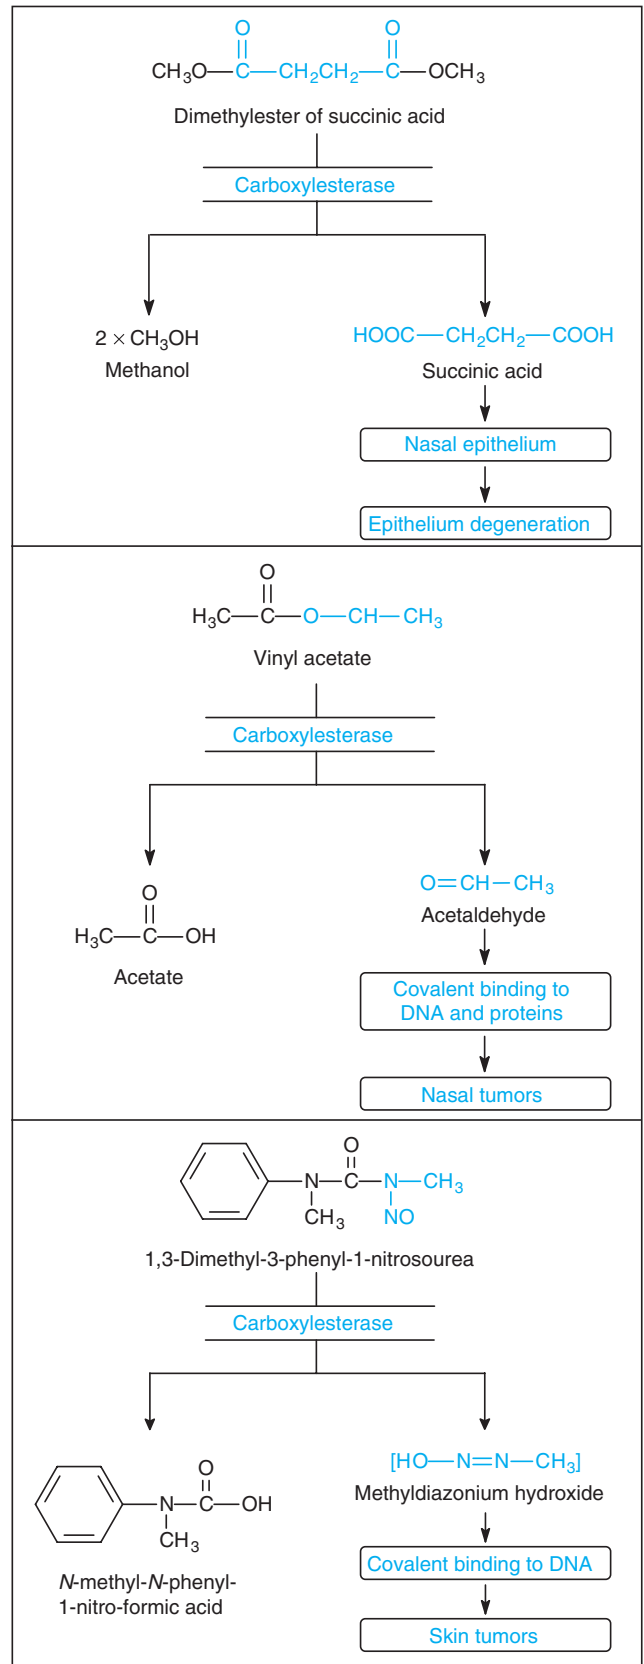
Carboxylesterases Carboxylesterases are ~60 kDa glycoproteins that are present in a wide variety of tissues, including serum. Most of the carboxylesterase activity in liver is associated with the endoplasmic reticulum, although considerable carboxylesterase activity is present in lysosomes and cytosol. Although by some estimates human liver and brain may express 5 and 30 carboxylesterases, respectively (Liederer and Borchardt, 2006), the hydrolysis of xenobiotic esters and amides in humans is largely catalyzed by just two carboxylesterases called hCE1 and hCE2. hCE1 mRNA is detected at very high levels in the liver, followed by the trachea and lung (at less than 10% of the level detected in the liver) (Nishimura and Naito, 2006). It is encoded by two genes, namely, CES1A1 and CES1A2, that differ only in the amino acid sequence of the encoded signal peptide, for which reason both genes are considered to encode the same enzyme, hCE1. The second human carboxylesterase, hCE2, is encoded by CES2A1, and is expressed to approximately the same extent in the liver and small intestine, followed by the colon and kidney (at less than half of the level detected in the liver) (Nishimura and Naito, 2006). In various mammalian species, carboxylesterases are found in the plasma, whereas human plasma does not contain carboxylesterases, meaning that


Figure 6-5. *Activation of xenobiotics to toxic and tumorigenic metabolites by carboxylesterases.*

butyrylcholinesterases and paraoxonases, not carboxylesterases, are responsible for the hydrolysis of amide and ester-containing compounds in the plasma (Satoh and Hosokawa, 2006). In rats, hydrolases A and B appear to be the counterparts of hCE1 and hCE2, respectively. The HUGO Gene Nomenclature Committee has officially approved gene names for CES1, 2, 3, 4, and 7 (http://www.gene.ucl.ac.uk/nomenclature/index.html), with CES1 and CES2 corresponding to hCE1 and hCE2. However, Satoh and Hosokawa (2006) have proposed that in all mammalian species, the carboxylesterases can be assigned to one of five gene families (designated CES 1–5) with three human genes in the first gene family (namely, CES1A1, 1A2, and 1A3), and a single member of the remaining families (i.e., CES2A1, 3A1, 4C1, and 5A1).

As illustrated in Fig. 6-4, hCE1 generally catalyzes the hydrolysis of xenobiotics with a small alcoholic leaving group (such as ethanol, as in the case of delapril) whereas hCE2 generally catalyzes the hydrolysis of xenobiotics with a small acidic or large alcoholic leaving group (as in the case of procaine), although there are xenobiotics that are hydrolyzed by both enzymes. hCE1 is more active than hCE2 at catalyzing the hydrolysis of numerous xenobiotics such as oseltamivir, benazepril, cilazepril, quinapril, temocapril, imidapril, meperidine, delapril, and clopidogrel, as well as the transesterification of the methyl esters of cocaine (Fig. 6-4), whereas hCE2 is more active than hCE1 at hydrolyzing aspirin, heroin, cocaine benzoyl ester, 6-acetylmorphine, oxybutynin, and the anticancer drug irinotecan (7-ethyl-10-[4-(1-piperidino)-1-piperidino]carbonyoxycamptothecin, also known as CPT-11) (Satoh and Hosokawa, 2006; Shi *et al.*, 2006; Tang *et al.*, 2006). The hydrolysis of irinotecan by hCE2 (and, to a much lesser extent, by hCE1) produces SN-38, a topoisomerase inhibitor that is responsible for both the anticancer effects of irinotecan and many of its side effects, especially diarrhea, which can be understood, at least in part, by the high levels of hCE2 in the intestine (Satoh *et al.*, 2002).

Genetic polymorphisms (single nucleotide polymorphisms or SNPs) have been described for hCE2, some of which appear to lower the rate of hydrolysis of irinotecan to SN-38 (Kubo *et al.*, 2005). Genetic polymorphisms have also been described for hCE1, but these are less likely to impair overall hCE1 because the enzyme is encoded by two genes. Therefore, a true hCE1 PM would only arise if genetic polymorphisms affected both alleles of both hCES1A1 and hCES1A2. A phenotype for hCE1 that might be classified as high extensive metabolizer has been described. It arises from a single nucleotide polymorphism in the promoter region of hCES1A2 (but not hCES1A1) that increases the expression of hCE1 and thereby increases the rate of hydrolysis of imidapril to its active metabolite imidaprilat, an angiotensin-converting enzyme (ACE) inhibitor, which increases its antihypertensive effect (Geshi *et al.*, 2005).

In addition to hydrolyzing xenobiotics, carboxylesterases hydrolyze numerous endogenous compounds, such as palmitoyl-CoA, monoacylglycerol, diacylglycerol, retinyl ester, platelet-activating factor, and other esterified lipids. Carboxylesterases can also catalyze the synthesis of fatty acid ethyl esters, which represents a nonoxidative pathway of ethanol metabolism in adipose and certain other tissues. In the case of platelet-activating factor, carboxylesterases catalyze both the deacetylation of PAF and its subsequent esterification with fatty acids to form phosphatidylcholine (Satoh and Hosokawa, 1998).

Certain carboxylesterases also have a physiologic function in anchoring other proteins to the endoplasmic reticulum. For example, the lysosomal enzyme β-glucuronidase is also present in the endoplasmic reticulum, where it is anchored in the lumen by egasyn,

a microsomal carboxylesterase related to hCE1. Egasyn binds to β-glucuronidase at its active site serine residue, which effectively abolishes the carboxylesterase activity of egasyn, although there is no corresponding loss of β-glucuronidase activity. Binding of OP compounds to egasyn causes the release of β-glucuronidase into plasma, which serves as the basis for a test for OP exposure (Fujikawa *et al.*, 2005). The retention of β-glucuronidase in the lumen of the ER is thought to be physiologically significant. Glucuronidation by microsomal UGTs is a major pathway in the clearance of many of the endogenous aglycones (such as bilirubin) and xenobiotics (such as drugs). However, hydrolysis of glucuronides by β-glucuronidase complexed with egasyn in the lumen of the ER appears to be an important mechanism for recycling endogenous compounds, such as steroid hormones (Dwivedi *et al.*, 1987). The acute-phase response protein, C-reactive protein, is similarly anchored in the endoplasmic reticulum by egasyn.

The mechanism of catalysis by carboxylesterases is analogous to the mechanism of catalysis by serine-proteases. In the case of carboxylesterases, it involves charge relay among a catalytic triad comprising an acidic amino acid residue (glutamate [Glu_{335}]), a basic residue (histidine [His_{448}]), and a nucleophilic residue (serine [Ser_{203}]) (Yan *et al.*, 1994; Satoh and Hosokawa, 1998). (These amino acid residues, numbered for a rat carboxylesterase, differ slightly in other species, but the overall location and function of these residues are the same in all mammalian carboxylesterases.) The mechanism of catalysis of carboxylesterases is shown in Fig. 6-6, and is discussed in more detail in the section on *Epoxide Hydrolase*. Organophosphorus compounds bind to the nucleophilic OH-group on the active site serine residue to form a phosphorus–oxygen bond, which is not readily cleaved by water. Therefore, OP compounds bind stoichiometrically to carboxylesterases and inhibit their enzymatic activity, for which reason they are also classified as B-esterases (Aldridge, 1953). Surprisingly, the stoichiometric binding of OP compounds to carboxylesterases is an important determinant of OP toxicity, as outlined in the following section on cholinesterases.

Cholinesterases (AChE and BChE)   Acetylcholinesterase (AChE) and butyrylcholinesterase (BChE, also known as pseudo-cholinesterase) are related enzymes. As the names imply, AChE and BChE have high activity toward acetylcholine and butyrylcholine (and propionylcholine), respectively. BChE can also hydrolyze bambuterol, chlorpropaine, cocaine, methylprednisolone acetate, heroin, isosorbide diaspirinate, mivacurium, procaine, succinylcholine, tetracaine, and other drugs. Eserine is an inhibitor of both enzymes, whereas BW284C51 is a selective inhibitor of AChE, and iso-OMPA is a selective inhibitor of BChE (Liederer and Borchardt, 2006). Drugs that selectively inhibit brain AChE and BChE activity, such as rivastigmine (Exelon®), have been used to treat Alzheimer's disease. Other drugs that inhibit AChE and are used to treat Alzheimer's disease include tacrine (Cognex®), gelantamine (Reminyl®), and donepezil (Aricept®).

Both enzymes exist in six different forms with differing solubility: monomer (G1), dimer (G2), tetramer (G4), tailed tetramers (A4), double tetramers (A8), and triple tetramers (A12). G1, G2, and G4 contain 1, 2, and 4 subunits, each with a catalytic site. These various forms can each exist in three states: soluble (hydrophilic), immobilized (asymmetric), and amphiphilic globular (membrane-bound through attachment to the phospholipid bilayer) (Nigg and Knaak, 2000). All forms are expressed in muscle. In the case of AChE, the

Figure 6-6. Catalytic cycle of microsomal carboxylesterase (left) and microsomal epoxide hydrolase (right), two α/β-hydrolase fold enzymes.

Based on measurements of erythrocyte AChE activity, familial reductions of 30% have been reported, and a reduction of 50% has been linked to paroxysmal nocturnal hemoglobinuria (Nigg and Knaak, 2000).

At least 10 genetic variants of BChE have been described following the discovery of PMs of succinylcholine. Succinylcholine is a muscle relaxant whose duration of action is determined by serum BChE. In some individuals (∼2% of Caucasians), succinylcholine causes prolonged muscular relaxation and apnea, which led to the discovery of a genetic variant of BChE ($Asp_{70} \rightarrow Gly_{70}$) (La Du, 1992; Lockridge, 1992). Although this allelozyme has markedly diminished activity toward succinylcholine (which is the genetic basis for the exaggerated response to this muscle relaxant in affected individuals), it nevertheless has appreciable activity toward other substrates, such as acetylcholine and benzoylcholine. The wild type and variant form of BChE are equally sensitive to the inhibitory effect of OP compounds, but the allelic variant is relatively resistant to the inhibitory effect of dibucaine, a local anesthetic, which forms the basis of a diagnostic test for its presence (frequently called a test for atypical pseudocholinesterase). The discovery of the BChE allelozyme (the so-called atypical pseudocholinesterase) is of historical interest because it ushered in the new field of pharmacogenetics. Since its initial discovery in the late 1950s, several allelic variants of BChE and many other xenobiotic-biotransforming enzymes have been identified (see Point 23).

Carboxylesterases and cholinesterases in the blood and tissues play an important role in limiting the amount of OP compounds that reaches AChE in the brain, inhibition of which is the mechanism of toxicity of OP pesticides (and carbamate insecticides), such that a 70–90% loss of AChE activity is lethal to mammals, insects, and nematodes. The symptoms of OP toxicity resemble those caused by excessive stimulation of cholinergic nerves. The covalent interaction between OP compounds and brain AChE is analogous to their binding to the active site serine residue in all serine esterases (B-esterases). As previously mentioned, certain OP compounds are hydrolyzed by A-esterases (the paraoxonases) but bind stoichiometrically and, for the most part, irreversibly to B-esterases (carboxylesterases and cholinesterases). Surprisingly, stoichiometric binding of OP compounds to carboxylesterase and cholinesterase (and perhaps to numerous other enzymes and receptors that have structural features common to serine esterases) plays an important role in limiting the toxicity of OP compounds. Numerous studies have shown an inverse relationship between serine esterase activity and susceptibility to the toxic effect of OP compounds. Factors that decrease serine esterase activity potentiate the toxic effects of OP compounds, whereas factors that increase serine esterase activity have a protective effect. For example, the susceptibility of animals to the toxicity of parathion, malathion, and diisopropylfluorophosphate (DFP) is inversely related to the level of serum esterase activity (which reflects both carboxylesterase and BChE activity). Differences in the susceptibility of several mammalian species to OP toxicity can be abolished by pretreatment with selective serine esterase inhibitors such as cresylbenzodioxaphosphorin oxide, the active metabolite of tri-*ortho*-tolylphosphate (which is also known as tri-*ortho*-cresylphosphate or TOCP). Esterases are not the only enzymes involved in the detoxication of OP pesticides. Certain OP compounds are detoxified by cytochrome P450, flavin monooxygenases, and glutathione transferases. However, paraoxonases, enzymes that catalyze the hydrolysis of certain OP compounds, appear to play only a minor role in determining susceptibility to OP toxicity, as outlined in the following section.

major form in brain is the tetramer G4 (anchored with a 20-kDa side chain containing fatty acids), but the major form in erythrocytes is the dimer G2 (anchored with a glycolipid-phosphatidylinositol side chain). In the case of BChE, the major form in serum is the tetramer G4 (a glycoprotein with Mr 342 kDa). In both AChE and BChE, the esteratic site (containing the active site serine residue) is adjacent to an anionic (negatively charged) site that interacts with the positively charged nitrogen on acetylcholine and butyrylcholine.

Genetic variants of AChE that severely impair its activity have not been described, which is not surprising given the key role that AChE plays in terminating neurotransmission by acetylcholine.

Paraoxonases (Lactonases)   Paraoxonases catalyze the hydrolysis of a broad range of organophosphates, organophosphinites, aromatic carboxylic acid esters, cyclic carbonates, and lactones. They are calcium-dependent enzymes containing a critical sulfhydryl (-SH) group; as such they are inhibited by EDTA, metal ions (Cu and Ba), and various mercurials such as phenylmercuric acetate (PMA) and *para*-chloromercuribenzoate (PCMB). Based on the observation that A-esterases are inhibited by PCMB but not OP compounds, Augustinsson (1966) postulated that, in the case of paraoxonases, OP compounds bind to a nucleophilic SH-group on an active site cysteine residue and form a phosphorus–sulfur bond, which is readily cleaved by water. A strong argument against this postulate is the fact that there is no loss of activity when the only potential active site cysteine residue in human paraoxonase (Cys283) is substituted with serine or alanine (Sorenson *et al.*, 1995). Paraoxonase requires Ca^{2+}, both for stability and catalytic activity, which raises the possibility that the hydrolysis of OP compounds by paraoxonase involves metal-catalyzed hydrolysis, analogous to that proposed for calcium-dependent phospholipase A2 or zinc-dependent phosphotriesterase activity (Sorenson *et al.*, 1995).

Humans express three paraoxonases designated hPON1, hPON2, and hPON3. hPON1 is present in liver microsomes and plasma, where it is associated exclusively with high-density lipoprotein (HDL). hPON2 is not present in plasma but it is expressed in several tissues. hPON3 is expressed in serum and liver and kidney microsomes. In addition to differences in tissue distribution, the three paraoxonases in mice respond differently to oxidative stress, which decreases PON1, increases PON3, and has no effect on PON2.

Only hPON1 has appreciable arylesterase activity and the ability to hydrolyze the toxic oxon metabolites of OP insecticides such as parathion, diazinon, and chlorpyrifos (Draganov and La Du, 2004). However, all three enzymes can catalyze the hydrolysis of various lactones, for which reason the name "lactonase" is more encompassing. They also catalyze the reverse reaction, i.e., the lactonization of hydroxy-carboxylic acids, as illustrated in Fig. 6-2. Hydrolysis and lactonization of statins, such a lovastatin and simvastatin, is catalyzed only by hPON3. Reports of the same reaction being catalyzed by hPON1 appear to be attributable to trace contamination with hPON3 (Draganov and La Du, 2004). The lactone dihydrocoumarin is the only substrate reported for hPON2.

There is evidence to suggest that hPON1 protects against atherosclerosis by hydrolyzing specific derivatives of oxidized cholesterol and/or phospholipids in atherosclerotic lesions and in oxidized low-density lipoprotein (LDL). For example, mice lacking PON1 (knockout mice or PON1 null mice) are predisposed to atherogenesis (Draganov and La Du, 2004). It has been suggested that PON1 has two active sites, one involved in hydrolytic reactions and the other involved in protecting LDL against oxidation. The ability of PON1 to protect LDL from copper-induced oxidation requires a cysteine residue at position 284 (which is *not* required for esteratic activity) but which does not require calcium (which *is* required for catalytic activity).

Based on its ability to hydrolyze OP compounds, it seems reasonable to assume that PON1 would play an important role in determining susceptibility to OP toxicity, but this may not be the case. PON1 knockout mice are no more susceptible than wild-type mice to the toxic effects of paraoxon (the active metabolite of parathion). However, it is possible that PON1 plays a larger role in limiting the toxicity of other OP compounds such as diazoxon and chlorpyrifos oxon because it hydrolyzes these oxons 10–20 times faster than it hydrolyzes paraoxon (Draganov and La Du, 2004).

hPON1 hydrolyzes the unsaturated cyclic carbonate prodrug prulifloxacin to its active metabolite NM394, and the rate of hydrolysis is influenced by a genetic polymorphism at amino acid 192. Whether this position is a glutamine or arginine residue affects the hydrolytic activity of hPON1 in a substrate-dependent manner, with some substrates being hydrolyzed faster by hPON1$_{192R}$, such as paraoxon, and others being hydrolyzed faster by hPON1$_{192Q}$, such as certain lactones. There is clinical evidence supporting—but also some excluding—a link between the hPON1$_{192R}$ genetic polymorphism and the development of cardiovascular disease, which is consistent with the decreased ability of this allelozyme to metabolize oxidized lipids (Draganov and La Du, 2004).

Diisopropylfluorophosphatase (DFPase), which catalyzes the release of fluoride from DFP, is a hydrolytic enzyme related to the paraoxonases. It hydrolyzes the nerve gas agents sarin and soman (Liederer and Borchardt, 2006).

Prodrugs and Alkaline Phosphatase   Many prodrugs are designed to be hydrolyzed by hydrolytic enzymes (reviewed by Liederer and Borchardt, 2006). Some prodrugs, such as propranolol ester, are hydrolyzed by both carboxylesterases and cholinesterases (both AChE and BChE), whereas others are preferentially or specifically hydrolyzed by carboxylesterases (capecitabine, irinotecan), BChE (bambuterol, methylprednisolone acetate), hPNO1 (prulifloxacin) or hPON3 (lovastatin, simvastatin). In some cases the prodrug is hydrolyzed by an enzyme that has yet to be fully characterized. For example, the hydrolysis of valacyclovir to the antiviral drug acyclovir is catalyzed by a human enzyme named valacyclovirase (genesymbol: BPHL). Some prodrugs are hydrolyzed with a high degree of stereoselectivity. For example, in the case of prodrugs of ibuprofen and flurbiprofen, the *R*-enantiomer is hydrolyzed about 50 times faster than the *S*-enantiomer.

Some prodrugs, such as fosphenytoin (Cerebyx®) and fosamprenavir (Lexiva®), are designed to be hydrolyzed by alkaline phosphatase, high concentrations of which are present on the luminal surface of the enterocytes lining the wall of the small intestine. Hydrolysis of these prodrugs by alkaline phosphatase releases the active drug at the surface of the enterocytes, where it can be readily absorbed.

As a result of their ability to hydrolyze prodrugs, hydrolytic enzymes may have clinical applications in the treatment of certain cancers. They might be used, for example, to activate prodrugs in vivo and thereby generate potent anticancer agents in highly selected target sites (e.g., at the surface of tumor cells, or inside the tumor cells themselves). For example, carboxylesterases might be targeted to tumor sites with hybrid monoclonal antibodies (i.e., bifunctional antibodies that recognize the carboxylesterase and the tumor cell), or the cDNA encoding a carboxylesterase might be targeted to the tumor cells via a viral vector. In the case of irinotecan, this therapeutic strategy would release the anticancer drug SN-38 in the vicinity of the tumor cells, which would reduce the systemic levels and side effects of this otherwise highly toxic drug (Senter *et al.*, 1996). Some prodrugs, such as capecitabine, are activated by hydrolytic enzymes in the tumors themselves. There is evidence to suggest that, by hydrolyzing SN-38-glucuronide (a metabolite of the anticancer drug irinotecan), β-glucuronidase in colonic tumor cells may play a role in exposing such tumors to the topoisomerase inhibitor SN-38 (Tobin *et al.*, 2006).

Peptidases   With the advent of recombinant DNA technology, numerous human peptides have been mass-produced for use as therapeutic agents, and several recombinant peptide hormones, growth factors, cytokines, soluble receptors, and humanized monoclonal antibodies currently are used clinically. To avoid acid-precipitation and proteolytic degradation in the gastrointestinal tract, peptides are administered parenterally. Nevertheless, peptides are hydrolyzed in the blood and tissues by a variety of peptidases, including aminopeptidases and carboxypeptidases, which hydrolyze amino acids at the N- and C-terminus, respectively, and endopeptidases, which cleave peptides at specific internal sites (trypsin, for example, cleaves peptides on the C-terminal side of arginine or lysine residues) (Humphrey and Ringrose, 1986). Peptidases cleave the amide linkage between adjacent amino acids, hence, they function as amidases. As in the case of carboxylesterases, the active site of peptidases contains either a serine or cysteine residue, which initiates a nucleophilic attack on the carbonyl moiety of the amide bond. As previously noted, the mechanism of catalysis by serine proteases, such as chymotrypsin, is similar to that by serine esterases (B-esterases).

Epoxide Hydrolases   Epoxide hydrolases catalyze the *trans*-addition of water to alkene epoxides and arene oxides (oxiranes), which can form during the cytochrome P450-dependent oxidation of aliphatic alkenes and aromatic hydrocarbons, respectively. As shown in Fig. 6-7, the products of this hydrolysis are vicinal diols with a *trans*-configuration (i.e., *trans*-1,2-dihydrodiols); a notable exception being the conversion of leukotriene A4 (LTA4) to leukotriene B4 (LTB4), in which case the two hydroxyl groups that result from epoxide hydrolysis appear on nonadjacent carbon atoms. Epoxide hydrolases play an important role in detoxifying electrophilic epoxides that might otherwise bind to proteins and nucleic acids and cause cellular toxicity and genetic mutations. Although the levels vary from one tissue to the next, epoxide hydrolase has been found in the microsomal fraction of virtually all tissues, including the liver, testis, ovary, lung, kidney, skin, intestine, colon, spleen, thymus, brain, and heart.

There are five distinct forms of epoxide hydrolase in mammals: microsomal epoxide hydrolase (mEH, which is the product of the gene EPHX1), soluble epoxide hydrolase (the gene product of EPHX2), cholesterol epoxide hydrolase, leukotriene A4 (LTA4, the gene product of LTA4H) hydrolase, and hepoxilin hydrolase (Fretland and Omiecinski, 2000; Morisseau and Hammock, 2005).
As their names imply, the latter three enzymes appear to hydrolyze endogenous epoxides exclusively, and have virtually no capacity to detoxify xenobiotic oxides. LTA4 hydrolase is distinct from the other epoxide hydrolases because it is a bifunctional zinc metalloenzyme that has both epoxide hydrolase and peptidase activity, and because the two hydroxyl groups introduced during the conversion of LTA4 to LTB4 are eight carbon atoms apart.

In contrast to the high degree of substrate specificity displayed by the cholesterol, LTA4 and hepoxilin epoxide hydrolases, mEH hydrolyzes a wide variety of xenobiotics with an alkene epoxide or arene oxide. sEH hydrolyzes some xenobiotic epoxides and oxides, such a *trans*-stilbene oxide, but it also plays an important role in the hydrolysis of endogenous fatty acid epoxides, such as the epoxyeicosatrienoic acids (EETs) that are formed by epoxidation of arachidonic acid by cytochrome P450 and the leukotoxins that are formed by the epoxidation of linoleic acid by leukocytes (Fretland and Omiecinski, 2000; Morisseau and Hammock, 2005).

In the case of EETs, hydrolysis by sEH terminates their vasodilatory effects. Male sEH knockout mice (sEH null mice) have significantly lower blood pressure than wild-type mice, supporting the important role of sEH in EET hydrolysis (and the important vasodilatory effects of EETs), and supporting the notion that inhibitors of sEH might be useful in the treatment of hypertension. In the case of leukotoxins, hydrolysis by sEH can be considered an activation process because it produces diols that perturb membrane permeability and calcium homeostasis, which results in vascular inflammation and cardio-pulmonary toxicity, including acute respiratory distress syndrome (ARDS) and multiple organ failure (Morisseau and Hammock, 2005).

In general, mEH prefers mono-substituted epoxides and di-substituted epoxides with a *cis* configuration, such as *cis*-stilbene oxide, whereas sEH prefers tetra- and tri-substituted epoxides and di-substituted epoxides with a *gem* configuration (both substituents on the same carbon atom) or the *trans* configuration, such as *trans*-stilbene oxide, as shown in Fig. 6-8. In rodents, sEH and mEH are both inducible enzymes; sEH is under the control of PPARα, so it is induced following treatment of rats and mice with peroxisome

Figure 6-7. Examples of the hydrolation of an alkene epoxide (top) and an arene oxide (bottom) by epoxide hydrolase.
Figure 6-8. Stereoselective hydrolation of stilbene oxide by microsomal and soluble epoxide hydrolase.

proliferators, whereas mEH is under the control of Nrf2, so it is induced in response to oxidative stress or exposure to electrophiles and glutathione depletors (see section "Quinone Reduction—NQO1 and NQO2"). Treatment of mice with the CAR agonist phenobarbital induces mEH about two- to threefold, whereas treatment with Nrf2 activators such as butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA), and ethoxyquin induces mEH by an order of magnitude or more.

Many epoxides and oxides are intermediary metabolites formed during the cytochrome P450-dependent oxidation of unsaturated aliphatic and aromatic xenobiotics. These electrophilic metabolites might otherwise bind to proteins and nucleic acids and cause cellular toxicity and genetic mutations. In general, sEH and mEH are found in the same tissues and cell types that contain cytochrome P450. For example, the distribution of epoxide hydrolase parallels that of cytochrome P450 in liver, lung, and testis. In other words, both enzymes are located in the centrilobular region of the liver (zone 3), in Clara and type II cells in the lung, and in Leydig cells in the testis. The co-localization of epoxide hydrolase and cytochrome P450 presumably ensures the rapid detoxication of alkene epoxides and arene oxides generated during the oxidative metabolism of xenobiotics.

Electrophilic epoxides and arene oxides are constantly produced during the cytochrome P450-dependent oxidation of unsaturated aliphatic and aromatic xenobiotics, and are highly reactive to cellular macromolecules such as DNA and protein. Epoxide hydrolase can rapidly convert these potentially toxic metabolites to the corresponding dihydrodiols, which are less reactive and easier to excrete. Thus, epoxide hydrolases are widely considered as a group of detoxication enzymes. In some cases, however, further oxidation of a dihydrodiol can lead to the formation of diol epoxide derivatives that are no longer substrates for epoxide hydrolase because the oxirane ring is protected by bulky substituents that sterically hinder interaction with the enzyme. This point proved to be extremely important in elucidating the mechanism by which polycyclic aromatic hydrocarbons cause tumors in laboratory animals (Conney, 1982). Tumorigenic polycyclic aromatic hydrocarbons, such as benzo[a]pyrene, are converted by cytochrome P450 to a variety of arene oxides that bind covalently to DNA, making them highly mutagenic to bacteria. One of the major arene oxides formed from benzo[a]pyrene, namely, the 4,5-oxide, is highly mutagenic to bacteria but weakly mutagenic to mammalian cells. This discrepancy reflects the rapid inactivation of benzo[a]pyrene 4,5-oxide by epoxide hydrolase in mammalian cells. However, one of the arene oxides formed from benzo[a]pyrene, namely, benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide, is not a substrate for epoxide hydrolase and is highly mutagenic to mammalian cells and considerably more potent than benzo[a]pyrene as a lung tumorigen in mice.

Benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide is known as a bay-region diolepoxide, and analogous bay-region diolepoxides are now recognized as tumorigenic metabolites of numerous polycyclic aromatic hydrocarbons. A feature common to all bay-region epoxides is their resistance to hydrolyation by epoxide hydrolase, which results from steric hindrance from the nearby dihydrodiol group. As shown in Fig. 6-9, benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide is formed in three steps: Benzo[a]pyrene is converted to the 7,8-oxide, which is converted to the 7,8-dihydrodiol, which is converted to the corresponding 9,10-epoxide. The first and third steps are epoxidation reactions catalyzed by cytochrome P450 or prostaglandin H synthase, but the second step is catalyzed by epoxide hydrolase. Consequently, even though epoxide hydrolase plays a major role in detoxifying several benzo[a]pyrene oxides, such as the 4,5-oxide, it nevertheless plays a role in converting benzo[a]pyrene to its ultimate tumorigenic metabolite, benzo[a]pyrene 7,8-dihydrodiol-9,10-oxide.

The importance of mEH in the conversion of polycyclic aromatic hydrocarbons to their ultimate carcinogenic metabolites, namely, diol-epoxides, is illustrated by the observation that mEH knockout mice (mEH-null mice) are less sensitive than wild-type mice to the tumorigenic effects of 7,12-dimethylbenz[a]anthracene (DMBA) (Fretland and Omiecinski, 2000; Morisseau and Hammock, 2005).

Not all epoxides are highly reactive and toxic to the cells that produce them. The major metabolite of carbamazepine is an epoxide, which is so stable that carbamazepine 10,11-epoxide is a major circulating metabolite in patients treated with this antiepileptic drug. (Carbamazepine is converted to a second epoxide, which is less stable and more cytotoxic, as shown in the section on *Cytochrome P450.*) Vitamin K epoxide is also a nontoxic epoxide, which is formed and consumed during the vitamin K-dependent γ-carboxylation of prothrombin and other clotting factors in the liver. Vitamin K epoxide is not hydrated by epoxide hydrolase but is reduced by vitamin K epoxide reductase. This enzyme is inhibited by warfarin and related coumarin anticoagulants, which interrupts the synthesis of several clotting factors. Some drugs actually contain an epoxide, such as scopolamine and tiotropium.

Epoxide hydrolase is one of several proteins (so-called preneoplastic antigens) that are overexpressed in chemically induced foci and nodules that eventually develop into liver tumors. Several alcohols, ketones, and imidazoles stimulate microsomal epoxide hydrolase activity in vitro. Epoxide hydrolase cannot be inhibited by antibodies raised against the purified enzyme, but it can be inhibited by certain epoxides, such as 1,1,1-trichloropropene oxide and cyclohexene oxide, and certain drugs, such as valpromide (the amide analog of valproic acid) and progabide, a γ-aminobutyric acid (GABA) agonist. These latter two drugs potentiate the neurotoxicity of carbamazepine by inhibiting epoxide hydrolase, leading to increased plasma levels of carbamazepine 10,11-epoxide and presumably the more toxic 2,3-epoxide (Kroetz *et al*., 1993). Several genetic polymorphisms have been identified in the coding region and the 5′ region (i.e., the regulatory region) of the gene encoding human mEH (Daly, 1999). Two variants involve substitutions at amino acid 113 (Tyr → His) or amino acid 139 (His → Arg), which are encoded by exons 3 and 4, respectively. Although these allelic variant forms of mEH have near-normal enzymatic activity (at least 65% of normal), they appear to be less stable than the wild-type enzyme. The possibility that these amino acid substitutions might predispose individuals to the adverse effects of antiepileptic drugs has been examined, but no such association was found (Daly, 1999). More recently, a case was reported of a man who had a defect in mEH expression and suffered acute and severe phenytoin toxicity (Morisseau and Hammock, 2005).

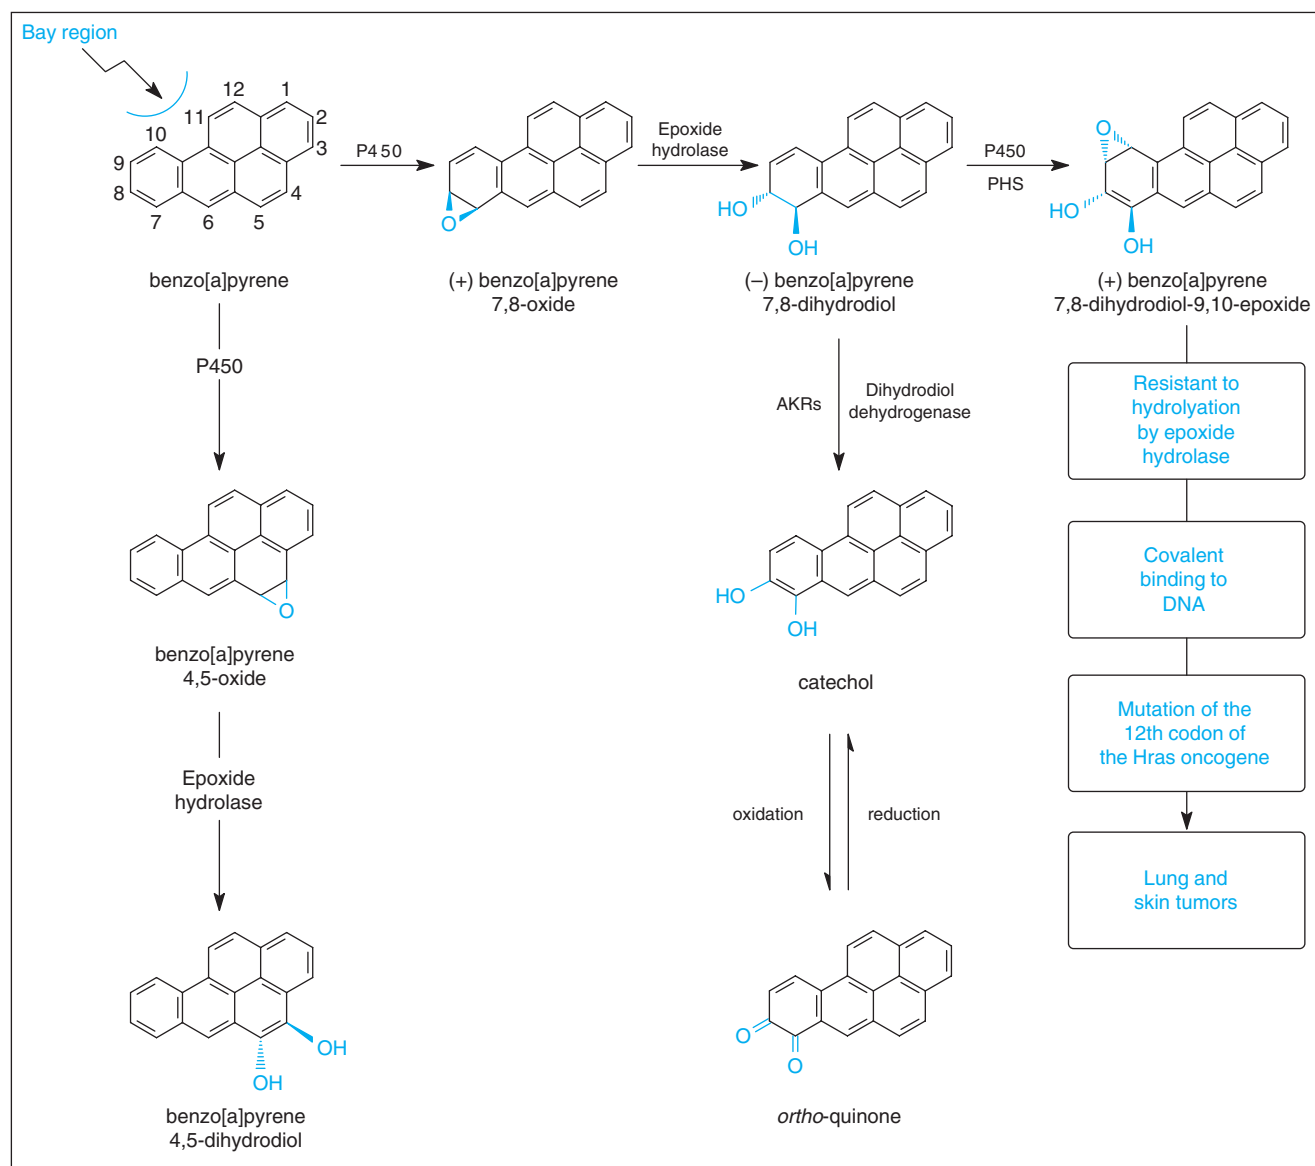
The microsomal and soluble forms of epoxide hydrolase show no evident sequence identity and, accordingly, are immunochemically distinct proteins (Beetham *et al*., 1995). Nevertheless, mEH and sEH catalyze reactions by the same mechanism, and similar amino acids are involved in catalysis, namely, a nucleophilic acid (Asp_{226} in mEH and Asp_{334} in sEH), a basic histidine (His_{431} in mEH and His_{523} in sEH), an orienting acid (Glu_{404} in mEH and Asp_{495} in sEH) and polarizing tyrosine residues (Tyr_{299} and Tyr_{374} in mEH and Tyr_{382} and Tyr_{465} in mEH) (Morisseau and Hammock, 2005). The mechanism of catalysis by epoxide hydrolase is similar to that of carboxylesterase, in that the catalytic site comprises


Figure 6-9. *Role of epoxide hydrolase in the inactivation of benzo[a]pyrene 4,5-oxide and in the conversion of benzo[a]pyrene to its tumorigenic bay-region diolepoxide. Also shown is the role of dihydrodiol dehydrogenase, a member of the aldo–keto reductase (AKR) superfamily, in the formation of reactive catechol and ortho-quinone metabolites of benzo[a]pyrene.*

three amino acid residues that form a catalytic triad, as shown in Fig. 6-6. The attack of the nucleophile Asp_{226} on the carbon of the oxirane ring initiates enzymatic activity, leading to the formation of an α-hydroxyester–enzyme intermediate, with the negative charge developing on the oxygen atom stabilized by a putative oxyanion hole. The His_{431} residue (which is activated by Glu_{376} and Glu_{404}) activates a water molecule by abstracting a proton (H^+). The activated (nucleophilic) water then attacks the $C\gamma$ atom of Asp_{226}, resulting in the hydrolysis of the ester bond in the acyl–enzyme intermediate, which restores the active enzyme and results in formation of a vicinal diol with a trans-configuration (Armstrong, 1999). The second step, namely, cleavage of the ester bond in the acyl–enzyme intermediate, resembles the cleavage of the ester or amide bond in substrates for serine esterases and proteases.

Although epoxide hydrolase and carboxylesterase both have a catalytic triad comprising a nucleophilic, basic, and acidic amino

acid residue, there are striking differences in their catalytic machinery, which account for the fact that carboxylesterases primarily hydrolyze esters and amides, whereas epoxide hydrolases primarily hydrolyze epoxides and oxides. In the triad, both enzymes have histidine as the base and either glutamate or aspartate as the acid, but they differ in the type of amino acids for the nucleophile. Even during catalysis, there is a major difference. In carboxylesterases, the same carbonyl carbon atom of the substrate is attacked initially by the nucleophile Ser_{203} to form an α-hydroxyester-enzyme ester that is subsequently attacked by the activated water to release the alcohol product. In contrast, two different atoms in epoxide hydrolase are targets of nucleophilic attacks. First the less hindered carbon atom of the oxirane ring is attacked by the nucleophile Asp_{226} to form a covalently bound ester, and next this ester is hydrolyzed by an activated water molecule that attacks the $C\gamma$ atom of the Asp_{226} residue, as illustrated in Fig. 6-6. Therefore, in carboxylesterase,
Figure 6-10. *Examples of drugs that undergo azo reduction (prontosil) and nitro reduction (chloramphenicol and nitrobenzene).*

the oxygen introduced to the product is derived from the activated water molecule. In contrast, in epoxide hydrolase, the oxygen introduced to the product is derived from the nucleophile Asp$_{226}$ (Fig. 6-6).

Carboxylesterases and epoxide hydrolases exhibit no primary sequence identity, but they share surprising similarities in the topology of the structure and sequential arrangement of the catalytic triad. Both are members of the α/β-hydrolase fold enzymes, a superfamily of proteins that include lipases, esterases, and haloalkane dehydrogenases (Beetham *et al.*, 1995). Functionally, proteins in this superfamily all catalyze hydrolytic reactions; structurally, they all contain a similar core segment that is composed of eight β-sheets connected by α-helices. They all have a catalytic triad and the arrangement of the amino acid residues in the triad (i.e., the order of the nucleophile, the acid, and the base in the primary sequence) is the mirror image of the arrangement in other hydrolytic enzymes such as trypsin. All three active-site residues are located on loops that are the best conserved structural features in the fold, which likely provides catalysis with certain flexibility to hydrolyze numerous structurally distinct substrates.

Reduction

Certain metals (e.g., pentavalent arsenic) and xenobiotics containing an aldehyde, ketone, alkene, disulfide, sulfoxide, quinone, *N*-oxide, hydroxamic acid, amidoxime, isoxazole, isothiazole, azo, or nitro group are often reduced in vivo, although it is sometimes difficult to ascertain whether the reaction proceeds enzymatically or nonenzymatically by interaction with reducing agents (such as the reduced forms of glutathione, FAD, FMN, and NAD[P]). Some of these functional groups can be either reduced or oxidized. For example, aldehydes (R–CHO) can be reduced to an alcohol (R–CH$_2$OH) or oxidized to a carboxylic acid (R–COOH), whereas sulfoxides (R$_1$–SO–R$_2$) can be reduced to a sulfide (R$_1$–S–R$_2$) or oxidized to a sulfone (R$_1$–SO$_2$–R$_2$). Likewise, some enzymes, such as alcohol dehydrogenase, aldehyde oxidase, and cytochrome P450, can catalyze both reductive and oxidative reactions depending on the substrate or conditions. In the case of halogenated hydrocarbons, such as halothane, dehalogenation can proceed by an oxidative or reductive pathway, both of which are catalyzed by the same enzyme (namely, cytochrome P450). In some cases, such as azo-reduction, nitro-reduction, and the reduction of certain alkenes, the reaction is largely catalyzed by intestinal microflora.

Azo- and Nitro-Reduction   Prontosil and chloramphenicol are examples of drugs that undergo azo- and nitro-reduction, respectively, as shown in Fig. 6-10. Reduction of prontosil is of historical interest. Treatment of streptococcal and pneumococcal infections with prontosil marked the beginning of specific antibacterial chemotherapy. Subsequently, it was discovered that the active drug was not prontosil but its metabolite, sulfanilamide (*para*-aminobenzene sulfonamide), a product of azo-reduction. During azo-reduction, the nitrogen–nitrogen double bond is sequentially reduced and cleaved to produce two primary amines, a reaction requiring four reducing equivalents. Nitro-reduction requires six reducing equivalents,
Figure 6-11. Role of nitro reduction by intestinal microflora in the activation of the rat liver tumorigen, 2,6-dinitrotoluene.

which are consumed in three sequential reactions, as shown in Fig. 6-10 for the conversion of nitrobenzene to aniline.

Azo- and nitro-reduction reactions are generally catalyzed by intestinal microflora. However, under certain conditions, such as low oxygen tension, the reactions can be catalyzed by liver microsomal cytochrome P450 and NAD(P)H-quinone oxidoreductase (NQO1, a cytosolic flavoprotein that is also known as DT-diaphorase) and, in the case of nitroaromatics, by cytosolic aldehyde oxidase. The anaerobic environment of the lower gastrointestinal tract is well suited for azo- and nitro-reduction, which is why intestinal microflora contribute significantly to these reactions. The reduction of quinic acid to benzoic acid is another example of a reductive reaction catalyzed by gut microflora, as shown in Fig. 6-1.

Nitro-reduction by intestinal microflora is thought to play an important role in the toxicity of several nitroaromatic compounds including 2,6-dinitrotoluene, which is hepatotumorigenic to male rats. The role of nitro-reduction in the metabolic activation of 2,6-dinitrotoluene is shown in Fig. 6-11 (Long and Rickert, 1982; Mirsalis and Butterworth, 1982). The biotransformation of 2,6-dinitrotoluene begins in the liver, where it is oxidized by cytochrome P450 and conjugated with glucuronic acid. This glucuronide is excreted in bile and undergoes biotransformation by intestinal microflora. One or both of the nitro groups are reduced to amines by nitroreductase, and the glucuronide is hydrolyzed by β-glucuronidase. The deconjugated metabolites are absorbed and transported to the liver, where the newly formed amine group is

N-hydroxylated by cytochrome P450 and conjugated with acetate or sulfonate. These conjugates form good leaving groups, which renders the nitrogen highly susceptible to nucleophilic attack from proteins and DNA; this ostensibly leads to mutations and the formation of liver tumors. The complexity of the metabolic scheme shown in Fig. 6-11 underscores an important principle, namely, that the activation of some chemical tumorigens to DNA-reactive metabolites involves several different biotransforming enzymes and may take place in more than one tissue. Consequently, the ability of 2,6-dinitrotoluene to bind to DNA and cause mutations is not revealed in most of the short-term assays for assessing the genotoxic potential of chemical agents. These in vitro assays for genotoxicity do not make allowance for biotransformation by intestinal microflora or, in some cases, the conjugating enzymes.

Nitro-reduction by intestinal microflora also plays an important role in the biotransformation of musk xylene (1,3,5-trinitro-2-*t*butyl-4,6-dimethylbenzene). Reduction of one or both of the nitro groups is required for musk xylene to induce (as well as markedly inhibit) liver microsomal cytochrome P450 (namely, CYP2B) in rodents (Lehman-McKeeman *et al.*, 1999).

Carbonyl Reduction—SDRs and AKRs A variety of xenobiotics contain a carbonyl function (R–CHO and R_1–CO–R_2) that undergoes reduction in vivo. The reduction of aldehydes to primary alcohols and of ketones to secondary alcohols is generally
Figure 6-12. Reduction of xenobiotics by carbonyl reductase (A) and alcohol dehydrogenase (B).

catalyzed in mammals by NAD(P)H-dependent reductases belonging to one of two superfamilies, the aldo–keto reductases (AKRs), and the short-chain dehydrogenases/reductases (SDRs), as shown in Table 6-5 (Jez and Penning, 2001; Oppermann *et al*., 2001; Matsunaga *et al*., 2006). Humans contain 39 SDR members, two of which, namely, cytosolic and microsomal carbonyl reductase, play a role in the reduction of a wide variety of carbonyl-containing xenobiotics (other species express more than two carbonyl reductases). Erythrocytes also contain carbonyl reductase, which contributes significantly to the reduction of haloperidol, as shown in Fig. 6-12. From the alternative names given in Table 6-5, it is apparent that the cytosolic and microsomal carbonyl reductases have both been studied for their role in endobiotic metabolism, namely, the reduction of prostaglandin derivatives and 11β-hydroxysteroids, respectively. The AKRs are members of a superfamily of cytosolic enzymes that reduce both xenobiotic and endobiotic compounds, as their alternative names imply (Table 6-5). Various members of the AKR superfamily can function as dihydrodiol dehydrogenases and oxidize the *trans*-dihydrodiols of various polycyclic aromatic hydrocarbon oxiranes (formed by epoxide hydrolase) to the corresponding *ortho*-quinones, as shown previously in Fig. 6-9. The role of AKR as an oxidizing enzyme is discussed in the section on oxidative enzymes (see section "Dihydrodiol Dehydrogenase"). As mentioned earlier (see Point 8), one of the AKRs, namely, AKR7A (also known as aflatoxin aldehyde reductase) is one of the many enzymes induced following activation of Nrf2 by oxidative stress, exposure to electrophiles, or depletion of glutathione.

In certain cases, the reduction of aldehydes to alcohols can be catalyzed by alcohol dehydrogenase, as shown in Fig. 6-12

for the conversion of the sedative-hypnotic, chloral hydrate, to trichloroethanol. As shown in Table 6-5, alcohol dehydrogenases belong to the medium chain dehydrogenases/reductases (MDRs). They typically convert alcohols to aldehydes, for which reason they are discussed later in the section on oxidative reactions (see section "Alcohol Dehydrogenases"). In the case of chloral hydrate, the reverse reaction is favored by the presence of the trichloromethyl group, which is a strong electron-withdrawing group.

The SDR carbonyl reductases are monomeric, NADPH-dependent enzymes present in erythrocytes and both the cytosolic and microsomal fraction of the liver, kidney, brain, and many other tissues. The major circulating metabolite of the antipsychotic drug, haloperidol, is a secondary alcohol formed by carbonyl reductases in the blood and liver, as shown in Fig. 6-12. Other xenobiotics that are reduced by carbonyl reductases include pentoxifylline (see Fig. 6-2), acetohexamide, daunorubicin, doxorubicin, loxoprofen, menadione, 4-nitroacetophenone, timiperone, and *R*-warfarin (Rosemond and Walsh, 2004). As shown in Fig. 6-2, the reduction of ketones to secondary alcohols by carbonyl reductases may proceed with a high degree of stereoselectivity, as in the case of pentoxifylline (Lillibridge *et al*., 1996).

Liver cytosol and microsomes contain different forms of carbonyl reductase, and these can differ in the degree to which they stereoselectively reduce ketones to secondary alcohols. For example, keto-reduction of pentoxifylline produces two enantiomeric secondary alcohols: one with the *R*-configuration (which is known as lisofylline) and one with the *S*-configuration, as shown in Fig. 6-2. Reduction of pentoxifylline by cytosolic carbonyl reductase results in the stereospecific formation of the optical antipode of lisofylline, whereas the same reaction catalyzed by microsomal

Table 6-5
Human Aldo–Keto Reductases (AKRs), Short-Chain Dehydrogenases/Reductases (SDRs), Medium-Chain Dehydrogenases/Reductases (MDRs), and Quinone Reductases (NQOs)

ENZYME SUPERFAMILY	EXAMPLE ENZYMES	ALTERNATIVE NAMES	SUBCELLULAR LOCALIZATION
Aldo–keto reductase (AKR) 13 enzymes	AKR1A1	Aldehyde reductase	Cytosol
	AKR1B1	Aldose reductase	Cytosol

NQO 2 enzymes	NQO1	DT diaphorase, menadione reductase	Cytosol
	NQO2	N-Ribosyldihydronicotinamide dehydrogenase	Cytosol

NQO, NADPH-Quinone oxidoreducta2e.

carbonyl reductase produces both lisofylline and its optical antipode in a ratio of about 1 to 5 (Lillibridge *et al.*, 1996).

In rat liver cytosol, the reduction of quinones is primarily catalyzed by NQO1 and NQO2 (see section "Quinone Reduction—NQO1 and NQO2"), whereas in human liver cytosol, quinone reduction is catalyzed by both NQO and carbonyl reductases.

Various members of the AKR superfamily have been implicated in the reduction of such carbonyl-containing xenobiotics as the tobacco-specific nitrosamine NNK, acetohexamide, daunorubicin, naloxone, naltrexone, befunolol, ethacrynic acid, ketoprofen, ketotifen, haloperidol, loxoprofen, metyrapone, oxo-nortyptyline, and numerous aromatic and aliphatic aldehydes (Rosemond and Walsh, 2004). Many of the xenobiotics reduced by AKRs and also reduced by SDRs, and in most cases the relative contribution of individual carbonyl-reducing enzymes is not known. Genetic polymorphisms of AKRs or SDRs have not been shown to impact the disposition or safety of carbonyl-containing drugs, and there appear to be no reports of drug–drug interactions involving the inhibition or induction of AKRs or SDRs (Rosemond and Walsh, 2004).

Disulfide Reduction   Some disulfides are reduced and cleaved to their sulfhydryl components, as shown in Fig. 6-13 for the alcohol deterrent, disulfiram (Antabuse). As shown in Fig. 6-13, disulfide reduction by glutathione is a three-step process, the last of which is catalyzed by glutathione reductase. The first steps can be catalyzed by glutathione transferase, or they can occur nonenzymatically.

Sulfoxide and *N*-Oxide Reduction   Thioredoxin-dependent enzymes in liver and kidney cytosol have been reported to reduce sulfoxides, which themselves may be formed by cytochrome P450 or flavin monooxygenases (Anders *et al.*, 1981). It has been suggested that recycling through these counteracting enzyme systems may prolong the half-life of certain xenobiotics. Sulindac is a sulfoxide that undergoes reduction to a sulfide, which is excreted in bile and reabsorbed from the intestine (Ratnayake *et al.*, 1981). This enterohepatic cycling prolongs the duration of action of the drug such that this nonsteroidal anti-inflammatory drug (NSAID) need only be taken twice daily.

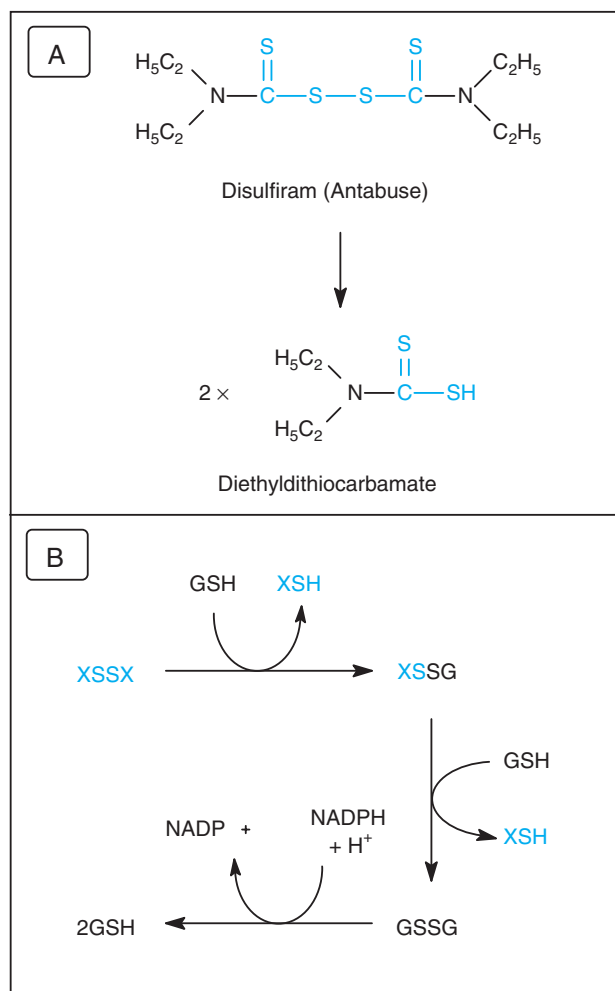
Sulfoxide reduction may also occur nonenzymatically at an appreciable rate, as in the case of the proton pump inhibitor rabeprazole (Miura *et al.*, 2006). Diethyldithiocarbamate methyl ester, a metabolite of disulfiram, is oxidized to a sulfine, which is reduced to the parent methyl ester by glutathione. In the latter reaction, two molecules of glutathione (GSH) are oxidized with reduction


Figure 6-13. Biotransformation of disulfiram by disulfide reduction (A) and the general mechanism of glutathione-dependent disulfide reduction of xenobiotics (B).

GSH, glutathione; XSSX, xenobiotic disulfide; GSSG, reduced glutathione. The last reaction in (B) is catalyzed by glutathione reductase.

of the sulfine oxygen to water (Madan *et al.*, 1994), as shown below:

$$R_1R_2C = S^+–O^- + 2GSH \rightarrow R_1R_2C = S + GSSG + H_2O$$
Just as sulfoxide reduction can reverse the effect of sulfoxidation, so the reduction of *N*-oxides can reverse the *N*-oxygenation of amines, which is catalyzed by flavin monooxygenases and cytochrome P450. Under reduced oxygen tension, reduction of the *N*-oxides of imipramine, tiaramide, indicine, and *N*,*N*-dimethylaniline can be catalyzed by mitochondrial and/or microsomal enzymes in the presence of NADH or NADPH (Sugiura and Kato, 1977). The NADPH-dependent reduction of *N*-oxides in liver microsomes appears to be catalyzed by cytochrome P450 (Sugiura *et al.*, 1976), although in some cases NADPH-cytochrome P450 reductase may play an important role.

As a class, *N*-oxides are not inherently toxic compounds. However, certain aromatic and aliphatic *N*-oxides have been exploited as bioreductive drugs (also known as DNA affinic drugs) for the treatment of certain cancers and infectious diseases (Wardman *et al.*, 1995). In these cases, *N*-oxides have been used as prodrugs that are converted to cytotoxic or DNA-binding drugs under hypoxic conditions. The fact that *N*-oxides of certain drugs are converted to toxic metabolites under hypoxic conditions is the basis for their selective toxicity to certain solid tumors (namely, those that are hypoxic and, hence, resistant to radiotherapy) and anaerobic bacteria. For example, tirapazamine (SR 4233) is a benzotriazine di-*N*-oxide that is preferentially toxic to hypoxic cells, such as those present in solid tumors, apparently due to its rapid activation by one-electron reduction of the *N*-oxide to an oxidizing nitroxide radical, as shown in Fig. 6-14 (Walton *et al.*, 1992). This reaction is catalyzed by cytochrome P450 and NADPH-cytochrome P450 reductase (Saunders *et al.*, 2000). Two-electron reduction of the di-*N*-oxide, SR 4233, produces a mono-*N*-oxide, SR 4317, which undergoes a second *N*-oxide reduction to SR 4330. Like SR 4233, the antibacterial agent, quindoxin, is a di-*N*-oxide whose cytotoxicity is dependent on reductive activation, which is favored by anaerobic conditions.

Bioreductive alkylating agents, which include such drugs as mitomycins, anthracyclins, and aziridinylbenzoquinones represent another class of anticancer agents that require activation by reduction. However, for this class of agents, bioactivation also involves a two-electron reduction reaction, which is largely catalyzed by NQO, which is described in the next section.

Quinone Reduction—NQO1 and NQO2 Quinones can be reduced to hydroquinones by two closely related, cytosolic flavoproteins, namely, NQO1 and NQO2. The former enzyme, NAD(P)H-quinone oxidoreductase-1, is also known as DT-diaphorase. The latter enzyme, NAD(P)H-quinone oxidoreductase-2, is also known as NRH-quinone oxidoreductase because it prefers the unusual electron donor dihydronicotinamide riboside (NMR) over NAD(P)H. Although they are closely related enzymes (both contain two 27-kDa subunits each with an FAD prosthetic group), NQO1 and NQO2 have different substrate specificities, and they can be distinguished on the basis of their differential inhibition by dicoumarol and quercetin (which are selective inhibitors of NQO1 and NQO2, respectively). NQO2 may have a physiological role in the metabolism of vitamin K hydroquinone (Chen *et al.*, 2000).

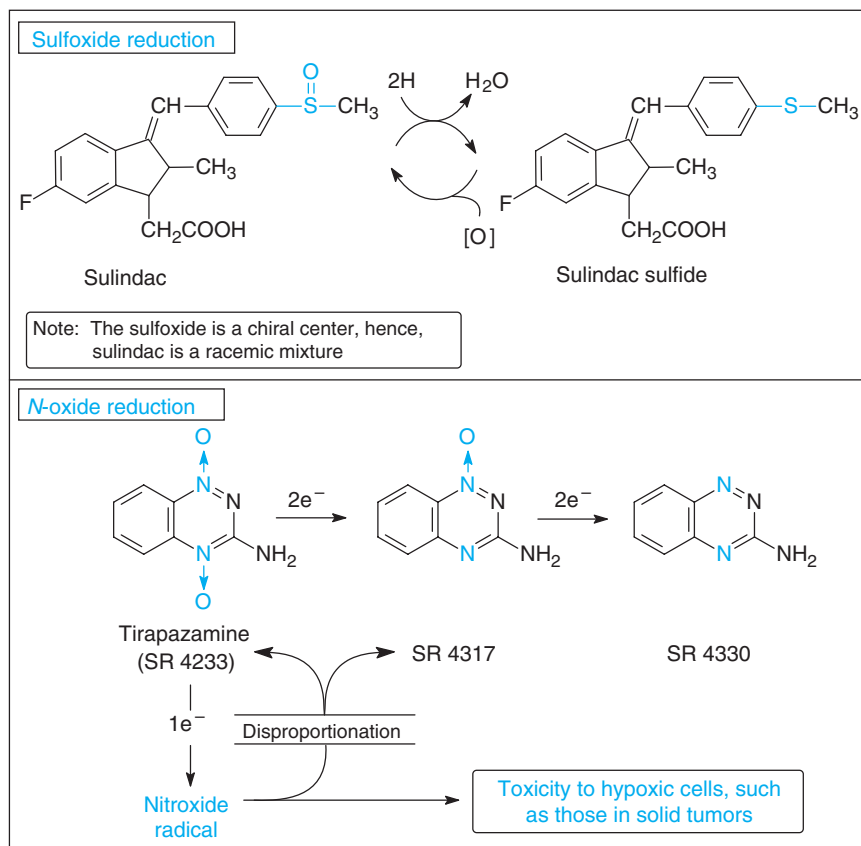
An example of the type of reaction catalyzed by NQO is shown in Fig. 6-15. Formation of the hydroquinone involves a two-electron reduction of the quinone with stoichiometric oxidation of NAD[P]H *without* oxygen consumption. (The two-electron reduction of certain quinones can also be catalyzed by carbonyl reductase, especially in humans.) In contrast, NADPH-cytochrome P450 reductase, a microsomal flavoprotein, catalyzes the one-electron reduction of quinones to semiquinone radicals that, in addition to being reactive metabolites themselves, cause oxidative stress by reacting with oxygen to form reactive oxygen species (ROS), which leads to nonstoichiometric oxidation of NADPH and oxygen consumption, as shown in Fig. 6-15. The two-electron reduction of quinones is a nontoxic reaction—one that is not associated with semiquinone formation and oxidative stress—provided the resultant hydroquinone is sufficiently stable to undergo glucuronidation or sulfonation. However, there are quinone-containing xenobiotics that, despite undergoing two-electron reduction by NQO, produce semiquinone free radicals, oxidative stress, DNA damage, and cytotoxicity. Many of these xenobiotics are being developed as anticancer drugs because NQO1 is often overexpressed in tumor cells. The properties of the hydroquinone determine whether, during the metabolism of quinone-containing xenobiotics, NQO functions as a protective antioxidant


Figure 6-14. Examples of sulfoxide and N-oxide reduction.

Note that tirapazamine (3-amino-1,2,4-benzotriazine-1,4-dioxide) is a representative of a class of agents that are activated by reduction, which may be clinically useful in the treatment of certain tumors.

or a pro-oxidant activator leading to the formation of reactive oxygen species and reactive semiquinone free radicals. The latter are thought to form not from the one-electron reduction of the quinone but from the two-electron reduction of the quinone (Q) to the hydroquinone (QH$_2$), which then undergoes one-electron oxidation or perhaps disproportionation to form the reactive semiquinone (QH):

$$QH_2 + Q \leftrightarrow 2QH$$
Drugs or drug candidates that are activated by NQO to anticancer agents include the aziridinylbenzoquinone diaziquone, the anthraquinone mitoxantrone, the indolquinones mitomycin C and EO9 (an analog of mitomycin C that is more rapidly reduced by NQO1), and the anthracycline antibiotics daunorubicin and doxorubicin (Gutierrez, 2000). These so-called bioreductive alkylating agents are reduced by NQO1 to generate semiquinone free radicals and other reactive intermediates that undergo nucleophilic additions with DNA, resulting in single-strand DNA breaks. The reason such drugs are preferentially toxic to tumor cells is that tumor cells, especially those in solid tumors, are hypoxic, and hypoxia induces the synthesis of NQO1 (by a mechanism that involves the Activator Protein 1 [AP-1] and Nuclear Factor-κB [NF-κB] response elements in the 5′-promoter region of the NQO1 gene). Therefore, tumor cells often express high levels of NQO1, which predisposes them to the toxic effects of quinone-reductive anticancer drugs like mitomycin C. Interestingly, mitomycin C also upregulates the expression of NQO1, which may enable this anticancer

drug to stimulate its own metabolic activation in tumor cells (Yao *et al.*, 1997). Some cancer chemotherapeutic agents, such as the *N*-oxide SR 4233, are inactivated, not activated, by NQO, as shown in Fig. 6-14.

NQO can activate certain nitroaromatic compounds (R–NO$_2$) to the corresponding hydroxylamine (R–NHOH), which can be activated by acetylation or sulfonation (by pathways analogous to those shown in Fig. 6-11). Dinitropyrenes and the nitroaromatic compound CB 1954 are activated by NQO. The latter compound was under consideration as an anticancer agent. However, although it is activated by reduction by rat NQO, the nitroaromatic compound CB 1954 is not activated by human NQO.

Oxidative stress appears to be an important component to the mechanism of toxicity of several xenobiotics that either contain a quinone or can be biotransformed to a quinone (Anders, 1985). The production of superoxide anion radicals and oxidative stress are responsible, at least in part, for the cardiotoxic effects of doxorubicin (adriamycin) and daunorubicin (daunomycin), the pulmonary toxicity of paraquat and nitrofurantoin, and the neurotoxic effects of 6-hydroxydopamine. Oxidative stress also plays an important role in the destruction of pancreatic beta cells by alloxan and dialuric acid. Tissues low in superoxide dismutase activity, such as the heart, are especially susceptible to the oxidative stress associated with the redox cycling of quinones. This accounts, at least in part, for the cardiotoxic effects of adriamycin and related anticancer agents, although other susceptibility factors have been proposed (Mordente *et al.*, 2001).
Figure 6-15. *Two-electron reduction of menadione to a hydroquinone, and production of reactive oxygen species during its one-electron reduction to a semiquinone radical.*

As already mentioned in this section, it is now apparent that the structure of the hydroquinones produced by NQO determines whether the two-electron reduction of quinones results in xenobiotic detoxication or activation. Hydroquinones formed by two-electron reduction of unsubstituted or methyl-substituted 1,4-naphthoquinones (such as menadione) or the corresponding quinone epoxides are relatively stable to autoxidation, whereas the methoxyl, glutathionyl, and hydroxyl derivatives of these compounds undergo autoxidation with production of semiquinones and reactive oxygen species. The ability of glutathionyl derivatives to undergo redox cycling indicates that conjugation with glutathione does not prevent quinones from serving as substrates for NQO. The glutathione conjugates of quinones can also be reduced to hydroquinones by carbonyl reductases, which actually have a binding site for glutathione. In human carbonyl reductase, this binding site is Cys_{227}, which is involved in binding both substrate and glutathione (Tinguely and Wermuth, 1999). Although oxidative stress is an important mechanism by which quinones cause cellular damage (through the intermediacy of semiquinone radicals and the generation of reactive oxygen species), it should be noted that quinones are Michael acceptors, and cellular damage can occur through direct alkylation of critical cellular proteins and/or DNA (Bolton *et al.*, 2000).

NQO1 is inducible up to tenfold by two classes of inducers, which have been categorized as *bifunctional* and *monofunctional* inducers (Prochaska and Talalay, 1988). The bifunctional inducers include compounds like *β*-naphthoflavone, benzo[*a*]pyrene, 3-methylcholanthrene and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD or dioxin), which induce both oxidative enzymes (such

as the cytochrome P450 enzyme CYP1A1) and conjugating enzymes (such as glutathione transferase and UDP-glucuronosyltransferase). The monofunctional inducers tend to induce conjugating and other non-CYP enzymes (although in mice, monofunctional inducers can induce CYP2C55 and 2U1, as well as aldehyde oxidase). These inducers signal through two distinct mechanisms, one involving the XRE (xenobiotic-response element) and one involving the ARE (antioxidant response element), which is also known as the EpRE (electrophilic response element). (Response elements are short sequences of DNA, often located in the 5′-promoter region of a gene, that bind the transcription factors that control gene expression.) Some enzymes, such as CYP1A1, are largely regulated by the XRE, whereas others are largely regulated by ARE, such as glutathione transferase (see Point 8). Some enzymes, such as NQO1, are regulated by both. The monofunctional inducers can be subdivided into two chemical classes: those that cause oxidative stress through redox cycling (e.g., the quinone, menadione, and the phenolic antioxidants *tert*-butylhydroquinone and 3,5-di-*tert*-butylcatechol), and those that cause oxidative stress by depleting glutathione (e.g., fumarates, maleates, acrylates, isothiocyanates, and other Michael acceptors that react with glutathione).

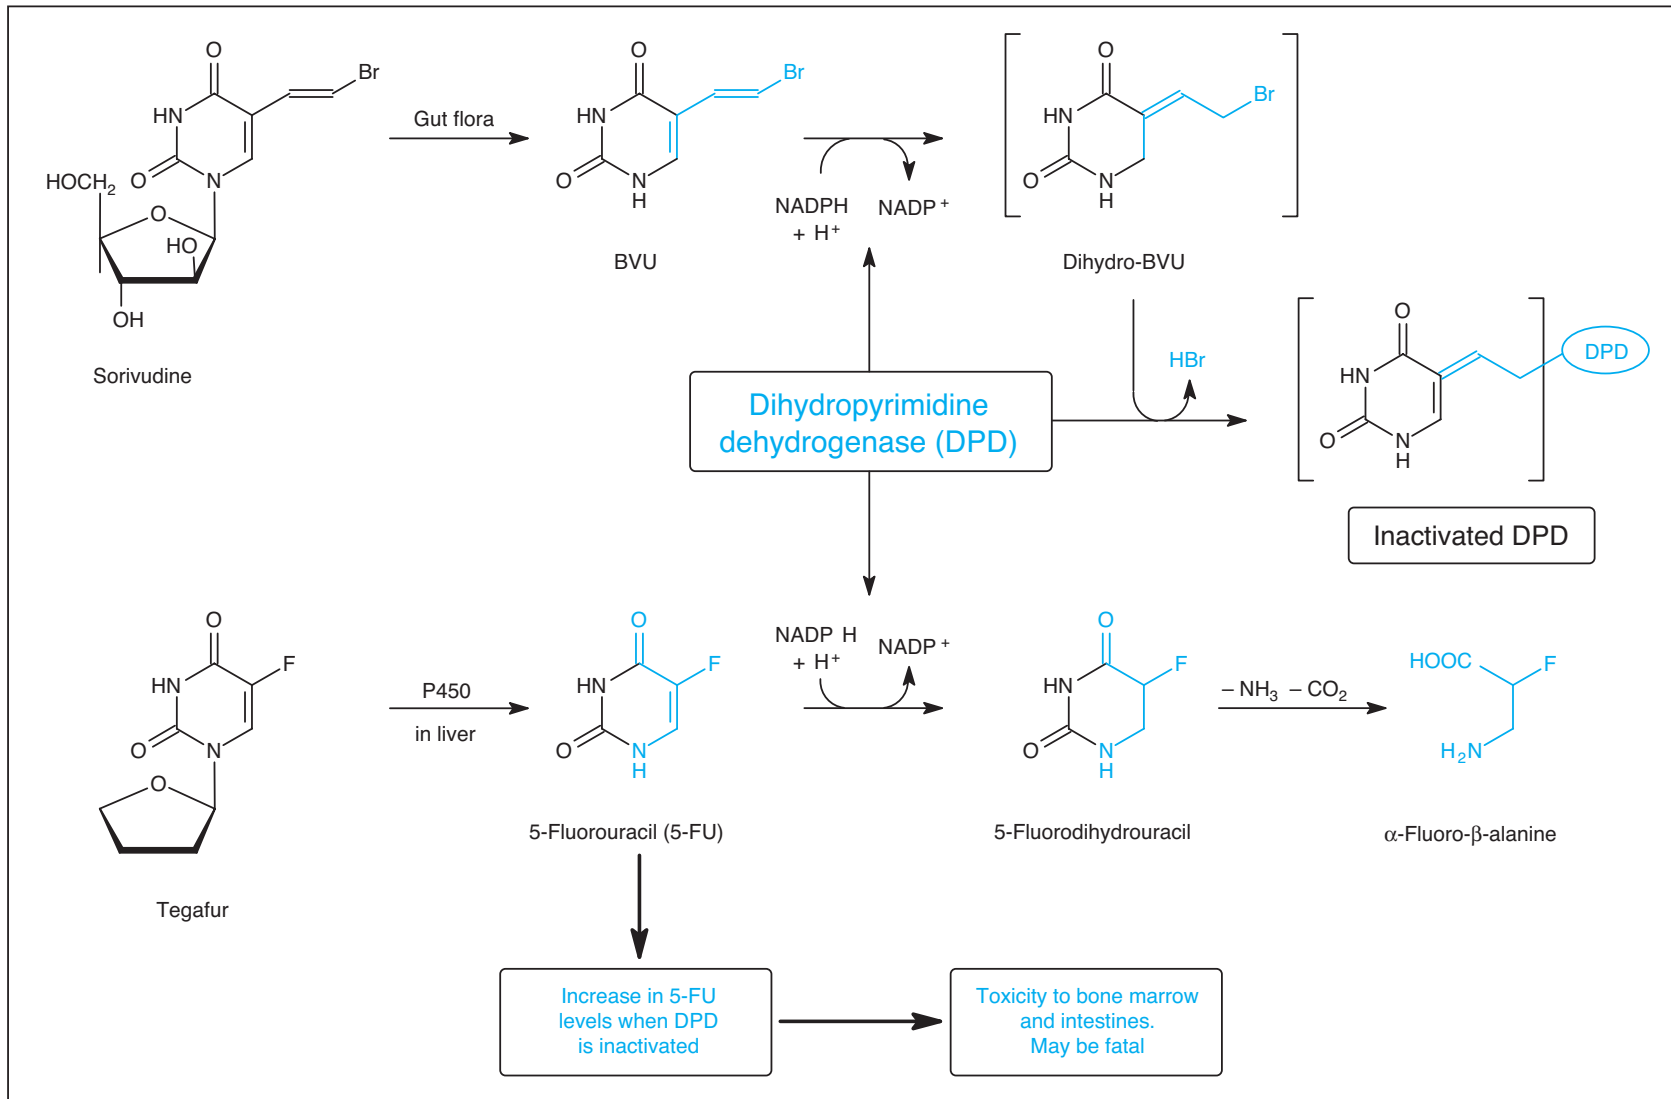
The flavonoid *β*-naphthoflavone and the polycyclic aromatic hydrocarbon benzo[*a*]pyrene induce NQO1 by both mechanisms; the parent compound binds to the *Ah* receptor and is responsible for inducing CYP1A1, as well as NQO1, via the XRE, whereas electrophilic and/or redox active metabolites of *β*-naphthoflavone and benzo[*a*]pyrene are responsible for inducing glutathione


Figure 6-16. *Reduction of 5-fluorouracil by dihydropyrimidine dehydrogenase and its inhibition (suicide inactivation) by Sorivudine.*
Note: Inhibition of dihydropyrimidine dehydrogenase is the mechanism of fatal interactions between Sorivudine and the 5-fluorouracil prodrug, tegafur.

transferase, as well as NQO1, via the ARE. The situation with benzo[*a*]pyrene is quite intriguing. This polycyclic aromatic hydrocarbon binds directly to the *Ah* receptor, which binds to the XRE and induces the synthesis of CYP1A1, which in turn converts benzo[*a*]pyrene to electrophilic metabolites (such as arene oxides and diolepoxides) and redox active metabolites (such as catechols), as shown in Fig. 6-9. These electrophilic and redox active metabolites then induce enzymes that are regulated by the ARE. However, the catechol metabolites of benzo[*a*]pyrene are further converted by dihydrodiol dehydrogenase to *ortho*-quinones (Fig. 6-9), and are thereby converted back into planar, hydrophobic compounds that are highly effective ligands for the *Ah* receptor (Burczynski and Penning, 2000). This may be toxicologically important, because the *Ah* receptor may translocate *ortho*-quinone metabolites of benzo[*a*]pyrene into the nucleus, where they might damage DNA (Bolton *et al.*, 2000).

Among the monofunctional inducers that apparently increase NQO1 via ARE is sulforaphane, an ingredient of broccoli that may be responsible for the anticarcinogenic effects of this cruciferous vegetable (Zhang *et al.*, 1992). Isothiocyanates (which are also present at high levels in cruciferous vegetables) likely exert their chemopreventive effects largely through induction of the detoxifying enzymes under the control of ARE, namely, glutathione transferase (GSTA1), microsomal epoxide hydrolase, aldo–keto reductase (AKR7A, also known as aflatoxin aldehyde reductase), NAD(P)H-quinone oxidoreductase (NQO1, also known as DT-diaphorase), glutamate-cysteine ligase (GCL), as well as genes involved in apoptosis. One isothiocyanate in particular, phenethyl isothiocyanate, has been found to activate Nrf2 and activate numerous genes in addition to those encoding xenobiotic-biotransforming enzymes and oxidant defense systems. Microarray studies carried out in wild-type and Nrf2 knockout mice treated with phenethylisothiocyanate showed that the most highly inducible genes include the very low density lipoprotein (VLDL) receptor, G-protein signaling modulator 2, early growth response 1, pancreatic lipase-related protein 2, histocompatibility 2 (K region), general transcription factor IIB, myoglobin, potassium voltage-gated channel Q2, and SLC39A10 (Hu *et al.*, 2006). As with other xenosensors, activation of Nrf2 results in a pleiotypic response in which a large number of genes are activated (or repressed). As mentioned above (this section), hypoxia and the anticancer agent mitomycin C are also inducers of NQO1, which has implications for cancer chemotherapy.

NQO1 and NQO2 are polymorphically expressed enzymes, and several lines of evidence suggest that NQO1 and/or NQO2 plays a key role in protecting bone marrow from the hematotoxic effects of benzene or other environmental factors (Iskander and Jaiswal, 2005). In humans, a high percentage of individuals with myeloid and other types of leukemia are homo- or heterozygous for a null mutant allele of NQO1. This polymorphism, NQO1*2, is a SNP ($C_{609}T$) that changes Pro_{187} to Ser_{187}, which destabilizes the protein and targets it for rapid degradation by the ubiquitin proteasomal pathway (Ross, 2005). Mice lacking NQO1 or NQO2 (knockout or null mice) have no developmental abnormalities but have increased granulocytes in the blood and myelogenous hyperplasia of the bone marrow (due to decreased apoptosis). Mice lacking NQO1 are substantially more susceptible than wild-type mice to benzene-induced hematotoxicity (Iskander and Jaiswal, 2005; Ross, 2005). The hematotoxicity of benzene is thought to involve its conversion to hydroquinone in the liver and its subsequent oxidation to benzoquinone by myeloperoxidase in the bone marrow (discussed later in

the section on *Peroxidase-dependent cooxidation*). NQO would be expected to play a role in detoxifying benzoquinone, and the loss of this protective mechanism may be the mechanism by which loss of NQO potentiates benzene hematotoxicity. However, loss of NQO also impairs apoptosis, which also represents a plausible explanation for the association between loss of NQO and increased susceptibility to benzene hematotoxicity. This latter mechanism (i.e., impaired apoptosis) likely accounts for the observation that NQO1 and NQO2 null mice are more susceptible than wild-type mice to skin carcinogenesis by benzo[*a*]pyrene and 7,12-dimethylbenz[*a*]anthracene, an effect attributable to the diol-epoxides, not the quinone metabolites, of these polycyclic aromatic hydrocarbons (Iskander and Jaiswal, 2005).

Dihydropyrimidine Dehydrogenase (DPD)   In 1993, 15 Japanese patients died as a result of an interaction between two oral medications: Sorivudine—a new antiviral drug for herpes zoster—and Tegafur—a prodrug that is converted in the liver to the anticancer agent, 5-fluorouracil. The deaths occurred within 40 days of the Japanese government's approval of Sorivudine for clinical

use. The mechanism of the lethal interaction between Sorivudine and Tegafur is illustrated in Fig. 6-16, and involves inhibition of dihydropyrimidine dehydrogenase (DPD), an NADPH-requiring, homodimeric protein (Mr ~210 kDa) containing FMN/FAD and an iron–sulfur cluster in each subunit. The enzyme is located mainly in liver cytosol, where it catalyzes the reduction of 5-fluorouracil and related pyrimidines. Sorivudine is converted in part by gut flora to (*E*)-5-(2-bromovinyl) uracil (BVU), which lacks antiviral activity but which is converted by DPD to a metabolite that binds covalently to the enzyme. The irreversible inactivation (a.k.a. suicidal inactivation) of DPD by Sorivudine causes a marked inhibition of 5-fluorouracil metabolism, which increases blood levels of 5-fluorouracil to toxic and, in some cases, lethal levels (Ogura *et al.*, 1998; Kanamitsu *et al.*, 2000).

Several genetic polymorphisms that result in a partial or complete loss of DPD activity have been described (van Kuilenburg *et al.*, 2004; Robert *et al.*, 2005). Severe 5-fluorouracil toxicity has also been documented in individuals who are heterozygous for allelic variants of DPD, and 5-fluorouracil lethality has been documented in rare individuals who are completely deficient in DPD (one individual in about 10,000). 5-Fluorouracil is one of the most frequently prescribed anticancer drugs, for which reason assessing an individual's DPD genotype (by analyzing DNA for allelic variants) or phenotyping (by measuring DPD activity in peripheral blood

mononuclear cells or PBMCs) is advocated prior to 5-fluorouracil therapy so that the dosage of this anticancer drug can be adjusted on an individual basis.

Dehalogenation   There are three major mechanisms for removing halogens (F, Cl, Br, and I) from aliphatic xenobiotics (Anders, 1985). The first, known as *reductive dehalogenation*, involves replacement of a halogen with hydrogen, as shown below:
In the second mechanism, known as *oxidative dehalogenation*, a halogen and hydrogen on the same carbon atom are replaced with oxygen. Depending on the structure of the haloalkane, oxidative dehalogenation leads to the formation of an acylhalide or aldehyde, as shown below:
A third mechanism of dehalogenation involves the elimination of two halogens on adjacent carbon atoms to form a carbon–carbon double bond, as shown below:

Pentahaloethane   Trihaloethylene
A variation on this third mechanism is *dehydrohalogenation*, in which a halogen and hydrogen on adjacent carbon atoms are eliminated to form a carbon–carbon double bond.

Reductive and oxidative dehalogenation are both catalyzed by cytochrome P450. (The ability of cytochrome P450 to catalyze both reductive and oxidative reactions is explained later in the section on *Cytochrome P450*.) Dehalogenation reactions leading to double bond formation are catalyzed by cytochrome P450 and glutathione transferase. These reactions play an important role in the biotransformation and metabolic activation of several halogenated alkanes, as the following examples illustrate.

The hepatotoxicity of carbon tetrachloride (CCl_4) and several related halogenated alkanes is dependent on their biotransformation by reductive dehalogenation (Plaa, 2000). The first step in reductive dehalogenation is a one-electron reduction catalyzed by cytochrome P450, which produces a potentially toxic, carbon-centered radical and inorganic halide. In the case of CCl_4, reductive dechlorination produces a trichloromethyl radical ($\bullet CCl_3$), which initiates lipid peroxidation and produces a variety of other metabolites, as shown in Fig. 6-17.

Halothane can also be converted by reductive dehalogenation to a carbon-centered radical, as shown in Fig. 6-18. The mechanism is identical to that described for carbon tetrachloride, although in the case of halothane the radical is generated through loss of bromine, which is a better leaving group than chlorine. Figure 6-18 also shows that halothane can undergo oxidative dehalogenation, which involves oxygen insertion at the C–H bond to generate an unstable halohydrin ($CF_3COHClBr$) that decomposes to a reactive acylhalide (CF_3COCl), which can bind to cellular proteins (particularly to amine groups) or further decompose to trifluoroacetic acid (CF_3COOH).

Both the oxidative and reductive pathways of halothane metabolism generate reactive intermediates capable of binding to proteins and other cellular macromolecules. The relative importance of these two pathways to halothane-induced hepatotoxicity appears to be species dependent. In rats, halothane-induced hepatotoxicity is promoted by those conditions favoring the reductive dehalogenation of halothane, such as moderate hypoxia (10–14% oxygen) plus treatment with the cytochrome P450 inducers, phenobarbital, and pregnenolone-16α-carbonitrile. In contrast to the situation in rats, halothane-induced hepatotoxicity in guinea pigs is largely the result of oxidative dehalogenation of halothane (Lunam *et al.*, 1989). In guinea pigs, halothane hepatotoxicity is not enhanced by moderate hypoxia and is diminished by the use of deuterated halothane, which impedes the oxidative dehalogenation of halothane because the P450-dependent insertion of oxygen into a carbon–deuterium bond is energetically less favorable (and therefore slower) than inserting oxygen into a carbon–hydrogen bond.

Halothane hepatitis in humans is a rare but severe form of liver necrosis associated with repeated exposure to this volatile anesthetic. In humans, as in guinea pigs, halothane hepatotoxicity appears to result from the oxidative dehalogenation of halothane, as shown in Fig. 6-18. Serum samples from patients suffering from halothane hepatitis contain antibodies directed against neoantigens formed by the trifluoroacetylation of proteins. These antibodies have been used to identify which specific proteins in the endoplasmic reticulum are targets for trifluoroacetylation during the oxidative dehalogenation of halothane (Pohl *et al.*, 1989).

The concept that halothane is activated by cytochrome P450 to trifluoroacetylhalide, which binds covalently to proteins and elicits an immune response, has been extended to other volatile anesthetics, such as enflurane, methoxyflurane, and isoflurane. In other words, these halogenated aliphatic hydrocarbons, like halothane, may be converted to acylhalides that form immunogens by binding covalently to proteins. In addition to accounting for rare instances of enflurane hepatitis, this mechanism of hepatotoxicity can also account for reports of a *cross-sensitization* between enflurane and halothane, in which enflurane causes liver damage in patients previously exposed to halothane.

One of the metabolites generated from the reductive dehalogenation of halothane is 2-chloro-1,1-difluoroethylene (Fig. 6-18). The formation of this metabolite involves the loss of two halogens

Figure 6-21. Dehydroxylation by cytochrome b₅ and aldehyde oxidase.

from adjacent carbon atoms with formation of a carbon–carbon double bond. This type of dehalogenation reaction can also be catalyzed by glutathione transferases. Glutathione initiates the reaction with a nucleophilic attack either on the electrophilic carbon to which the halogen is attached (mechanism A) or on the halide itself (mechanism B), as shown in Fig. 6-19 for the dehalogenation of 1,2-dihaloethane to ethylene. The insecticide DDT is detoxified by dehydrochlorination to DDE by DDT-dehydrochlorinase, as shown in

Fig. 6-20. The activity of this glutathione-dependent reaction correlates well with resistance to DDT in houseflies.

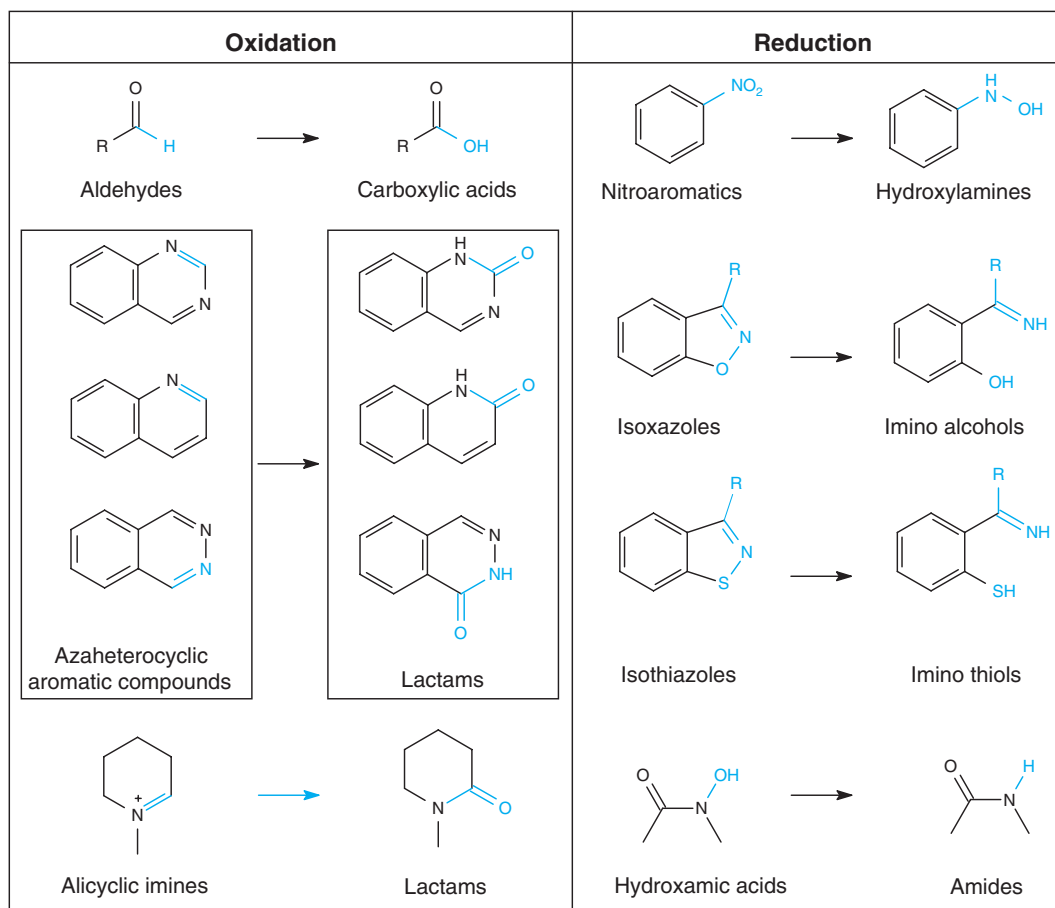
Dehydroxylation—Cytochrome b₅ and Aldehyde Oxidase
In the presence of NADH and NADH-cytochrome b₅ reductase (CYB5R3), the microsomal hemoprotein cytochrome b₅ (CYB5A) can catalyze the *N*-dehydroxylation of various amidoximes, as shown in Fig. 6-21 for the amidoxime metabolite of


Figure 6-22. Examples of oxidation and reduction catalyzed by aldehyde oxidase.

the antimicrobial prodrug DB289 (Saulter *et al.*, 2005). The complex of NADH-cytochrome b₅ reductase and cytochrome b₅, in the presence of NADH, can also efficiently reduce arylhydroxylamine metabolites of drugs such as sulfamethoxazole and dapsone, as well as carcinogens that are generated through the oxidation of compounds such as 4-aminobiphenyl and PhIP by CYP1A1, 1A2, 1B1, lactoperoxidase, and myeloperoxidase (see sections "Cytochrome P450" and "Peroxidase-Dependent Cooxidation") (Kurian *et al.*, 2006). Because these carcinogenic arylhydroxylamines can be further activated by glucuronidation, sulfonation, or acetylation in various tissues (see sections "Glucuronidation," "Sulfonation," and "Acetylation"), reduction by NADH-cytochrome b₅ reductase and cytochrome b₅ represents a competing detoxication pathway. Figure 6-21 also shows a similar dehydroxylation reaction catalyzed by aldehyde oxidase, an enzyme that can catalyze both reductive and oxidative reaction, as discussed in the next section.

Aldehyde Oxidase—Reductive Reactions   Aldehyde oxidase is a cytosolic molybdozyme that catalyzes the oxidation of some xenobiotics and the reduction of others. The types of oxidative and reductive reactions catalyzed by aldehyde oxidase are shown in Fig. 6-22. In contrast to the large number of drugs that are known to be (or suspected of being) oxidized by aldehyde oxidase in vivo, only a few drugs are known to be (or suspected of being) reduced by aldehyde oxidase in vivo, including nitrofurazone, zonisamide, and ziprasidone. The reductive metabolism of ziprasidone by aldehyde

oxidase is shown in Fig. 6-3, and the reductive dehydroxylation of CP-544,439 is shown in Fig. 6-21. The features of aldehyde oxidase and the oxidative reactions it catalyzes are discussed later in the section on "Aldehyde Oxidase."

Oxidation

Alcohol, Aldehyde, Ketone Oxidation–Reduction Systems   Alcohols, aldehydes, and ketones are oxidized by a number of enzymes, including alcohol dehydrogenase, aldehyde dehydrogenase, AKRs (such as those with dihydrodiol dehydrogenase activity), the molybdenum-containing enzymes, aldehyde oxidase, and xanthine dehydrogenase/oxidase, and cytochrome P450. For example, simple alcohols (such as methanol and ethanol) are oxidized to aldehydes (namely, formaldehyde and acetaldehyde) by alcohol dehydrogenase. These aldehydes are further oxidized to carboxylic acids (formic acid and acetic acid) by aldehyde dehydrogenase, as shown in Fig. 6-23. Many of the aforementioned enzymes can also catalyze the reduction of xenobiotics, as discussed in the previous section on "Reduction."

Alcohol Dehydrogenase   Alcohol dehydrogenases (ADHs) belong to the medium-chain dehydrogenases/reductases (MDRs), as shown in Table 6-5. ADHs are zinc-containing, cytosolic enzymes present in several tissues including liver, which has the highest levels, kidney, lung, and gastric mucosa (Agarwal, 1992). Human ADHs are dimeric proteins consisting of two 40-kDa subunits designated
Figure 6-23. *Oxidation of alcohols to aldehydes and carboxylic acids by alcohol dehydrogenase (ADH) and aldehyde dehydrogenase (ALDH).*

α, β, γ, π, χ, and either σ or μ. As shown in Table 6-5, there are seven human ADHs, and these are categorized into five classes (I–V). Class I comprises three enzymes: ADH1A, which contains at least one alpha subunit ($\alpha\alpha$, $\alpha\beta$, or $\alpha\gamma$), ADH1B, which contains at least one beta subunit ($\beta\beta$ or $\beta\gamma$), and ADH1C, which contains two gamma subunits ($\gamma\gamma$). ADH1A, -1B, and 1C were formerly known as ADH1, -2, and -3. Class II contains ADH4, which is composed of two pi subunits ($\pi\pi$). Class III contains ADH5, which is composed of two chi subunits ($\chi\chi$). Class IV contains ADH7, which is composed of two subunits designated mu ($\mu\mu$) or sigma ($\sigma\sigma$). Class V contains ADH6 (for which there is no subunit designation) (Brennan *et al.*, 2004); see also www.gene,ucl.ac.uk/ nomenclature/genefamily/ADH.shtml.

Of the seven ADHs, only ADH1B and ADH1C are polymorphic. There are three allelic variants of the beta subunit (β_1, β_2, and β_3), which differ by a single amino acid, and two allelic variants of the gamma subunit (γ_1 and γ_2), which differ by two amino acids. Consequently, the human ADH enzymes comprise nine subunits, all of which can combine as homodimers. In addition, the α, β, and γ subunits (and their allelic variants) can form heterodimers with each other (but not with the π, χ, or σ/μ subunits, which only form homodimers). ADH1B enzymes that differ in the type of β subunits are known as allelozymes, as are ADH1C enzymes that differ in the type of γ subunit.

The class I ADH isozymes (ADH1A or α-ADH, ADH1B or β-ADH, and ADH1C or γ-ADH) are responsible for the oxidation of ethanol and other small, aliphatic alcohols, and they are strongly inhibited by pyrazole and its 4-alkyl derivatives (e.g., 4-methylpyrazole). High levels of class I ADH isozymes are expressed in liver and adrenals, with lower levels in kidney, lung, blood vessels (in the case of ADH1B) and other tissues, but not brain.

The class II enzyme ADH4 (π-ADH) is primarily expressed in liver (with lower levels in stomach), where it preferentially oxidizes larger aliphatic and aromatic alcohols. ADH4 differs from the ADH1 isozymes in that it plays little or no role in ethanol and methanol oxidation, and it is not inhibited by pyrazole.

The class III enzyme ADH5 (χ-ADH) preferentially oxidizes long-chain alcohols (pentanol and larger) and aromatic alcohols (such as cinnamyl alcohol). Like ADH4, ADH5 is not inhibited by pyrazole. However, in contrast to ADH4, which is largely confined to the liver, ADH5 is ubiquitous, being present in virtually all tissues (including brain), where it appears to play an important role in detoxifying formaldehyde. In fact, ADH5 and formaldehyde dehydrogenase are identical enzymes (Koivusalo *et al.*, 1989).

The class IV enzyme ADH7 (μ- or σ-ADH) is a low-affinity (high K_m), high-capacity (high V_{max}) enzyme, and is the most active of the medium-chain ADHs in oxidizing retinol. It is the major ADH expressed in human stomach and other areas of the gas-

trointestinal tract (esophagus, gingiva, mouth, and tongue). In contrast the other ADHs, ADH7 is not expressed in adult human liver. Inasmuch as ADH7 is expressed in the upper gastrointestinal tract, where chronic alcohol consumption leads to cancer development, there is considerable interest in the role of ADH7 in the conversion of ethanol to acetaldehyde (a suspected upper GI tract carcinogen or co-carcinogen) and in its role in the metabolism of retinol (a vitamin required for epithelial cell growth and differentiation), which might be inhibited by alcohol consumption (Seitz and Oneta, 1998).

The class I ADH isozymes differ in their capacity to oxidize ethanol. Even the allelozymes, which differ in a single amino acid, differ markedly in the affinity (K_m) and/or capacity (V_{max}) for oxidizing ethanol to acetaldehyde. The homodimer, $\beta_2\beta_2$ and heterodimers containing at least one β_2 subunit (i.e., the ADH1B*2 allelozymes) are especially active in oxidizing ethanol at physiological pH. ADH1B*2 (formerly known as ADH2*2) is known as *atypical* ADH, and is responsible for the unusually rapid conversion of ethanol to acetaldehyde in 90% of the Pacific Rim Asian population (Japanese, Chinese, Korean). The atypical ADH is expressed to a much lesser degree in Caucasians (<5% of Americans, ~8% of English, ~12% of Germans, and ~20% of Swiss), African Americans (<10%), Native Americans (0%), and Asian Indians (0%) (Agarwal, 1992). The three ADH1B alleles, ADH1B*1 (β_1-ADH), ADH1B*2 (β_2-ADH), and ADH1B*3 (β_3-ADH) are mainly expressed in Caucasians (up to 95%), Pacific Rim Asians (~90%), and Africans/African Americans (~24%), respectively. These population differences in ADH1B allelozyme expression contribute to ethnic differences in alcohol consumption and toxicity, as discussed in the next section on *Aldehyde Dehydrogenase.*

Unlike the allelic variants of ADH1B, the allelic variants of ADH1C do not differ markedly in their ability to oxidize ethanol. However, as in the case of the ADH1B allelozymes, the expression of the ADH1C allelozymes also varies from one ethnic group to the next. The two allelozymes of ADH1C, namely, ADH1C*1 (γ_1-ADH) and ADH1C*2 (γ_2-ADH), are respectively expressed 50:50 in Caucasians, but 90:10 in Pacific Rim Asians (Li, 2000).

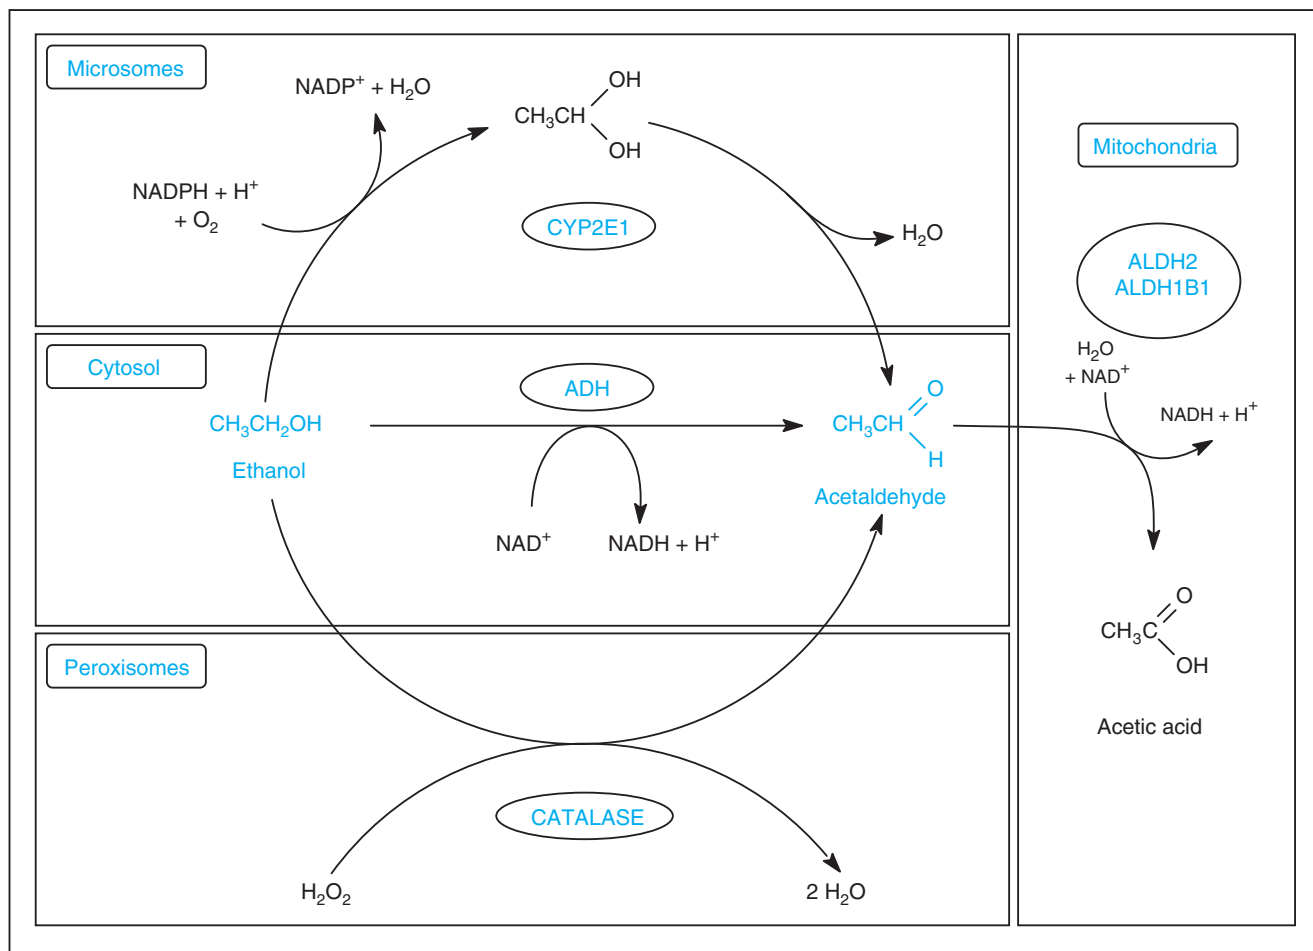
The various class I ADH isozymes and allelozymes in human liver oxidize ethanol with a K_m of 50 μM to 4 mM. For comparison, legal intoxication in the United States is defined as a blood alcohol level of 0.08%, which corresponds to 18 mM (Edenberg, 2000). Therefore, during intoxication, the hepatic metabolism of ethanol by ADH becomes saturated, and the kinetics of ethanol disappearance conform to zero-order kinetics, meaning that a constant *amount* of ethanol is metabolized per unit time. When the concentration of ethanol falls within the range of K_m, the kinetics of ethanol disappearance conform to a first-order process, meaning that a constant *percentage* of the remaining ethanol is metabolized per unit time.


Figure 6-24. Oxidation of alcohol to acetaldehyde by alcohol dehydrogenase (ADH), cytochrome P450 (CYP2E1), and catalase.

Note: The oxidation of alcohol to acetic acid involves multiple organelles.

The metabolism of alcohol is usually thought of as a linear progression from ethanol to acetaldehyde to acetic acid. However, ADH1 not only oxidizes ethanol to acetaldehyde, it also reduces acetaldehyde back to ethanol. Umulis *et al*. (2005) estimated that, if the reverse reaction did not occur, levels of acetaldehyde would be 10 times higher than those actually observed in vivo. Acetaldehyde is considerably more toxic than ethanol or acetic acid; hence, blood levels of acetaldehyde are an important determinant of alcohol tolerability, as discussed in the next section on Aldehyde Dehydrogenases.

Compared with hepatic ADH, gastric ADH has a lower affinity (higher K_m) but higher capacity (larger V_{max}) for oxidizing ethanol; the former being dominated by the class I ADH isozymes (ADH1A, -1B, and 1C), the latter by the class IV enzyme ADH7. Although ethanol is largely biotransformed by hepatic ADH1, gastric ADH7 nevertheless can limit the systemic bioavailability of alcohol. This first-pass elimination of alcohol by gastric ADH7 can be significant depending on the manner in which the alcohol is consumed; large doses over a short time produce high ethanol concentrations in the stomach, which compensate for the low affinity (high K_m) of gastric ADH7. Young women have lower gastric ADH7 activity than do men, and gastric ADH7 activity tends to be lower in alcoholics (Frezza *et al*., 1990). Some alcoholic women have no detectable gastric ADH7, and blood levels of ethanol after oral consumption of alcohol are the same as those that are obtained after intravenous administration. Gastric ADH7 activity decreases during fasting, which is one reason alcohol is more intoxicating when consumed on an empty stomach. Several commonly used drugs (e.g., cimetidine, ranitidine, aspirin) are noncompetitive inhibitors of gastric ADH7. Under certain circumstances these drugs increase the systemic availability of alcohol, although the effect is too small to have serious medical, social, or legal consequences (Levitt, 1993). About 30% of Asians appear to be genetically deficient in class IV ADH7, the main gastric ADH. In addition to biotransforming ethanol and retinol, class IV ADH7 also detoxifies the dietary carcinogen, nitrobenzaldehyde. It has been suggested that a lack of class IV ADH7 in Japanese subjects may impair their ability to detoxify nitrobenzaldehyde and may possibly be linked to the high rate of gastric cancer observed in the Japanese population (Seitz and Oneta, 1998).

Alcohols can be oxidized to aldehydes by non-ADH enzymes in microsomes and peroxisomes, although these are quantitatively less important than ADH for ethanol oxidation (Lieber, 2004). The microsomal ethanol oxidizing system (formerly known as MEOS) is the cytochrome P450 enzyme, CYP2E1. The corresponding peroxisomal enzyme is catalase. The oxidation of ethanol to acetaldehyde by these three enzyme systems is shown in Fig. 6-24.

Table 6-6
Properties of the Human Aldehyde Dehydrogenases (ALDHs)

ALDH	ALTERNATIVE NAMES	TISSUE	SUBCELLULAR LOCALIZATION	MAJOR SUBSTRATE
1A1	ALDH1	Liver, stomach, etc.	Cytosol	Retinal
1A2	ALDH11	Testis, liver, kidney, etc.	Cytosol	Retinal
1A3	ALDH6	Prostate, salivary gland, stomach, kidney	Cytosol	Aliphatic aldehyde, retinal
1B1	ALDH5	Muscle, liver, kidney, etc.	Mitochondria	Acetaldehyde
1L1	FDH	Liver, kidney, pancreas, muscle	Cytosol	10-Formyltetrahydrofolate
1L2	FLJ38508	Cervix, uterus	Cytosol	Unknown
2	ALDM	Liver, stomach, muscle, etc.	Mitochondria	Acetaldehyde
3A1	ALDH3	Trachea, stomach, lung, etc.	Cytosol	Aromatic aldehydes
3A2	FALDH	Adrenal, liver, heart, muscle, etc.	Microsomes	Fatty and aromatic aldehydes
3B1	ALDH7	Kidney, lung	Microsomes	Aliphatic and aromatic aldehydes
3B2	ALDH8	Parotid	Microsomes	Unknown
4A1	ALDH4	Liver, kidney	Mitochondria	Glutamate, γ-semialdehyde
5A1	SSDH	Brain, liver, heart	Mitochondria	Succinic semialdehyde
6A1	MMSDH	Kidney, liver, heart	Mitochondria	Methylmalonate semialdehyde
7A1	ATQ1	Kidney, heart, ovary, etc.	Cytosol	Unknown
8A1	ALDH12	Liver, kidney, etc.	Cytosol	Unknown
9A1	γ ABHD, ALDH9	Liver, kidney, muscle	Cytosol	Amine aldehyde
16A1	MGC10204	Uterus, placenta	Unknown	Unknown
18A1	Δ^1-P5CS[a]	Kidney, heart, muscle, etc.	Mitochondria	Glutamate

Data adapted from Sládek NE: Human aldehyde dehydrogenases: Potential pathological, pharmacological, and toxicological impact. *J Biochem Mol Toxicol* 17:7–23, 2003; Vasiliou V, Pappa A, Estey T: Role of human aldehyde dehydrogenases in endobiotic and xenobiotic metabolism. *Drug Metab Rev* 36:279–299, 2004.

Aldehyde Dehydrogenase   Aldehyde dehydrogenase (ALDH) oxidizes aldehydes to carboxylic acids with NAD$^+$ as the cofactor. Several ALDH enzymes are involved in the oxidation of xenobiotic aldehydes. The enzymes also have esterase activity (Yoshida *et al.*, 1998). Formaldehyde dehydrogenase, which specifically oxidizes formaldehyde that is complexed with glutathione, is not a member of the ALDH family but is a class III ADH (ADH5) (Koivusalo *et al.*, 1989). At least 19 ALDH genes have been identified in humans, and a correspondingly large number of ALDH genes appear to be present in other mammalian species (Sládek, 2003; Vasiliou *et al.*, 2004). The name, tissue distribution, subcellular location, and major substrate for the human ALDHs are summarized in Table 6-6. The ALDHs differ in their primary amino acid sequences. They may also differ in the quaternary structure. For example, ALDH3A1 appears to be a dimer of two 85-kDa subunits, whereas ALDH1A1 and ALDH2 appear to be homotetramers of 54-kDa subunits (Goedde and Agarwal, 1992). In contrast to ALDH1A1 and ALDH2, which specifically reduce NAD$^+$, ALDH3A1 reduces both NAD$^+$ and NADP$^+$ due to its low affinity for these cofactors.

As shown in Fig. 6-24, ALDH2 is a mitochondrial enzyme that, by virtue of its high affinity, is primarily responsible for oxi-dizing simple aldehydes, such as acetaldehyde (K_m for acetaldehyde $<5\ \mu M$ at pH 7.4). A genetic polymorphism for ALDH2 has been documented in humans. A high percentage (45–53%) of Japanese, Chinese, Koreans, Taiwanese, and Vietnamese populations are deficient in ALDH2 activity due to a point mutation (Glu$_{487}$ $\rightarrow$ Lys$_{487}$). This inactive allelic variant of ALDH2 is known as ALDH2*2, to distinguish it from the active, wild-type enzyme, ALDH2*1. This same population (i.e., Pacific Rim Asians) also have a high incidence of the atypical form of ADH (i.e., ADH2*2), which means that they rapidly convert ethanol to acetaldehyde but only slowly convert acetaldehyde to acetic acid. (They also have a relatively high prevalence of a deficiency of class IV ADH activity, which impairs gastric metabolism of ethanol.) As a result, many Asian subjects experience a flushing syndrome after consuming alcohol due to a rapid build-up of acetaldehyde, which triggers the dilation of facial blood vessels through the release of catecholamines. Native Americans also experience a flushing syndrome after consuming alcohol, apparently because they express another allelic variant of ALDH2 and/or because acetaldehyde oxidation in blood erythrocytes is impaired in these individuals, possibly due to the expression of a variant form of ALDH1A1. The functional genetic variants of

ADH that rapidly convert ethanol to acetaldehyde (i.e., ADH2*2), and the genetic variants of ALDH that slowly detoxify acetaldehyde both protect against heavy drinking and alcoholism. Inhibition of ALDH by disulfiram (Antabuse) causes an accumulation of acetaldehyde in alcoholics. The nauseating effect of acetaldehyde serves to deter continued ethanol consumption (Goedde and Agarwal, 1992). However, it is important to note that a predisposition toward alcoholism is not simply determined by factors that affect the pharmacokinetics of ethanol and its metabolites. Studies in humans and rodents implicate serotonin 1b receptor, dopamine D2 receptor, tryptophan hydroxylase, and neuropeptide Y as candidate targets of genetic susceptibility in the pharmacodynamic actions of ethanol (Li, 2000). Monoamine oxidase may also be a risk factor for alcoholism, as discussed later (see section "Monoamine Oxidase").

Genetic deficiencies in other ALDHs impair the metabolism of other aldehydes, which is the underlying basis of certain diseases. For example, ALDH4A1 deficiency disturbs proline metabolism and causes type II hyperprolinemia, symptoms of which include mental retardation and convulsions. Various missense and other mutations in the ALDH3A2 gene (formerly ALDH10 or FALDH) cause a deficiency of the active enzyme that detoxifies fatty aldehydes, which disturbs the metabolism of membrane lipids, and is the underlying basis of Sjögren–Larsson syndrome, symptoms of which include ichthyosis, neurological problems, and oligophrenia. Treatment of Sjögren–Larsson syndrome consists of inhibition of 5-lipoxygenase (ALOX5) with zileuton and stimulation of ALDH3A2 transcription with the PPAR agonist bezafibrate in patients with certain missense mutations (Rizzo, 2007).

The toxicological consequences of an inherited (i.e., genetic) or acquired (e.g., drug-induced) deficiency of ALDH illustrate that aldehydes are more cytotoxic than the corresponding alcohol. This is especially true of allyl alcohol (CH_2=CHCH$_2$OH), which is converted by ADH to the highly hepatotoxic aldehyde, acrolein (CH_2=CHCHO).

The oxidation of ethanol by ADH and ALDH leads to the formation of acetic acid, which is rapidly oxidized to carbon dioxide and water. However, in certain cases, alcohols are converted to toxic carboxylic acids, as in the case of methanol and ethylene glycol, which are converted via aldehyde intermediates to formic acid and oxalic acid, respectively. Formic and oxalic acids are considerably more toxic than acetic acid. For this reason, methanol and ethylene glycol poisoning are commonly treated with ethanol, which competitively inhibits the oxidation of methanol and ethylene glycol by ADH and ALDH. The potent inhibitor of ADH, 4-methylpyrazole (fomepizole), is also used to treat methanol and ethylene glycol poisoning.

The reduction of aldehydes and ketones to primary and secondary alcohols by carbonyl reductases has already been discussed (see section "Carbonyl Reduction—SDRs and AKRs"). In contrast to ADH and ALDH, carbonyl reductases typically use NADPH as the source of reducing equivalents. Aldehydes, especially aromatic aldehydes, can also be oxidized by aldehyde oxidase and xanthine oxidase, which are discussed in the section "Molybdenum Hydroxylases."

Dihydrodiol Dehydrogenase   As mentioned in the section on "Carbonyl Reduction—SDRs and AKRs", several members of the aldo–keto reductase (AKR) superfamily are dihydrodiol dehydrogenases that oxidize the *trans*-dihydrodiols of various polycyclic aromatic hydrocarbons to the corresponding *ortho*-quinones, as shown in Fig. 6-9 (Penning, 1997; Burczynski and Penning, 2000). There is also a gene, DHDH, that is unrelated to AKRs and encodes a dimeric enzyme that is only expressed in the intestine (Arimitsu *et al.*, 1999). Polycyclic aromatic hydrocarbons can be oxidized by cytochrome P450 to an arene oxide, an electrophilic and potentially toxic metabolite that is detoxified by its conversion to a *trans*-dihydrodiol by epoxide hydrolase. By oxidizing the *trans*-dihydrodiol to an *ortho*-quinone, AKRs generate yet another potentially toxic metabolite. In terms of their ability to cause oxidative stress and cellular toxicity, *ortho*-quinones can be considered equivalent to *para*-quinones, which were discussed earlier in the section "Quinone Reduction—NQO1 and NQO2."

Molybdenum Hydroxylases (Molybdozymes)   There are two major molybdenum hydroxylases or molybdozymes that participate in the biotransformation of xenobiotics: aldehyde oxidase and xanthine oxidoreductase (XOR, also known as xanthine oxidase) (Rettie and Fisher, 1999; Beedham, 2002). Sulfite oxidase is a third molybdozyme; it will not be described here except to say sulfite oxidase, as the name implies, oxidizes sulfite, an irritating air pollutant, to sulfate, which is relatively innocuous. Genetic deficiencies in the synthesis of molybdenum cofactor results in the loss of xanthine oxidoreductase, aldehyde oxidase, and sulfite oxidase, but it is loss of the latter enzyme that gives rise to the progressive neurological damage that leads to death in early childhood (Reiss and Johnson, 2003).

All three molybdozymes are flavoprotein enzymes consisting of two identical ∼150 kDa subunits, each of which contains FAD, molybdenum, in the form of a pterin molybdenum cofactor ([Mo^{VI} (=S) (=O)]$^{2+}$) and two iron–sulfur (Fe$_2$S$_2$) centers (known as FeSI and FeSII). The catalytic cycle involves an interaction between the molybdenum center with a reducing substrate, which results in the reduction of the molybdenum cofactor, after which reducing equivalents are transferred intramolecularly to the flavin and iron–sulfur centers, with reoxidation occurring via the flavin moiety by molecular oxygen (in the case of aldehyde oxidase and xanthine oxidase) or NAD$^+$ (in the case of xanthine dehydrogenase). During substrate oxidation, aldehyde oxidase and xanthine oxidase are reduced and then reoxidized by molecular oxygen; hence, they function as true oxidases. The oxygen incorporated into the xenobiotic is derived from water rather than oxygen, which distinguishes the oxidases from oxygenases. The overall reaction is as follows:

$$RH \xrightarrow[-2H^+, -2e^-]{+H_2O} ROH$$
Additional details of the catalytic cycle are described in the next section "Xanthine Oxidoreductase." Xanthine oxidase and aldehyde oxidase catalyze the oxidation of electron-deficient sp^2-hybridized (i.e., double-bonded) carbon atoms found, more often than not, in nitrogen heterocycles, such as purines, pyrimidines, pteridines, and iminium ions. This contrasts with oxidation by cytochrome P450, which generally catalyzes the oxidation of carbon atoms with a high electron density. For this reason, xenobiotics that are good substrates for molybdozymes tend to be poor substrates for cytochrome P450, and vice versa (Rettie and Fisher, 1999). In nitrogen heterocycles, the carbon atom with lowest electron density is adjacent to the nitrogen atom, for which reason xanthine oxidase and aldehyde oxidase tend to hydroxylate the α-carbon atom to form a hydroximine that rapidly tautomerizes to the corresponding α-aminoketone. As the name implies, aldehyde oxidase can convert certain aldehydes to the
Figure 6-25. Examples of reactions catalyzed by the molybdozymes, xanthine oxidase, and aldehyde oxidase.

corresponding carboxylic acid; a property that is also shared by xanthine oxidase, albeit with lower activity. Certain aromatic aldehydes, such as tamoxifen aldehyde and benzaldehyde, are good substrates for aldehyde oxidase and xanthine oxidase, whereas aliphatic aldehydes tend to be poor substrates. Consequently, aldehyde oxidase and xanthine oxidase contribute negligibly to the metabolism of acetaldehyde. Some reactions catalyzed by aldehyde oxidase and xanthine oxidase are shown in Fig. 6-25. Under certain conditions, both enzymes can also catalyze the reduction of xenobiotics. Examples of reductive reactions catalyzed by aldehyde oxidase are shown in Fig. 6-22.

Xanthine Oxidoreductase   Xanthine dehydrogenase (XD) and xanthine oxidase (XO) are two forms of the same enzyme that differ in the electron acceptor used in the final step of catalysis. In the case of XD, the final electron acceptor is NAD^+ (dehydrogenase activity), whereas in the case of XO the final electron acceptor is oxygen (oxidase activity). XD is converted to XO by oxidation of cysteine residues (Cys_{993} and Cys_{1326} of the human enzyme) and/or proteolytic cleavage. The conversion of XD to XO by cysteine oxidation appears to be reversible. Under normal physiologic conditions, XD is the predominant form of the enzyme found in vivo. However, during tissue processing, the dehydrogenase form tends to be converted

to the oxidase form; hence, most in vitro studies are conducted with XO or a combination of XO and XD. The induction (upregulation) of XD and/or the conversion of XD to XO in vivo is thought to play an important role in ischemia-reperfusion injury, lipopolysaccharide (LPS)-mediated tissue injury, and alcohol-induced hepatotoxicity (Pacher *et al*., 2006). During ischemia, XO levels increase because hypoxia induces XOR gene transcription, and because XD is converted to XO. During reperfusion, XO contributes to oxidative stress and lipid peroxidation because the oxidase activity of XO involves the reduction of molecular oxygen, which can lead to the formation of reactive oxygen species of the type shown in Fig. 6-15. Similarly, treatment with LPS, a bacterial endotoxin that triggers an acute inflammatory response, increases XO activity both by inducing XOR transcription and by converting XD to XO. The associated increase in oxidative stress has been implicated in LPS-induced cytotoxicity. Ethanol facilitates the conversion of XD to XO, and the conversion of ethanol to acetaldehyde provides a substrate and, hence, a source of electrons for the reduction of oxygen. Hereafter, the two forms of the enzyme will be referred to as xanthine oxidoreductase (XOR).

Typical reactions catalyzed by XOR are shown in Fig. 6-25. XOR contributes significantly to the first-pass elimination of several purine derivatives (e.g., 6-mercaptopurine and 2,6-dithiopurine), and limits the therapeutic effects of these cancer chemotherapeutic agents. In contrast, certain prodrugs are activated by xanthine oxidase. For example, the antiviral prodrugs 6-deoxyacyclovir and 2′-fluoroarabino-dideoxypurine, which are relatively well absorbed after oral dosing, are oxidized by xanthine oxidase to their respective active forms, acyclovir and 2′-fluoroarabino-dideoxyinosine, which are otherwise poorly absorbed (see Fig. 6-25). Furthermore, XOR has been implicated in the bioactivation of mitomycin C and related antineoplastic drugs, although this bioactivation reaction is thought to be largely catalyzed by NQO1 (DT-diaphorase), as discussed previously in the section "Quinone Reduction–NQO1 and NQO2."

XOR catalyzes an important physiological reaction, namely, the sequential oxidation of hypoxanthine to xanthine and uric acid, as shown in Fig. 6-25 (Rajagopalan, 1980). By competing with hypoxanthine and xanthine for oxidation by XD/XO, allopurinol inhibits the formation of uric acid, making allopurinol a useful drug in the treatment of gout (a complication of hyperuricemia). Allopurinol can also be used to evaluate the contribution of XOR to xenobiotic biotransformation in vivo. Like allopurinol, hydroxylated coumarin derivatives, such as umbelliferone (7-hydroxycoumarin) and esculetin (7,8-dihydroxycoumarin), are potent inhibitors of XD/XO. Allopurinol and other XOR inhibitors are being evaluated for the treatment of various types of ischemia-reperfusion and vascular injury that appear to be mediated, at least in part, by XOR (Pacher *et al*., 2006).

Monomethylated xanthines are preferentially oxidized to the corresponding uric acid derivatives by XD/XO. In contrast, dimethylated and trimethylated xanthines, such as theophylline (1,3-dimethylxanthine) and caffeine (1,3,7-trimethylxanthine), are oxidized to the corresponding uric acid derivatives primarily by cytochrome P450. Through two sequential *N*-demethylation reactions, cytochrome P450 converts caffeine to 1-methylxanthine, which is converted by XOR to 1-methyluric acid. The urinary ratio of 1-methylxanthine to 1-methyluric acid provides an in vivo marker of XOR activity.

The mechanism of catalysis by molybdozymes depicted in Fig. 6-26 is based on studies xanthine oxidase by Okamoto *et al.* (2004) and Amano *et al.* (2007). The molybdopterin active center

of the enzyme consists of molybdenum (Mo) bound to the following groups: pterin cofactor, thioxo ($=$S), oxo ($=$O) and hydroxyl ($-$OH). The hydroxyl group (Mo-OH) is activated by a nearby glutamic acid residue in the enzyme to Mo-O-, which initiates a nucleophilic attack on the substrate. This oxygen is incorporated into the substrate (e.g., xanthine) to form product (e.g., uric acid) and is replaced by oxygen from water. The resting enzyme is restored by the removal of two reducing equivalents, which may be transferred to NAD (in the case of XD) or oxygen (in the case of XO), as shown in Fig. 6-26.

In humans, XOR is a cytosolic enzyme that is widely distributed throughout the body, with the highest levels in heart, brain, liver, skeletal muscle, pancreas, small intestine, colon, and placenta. In humans, XOR appears to be encoded by a single gene (i.e., XDH). Although the sequences of two enzymes have been reported in the literature, the first report is now known to describe the sequence of human aldehyde oxidase. A complete deficiency of XOR (which may also involve a deficiency of aldehyde oxidase) gives rise to the rare genetic disorder, xanthinuria.

Aldehyde Oxidase   Aldehyde oxidase is the second of two molybdozymes that play an important role in xenobiotic biotransformation; the other being xanthine oxidase (discussed in the preceding section). Whereas xanthine oxidase exists in two forms, a dehydrogenase form (XD) that relays electrons to NAD$^+$ and an oxidase form (XO) that relays electrons to molecular oxygen, aldehyde oxidase exists only in the oxidase form apparently because it lacks an NAD$^+$ binding site (Terao *et al*., 1998). Another significant difference between these two molybdozymes is that high levels of xanthine oxidase appear to be widely distributed throughout the body, whereas high levels of aldehyde oxidase are found in the liver, with considerably less activity in other tissues, at least in humans. Apart from these differences, many of the features of xanthine oxidase apply to aldehyde oxidase, including subcellular location (cytosol), enzyme structure and cofactor composition, mechanism of catalysis, preference for oxidizing carbon atoms adjacent to the nitrogen atoms in nitrogen heterocycles, and its preference for oxidizing aromatic aldehydes over aliphatic aldehydes. Furthermore, aldehyde oxidase also transfers electrons to molecular oxygen, which can generate reactive oxygen species and lead to oxidative stress and lipid peroxidation. Therefore, the pathophysiologic features described for xanthine oxidase may similarly apply to aldehyde oxidase, especially in the case of ethanol-induced liver damage.

As shown in Figs. 6-22 and 6-25, aldehyde oxidase can oxidize a number of substituted pyrroles, pyridines, pyrimidines, purines, pteridines, and iminium ions by a mechanism that is presumably similar to that described for xanthine oxidase in the previous section. Aldehyde oxidase can oxidize aldehydes to their corresponding carboxylic acids, but the enzyme shows a marked preference for aromatic aldehydes (e.g., benzaldehyde, tamoxifen aldehyde). Consequently, aldehyde oxidase contributes negligibly to the oxidation of aliphatic aldehydes, such as acetaldehyde. Rodrigues (1994) found that, in a bank of human liver samples, aldehyde oxidase activity toward N^1-methylnicotinamide varied more than 40-fold, whereas activity toward 6-methylpurine varied less than threefold. Although this suggests human liver cytosol contains two or more forms of aldehyde oxidase, subsequent Southern blot analysis has provided evidence for only a single copy of the aldehyde oxidase gene in humans (Terao *et al*., 1998), although genomic analysis of chromosome 2 has revealed the presence of 3 nearby pseudogenes
Figure 6-26. Catalytic cycle of the molybdozyme xanthine oxidoreductase.

Xanthine oxidoreductase is a molybdozyme with xanthine dehydrogenase (XD) and xanthine oxidase (XO) activities. During the final step of the catalytic cycle, the enzyme is re-oxidized by transferring electrons to NAD$^+$ (in the case of XD) or oxygen (in the case of XO). The same mechanism of catalysis likely applies to aldehyde oxidase, although there is no dehydrogenase form of this molybdozyme.

(Dupl. 1-3) (Garrattini *et al.*, 2003). On the other hand, the mouse likely expresses multiple aldehyde oxidase enzymes because the mouse AOX1 gene (on chromosome 1) is followed by three homologous genes (AOH1-3) that, in contrast to human Dupl. 1-3, appear to encode functional enzymes.

A number of physiologically important aldehydes are substrates for aldehyde oxidase, including homovanillyl aldehyde (formed from dopamine), 5-hydroxy-3-indoleacetaldehyde (formed from serotonin), and retinal, which is converted by aldehyde oxidase to retinoic acid, an important regulator of cell growth, differentiation, and morphogenesis. The catabolism of catecholamines by monoamine oxidase produces dihydromandelaldehyde, which is oxidized by aldehyde oxidase to dihydromandelic acid. Therefore, aldehyde oxidase plays an important role in the catabolism of biogenic amines and catecholamines. In humans, the gene for aldehyde oxidase has been mapped to chromosome 2q33, placing it near a genetic marker that co-segregates with the recessive familial form of amyotrophic lateral sclerosis (Lou Gehrig disease). In mouse brain, aldehyde oxidase is localized in the choroid plexus and motor neurons, which lends further support to the proposal that aldehyde oxidase is a candidate gene for this particular motor neuron disease (Bendotti *et al.*, 1997).

In general, xenobiotics that are good substrates for aldehyde oxidase are poor substrates for cytochrome P450, and vice versa (Rettie and Fisher, 1999). Naphthalene (with no nitrogen atoms) is oxidized by cytochrome P450, but not by aldehyde oxidase, whereas the opposite is true of pteridine (1,3,5,8-tetraazanaphthalene), which contains four nitrogen atoms. The intermediate structure, quinazolone (1,3-diazanaphthalene) is a substrate for both enzymes. This complementarity in substrate specificity reflects the opposing preference of the two enzymes for oxidizing carbon atoms; cytochrome P450 prefers to oxidize carbon atoms with high electron density, whereas aldehyde oxidase (and XD/XO) prefers to oxidize carbon atoms with low electron density. The substrate specificity of aldehyde oxidase differs among mammalian species, with substrate size being the main differentiating factor. The active site of human aldehyde oxidase accommodates much smaller substrates than rabbit or guinea pig aldehyde oxidase. Substituents on a substrate that increase electronegativity tend to enhance V_{max}, whereas substituents that increase lipophilicity tend to increase affinity (decrease K_m). Another interesting species difference is that dogs possess little or no aldehyde oxidase activity. However, aldehyde oxidase in human liver has proven to be rather unstable, which complicates an in vitro assessment of species differences in aldehyde oxidase activity (Rodrigues, 1994; Rettie and Fisher, 1999). A further complication is the observation of species differences in the relative roles of aldehyde oxidase and XOR in xenobiotic biotransformation. For example, the 6-oxidation of antiviral deoxyguanine prodrugs is catalyzed exclusively in rats by XD/XO, but by aldehyde oxidase in humans (Rettie and Fisher, 1999).

Aldehyde oxidase is the second of two enzymes involved in the formation of cotinine, a major metabolite of nicotine excreted in the urine of cigarette smokers. The initial step in this reaction is the formation of a double bond (C=N) in the pyrrole ring, which produces nicotine $\Delta^{1',5'}$-iminium ion. Like nicotine, several other drugs are oxidized either sequentially or concomitantly by cytochrome P450 and aldehyde oxidase, including quinidine, azapetine, cyclophosphamide, carbazeran, and prolintane. Other drugs that are oxidized

by aldehyde oxidase include bromonidine, citalopram, proprion-aldehyde, O^6-benzylguanine, 6-mercaptopurine, metyrapone, quinine, pyrazinamide, methotrexate, vanillin, isovanillin, zaleplon, and famciclovir (an antiviral prodrug that is converted by aldehyde oxidase to penciclovir). Several pyrimidine derivatives are oxidized by aldehyde oxidase, including 5-ethyl-2($1H$)-pyrimidone, which is converted by aldehyde oxidase to 5-ethynyluracil. Like Sorivudine, 5-ethynyluracil is a metabolism-dependent (suicide) inactivator of dihydropyrimidine dehydrogenase (see Fig. 6-16).

Raloxifene and perphenazine are extraordinarily potent inhibitors of aldehyde oxidase (Obach, 2004). Menadione is also a potent inhibitor of aldehyde oxidase (K_i ∼0.1 μM) and is often used together with allopurinol to discriminate between aldehyde oxidase- and XOR-catalyzed reactions. Hydralazine has been used to assess the role of aldehyde oxidase in human drug metabolism in vivo. The ability of proadifen to inhibit aldehyde oxidase is noteworthy because this methadone analog, commonly known as SKF 525A, is widely used as a cytochrome P450 inhibitor.

Under certain conditions, aldehyde oxidase and XOR can also catalyze the reduction of xenobiotics, including azo-reduction (e.g., 4-dimethylaminoazobenzene), nitro-reduction (e.g., 1-nitropyrene), N-oxide reduction (e.g., S-(-)-nicotine-$1'$-N-oxide), nitrosamine reduction (e.g., N-nitrosodiphenylamine), hydroxamic acid reduction (e.g., N-hydroxy-2-acetylaminofluorene), sulfoxide reduction (e.g., sulindac; see Fig. 6-14), and epoxide reduction (e.g., benzo[a]pyrene 4,5-oxide). Oximes (C=NOH) can also be reduced by aldehyde oxidase to the corresponding ketimines (C=NH), which may react nonenzymatically with water to produce the corresponding ketone or aldehyde (C=O) and ammonia. An analogous reaction allows aldehyde oxidase to catalyze the reductive ring opening of zonisamide and 1,2-benzisoxazole, which results in the formation of an oxo-containing metabolite and ammonia (Sugihara *et al.*, 1996). The reduction of ziprasidone by aldehyde oxidase is shown in Fig. 6-3, and examples of other reductive reactions catalyzed by aldehyde oxidase are shown in Fig. 6-22. Xenobiotic reduction by aldehyde oxidase in vitro requires anaerobic conditions or the presence of a reducing substrate, such as N^1-methylnicotinamide, 2-hydroxypyrimidine, or benzaldehyde. These "co-substrates" reduce the enzyme, which in turn catalyzes azo-reduction, nitro-reduction, etc. by relaying electrons to xenobiotics (rather than molecular oxygen). These unusual requirements make it difficult to assess the degree to which aldehyde oxidase functions as a reductive enzyme in vivo.

Monoamine Oxidase, Diamine Oxidase, and Polyamine Oxidase
Monoamine oxidase (MAO; gene symbols MAOA and MAOB), diamine oxidase (DAO; gene symbol ABP1), and polyamine oxidase (PAO; gene symbol PAOX) are all involved in the oxidative deamination of primary, secondary, and tertiary amines (Benedetti, 2001; Agostinelli *et al.*, 2004; Edmondson *et al.*, 2004). Substrates for these enzymes include several naturally occurring amines, such as the monoamine serotonin (5-hydroxytryptamine), the diamine putrescine, and monoacetylated derivatives of the polyamines spermine and spermidine. A number of xenobiotics are substrates for these enzymes, particularly MAO. Oxidative deamination of a primary amine produces ammonia and an aldehyde, whereas oxidative deamination of a secondary amine produces a primary amine and an aldehyde. (The products of the former reaction—i.e., an aldehyde and ammonia—are those produced during the reductive biotransformation of certain oximes by aldehyde oxidase, as described in the

preceding section on "Aldehyde Oxidase"). The aldehydes formed by MAO are usually oxidized further by other enzymes to the corresponding carboxylic acids, although in some cases they are reduced to alcohols. Examples of reactions catalyzed by MAO, DAO, and PAO are shown in Fig. 6-27.

Monoamine oxidase is located throughout the brain, and is present in the liver, kidney, intestine, and blood platelets in the outer membrane of mitochondria. Its substrates include milacemide (Fig. 6-27), a dealkylated metabolite of propranolol (Fig. 6-27), primaquine, haloperidol, doxylamine, β-phenylethylamine, tyramine, catecholamines (dopamine, norepinephrine, epinephrine), tryptophan derivatives (tryptamine, serotonin), and tryptophan analogs known as triptans, which include the antimigraine drugs sumatriptan, zolmitriptan, and rizatriptan.

There are two forms of monoamine oxidase, called MAO-A and MAO-B. MAO-A preferentially oxidizes serotonin (5-hydroxytryptamine), norepinephrine, and the dealkylated metabolite of propranolol, and is preferentially inhibited by clorgyline, whereas MAO-B preferentially oxidizes β-phenylethylamine and benzylamine, and is preferentially inhibited by L-deprenyl (selegiline). Species differences in the substrate specificity of MAO have been documented. For example, dopamine is oxidized by MAO-B in humans, but by MAO-A in rats, and by both enzymes in several other mammalian species. Most tissues contain both forms of the enzyme, each encoded by a distinct gene, although some tissues express only one MAO. In humans, for example, only MAO-A is expressed in the placenta, whereas only MAO-B is expressed in blood platelets and lymphocytes. The distribution of MAO in the brain shows little species variation, with the highest concentration of MAO-A in the locus coeruleus, and the highest concentration of MAO-B in the raphe nuclei. MAO-A is expressed predominantly in catecholaminergic neurons, whereas MAO-B is expressed largely in serotonergic and histaminergic neurons and glial cells. The distribution of MAO throughout the brain does not always parallel that of its substrates. For example, serotonin is preferentially oxidized by MAO-A, but MAO-A is not found in serotonergic neurons.

MAO-A and -B are encoded by two distinct genes, both localized on the X-chromosome (Xp11.4-p11.3) and both comprise 15 exons with an identical intron–exon organization, which suggests they are derived from a common ancestral gene (Shih *et al.*, 1999). The amino acid sequence of MAO-A (Mr 59.7 kDa) is 70% identical to that of MAO-B (Mr 58.0 kDa). The deletion of both MAO-A and -B gives rise to Norrie disease, an X-linked recessive neurologic disorder characterized by blindness, hearing loss, and mental retardation (Shih *et al.*, 1999). Selective loss of MAO-A (due to a point mutation) gives rise to abnormal aggressiveness, whereas alterations in MAO-B have been implicated in Parkinson's disease (discussed later in this section).

The mechanism of catalysis by monoamine oxidase is illustrated below:

$$RCH_2NH_2 + FAD \rightarrow RCH=NH + FADH_2$$
$$RCH=NH + H_2O \rightarrow RCHO + NH_3$$
$$FADH_2 + O_2 \rightarrow FAD + H_2O_2$$
The substrate is oxidized by the enzyme, which itself is reduced (FAD → $FADH_2$). The oxygen incorporated into the substrate is derived from water, not molecular oxygen; hence, the enzyme functions as a true oxidase. The catalytic cycle is completed by reoxidation of the reduced enzyme ($FADH_2$ → FAD) by oxygen, which generates hydrogen peroxide (which may be a cause of oxidative
Figure 6-27. Examples of reactions catalyzed by monoamine oxidase (MAO), diamine oxidase (DAO), and polyamine oxidase (PAO).

Note that phenelzine is a metabolism-dependent (mechanism-based) inhibitor of MAO-A and MAO-B.
Figure 6-28. Activation of MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) to the neurotoxic metabolite, MPP$^+$ (1-methyl-4-phenylpyridine), by monoamine oxidase B.

The toxic pyridinium metabolite, MPP$^+$, is structurally similar to the herbicide paraquat MPDP$^+$, 1-methyl-4-phenyl-2,3-dihydropyridine.

stress). The initial step in the catalytic cycle appears to be abstraction of hydrogen from the α-carbon adjacent to the nitrogen atom, hence, the oxidative deamination of xenobiotics by MAO is generally blocked by substitution of the α-carbon. For example, amphetamine and other phenylethylamine derivatives carrying a methyl group on the α-carbon atom are not oxidized well by MAO. (Amphetamines can undergo oxidative deamination, but the reaction is catalyzed by cytochrome P450.) The abstraction of hydrogen from the α-carbon adjacent to the nitrogen atom can occur stereospecifically; therefore, only one enantiomer of an α-substituted compound may be oxidized by MAO. For example, whereas MAO-B catalyzes the oxidative deamination of both R- and S-β-phenylethylamine, only the R-enantiomer is a substrate for MAO-A. The oxidative deamination of the dealkylated metabolite of propranolol is catalyzed stereoselectively by MAO-A, although in this case the preferred substrate is the S-enantiomer (which has the same absolute configuration as the R-enantiomer of β-phenylethylamine) (Benedetti and Dostert, 1994).

Clorgyline and L-deprenyl (selegiline) are metabolism-dependent inhibitors (i.e., mechanism-based or suicide inactivators) of MAO-A and MAO-B, respectively. Both enzymes are irreversibly inhibited by phenelzine, a hydrazine that can be oxidized either by abstraction of hydrogen from the α-carbon atom, which leads to oxidative deamination with formation of benzaldehyde and benzoic acid, or by abstraction of hydrogen from the terminal nitrogen atom, which leads to formation of phenylethyldiazene and covalent modification of the enzyme, as shown in Fig. 6-27.

Monoamine oxidase has received considerable attention for its role in the activation of MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) to a neurotoxin that causes symptoms characteristic of Parkinson's disease in humans and monkeys but not rodents (Gerlach et al., 1991). In 1983, Parkinsonism was observed in young individuals who, in attempting to synthesize and use a narcotic drug related to meperidine (Demerol®), instead synthesized and self-administered MPTP, which causes selective destruc-

tion of dopaminergic neurons in the substantia nigra. MPTP crosses the blood–brain barrier, where it is oxidized by MAO in the astrocytes (a type of glial cell) to 1-methyl-4-phenyl-2,3-dihydropyridine (MPDP$^+$), which in turn autoxidizes to the neurotoxic metabolite, 1-methyl-4-phenylpyridine MPP$^+$, as shown in Fig. 6-28. Because it is transported by the dopamine transporter, MPP$^+$ concentrates in dopaminergic neurons, where it impairs mitochondrial respiration. The neurotoxic effects of MPTP can be blocked with pargyline (an inhibitor of both MAO-A and MAO-B), by L-deprenyl (a selective inhibitor of MAO-B) but not by clorgyline (a selective inhibitor of MAO-A). This suggests that the activation of MPTP to its neurotoxic metabolite is catalyzed predominantly by MAO-B. This interpretation is consistent with the finding that MAO-B knockout mice (i.e., transgenic mice that lack MAO-B) do not sustain damage to the dopaminergic terminals of nigrostriatal neurons after MPTP treatment (Shih et al., 1999; Quinn et al., 2007).

Genetic and environmental factors both appear to play important roles in the etiology of Parkinson's disease. Apart from MPTP, Parkinsongenic neurotoxins to which humans are exposed have not been identified unequivocally; hence, the environmental factors that cause Parkinson's disease remain to be identified. It is interesting that the bipyridyl herbicide, paraquat, is similar in structure to the toxic metabolite of MPTP, as shown in Fig. 6-28. Some epidemiological studies have shown a positive correlation between herbicide exposure and the incidence of Parkinsonism in some but not all rural communities. Haloperidol can also be converted to a potentially neurotoxic pyridinium metabolite (Subramanyam et al., 1991).

MAO-B may be among the genetic factors that affect susceptibility to Parkinson's disease. MAO-B activity in the human brain increases with aging, perhaps due to a proliferation of glial cells. It has been proposed that increased oxidation of dopamine by MAO-B in the elderly may lead to a loss of dopaminergic neurons in the substantia nigra, which underlies Parkinson's disease. Such damage may be caused by the oxidative stress associated with the oxidative deamination of dopamine by MAO-B. In support of this proposal,
Figure 6-29. Aromatization of cyclohexane carboxylic acid, a reaction catalyzed by rabbit and guinea pig liver mitochondria.

patients with Parkinson's disease have elevated MAO-B activity in the substantia nigra, and the MAO-B inhibitor L-deprenyl (selegiline) delays the progression of symptoms (Sano *et al.*, 1997). Furthermore, there are allelic variants of MAO-B, some of which (such as allele 1 and allele B4) appear to be associated with an increased risk of developing Parkinson's disease (Shih *et al.*, 1999). No such association has been found between Parkinson's disease and MAO-A gene polymorphisms. Cigarette smoking, which carries a number of health risks, has been shown nevertheless to provide some protection against Parkinson's disease (Gorell *et al.*, 1999). Although the mechanism of protection remains to be determined, it is interesting to note that cigarette smokers are known to have decreased levels of MAO-B (and MAO-A) (Shih *et al.*, 1999), the degree of which is proportional to cigarette usage (i.e., it is dose related) (Whitfield *et al.*, 2000).

MAO-A knockout mice have elevated brain levels of serotonin and a distinct behavioral syndrome, including enhanced aggression in adult males. The enhanced aggressive behavior exhibited by MAO-A knockout mice is consistent with the abnormal aggressive behavior in individuals who lack MAO-A activity due to a point mutation in the MAO-A gene (Shih *et al.*, 1999). Other polymorphisms in the MAO-A gene appear to be risk factors for alcoholism among Euro-Americans and Han Chinese (Shih *et al.*, 1999). MAO-B may also be a factor in alcoholism inasmuch as alcoholics (especially male Type 2 alcoholics) tend to have lower MAO activity in platelets, which only contain MAO-B. However, MAO-B activity is not lower in alcoholics when cigarette smoking status is taken into account, which suggests that MAO-B activity tends to be lower in alcoholics because smoking and alcohol dependence are strongly associated with each other (Whitfield *et al.*, 2000).

Although not present in mitochondria, PAO resembles MAO in its cofactor requirement and basic mechanism of action. Both enzymes use oxygen as an electron acceptor, which results in the production of hydrogen peroxide. The MAO inhibitor pargyline also inhibits PAO. The anticonvulsant milacemide is one of the few xenobiotic substrates for PAO, although it is also a substrate for MAO (Fig. 6-27). By converting milacemide to glycine (via glycinamide), MAO plays an important role in the anticonvulsant therapy with milacemide (Benedetti and Dostert, 1994).

Diamine oxidase is a cytosolic, copper-containing, pyridoxal phosphate-dependent enzyme present in liver, kidney, intestine, and placenta. Its preferred substrates include histamine and simple alkyl diamines with a chain length of 4 (putrescine) or 5 (cadaverine) carbon atoms. Diamines with carbon chains longer than 9 are not substrates for DAO, although they can be oxidized by MAO. DAO or a similar enzyme is present in cardiovascular tissue and appears to be responsible for the cardiotoxic effects of allylamine, which is converted by oxidative deamination to acrolein. Although histamine is a substrate for DAO, there is little or no DAO in brain (nor is there a receptor-mediated uptake system for histamine, in contrast to other neurotransmitters). For this reason, the major pathway of histamine metabolism in the brain is by methylation (see section "Methylation").

Semicarbazide-Sensitive Amine Oxidase (SSAO)   Semicarbazide-sensitive amine oxidase (SSAO; gene symbol AOC3) is a copper-containing enzyme that catalyzes fundamentally the same reaction catalyzed by monoamine oxidase:

$$RCH_2NH_2 + H_2O + O_2 \rightarrow RCHO + H_2O_2 + NH_3$$
SSAO can be distinguished from MAO by its sensitivity to inhibitors (it is inhibited by semicarbazide but not by clorgyline, deprenyl, or pargyline, whereas the opposite is true for MAO), and it is found on various cell surfaces and in plasma, whereas MAO is found in mitochondria. SSAO has been cloned and shown to be identical to vascular adhesion protin-1 (VAP-1). Plasma SSAO is a soluble, proteolytic cleavage product of membrane-bound SSAO. SSAO levels are increased in diabetic patients and decreased in individuals with major depression. Although SSAO activity in vitro is measured with benzylamine, there is little evidence to suggest that SSAO plays a major role in the metabolism of drugs or other xenobiotics in vivo (Obata, 2006; Roessner *et al.*, 2006; Wang *et al.*, 2006a).

Aromatization   The conversion of MPTP to MPP$^+$ (Fig. 6-28) is an example of a xenobiotic whose oxidation involves the introduction of multiple double bonds to achieve some semblance of aromaticity (in this case, formation of a pyridinium ion). Aromatization of xenobiotics is an unusual reaction, but some examples have been documented. A mitochondrial enzyme in guinea pig and rabbit liver can oxidize several cyclohexane derivatives to the corresponding aromatic hydrocarbon, as shown in Fig. 6-29 for the aromatization of cyclohexane carboxylic acid (hexahydrobenzoic acid) to benzoic acid. Mitochondria from rat liver are less active, and those from cat, mouse, dog, monkey, and human are completely inactive. The reaction requires magnesium, coenzyme A, oxygen, and ATP. The first step appears to be the formation of hexahydrobenzoyl-CoA, which is then dehydrogenated to the aromatic product. Glycine

Table 6-7
Characteristics of Some Human Peroxidases

PEROXIDASES	CELLULAR LOCATION	SUBCELLULAR LOCATION	HOMOLOGY WITH MPO
Myeloperoxidase (MPO)	Neutrophils, leukocytes	Lysosomes (human milk)	100%
Eosinophil peroxidase (EPO)	Eosinophils	Lysosomes	70%
Lactoperoxidase (LPO)	Mammary duct epithelial cells	Saliva, tears (bovine milk)	61%
Thyroid peroxidase (TPO)	Thyroid follicular cells	Microsomes, Golgi	47%
Prostaglandin-H synthase			
PHS1	Numerous extrahepatic tissues	Microsomes	
PHS2	Inflammatory cells	Microsomes	

Data adapted from O'Brien PJ: Peroxidases. *Chem Biol Interact* 129:113–139, 2000.

stimulates the reaction, probably by removing benzoic acid through conjugation to form hippuric acid. The conversion of androgens to estrogens involves aromatization of the A-ring of the steroid nucleus. This reaction is catalyzed by CYP19A1, one of the cytochrome P450 enzymes involved in steroidogenesis. Gut microflora can catalyze aromatization reactions, as shown in Fig. 6-1 for the conversion of quinic acid to benzoic acid.

Peroxidase-Dependent Cooxidation The oxidative biotransformation of xenobiotics generally requires the reduced pyridine nucleotide cofactors, NADPH and NADH. An exception is xenobiotic biotransformation by peroxidases, heme-containing enzymes that couple the reduction of hydrogen peroxide (or a lipid hydroperoxide) to the oxidation of other substrates (O'Brien, 2000; Tafazoli and O'Brien, 2005). Several different peroxidases catalyze the biotransformation of xenobiotics (in addition to performing important physiological functions), and these enzymes occur in a variety of tissues and cell types. Peroxidases do not play an important role in the first-pass metabolism or clearance of drugs and most other xenobiotics because their contribution is usually negligible compared with cytochrome P450 and other oxidative enzymes. However, peroxidases do play an important role in xenobiotic toxicity, especially the activation of drugs associated with idiosyncratic hepatotoxicity, blood dyscrasias (e.g., agranulocytosis, aplastic anemia) and skin rashes, and the activation of xenobiotics (including the activation of proximate carcinogens to ultimate carcinogens) in skin, bladder, bone marrow, and various other extrahepatic tissues.

In humans, the family of peroxidases includes myeloperoxidase (MPO), eosinophil peroxidase (EPO; gene symbol EPX), lactoperoxidase (LPO), thyroid peroxidase (TPO), and two forms of prostaglandin H synthase (PHS1 and PHS2; gene symbols PTGS1 and 2). Some basic features of these peroxidases are summarized in Table 6-7. These peroxidases all have physiological functions: MPO, EPO, and LPO are lysosomal enzymes present in neutrophils, eosinophils, and secretory cells of exocrine glands, respectively. During infection, MPO and EPO are released into phagocytic vacuoles (granules) and into the plasma, whereas LPO is released into saliva and tears, where they kill microorganisms and thereby provide protection against infectious agents such as bacteria and parasites. (Peroxidases are also present in milk: LPO is the predominant peroxidase in cow's milk, whereas MPO is the predominant peroxidase in human milk.) The hydrogen peroxide required by MPO and EPO is produced by a membrane-bound NADPH oxidase that is activated by the presence of infectious agents. Unlike MPO, EPO, and LPO, which are soluble enzymes, TPO is a membrane-bound peroxidase located on the apical membrane of thyroid follicular cells; it

catalyzes the iodination of tyrosine residues and the oxidative coupling of di- and mono-iodinated tyrosine residues in thyroglobulin to form triiodothyronine- and thyroxine-bound thyroglobulin, from which thyroid hormones are released. An NAD(P)H-oxidase known as p138 TOX (gene symbol DUOX2), which is also localized on the apical plasma membrane, produces the hydrogen peroxide required by TPO to synthesize thyroid hormones. PHS1 and PHS2 are the peroxidase component of cyclooxygenase 1 and 2 (COX1 and COX2); they are enzymes that convert arachidonic acid (and closely related fatty acids) to a variety of eicosanoids (prostaglandins, leukotrienes, thromboxane, and prostacyclin). In contrast to the other peroxidases, PHS1 and PHS2 do not require a source of hydrogen peroxide (although they can use it); hence, their activity is not dependent on an H_2O_2-generating NAD(P)H-oxidase. Catalase is also a peroxidase. This peroxisomal enzyme catalyzes the disproportionation of hydrogen peroxide to water and oxygen ($2H_2O_2 \rightarrow 2H_2O + O_2$). At low concentrations of hydrogen peroxide, catalase can catalyze the oxidation of ethanol (see Fig. 6-24) and various other small molecules. Glutathione peroxidases (GPXs) are a family of selenium-containing enzymes that also detoxify hydrogen peroxide (and lipid hydroperoxides) by reducing it to water, which is associated with the formation of oxidized glutathione as follows:

$$2GSH + HOOH \rightarrow GS.SG + H_2O + H_2O$$

In mammalian peroxidases (in contrast to plant peroxidases), the heme prosthetic group is covalently attached to the enzyme. Iron is bound to four pyrrole nitrogens with the nitrogen on the imidazole ring of histidine serving as the usual fifth ligand. The sixth coordination position is vacant so that peroxidases can interact with hydrogen peroxide (or other hydroperoxides), just as the sixth coordinate position of hemoglobin and myoglobin (both of which have low peroxidase activity) is available to bind molecular oxygen. The oxidation of a xenobiotic ($X \rightarrow XO$ or $2XH \rightarrow 2X\bullet + H_2O$) by peroxidase involves the conversion of hydrogen peroxide to water or the conversion of a hydroperoxide to the corresponding alcohol ($ROOH \rightarrow ROH$), during which the peroxidase (Fe^{III}) is converted to spectrophotometrically distinct states known as Compound I and Compound II, as shown below for the conversion of a xenobiotic phenol (X–OH) to the corresponding phenoxyl radical (R–O):

$$Peroxidase + ROOH \rightarrow Compound\ I + ROH$$
$$Compound\ I + XOH \rightarrow Compound\ II + XO\bullet + H^+$$
$$Compound\ II + XOH \rightarrow Peroxidase + XO\bullet + H_2O$$
In this example, the hydroperoxide is converted to the corresponding alcohol ($ROOH \rightarrow ROH$), and the peroxyl oxygen atom

is reduced to water (H_2O) by the one-electron oxidation of two molecules of xenobiotic (XOH) to produce two xenobiotic radicals (XO•). In some cases, the oxygen from the hydroperoxide is incorporated into the xenobiotic itself (XH → XOH). Examples of each reaction are given later in this section. The conversion of ROOH to ROH involves the release of an oxygen atom that coordinates with the heme iron (initially in the ferric or Fe^{III} state). This iron-bound oxygen formally contains only six (instead of eight) valence electrons, making it a powerful oxidizing species. One electron is removed from the iron to produce Fe^{IV}=O, and a second electron is removed from the tetrapyrrole ring to produce a π-porphyrin–cation radical (Por•$^+$), which corresponds to Compound I (Fe^{IV}=O–Por•$^+$). The transfer of an electron from a xenobiotic (XOH → XO• + H$^+$) to the porphyrin cation radical produces Compound II (Fe^{IV}=O–Por). In some cases, such as PHS, the electron donated to the initial Fe=O complex comes directly or indirectly from an amino acid rather than the tetrapyrrole ring, and this accounts in part for some of the differences among the various peroxidases (such as the ability of TPO to catalyze the iodination of tyrosine residues and the subsequent formation of thyroid hormones).

Although peroxidases are renowned for catalyzing one-electron oxidation reactions, they can catalyze the two-electron oxidation of iodide (I$^-$) to hypoiodous acid (HOI) and iodine which, in the case of TPO, is important for the synthesis of thyroid hormones:

Peroxidase Compound I(O) + I$^-$ + H$^+$ → HOI (hypoiodous acid)
Peroxidase Compound I(O) + 2 × I$^-$ + H$^+$ → I$_2$ (iodine) + OH$^-$
MPO, EPO, and LPO can all oxidize the pseudo-halide thiocyanate (SCN$^-$) faster than iodide, which in turn is oxidized faster than bromide, which is oxidized much faster than chloride. In fact, MPO is the only peroxidase with appreciable ability to oxidize chloride to hypochlorous acid. There is an inverse relationship between the rate of conversion of halides to hypohalous acids and their physiological plasma concentrations: chloride = 100–140 mM, bromide = 20–100 μM, and iodide = 0.1–0.5 μM. Consequently, the relatively low rate of chloride oxidation is offset by the high levels of chloride such that about half (20–70%) of the hydrogen peroxide produced by activated neutrophils is converted to hypochlorous acid, which reacts with glutathione, proteins, thiols, and amines, unsaturated fatty acids and cholesterol, all of which disrupt cell membranes and lead to cell lysis and death (of both infectious organisms and host cells). Formation of hypochlorous acid by MPO is not only important from a physiological perspective but also from a drug metabolism and toxicity perspective, as discussed later in this section. The preferred "halide" substrate for MPO is thiocyanate, which is present in plasma at concentrations ranging from 20 to 120 μM, which is sufficiently high that oxidation of thiocyanate consumes the other half of the hydrogen peroxide produced by activated neutrophils. Whereas MPO oxidizes chloride to hypochlorous acid, which is cytotoxic, it oxidizes thiocyanate to thiocyanogen [(SCN$_2$)], which rapidly hydrolyzes to hypothiocyanic acid (HOSCN). Hypothiocyanic acid is much less reactive and cytotoxic than hypochlorous acid, such that the oxidation of thiocyanate by peroxidases is a mechanism to remove hydrogen peroxide without forming hypochlorous acid. This appears to represent an important mechanism of hydrogen peroxide detoxication in saliva, which contains low levels of catalase but high levels (1–5 mM) of thiocyanate, and in the stomach, where the levels of thiocyanate in parietal cells are three times greater than plasma levels, which allows gastric peroxidase to inactivate hydrogen peroxide that otherwise stimulates gastric acid secretion by stimulating histamine release from mast cells. Inactivation of gastric peroxidase by aspirin, dexamethasone, indomethacin, or methimazole can result in gastric ulceration due to impaired detoxication of hydrogen peroxide and impaired synthesis of cytoprotective prostaglandins.

MPO and EPO can be distinguished by (1) their cellular distribution (neutrophils/leukocytes versus eosinophils); (2) their ability to oxidize halides (MPO is better than EPO at converting chloride to hypochlorous acid whereas EPO is better than MPO at converting bromide to hypobromous acid), and (3) their sensitivity to inhibitors (MPO is more sensitive to the inhibitory effect of cyanide over azide, whereas the opposite is true of EPO).

The level of EPO (or a related peroxidase) in uterine epithelial cells is regulated by estrogen; uterine peroxidase activity is inducible several hundred fold by estrogenic steroids, including the synthetic estrogens diethylstilbestrol and tamoxifen. The level of TPO in thyroid follicular cells is regulated by TSH. The enzyme is inactivated by a variety of ethylenethiourea drugs, such as propylthiouracil and methimazole (which is used as an antithyroid drug in patients with Grave's disease), as well as a number of naturally occurring flavonoid/resorcinol compounds that also have antithyroid effects. By inactivating TPO and impairing thyroid hormone synthesis, these chemicals trigger a large and prolonged increase in TSH that in rodents (but apparently not in humans) can result in thyroid follicular cell tumor formation.

MPO is an abundant enzyme is granulocytes, where it accounts for 5% of the dry weight. MPO can be used as a diagnostic marker to differentiate myeloid leukemia from lymphoid leukemia.

MPO has been implicated in the formation of reactive metabolites of drugs that cause idiosyncratic agranulocytosis, including clozapine, aminopyrine, vesnarinone, propylthiouracil, dapsone, sulfonamides, procainamide, amodiaquine, and ticlopidine (Liu and Uetrecht, 2000; O'Brien, 2000; Tafazoli and O'Brien, 2005). Many of these drugs are aromatic amines, and both MPO and PHS have also been implicated in the activation of several carcinogenic aromatic amines, such as benzidine, methylaminoazobenzene, and aminofluorene. Furthermore, inactivating polymorphisms in MPO (such as MPO-463A) appear to afford protection against both the activation of aromatic amines and PAH in tobacco smoke and the tumor-promoting effects of hydrogen peroxide formed by tobacco smoke-activated neutrophils (O'Brien, 2000).

In the presence of hydrogen peroxide and chloride (which are converted to hypochlorous acid by MPO), activated neutrophils and monocytes oxidize the aforementioned drugs to reactive intermediates (such as nitrogen-centered radicals, hydroxylamines, *N*-chloramines and, in the case of aromatic amines with a hydroxyl group in the *para*-position, quinoneimines or the corresponding semiquinoneimine radicals). In the case of ticlopidine, MPO converts the thiophene ring of this antiplatelet drug to a thiophene-*S*-chloride, a reactive metabolite that rearranges to 2-chloroticlopidine (minor) and dehydro-ticlopidine (major), or reacts with glutathione, as shown in Fig. 6-30. When catalyzed by activated neutrophils, ticlopidine oxidation is inhibited by low concentrations of azide and catalase. When catalyzed by purified myeloperoxidase, ticlopidine oxidation requires hydrogen peroxide and chloride, although all components of this purified system can be replaced with hypochlorous acid (HOCl). It is not known whether drugs that cause agranulocytosis are activated in the bone marrow by neutrophils or their precursors that contain myeloperoxidase, or are activated in neutrophils in the general circulation. In the latter case, agranulocytosis would presumably involve an immune response triggered by neoantigens
Figure 6-30. Activation of ticlopidine to a reactive thiophene S-chloride by myeloperoxidase.

formed in neutrophils by the covalent modification of cellular component by one or more of the reactive metabolites formed by MPO.

MPO has also been implicated in the formation of pro-oxidant phenoxyl radicals of etoposide, a topoisomerase inhibitor that causes myelogenous leukemia, and both MPO and PHS have been implicated in the formation of phenoxyl radicals of benzene, an industrial solvent linked to bone marrow suppression and leukemia. MPO and PHS cannot oxidize benzene itself. Liver cytochrome P450 converts benzene to phenol, which in turn is oxidized to hydroquinone, which can be converted to DNA-reactive metabolites by MPO in bone marrow leukocytes and by PHS in bone marrow. The myelosuppressive effect of benzene can be blocked by the PHS inhibitor, indomethacin, which suggests an important role for PHS-dependent activation in the myelotoxicity of benzene. The formation of phenol and hydroquinone in the liver is also impor-

tant for myelosuppression by benzene. However, such bone marrow suppression cannot be achieved simply by administering phenol or hydroquinone to mice, although it can be achieved by coadministering hydroquinone with phenol. Phenol stimulates the MPO- and PHS-dependent activation of hydroquinone. Therefore, bone marrow suppression by benzene involves the cytochrome P450-dependent oxidation of benzene to phenol and hydroquinone in the liver, followed by the phenol-enhanced, MPO- and PHS-catalyzed peroxidative oxidation of hydroquinone to reactive intermediates that bind to protein and DNA in the bone marrow (Fig. 6-31). It is noteworthy that the cytochrome CYP enzyme responsible for hydroxylating benzene has been identified as CYP2E1 (see section "Cytochrome P450"). Although CYP2E1 was first identified in liver, this same enzyme has been identified in bone marrow where it can presumably convert benzene to phenol and possibly hydroquinone.
Figure 6-31. Role of cytochrome P450 and peroxidases in the activation of benzene to myelo-toxic metabolites.

The importance of CYP2E1 in the metabolic activation of benzene was confirmed by the demonstration that CYP2E1 knockout mice are relatively resistant to the myelosuppressive effects of benzene (Gonzalez, 2003; Gonzalez and Yu, 2006).

Prostaglandin H synthase (PHS) is one of the most extensively studied peroxidases involved in xenobiotic biotransformation. As shown in Fig. 6-32, PHS is a dual-function enzyme composed of a *cyclooxygenase*, which converts arachidonic acid to PGG_2, a 15-hydroperoxide-endoperoxide (which involves the addition of two molecules of oxygen to each molecule of arachidonic acid), and a *peroxidase* that converts the 15-hydroperoxide to the corresponding 15-alcohol PGH_2, which can be accompanied by the oxidation of xenobiotics. The two forms of PHS, namely, PHS1 and PHS2, are better known as two forms of cyclooxygenase, namely, COX1 and COX2. A third cyclooxygenase, namely, COX3, has also been described, and is expressed predominantly in the cerebral cortex and heart. This enzyme is a splice variant of PHS1; one that retains the first intron in its mRNA (Chandrasekharan *et al*., 2002). PHS1 is a microsomal enzyme expressed in a wide variety of tissues that synthesize and release eicosanoids (prostaglandins, leukotrienes, thromboxane, prostacyclin), which generally bind to G-coupled cell surface receptors and regulate cellular function, largely in a paracrine (local) fashion. In contrast, PHS2 is expressed on the nuclear membrane of cells that respond to inflammatory cytokines, mitogens, tumor promoters, and AhR agonists (i.e., agents such as TNF-α, lipopolysaccharide, phorbol esters, TPA, dioxin). PGH2 appears to produce prostaglandins that activate receptors on the nuclear membrane, and high levels of the enzyme are expressed in colorectal and other tumors, which appear to be important for tumor promotion and angiogenesis (the process of stimulating the blood vessel supply). Both enzymes play an important role in the activation of xenobiotics to toxic or tumorigenic metabolites, particularly in extrahepatic tissues that contain low levels of cytochrome P450. PHS2 (COX2) also appears to play an important role in the subsequent response of tissues to cell damage and tumor initiation, and is a possible target for the treatment or prevention of certain types of cancer.

In certain cases, the oxidation of xenobiotics by peroxidases involves direct transfer of the peroxide oxygen to the xenobiotic, as shown in Fig. 6-32 for the conversion of substrate X to product XO. An example of this type of reaction is the PHS-catalyzed epoxidation of benzo[*a*]pyrene 7,8-dihydrodiol to the corresponding 9,10-epoxide (see Fig. 6-9). Although PHS can catalyze the final step (i.e., 9,10-epoxidation) in the formation of this tumorigenic metabolite of benzo[*a*]pyrene, it cannot catalyze the initial step (i.e., 7,8-epoxidation), which is catalyzed by cytochrome P450. Several lines of evidence suggest that both PHS1 and PHS2 play an important role in PAH-induced skin carcinogenesis. First, PHS1 knockout and PHS2 knockout mice are both resistant to PAH-induced skin cancer. (It is noteworthy that PHS1 knockout mice appear normal despite having only 1% of the prostaglandin levels of wild-type mice, whereas only 60% of PHS2 knockout mice survive until weaning, and the 40% that survive past weaning usually die within the year of kidney disease.) Resveratrol (an inhibitor of PHS1 and CYP1A1) and SC-58125 (an inhibitor of PHS2) both block PAH-induced skin cancer in mice.

PHS can also catalyze the 8,9-epoxidation of aflatoxin B_1, which is one of the most potent hepatotumorigens known. Epoxidation by cytochrome P450 is thought to be primarily responsible for the hepatotumorigenic effects of aflatoxin B_1. However, aflatoxin B_1 also causes neoplasia of rat renal papilla. This tissue has very low levels of cytochrome P450, but contains relatively high levels of PHS, which is suspected, therefore, of mediating the nephrotumorigenic effects of aflatoxin (Fig. 6-33).

The direct transfer of the peroxide oxygen from a hydroperoxide to a xenobiotic is not the only mechanism of xenobiotic oxidation by peroxidases, nor is it the most common. Xenobiotics that can serve as electron donors, such as amines and phenols, can be oxidized to free radicals during the reduction of a hydroperoxide. In this case, the hydroperoxide is still converted to the corresponding alcohol, but the peroxide oxygen is reduced to water instead of being incorporated into the xenobiotic. For each molecule of hydroperoxide reduced (which is a two-electron process), two molecules of xenobiotic can be oxidized (each by a one-electron process). Important
Figure 6-32. Cooxidation of xenobiotics (X) during the conversion of arachidonic acid to PGH₂ by prostaglandin H synthase.

classes of compounds that undergo one-electron oxidation reactions by peroxidase include aromatic amines, phenols, hydroquinones, and polycyclic hydrocarbons. Many of the metabolites produced are reactive electrophiles. For example, polycyclic aromatic hydrocarbons, phenols, and hydroquinones are oxidized to electrophilic quinones. Acetaminophen is similarly converted to a quinoneimine, namely, N-acetyl-benzoquinoneimine, a cytotoxic electrophile that binds to cellular proteins, as shown in Fig. 6-34. The formation of this toxic metabolite by cytochrome P450 causes centrilobular necrosis of the liver. However, acetaminophen can also damage the kidney medulla, which contains low levels of cytochrome P450 but relatively high levels of PHS; hence, PHS may play a significant role in the nephrotoxicity of acetaminophen. The two-electron oxidation of acetaminophen to N-acetyl-benzoquinoneimine by PHS likely involves the formation of a one-electron oxidation product, namely, N-acetyl-benzosemiquinoneimine radical. Formation of this semiquinoneimine radical by PHS likely contributes to the

nephrotoxicity of acetaminophen and related compounds, such as phenacetin and 4-aminophenol.

Like the kidney medulla, urinary bladder epithelium also contains low levels of cytochrome P450 but relatively high levels of PHS. Just as PHS in kidney medulla can activate aflatoxin and acetaminophen to nephrotoxic metabolites, so PHS in urinary bladder epithelium can activate certain aromatic amines, such as benzidine, 4-aminobiphenyl, and 2-aminonaphthalene, to DNA-reactive metabolites that cause bladder cancer in certain species, including humans and dogs. PHS can convert aromatic amines to reactive radicals, which can undergo nitrogen–nitrogen or nitrogen–carbon coupling reactions, or they can undergo a second one-electron oxidation to reactive diimines. Binding of these reactive metabolites to DNA is presumed to be the underlying mechanism by which several aromatic amines cause bladder cancer in humans and dogs. In some cases the one-electron oxidation of an amine leads to N-dealkylation. For example, PHS catalyzes the N-demethylation of aminopyrine, although in vivo this reaction is mainly catalyzed by cytochrome P450. In contrast to cytochrome P450, PHS does not
Figure 6-33. Activation of aflatoxin B₁ by cytochrome P450, leading to liver tumor formation, and by peroxidases, leading to renal papilla neoplasia.
Figure 6-34. Activation of acetaminophen by cytochrome P450, leading to hepatotoxicity, and by prostaglandin H synthase (PHS), leading to nephrotoxicity.

Conjugation with sulfonate, glucuronic acid, or glutathione represents detoxication reactions.

appear to catalyze the N-hydroxylation of carcinogenic aromatic amines (an important step in their metabolic activation), although MPO and LPO have been shown to catalyze this reaction. In liver, activation of aromatic amines by N-hydroxylation appears to be catalyzed predominantly by CYP1A2, whereas this same reaction in the bladder epithelium appears to be catalyzed by another enzyme, possibly a CYP enzyme other than CYP1A2, such as CYP2A13, CYP4B1, or CYP2S1 (Nakajima *et al.*, 2006), or a peroxidase other than PHS.

Many of the aromatic amines known or suspected of causing bladder cancer in humans have been shown to cause bladder tumors in dogs. In rats, however, aromatic amines cause liver tumors by a process that involves N-hydroxylation by cytochrome P450, followed by conjugation with acetate or sulfonate, as shown in Fig. 6-11. This species difference has complicated an assessment of the role of PHS in aromatic amine-induced bladder cancer,

because such experiments must be carried out in dogs. However, another class of compounds, the 5-nitrofurans, such as *N*-[4-(5-nitro-2-furyl)-2-thiazole]formamide (FANFT) and its deformylated analog 2-amino-4-(5-nitro-2-furyl)thiazole (ANFT), are substrates for PHS and are potent bladder tumorigens in rats. The tumorigenicity of FANFT is thought to involve deformylation to ANFT, which is oxidized to DNA-reactive metabolites by PHS. The ability of FANFT to cause bladder tumors in rats is blocked by the COX inhibitor, aspirin, which suggests that PHS plays an important role in the metabolic activation and tumorigenicity of this nitrofuran. Unexpectedly, combined treatment of rats with FANFT and aspirin causes forestomach tumors, which are not observed when either compound is administered alone.

Increased expression of PHS2 (COX2) has been documented in a number of tumors, including human colorectal, gastric, esophageal, pulmonary, and pancreatic carcinomas (Gupta and
Figure 6-35. Metabolite interaction between the phenolic antioxidants, butylated hydroxytoluene (BHT), and butylated hydroxyanisole (BHA).

Note that activation of BHT to a toxic quinone methide can be catalyzed by cytochrome P450 or, in the presence of BHA, by prostaglandin H synthase.

DuBois, 1998; Molina *et al.*, 1999). Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) block the formation of colon cancer in experimental animals, and there is epidemiological evidence that long-term use of certain NSAIDs (aspirin and sulindac), but not acetaminophen (which does not inhibit COX2), decreases the incidence of colorectal polyps and cancer in humans, and also decreases the number of deaths from esophageal, gastric, and rectal cancers. The incidence of intestinal neoplasms in Apc$^{\Delta 716}$ knockout mice is dramatically suppressed by crossing these transgenic animals with PHS2 (COX-2) knockout mice (Oshima *et al.*, 1996). From these few examples it is apparent that PHS2 may play at least two distinct roles in tumor formation; it may convert certain xenobiotics to DNA-reactive metabolites (and thereby *initiate* tumor formation), and it may somehow *promote* subsequent tumor growth, perhaps through formation of growth-promoting eicosanoids.

Many phenolic compounds can serve as reducing substrates for PHS peroxidase. The phenoxyl radicals produced by one-electron oxidation reactions can undergo a variety of reactions, including binding to critical nucleophiles, such as protein and DNA, reduction by antioxidants such as glutathione, and self-coupling. The reactions of phenoxyl radicals are analogous to those of the nitrogen-centered free radicals produced during the one-electron oxidation of aromatic amines by PHS.

It was previously mentioned in this section that phenol can enhance the peroxidative metabolism of hydroquinone, which is an

important component to benzene myelotoxicity. An analogous interaction has been described between the phenolic antioxidants, butylated hydroxytoluene (BHT), and butylated hydroxyanisole (BHA). In mice, the pulmonary toxicity of BHT, which is a relatively poor substrate for PHS, is enhanced by BHA, which is a relatively good substrate for PHS. The mechanism by which BHA enhances the pulmonary toxicity of BHT appears to involve the peroxidase-dependent conversion of BHA to a phenoxyl radical that interacts with BHT, converting it to a phenoxyl radical (by one-electron oxidation) or a quinone methide (by two-electron oxidation), as shown in Fig. 6-35. Formation of the toxic quinone methide of BHT can also be catalyzed by cytochrome P450, which is largely responsible for activating BHT in the absence of BHA.

Several reducing substrates, such as phenylbutazone, retinoic acid, 3-methylindole, sulfite, and bisulfite, are oxidized by PHS to carbon- or sulfur-centered free radicals that can trap oxygen to form a peroxyl radical, as shown in Fig. 6-36 for phenylbutazone. The peroxyl radical can oxidize xenobiotics in a peroxidative manner. For example, the peroxyl radical of phenylbutazone can convert benzo[*a*]pyrene 7,8-dihydrodiol to the corresponding 9,10-epoxide.

PHS is unique among peroxidases because it can both generate hydroperoxides and catalyze peroxidase-dependent reactions, as shown in Fig. 6-32. Xenobiotic biotransformation by PHS is controlled by the availability of arachidonic acid. The biotransformation of xenobiotics by other peroxidases is controlled by the availability
Figure 6-36. Oxidation of phenylbutazone by prostaglandin H synthase (PHS) to a carbon-centered radical and peroxyl radical.

Note that the peroxyl radical can oxidize xenobiotics (X) in a peroxidative manner.

of hydroperoxide substrates. Hydrogen peroxide is a normal product of cellular respiration, and lipid peroxides can form during lipid peroxidation. The level of these peroxides and their availability for peroxidase reactions depends on the efficiency of hydroperoxide scavenging by glutathione peroxidase and catalase.

Flavin Monooxygenases   Liver, kidney, intestine, brain, and lung contain one or more FAD-containing monooxygenases (FMO) that oxidize the nucleophilic nitrogen, sulfur, and phosphorus heteroatom of a variety of xenobiotics (Ziegler, 1993; Lawton *et al.*, 1994; Cashman, 1995, 1999; Rettie and Fisher, 1999; Cashman and Zhang, 2006). The mammalian FMO gene family comprises five enzymes (designated FMO1–FMO5) that contain 532–558 amino acid residues each and are 48–60% identical in amino acid sequence within a species, whereas orthologous forms are 82–86% identical across species (Hines *et al.*, 2002). Up to six FMO pseudogenes have also been observed, including one that shares 71% sequence identity with FMO3, namely, FMO6, for which nine distinct transcripts were identified in liver, but not kidney. All of these variant FMO6 transcripts arise by alternative splicing and lead to truncated,

and therefore nonfunctional, enzymes. The possibility remains that rare SNPs in the FMO6 pseudogene would lead to normal expression in some rare individuals, but this has not yet been documented (Hines *et al.*, 2002). The tertiary structure of human FMO has not yet been determined, but each FMO enzyme contains a highly conserved glycine-rich region (residues 4-32) that binds one mole of FAD (noncovalently) near the active site, which is adjacent to a second highly conserved glycine-rich region (residues 186–213) that binds NADPH. Other structural motifs have been reviewed in detail by Ziegler (2002).

Like CYP, the FMOs are microsomal enzymes that require NADPH and O_2, and many of the reactions catalyzed by FMO also can be catalyzed by CYP. Several in vitro techniques have been developed to distinguish reactions catalyzed by FMO from those catalyzed by CYP. In general, and in contrast to CYP, FMO is heat labile and can be inactivated in the absence of NADPH by warming microsomes to 50°C for 1 minute. By comparison, CYP can be inactivated with nonionic detergent, such as 1% Emulgen 911, which has a minimal effect on FMO activity. The pH optimum for FMO-catalyzed reactions (pH 8–10) tends to be higher than that for most (but not all) CYP reactions (pH 7–8). Antibodies raised against

purified CYP enzymes can be used not only to establish the role of CYP in a microsomal reaction but also to identify which particular CYP enzyme catalyzes the reaction. In contrast, antibodies raised against purified FMO do not inhibit the enzyme. The use of chemical inhibitors to ascertain the relative contribution of FMO and CYP to microsomal reactions is often complicated by a lack of specificity. For example, cimetidine and SKF 525A, which are well-recognized CYP inhibitors, are both substrates for FMO. Conversely, the FMO inhibitor methimazole is known to inhibit several of the CYP enzymes in human liver microsomes (namely, CYP2B6, CYP2C9, and CYP3A4). The situation is further complicated by the observation that the various forms of FMO differ in their thermal stability and sensitivity to detergents and other chemical modulators (examples of which are described later in this section).

FMO catalyzes the oxidation of nucleophilic tertiary amines to N-oxides, secondary amines to hydroxylamines and nitrones, and primary amines to hydroxylamines and oximes. Amphetamine, benzydamine, chlorpromazine, clozapine, guanethidine, imipramine, methamphetamine, olanzapine, and tamoxifen are examples of nitrogen-containing drugs that are N-oxygenated by FMO (and by CYP in most cases). FMO also oxidizes several sulfur-containing xenobiotics (such as thiols, thioethers, thiones, and thiocarbamates) and phosphines to S- and P-oxides, respectively. Cimetidine and sulindac sulfide are examples of sulfur-containing drugs that are converted to sulfoxides by FMO. Figure 6-14 shows how sulindac is reduced to sulindac sulfide, only to be oxidized by FMO back to the parent drug in what is often called a futile cycle. Hydrazines, iodides, selenides, and boron-containing compounds are also substrates for FMO. Examples of FMO-catalyzed reactions are shown in Fig. 6-37a and b. Zwitterions, positively-multiple charged compounds, and diamines such as cadaverine are generally not substrates (Krueger *et al.*, 2006).

In general, the metabolites produced by FMO are the products of a chemical reaction between a xenobiotic and a peracid or peroxide, which is consistent with the mechanism of catalysis of FMO (discussed later in this section). The reactions catalyzed by FMO are generally detoxication reactions, although there are exceptions to this rule, which are described below (this section). Inasmuch as FMO attacks nucleophilic heteroatoms, it might be assumed that substrates for FMO could be predicted simply from their pKa values (i.e., from a measure of their basicity). Although there is some truth to this—for example, xenobiotics containing an sp^3-hybridized nitrogen atom with a pKa of 5–10 are generally good substrates for FMO—predictions of substrate specificity based on pKa alone are not very reliable presumably because steric effects influence access of substrates to the FMO active site, which is consistent with the reported lack of rabbit FMO2 activity toward imipramine and chlorpromazine (Rettie and Fisher, 1999; Krueger *et al.*, 2006).

With few exceptions, FMO acts as an electrophilic oxygenating catalyst, which distinguishes it from most other flavoprotein oxidases and monooxygenases (which will be discussed further in the section "Cytochrome P450"). The mechanism of catalysis by FMO is depicted in Fig. 6-38. After the FAD moiety is reduced to FADH$_2$ by NADPH, the oxidized cofactor, NADP$^+$, remains bound to the enzyme. FADH$_2$ then binds oxygen to produce a peroxide (i.e., the 4a-hydroperoxyflavin of FAD). The peroxide is relatively stable, probably because the active site of FMO comprises nonnucleophilic, lipophilic amino acid residues, and this is thought to be the form in which FMO exists in vivo. During the oxygenation of xenobiotics, the 4a-hydroperoxyflavin is converted to 4a-hydroxyflavin with transfer of the flavin peroxide oxygen to the substrate (depicted
Figure 6-38. Catalytic cycle of flavin monooxygenase (FMO).

X and XO are the xenobiotic substrate and oxygenated product, respectively. The 4a-hydroperoxyflavin and 4a-hydroxyflavin of FAD are depicted as FADHOOH and FADHOH, respectively.

as X $\rightarrow$ XO in Fig. 6-38). From this latter step, it is understandable why the metabolites produced by FMO are generally the products of a chemical reaction between a xenobiotic and a peroxide or peracid. The final step in the catalytic cycle involves dehydration of 4a-hydroxyflavin (which restores FAD to its resting, oxidized state) and release of NADP$^+$. This final step is important because it is rate limiting, and it occurs after substrate oxygenation. Consequently, this step determines the upper limit of the rate of substrate oxidation. Therefore all good substrates for FMO are converted to products at the same maximum rate (i.e., V_{max} is determined by the final step in the catalytic cycle). Binding of NADP$^+$ to FMO during catalysis is important because it prevents the reduction of oxygen to H$_2$O$_2$. In the absence of bound NADP$^+$, FMO would function as an NADPH-oxidase that would consume NADPH and cause oxidative stress through excessive production of H$_2$O$_2$.

The oxygenation of substrates by FMO does not lead to inactivation of the enzyme, even though some of the products are strong electrophiles capable of binding covalently to critical and noncritical nucleophiles such as protein and glutathione, respectively. The products of the oxygenation reactions catalyzed by FMO and/or the oxygenation of the same substrates by CYP can inactivate CYP. For example, the FMO-dependent S-oxygenation of spironolactone thiol (which is formed by the deacetylation of spironolactone by carboxylesterases, as shown in Fig. 6-4) leads to the formation of an electrophilic sulfenic acid (R–SH $\rightarrow$ R–SOH) that can undergo redox cycling, or be further converted to the reactive sulfinic acid that inactivates CYP and binds covalently to other proteins (Krueger *et al.*, 2006).

In humans, FMO plays an important role in the biotransformation of several drugs (e.g., benzydamine, cimetidine, clozapine, guanethidine, methimazole, olanzapine, ranitidine, sulindac sulfide, tamoxifen, hydrazines such as procarbazine, and various dimethylaminoalkyl phenothiazine derivatives such as chlorpromazine and imipramine), xenobiotics (e.g., aldicarb, cocaine, disulfoton, fenthion, methamphetamine, nicotine, tyramine), and endogenous substrates (e.g., trimethylamine, cysteamine, and lipoic acid). The

major flavin monooxygenase in human liver microsomes, FMO3, is predominantly if not solely responsible for converting (*S*)-nicotine to (*S*)-nicotine *N*-1′-oxide (which is one of the reactions shown in Fig. 6-37a). The reaction proceeds stereospecifically; only the *trans* isomer is produced by FMO3, and this is the only isomer of (*S*)-nicotine *N*-1′-oxide excreted in the urine of cigarette smokers or individuals wearing a nicotine patch (Cashman and Zhang, 2006). Therefore, the urinary excretion of *trans*-(*S*)-nicotine *N*-1′-oxide can be used as an in vivo probe of FMO3 activity in humans. FMO3 is also the principal enzyme involved in the S-oxygenation of cimetidine, an H_2-antagonist widely used in the treatment of gastric ulcers and other acid-related disorders (this reaction is shown in Fig. 6-37b). Cimetidine is stereoselectively sulfoxidated by FMO3 to an 84:16 mixture of (+) and (−) enantiomers, which closely matches the 75:25 enantiomeric composition of cimetidine *S*-oxide in human urine. Therefore, the urinary excretion of cimetidine *S*-oxide, like that of (*S*)-nicotine *N*-1′-oxide, is an in vivo indicator of FMO3 activity in humans.

Sulindac is a sulfoxide that exists in two stereochemical forms (as do most sulfoxides), and a racemic mixture of *R*- and *S*-sulindac is used therapeutically as a nonsteroidal anti-inflammatory drug (NSAID). As shown in Fig. 6-14, the sulfoxide group in sulindac is reduced to the corresponding sulfide (which is achiral), which is then oxidized back to sulindac (a process often described as futile cycling). In human liver, the sulfoxidation of sulindac sulfide is catalyzed by FMO3 with little or no contribution from CYP. At low substrate concentrations (30 μM), FMO3 converts sulindac sulfide to *R*−and *S*-sulindac in an 87:13 ratio (Hamman *et al.*, 2000). Consequently, although sulindac is administered as a racemic mixture (i.e., a 1:1 mixture of *R*- and *S*-enantiomers), the reduction of this drug to the corresponding sulfide and its preferential sulfoxidation by FMO3 to *R*-sulindac results in stereoselective enrichment of *R*-sulindac in serum and urine.

In the case of sulindac sulfide, stereoselective sulfoxidation occurs not only with human FMO3 (the major drug-metabolizing FMO in human liver), but also with porcine FMO1 (the major form expressed in pig liver) and rabbit FMO2 (the major form expressed in rabbit lung) (Hamman *et al.*, 2000). However, this conformity is the exception, rather than the rule. For example, in contrast to the stereoselective oxygenation of (*S*)-nicotine and cimetidine by human FMO3 (see above), FMO1 (which is the major FMO expressed in pig, rat, and rabbit liver) converts (*S*)-nicotine to a 1:1 mixture of *cis*- and *trans*-(*S*)-nicotine *N*-1′-oxide, and similarly converts cimetidine to a 1:1 mixture of (+) and (−) cimetidine *S*-oxide, respectively. Therefore, statements concerning the role of FMO in the disposition of xenobiotics in humans may not apply to other species, or vice versa.

Several sulfur-containing xenobiotics are oxygenated by FMO to electrophilic reactive intermediates. Such xenobiotics include various thiols, thioamides, 2-mercaptoimidazoles, thiocarbamates, and thiocarbamides. The electrophilic metabolites of these xenobiotics do not inactivate FMO, but they can covalently modify and inactivate neighboring proteins, including CYP. Some of these same xenobiotics are substrates for CYP, and their oxygenation to electrophilic metabolites leads to inactivation of CYP, a process known variously as metabolism-dependent inhibition, mechanism-based inhibition, and suicide inactivation. 2-Mercaptoimidazoles undergo sequential S-oxygenation reactions by FMO, first to sulfenic acids and then to sulfinic acids ($R–SH \rightarrow R–SOH \rightarrow R–SO_2H$). These electrophilic metabolites, like the sulfenic acid metabolite produced from spironolactone thiol (see above), bind to critical nucleophiles

(such as proteins) or interact with glutathione to form disulfides. The thiocarbamate functionality present in numerous agricultural chemicals is converted by FMO to *S*-oxides (sulfoxides), which can be further oxygenated to sulfones. These reactions involve S-oxygenation adjacent to a ketone, which produces strong electrophilic acylating agents, which may be responsible for the toxicity of many thiocarbamate herbicides and fungicides. The hepatotoxicity of thiobenzamide is dependent on S-oxidation by FMO and/or CYP. As shown in Fig. 6-37b, the S-oxidation of thiobenzamide produces an *S*-oxide, which can rearrange to an oxathiirane (a three-membered ring of carbon, sulfur, and oxygen) upon photolysis or thermolysis. However, such oxathiiranes are readily reduced back to the *S*-oxide. In vivo, the *S*,*S*-dioxide is more likely to form, which readily tautomerizes to iminosulfinic acid, binds covalently to protein (which leads to hepatocellular necrosis) or rearranges to benzamide, a reaction known as *oxidative group transfer*.

Endogenous FMO substrates include cysteamine, which is oxidized to the disulfide, cystamine, and trimethylamine (TMA), which is converted to TMA *N*-oxide (Fig. 6-37b). By converting cysteamine to cystamine, FMO may serve to produce a low-molecular weight disulfide-exchange agent, which may participate in the formation of disulfide bridges during peptide synthesis or the renaturation of proteins. By converting TMA to TMA *N*-oxide, FMO converts a malodorous and volatile dietary product of choline, lecithin, and carnitine catabolism to an inoffensive metabolite. TMA smells of rotting fish, and people who are genetically deficient in FMO3 suffer from trimethylaminuria or *fish-odor syndrome*, which is caused by the excretion of TMA in urine, sweat, and breath (Ayesh and Smith, 1992). The underlying genetic basis of trimethylaminuria is a mutation ($Pro_{153} \rightarrow Leu_{153}$) in exon 4 of the FMO3 gene (Dolphin *et al.*, 1997). Although this mutation (and hence trimethylaminuria) occurs only rarely, it is now known to be just one of several mutations that decrease or eliminate FMO3 activity; these other mutations include missense mutations ($Glu_{32} \rightarrow Lys_{32}$, $Ala_{52} \rightarrow Thr_{52}$, $Met_{66} \rightarrow Ile_{66}$, $Met_{82} \rightarrow Thr_{82}$, $Glu_{314} \rightarrow X_{314}$, $Arg_{387} \rightarrow Leu_{387}$, $Arg_{492} \rightarrow Trp_{492}$, etc.) and the nonsense mutation $Glu_{305} \rightarrow X_{305}$ (Cashman *et al.*, 2000; Cashman and Zhang, 2006). As might be expected, trimethylaminuria is associated with an impairment of nicotine N-oxidation and other pathways of drug biotransformation that are primarily catalyzed by FMO3 (Rettie and Fisher, 1999). For instance, benzydamine N-oxygenation has been correlated with FMO3 genotype in trimethylaminurics (Cashman and Zhang, 2006).

Humans and other mammals express five different flavin monooxygenases (FMO1, FMO2, FMO3, FMO4, and FMO5) in a species- and tissue-specific manner, as shown in Table 6-8 (adapted from Cashman, 1995; Cashman and Zhang, 2006; Zhang and Cashman, 2006). For example, the major hepatic FMOs expressed in humans are FMO3 and FMO5, whereas FMO1 is the major FMO expressed in rat, rabbit, and pig liver. Previously, FMO3 has been considered to be the dominant FMO in human liver, but FMO5 expression is higher, but has activity toward fewer xenobiotic substrates, and likely plays only a minor role in xenobiotic metabolism (Cashman and Zhang, 2006). FMO5 is also the most highly expressed FMO in the small intestine. In humans, high levels of FMO1 are expressed in the kidney, and low levels of FMO2 are expressed in the lungs of Caucasians and Asians. However, lung microsomes from other species, particularly rabbit, mouse, and monkey, contain high levels of expressed FMO2, and of the FMO transcripts detected in human lung, the FMO2 transcript is found at the highest levels by far (Zhang and Cashman, 2006). The uncharacteristically low levels of active FMO2 in human lung is caused by a mutation (a C $\rightarrow$ T

[a] Human levels are based on tissue expression of FMO as reported in Cashman and Zhang (2006) and are based on mRNA levels.
[b] FMO2 mRNA levels in human lung are high, but this mRNA is not translated into functional enzyme due to the presence of a truncation mutation in Caucasians and Asians. About 26% of African Americans, 7% of Puerto Ricans, and 2% of Mexicans have one normal allele and express a functional protein.
SOURCE: Data adapted from Cashman JR, Zhang J: Human flavin-containing monooxygenases. *Annu Rev Pharmacol Toxicol* 46:65–100, 2006; Zhang J, Cashman JR: Quantitative analysis of FMO gene mRNA levels in human tissues. *Drug Metab Dispos* 34:19–26, 2006; Cashman JR: Structural and catalytic properties of the mammalian flavin-containing monooxygenase. *Chem Res Toxicol* 8:166–181, 1995.

transition at codon 472) in the major human FMO2*2 allele found in Caucasians and Asians, which results in the synthesis of a nonfunctional, truncated protein (one lacking the last 64 amino acid residues from the C-terminus) (Dolphin *et al.*, 1998). In contrast, 26% of African Americans, 7% of Puerto Ricans, and 2% of Mexicans have one normal allele and express a functional protein (Cashman and Zhang, 2006). In pulmonary microsomes from individuals who express one or more functional FMO2 alleles, the protein level is equal to or greater than that of CYPs. Functional FMO2 appears to have high S-oxygenation activity toward thioureas and thioamides, which implies that individuals who express a functional FMO2 may be more susceptible to the toxic effects of sulfenic acids, whereas Caucasians and Asians may be protected from thioether-containing pesticides (Cashman and Zhang, 2006). FMO4 appears to be expressed at low levels in the brain of several mammalian species, where it might terminate the action of several centrally active drugs and other xenobiotics. FMO4 is unstable, however, which makes its characterization somewhat difficult (Cashman and Zhang, 2006).

The various forms of FMO are distinct gene products with different physical properties and substrate specificities. For example, FMO2 *N*-oxygenates *n*-octylamine, whereas such long aliphatic primary amines are not substrates for FMO1, although they stimulate its activity toward other substrates (in some cases causing a change in stereospecificity). Conversely, short-chain tertiary amines, such as chlorpromazine, orphenadrine, and imipramine, are substrates for FMO1 but not FMO2. FMO2 exhibits no activity toward phenothiazine derivatives with only a 3-carbon side chain or 1,3-diphenylthiourea (Krueger *et al.*, 2006). FMO3 is highly selective in the N-oxygenation of trimethylamine, whereas FMO5 is selective for the N-oxygenation of short-chain aliphatic primary amines such as *N*-octylamine, but has little activity toward other typical

FMO substrates (Krueger *et al.*, 2006). The substrate specificity of FMO4 also appears to be somewhat restricted. Certain substrates are oxygenated stereospecifically by one FMO enzyme but not another. For example, FMO2 and FMO3 convert (*S*)-nicotine exclusively to *trans*-(*S*)-nicotine *N*-1′-oxide, whereas the *N*-oxides of (*S*)-nicotine produced by FMO1 are a 1:1 mixture of *cis* and *trans* isomers. FMO2 is heat stable under conditions that completely inactivate FMO1, and FMO2 is resistant to anionic detergents that inactivate FMO1. Low concentrations of bile acids, such as cholate, stimulate FMO activity in rat and mouse liver microsomes but inhibit FMO activity in rabbit and pig liver.

The FMO enzymes expressed in liver microsomes are not under the same regulatory control as CYP enzymes. In rats, the expression of FMO1 is suppressed rather than induced by treatment with phenobarbital or 3-methylcholanthrene (although some studies point to a modest [∼3 fold] induction of rat FMO1 by 3-methylcholanthrene). Indole-3-carbinol, which induces the same CYP enzymes as 3-methylcholanthrene, causes a marked decrease in FMO activity in rat liver and intestine. A similar decrease in FMO3 activity occurs in human volunteers following the consumption of large amounts of Brussels sprouts, which contain high levels of indole-3-carbinol and related indoles. The decrease in FMO3 activity may result from direct inhibition of FMO3 by indole-3-carbinol and its derivatives rather than from an actual decrease in enzyme levels (Cashman *et al.*, 1999). However, the AHR-agonist, TCDD was found to induce FMO2 and FMO3 mRNA levels in mice by 30- and 80-fold, respectively (Tijet *et al.*, 2006).

The levels of FMO3 and, to a lesser extent, the levels of FMO1 in mouse liver microsomes are sexually differentiated (female > male) due to suppression of expression by testosterone. The opposite is true of FMO1 levels in rat liver microsomes, the expression of which is positively regulated by testosterone and negatively

regulated by estradiol. In pregnant rabbits, lung FMO2 is positively regulated by progesterone and/or corticosteroids.

Species differences in the relative expression of FMO and CYP appear to determine species differences in the toxicity of the pyrrolizidine alkaloids, senecionine, retrorsine, and monocrotaline. These compounds are detoxified by FMO, which catalyzes the formation of tertiary amine *N*-oxides, but are activated by CYP, which oxidizes these alkaloids to pyrroles that generate toxic electrophiles through the loss of substituents on the pyrrolizidine nucleus (details of which appear in the section "Cytochrome P450"). Rats have a high pyrrole-forming CYP activity and a low *N*-oxide forming FMO activity, whereas the opposite is true of guinea pigs. This likely explains why pyrrolizidine alkaloids are highly toxic to rats but not to guinea pigs. Many of the reactions catalyzed by FMO are also catalyzed by CYP, but differences in the oxidation of pyrrolizidine alkaloids by FMO and CYP illustrate that this is not always the case.

Cytochrome P450   Of all the xenobiotic-biotransforming enzymes, the cytochrome P450 (CYP) enzyme system ranks first in terms of catalytic versatility and the sheer number of xenobiotics it detoxifies or activates to reactive intermediates. The highest levels of CYP enzymes involved in xenobiotic biotransformation are found in liver endoplasmic reticulum (microsomes), but CYP enzymes are present in virtually all tissues. The liver microsomal CYP enzymes play a very important role in determining the intensity and duration of action of drugs, and they also play a key role in the detoxication of xenobiotics. CYP enzymes in liver and extrahepatic tissues play important roles in the activation of xenobiotics to toxic and/or tumorigenic metabolites. The catalytic versatility of CYP enzymes is apparent from Table 6-2, which shows some of the many chemical groups that can be metabolized by cytochrome P450.

Microsomal and mitochondrial CYP enzymes play key roles in the biosynthesis or catabolism of steroid hormones, bile acids, fat-soluble vitamins such as vitamins A and D, fatty acids, and eicosanoids such as prostaglandins, thromboxane, prostacyclin, and leukotrienes, which underscores the catalytic versatility of cytochrome P450. In humans, the metabolism of the aforementioned endobiotics and the biotransformation of innumerable xenobiotics are catalyzed by 57 CYP enzymes, as shown in Table 6-9. In several cases, there is no clear functional distinction in terms of endobiotic and xenobiotic metabolism because there are many examples of CYP enzymes playing an important role in the metabolism of both an endobiotic and a drug or other xenobiotic.

All CYP enzymes are heme-containing proteins. The heme iron in cytochrome P450 is usually in the ferric (Fe^{3+}) state. When reduced to the ferrous (Fe^{2+}) state, cytochrome P450 can bind ligands such as O_2 and carbon monoxide (CO). The complex between ferrous cytochrome P450 and CO absorbs light maximally at 450 nm, from which cytochrome P450 derives its name. The absorbance maximum of the CO complex differs slightly among different CYP enzymes and ranges from 447 nm to 452 nm. All other hemoproteins that bind CO absorb light maximally at ~420 nm. The unusual absorbance maximum of cytochrome P450 is due to an unusual fifth ligand to the heme (a cysteine-thiolate). The amino acid sequence around the cysteine residue that forms the thiolate bond with the heme moiety is highly conserved in all CYP enzymes. When this thiolate bond is disrupted, cytochrome P450 is converted to a catalytically inactive form called cytochrome P420.

Table 6-9

Classification of the 57 Human CYP Enzymes

XENOBIOTICS	STEROIDOGENIC	FATTY ACIDS/ EICOSANOIDS	UNKNOWN
CYP1A1	CYP11A1	CYP4A11	CYP2A7
CYP1A2	CYP11B1	CYP4B1	CYP2S1
CYP1B1	CYP11B2	CYP4F2	CYP2U1
CYP2A6	CYP17A1	CYP4F8	CYP2W1
CYP2A13	CYP19A1	CYP4F12	CYP3A43
CYP2B6	CYP21A2	CYP5A1[a]	CYP4A22
CYP2C8[b]		CYP8A1[c]	CYP4F11
CYP2C9[b]	**BILE ACID**		CYP4F22
CYP2C18	CYP7A1	**VITAMIN D**	CYP4V2
CYP2C19	CYP7B1	CYP24A1	CYP4X1
CYP2D6	CYP8B1	CYP26C1[d]	CYP4Z1
CYP2E1	CYP27A1[e]	CYP27B1	CYP20A1
CYP2F1	CYP39A1	CYP2R1	CYP27C1
CYP2J2[b]	CYP46A1		
CYP3A4[f]	CYP51A1[g]	**RETINOIC ACID**	
CYP3A5		CYP26A1	
CYP3A7		CYP26B1	
CYP4F3[b]			

[a] Thromboxane A synthase (TBXAS1).
[b] Also involved in fatty acid and eicosanoid metabolism.
[c] Prostaglandin I_2 (prostacyclin) synthase (PTGIS).
[d] Also involved in retinoic acid metabolism.
[e] Also involved in vitamin D metabolism.
[f] Also involved in bile acid synthesis.
[g] Also involved in cholesterol biosynthesis.

By competing with oxygen, CO inhibits cytochrome P450. The inhibitory effect of carbon monoxide can be reversed by irradiation with light at 450 nm, which photodissociates the cytochrome P450–CO complex. These properties of cytochrome P450 are of historical importance. The observation that treatment of rats with certain chemicals, such as 3-methylcholanthrene, causes a shift in the peak absorbance of cytochrome P450 (from 450 nm to 448 nm) provided some of the earliest evidence for the existence of multiple forms of cytochrome P450 in liver microsomes. The conversion of cytochrome P450 to cytochrome P420 by detergents and phospholipases helped to establish the hemoprotein nature of cytochrome P450. The inhibition of cytochrome P450 by CO and the reversal of this inhibition by photodissociation of the cytochrome P450–CO complex established cytochrome P450 as the microsomal and mitochondrial enzyme involved in drug biotransformation and steroid biosynthesis.

The basic reaction catalyzed by CYP enzymes is monooxygenation in which one atom of oxygen is incorporated into a substrate, designated RH, and the other is reduced to water with reducing equivalents derived from NADPH, as follows:

$$\text{Substrate (RH)} + O_2 + \text{NADPH} + H^+ \rightarrow$$
$$\text{Product (ROH)} + H_2O + \text{NADP}^+$$

Although cytochrome P450 functions as a monooxygenase, the products are not limited to alcohols and phenols due to rearrangement reactions (Guengerich, 1991, 2001b; Isin and Guengerich, 2007). During catalysis, cytochrome P450 binds directly to the substrate and molecular oxygen, but it does not interact directly with NADPH or NADH. The mechanism by which cytochrome

P450 receives electrons from NAD(P)H depends on the subcellular localization of cytochrome P450. In the endoplasmic reticulum, which is where most of the CYP enzymes involved in xenobiotic biotransformation are localized, electrons are relayed from NADPH to cytochrome P450 via a flavoprotein called NADPH-cytochrome P450 reductase (also known as an oxidoreductase or OR; gene symbol POR). Within this flavoprotein, electrons are transferred from NADPH to cytochrome P450 via FMN and FAD. In mitochondria, which house many of the CYP enzymes involved in steroid hormone biosynthesis and vitamin D metabolism, electrons are transferred from NAD(P)H to cytochrome P450 via two proteins; an iron–sulfur protein called ferredoxin (gene symbol FDX1), and an FMN-containing flavoprotein called ferredoxin reductase (gene symbol FDXR). These proteins are also known as adrenodoxin and adrenodoxin reductase. In bacteria such as *Pseudomonas putida* electron flow is similar to that in mitochondria (NADH → flavoprotein → putidaredoxin → P450).

There are some notable exceptions to the general rule that cytochrome P450 requires a second enzyme (i.e., a flavoprotein) for catalytic activity. One exception applies to two CYP enzymes involved in the conversion of arachidonic acid to eicosanoids, namely, thromboxane A synthase (CYP5A1) and prostaglandin I$_2$ synthase, which is also known as prostacyclin synthase (CYP8A1). These two CYP enzymes convert the endoperoxide, PGH$_2$, to thromboxane (TXA$_2$) and prostacyclin (PGI$_2$) in platelets and the endothelial lining of blood vessels, respectively. In both cases, cytochrome P450 functions as an isomerase and catalyzes a rearrangement of the oxygen atoms introduced into arachidonic acid by cyclooxygenase (see Fig. 6-32). The plant cytochrome P450, allene oxide synthase (CYP74A1), and certain invertebrate CYP enzymes also catalyze the rearrangement of oxidized chemicals.

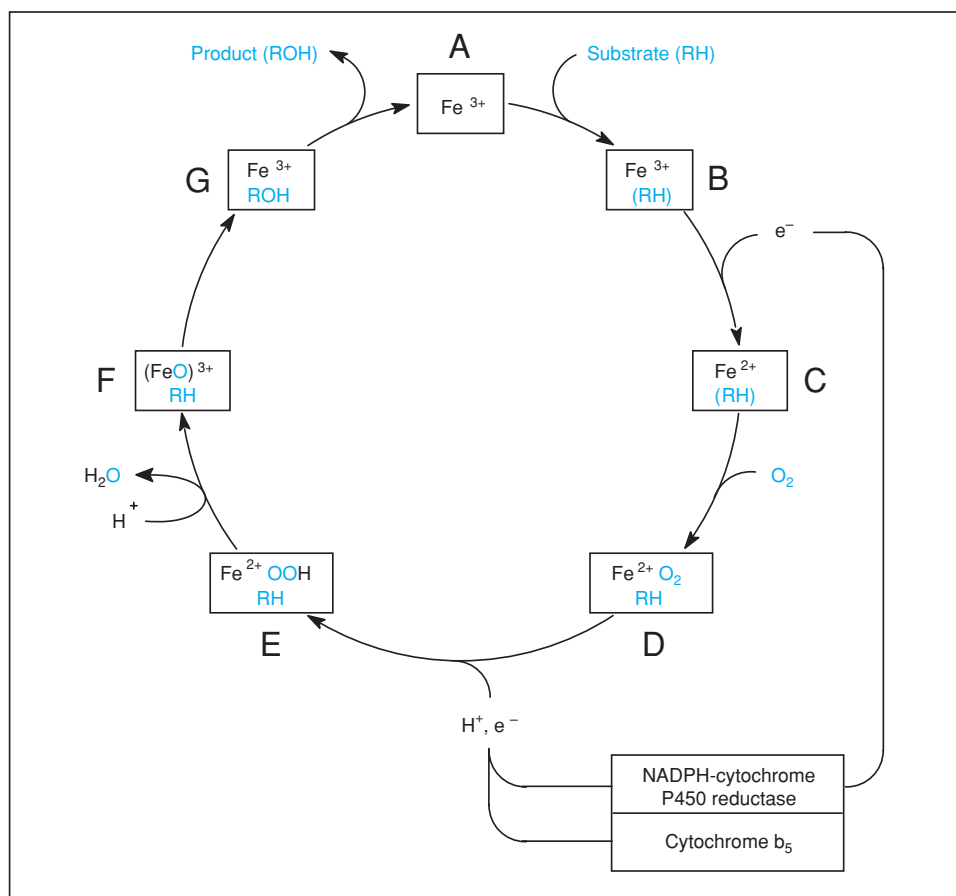
The second exception is represented by two CYP enzymes expressed in the bacterium *Bacillus megaterium*, which are known as BM-1 (CYP106A1) and BM-3 (CYP102A1). These CYP enzymes are considerably larger than most CYP enzymes because they are linked directly to a flavoprotein. In other words, the cytochrome P450 moiety and oxidoreductase flavoprotein are expressed in a single protein encoded by a single gene. Through recombinant DNA techniques, mammalian CYP enzymes have been linked directly to NADPH-cytochrome P450 reductase and, like the bacterial enzyme, the resultant fusion protein is catalytically active. Most mammalian CYP enzymes are not synthesized as a single enzyme containing both the hemoprotein and flavoprotein moieties, but this arrangement is found in the nitric oxide (NO) synthases. In addition to its atypical structure, the CYP enzyme expressed in *Bacillus megaterium*, CYP102A1, is unusual for another reason: It is inducible by phenobarbital, which has provided insight into the mechanism of cytochrome P450 induction.

Phospholipids and cytochrome b$_5$ also play an important role in cytochrome P450 reactions. Cytochrome P450 and NADPH-cytochrome P450 reductase are embedded in the phospholipid bilayer of the endoplasmic reticulum, which facilitates their interaction. When the C-terminal region that anchors NADPH-cytochrome P450 reductase in the membrane is cleaved with trypsin, the truncated flavoprotein can no longer support cytochrome P450 reactions, although it is still capable of reducing cytochrome c and other soluble electron acceptors. The ability of phospholipids to facilitate the interaction between NADPH-cytochrome P450 reductase and cytochrome P450 does not appear to depend on the nature of the polar head group (serine, choline, inositol, ethanolamine), although certain CYP enzymes (those in the CYP3A subfamily)

have a requirement for phospholipids containing unsaturated fatty acids.

Cytochrome b$_5$ can donate the second of two electrons required by cytochrome P450. Although this would be expected simply to increase the rate of catalysis of cytochrome P450, cytochrome b$_5$ can also increase the apparent affinity with which certain CYP enzymes bind their substrates, hence, cytochrome b$_5$ can increase V_{max} and/or decrease the apparent K_m of cytochrome P450 reactions. Liver microsomes contain numerous forms of cytochrome P450 but contain a single form of NADPH-cytochrome P450 reductase (POR) and cytochrome b$_5$ (CYB5A). For each molecule of NADPH-cytochrome P450 reductase in rat liver microsomes, there are 5–10 molecules of cytochrome b$_5$ and 10–20 molecules of cytochrome P450. NADPH-cytochrome P450 reductase will reduce electron acceptors other than cytochrome P450, which enables this enzyme to be measured based on its ability to reduce cytochrome c (which is why NADPH-cytochrome P450 reductase is often called NADPH-cytochrome c reductase). NADPH-cytochrome P450 reductase can transfer electrons much faster than cytochrome P450 can use them, which more than likely accounts for the low ratio of NADPH-cytochrome P450 reductase to cytochrome P450 in liver microsomes. Low levels of NADPH-cytochrome P450 reductase may also be a safeguard to protect cells from the often deleterious one-electron reduction reactions catalyzed by this flavoprotein (see Fig. 6-15). In addition to supporting certain CYP-catalyzed reactions, cytochrome b$_5$ and NADH-cytochrome b$_5$ reductase can catalyze the dehydroxylation of certain amidoximes and arylhydroxylamines (formed by N-hydroxylation of aromatic amines), which can reverse their formation by CYP enzymes (see Fig. 6-21).

The catalytic cycle of cytochrome P450 is shown in Fig. 6-39 (Dawson, 1988). The first part of the cycle involves the activation of oxygen, and the final part of the cycle involves substrate oxidation, which entails the abstraction of a hydrogen atom or an electron from the substrate followed by oxygen rebound (radical recombination). Following the binding of substrate to the CYP enzyme, the heme iron is reduced from the ferric (Fe^{3+}) to the ferrous (Fe^{2+}) state by the addition of a single electron from NADPH-cytochrome P450 reductase. The reduction of cytochrome P450 is facilitated by substrate binding, possibly because binding of the substrate in the vicinity of the heme moiety converts the heme iron from a low-spin to a high-spin state. Oxygen binds to cytochrome P450 in its ferrous state, and the Fe^{2+}O$_2$ complex is converted to an Fe^{2+}OOH complex by the addition of a proton (H$^+$) and a second electron, which is derived from NADPH-cytochrome P450 reductase or cytochrome b$_5$. Introduction of a second proton cleaves the Fe^{2+}OOH complex to produce water and an (FeO)$^{3+}$ complex, which transfers its oxygen atom to the substrate. Release of the oxidized substrate returns cytochrome P450 to its initial state. If the catalytic cycle is interrupted (uncoupled) following introduction of the first electron, oxygen is released as superoxide anion (see "Other Reactions" in Fig. 6-39). If the cycle is interrupted after introduction of the second electron, oxygen is released as hydrogen peroxide (H$_2$O$_2$). The final oxygenating species (FeO)$^{3+}$ can be generated directly by the transfer of an oxygen atom from hydrogen peroxide and certain other hydroperoxides, a process known as the peroxide shunt. For this reason certain P450 reactions can be supported by hydroperoxides in the absence of NADPH-cytochrome P450 reductase and NADPH.

Cytochrome P450 catalyzes several types of oxidation reactions, including:


Other reactions

One-electron reduction	C $(Fe^{2+} RH)$	$\longrightarrow$ A (Fe^{3+}) + $RH \cdot$
Superoxide anion production	D $(Fe^{2+} O_2 RH)$	$\longrightarrow$ B $(Fe^{3+} RH)$ + $O_2 \cdot^-$
Hydrogen peroxide production	E $(Fe^{2+}OOH\ RH)$ + H^+	$\longrightarrow$ B $(Fe^{3+}RH)$ + H_2O_2
Peroxide shunt	B $(Fe^{3+} RH)$ + $XOOH$	$\longrightarrow$ F $(FeO)^{3+} RH$ + XOH

Figure 6-39. Catalytic cycle of cytochrome P450.

1. Hydroxylation of an aliphatic or aromatic carbon;
2. Epoxidation of a double bond;
3. Heteroatom (S-, N-, and I-) oxygenation and N-hydroxylation;
4. Heteroatom (O-, S-, and N-) dealkylation;
5. Oxidative group transfer;
6. Cleavage of esters;
7. Dehydrogenation.

In the first three cases, oxygen from the $(FeO)^{3+}$ complex is incorporated into the substrate, which otherwise remains intact. In the fourth case, oxygenation of the substrate is followed by a rearrangement reaction leading to cleavage of an amine (N-dealkylation) or an ether (O- and S-dealkylation). Oxygen from the $(FeO)^{3+}$ complex is incorporated into the alkyl-leaving group, producing an aldehyde or ketone. In the fifth case, oxygenation of the substrate is followed by a rearrangement reaction leading to loss of a heteroatom (oxidative group transfer). The sixth case, the cleavage of esters, resembles heteroatom dealkylation in that the functional group is cleaved with incorporation of oxygen from the $(FeO)^{3+}$ complex into the leaving group, producing an aldehyde. In the seventh case, two hydrogens are abstracted from the substrate with the formation of a double bond (C=C, C=O, or C=N), with the reduction of oxygen from the $(FeO)^{3+}$ complex to water. It should be noted that this long list of reactions does not encompass all the reactions catalyzed by cytochrome P450. Cytochrome P450 can catalyze reductive reactions (such as azo reduction, nitro reduction, and reductive dehalogenation) and isomerization reactions (such as the conversion of PGH$_2$ to thromboxane and prostacyclin). During the synthesis of steroid hormones, cytochrome P450 catalyzes the cleavage of carbon–carbon bonds, which occurs during the conversion of cholesterol to pregnenolone by side-chain cleavage enzyme (CYP11A1, which is also known as P450$_{scc}$) and the aromatization of a substituted cyclohexane, which occurs during the conversion of androgens to estrogens by aromatase (CYP19A1, also known as CYP19 and P450$_{arom}$).
Figure 6-40. *Examples of reactions catalyzed by cytochrome P450: Hydroxylation of aliphatic carbon.*

Examples of aliphatic and aromatic hydroxylation reactions catalyzed by cytochrome P450 are shown in Figs. 6-40 and 6-41, respectively. The hydroxylation of aromatic hydrocarbons may proceed via an oxirane intermediate (i.e., an arene oxide) that isomerizes to the corresponding phenol. Alternatively, aromatic hydroxylation can proceed by a mechanism known as direct insertion. The *ortho*-hydroxylation and *para*-hydroxylation of chlorobenzene proceed via 2,3- and 3,4-epoxidation, whereas *meta*-hydroxylation proceeds by direct insertion, as shown in Fig. 6-42. When aromatic hydroxylation involves direct insertion, hydrogen abstraction (i.e., cleavage of the C–H bond) is the rate-limiting step, so that substitution of hydrogen with deuterium or tritium considerably slows the hydroxylation reaction. This *isotope effect* is less marked when aromatic hydroxylation proceeds via an arene oxide intermediate. Arene oxides are electrophilic and, therefore, potentially toxic metabolites that are detoxified by such enzymes as epoxide hydrolase (see Figs. 6-7 to 6-9) and glutathione transferase (see section "Glutathione Conjugation"). Depending on the ring substituents, the rearrangement of arene oxides to the corresponding phenol can lead to an intramolecular migration of a substituent (such as hydrogen or a halogen) from one carbon to the next. This intramolecular migration occurs at the site of oxidation and is known as the NIH shift; so named for its discovery at the National Institutes of Health.

Aliphatic hydroxylation involves insertion of oxygen into a C–H bond. As in the case of aromatic hydroxylation by direct in-

sertion, cleavage of the C–H bond by hydrogen abstraction is the rate-limiting step, as shown below:

$$(FeO)^{3+} \quad HC{-} \longrightarrow Fe(OH)^{3+} \quad {\cdot}C{-} \longrightarrow Fe^{3+} \quad HO{-}C{-}$$
In the case of simple, straight-chain hydrocarbons, such as *n*-hexane, aliphatic hydroxylation occurs at both the terminal methyl groups and the internal methylene groups. In the case of fatty acids and their derivatives (i.e., eicosanoids such as prostaglandins and leukotrienes), aliphatic hydroxylation occurs at the ω-carbon (terminal methyl group) and the ω-1 carbon (penultimate carbon), as shown for lauric acid in Fig. 6-40. Most CYP enzymes preferentially catalyze the ω-1 hydroxylation of fatty acids and their derivatives, but one group of CYP enzymes (those encoded by the CYP4A genes) preferentially catalyzes the ω-hydroxylation of fatty acids, which can be further oxidized to dicarboxylic acids.

Xenobiotics containing a carbon–carbon double bond (i.e., alkenes) can be epoxidated (i.e., converted to an oxirane) in an analogous manner to the oxidation of aromatic compounds to arene oxides. Just as arene oxides can isomerize to phenols, so aliphatic epoxides can isomerize to the corresponding ene-ol, the formation of which may involve an intramolecular migration (NIH shift) of a substituent at the site of oxidation. Like arene oxides, aliphatic epoxides are also potentially toxic metabolites that are inactivated by other xenobiotic-metabolizing enzymes. Oxidation
Figure 6-41. Examples of reactions catalyzed by cytochrome P450: Hydroxylation of aromatic carbon.

of some aliphatic alkenes and alkynes produces metabolites that are sufficiently reactive to bind covalently to the heme moiety of cytochrome P450, a process known as suicide inactivation or mechanism-based inhibition (discussed later in section "Inhibition of Cytochrome P450"). As previously discussed in the section on epoxide hydrolase, not all epoxides are highly reactive electrophiles. Although the 3,4-epoxidation of coumarin produces an hepatotoxic metabolite, the 10,11-epoxidation of carbamazepine produces a stable, relatively nontoxic metabolite (Fig. 6-42).

In the presence of NADPH and O_2, liver microsomes catalyze the oxygenation of several sulfur-containing xenobiotics, including chlorpromazine, cimetidine, lansoprazole, and omeprazole. Sulfur-containing xenobiotics can potentially undergo two consecutive sulfoxidation reactions: one that converts the sulfide (S) to the sulfoxide (SO), which occurs during the sulfoxidation of chlorpromazine and cimetidine, and one that converts the sulfoxide (SO) to the sulfone (SO_2), which occurs during the sulfoxidation of omeprazole and lansoprazole, as shown in Fig. 6-43. Albendazole is converted first to a sulfoxide and then to a sulfone. All of these reactions are catalyzed by FMO (as shown in Fig. 6-37b) and/or cytochrome P450 (as shown in Fig. 6-43). Both enzymes are efficient catalysts of S-oxygenation, and both contribute significantly to the sulfoxidation of various xenobiotics. For example, the sulfoxidation of omeprazole, lansoprazole, chlorpromazine, and phenothiazine by human liver microsomes is primarily catalyzed by a CYP enzyme (namely, CYP3A4), whereas the sulfoxidation of cimetidine is primarily catalyzed by FMO (namely, FMO3).

In the presence of NADPH and O_2, liver microsomes catalyze the oxygenation of several nitrogen-containing xenobiotics, including chlorpromazine, doxylamine, oflaxacin, morphine, nicotine, MPTP, methapyrilene, methaqualone, metronidazole, pargyline, pyridine, senecionine, strychnine, trimethylamine, trimipramine, and verapamil, all of which are converted to stable N-oxides. Whereas S-oxygenation might be catalyzed by both cytochrome P450 and FMO, N-oxygenation is more likely to be catalyzed by just one of these enzymes. For example, the conversion of (S)-nicotine to *trans*-(S)-nicotine N-1′-oxide by human liver microsomes is catalyzed by FMO3, with little or no contribution from cytochrome P450. Conversely, the conversion of pyridine to its N-oxide is primarily catalyzed by cytochrome P450. Both enzymes can participate in the N-oxygenation of certain xenobiotics. For example, the N-oxygenation of chlorpromazine is catalyzed by FMO3 and, to a lesser extent, by two CYP enzymes (CYP2D6 and CYP1A2). In general, FMO catalyzes the N-oxygenation of xenobiotics containing electron-deficient nitrogen atoms, whereas cytochrome P450 catalyzes the N-oxygenation of xenobiotics containing electron-rich nitrogen atoms. Therefore, substrates primarily N-oxygenated by cytochrome P450 are somewhat limited to pyridine-containing xenobiotics, such as the tobacco-specific nitrosamine NNK and the antihistamine temelastine, and to xenobiotics containing a quinoline or isoquinoline group, such as the muscle relaxant 6,7-dimethoxy-4-(4′-chlorobenzyl)isoquinoline.

The initial step in heteroatom oxygenation by cytochrome P450 involves the abstraction of an electron from the heteroatom (N, S,
Figure 6-42. Examples of reactions catalyzed by cytochrome P450: Epoxidation.

or I) by the $(FeO)^{3+}$ complex, as shown below for sulfoxidation.

$$(FeO)^{3+} \quad :\overset{|}{\underset{|}{S}} \longrightarrow (FeO)^{2+} \quad \overset{|}{\underset{|}{\overset{+}{S}}} \longrightarrow Fe^{3+} \quad O^{-}\overset{+}{\underset{|}{\overset{|}{S}}}$$
Abstraction of an electron from N, O, or S by the $(FeO)^{3+}$ complex is also the initial step in heteroatom dealkylation, but in

this case abstraction of the electron from the heteroatom is quickly followed by abstraction of a proton (H^+) from the α-carbon atom (the carbon atom attached to the heteroatom). Oxygen rebound leads to hydroxylation of the α-carbon, which then rearranges to form the corresponding aldehyde or ketone with cleavage of the α-carbon from the heteroatom, as shown below for the N-dealkylation of an
Figure 6-43. *Examples of reactions catalyzed by cytochrome P450: Heteroatom oxygenation.*

N-alkylamine:
Although the initial steps in heteroatom oxygenation and heteroatom dealkylation are the same (abstraction of an electron from the heteroatom to produce a radical cation), the nature of the radical cation determines whether the xenobiotic will undergo oxygenation or dealkylation. The sulfur radical cations of numerous xenobiotics are sufficiently stable to allow oxygen rebound with the heteroatom

itself, which results in S-oxygenation. However, this is not generally the case with nitrogen radical cations, which undergo rapid deprotonation at the α-carbon, which in turn results in N-dealkylation. In general, therefore, cytochrome P450 catalyzes the N-dealkylation, not the N-oxygenation, of amines. N-Oxygenation by cytochrome P450 can occur if the nitrogen radical cation is stabilized by a nearby electron-donating group (making the nitrogen electron rich) or if α-protons are either absent (e.g., aromatic amines) or inaccessible (e.g., quinidine). In the case of primary and secondary aromatic amines, N-oxygenation by cytochrome P450 usually results in the formation of arylhydroxylamines, as illustrated in Fig. 6-11. N-Hydroxylation of aromatic amines with subsequent O-acetylation or O-sulfonation is one mechanism by which tumorigenic aromatic amines, such as 2-acetylaminofluorene and 4-aminobiphenyl, are converted to electrophilic reactive intermediates that bind covalently to DNA.

O-Dealkylation

7-Ethoxyresorufin → CYP1A2 → Resorufin (CH₃CHO)

Dextromethorphan → CYP2D6 → Dextrorphan (HCHO)

S-Dealkylation

6-Methylmercaptopurine → [O] → 6-Mercaptopurine (HCHO)

Si-Dealkylation

Octamethylcyclotetrasiloxane (D₄) → (HCHO)

N-Dealkylation

Diazepam → CYP2C19 / CYP3A4 → Nordiazepam (HCHO)

Caffeine → (HCHO)
- N₁-demethylation (CYP2E1) → Theobromine
- N₃-demethylation (CYP1A2) → Paraxanthine
- N₇-demethylation (CYP2E1) → Theophylline
Figure 6-44. Examples of reactions catalyzed by cytochrome P450: Heteroatom dealkylation.

In contrast to cytochrome P450, which oxidizes nitrogen-containing xenobiotics by a radicaloid mechanism involving an initial one-electron oxidation of the heteroatom, FMO oxidizes nitrogen-containing xenobiotics by a heterolytic mechanism involving a two-electron oxidation by the 4a-hydroperoxide of FAD (see Fig. 6-38). These different mechanisms explain why the N-oxygenation of xenobiotics by cytochrome P450 generally results in N-dealkylation, whereas N-oxygenation by the FMO results in *N*-oxide formation. In contrast to cytochrome P450, FMO does not catalyze N-, O-, or S-dealkylation reactions.

Numerous xenobiotics are N-, O-, or S-dealkylated by cytochrome P450, and some examples of these heteroatom dealkylation reactions are shown in Fig. 6-44. The dealkylation of xenobiotics containing an N-, O-, or S-methyl group results in the formation of formaldehyde, which can easily be measured by a simple colorimetric assay to monitor the demethylation of substrates in vitro. The expiration of ^{13}C- or ^{14}C-labelled carbon dioxide following the demethylation of drugs containing a ^{13}C- or ^{14}C-labelled methyl group has been used to probe cytochrome P450 activity in vivo (Watkins, 1994). The activity of the human CYP enzymes involved in the N-demethylation of aminopyrine, erythromycin, and caffeine can be assessed by this technique. Although caffeine has three *N*-methyl groups, all of which can be removed by cytochrome P450, the major pathway in humans involves N3-demethylation of caffeine to paraxanthine (see Fig. 6-44).

Whereas the metabolism of *N*-methyl amines by cytochrome P450 generally results in N-demethylation, with the hydroxylation of the methyl group leading to the release of formaldehyde, the metabolism of *N*-methyl amides and carbamates by cytochrome P450 often results in the formation of a stable methyl-hydroxylated metabolite; one that does not release formaldehyde (which would otherwise complete an N-demethylation reaction) possibly because of the hydroxymethyl metabolite formation of a six-membered configuration that is stabilized by hydrogen bonding, as illustrated below:
Zolpidem and camazepam are amide- and carbamate-containing drugs, respectively, that undergo such *N*-methyl-hydroxylation reactions.

Seto and Guengerich have shown that the N-demethylation and N-deethylation of *N*-ethyl, *N*-methylaniline not only proceed at different rates (with N-demethylation proceeding up to 20 times faster than N-deethylation), they proceed by different mechanisms (Seto and Guengerich, 1993; Guengerich, 2001a). The initial step in the N-deethylation reaction involves hydrogen atom abstraction from the α-carbon atom (i.e., the carbon atom attached to the nitrogen) whereas the initial step in the N-demethylation reaction involves a much faster reaction, namely, a one-electron transfer from the nitrogen atom, which is transferred to the FeO^{3+} complex in cytochrome

P450. Although the N-demethylation of *N,N*-substituted *amines* proceeds by the relatively rapid process of one-electron transfer, the *N*-demethylation of *N,N*-substituted *amides*, where the adjacent carbonyl causes electrons to be withdrawn from the nitrogen atom, proceeds by the relatively slow process of hydrogen atom abstraction, for which reason the latter reactions, in contrast to the former, show a large intrinsic isotope effect when the hydrogen atoms are replaced with deuterium (because it requires more energy to break a C–D bond than a C–H bond).

In addition to N-dealkylation, primary amines can also undergo oxidative deamination by cytochrome P450, which is an example of oxidative group transfer. The mechanism is similar to that of N-dealkylation: The α-carbon adjacent to the primary amine is hydroxylated, which produces an unstable intermediate that rearranges to eliminate ammonia with the formation of an aldehyde or ketone. The conversion of amphetamine to phenylacetone is an example of oxidative deamination, as shown in Fig. 6-45. Oxidative deamination is also catalyzed by monoamine oxidase (MAO). In the example given above, however, the substrate, amphetamine, contains an α-methyl group which renders it a poor substrate for MAO (as described in the section "Monoamine Oxidase, Diamine Oxidase, and Polyamine Oxidase", above).

In addition to oxidative deamination, cytochrome P450 catalyzes two other types of oxidative group transfer, namely, oxidative desulfuration and oxidative dehalogenation. In all cases the heteroatom (N, S, or halogen) is replaced with oxygen. As shown in Fig. 6-46, oxidative desulfuration converts parathion, which has little insecticidal activity, to paraoxon, which is a potent insecticide. The same reaction converts thiopental to pentobarbital. Diethyldithiocarbamate methyl ester, a metabolite of disulfiram, also undergoes oxidative desulfuration. The initial reaction involves S-oxidation by cytochrome P450 or FMO to a sulfine ($R_1R_2C = S \rightarrow R_1R_2C = S^+–O^-$). In the presence of glutathione (GSH) and glutathione transferase, this sulfine is either converted back to the parent compound ($R_1R_2C = S^+–O^- + 2\ GSH \rightarrow R_1R_2C = S + GSSG + H_2O$) or it undergoes desulfuration ($R_1R_2C = S^+–O^- + 2\ GSH \rightarrow R_1R_2C = O + GSSG + H_2S$) (Madan *et al.*, 1994).

Cytochrome P450 catalyzes both reductive and oxidative dehalogenation reactions (Guengerich, 1991). During oxidative dehalogenation, a halogen and hydrogen from the same carbon atom are replaced with oxygen ($R_1R_2CHX \rightarrow R_1R_2CO$) to produce an aldehyde or acylhalide, as shown in Fig. 6-18 for the conversion of halothane (CF$_3$CHClBr) to trifluoroacetylchloride (CF$_3$COCl). Oxidative dehalogenation does not involve a direct attack on the carbon–halogen bond, but it involves the formation of an unstable halohydrin by oxidation of the carbon atom bearing the halogen substituent. The carbon–halogen bond is broken during the rearrangement of the unstable halohydrin. When the carbon atom contains a single halogen, the resulting product is an aldehyde, which can be further oxidized to a carboxylic acid or reduced to a primary alcohol. When the carbon atom contains two halogens, the dihalohydrin intermediate rearranges to an acylhalide, which can be converted to the corresponding carboxylic acid (see Fig. 6-18). As discussed previously, aldehydes and, in particular, acylhalides are reactive compounds that can bind covalently to protein and other critical cellular molecules. The immune hepatitis caused by repeated exposure of humans to halothane and related volatile anesthetics is dependent on oxidative dehalogenation by cytochrome P450, with neoantigens produced by the trifluoroacetylation of proteins, as shown in Fig. 6-18.
Figure 6-45. Examples of reactions catalyzed by cytochrome P450: Oxidative group transfer.

Cytochrome P450 can catalyze the reductive dehalogenation of halogenated alkanes (see Figs. 6-17 and 6-18) and the reduction of certain azo- and nitro-containing xenobiotics, although these latter reactions are largely catalyzed by gut microflora (see Fig. 6-10). The ability of cytochrome P450 to reduce xenobiotics can be understood from the catalytic cycle shown in Fig. 6-39. Binding of a substrate to cytochrome P450 is followed by a one-electron reduction by NADPH-cytochrome P450 reductase. Under aerobic conditions, reduction of the heme iron to the ferrous state permits binding of oxygen. Anaerobic conditions, in contrast, interrupt the cycle at this point, which allows cytochrome P450 to reduce those substrates capable of accepting an electron. Therefore, cytochrome P450 can catalyze reduction reactions, such as azo-reduction, nitro-reduction, and reductive dehalogenation, particularly under conditions of low oxygen tension. In effect, the substrate rather than molecular oxygen accepts electrons and is reduced. In fact, oxygen acts as an inhibitor of these reactions because it competes with the substrate for the reducing equivalents. The toxicity of many halogenated alkanes is dependent on their biotransformation by reductive dehalogenation. The first step in reductive dehalogenation is a one-electron reduction catalyzed by cytochrome P450, which produces a potentially toxic, carbon-centered radical and inorganic halide. The conversion of CCl_4 to a trichloromethyl radical and other toxic metabolites is shown in Fig. 6-17.

The oxidative desulfuration of parathion (see Fig. 6-45) involves the production of an intermediate that rearranges to paraoxon (as shown in Fig. 6-46). This same intermediate can decompose to 4-nitrophenol and diethylphosphorothioic acid, which are the same products formed by the hydrolysis of parathion (Fig. 6-46). In addition to facilitating the hydrolysis of phosphoric acid esters, cy-

tochrome P450 also catalyzes the cleavage of carboxylic acid esters, as shown in Fig. 6-46. Carboxylic acid esters typically are cleaved by carboxylesterases, which results in the formation of an acid and an alcohol ($R_1COOCH_2R_2 + H_2O \rightarrow R_1COOH + R_2CH_2OH$). In contrast, cytochrome P450 converts carboxylic acid esters to an acid plus aldehyde ($R_1COOCH_2 R_2 + [O] \rightarrow R_1COOH + R_2CHO$), as shown in Fig. 6-46. The deacylation of loratadine is the major route of biotransformation of this nonsedating antihistamine. The reaction is catalyzed predominantly by cytochrome P450 (namely, CYP3A4 with a minor contribution from CYP2D6), with little contribution from carboxylesterases.

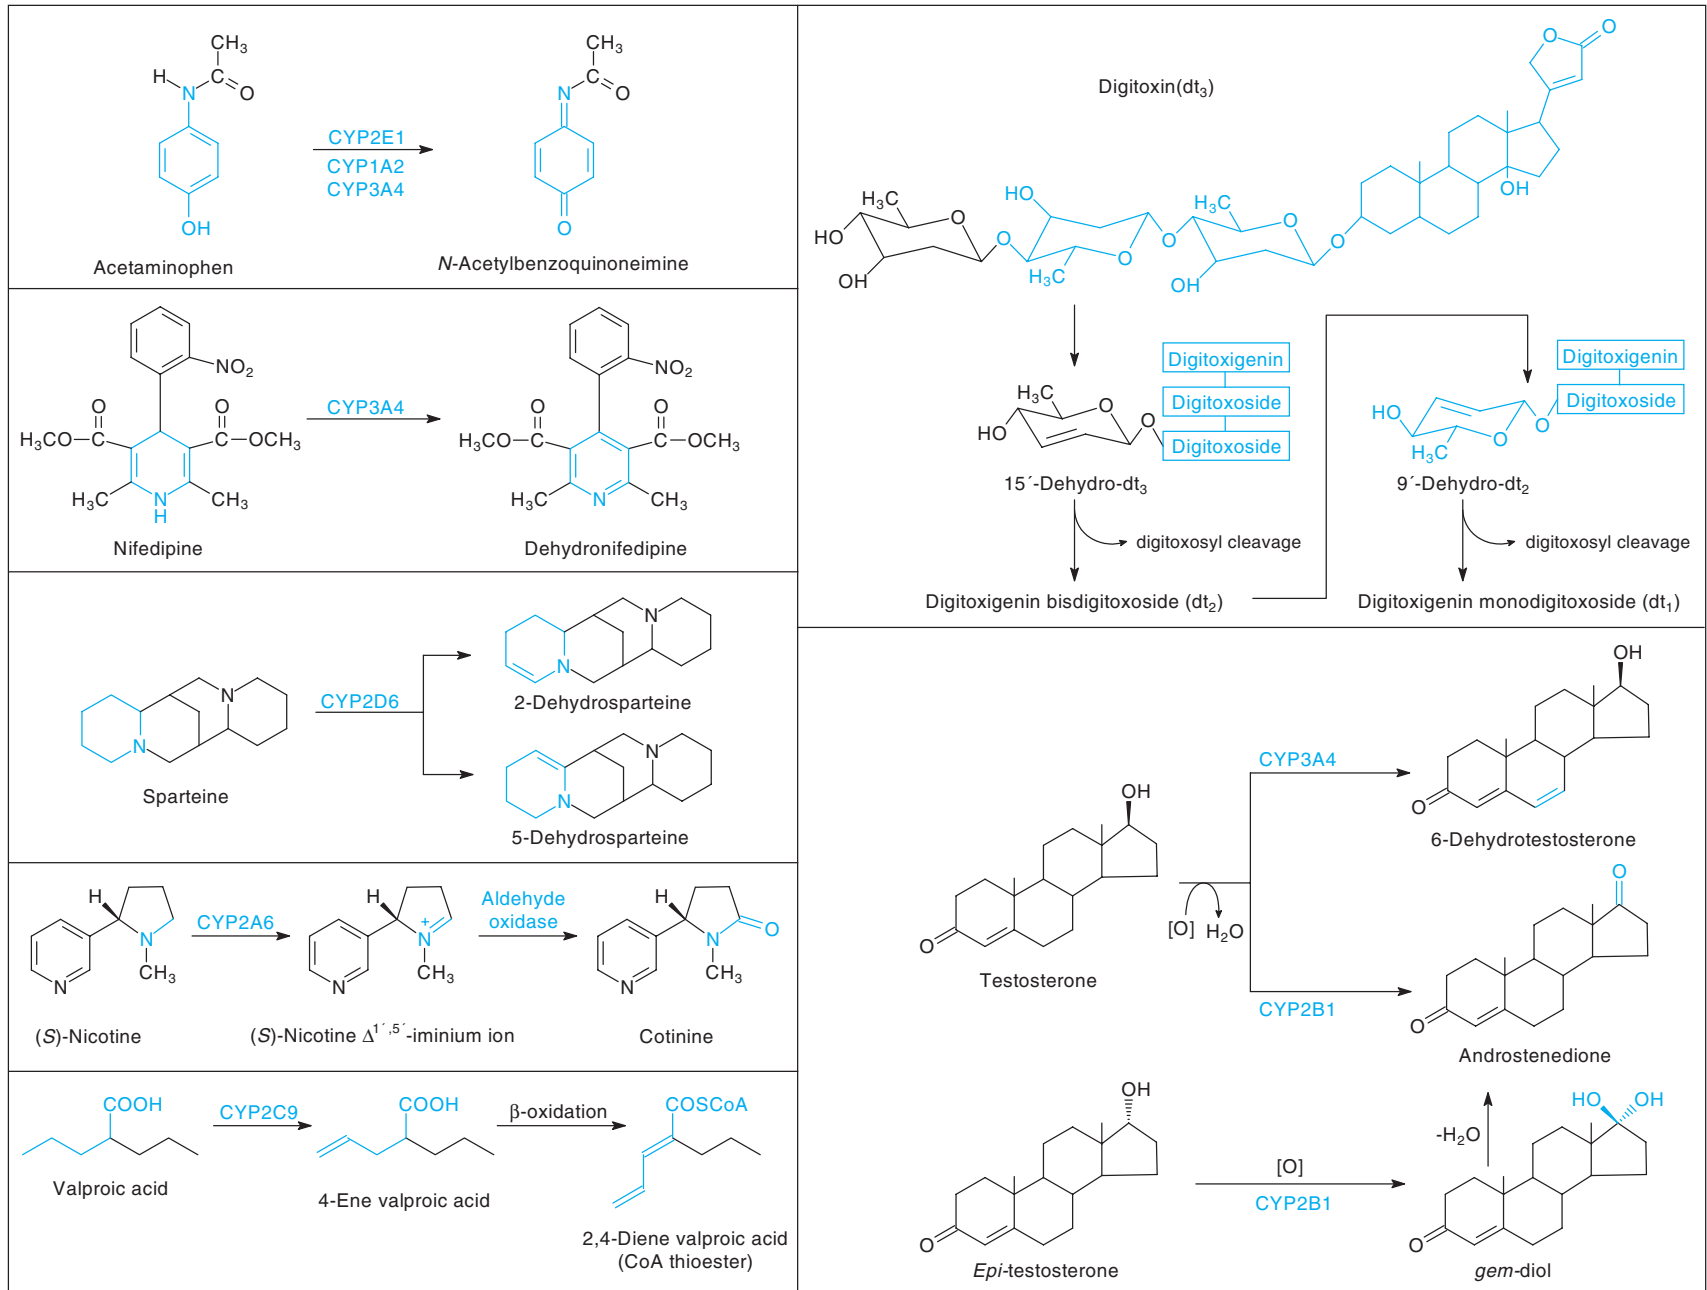
Cytochrome P450 can also catalyze the dehydrogenation of a number of compounds, including acetaminophen, nifedipine, and related dihydropyridine calcium-channel blockers, sparteine, nicotine, and testosterone, as shown in Fig. 6-47. Dehydrogenation by cytochrome P450 converts acetaminophen to its hepatotoxic metabolite, N-acetylbenzoquinoneimine, as shown in Fig. 6-34. The formation of a double bond during the conversion of digitoxin (dt_3) to 15′-dehydro-dt_3 leads to cleavage of the terminal sugar residue to produce digitoxigenin bisdigitoxoside (dt_2) (Fig. 6-47), which can similarly be converted to 9′-dehydro-dt_2, which undergoes digitoxosyl cleavage to digitoxigenin monodigitoxoside (dt_1). In contrast to digitoxin, this latter metabolite is an excellent substrate for glucuronidation. In rats, the CYP enzymes responsible for converting digitoxin to dt_1 (namely, the CYP3A enzymes) and the UGT responsible for glucuronidating dt_1 are inducible by dexamethasone, pregnenolone-16α-carbonitrile and spironolactone, all of which protect rats from the toxic effects of digitoxin. The dehydrogenation of nicotine produces nicotine $\Delta^{1',5'}$-iminium ion, which is oxidized by cytosolic aldehyde oxidase to cotinine, a major metabolite of nicotine excreted in the urine of cigarette smokers (see Fig. 6-47).
Figure 6-46. Examples of reactions catalyzed by cytochrome P450: Cleavage of esters.


Figure 6-47. Examples of reactions catalyzed by cytochrome P450: Dehydrogenation.

Testosterone is dehydrogenated by cytochrome P450 to two metabolites: 6-dehydrotestosterone, which involves formation of a carbon–carbon double bond, and androstenedione, which involves formation of a carbon–oxygen double bond, as shown in Fig. 6-47. The conversion of testosterone to androstenedione is one of several cases where cytochrome P450 converts a primary or secondary alcohol to an aldehyde or ketone, respectively. The reaction can proceed by formation of a *gem*-diol (two hydroxyl groups on the same carbon atom), with subsequent dehydration to a keto group, as shown in Fig. 6-24 for the conversion of ethanol to acetaldehyde. However, *gem*-diols are not obligatory intermediates in the oxidation of alcohols by cytochrome P450, and in fact the conversion of testosterone to androstenedione by CYP2B1 (the major phenobarbital-inducible CYP enzyme in rats) does not involve the intermediacy of a *gem*-diol but proceeds by direct dehydrogenation (Fig. 6-47). In contrast, a *gem*-diol is involved in the formation of androstenedione from *epi*-testosterone (which is identical to testosterone except the hydroxyl group at C17 is in the α-configuration, not the β-configuration). The fact that formation of androstenedione from *epi*-testosterone involves formation of a *gem*-diol, whereas its formation from testosterone does not, makes it difficult to generalize the mechanism by which cytochrome P450 converts alcohols to aldehydes and ketones.

Liver microsomes from all mammalian species contain numerous CYP enzymes, each with the potential to catalyze the various types of reactions shown in Figs. 6-40 through 6-47. In other words, all of the CYP enzymes expressed in liver microsomes have the potential to catalyze xenobiotic hydroxylation, epoxidation, dealkylation, oxygenation, dehydrogenation, and so forth. The broad and often overlapping substrate specificity of liver microsomal CYP enzymes precludes the possibility of naming these enzymes for the reactions they catalyze, which are now categorized into families and subfamilies and named individually on the basis of their amino acid sequence. As shown in Table 6-9, the CYP enzymes involved in xenobiotic biotransformation belong mainly to the CYP1, 2, and 3 gene families. The CYP enzymes involved in endobiotic metabolism generally have the same name in all mammalian species. Some of the xenobiotic-biotransforming CYP enzymes have the same name in all mammalian species, whereas others are named in a species-specific manner. For example, all mammalian species contain two CYP enzymes belonging to the CYP1A subfamily, and in all cases these are known as CYP1A1 and CYP1A2 because the function and regulation of these enzymes are highly conserved among mammalian species. The same is true of CYP1B1, 2E1, 2R1, 2S1, 2U1, and 2W1, all of which are highly conserved orthologs that can be given the same name across mammalian species. In most other cases, functional or evolutionary relationships are not immediately apparent; hence, the CYP enzymes are named in a species-specific manner, and the names are assigned in chronological order regardless of the species of origin. For example, human liver microsomes express CYP2D6, but this is the only functional member of the CYP2D subfamily found in human liver. CYP2D7 and 2D8 are human pseudogenes. The other members of this subfamily (i.e., CYP2D1–CYP2D5 and CYP2D5 onward) are the names given to CYP2D enzymes in other species.

Without exception, the levels and activity of each CYP enzyme have been shown to vary from one individual to the next, due to environmental and/or genetic factors. Decreased CYP enzyme activity can result from (1) a genetic mutation that either blocks the synthesis of a CYP enzyme or leads to the synthesis of a catalytically compromised, inactive, or unstable enzyme, which give rise to the poor and intermediate metabolizer (PM and IM) genotypes; (2) exposure to an environmental factor (such as an infectious disease or an inflammatory process) that suppresses CYP enzyme expression, or (3) exposure to a xenobiotic that inhibits or inactivates a preexisting CYP enzyme. By inhibiting cytochrome P450, one drug can impair the biotransformation of another, which may lead to an exaggerated pharmacological or toxicological response to the second drug. In this regard, inhibition of cytochrome P450 by a drug (and suppression of cytochrome P450 by infection, vaccination, or inflammation) essentially mimics the effects of a genetic deficiency in CYP enzyme expression (i.e., these environmental factors mimic the IM or PM genotype depending on the degree to which they decrease CYP activity). Genetic deficiencies in CYP expression, CYP inhibition and, to a lesser extent, CYP suppression all contribute significantly to inter-individual variability in drug metabolism and toxicity, and inhibition of CYP activity is a major cause of drug–drug interactions. Examples of the impact of these genetic and environmental factors on drug metabolism and toxicity are given later in this section in the overviews of individual CYP enzymes and in the section "Inhibition of Cytochrome P450."

Increased CYP enzyme activity can result from (1) gene duplication leading to overexpression of a CYP enzyme, which gives rise to the ultra-rapid metabolizer (UM) genotype; (2) exposure to drugs and other xenobiotics that induce the synthesis of cytochrome P450, or (3) exposure to drugs and other xenobiotics that stimulate the activity of a preexisting enzyme (a process known as homotropic or heterotropic activation depending on whether the drug stimulates its own metabolism or the metabolism of other drugs, respectively). Activation of cytochrome P450 has been documented in vitro and in some in situ situations, such as the pronounced (up to 25-fold) activation of *R*-warfarin 10-hydroxylation by quinidine in rabbit liver microsomes and perfused rabbit liver (Chen *et al*., 2004a). However, in general, activation does not appear to be a major cause of drug–drug interactions. Although duplication of functional CYP2D6 genes has been documented (and shown to be relevant to drug metabolism and safety [see section "CYP2D6"]), induction of cytochrome P450 by xenobiotics is the most common mechanism by which CYP enzyme activity is increased to a pharmacologically relevant extent. By inducing cytochrome P450, one drug can stimulate the metabolism of a second drug and thereby decrease or ameliorate its therapeutic effect. Enzyme induction is a particular concern when it compromises the therapeutic effectiveness of drugs that have a narrow therapeutic index and are being used to treat a life-threatening illness, such as anti-HIV drugs, antirejection drugs (like cyclosporine and tacrolimus), and oral anticoagulants (like warfarin), or when it is used with drugs that exhibit a quantal (all-or-nothing) dose–response relationship, such as oral contraceptive steroids (which either block or don't block ovulation and thereby provide or don't provide protection against unwanted pregnancy).

The environmental factors known to affect P450 levels include medications (e.g., prescription drugs as well as herbal remedies), foods (e.g., cruciferous vegetables, charcoal-broiled beef), social habits (e.g., alcohol consumption, cigarette smoking), and disease status (diabetes, infection, inflammation, vaccination, liver and kidney disease, and both hyper- and hypothyroidism). When environmental factors influence CYP enzyme levels, considerable variation may be observed during repeated measures of xenobiotic biotransformation (e.g., drug metabolism) in the same individual. Such variation is not observed when alterations in CYP activity are determined genetically.

Due to their broad substrate specificity, it is possible that two or more CYP enzymes can contribute to the metabolism of a single compound. For example, two CYP enzymes, designated CYP2D6 and CYP2C19, both contribute significantly to the metabolism of propranolol in humans: CYP2D6 oxidizes the aromatic ring to give 4-hydroxypropranolol, whereas CYP2C19 oxidizes the isopropanolamine side chain to give naphthoxylactic acid (see Fig. 6-27). Consequently, changes in either CYP2D6 or CYP2C19 alone do not markedly affect the disposition of propranolol, but a rare combined genetic deficiency of both enzymes severely impairs propranolol metabolism. Three human CYP enzymes, CYP1A2, CYP2E1, and CYP3A4, can convert the commonly used analgesic, acetaminophen, to its hepatotoxic metabolite, N-acetylbenzoquinoneimine (Figs. 6-34 and 6-47). It is also possible for a single CYP enzyme to catalyze two or more metabolic pathways for the same drug. For example, CYP2D6 catalyzes both the O-demethylation and 5-hydroxylation (aromatic ring hydroxylation) of methoxyphenamine, and CYP3A4 catalyzes the 3-hydroxylation and N-oxygenation of quinidine, the 1′- and 4-hydroxylation of midazolam, the *tert*-butyl-hydroxylation and N-dealkylation of terfenadine, and several pathways of testosterone oxidation, including 1β-, 2β-, 6β-, and 15β-hydroxylation and dehydrogenation to 6-dehydrotestosterone (Figs. 6-40 and 6-47).

The pharmacological or toxic effects of certain drugs are exaggerated in a significant percentage of the population due to a heritable deficiency in a CYP enzyme (Meyer, 1994; Tucker, 1994). The observation that individuals who are genetically deficient in a particular CYP enzyme are poor metabolizers of one or more drugs illustrates a very important principle, namely, that the rate of elimination of drugs can be largely determined by a single CYP enzyme. This observation seems to contradict the fact that CYP enzymes have broad and overlapping substrate specificities. The resolution to this apparent paradox lies in the fact that although more than one human CYP enzyme can catalyze the biotransformation of a xenobiotic, they may do so with markedly different affinities. Consequently, xenobiotic biotransformation in vivo, where only low substrate concentrations are usually achieved, is often determined by the CYP enzyme with the highest affinity (lowest apparent K_m) for the xenobiotic. For example, the N-demethylation of diazepam (shown in Fig. 6-44) and the 5-hydroxylation of omeprazole are both catalyzed by two human CYP enzymes, namely, CYP2C19 and CYP3A4. However, these reactions are catalyzed by CYP3A4 with such low affinity that the N-demethylation of diazepam and the 5-hydroxylation of omeprazole in vivo are largely determined by CYP2C19. When several CYP enzymes catalyze the same reaction, their relative contribution to xenobiotic biotransformation is determined by the kinetic parameter, V_{max}/K_m, which is a measure of in vitro intrinsic clearance at low substrate concentrations (<10% of K_m).

A drug whose clearance is largely determined by a single CYP enzyme (or any single route of elimination) is said to have high *victim* or *object* potential, meaning its rate of clearance will be decreased by genetic polymorphisms and inhibitory drugs that result in a loss of that particular CYP activity and increased by drugs and other xenobiotics that induce that particular CYP enzyme. For example, a drug that is largely cleared by CYP2D6 will be slowly metabolized in CYP2D6 PMs and rapidly metabolized in CYP2D6 UMs, whereas a drug whose clearance is largely determined by CYP3A4 will be slowly metabolized in the presence of ketoconazole (and other CYP3A4 inhibitors) and rapidly metabolized in the presence of rifampin or St. John's wort (and other CYP3A4 in-

ducers). Accordingly, for drugs under development, considerable attention is paid to identifying which CYP enzyme or enzymes are involved in eliminating the drug, a process known as *reaction phenotyping* or *enzyme mapping*. Four in vitro approaches have been developed for reaction phenotyping. Each has its advantages and disadvantages, and a combination of approaches is usually required to identify which human CYP enzyme is responsible for metabolizing a xenobiotic. The four approaches to reaction phenotyping are as follows:

1. Correlation analysis, which involves measuring the rate of xenobiotic metabolism by several samples of human liver microsomes and correlating reaction rates with the variation in the level or activity of the individual CYP enzymes in the same microsomal samples. This approach is successful because the levels of the CYP enzymes in human liver microsomes vary enormously from sample to sample (up to 100-fold) but vary independently from each other.

2. Chemical inhibition, which involves an evaluation of the effects of known CYP enzyme inhibitors on the metabolism of a xenobiotic by human liver microsomes. Chemical inhibitors of cytochrome P450, which are discussed later, must be used cautiously because most of them can inhibit more than one CYP enzyme. Some chemical inhibitors are mechanism-based inhibitors that require biotransformation to a metabolite that inactivates or noncompetitively inhibits cytochrome P450.

3. Antibody inhibition, which involves an evaluation of the effects of inhibitory antibodies against selected CYP enzymes on the biotransformation of a xenobiotic by human liver microsomes. Due to the ability of antibodies to inhibit selectively and noncompetitively, this method alone can potentially establish which human CYP enzyme is responsible for biotransforming a xenobiotic. Unfortunately, the utility of this method is limited by the availability of specific inhibitory antibodies.

4. Biotransformation by purified or recombinant (cDNA-expressed) human CYP enzymes, which can establish whether a particular CYP enzyme can or cannot biotransform a xenobiotic, but it does not address whether that CYP enzyme contributes substantially to reactions catalyzed by human liver microsomes. The information obtained with purified or recombinant human CYP enzymes can be improved by taking into account large differences in the extent to which the individual CYP enzymes are expressed in human liver microsomes, which is summarized in Table 6-10.

Some CYP enzymes, such as CYP1A1 and CYP1B1, are expressed at such low levels in human liver microsomes that they do not contribute significantly to the hepatic biotransformation of xenobiotics that are excellent substrates for these enzymes. Other CYP enzymes are expressed in some but not all livers. For example, CYP3A5 is expressed in ~25% of human livers. It should be emphasized that reaction phenotyping in vitro is not always carried out with pharmacologically or toxicologically relevant substrate concentrations. As a result, the CYP enzyme that appears responsible for biotransforming the drug in vitro may not be the CYP enzyme responsible for biotransforming the drug in vivo. This may be particularly true of CYP3A4, which metabolizes several drugs with high capacity but low affinity.

Reaction phenotyping (often in conjunction with clinical observation) has been used to characterize the substrate specificity of many of the CYP enzymes expressed in human liver microsomes.

Table 6-10
Concentration of Individual P450 Enzymes in Human Liver and Intestinal Microsomes

| P450 ENZYME | LIVER | | | | INTESTINE |
| | SPECIFIC CONTENT (PMOL/MG PROTEIN) | | | | |
	SOURCE 1[a]	SOURCE 2[b]	SOURCE 3[b]	SOURCE 4[b]	SOURCE 5[c]
CYP1A2	52	45	42	15	
CYP2A6	36	68	42	12	
CYP2B6	11	39	1.0	3.0

Examples of reactions catalyzed by individual human CYP enzymes are shown in Figs. 6-40 through 6-47, and lists of substrates, inhibitors, and inducers for each CYP enzyme are given in Table 6-11. The examples listed in Table 6-11 are largely based on examples cited by the U.S. Food and Drug Administration (FDA), which has provided, where possible, the following lists to guide the conduct of in vitro and in vivo pharmacokinetic drug–drug interaction studies: (1) preferred and acceptable CYP substrates and chemical inhibitors for reaction phenotyping in vitro; (2) sensitive probe substrates to monitor CYP activity in vivo (a sensitive substrate is one whose clearance is largely [>80%] determined by a single CYP enzyme such that loss of that CYP enzyme causes a fivefold or higher increase in exposure); (3) drugs that are strong or weak inhibitors of CYP enzymes in vivo; (4) preferred and acceptable inhibitors and inducers for use as positive controls for CYP inhibition and induction studies in vitro, and (5) drugs that are effective inducers of CYP enzymes in vivo (U.S. Food and Drug Administration, 2006).

The global features of the major xenobiotic-biotransforming human CYP enzymes are as follows:

1. Two CYP enzymes, namely, CYP2D6 and CYP3A4, metabolize the majority of orally effective drugs, but they often metabolize different drugs and they do not metabolize all drugs; consequently there are many drugs whose clearance is largely determined by CYP enzymes other than CYP2D6 or CYP3A4. Inter-individual variation in CYP2D6, which is largely confined to the liver, is largely determined by genetic factors whereas inter-individual variation in CYP3A4, which is expressed in liver and small intestine, is largely determined by environmental factors (such as inhibitory and inducing drugs).

2. CYP2D6, CYP2C9, CYP2C19, and CYP3A5 are four xenobiotic-biotransforming CYP enzymes whose expression is significantly influenced by genetic polymorphisms that give rise to poor metabolizer (PM) and extensive metabolizer (EM) phenotypes, the incidence of which varies from one ethnic group to

the next. Genetic polymorphisms do affect other CYP enzymes, but not to the same extent as these four CYP enzymes.

3. The induction of CYP3A4 is often associated with induction of CYP2A6, 2B6, 2C8, 2C9, and 2C19. CYP1A2, and CYP2E1 are also inducible enzymes, but they are induced by different mechanisms and xenobiotics. Consequently, CYP1A2, 2E1, and 3A4 represent three distinct classes of inducible human CYP enzymes. CYP2D6 is considered a noninducible enzyme.

The salient features of each of the major xenobiotic-biotransforming CYP enzymes, with emphasis on the CYP enzymes in human liver microsomes, are summarized below:

CYP1A1/2 All mammalian species possess two inducible CYP1A enzymes, namely, CYP1A1 and CYP1A2. Human liver microsomes contain relatively high levels of CYP1A2, but not CYP1A1, even though this enzyme is readily detectable in the human lung, intestine, skin, lymphocytes, and placenta, particularly from cigarette smokers. In contrast to CYP1A1, CYP1A2 is not expressed in extrahepatic tissues; therefore, in humans, CYP1A2 and CYP1A1 can be considered hepatic and extrahepatic enzymes, respectively. In addition to cigarette smoke, inducers of the CYP1A enzymes include charcoal-broiled meat (a source of polycyclic aromatic hydrocarbons), cruciferous vegetables (a source of various indoles), and omeprazole and lansoprazole, two proton-pump inhibitors used to suppress gastric acid secretion. In contrast, oral contraceptive drugs suppress the expression of CYP1A2.

CYP1A1 and CYP1A2 both catalyze the O-dealkylation of 7-methoxyresorufin and 7-ethoxyresorufin (see Fig. 6-44). Reactions preferentially catalyzed by CYP1A1 include the hydroxylation and epoxidation of polycyclic aromatic hydrocarbons (PAHs) like benzo[*a*]pyrene (B[*a*]P) (see Fig. 6-9) and the epoxidation of the leukotriene D_4 receptor antagonist, verlukast (Fig. 6-42). CYP1A2 catalyzes the N-hydroxylation of aromatic amines, such as 4-aminobiphenyl, 2-aminonaphthalene, and several carcinogenic

Table 6-11

Examples of Clinically Relevant Substrates, Inhibitors, and Inducers of the Major Human Liver Microsomal P450 Enzymes Involved in Xenobiotic Biotransformation

	CYP1A2	CYP2A6	CYP2B6	CYP2C8	CYP2C9	CYP2C19	CYP2E1
Substrates	Alosetron[a]	Coumarin[d]	Bupropion[d]	Amodiaquine[b]	Diclofenac[d]	Fluoxetine[b]	Aniline[b]

	Lansoprazole[b]						
	TCDD						

[a]Classified by the FDA as a "sensitive substrate" (i.e., drugs whose plasma AUC values have been shown to increase by ≥fivefold when coadministered with a known CYP inhibitor).

[b]FDA-acceptable in vitro substrate, inhibitor, or inducer.

[c]FDA-provided examples of in vivo substrates, inhibitors, or inducers for oral administration. Substrates in this category have plasma AUCs that are increased by at least twofold (fivefold for CYP3A4 substrates) when co-administered with inhibitors of the enzyme. Inhibitors in this category increase the AUC of substrates for that enzyme by at least twofold (fivefold for CYP3A4). Inducers in this category decrease the plasma AUC of substrates for that enzyme by at least 30%.

[d]FDA-preferred in vitro substrate, inhibitor, or inducer.

[e]Classified by the FDA as a "substrate with narrow therapeutic range" (i.e., drugs whose exposure-response indicates that increases in their exposure levels by concomitant use of CYP inhibitors may lead to serious safety concerns such as Torsades de Pointes).

[f]Classified by the FDA as a "weak inhibitor" (i.e., caused a ≥1.25-fold but <twofold increase in plasma AUC or 20–50% decrease in the clearance of *sensitive* CYP substrates when the inhibitor was given at the highest approved dose and the shortest dosing interval in clinical evaluations).

[g]Classified by the FDA as a "moderate inhibitor" (i.e., caused a ≥ twofold but < fivefold increase in plasma AUC or 50–80% decrease in the clearance of *sensitive* CYP substrates when the inhibitor was given at the highest approved dose and the shortest dosing interval in clinical evaluations).

[h]Classified by the FDA as a "strong inhibitor" (i.e., caused a ≥ fivefold increase in plasma AUC or ≥ 80% decrease in the clearance of CYP substrates in clinical evaluations). Note: All FDA classifications are based on information available as of May 1, 2006 at the following URL: http://www.fda.gov/cder/drug/drugInteractions/tableSubstrates.htm#classInhibit

aromatic amines in tobacco smoke or cooked food, which in many cases represents the initial step in the conversion of aromatic amines to tumorigenic metabolites (see Fig. 6-11). Compared with their wild-type littermates, CYP1A1 knockout mice and CYP1A2 knockout mice would be expected to be resistant to the tumorigenic effects of PAHs like B[a]P and aromatic amines like 4-aminobiphenyl and the cooked-food mutagens IQ and PhIP, but they are not: Deletion of CYP1A2 has a potentiating effect on adduct and tumor formation (and methemoglobinemia) by aromatic amines, whereas deletion of CYP1A1 has a potentiating effect on the acute toxicity of oral B[a]P and the levels of adduct formation in extrahepatic tissues, presumably because CYP1A1 in the liver and small intestine of mice plays an important role in the presystemic clearance of B[a]P (which does not cause tumors in these tissues). These results suggest that, at least in mice, enzymes other than CYP1A1 (such as peroxidases and other CYP enzymes like CYP1B1) play important roles in the activation of PAH to reactive metabolites that induce skin and lung tumors, whereas enzymes other than CYP1A2 (such as peroxidases and other CYP enzymes, possibly members of the CYP2-4 families) play important roles in the activation of aromatic amines to reactive metabolites that cause liver and bladder tumors (Nebert and Dalton, 2006).

Drugs and other xenobiotics that are substrates, inhibitors, or inducers of human CYP1A2 are shown in Table 6-11. CYP1A2 catalyzes the O-dealkylation of phenacetin and the 4-hydroxylation of acetanilide, both of which produce acetaminophen, which can be converted by CYP1A2 and other CYP enzymes to a toxic benzoquinoneimine (Fig. 6-34). As shown in Fig. 6-44, CYP1A2 catalyzes the N3-demethylation of caffeine to paraxanthine. By measuring rates of formation of paraxanthine in blood, urine, or saliva or by measuring the exhalation of isotopically labeled CO_2 from ^{13}C- or ^{14}C-labeled caffeine, the N3-demethylation of caffeine can be used as an in vivo probe of CYP1A2 activity, which varies enormously from one individual to the next.

Although CYP1A1 and CYP1A2 are expressed in all mammals, there are species differences in their function and regulation.

For example, although CYP1A1 is not expressed in human liver (or in the liver of most other mammalian species), it appears to be constitutively expressed in Rhesus monkey and guinea pig liver. Conversely, although CYP1A2 is expressed in human liver (and in most other mammalian species), it does not appear to be constitutively expressed in Cynomolgus monkey liver. Polycyclic and polyhalogenated aromatic hydrocarbons appear to induce CYP1A enzymes in all mammalian species. In contrast, omeprazole is an inducer of CYP1A enzymes in humans, but not in mice or rabbits (Diaz *et al*., 1990). The function of the CYP1A enzymes is fairly well conserved across species, although there are subtle differences. For example, in some species, such as the rat, CYP1A1 is considerably more effective than CYP1A2 as a catalyst of 7-ethoxyresorufin O-dealkylation, whereas the opposite is true in other species, such as rabbit. In mice, CYP1A1 and CYP1A2 catalyze the O-dealkylation of 7-ethoxyresorufin at comparable rates. In the rat, CYP1A1 preferentially catalyzes the O-dealkylation of 7-ethoxyresorufin whereas CYP1A2 preferentially catalyzes the O-dealkylation of 7-methoxyresorufin. However, in other species, such as the mouse and the human, CYP1A2 catalyzes the O-dealkylation of 7-ethoxyresorufin and 7-methoxyresorufin at about the same rate. In addition to differences in tissue distribution and substrate specificity, CYP1A1 and 1A2 can be distinguished by differences in their affinity for various inhibitors. Ellipticine and resveratrol preferentially inhibit CYP1A1, whereas the mechanism-based inhibitor furafylline is a specific inhibitor of CYP1A2 (in humans, but not in other species). CYP1A1 and CYP1A2 are both inhibited by α-naphthoflavone.

Although the levels of CYP1A2 vary enormously from one individual to the next, genetic defects in CYP1A2 (i.e., CYP1A2 poor metabolizers) are extremely rare. Several clinical studies have reported gender differences in CYP1A2, with most—but not all—studies reporting slightly higher CYP1A2 in males compared with females (with wide variation in both genders). Rasmussen *et al*. (2002) reported that, based on a clinical study of caffeine metabolism in 378 individuals, males have higher CYP1A2 activity than females. Although oral contraceptive treatment reduces CYP1A2 activity, the gender difference reported by Rasmussen *et al*. was significant even when women on oral contraceptive steroids were excluded from the analysis. Rasmussen *et al*. (2002) also demonstrated a strong correlation in CYP1A2 activity between identical (monozygous) twins and concluded that, despite the large number of environmental factors that can potentially influence CYP1A2 expression, genetic factors account for 70–75% of the observed variation in CYP1A2 activity.

CYP1B1   Human CYP1B1 shares many properties with CYP1A1: Both can activate polycyclic aromatic hydrocarbons (PAHs) to DNA-reactive (mutagenic) metabolites; both are expressed in extrahepatic tissues but not liver, and both are inducible by TCDD and other Ah receptor agonists, such that the levels of CYP1B1 in the aerodigestive tract, like those of CYP1A1, are elevated in cigarette smokers (Port *et al*., 2004). In addition to being expressed in the respiratory and gastrointestinal tract, CYP1B1 is expressed in several estrogen-responsive tissues, such as mammary gland, ovary, and uterus. CYP1B1 is expressed in the eye, and genetic polymorphisms in CYP1B1 are associated with primary congenital glaucoma. CYP1B1 knockout mice also have structural eye defects, which suggest that CYP1B1 has an important physiological role in eye development. In addition to metabolizing PAHs, CYP1B1 also catalyzes the 4-hydroxylation of 17β-estradiol, which produces a catechol that can potentially oxidize to a toxic *ortho*-quinone.

Methylation of 4-hydroxyestradiol acts as a detoxication pathway in some tissues, as discussed in the section entitled *Methylation*. A role for CYP1B1 in chemical carcinogenesis is suggested by the observation that, compared with their wild-type littermates, CYP1B1 knockout mice are relatively resistant to PAH-induced tumor and lymphoma formation.

In addition to being under the transcriptional control of the Ah receptor, the expression of human CYP1B1 is controlled post-transcriptionally by the microRNA known as miR-27b, a small noncoding RNA that blocks the synthesis of CYP1B1 by binding to near-perfect matching sequences in the 3′-untranslated region of CYP1B1. The level of miR-27b is decreased and the level of CYP1B1 is correspondingly increased (overexpressed) in breast cancerous cells (and other cancerous tissues) (Tsuchiya *et al*., 2006). The overexpression of CYP1B1 in malignant cells (coupled with and its ability to activate xenobiotics to reactive metabolites) is being exploited to activate a prodrug to a cytotoxic metabolite as a possible cancer treatment. A related approach is the development of CYP1B1 DNA vaccine, which has been shown in clinical trials to kill CYP1B1-expressing cancer cells (Maecker *et al*., 2003).

CYP2A6 and 2A13   Enzymes belonging to the *CYP2A* gene family show marked species differences in catalytic function. For example, the two CYP2A enzymes expressed in rat liver, namely, CYP2A1 and CYP2A2, primarily catalyze the 7α- and 15α-hydroxylation of testosterone, respectively. In contrast, the CYP2A enzyme expressed in human liver, namely, CYP2A6, catalyzes the 7-hydroxylation of coumarin, as shown in Fig. 6-41. Just as rat CYP2A1 and CYP2A2 have little or no capacity to 7-hydroxylate coumarin, human CYP2A6 has little or no capacity to hydroxylate testosterone. Mouse liver microsomes contain three CYP2A enzymes; a testosterone 7α-hydroxylase (CYP2A12), a testosterone 15α-hydroxylase (CYP2A4), and a coumarin 7-hydroxylase (CYP2A5). Functionally, CYP2A5 can be converted to CYP2A4 by a single amino acid substitution (Phe$_{209}$ → Leu$_{209}$). In other words, this single amino substitution converts CYP2A5 from a coumarin 7-hydroxylating to a testosterone 15α-hydroxylating enzyme (Lindberg and Negishi, 1989). The fact that a small change in primary structure can have a dramatic effect on substrate specificity makes it difficult to predict whether orthologous proteins in different species (which are structurally similar but never identical) will catalyze the same reactions.

Differences in CYP2A function have important implications for the adverse effects of coumarin, which is hepatotoxic to rats but not humans. Whereas coumarin is detoxified in humans by conversion to 7-hydroxycoumarin, which is subsequently conjugated with glucuronic acid and excreted, a major pathway of coumarin biotransformation in rats involves formation of the hepatotoxic metabolite, coumarin 3,4-epoxide, as shown in Fig. 6-42. In addition to catalyzing the 7-hydroxylation of coumarin, CYP2A6 converts 1,3-butadiene to butadiene monoxide and nicotine to nicotine $\Delta^{1',5'}$-iminium ion, which is further oxidized by aldehyde oxidase to cotinine, as shown in Fig. 6-47.

Humans possess two functional CYP2A genes, namely, CYP2A6 and 2A13, and one nonfunctional CYP2A gene, namely, CYP2A7. CYP2A6 and the nonfunctional CYP2A7 are expressed in the liver but few extrahepatic tissues (with the notable exception of mammary gland), whereas CYP2A13 is expressed mainly in the lung (bronchus and trachea) and bladder, with lower levels in reproductive organs such as testis, ovary, uterus, and mammary gland. Hepatic CYP2A6 plays a major role in the metabolism of coumarin and nicotine, and plays a role in the metabolism of tegafur, fadrozole, methoxyflurane, and valproic acid. 8-Methoxypsoralen,

a structural analog of coumarin, is a potent, mechanism-based inhibitor of CYP2A6. Other inhibitors of CYP2A6 are listed in Table 6-11. CYP2A13 does not appear to contribute to drug clearance, but it may play an important role in the activation of xenobiotics to toxic and carcinogenic metabolites in lung and bladder. CYP2A6 and CYP2A13 both activate nitrosamines to DNA-reactive (mutagenic) metabolites, especially those nitrosamines with bulky alkyl substituents such as NNK, N'-nitrosonorcotinine, and related nitrosomines found in tobacco smoke. (CYP2E1 also activates nitrosamines, but it preferentially activates nitrosamines with small alkyl substituents such as N-nitrosodimethylamine.)

The identification of three Japanese individuals who were poor metabolizers of SM-12502, an antiplatelet drug whose clearance is largely determined by CYP2A6, led to the identification of a genetic polymorphism that, in homozygous individuals, leads to the complete loss of CYP2A6 (CYP2A6*4C/*4C). The incidence of the CYP2A6 PM genotype is relatively high in Asians (up to 5% of Japanese, 3% of Chinese, 1.9% of Koreans, and 1.5% of Thais), but no such CYP2A6 PMs have been identified in Caucasians. Individuals who are genetically deficient in CYP2A6 have a considerably lower risk of cigarette-smoking-induced lung cancer presumably because these individuals have a reduced capacity for activating tobacco-smoke nitrosamines to carcinogenic metabolites (Kamataki *et al.*, 2005). In support of this interpretation, the CYP2A inhibitor 8-methoxypsoralen protects mice from NNK-induced lung adenomas. CYP2A6 PMs are not only poor metabolizers of nitrosamines but they also are poor metabolizers of nicotine. Therefore, decreased cigarette consumption may also contribute to the lowered risk of lung cancer in CYP2A6 PMs. CYP2A6 is detectable in human lung, but the levels are considerably less than those of CYP2A13, which can activate the same carcinogens as CYP2A6. Therefore, it is not immediately obvious why a genetic deficiency in CYP2A6 protects against lung cancer. A similar situation occurs with CYP2D6 inasmuch as individuals lacking this hepatic enzyme (i.e., CYP2D6 PMs) also have a decreased risk of cigarette-smoking-induced lung cancer.

It seems somewhat paradoxical but just as CYP2A6 PMs have a decreased risk of lung cancer, so they have an increased risk of nasopharyngeal cancer, which is rare in Caucasians (Western countries) but endemic in Southern China and Southeast Asia. It has been postulated that, in the absence of CYP2A6, higher levels of nitrosamines and other carcinogens reach the nasal epithelium where they can be activated to carcinogenic metabolites by CYP2E1 and CYP2A13, both of which are expressed in nasal epithelium (Tiwawech *et al.*, 2006).

Like CYP2A6, CYP2A13 can activate several carcinogens including many of the nitrosamines (e.g., NNK) and aromatic amines (e.g., 4-aminobiphenyl) that are present in cigarette smoke, and the mycotoxin aflatoxin B1. CYP2A13 is suspected of playing a role in the activation of carcinogens in tobacco smoke because it is localized in the two sites where cigarette smoking causes cancer, namely, the lung bronchus and bladder (Nakajima *et al.*, 2006).

CYP2B6   CYP2B6 is expressed in human liver and, to a lesser extent, in kidney, intestine, and lung. It plays a major role in the metabolism of bupropion, efavirenz, and propofol, and the metabolism of these substrates (in addition to the N-demethylation, but not the 4′-hydroxylation, of *S*-mephenytoin) can be used in vitro or in vivo to assess CYP2B6 activity, as shown in Table 6-11. Other substrates for CYP2B6 include the anticancer drugs cyclophosphamide and tamoxifen. As shown in Table 6-11, several drugs have been shown to inhibit CYP2B6, and many of them do

so in a metabolism-dependent manner, such as clopidogrel, ticlopidine, and thio-TEPA. CYP2B6 is an inducible enzyme; it is generally co-induced with CYP3A4 and several CYP2C enzymes by xenobiotics that activate CAR and/or PXR, such as rifampin, the enzyme-inducing antiepileptic drugs (EIAEDs) such as phenobarbital, phenytoin, carbamazepine, and felbamate, and the herbal preparation of St. John's wort, which is the topic of a subsequent section (see the section "Induction of Cytochrome P450—Xenosensors").

CYP2C Enzymes   Humans express four CYP2C enzymes, namely, CYP2C8, CYP2C9, 2C18, and 2C19. With the exception of CYP2C18, these CYP2C enzymes play a significant role in drug metabolism, and their inhibition or induction is the basis of a number of clinically important drug interactions. In the case of CYP2C9 and 2C19, genetic polymorphisms give rise to a PM phenotype, which also impacts the metabolism and safety or efficacy of certain drugs. As a general rule (to which there are many exceptions), CYP2C8 metabolizes large, acidic drugs, including several glucuronide conjugates; CYP2C9 metabolizes (or is inhibited by) smaller acid- or sulfonamide-containing drugs, and CYP2C19 metabolizes drugs often with a high degree of stereoselectivity (i.e., it preferentially metabolizes one enantiomer over the other). All four enzymes appear to be inducible by CAR/PXR agonists; hence, they tend to be co-induced together with CYP2B6 and CYP3A4. Substrates, inhibitors, and inducers of CYP2C8, 2C9, and 2C19 are listed in Table 6-11.

CYP2C8   CYP2C8 has been implicated in the metabolism of the following drugs and endobiotics: all-*trans* retinoic acid, arachidonic acid, amiodarone, amodiaquine, carbamazepine, cerivastatin (withdrawn), chloroquine, cilostazol, *R*-ibuprofen, lovastatin, morphine, pioglitazone, paclitaxel (Taxol®), repaglinide, rosiglitazone, rosuvastatin, simvastatin, tazarotene, torsemide, troglitazone (withdrawn), verapamil and zopiclone. However, with the exception of the antidiabetic drug, repaglinide, all of the above drugs are metabolized to a significant extent by enzymes other than CYP2C8. Repaglinide is classified by the FDA as a sensitive CYP2C8 substrate. In the presence of the CYP2C8 inhibitor gemfibrozil, exposure to repaglinide (based on plasma AUC) increases about eightfold (from 5.5 to 15-fold).

Substrates for CYP2C8 tend to be large and acidic as evidenced by the observation that CYP2C8 metabolizes several glucuronides. For example, whereas 17β-estradiol and diclofenac are metabolized by CYP2C9, the glucuronide metabolites of these compounds (namely, estradiol-17β-glucuronide and diclofenac acyl glucuronide) are metabolized by CYP2C8 (at the same site as that metabolized by CYP2C9, which is distal to the glucuronide moiety).

The ability of CYP2C8 to metabolize glucuronide conjugates appears to play an important role in the mechanism by which the hypolipidemic drug gemfibrozil inhibits the metabolism, and thereby increases in the toxicity (a sometimes fatal muscle disorder known as rhabdomyolysis) of cerivastatin (Baycol), a member of the statin class of cholesterol synthesis inhibitors that was withdrawn from the market (Ogilvie *et al.*, 2006). Gemfibrozil glucuronide, but not gemfibrozil itself, is a potent mechanism-based inhibitor of CYP2C8. In other words, CYP2C8 metabolizes gemfibrozil glucuronide to a metabolite that inactivates the enzyme. The sometimes fatal interaction between gemfibrozil (the perpetrator drug) and cerivastatin (the victim drug) was a significant factor in the decision to withdraw cerivastatin from the U.S., European, and Japanese markets.

CYP2C9   CYP2C9 plays a major role in the metabolism of a wide variety of therapeutic agents including NSAIDs (e.g.,

diclofenac, celecoxib, ibuprofen, flurbiprofen, naproxen, piroxicam, mefenamic acid, and suprofen), oral hypoglycemics (e.g., glyburide, glipizide, glimepiride, tolbutamide), oral anticoagulants (e.g., S-warfarin, S-acenocoumarol, and phenprocoumon), diuretics and uricosurics (e.g., sulfinpyrazone sulfide, torsemide, tienilic acid [ticrynafen]), angiotensin II blockers (e.g., candesartan, irbesartan, losartan), anticonvulsants (e.g., phenytoin), and many others. It also metabolizes Δ^9-tetrahydrocannabinol and certain endobiotics such as arachidonic acid, linoleic acid, and serotonin (5-hydroxytryptamine). Substrates for—and inhibitors of—CYP2C9 tend to be acid- or sulfonamide-containing compounds, but there are exceptions to this general rule. In fact, the most potent CYP2C9 inhibitors known, namely, benzbromarone and 2-methyl-3-(3′,5′-diiodo-4′-hydroxybenzoyl)benzofluran, are neither acid-nor sulfonamide-containing compounds (Rettie and Jones, 2005).

CYP2C9 is a polymorphically expressed enzyme. Two allelic variants, CYP2C9*2 and CYP2C9*3, are each present in about 10% of Northern European populations such that about 40% of Caucasians possess one or two allelic variants of CYP2C9. CYP2C9*2 is generally associated with no more than a small decrease in catalytic activity, whereas CYP2C*3 is associated with a marked decrease in catalytic activity. Individuals who are homozygous for the *3 allele are considered CYP2C9 PMs (i.e., poor metabolizers of drugs that are otherwise cleared by CYP2C9). Estimates of the CYP2C9 PM genotype are in the range of 1–10% in Caucasians, 1–4% in Africans, and 0–2% in Asians. The PM genotype is particularly important for S-warfarin, tolbutamide, and phenytoin. These three drugs have a low therapeutic index, and their dose must be reduced in CYP2C9 PMs to prevent adverse drugs events. Dosage adjustment is also required when these drugs are combined with a CYP2C9 inhibitor or inducer, examples of which are given in Table 6-11.

Tienilic acid is also metabolized by CYP2C9, but with potentially deleterious effects. CYP2C9 converts tienilic acid to an electrophilic thiophene sulfoxide that can react either with water to give 5-hydroxytienilic acid or with a nucleophilic amino acid in CYP2C9 to form a covalent adduct, which inactivates the enzyme (Lecoeur et al., 1994). Antibodies directed against the adduct between CYP2C9 and tienilic acid are thought to be responsible for the immunoallergic hepatitis that develops in about 1 out of every 10,000 patients treated with this uricosuric diuretic drug. As shown in Table 6-3, these auto-antibodies against CYP2C9 are known as anti-LKM$_2$ because they are directed against **L**iver and **K**idney **M**icrosomes. The subscript number 2 distinguishes these antibodies against CYP2C9 from those against CYP2D6, which are known as anti-LKM$_1$.

CYP2C18   In contrast to the other three CYP2C enzymes expressed in human liver, CYP2C18 appears to play little or no role in drug metabolism. CYP2C18 is the most abundant CYP2C enzyme in skin and lung, and it also appears to be expressed in brain, uterus, mammary gland, kidney, and duodenum. CYP2C18 is more than an order of magnitude more active than either CYP2C9 or CYP2C19 at catalyzing the *para*-hydroxylation of phenytoin to HPPH, and CYP2C18 can further hydroxylate HPPH to a catechol (Kinobe et al., 2005). Autoxidation of this catechol to an *ortho*-quinone is thought to be responsible, at least in part, for rare incidences of hypersensitivity reactions to phenytoin. Therefore, although hepatic CYP2C9 and CYP2C19 are largely responsible for determining the systemic clearance of phenytoin, it is possible that CYP2C18 is responsible for activating phenytoin by the catechol/quinone pathway

in the skin, the tissue where the first signs of hypersensitivity to phenytoin are observed.

CYP2C19   CYP2C19 is a polymorphically expressed enzyme that metabolizes several drugs with a high degree of stereospecificity such that, in the case of drugs administered as a racemic mixture, it metabolizes one enantiomer faster than the other, as in the case of mephenytoin (Mesantoin®), which is of historical interest with respect to CYP2C19. A genetic polymorphism for the metabolism of S-mephenytoin was first described in 1984 (reviewed in Wilkinson et al., 1989). The deficiency affects the 4′-hydroxylation (aromatic ring hydroxylation) of this anticonvulsant drug (see Fig. 6-41). The other major pathway of S-mephenytoin metabolism, namely, N-demethylation to S-nirvanol, is not affected. (This pathway was subsequently shown to be catalyzed by CYP2B6.) Consequently, poor metabolizers excrete little or no 4′-hydroxymephenytoin in their urine, but they do excrete increased amounts of the N-demethylated metabolite, S-nirvanol (S-phenylethylhydantoin). The enzyme responsible for this genetic polymorphism is CYP2C19, and it is highly stereoselective for the S-enantiomer of mephenytoin. In contrast to the S-enantiomer, the R-enantiomer is not converted to 4′-hydroxymephenytoin, but it is N-demethylated to R-nirvanol (R-phenylethylhydantoin). Individuals who are genetically deficient in CYP2C19 are at increased risk of adverse events from Mesantoin® (a racemic mixture of the S- and R-enantiomers of mephenytoin). An exaggerated central response has been observed in CYP2C19 PMs administered Mesantoin® at doses that were without effect in CYP2C19 EMs.

CYP2C19 plays an important role in the metabolism of several proton pump inhibitors including omeprazole and lansoprazole, the structures of which are shown in Fig. 6-43. The sulfoxide group in omeprazole and lansoprazole (and other proton pump inhibitors) is a chiral center, and CYP2C19 preferentially metabolizes one enantiomer over the other: it preferentially hydroxylates the R-enantiomer in the case of omeprazole, and it preferentially hydroxylates the S-enantiomer in the case of lansoprazole. These reactions are equivalent inasmuch as these two proton pump inhibitors are hydroxylated on opposite ends of the molecule (on the pyridine ring in the case of omeprazole and on the benzimidazole ring in the case of lansoprazole), meaning the sulfoxide in each case binds to the active site of CYP2C19 in the same orientation (Kim et al., 2003). CYP2C19 PMs are poor metabolizers of omeprazole and lansoprazole. However, CYP2C19 PMs are not at increased risk for adverse drug events but actually derive greater therapeutic benefit (better control of gastroesophageal reflux disease or GERD) from standard doses of proton pump inhibitors (Furuta et al., 2005). Esomeprazole, the S-enantiomer of omeprazole, was approved for the treatment of GERD and related gastric acid disorders. Compared with the R-enantiomer, esomeprazole is not rapidly metabolized by CYP2C19, and its improved pharmacokinetic behavior provides CYP2C19 EMs with the same therapeutic benefit as CYP2C19 PMs administered omeprazole. Other substrates, inhibitors, and inducers of CYP2C19 are listed in Table 6-11.

The incidence of the CYP2C19 PM genotype varies considerably from one ethnic group to the next: It ranges from 13 to 23% in Japanese, Chinese, Korean, Turkish, and Saudi Arabian subjects, but the incidence is considerably lower (1–5%) in Caucasians and Africans. No CYP2C19 UMs (individuals with functional CYP2C19 gene duplications) have been identified, although CYP2C19 is an inducible enzyme whose activity can be increased by CAR/PXR agonists (see Table 6-11).

CYP2D6   In the late 1950s, clinical trials in the United States established that sparteine was as potent as oxytocin for inducing labor at term. However, the duration and intensity of action of sparteine was dramatically increased in ~7% of all patients tested. The exaggerated response to sparteine included prolonged (tetanic) uterine contraction and abnormally rapid labor. In some cases, sparteine caused the death of the fetus. The drug was not recommended for clinical use because these side effects were unpredictable and occurred at doses of 100–200 mg, which were well tolerated by other patients. The antihypertensive drug, debrisoquine, was subsequently found to cause a marked and prolonged hypotension in 5–10% of patients, and a genetic polymorphism for the metabolism of debrisoquine and sparteine was discovered in 1977–1979. Poor metabolizers lack CYP2D6, which catalyzes the 4-hydroxylation of debrisoquine and the dehydrogenation (Δ^2- and Δ^5-oxidation) of sparteine (see Fig. 6-47).

In addition to debrisoquine and sparteine, CYP2D6 biotransforms an extraordinarily large number of drugs, as shown in Table 6-11. Individuals lacking CYP2D6 have an exaggerated response to some but not all these drugs. For example, even though debrisoquine and propranolol are both biotransformed by CYP2D6, the effects of propranolol are not exaggerated in poor metabolizers of debrisoquine, for two reasons. First, 4-hydroxypropranolol is a β-adrenoceptor antagonist, so the 4-hydroxylation of propranolol by CYP2D6 does not terminate the pharmacological effects of the drug. Second, CYP2D6 is not the only CYP enzyme to biotransform propranolol. As mentioned above, CYP2C19 catalyzes the side-chain oxidation of propranolol to naphthoxylactic acid (see Fig. 6-27). Because CYP2D6 and CYP2C19 both contribute significantly to the biotransformation of propranolol, a deficiency in either one of these enzymes does not markedly alter the pharmacokinetics of this beta blocker. However, in one individual who lacked both enzymes, the total oral clearance of propranolol was markedly reduced (Wilkinson *et al.*, 1989). The biotransformation of substrates for CYP2D6 occurs 5–7.5Å from a basic nitrogen, which interacts with an anionic residue (Glu^{301}) in the enzyme's substrate-binding site. Quinidine is a potent inhibitor of CYP2D6 because it interacts favorably with the anionic site on CYP2D6 but it cannot be oxidized at a site 5–7.5Å from its basic nitrogen atoms. Quinidine, paroxetine, and fluoxetine (and especially norfluoxetine, its *N*-demethylated metabolite) are strong CYP2D6 inhibitors in vivo, and a PM phenotype can be induced pharmacologically with these particular inhibitors. Quinine, the levorotatory diastereomer of quinidine, is not a potent inhibitor of CYP2D6, and neither drug is a potent inhibitor of the CYP2D enzymes expressed in rats.

As shown in Fig. 6-44, CYP2D6 catalyzes the O-demethylation of dextromethorphan to dextrorphan, which is glucuronidated and excreted in urine. Dextromethorphan can also be N-demethylated, a reaction catalyzed predominantly by CYP3A4 and CYP2B6, but this metabolite is not glucuronidated and excreted in urine. Because the urinary excretion of dextromethorphan is dependent on O-demethylation, this over-the-counter antitussive drug can be used to identify individuals lacking CYP2D6, and it can be used as an in vivo probe to identify drugs capable of causing clinically significant inhibition of CYP2D6. Other FDA-acceptable in vivo probes of CYP2D6 include desipramine and atomoxetine (see Table 6-11).

Genetic polymorphisms of CYP2D6 have been so extensively studied that it is possible not only to categorize individuals into four genotypes, namely, poor metabolizers (PMs), intermediate metabolizers (IMs), extensive metabolizers (EMs), and ultra-rapid metabolizers (UMs), but it is also possible to subdivide the extensive metabolizers into three categories, namely, High Activity EM, Medium Activity EM, and Low Activity EM, as summarized in Table 6-4. The incidence of the CYP2D6 PM genotype varies considerably from one ethnic group to the next: It is 5–7% in Caucasians, 2–4% in Africans and African Americans, and 1–2% in Turkish and Asian (Thai, Chinese, and Japanese) subjects. Similarly, the incidence of the CYP2D6 gene duplication, which gives rise to the CYP2D6 UM genotype, varies among ethnic groups: It is up to 29% in Ethiopians, 20% in Saudi Arabians, 5–10% in Southern European Caucasians, but only 1–2% of Northern European Caucasians, 5–10% of Turkish subjects, and up to 2% in African, African-American, and Asian subjects. CYP2D6 PMs are often at increased risk of an exaggerated pharmacological response, such as the prolonged uterine contractions caused by sparteine or the prolonged hypotension caused by debrisoquine, or a toxicological response, such as the hepatotoxic effects of perhexiline (three drugs that, because of the adverse events in CYP2D6 PMs, were not approved by the FDA). Some drugs, such as the analgesic codeine (which is O-demethylated to morphine) and the anticancer drug tamoxifen (which is hydroxylated and N-demethylated to endoxifen), are converted to pharmacologically active metabolites by CYP2D6. Consequently, CYP2D6 PMs derive less therapeutic benefit than CYP2D6 EMs. In contrast, in the case of codeine, CYP2D6 UMs are at increased risk from morphine toxicity. The death of an elderly man administered a recommended dose of codeine and the death of baby who was breast-fed by a woman on codeine have been attributed to the CYP2D6 UM genotype that causes rapid conversion of codeine to morphine (which causes respiratory suppression) (Gasche *et al.*, 2004; Koren *et al.*, 2006).

Individuals lacking CYP2D6 have an unusually low incidence of some chemically induced neoplastic diseases (Idle, 1991). For example, CYP2D6 PMs appear to be relatively resistant to lung cancer whereas CYP2D6 UMs appear to be at increased risk (Agundez *et al.*, 2001). It has been hypothesized that CYP2D6 may play a role in the metabolic activation of chemical carcinogens, such as those present in the environment, in the diet, and/or in cigarette smoke. According to this hypothesis, CYP2D6 PMs have a low incidence of cancer because they fail to activate chemical carcinogens, whereas CYP2D6 UMs have an increased risk because they rapidly and/or extensively activate pro-carcinogens. However, CYP2D6 appears to play little or no role in the activation of known chemical carcinogens to DNA-reactive or mutagenic metabolites, with the notable exception of the tobacco-smoke-specific nitrosamine, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK), which is also activated by numerous other CYP enzymes (see the previous section on "CYP2A6 and 2A13"). Although the association between CYP2D6 status and lung cancer incidence was first described in 1984, the mechanism underlying this association remains to be determined.

CYP2E1   As shown in Fig. 6-24, CYP2E1 was first identified as the microsomal ethanol oxidizing system (MEOS, Lieber, 1999). In addition to ethanol, CYP2E1 catalyzes the biotransformation—and in many cases the metabolic activation—of a large number of halogenated alkanes and nitrosamines, as shown in Table 6-12 (Guengerich *et al.*, 1991). CYP2E1 is expressed constitutively in human liver and several extrahepatic tissues, such as the kidney, lung, bone marrow, and lymphocytes. As illustrated in Fig. 6-31, CYP2E1 in the liver and possibly the bone marrow itself plays an important role in activating benzene to myelotoxic metabolites, as evidenced by the protective effect of CYP2E1 gene deletion in mice (Gonzalez, 2003).

Table 6-12
Examples of Xenobiotics Activated by Human P450

CYP1A2	CYP2E1
Acetaminophen	Acetaminophen
2-Acetylaminofluorene	Acrylonitrile
4-Aminobiphenyl	Benzene
2-Aminofluorene	Carbon tetrachloride
2-Naphthylamine	Chloroform
NNK	Dichloromethane
Amino acid pyrolysis products	1,2-Dichloropropane
(DiMeQx, MeIQ, MeIQx, Glu P-1,	Ethylene dibromide
Glu P-2, IQ, PhIP, Trp P-1, Trp P-2)	Ethylene dichloride
Tacrine	Ethyl carbamate
CYP2A6 and 2A13	Halothane
NNK and bulky nitrosamines	*N*-Nitrosodimethylamine
N-Nitrosodiethylamine	Styrene
Aflatoxin B1	Trichloroethylene
CYP2B6	Vinyl chloride
6-Aminochrysene	CYP3A4
Cyclophosphamide	Acetaminophen
Ifosfamide	Aflatoxin B_1 and G_1
CYP2C8, 9, 18, 19	6-Aminochrysene
Tienilic acid	Benzo[*a*]pyrene 7,8-dihydrodiol
Phenytoin	Cyclophosphamide
Valproic acid	Ifosfamide
CYP2D6	1-Nitropyrene
NNK	Sterigmatocystin
CYP2F1	Senecionine
3-Methylindole	*Tris*(2,3-dibromopropyl) phosphate
Acetaminophen	CYP4B1
Valproic acid	Ipomeanol
CYP1A1 and 1B1	3-Methylindole
Benzo[*a*]pyrene and	2-Aminofluorene
other polycyclic	
aromatic hydrocarbons	

NNK, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, a tobacco-specific nitrosamine.
Data adapted from Guengerich FP, Shimada T: Oxidation of toxic and carcinogenic chemicals by human cytochrome
   P-450 enzymes. *Chem Res Toxicol* 4:391–407, 1991.

The function and regulation of CYP2E1 are relatively well conserved among mammalian species. In humans and most other mammalian species, CYP2E1 is inducible by ethanol, isoniazid, and ketone bodies (which form during uncontrolled diabetes). In contrast to the induction of most other CYP enzymes, the induction of CYP2E1 often involves increased translation of preexisting mRNA and/or protein stabilization rather than transcriptional activation of the CYP2E1 gene; hence, induction of CYP2E1 often occurs in the absence of an increase in mRNA levels.

CYP2E1 can activate acetaminophen to the hepatotoxic metabolite, *N*-acetylbenzoquinoneimine, as shown in Figs. 6-34 and 6-47. Compared with their wild-type littermates, CYP2E1 knockout mice are relatively resistant to acetaminophen hepatotoxicity (Gonzalez, 2003). The mechanism by which alcohol potentiates the hepatotoxic effects of acetaminophen (Tylenol®) is thought to involve increased activation of acetaminophen, due to the induction of CYP2E1, and decreased inactivation, due to a lowering of glutathione levels. Induction of CYP2E1 by isoniazid stimulates the dehalogenation of the volatile anesthetics, enflurane and isoflurane. In human liver microsomes, CYP2E1 activity can be conveniently measured by the 6-hydroxylation of chlorzoxazone and the hydroxylation of 4-nitrophenol (Table 6-11). The 6-hydroxylation of chlorzoxazone can also be catalyzed by CYP1A1, but this enzyme is rarely expressed in human liver. Chlorzoxazone is an FDA-approved muscle relaxant (Paraflex®), and the urinary excretion of 6-hydroxychlorzoxazone and the plasma ratio of 6-hydroxychlorzoxazone to chlorzoxazone have been used as noninvasive in vivo probes of CYP2E1. The levels of CYP2E1 are by no means constant among individuals, but they do not exhibit the marked interindividual variation characteristic of other CYP enzymes. CYP2E1 is one of the CYP enzymes that require cytochrome b_5, which lowers the K_m for several substrates biotransformed by CYP2E1.

CYP2F1 and 2J2　　CYP2F1 is expressed in the lung and plays an important role in activating the pulmonary toxin 3-methylindole to a reactive metabolite (formed by a dehydrogenation reaction analogous to those shown in Fig. 6-47 (Nichols *et al.*, 2003).

CYP2J2 is expressed in liver, small intestine, heart, and kidney. Although it has been shown to contribute significantly to

the biotransformation of ebastine and, to a lesser extent, astemizole, CYP2J2 is better known for its ability to epoxygenate arachidonic acid to vasoactive metabolites, such as *cis*-11,12-epoxyeicosatrienoic acid (11,12-EET), which is one of four EETs formed by the CYP-dependent epoxygenation of arachidonic acid (Liu *et al*., 2006a; Spiecker and Liao, 2006). As such, CYP2J2 is one of several CYP enzymes involved in EET formation, including other members of the CYP2 family (see "CYP2C8" and "CYP2C9" above) and several members of the CYP4 family (see "CYP4 Enzymes" below).

CYP2R1, 2S1, 2U1, and 2W1   CYP2R1, 2S1, 2U1, and 2W1 are four of the eight members of the CYP1 and 2 families that are so well conserved from an evolutionary perspective that they have been given the same names across all mammalian species (the other members are CYP1A1, 1A2, 1B1, and 2E1). These enzymes have been conserved during evolution presumably because they perform an important physiological function. In support of this possibility, CYP2R1, 2S1, 2U1, and 2W1 have been shown to metabolize vitamin D, all-*trans* retinoic acid, fatty acids, and arachidonic acid, respectively, although the ability of CYP2W1 to metabolize arachidonic acid (or any of several other fatty acids) is not supported by recent studies (Yoshioka *et al*., 2006). Notwithstanding their ability to metabolize all-*trans* retinoic acid or fatty acids, CYP2S1, 2U1, and 2W1 are suspected of performing an as-yet unidentified physiologic function, for which reason they are classified as orphan enzymes of unknown function (Table 6-9).

Like CYP1A1, CYP1A2, and CYP1B1, the recently identified CYP enzyme known as CYP2S1 is inducible by TCDD and other Ah receptor agonists. Like CYP1A1 and CYP1B1, CYP2S1 is expressed mainly in extrahepatic tissues such as lung, trachea, stomach, small intestine, colon, spleen, bladder, and skin. CYP2S1 metabolizes all-*trans* retinoic acid, which is a physiologic substrate. In view of its structural similarities to—and co-localization with—CYP2A13, and in view of its inducibility by Ah receptor agonists, CYP2S1 has been conjectured to play a role in the metabolic activation of xenobiotics in extrahepatic tissues. However, in bacterial mutagenicity assays, CYP2S1 has been shown NOT to activate the pro-carcinogens NNK, PhIP, aflatoxin B1, and a series of polycyclic aromatic hydrocarbons and their diol-epoxides (Wang *et al*., 2005b; Wu *et al*., 2006).

CYP2W1 is expressed in a large number of tumors, and yet it does not appear to be expressed to a significant extent in normal (i.e., noncancerous) hepatic or extrahepatic tissues (Karlgren *et al*., 2006). Like CYP1B1, which is also overexpressed in malignant cells (see "CYP1B1" above), CYP2W1 can activate a wide variety of polycyclic aromatic hydrocarbons and their diol-epoxides to mutagenic metabolites (Wang *et al*., 2005b; Wu *et al*., 2006). Whether expression of CYP2W1 contributes to tumor formation or is expressed only as a result of malignancy remains to be determined.

CYP3A Enzymes   The most abundant CYP enzymes in human liver microsomes belong to the CYP3A gene subfamily, which includes CYP3A4, 3A5, 3A7, and 3A43. CYP3A43 is considered an orphan enzyme of unknown function (see Table 6-9). CYP3A7 is considered a fetal enzyme that may play a role in the activation of drugs to teratogenic metabolites (Li *et al*., 1997). This is a concern because laboratory animals do not express a fetal CYP3A enzyme, raising the possibility that teratogenic metabolites formed

by CYP3A7 may go undetected during reproductive toxicity testing in animals. Whereas CYP3A7 is considered to be a fetal enzyme, CYP3A4 and 3A5 are considered to be adult enzymes, although livers from some adults contain CYP3A7 and some fetal livers contain CYP3A5.

CYP3A4   CYP3A4 is abundantly expressed in liver and small intestine, where it biotransforms an extraordinary array of steroid hormones and xenobiotics, including drugs from numerous therapeutic classes (Table 6-11). By some estimates, CYP3A4 metabolizes about 70% of all drugs. A large number of clinically significant drug–drug, drug–herbal, and drug–food interactions involve the inhibition or induction of hepatic and/or intestinal CYP3A4. Three victim drugs whose clearance is mainly determined by CYP3A4, namely, terfenadine (Seldane), cisapride (Propulsid), and astemizole (Hismanal), have been withdrawn from the market because of their potential to cause ventricular arrhythmias (and on rare occasions heart attacks) when their metabolism by CYP3A4 was inhibited by drugs like ketoconazole and erythromycin. One perpetrator drug, namely, mibefradil (Posicor) has been withdrawn from the market because of its ability to cause marked and prolonged inhibition of CYP3A4 by virtue of its ability to cause mechanism-based inhibition of CYP3A4 (which persists after the inhibitory drug is withdrawn and until new enzyme is synthesized).

CYP3A4 is abundantly expressed in the small intestine where it contributes substantially to the first-pass metabolism (presystemic clearance) of numerous drugs. The inhibition of intestinal CYP3A4 by furanocoumarins in grapefruit juice, which can cause large increases in exposure to drugs that otherwise undergo first-pass elimination, is an important mechanism of drug–food interaction. The induction of intestinal and hepatic CYP3A4 by St. John's wort, which can result in a loss of therapeutic efficacy of oral contraceptive steroids, anti-HIV, and antiorgan rejection drugs, is an important mechanism of drug–herbal interactions.

The induction of CYP3A4 is mediated by CAR and PXR, agonists for which include several antibiotics, such as rifampin and rifabutin, and several enzyme-inducing antiepileptic drugs (EIAEDs), such as phenobarbital, phenytoin, carbamazepine, and felbamate, as shown in Table 6-11 (a more complete list of CYP3A4 inducers is given in the later section "Cytochrome P450 Induction - Xenosensors)."

The function and regulation of the CYP3A enzymes is fairly well conserved among mammalian species, with some notable exceptions. For example, rifampin is an inducer of the CYP3A enzymes in humans and rabbits but not rats or mice, whereas the opposite appears to be true of pregnenolone-16α-carbonitrile (PCN). In adult rats, the levels of CYP3A2 in males are much greater (>tenfold) than in females. In humans, men do not have higher levels of CYP3A4 than women; in fact there is evidence to suggest that the reverse is true; that women have slightly higher levels of CYP3A4 than men, although it should be noted that CYP3A4 levels vary widely in both men and women.

CYP3A4 metabolizes more drugs than any other xenobiotic-biotransforming enzyme, which is apparent from the large list of CYP3A4 substrates listed in Table 6-11. Like CYP2C8, CYP3A4 can metabolize large substrates, such as paclitaxel (Taxol®), which is a substrate for both enzymes. The active site of CYP3A4 is sufficiently large to bind two drugs simultaneously, and individual drugs tend to bind to discrete regions, which has several consequences. First, the binding of two substrates to CYP3A4 allows for homotropic activation (where a substrate stimulates its

own metabolism, as in the case of testosterone and diazepam) and heterotropic activation (where one compound, such as α-naphthoflavone, stimulates the metabolism of another). These effects give rise to non-Michaelis–Menten or atypical enzyme kinetics, which is characteristic of the metabolism of several drugs by CYP3A4. The binding of one ligand (substrate, inhibitor, or activator) to CYP3A4 can cause conformational changes that increase the size of the active site by 80% or more, which allows additional ligands to bind, possibly in a stacked or side-by-side configuration (Ekroos and Sjögren, 2006). Second, substrates can bind to relatively discrete sites within the active site. Testosterone and midazolam appear to bind to distinct sites (called the steroid and benzodiazepine binding site, respectively); consequently these two prototypical substrates only weakly inhibit each other's metabolism by CYP3A4. As a result of these different substrate-binding sites or orientations, it is possible for a drug to inhibit CYP3A4 in a substrate-dependent manner. However, inhibitors that coordinate directly with the heme moiety of CYP3A4 will inhibit the metabolism of all CYP3A4 substrates, as will most mechanism-based inhibitors of CYP3A4 (see the later section "Inhibition of Cytochrome P450"). Although the active site of CYP3A4 is sufficiently large to bind substrates in apparently discrete sites and to bind two molecules simultaneously, it nevertheless often catalyzes reactions with a high degree of regio- and stereoselectivity. In the case of testosterone, for example, CYP3A4 catalyzes hydroxylation at several sites on the β-face of the molecule (e.g., 1β-, 2β-, 6β-, and 15β-hydroxylation) but none on the α-face.

CYP3A5   CYP3A5 is a polymorphically expressed enzyme. Functional enzyme (encoded by the CYP3A5*1 or wild-type allele) is expressed in the liver of only 10–30% of Caucasians, ~50% of Chinese, ~60% of African Americans, and 60–70% of Japanese. No CYP3A5 UMs (individuals with functional CYP3A5 gene duplications) have been identified. There are conflicting reports on the relative levels of CYP3A5 and CYP3A4 in liver. Some reports indicate that the levels of CYP3A5 are uniformly low (Patki *et al.*, 2003; Westlind-Johnsson *et al.*, 2003) whereas others indicate that, in some liver samples, the levels of CYP3A5 can approach those of CYP3A4 (Lin *et al.*, 2002). There are also conflicting reports on the relative rate of drug and steroid metabolism by CYP3A5 and CYP3A4. Studies with recombinant enzymes generally show that CYP3A4 is considerably more active than CYP3A5 in the metabolism of a wide range of substrates. Many of these studies were recently criticized (Huang *et al.*, 2004) on the basis that few of them were conducted with recombinant enzymes in the presence of both NADPH-cytochrome P450 reductase and cytochrome b_5. Under such conditions, the catalytic activity of CYP3A5 can rival or even surpass that of CYP3A4. Of the eight substrates examined, midazolam represented the extreme case. In the presence of both NADPH-cytochrome P450 reductase and cytochrome b_5, recombinant CYP3A5 was three times more active than CYP3A4 at catalyzing the $1'$-hydroxylation of midazolam, based on estimates of in vitro intrinsic clearance (i.e., V_{max}/K_m) (Huang *et al.*, 2004). However, when this same group evaluated the metabolism of the same eight substrates in two pools ($n = 10$) of human liver microsomes each with the same levels of CYP3A4 but with markedly different levels of CYP3A5 (to mimic the CYP3A5 polymorphism), it was found that CYP3A5 contributed nothing to the metabolism of testosterone, carbamazepine, lidocaine, terfenadine, dextromethorphan, or itraconazole, but contributed 27, 26, and 35% to the metabolism of midazolam, erythromycin, and flunitrazepam, respectively.

The recent study by Huang *et al.* (2004) demonstrated that, under certain in vitro conditions, the catalytic activity of CYP3A5 can surpass that of CYP3A4 (in a substrate-dependent manner) and predicted that CYP3A5 could potentially contribute to the metabolism of midazolam, a drug whose disposition is known to be highly dependent on CYP3A-catalyzed metabolism in the liver and small intestine. The studies by (Huang *et al.*, 2004) predict a role, albeit not a major role, for CYP3A5 in the metabolism of midazolam. However, two in vivo studies have shown that CYP3A5 genotype has no influence on the disposition of midazolam in vivo (Goh *et al.*, 2002; Shih and Huang, 2002). Possible reasons for the discrepancy between the in vitro prediction of the contribution of CYP3A5 to drug metabolism and the in vivo observation have been reviewed by Williams *et al.* (2003a).

Other studies have evaluated the influence of CYP3A5 genotype on the disposition of cyclosporine and tacrolimus, two immunosuppressive (antirejection) drugs that are substrates for both *P*-glycoprotein and CYP3A4. The results with cyclosporine were unexpected: In individuals identified by genotyping analysis to be CYP3A5 poor metabolizers, the oral clearance of cyclosporine was 31% higher compared with CYP3A5 extensive metabolizers, suggesting that not only did CYP3A5 fail to contribute to the metabolism of cyclosporine, but that the expression of functional CYP3A5 somehow impaired the metabolism of cyclosporine by CYP3A4 (Yates *et al.*, 2002). In contrast to the unexpected findings with cyclosporine, two clinical studies provide evidence that CYP3A5 genotype significantly influences the disposition of tacrolimus, such that patients who expressed high levels of CYP3A5 required higher doses of tacrolimus to achieve desired blood levels of this calcineurin inhibitor (Macphee *et al.*, 2002; Zheng *et al.*, 2003).

Finally, it is noteworthy that, when evaluated as inhibitors of recombinant human CYP3A enzymes, 14 out of 14 compounds inhibited CYP3A4 more potently than they inhibited CYP3A5 (by a factor of 3.9- to 142-fold) (Ekins *et al.*, 2003).

CYP4 Enzymes   Humans express 12 members of the CYP4 family, namely, CYP4A11, 4A22, 4B1, 4F2, 4F3, 4F8, 4F11, 4F12, 4F22, 4V2, 4X1, and 4Z1. For the most part, these enzymes can be divided into two groups: a group that is known to metabolize fatty acids and/or eicosanoids and a group that has no known function (so-called orphan enzymes), as shown in Table 6-9. The first group (CYP4A11, 4B1, 4F2, 4F3, 4F8, and 4F12) is part of a larger group of fatty acid- and eicosanoid-metabolizing enzymes, which includes CYP2C8, 2C9, and 2J2. These enzymes are collectively involved in the formation or further metabolism of numerous vasoactive agents, such as the various epoxidation products of arachidonic acid (EETs), leukotoxins (formed by the epoxidation of C_{18} unsaturated fatty acids) and mediators of inflammation, such as prostaglandins and leukotrienes (notably LTB_4) (Baer and Rettie, 2006; Kalsotra and Strobel, 2006). In many cases, these enzymes hydroxylate the terminal methyl group (ω-hydroxylation) distal to the carboxylic group, which is thermodynamically unfavorable compared with hydroxylation of a methylene group (e.g., ω-1 hydroxylation). Following ω-hydroxylation, the terminal hydroxymethyl group can be further oxidized to convert the original fatty acid/eicosanoid to a dicarboxylic acid.

Several CYP4 enzymes have been shown to metabolize drugs and other xenobiotics, but in nearly all cases the drugs that are metabolized by the CYP4 enzymes are also metabolized more extensively by CYP1, 2, or 3 family members. A notable exception is the antiparasitic prodrug DB-287, which is O-demethylated in human liver

microsomes by CYP4F2 and CYP4F3 with negligible contribution from CYP enzymes in the 1, 2, or 3 family, as shown in Fig. 6-21 (Wang *et al.*, 2006b). Another notable exception is CYP4B1, which is expressed in a wide range of extrahepatic tissues and which activates several protoxicants including the pneumotoxins ipomeanol and 3-methylindole, and the bladder carcinogen 2-aminofluorene (Baer and Rettie, 2006).

Activation of Xenobiotics by Cytochrome P450   Biotransformation by cytochrome P450 does not always lead to detoxication, and several examples have been given previously where the toxicity or tumorigenicity of a chemical depends on its activation by cytochrome P450. The role of individual human CYP enzymes in the activation of selected procarcinogens and protoxicants is summarized in Table 6-12 (adapted from Guengerich and Shimada, 1991). A variety of cytochrome P450-dependent reactions are involved in the activation of the chemicals listed in Table 6-12. The conversion of polycyclic aromatic hydrocarbons to tumor-forming metabolites involves the formation of bay-region diolepoxides, as shown in Fig. 6-9, for the conversion of benzo[*a*]pyrene to benzo[*a*]pyrene 7,8-dihydrodiol-9,10, epoxide. Epoxidation generates hepatotoxic metabolites of chlorobenzene and coumarin (Fig. 6-42), and generates an hepatotumorigenic metabolite of aflatoxin B_1 (Fig. 6-33).

The initial step in the conversion of aromatic amines to tumor-forming metabolites involves N-hydroxylation, as shown for 2-amino-6-nitrobenzylalcohol (Fig. 6-11) and 2-acetylaminofluorene (Fig. 6-37a). In the case of acetaminophen, activation to hepatotoxic metabolite involves dehydrogenation to *N*-acetylbenzoquinoneimine, as shown in Fig. 6-34. A similar reaction converts butylated hydroxytoluene to a toxic quinone methide, as shown in Fig. 6-35. The myelotoxicity of benzene depends on its conversion to phenol and hydroquinone (Fig. 6-31). The toxicity of several organophosphorus insecticides involves oxidative group transfer to the corresponding organophosphate, as shown for the conversion of parathion to paraoxon in Figs. 6-45 and 6-46. The hepatotoxicity of carbon tetrachloride involves reductive dechlorination to a trichloromethyl free radical, which binds to protein and initiates lipid peroxidation, as shown in Fig. 6-17. The hepatotoxicity and nephrotoxicity of chloroform involves oxidative dechlorination to phosgene (Fig. 6-17). Oxidative and reductive dehalogenation both play a role in the activation of halothane, although hepatotoxicity in rats is more dependent on reductive dehalogenation, whereas the immune hepatitis in humans is largely a consequence of oxidative dehalogenation, which leads to the formation of neoantigens (Pohl *et al.*, 1989). Formation of neoantigens (by covalent binding to CYP2C9) is also the mechanism by which the uricosuric diuretic drug, tienilic acid, causes immune hepatitis (Lecoeur *et al.*, 1994).

Some of the chemicals listed in Table 6-12 are activated to toxic or tumorigenic metabolites by mechanisms not mentioned previously. For example, *N*-nitrosodimethylamine, which is representative of a large class of tumorigenic nitrosamines, is activated to an alkylating electrophile by *N*-demethylation, as shown in Fig. 6-48. The activation of ethyl carbamate (urethane) involves two sequential reactions catalyzed by cytochrome P450 (CYP2E1): dehydrogenation to vinyl carbamate followed by epoxidation, as shown in Fig. 6-48. CYP2E1 is one of several CYP enzymes that can catalyze the epoxidation of tetrachloroethylene. The rearrangement of this epoxide to a carbonyl is accompanied by migration of chlorine,

which produces the highly reactive metabolite, trichloroacetyl chloride, as shown in Fig. 6-48. The toxic pyrrolizidine alkaloids, such as senecionine, are cyclic arylamines that are dehydrogenated by cytochrome P450 (CYP3A4) to the corresponding pyrroles. Pyrroles themselves are nucleophiles, but electrophiles are generated through the loss of substituents on the pyrrolizidine nucleus, as shown in Fig. 6-48. Cyclophosphamide and ifosfamide are examples of chemicals designed to be activated to toxic electrophiles for the treatment of malignant tumors and other proliferative diseases. These drugs are nitrogen mustards, which have a tendency to undergo intramolecular nucleophilic displacement to form an electrophilic aziridinium species. In the case of cyclophosphamide and ifosfamide, the nitrogen mustard is stabilized by the presence of a phosphoryl oxygen, which delocalizes the lone pair of nitrogen electrons required for intramolecular nucleophilic displacement. For this reason, formation of an electrophilic aziridinium species requires hydroxylation by cytochrome P450, as shown in Fig. 6-48 for cyclophosphamide. Hydroxylation of the carbon atom next to the ring nitrogen leads spontaneously to ring opening and elimination of acrolein. In the resultant phosphoramide mustard, delocalization of the lone pair of nitrogen electrons to the phosphoryl oxygen is now disfavored by the presence of the lone pair of electrons on the oxygen anion; hence, the phosphoramide undergoes an intramolecular nucleophilic elimination to generate an electrophilic aziridinium species. This reaction is catalyzed by CYP3A4 and CYP2B6. Activation of cyclophosphamide by CYP enzymes in the skin would generate a cytotoxic metabolite at the base of hair follicles, which may be the reason why hair loss is one of the side effects of cyclophosphamide treatment.

Many of the chemicals listed in Table 6-12 are also detoxified by cytochrome P450 by biotransformation to less toxic metabolites. In some cases, the same CYP enzyme catalyzes both activation and detoxication reactions. For example, CYP3A4 activates aflatoxin B_1 to the hepatotoxic and tumorigenic 8,9-epoxide, but it also detoxifies aflatoxin B_1 by 3-hydroxylation to aflatoxin Q_1. Similarly, CYP3A4 activates senecionine by converting this pyrrolizidine alkaloid to the corresponding pyrrole, but it also detoxifies senecionine through formation of an *N*-oxide (a reaction mainly catalyzed by FMO3). Epoxidation of trichloroethylene by CYP2E1 appears to be both an activation and detoxication pathway, as shown in Fig. 6-48. Rearrangement of trichloroethylene epoxide can be accompanied by migration of chlorine, which produces chloral (trichloroacetaldehyde), or hydrogen, which produces dichloroacetylchloride. Chloral is much less toxic than dichloroacetylchloride; hence, migration of the chlorine during epoxide rearrangement is a detoxication reaction, whereas migration of the hydrogen is an activation reaction. These few examples serve to underscore the complexity of factors that determine the balance between xenobiotic activation and detoxication.

Inhibition of Cytochrome P450   Inhibition of cytochrome P450 is a major cause of drug–drug interactions (and occasionally the withdrawal of regulatory approval), as illustrated by the examples cited earlier (terfenadine, cisapride, astemizole, cerivastatin, and mibefradil) in the sections "CYP3A4" and "CYP2C8".

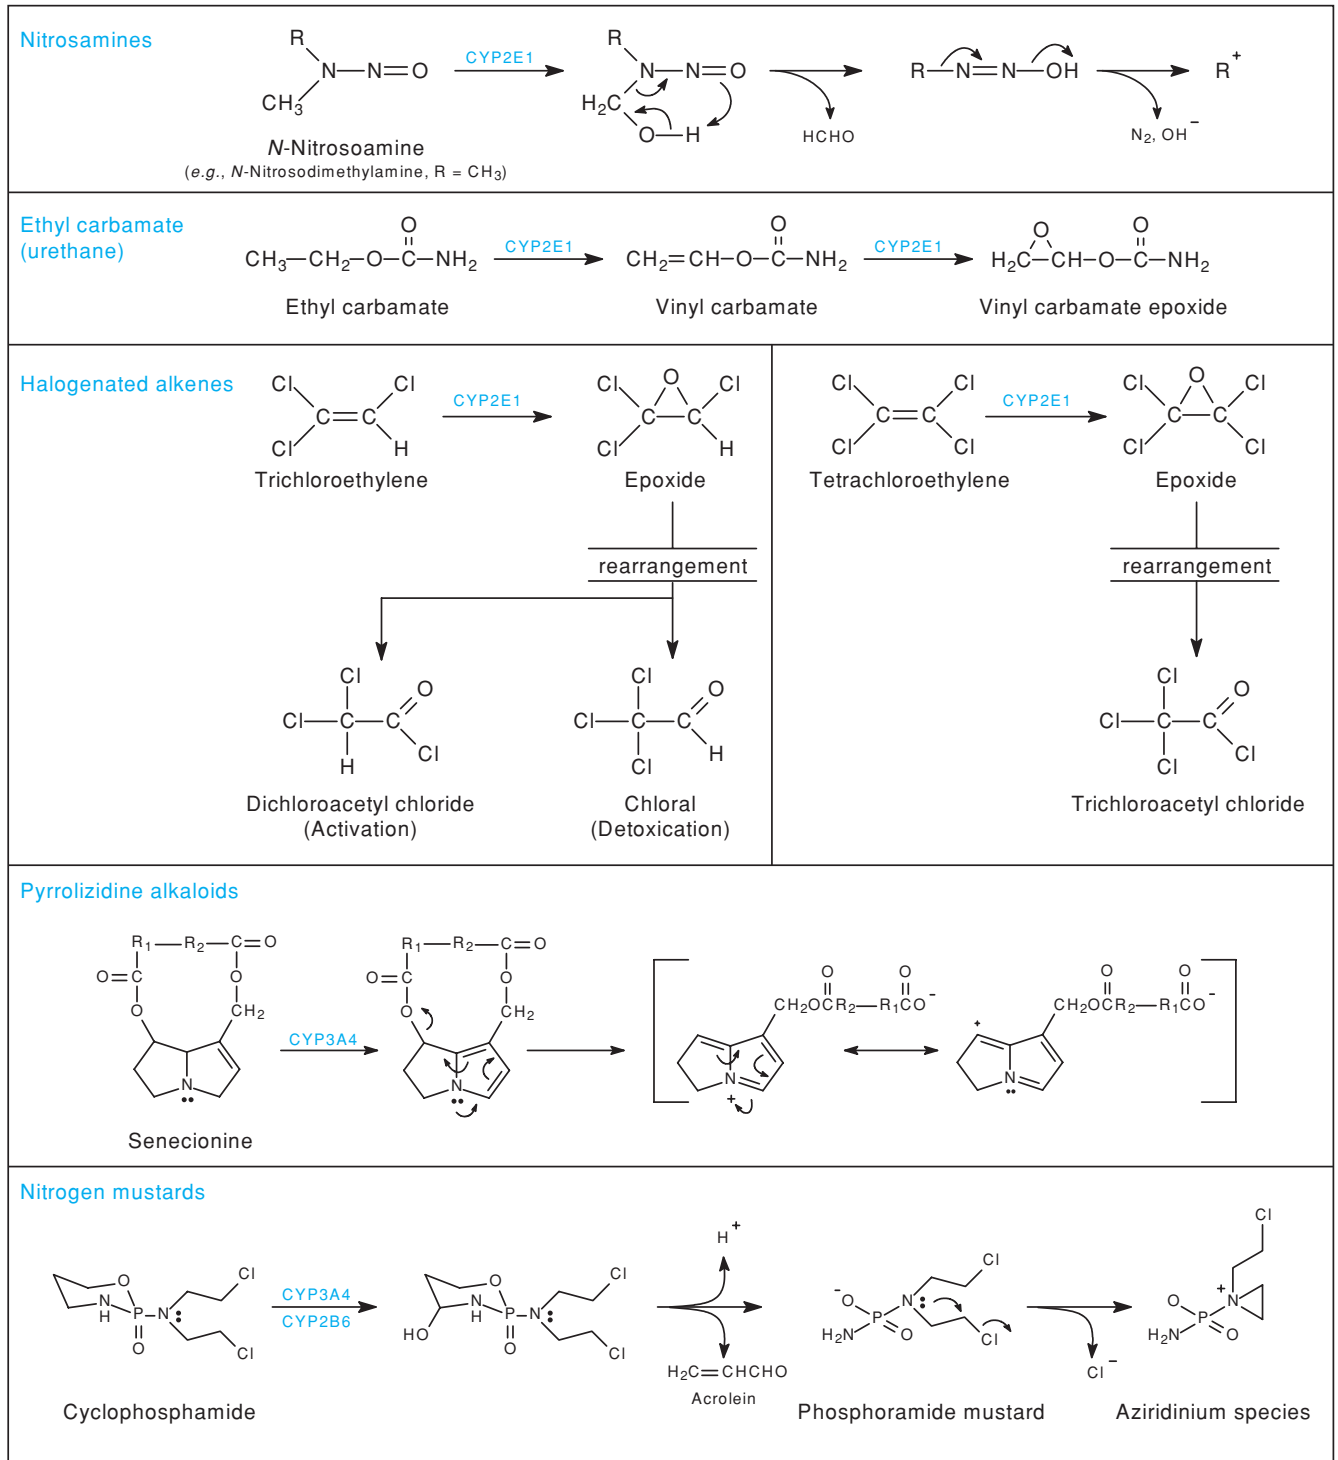
Inhibitory drug interactions generally fall into two categories: direct and metabolism-dependent inhibition. Direct inhibition can be subdivided into two types. The first involves competition between two drugs that are metabolized by the same CYP enzyme. For example, omeprazole and diazepam are both metabolized by


Figure 6-48. *Additional mechanisms of cytochrome P450-dependent activation of xenobiotics to reactive (electrophilic) metabolites.*

CYP2C19. When the two drugs are administered simultaneously, omeprazole decreases the plasma clearance of diazepam and prolongs its plasma half-life. The inhibition of diazepam metabolism by omeprazole is presumed to involve competition for metabolism by CYP2C19 because no such inhibition occurs in CYP2C19 PMs (individuals who lack CYP2C19). The second type of direct inhibition is when the inhibitor is not a substrate for the affected CYP enzyme. The inhibition of dextromethorphan biotransformation by

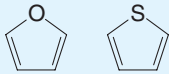
quinidine is a good example of this type of drug interaction. Dextromethorphan is O-demethylated by CYP2D6, and the clearance of dextromethorphan is impaired in individuals lacking this polymorphically expressed enzyme. The clearance of dextromethorphan is similarly impaired when this antitussive drug is taken with quinidine, a potent inhibitor of CYP2D6. However, quinidine is not biotransformed by CYP2D6, even though it binds to this enzyme with high affinity ($K_i \sim 100$ nM). Quinidine is actually biotransformed

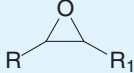
by CYP3A4, and is a weak competitive inhibitor of this enzyme ($K_i > 100$ μM), although its effects are highly dependent on the CYP3A4 substrate employed.

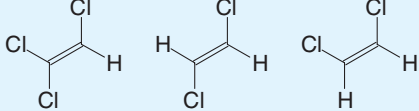
Although there are many exceptions, certain structural motifs are often associated with the inhibition of certain xenobiotic-metabolizing CYP enzymes some of which were discussed in the sections on individual CYPs (e.g., sections "CYP1A1/2," "CYP2C Enzymes," "CYP2D6," and "CYP3A4"). The most potent direct inhibitors of CYP1A2 (i.e., K_i or $IC_{50} < 0.1$ μM) are small (i.e., <300 Da), planar, polycyclic compounds such as flavonoids (e.g., galangin, α-naphthoflavone, kaempferol). Potent direct CYP2A6 inhibitors (i.e., K_i or $IC_{50} < 1$ μM) also include small molecules such as tranylcypromine, 2-(p-tolyl)-ethylamine and 4-methylbenzaldehyde as well as certain azoles (e.g., clotrimazole, letrozole, and miconazole). CYP2B6 is most potently inhibited (i.e., K_i or $IC_{50} < 2$ μM) by azoles (e.g., sulconazole, tioconazole) and polycyclic, nitrogen-containing compounds such as sertraline, memantine, raloxifene, paroxetine, amlodipine, and N,N',N''-triethylenethiophosphamide (thio-TEPA). CYP2C8 is most potently inhibited in a direct manner (i.e., K_i or $IC_{50} < 1$ μM) by large (i.e., >400 Da) acidic drugs such as montelukast, zafirlukast, and candesartan, as well as the corticosteroid, mometasone, and the platinum-containing drug, satraplatin, and in a mechanism-based manner by the acyl glucuronide of gemfibrozil (Ogilvie et al., 2006). CYP2C9 is most potently inhibited (i.e., K_i or $IC_{50} < 0.1$ μM) by azoles (fluconazole, sulconazole, sulfaphenazole), acidic drugs, and also by sulfonamides such as sulfaphenazole and sulfadiazine. Azoles are also some of the most potent direct inhibitors of CYP2C19 (i.e., K_i or $IC_{50} < 0.5$ μM), as are compounds such as fluvoxamine, (−)-N-3-benzyl-phenobarbital, (+)-N-3-benzyl-nirvanol, and nootkatone. CYP2D6 is generally inhibited with high potency (i.e., K_i or IC_{50} value < 0.1 μM) by compounds that contain a basic nitrogen (e.g., quinidine, ezlopitant, ajmalicine, terbinafine, propafenone, etc.). Direct inhibitors (i.e., K_i or IC_{50} 1–6 μM) of CYP2E1 are generally small compounds (i.e., 79–150 Da) such as 4-methylpyrazole, pyridine, tranylcypromine, and diethyldithiocarbamate. However, a few larger compounds such as lasofoxifene and tioconazole can inhibit CYP2E1 with K_i or IC_{50} values <0.5 μM. As noted above for several other CYPs, some of the most potent inhibitors of CYP enzymes are azole antifungals. This is especially true for CYP3A4, for which the most potent inhibitors (i.e., K_i or IC_{50} values <0.1 μM) are azole antifungal drugs, with clotrimazole, ketoconazole, and itraconazole demonstrating K_i or IC_{50} values from 0.00025 to 0.016 μM (K_i and IC_{50} values obtained from http://www.druginteractioninfo.org).

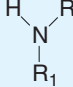
As the name implies, metabolism-dependent inhibition is when cytochrome P450 converts a xenobiotic to a metabolite that is a more potent inhibitor than the parent compound. In some cases, the metabolite, once formed, functions as a potent, reversible inhibitor, as occurs when fluoxetine is N-demethylated to norfluoxetine. In other cases, however, the metabolite functions as an irreversible inhibitor (which occurs when the metabolite alkylates the heme or apoprotein moiety of cytochrome P450) or a quasi-irreversible inhibitor (which occurs when the metabolite coordinates tightly but not covalently with the ferrous heme to form what is known as a metabolite-inhibitory complex or MIC). Metabolism-dependent inhibitors that cause irreversible inactivation of cytochrome P450 include furafylline (CYP1A2), 8-methoxypsoralen (CYP2A6), clopidogrel (CYP2B6), tienilic acid (CYP2C9), and ticlopidine (CYP2C19), all of which contain a furan or thiophene that is activated by cytochrome P450 to a reactive metabolite that in-

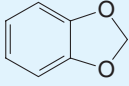
activates the enzyme (suicide inactivation). Metabolism-dependent inhibitors that form metabolite inhibitory complexes and cause quasi-irreversible inhibition include the CYP3A4 inhibitor troleandomycin, which contains a tertiary amine (R–N(CH$_3$)$_2$) that is converted by several successive oxidative N-demethylation reactions to a nitroso metabolite (R–N=O) that coordinately binds to the ferrous heme iron. This interaction resembles the binding of carbon monoxide to the ferrous heme iron, and indeed compounds that form inhibitory metabolite complexes with cytochrome P450 can be detected spectrophotometrically based on an absorbance peak at around 455 nm (which is similar to the peak at ~450 nm when carbon monoxide binds to cytochrome P450). The chemical structures commonly associated with metabolism-dependent inhibition of cytochrome P450 are shown in Table 6-13.

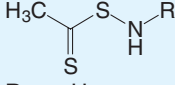
In some cases, the metabolism-dependent inhibition involves metabolism by enzymes other than the affected CYP enzyme. For example, the inhibition of CYP2C8 by gemfibrozil requires the formation of gemfibrozil glucuronide by UGT, after which gemfibrozil glucuronide functions as a metabolism-dependent inhibitor of CYP2C8 (Ogilvie et al., 2006).


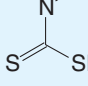












There are cases where inhibition of cytochrome P450 has proved advantageous, as in the case of certain combinations of anti-HIV drugs. For example, by inhibiting CYP3A4, the HIV protease inhibitor ritonavir improves the pharmacokinetic profile of saquinavir and lopinavir, protease inhibitors that are otherwise cleared so rapidly by CYP3A4 that blood levels easily fall below therapeutically effective concentrations.

Induction of Cytochrome P450—Xenosensors The induction (upregulation) of xenobiotic-biotransforming enzymes and transporters is a receptor-mediated, adaptive process that augments xenobiotic elimination during periods of high xenobiotic exposure. It is not a toxicological or pathological response, but enzyme induction is often associated with liver enlargement (due to both hepatocellular hypertrophy and hyperplasia), and it may be associated with toxicological and pharmacological consequences, especially for the safety evaluation of drug candidates in laboratory animals and for clinical practice in humans. In animals, enzyme induction may be associated with pharmacokinetic tolerance, whereby the xenobiotic induces its own elimination. During safety testing in animals, auto-induction may require increasing dosages of drug candidate to achieve the same degree of systemic exposure. In rodents, lifetime exposure to enzyme inducers may be associated with liver or thyroid tumor formation, as discussed later in this section. In humans, enzyme induction may also be associated with pharmacokinetic tolerance (autoinduction). Long-term treatment of humans with enzyme inducers can cause osteomalacia due to increased inactivation of 1α,25-dihydroxyvitamin D$_3$, the active metabolite of vitamin D (discussed later in this section), but it is not associated with liver or thyroid tumor formation. However, in humans, enzyme induction by one drug (the perpetrator) can augment the clearance of a concomitantly administered drug (the victim), which is a cause of drug–drug interactions.

As an underlying cause of serious adverse events, enzyme induction is generally less important than enzyme inhibition because the latter can cause a rapid and profound increase in blood levels of a victim drug, which can cause an exaggerated pharmacological or toxicological effect. In contrast, enzyme induction lowers blood levels, which does not cause an exaggerated pharmacological or toxicological response to the drug. However, enzyme induction may be associated with a loss of therapeutic effectiveness, which

Table 6-13

Structures Associated with Metabolism-Dependent Inhibition of Cytochrome P450 (CYP) Enzymes

CHEMICAL GROUPS (EXAMPLES)	STRUCTURES
Terminal (ω) and ω-1 acetylenes (Gestodene)	R—≡— R—≡
Furans and thiophenes (Furafylline and tienilic acid)	(furan, thiophene rings)
Epoxides (*R*-Bergamottin-6′,7′-epoxide)	(epoxide, R—O—R$_1$)
Dichloro- and trichloro-ethylenes (1,2,-Dichloroethylene and trichloroethylene)	(dichloro/trichloro ethylene structures)
Secondary amines (Nortriptyline)	H, R—N—R$_1$
Benzodioxoles (Paroxetine)	(benzodioxole ring)
Isothiocyanates (Phenethyl isothiocyanate)	R—N=C=S
Thioamides (Methimazole)	H$_3$C—C(=S)—S—NH—R
Dithiocarbamates (Disulfiram)	R—N(H)—C(=S)—SH
Conjugated structures (Rhapontigenin)	R—=—=—R
Terminal alkenes (Tiamulin)	R—CH=CH$_2$

Data adapted from Fontana E, Dansette PM, Poli SM: Cytochrome p450 enzymes mechanism based inhibitors: Common sub-structures and reactivity. *Curr Drug Metab* 6:413–454, 2005.

is a particular concern when it compromises the therapeutic effectiveness of drugs that have a narrow therapeutic index and are being used to treat a life-threatening illness, such as anti-HIV drugs, antirejection drugs (like cyclosporine and tacrolimus), and oral anticoagulants (like warfarin), or when it is used with drugs that exhibit a quantal (all-or-nothing) dose–response relationship, such as oral contraceptive steroids (which either block or don't block ovulation and thereby provide or don't provide protection against unwanted pregnancy).

CYP induction does not necessarily enhance the biotransformation of the inducer, in which case the induction is said to be gratuitous. Consequently, lack of autoinduction cannot be taken as evidence that a xenobiotic does not cause enzyme induction. For example, in humans, omeprazole induces CYP1A2, even though the disposition of this acid-suppressing drug is largely determined by CYP2C19 and, to a lesser extent, CYP3A4. Some of the most effective inducers of cytochrome P450 are polyhalogenated aromatic hydrocarbons (PHAHs), such as polychlorinated derivatives of dibenzo-*p*-dioxin (PCDDs), dibenzofurans (PCDFs), azobenzenes and azoxybenzenes, biphenyl (PCBs), and naphthalene. In general, highly chlorinated compounds are resistant to biotransformation and cause a prolonged induction of CYP and other enzymes. Some inducers are potent direct-acting or metabolism-dependent inhibitors such that they mask the activity of one or more of the enzymes they induce. Such dual-acting xenobiotics include macrolide antibiotics (e.g., erythromycin and troleandomycin), methylenedioxy-containing compounds (e.g., tadalafil [Cialis®], safrole, isosafrole), and imidazole antimycotics (e.g., clotrimazole, ketoconazole, and miconazole). In the case of dual-acting drugs (such as the induction/inhibition of CYP3A4 by ritonavir and several other HIV protease inhibitors, and the induction/inhibition of CYP2E1 by isoniazid), the initial effect—and often the effect observed during the period of drug treatment—is CYP inhibition, with induction becoming evident after prolonged drug treatment or following drug cessation. However, when ritonavir induces CYP3A4, for example, it also induces several other CYP enzymes, as well as conjugating enzymes and transporters that are regulated by CAR/PXR. Ritonavir does not inhibit all of the enzymes it induces. For example, in the presence of 2–20 μM ritonavir for 72 hours, CYP2B6 activity is increased by 4- to 6-fold in primary cultures of human hepatocytes, conditions that cause CYP3A4 inhibition (Faucette *et al*., 2004). Some dual-acting xenobiotics, like allylisopropylacetamide, cause certain types of porphyria (a disorder of heme synthesis) because they induce CYP enzymes and destroy the CYP heme moiety, which

greatly increases the demand for heme synthesis (discussed later in this section).

In general, CYP induction is mediated by four ligand-activated receptors, namely, AhR, CAR, PXR, and PPARα, as summarized in Table 6-14 (adapted from Tirona and Kim, 2005). These so-called xenosensors resemble other nuclear receptors, such as steroid and thyroid hormone receptors, which has consequences for receptor interactions (cross-talk among xenosensors and cross-talk between xenosensors and other nuclear receptors), the role that some xenosensors play in responding to endobiotics and regulating their metabolism (e.g., bilirubin, bile acids, and 1α,25-dihydroxyvitamin D$_3$), and the role that some nuclear receptors (such as FXR, VDR, SHP, NF-κB) play in inducing or suppressing the expression of xenobiotic-biotransforming enzymes and transporters, as discussed later in this section. Xenosensors have a ligand-binding domain (LBD) and a DNA-binding domain (DBD). In general, CYP induction involves the following steps (with steps 2 and 3 reversed in the case of AhR): (1) Binding of ligand (xenobiotic) to the receptor, which triggers conformational changes that promote its dissociation from accessory proteins (such as co-repressors, chaperones, and cytoplasm-retention proteins) and/or promote its association with co-activators; (2) dimerization of the ligand-bound receptor with a partner protein to form a DNA-binding heterodimer (which is analogous to the two halves of a clothes peg coming together to form a functional unit); (3) translocation of the functional receptor heterodimer from the cytoplasm to the nucleus; (4) binding of the functional receptor heterodimer to discrete regions of DNA (response elements) that are typically located in the 5′-promoter region of the gene (which is analogous to a clothes peg being fastened to a clothes line); (5) recruitment of other transcription factors and RNA-polymerase to form a transcription complex; and (6) gene transcription, which leads to increased levels of CYP mRNA and CYP enzyme (as well as other xenobiotic-biotransforming enzymes and transporters).

As shown in Table 6-14, the major ligand-activated receptors mediating CYP induction are (1) AhR (the aryl hydrocarbon receptor), which partners with ARNT to induce CYP1A1, 1A2, 1B1, and 2S1; (2) CAR (the constitutive androstane receptor; a.k.a. the constitutively active receptor), which partners with RXRα (the retinoid X receptor, which binds 9-*cis*-retinoic acid) to induce several members of the CYP2A, 2B, 2C, and 3A subfamilies; (3) PXR (the pregnane X receptor, a.k.a. SXR, the steroid X receptor) which, like CAR, partners with RXRα and induces several members of the CYP2A, 2B, 2C, and 3A subfamilies; and (4) PPARα (the peroxisome proliferator activated receptor-alpha), which partners with RXRα and induces CYP4A enzymes. The response elements (a.k.a. consensus sequences) to which xenosensors bind are generally a pair of hexanucleotide sequences in a direct repeat (DR), inverted repeated (IR), or everted repeat (ER) orientation, separated by a 0–8 nucleotide spacer. As shown in Table 6-14, activation of a xenosensor leads to the induction of multiple enzymes, which is called a pleiotypic response. However, in terms of fold induction, CYP enzymes tend to be the most inducible and, consequently, the most studied enzymes. Like induction of CYP enzymes, induction of conjugating and other non-CYP enzymes is an important mechanism of drug–drug and drug–endobiotic interactions. For example, induction of various conjugating enzymes (both SULT and UGT enzymes) plays a key role in the induction of oral contraceptive steroid metabolism in humans, which is associated with a loss of therapeutic effect, and the induction of thyroid hormone metabolism in rodents, which is associated with thyroid follicular cell hyperplasia and tumor forma-

tion. As shown in Table 6-14, AhR, CAR, PXR, and PPARα are not the only receptors that regulate CYP expression in response to xenobiotics (or certain endobiotics). Nrf2 plays a key role in regulating the induction of several enzymes in response to electrophilic metabolites, oxidative stress, or glutathione depletion, as discussed previously (see Point 8 and sections "Epoxide Hydrolases" and "Quinone Reduction—NQO1 and NQO2"). The enzymes regulated by Nrf2 include several conjugating but few CYP enzymes (notable exceptions are CYP2C55 and 2U1 in mice), whereas those regulated by AhR, CAR, PXR, and PPARα include both conjugating and CYP enzymes, for which reason xenobiotics that activate the former are known as *monofunctional inducers* whereas xenobiotics that activate the latter are known as *bifunctional inducers*, as described previously (see "Quinone Reduction—NQO1 and NQO2"). Some of the other receptors listed in Table 6-14 are discussed later in this section. CYP induction can also involve mechanisms other than receptor-mediated transcriptional activation. Increased translation of preexisting mRNA is the mechanism by which several xenobiotics increase the levels of CYP2E1, and increased translational efficiency and protein stabilization play important roles in the induction of several CYP enzymes including CYP1A2, 2E1, and 3A enzymes.

It might be assumed that xenobiotics can be divided into four categories of inducers represented by the four xenosensors (AhR, CAR, PXR, and PPARα). This is largely true of rats where 3-methylcholanthrene, phenobarbital, pregnenolone-16α-carbonitrile (PCN), and clofibric acid are prototypical inducers of CYP1A, 2B, 3A, and 4A by virtue of their ability to activate AhR, CAR, PXR, and PPARα, respectively. In fact, rats have five classes of inducible CYP enzymes with the fifth class represented by CYP2E1, which is inducible by the prototypical inducer isoniazid. However, the situation in other species (including rats on a xenobiotic-by-xenobiotic basis) is not so straightforward because (1) CAR and PXR have similar but not identical LBDs such that ligands that activate one receptor activate the other and vice versa, and (2) CAR and PXR have similar but not identical DBDs such that, once activated, CAR and PXR bind to some of the same response elements and induce the same enzymes. It was once thought that CYP2B induction was mediated only by CAR, and that CYP3A induction was only mediated by PXR. However, the PXR agonist dexamethasone can maximally induce both CYP2B10 and CYP3A11 in wild-type and CAR knockout mice, indicating that PXR can maximally induce both CYP2B and 3A enzyme in mice. Similarly, the CAR activator phenobarbital can maximally induce CYP2B10 and induce CYP3A11 (albeit submaximally) in wild-type and PXR knockout mice, indicating that CAR can also induce both CYP2B and 3A enzymes (Kodama and Negishi, 2006). The same is true of humans: PXR can maximally induce both CYP2B6 and CYP3A4, whereas CAR can maximally induce CYP2B6 and induce CYP3A4 (albeit submaximally) (Faucette *et al.*, 2006). Furthermore, there are species and strain differences in the LBDs, the DBDs, and the DNA-response elements that give rise to species and strain differences in enzyme induction, and even interindividual differences in humans. Some species differences in enzyme induction reflect differences in the catalytic activity of CYP enzymes. For example, although 7-methoxy- and 7-ethoxyresorufin are useful substrates to study CYP1A enzyme induction in all mammalian species (with some subtle differences, as noted in the section "CYP1A1/2"), 7-pentoxyresorufin is useful for studying CYP2B only in mouse and rat (not hamster, dog, monkey, or humans). However, many species, strain, and individual differences in enzyme induction reflect differences in xenosensor

Table 6-14

Receptors Mediating the Induction (or Suppression) of Cytochrome P450 Enzymes and Other Xenobiotic Biotransforming Enzymes

NUCLEAR RECEPTOR	RESPONSE ELEMENT(S)	RECEPTOR ACTIVATORS	REGULATED GENES[a]
AhR	XRE	PAHs, TCDD (other PHAHs), β-naphthoflavone, indigoids, tryptophan metabolites, omeprazole, lansoprazole	CYP1A1, 1A2, 1B1, 2S1, UGT1A1, UGT1A6
CAR	DR-3 DR-4 ER-6	Phenobarbital, phenytoin, carbamazepine, CITCO (human), TCPOBOP (mouse), clotrimazole, Yin Zhi Wuang (many PXR agonists are also CAR agonists, and vice versa)	CYP2A6, 2B6, 2C8, 2C9, 2C19, 3A4, UGT1A1, SULT1A1, ALAS, MRP2, MRP3
PXR	DR-3 DR-4 ER6 ER-8	Amprenavir, avasimibe, bosentan, bile acids, carbamazepine, clindamycin, clotrimazole, cortisol, cyproterone acetate, dicloxacillin, efavirenz, etoposide, dexamethasone, griseofulvin, guggulsterone, hyperforin (SJW), indinavir, lovastatin, mifepristone, nafcillin, nelfinavir, nifedipine, omeprazole, paclitaxel, PCBs, phenobarbital, phthalate monoesters, 5β-pregnane-3,20-dione, rifabutin, rifampin, ritonavir, saquinavir, simvastatin, spironolactone, sulfinpyrazole, TAO, tetracycline, topotecan, transnanoclor, troglitazone, verapamil, vitamin E, vitamin K_2	CYP2B6, 2C8, 2C9, 2C19, 3A4, 3A7, 7A1↓, SULT2A1, UGT1A1, 1A3, 1A4, PAPSS2, ALAS, MDR1, AhR
PPARα	DR-1	Fibrates, WY-14,643, perfluorodecanoic acid	CYP4A, UGT1A9, 2B4
Nrf2	ARE	β-Naphthoflavone, oltipraz, phenolic antioxidants (e.g., BHA and BHT) and various glutathione depletors	NQO1, mEH, AKR7A, UGTs, GSTA1, γ-GCL, MRP1
GR	GRE	Glucocorticoids	CYP2C9, 2B6, 3A4, 3A5, CAR, PXR
FXR	IR-1	Bile acids, GW4064, AGN29, AGN31	BSEP, I-BABP, MDR3, UGT2B4, SULT2A1, OATP8, PPARα, SHP
LXRα	DR-4	GW3965, T0901317, paxiline, F$_3$methylAA,[b] acetyl-podocarpic dimer (APD)	LRH1, SHP, CYP7A, LXRα, CYP3A4↓↓, 2B6↓
VDR	DR-3 ER-6 IR-0	1α,25-Dihydroxyvitamin D$_3$, lithocholate	CYP2B6, 2C9, 3A4, SULT2A1
HNF1α	[c]		OATP-C, OATP8, CYP7A1, UGT1A6, 1A8, 1A9, 1A10, HNF4α, PXR
HNF4α	DR		CYP2A6, 2B6, 2C9, 2D6, 3A4, DD4, MDR1, PXR, CAR, FXR, PPARα, HNF1α
LRH-1	DR-4		CYP7A, ASBT
SHP	None		Targets of PPARα ↓, AhR↓, PXR↓, CAR↓, LRH-1↓, HNF4α↓, LXRα↓, GR↓

[a] A downward arrow indicates downregulation (suppression). All others are upregulated (induced).
[b] [3-Chloro-4-(3-(7-propyl-3-trifluoromethyl-6-(4,5)-isoxazolyl)propylthio)-phenylacetic acid].

Data adapted from Tirona RG , Kim RB: Nuclear receptors and drug disposition gene regulation. *J Pharm Sci* 94:1169–1186, 2005.

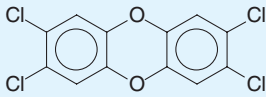
function, as discussed below (this section). The following descriptions of the individual xenosensors focus largely on the mouse and human receptors; studies of the latter have been driven by the desire to investigate drug–drug interactions whereas studies of the former have been facilitated by the ability to create transgenic mice in which a particular xenosensor has been deleted (so-called knockout or null mice) or replaced with the human receptor (so-called humanized mice).

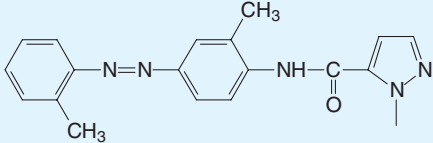
The Aryl Hydrocarbon Receptor (AhR) AhR and ARNT are cytosolic and nuclear transcription factors, respectively, that are expressed in most tissues and many cell lines. The binding of an agonist like 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD, the structure of which is shown in Table 6-15), to AhR initiates a number of changes (such as dissociation from heat-shock protein [hsp90] and other chaperones, dissociation from proteins that retain the unbound receptor in the cytoplasm, phosphorylation by tyrosine kinase) that

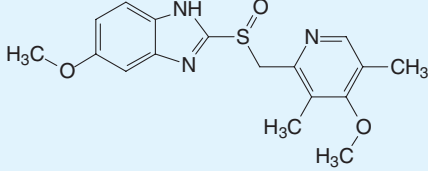
culminate in (1) the translocation of AhR to the nucleus, (2) the dimerization of AhR with ARNT (which is somewhat misnamed as the *aryl hydrocarbon receptor nuclear translocator* because it is a nuclear not a cytoplasmic protein that complexes with AhR after it translocates to the nucleus), (3) the binding of AhR–ARNT to DNA-response elements known as XRE, and (4) the increased transcription of CYP1A1 and numerous other genes listed in Table 6-14. Whereas members of the nuclear receptor superfamily (such as CAR, PXR, and PPARα) are "zinc-finger" proteins, AhR and ARNT are "bHLH-PAS" proteins, so-named because they belong to the per-arnt-sim (PAS) class of receptors and they have a basic helix-loop-helix (bHLH) domain near their N-terminus, which is involved in protein–protein interactions.

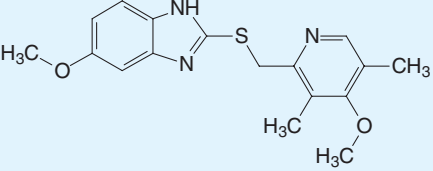
TCDD is a high affinity ligand for AhR (K_D values tend to be in the nanomolar-to-submicromolar range), and AhR mediates the toxicity of TCDD and related PHAHs (such as various chlorinated or brominated dibenzodioxins, dibenzofurans, and biphenyls), which is characterized by a wasting syndrome (progressive weight loss or cachexia resulting in death), immunosuppression (thymic atrophy), tumor promotion, fetal abnormalities (cleft palate and other teratogenic disorders) and, in some species, liver enlargement and a skin condition called chloracne. TCDD binds to AhR and induces CYP1A1 in all mammalian species, but it causes lethal cachexia in some species (such as guinea pig, where the LD$_{50}$ is $\sim$1 μg/kg) but not others (such as hamsters, where the LD$_{50}$ exceeds 1000 μg/kg). This species difference in toxicity but not in CYP1A1 induction raised the possibility that AhR does not mediate the toxicity of TCDD, but several lines of evidence established that AhR does in fact mediate many, perhaps all, of the toxic effects of TCDD and related compounds. First, naturally occurring strain differences in the responsiveness of mice (such as so-called responsive C57 and nonresponsive DBA mice) and rats (such as responsive Long–Evans and nonresponsive Han/Wistar rats) to TCDD toxicity are associated with polymorphisms in AhR (Pohjanvirta *et al.*, 1999). Second, AhR knockout mice are resistant to TCDD-induced toxicity, whereas transgenic mice that express a constitutively active form of AhR (CA-AhR mice) spontaneously display numerous signs of TCDD toxicity (even though the CYP1A1 levels in the liver of CA-AhR mice are elevated to a lesser extent than those in TCDD-treated wild-type mice) (Brunnberg *et al.*, 2006). Third, the AhR antagonist CH-223191 (see Table 6-15) blocks the enzyme-inducing effects and various toxic effects of TCDD (Kim *et al.*, 2006). Nevertheless, it remains to be determined why prolonged activation of AhR by TCDD and related compounds causes an irreversible cachexia that leads to death after a certain time (after a latency period that varies from one species to the next but that cannot be shortened by administering "super-lethal" doses of TCDD).

AhR agonists include PHAHs (like TCDD), PAHs (like 3-methylcholanthrene and benzo[*a*]pyrene), flavonoids (like β-naphthoflavone), and various acid-catalyzed condensation products or UV-induced derivatives of naturally occurring indoles (such as indole-3-carbinol and tryptophan). In general, AhR agonists induce CYP1A1 and other enzymes across all mammalian and many nonmammalian species. A notable exception is a class of benzimidazole-containing compounds that includes the proton-pump inhibitors omeprazole and lansoprazole. These drugs are not typical AhR agonists for two reasons. First, they do not bind to the ligand-binding domain of AhR but activate AhR either directly (by binding to a second site on AhR) or indirectly (by activating a tyrosine kinase that phosphorylates AhR). Second, they activate AhR and induce CYP1A enzymes in humans but not in rats or mice,

which is one of the few species differences in AhR activation by xenobiotics (Diaz *et al.*, 1990). An endogenous AhR ligand is suspected to exist because AhR function is so well conserved from fish to humans and because of developmental abnormalities observed in AhR knockout mice. However, an endogenous AhR ligand has yet to be identified.








Several compounds can disrupt AhR signaling at a variety of levels. CH-223191 (Table 6-15) and α-naphthoflavone are receptor antagonists that bind to the ligand-binding domain of AhR without activating the receptor. Omeprazole sulfide (which forms by reduction of the sulfoxide group in omeprazole [see Table 6-15]) antagonizes CYP1A1 induction by omeprazole by stabilizing AhR in an inactive conformation (Gerbal-Chaloin *et al.*, 2005). After AhR is activated, its translocation to the nucleus is blocked by 3'-methoxy-4-nitroflavone, its binding to XRE is blocked by salicylamide, and its ability to recruit transcription factors and initiate gene transcription is blocked by resveratrol (an antioxidant in red wine) (Gerbal-Chaloin *et al.*, 2005). The presence of exogenous (and perhaps endogenous) AhR antagonists is one of the many factors that are known or suspected of causing clinically observed interindividual differences in CYP1A induction. These factors have been reviewed by Ma and Lu (2003), who have documented that differences in the magnitude of CYP1A induction in humans can be attributed to (1) genetic polymorphisms in AhR, ARNT, or XRE; (2) altered levels or function of accessory proteins (some of which are associated with inflammation and other disease states that activate NF-κB, as discussed later in this section); (3) gender differences in basal CYP1A2 activity (which tends to be lower in females compared with males), and (4) variation in the intracellular concentration of the inducing drug, as exemplified by variation in the metabolism of omeprazole. The clearance of omeprazole is largely determined by its rate of metabolism by the polymorphically expressed enzyme CYP2C19. Based on measurements of caffeine metabolism, a daily dose of 40 mg omeprazole causes CYP1A2 induction in CYP2C19 PMs but not in CYP2C19 EMs, which require higher doses (120 mg) to achieve CYP1A2 induction. In a clinical setting, the formation of omeprazole sulfide (an AhR antagonist) does not prevent CYP1A induction by omeprazole (an agonist). However, it is possible that the formation of rabeprazole sulfide, which occurs rapidly and extensively (by nonenzymatic means), explains why rabeprazole is one of the proton-pump inhibitors that does not induce CYP1A.

Although strain differences in CYP1A inducibility have been linked to genetic polymorphisms in the mouse and rat AhR gene, species differences have been attributed either to the unusual interaction of AhR with benzimidazole-containing compounds like omeprazole and lansoprazole or to species differences in the location of XRE. For example, rat UGT1A6 and 1A7 are highly inducible (> 20-fold) enzymes because these conjugating genes are under the control of XRE in rats but in few other species.

Constitutive Androstane Receptor (CAR) and Pregnane X Receptor (PXR)   CAR and PXR are members of the nuclear receptor family 1 (NR1I2 and NR1I3, respectively). In contrast to AhR, which is expressed in most tissues and several cell lines, CAR and PXR are expressed in relatively few organs—liver, small intestine, and colon—and in few cell lines. CAR and PXR are both activated by some of the same compounds, and both dimerize with RXRα to form DNA-binding proteins that recognize some of the same response elements, as shown in Table 6-14. Consequently, there is considerable cross-talk between these two xenosensors, and it can sometimes be difficult to ascertain whether induction is mediated

Table 6-15

Examples of Agonists and Antagonists for the Receptors that Mediate Enzyme Induction (AhR, CAR, and PXR)

	AGONISTS			ANTAGONISTS		
AhR	TCDD			CH-223191		
	Omerprazole			Omerprazole sulfide		
CAR	Agonists	Human	Mouse	Inverse agonists	Human	Mouse
	Chlorpromazine	No	Yes	Chlorpromazine	Yes	No

	PCN	Weak	Yes			
	Rifampin	Yes	No			

PCN, Pregnenolone-16α-carbonitrile; TCDD, 2,3,7,8-tetrachlorodibenzo-p-dioxin.

by CAR, PXR, or both receptors. As shown in Table 6-14, three factors combine to make CAR and PXR the most important human xenosensors in terms of drug–drug interactions. First, CAR and PXR regulate several CYP enzymes (e.g., CYP2B6, 2C8, 2C9, 2C19, and 3A4), conjugating enzymes (several UGTs and SULTs), and transporters (such as P-glycoprotein [MDR1 or ABCB1]). Second, a large number of xenobiotics (drugs and the herbal preparations, St. John's wort and Yin Zhi Wuang) and certain endobiotics (such as bilirubin, bile acids, and 1α,25-dihydroxyvitamin D$_3$) activate CAR and/or PXR. Third, some of the genes regulated by CAR and PXR encode proteins with broad substrate specificities, such as CYP3A4 and P-glycoprotein, such that the induction mediated by CAR and PXR impacts the disposition of a large number of xenobiotics and certain endobiotics (see Table 6-11). In terms of drug–drug interactions, human xenosensors can be rank-ordered (from most important to least) as follows: CAR/PXR > AhR > "CYP2E1" > PPARα. PPARα is ranked last because its activation in humans, in contrast to its activation in rodents, does not lead to CYP4 induction (a family of enzymes that plays a limited role in drug metabolism compared with CYP1, 2, and 3 enzymes). CYP2E1 is an inducible enzyme in humans (by mechanisms that do not appear to involve any of the xenosensors listed in Table 6-15), but relatively few drugs are in-

ducers of—or substrates for—CYP2E1. AhR is less important than CAR/PXR because there are relatively few drugs that activate AhR and because the major hepatic enzyme regulated by AhR, namely, CYP1A2, plays a more limited role in drug metabolism than the hepatic and intestinal CYP enzymes regulated by CAR/PXR, namely, CYP2B6, 2C8, 2C9, 2C19, and 3A4.

The activation of PXR follows the canonical steps outlined above (this section), beginning with ligand binding, dissociation from cytoplasmic retention protein and co-repressors (like SMRT), and association with co-activators (like RAC3), dimerization with RXRα, translocation to the nucleus and binding to various DNA-response elements (multiple PXREs known as DR-3, DR-4, ER-6, and ER-8), which culminates in transcriptional activation of multiple genes, as shown in Table 6-14 (Chang and Waxman, 2006; Stanley *et al.*, 2006). Species differences in the LBD of PXR account for certain species differences in CYP3A induction. For example, PCN is a prototypical inducer of CYP3A in rats and mice, but not humans, whereas the opposite is true of rifampin. Transgenic mice with human PXR in place of mouse PXR (PXR-humanized mice) lose the ability to respond to PCN and gain the ability to respond to rifampin. Rifampin can also bind and activate rat PXR once the opening to the LBD is slightly widened (by changing a phenylalanine to a leucine

residue). As shown in Table 6-14, rifampin, artemisinin, clotrimazole, nicardipine, and nifedipine are agonists for human PXR but not mouse PXR, which exemplifies why enzyme induction studies in rodents often fail to predict enzyme induction in humans. Some agonists bind to human PXR with relatively high affinity (with K_D values in the [sub]micromolar range), including rifampin and hyperforin, the inducing agent in St. John's wort. In general, activation of CAR/PXR shows little or no stereospecificity, although the *C*-cyclopropylalkylamide known as S20 is a rare exception: $(-)$-C20 preferentially activates mouse PXR whereas $(+)$-C20 preferentially activates human PXR. This difference further underscores the lack of predictability of rodent data to the human situation.

Tang *et al.* (2005) have reviewed the factors that give rise to differences in the magnitude of enzyme induction by PXR/CAR agonists in humans; such differences can be attributed to (1) genetic polymorphisms or splicing variation in PXR or CAR and/or polymorphism in their DNA-response elements; (2) altered levels or function of accessory proteins (some of which are associated with inflammation and other disease states that activate NF-κB, as discussed later in this section); (3) gender differences in basal CYP3A4 activity (which tends to be lower in males compared with females); and (4) variation in the intracellular concentration of the inducing drug, as exemplified by variation in the metabolism of propafenone and celecoxib. Propafenone is metabolized by CYP2D6, 3A4, and 1A2. In CYP2D6 EMs, the clearance of propafenone is determined by CYP2D6, and treatment with rifampin causes no induction of propafenone metabolism. However, in CYP2D6 PMs, CYP3A4 plays a significant role in the clearance of propafenone, and treatment of CYP2D6 PMs with rifampin causes a doubling of propafenone clearance. The COX-2 inhibitor celecoxib is a PXR agonist whose in vivo clearance is largely determined by CYP2C9. There is evidence to suggest that, at recommended clinical doses, celecoxib induces CYP3A4 in CYP2C9 PMs but not in CYP2C9 EMs due to the higher levels of celecoxib in the poor metabolizers (Rodrigues *et al.*, 2006).

The activation of CAR is considerably more complex than that of PXR (Chang and Waxman, 2006; Kodama and Negishi, 2006; Stanley *et al.*, 2006). CAR is constitutively active, meaning that, in the absence of an exogenous ligand, it can complex with RXRα, translocate to the nucleus, bind to DNA-response elements (known as PBREM [for phenobarbital response elements] or Barbie boxes), and activate gene transcription, which is what generally happens when CAR is expressed in cell lines in vitro. In the in vivo situation (such as occurs in hepatocytes), CAR is prevented from being transcriptionally active by its retention in the cytoplasm by cytoplasmic CAR-retention protein (CCRP) and chaperones such as hsp90, and possibly by its binding to an endogenous reverse agonist such as androstanol (5α-androstan-3α-ol) and androstenol (5α-androst-16-en-3α-ol), the androstanes for which CAR is named (reverse agonists are discussed later in this section). The release of CAR from CCRP can be triggered either by *direct activators*, which bind directly to CAR, or by *indirect activators*, which trigger the phosphorylation of CAR by AMP-activated protein kinase (AMPK) (Rencurel *et al.*, 2006). The classical inducer phenobarbital is an indirect activator of CAR, which leads to induction of CYP2B and, to a lesser extent, CYP3A enzymes. The ability of phenobarbital to induce CYP2B10 and CYP3A11 is abolished in transgenic mice lacking either CAR or the α-subunit of AMPK, which is compelling evidence that activation of AMPK is the mechanism by which phenobarbital activates CAR (Rencurel *et al.*, 2006). AMPK is sensitive to energy charge; consequently it is activated by an increase in the ratio of AMP to ATP.

Consequently, AMPK is activated by fasting, which has been shown to induce CYP2B10 in mice. Metformin, a drug used to lower fasting blood glucose levels in patients with noninsulin-dependent (Type 2) diabetes, also activates AMPK, and metformin has been shown to induce CYP2B6 and 3A4 in human hepatocytes. It is interesting that, like metformin, phenobarbital also lowers glucose levels in patients with Type 2 diabetes (Rencurel *et al.*, 2006). This glucose-lowering effect appears to involve, at least in part, the following steps: (1) activation of AMPK by phenobarbital or metformin; (2) activation of CAR by AMPK-dependent phosphorylation; (3) binding of activated CAR to FoxO1, a transcription factor that binds to insulin-response sequences (IRS), which are DNA-response elements in the promoter region of gluconeogenic genes such as phosphoenolpyruvate carboxykinase-1 (PEPCK1) and glucose-6-phosphatase and (4) decreased gluconeogenesis (i.e., decreased glucose synthesis) as a result of FoxO1 repression by CAR (Kodama and Negishi, 2006; Rencurel *et al.*, 2006). Consistent with this mechanism of action, phenobarbital decreases glucose levels in wild-type mice but not in CAR knockout mice.

The interaction between CAR and FoxO1 has opposing effects on transcriptional activity: CAR is a *co-repressor* of FoxO1 whereas FoxO1 is a *co-activator* of CAR. Activation of FoxO1 by diabetes increases CYP2B and 3A expression in rats and mice, and this effect is reversed by insulin treatment (which stimulates the phosphorylation of FoxO1 and thereby decreases its activity). By inactivating FoxO1 (which removes a co-activator for CAR), insulin blunts the induction of CYP2B enzymes by phenobarbital (Kodama and Negishi, 2006).

Phosphorylation is required for both the retention of CAR in the cytoplasm and the release of CAR from CCRP, which seems paradoxical. However, the paradox is resolved by the fact that phosphorylation for CAR retention and phosphorylation for CAR activation occur at different sites. Phosphorylation of serine-202 in mouse CAR and of serine-192 in human CAR is required for the retention of CAR in the cytoplasm, and dephosphorylation by protein phosphatase 2A is an important step in CAR activation (as evidenced by the observation that the protein phosphatase 2A inhibitor okadaic acid blocks CAR translocation in mouse hepatocytes). In addition to dephosphorylation, activation of CAR also requires phosphorylation by AMPK, which occurs at sites other than serine-202 in mouse CAR and serine-192 in human CAR (Rencurel *et al.*, 2006).

Because CAR is constitutively active but retained in the cytoplasm, ligands can function as agonists, reverse agonists, or antagonists. Agonists activate CAR by displacing endogenous reverse agonists (e.g., androstanes) or by promoting the dissociation of co-repressors (such as NcoR) and the recruitment of co-activators (such as SRC-1, Sp1, ASC-2, and PBP). Reverse agonists have the opposite effect: they promote the dissociation of co-activators and the recruitment of co-repressors, and they may also decrease the transcriptional activity of CAR. Antagonists bind to the same LBD as agonists and reverse agonists; they neither activate nor deactivate CAR, but they block the binding of other ligands.

As shown in Table 6-15, xenobiotics can function as CAR agonists or antagonists in a species-specific manner. For example, chlorpromazine and meclizine are agonists for mouse CAR, but they are inverse agonists for human CAR. TCPOBOP and CITCO are potent direct activators of CAR, but they function as CAR agonists in a species-specific manner: TCPOBOP is a potent agonist for mouse CAR whereas CITCO is a potent agonist for human CAR. The use of these selective CAR agonists must be used in a species-specific manner, as underscored by the fact that the mouse CAR agonist

TCPOBOP is *not* an agonist for human CAR but it *is* an agonist for human PXR. Phenobarbital is an indirect activator of mouse and human CAR, but it is also an activator of human PXR (but not mouse or rat PXR). In contrast, another enzyme-inducing antiepileptic drug (EIAED) phenytoin does not activate human PXR and, like CITCO, is a selective activator of human CAR. These species differences in CAR, like those described earlier in this section for PXR, illustrate why, during the safety evaluation of drug candidates, enzyme induction studies in rodents are often of limited value in predicting enzyme induction in humans.

CAR and PXR are activated by certain endobiotics, and the enzymes regulated by these xenosensors play important roles in terminating the hormonal activity of $1\alpha,25$-dihydroxyvitamin D_3 $(1,25\text{-}(OH)_2\text{-}D_3$ and attenuating the toxicity of high levels of bilirubin and bile acids. The active form of vitamin D, namely, $1,25\text{-}(OH)_2\text{-}D_3$, binds to the vitamin D receptor (VDR) to induce the synthesis of calbindin-D9K, a calcium-binding protein that facilitates the uptake of calcium from the intestinal lumen to blood. VDR also induces CYP enzymes that further hydroxylate and thereby inactivate $1,25\text{-}(OH)_2\text{-}D_3$, which establishes a negative feedback loop. Two VDR-inducible CYP enzymes have been shown to inactivate $1,25\text{-}(OH)_2\text{-}D_3$ by hydroxylating the active hormone in the 24- and, to a lesser extent, the 23-position. The first is CYP24A1, which is expressed mainly in the kidney, and which catalyzes the $24R$-hydroxylation of $1,25\text{-}(OH)_2\text{-}D_3$. The second is CYP3A4, which is expressed mainly in intestine and liver, and which catalyzes the $24S$-hydroxylation of $1,25\text{-}(OH)_2\text{-}D_3$. The stereochemical differences in the 24-hydroxylation reaction helped to establish that CYP3A4 is the principal inactivator of $1,25\text{-}(OH)_2\text{-}D_3$ in the intestine, with little or no contribution from CYP24A1. These findings are important for two reasons. First, the ability of VDR to mimic PXR/CAR and induce CYP3A4 is an example of the cross-talk that can occur between a xenosensor and other nuclear receptors. Second, the key role played by CYP3A4 in the inactivation of $1,25\text{-}(OH)_2\text{-}D_3$ in the intestine provides an explanation for the clinical observation that long-term treatment of patients with rifampin, phenobarbital, phenytoin, or carbamazepine can lead to osteomalacia, a bone disorder that is symptomatic of vitamin D deficiency. These PXR/CAR agonists are thought to cause osteomalacia by inducing CYP3A4 in the intestine, which accelerates the inactivation of $1,25\text{-}(OH)_2\text{-}D_3$ and thereby impairs calcium absorption (Xu *et al*., 2006; Zhou *et al*., 2006a).

CAR plays an important role in detoxifying high levels of bilirubin, as might occur in patients with hemolytic anemia. Like phenobarbital, bilirubin is an indirect activator of CAR. When activated, CAR induces UGT1A1, the major hepatic enzyme responsible for glucuronidating bilirubin, as well as transporters of bilirubin/bilirubin glucuronide. When hemolytic anemia is induced by treating mice with phenylhydrazine, bilirubin levels rise to a greater extent in CAR knockout mice compared with wild-type mice, which demonstrates the important role CAR plays in responding to high levels of bilirubin. Phenobarbital was once used to treat neonatal jaundice, and the Chinese herbal Yin Zhi Wuang is still used for this purpose. Phenobarbital and scoparone (6,7-dimethylesculetin), the active ingredient in Yin Zhi Wuang, are CAR activators that, like bilirubin itself, induces the major bilirubin-conjugating enzyme UGT1A1 and related transporters (Chang and Waxman, 2006; Kodama and Negishi, 2006). In contrast, CAR appears to play a role in acetaminophen hepatotoxicity by allowing acetaminophen to induce its own activation to a toxic quinoneimine. CAR knockout mice are relatively resistant to acetaminophen hepatotoxicity com-

pared with both wild-type and CAR-humanized mice, which suggests early treatment with a CAR agonist might be a useful adjunct treatment for acetaminophen overdose.

CAR and PXR appear to act as backup receptors to prevent bile acid accumulation and toxicity when the principal bile acid sensor, FXR (the farnesoid X receptor), is overloaded. High concentrations of bile acids activate FXR, which suppresses the expression of CYP7A1, the cholesterol 7α-hydroxylase that catalyzes the rate-limiting step in bile acid synthesis, and which induces the expression of bile acid conjugating enzymes (UGT2B4 and SULT2A1) and bile acid transporters (such as BSEP, the bile salt export pump). When hepatocytes contain low concentrations of bile acids, FXR is inactive and the expression of CYP7A1 is stimulated by LRH-1 (liver receptor homolog-1), a constitutively active nuclear receptor. When hepatocytes contain high concentrations of bile acids, FXR is activated, and it inactivates LRH-1 by inducing the synthesis of small heterodimer partner-1 (SHP), so named because it lacks a DNA-binding domain (hence its small size) and because it forms heterodimers with LRH-1 and numerous other nuclear receptors including AhR, CAR, PXR, $LXR\alpha$, $HNF4\alpha$, and the glucocorticoid receptor (GR). Because it lacks a DBD, SHP inactivates all of these receptors; in the case of LRH-1, this results in a loss of CYP7A1 expression and a decrease in bile acid synthesis, which represents a negative feedback loop. FXR knockout mice are more sensitive than wild-type mice to bile acid toxicity, and treatment with the FXR ligand GW4064 further protects wild-type mice against experimentally induced extra- and intrahepatic cholestasis. Cholic acid is both an FXR and PXR agonist; it suppresses CYP7A1 expression first by activating FXR and then PXR. In contrast to the situation in wild-type or single receptor knockout mice, 1% dietary cholic acid is lethal to FXR/PXR double knockout mice. PXR and CAR play a similar role in attenuating the toxicity of lithocholic acid, which is both a PXR agonist and a substrate for many of the enzymes regulated by PXR, including CYP3A, SULT, and transporters involved in the hepatic uptake and efflux of lithocholic acid. In PXR/CAR double knockout mice, lithocholic acid causes lethal hepatotoxicity at doses that are well tolerated by wild-type mice. The mouse PXR agonist PCN can markedly suppress CYP7A1 expression and bile acid synthesis in mice, and the human PXR agonist rifampin can markedly suppress CYP7A1 expression in human hepatocytes. The ability of PXR/CAR to function as a backup system for FXR may be compromised by the expression of SHP, which represses the activity of these xenosensors. This complex interplay is one of the likely reasons why there are some conflicting results from studies of the role of PXR/CAR in bile acid detoxication.

As the preceding examples in this section illustrate, there is a complex interplay between many of the nuclear receptors listed in Table 6-14. Some nuclear receptors, such as the hepatic nuclear factors $HNF1\alpha$ and $HNF4\alpha$, play a critical permissive role in gene regulation by CAR, PXR, and other receptors, whereas others, such as SHP, play a widespread role in suppressing nuclear receptor activity. $HNF1\alpha$ is instrumental for the expression of high levels of CYP2E1 mRNA in liver, although it is not the only factor because disruption of the β-catenin gene in mice greatly reduces CYP2E1 mRNA levels in the liver in the absence of changes in $HNF1\alpha$ expression (Gonzalez, 2007). The glucocorticoid receptor (GR) plays an important role in inducing the synthesis of CAR and PXR (and individual xenobiotic-biotransforming enzymes like CYP2C9). The role of GR in regulating the synthesis of xenosensors and the interplay among nuclear receptors are instrumental to the mechanism by which infections and inflammatory diseases suppress the expression

and blunt the induction of xenobiotic-biotransforming enzymes and, conversely, the mechanism by which PXR agonists cause immuno-suppression.

The expression and induction of xenobiotic-biotransforming enzymes by AhR, CAR, PXR, and PPARα are all suppressed by infection (viral, bacterial, and parasitic), vaccination, inflammation, and treatment with endotoxin (lipopolysaccharide or LPS) or inflammatory cytokines such as interleukin-1β (IL-1β) and IL-6. The suppression involves (1) a decrease in the *levels* of PXR and CAR due to a decrease in GR activity, and (2) a decrease in the *activity* of GR, PXR, CAR, AhR, PPARα, and several other nuclear receptors including the androgen, estrogen, and mineralocorticoid receptors (De Bosscher *et al.*, 2006; Pascual and Glass, 2006; Zhou *et al.*, 2006b). The decrease in receptor activity is caused by NF-κB (nuclear factor kappa-B), which is activated during infection and inflammatory disease, and which induces the synthesis of COX-2, TNFα, ICAM-1, and several interleukins. NF-κB binds to the DBD of RXRα and thereby decreases the transcriptional activity of all nuclear receptors that form heterodimers with RXRα (such as PXR, CAR, PPARα, GR, etc.). It also decreases the transcriptional activity of AhR even though AhR forms heterodimers with ARNT, not RXRα. By lowering the levels and/or inhibiting the activity of the major xenosensors and numerous other nuclear factors, NF-κB mediates the widespread suppression of xenobiotic-biotransforming enzymes associated with infection and inflammatory disease. However, the converse is also true inasmuch as certain nuclear receptors, when activated, can complex NF-κB and thereby repress the expression of NF-κB-regulated genes (COX-2, TNFα, ICAM-1, interleukins). This is the basis, at least in part, for the immunosuppressive effect of corticosteroids, which activate GR, and the immunosuppressive effect of PXR ligands such as rifampin and mifepristone (RU-486). PXR appears to play an important role in suppressing NF-κB activity in the small intestine. PXR knockout mice show signs of inflammation of the small intestine, and certain genetic polymorphisms and splicing variants of PXR are associated with inflammatory bowel disease. The role of PXR in regulating NF-κB activity, responding to high levels of bile acids, terminating the actions of 1,25-$(OH)_2$-D_3, and the role of CAR in responding to high level of bilirubin and the activation of CAR by FoxO1 and food deprivation all illustrate that these so-called xenosensors do not simply respond to xenobiotics but play key roles in endobiotic homeostasis.

Peroxisome Proliferator Activated Receptor-Alpha (PPARα)
The distinction between xenobiotic- and endobiotic-sensing functions is particularly blurred in the case of PPARα, which is activated by endogenous fatty acids (e.g., arachidonic acid), eicosanoids and conjugated steroids such as dehydroepiandrosterone sulfate, as well as numerous acidic xenobiotics such as hypolipidemic fibrate drugs (e.g., clofibrate, fenofibrate, ciprofibrate), various NSAIDs, aspirin, leukotriene receptor antagonists (MK-0571 and RG 7512), organic solvents (trichloroacetic acid), phthalate ester plasticizers, herbicides (haloxyfab, lactyofen, 2,4-dichlorophenoxyacetic acid or 2,4-D), perfluorodecanoic acid, nicotinic acid, and the potent and widely used experimental PPARα agonist Wy-14643. Some of these ligands bind to PPARα stereoselectively; therefore, the enantiomers of certain drugs differ in their ability to activate PPARα. When activated with ligand and complexed with RXRα, PPARα activates the transcription of several genes that encode peroxisomal enzymes involved in the β-oxidation of fatty acids, including fatty acyl-CoA oxidase, bifunctional enzyme (enoyl-CoA hydratase/3-hydroxyacyl-CoA dehydrogenase), and fatty acid binding protein.

In rodents, this is associated with a proliferation of peroxisomes and hepatomegaly, which is why xenobiotics that activate PPARα are often called peroxisome proliferators. Increased peroxisomal fatty acid degradation is the mechanism by which the hypolipidemic fibrate drugs decrease the pool of fatty acyl-CoA required for triglyceride synthesis, but it is not clear where in the body this increased peroxisomal fatty acid degradation occurs. It appears to occur in the kidney, skeletal muscle, and heart, and it may also occur in the liver, although in humans fatty acids are thought to be degraded mainly by mitochondrial, not peroxisomal, β-oxidation. The limited role of liver peroxisomal fatty acid oxidation in mediating the hypolipidemic effects of fibrate drugs is further suggested by the observation that the levels of PPARα in human liver are relatively low (about one-tenth those in rodent liver), and in contrast to the situation in rodents, activation of human PPARα does not result in the induction of microsomal CYP4A enzymes or liver enlargement due to a proliferation of peroxisomes. In contrast to agonists for other xenosensors, PPARα agonists are not a concern as perpetrators of drug–drug interactions, but they are a concern from a tumor promotion perspective, as outlined in the next section.

Enzyme Induction and Chemical Carcinogenesis   In humans, induction of CYP2E1 and the associated increased activation of acetaminophen to *N*-acetylbenzoquinoneimine (NAPQI) is one of the mechanisms by which alcohol consumption and fasting potentiate acetaminophen hepatotoxicity (other contributing mechanisms include the impaired conjugation of acetaminophen due to lowered levels of UDPGA and PAPS and the impaired detoxication of NAPQI due to lowered levels of glutathione). By analogy, induction of CYP enzymes would be expected to increase the activation of procarcinogens to DNA-reactive metabolites, leading to increased tumor formation. However, contrary to expectation, treatment of rodents with a CYP inducer prior to treatment with a known proximate carcinogen (tumor initiators like aflatoxin, various nitrosamines, or polycyclic aromatic hydrocarbons) is generally associated with a decrease, not an increase, in tumor incidence (Parkinson and Hurwitz, 1991). The route of exposure to the carcinogen can affect the impact of enzyme induction; it protects against orally administered drugs but may increase the tumorigenicity of carcinogens applied directly to their site of action (Nebert *et al.*, 2004). Although treatment of rats and mice with a CYP inducer *before* treatment with an initiator (a genotoxic carcinogen) generally decreases tumor incidence, treatment with a CYP inducer *after* the initiator (such as diethylnitrosamine) generally increases tumor incidence because CYP inducers generally function as tumor promoters in rodents.

Phenobarbital is representative of a large number of compounds that appear to promote liver tumor formation in rats or mice by an epigenetic mechanism, including phenytoin, carbamazepine, chlordecone, butylated hydroxytoluene, DDT, dieldrin, hexachlorocyclohexane, certain polychlorinated and polybrominated biphenyls, loratadine, doxylamine, lansoprazole, musk xylene, and fenbuconazole (Williams and Iatropoulos, 2002; Juberg *et al.*, 2006). Although the exact mechanism of tumor formation remains unknown, it is critically dependent on CAR activation, as evidenced by the finding that phenobarbital and related compounds do not function as tumor promoters in CAR knockout mice (Gonzalez and Yu, 2006). Furthermore, phenobarbital and related compounds only cause liver tumors at doses that cause liver enlargement due to an increase in cell number (hepatocellular hyperplasia) and cell size (hepatocellular hypertrophy). The liver changes induced by phenobarbital, including an increase in DNA synthesis within 24 hours,

a wave of mitotic activity after 1–3 days, enzyme induction (e.g., CYP2B enzymes) and a progressive increase in liver weight, all exhibit nonlinear dose–response relationships, suggesting that there is a threshold dose below which no activation of CAR and no liver tumor promotion occur.

Although induction of CYP2B enzymes (and other xenobiotic-biotransforming enzymes and transporters) is a common feature of phenobarbital and related tumor-promoting chemicals, the two events do not appear to be mechanistically linked (Williams and Iatropoulos, 2002). After CAR activation, the key downstream events leading to liver tumor formation are not known in great detail, but the downregulation (suppression) of gap junctions, which impedes intercellular communication, is one such critical downstream event, as evidenced by the lack of tumor-promoting activity by phenobarbital in transgenic mice lacking connexin 32, a component of gap junctions, even though CYP2B10 and other enzymes can be induced in these knockout mice.

The mechanism of thyroid tumor formation is better understood. In rodents, CAR (and PPARα) agonists induce UGT and SULT enzymes and transporters that accelerate the conjugation and elimination of thyroid hormones, which triggers a compensatory increase in thyroid-stimulating hormone (TSH). Sustained stimulation of the thyroid gland by TSH leads to the development of thyroid follicular tumors, the development of which can be blocked by administering thyroxine, which blocks the release of TSH and thereby abrogates the hormonal stimulation of the thyroid gland. It is not clear why sustained stimulation of the thyroid gland by TSH results in tumor formation in rodents, but such tumors develop in other rodent organs following prolonged hormonal stimulation: LH causes Leydig cell tumors, gastrin causes stomach tumors, and corticosteroids cause pancreatic tumors. In addition, just as proliferation of the hepatic endoplasmic reticulum and peroxisomes by phenobarbital and Wy-14643 is associated with liver tumor formation, so the proliferation of hepatic lysosomes by Ponceau-S and the proliferation of mitochondria by methapyrilene are also associated with liver tumor formation (Grasso et al., 1991).

Epidemiological studies of epileptic patients treated for more than 35 years with phenobarbital or phenytoin have established that chronic liver microsomal enzyme induction in humans does not increase the incidence of liver or thyroid tumor formation (Singh et al., 2005). Prolonged elevation of TSH in humans does not lead to tumor formation but causes goiter, a reversible enlargement of the thyroid gland associated with iodide deficiency and treatment with drugs that block thyroid hormone synthesis. In humans and monkeys, circulating thyroxine (T4) is largely bound to thyroxine-binding globulin (TBG). This high-affinity binding protein is not present in rodents, for which reason T4 is rapidly conjugated and excreted in bile. Accordingly, the plasma half-life of thyroxine in rats (12–24 h) is considerably shorter than in humans (5–9 d). Similar differences are observed for triiodothyronine (T3). To compensate for the increased turnover of thyroid hormones, the rat pituitary secretes more TSH. Whereas baseline serum TSH levels in humans are ∼2.2 μU/mL, TSH levels in rats range from 55.5 to 65 μU/mL in males and 36.5 to 41 in females (Hill et al., 1989). It is estimated that rats require a tenfold higher rate of thyroxine production (on a per kilogram body weight basis) than do humans to maintain physiological T4 levels. These differences in plasma half-life, protein binding, thyroid hormone metabolism, and TSH secretion between rats and humans are thought to be one reason for the greater sensitivity of rats to developing hyperplastic and/or neoplastic nodules in response to chronic TSH stimulation (Capen, 1997).

PPARα plays a critical role in tumor formation by peroxisome proliferators as evidenced by the finding that Wy-14643 does not function as a tumor promoter in PPARα knockout mice (Gonzalez and Yu, 2006). Furthermore, there is excellent agreement between the potency with which agonists activate PPARα and the potency with which they promote liver tumor formation in rodents (which in turn is correlated with their ability to induce the proliferation of peroxisomes, induce peroxisomal enzymes involved in the β-oxidation of fatty acids, and induce microsomal CYP4A enzymes). Like CAR agonists, PPARα agonists are considered epigenetic (nongenotoxic) tumorigens because they are not mutagenic and they are not known to be converted to mutagenic metabolites. However, induction of acyl-CoA oxidase by Wy-14643 and other peroxisome proliferators leads to increased production of hydrogen peroxide, which can cause oxidative stress and DNA damage that possibly play a role in some of the downstream events leading to tumor promotion.

Activation of PPARα is required but apparently not sufficient to lead to liver tumor formation. Other key events include increased oxidant production (such as increased peroxisomal H_2O_2 production), increased cell proliferation (which fixes mutations), and suppression of apoptosis (which prevents the removal of genetically damaged cells and permits clonal expansion) (Klaunig et al., 2003; Lai, 2004; Bosgra et al., 2005). Kupffer cells appear to play an important role in liver tumor formation by releasing mitogenic cytokines and possibly by contributing to oxidative stress by releasing superoxide anion, although it is not clear how PPARα agonists trigger these events. Inhibition of gap junctional intercellular communication appears to play an important role in liver tumor formation by PPARα agonists, just as it does in the promotion of liver tumors by phenobarbital-type inducers.

Epidemiological studies designed to assess the human cancer risk posed by PPARα agonists have produced inconclusive results. Clofibrate has been reported to cause a statistically significant increase in cancer mortality rate during a 5- to 8-year treatment period. However, there were no significant increase in cancer rate in a follow-up study, which included a posttreatment period (Lai, 2004). Two compelling lines of evidence suggest that PPARα agonists will not cause liver tumors in humans. First, PPARα agonists do not cause peroxisome proliferation and microsomal CYP4A induction in human hepatocytes in vitro or in primates in vivo. Second, treatment of PPARα-humanized mice (transgenic mice with human PPARα in place of mouse PPARα) with Wy-14643 or fenofibrate does not result in the hepatocellular proliferation characteristic of wild-type mice (Gonzalez and Yu, 2006).

Enzyme Induction and Porphyria Due to the increased demand for heme, persistent induction of cytochrome P450 can lead to porphyria, a disorder characterized by excessive accumulation of intermediates in the heme biosynthetic pathway. In 1956, widespread consumption of wheat contaminated with the fungicide hexachlorobenzene caused an epidemic of porphyria cutanea tarda in Turkey. Another outbreak occurred in 1964 among workers at a factory in the United States manufacturing 2,4,5-trichlorophenoxyacetic acid (the active ingredient in several herbicides and in the defoliant, Agent Orange). The outbreak of porphyria cutanea tarda was caused not by the herbicide itself but by a contaminant, namely, TCDD. Drugs that cause P450 induction have not been shown to cause porphyria cutanea tarda under normal circumstances, but phenobarbital, phenytoin, and alcohol are recognized as *precipitating factors* because they cause episodes of porphyria

in individuals with an inherited deficiency in the heme-biosynthetic enzyme, uroporphyrinogen decarboxylase.

CONJUGATION

Conjugation reactions include glucuronidation, sulfonation (often called sulfation), acetylation, methylation, conjugation with glutathione (mercapturic acid synthesis), and conjugation with amino acids (such as glycine, taurine, and glutamic acid). The cofactors for these reactions, which are shown in Fig. 6-49, react with functional groups that are either present on the xenobiotic or introduced/exposed during oxidation, reduction, or hydrolysis. With the exception of methylation and acetylation, conjugation reactions result in a large increase in xenobiotic hydrophilicity, so they greatly promote the excretion of foreign chemicals. Glucuronidation, sulfonation, acetylation, and methylation involve reactions with activated or "high-energy" cofactors, whereas conjugation with amino acids or glutathione involves reactions with activated xenobiotics. Most conjugation enzymes are located in the cytosol; a notable exception is the UDP–glucuronosyltransferases, which are microsomal enzymes (Table 6-1).

Glucuronidation

Glucuronidation is a major pathway of xenobiotic biotransformation in mammalian species except for members of the cat family (lions, lynxes, civets, and domestic cats) (Tukey and Strassburg, 2000). Glucuronidation requires primarily the cofactor UDPGA, but can also use UDP–glucose, UDP–xylose, and UDP–galactose. The reaction is catalyzed by UDP–glucuronosyltransferases (UGTs), which are located predominantly in the endoplasmic reticulum of liver and other tissues, such as the kidney, gastrointestinal tract, lungs, prostate, mammary glands, skin, brain, spleen, and nasal mucosa (Fig. 6-50). Examples of xenobiotics that are glucuronidated are shown in Fig. 6-51. The site of glucuronidation is generally an electron-rich nucleophilic O, N, or S heteroatom. Therefore, substrates for glucuronidation contain functional groups such as aliphatic alcohols and phenols (which form O-glucuronide ethers), carboxylic acids (which form O-glucuronide esters), primary and secondary aromatic and aliphatic amines (which form N-glucuronides), and free sulfhydryl groups (which form S-glucuronides). In humans and monkeys, more than 30 tertiary amines (including tripelennamine, cyclobenzaprine, and imipramine) are substrates for N-glucuronidation, which leads to the formation of positively charged quaternary glucuronides, some of which may be carcinogenic (see below) (Hawes, 1998). Certain xenobiotics, such as phenylbutazone, sulfinpyrazone, suxibuzone, ethchlorvynol, Δ^6- tetrahydrocannabinol, and feprazone, contain carbon atoms that are sufficiently nucleophilic to form C-glucuronides. The C-glucuronidation of the enolic form of phenylbutazone is catalyzed specifically by UGT1A9 (Nishiyama $et\ al$., 2006). Coumarin and certain other carbonyl-containing compounds are glucuronidated to form arylenol-glucuronides. In spite of the broad and overlapping substrate specificities of the UGT1As, some generalities can be made regarding certain types of substrates and the UGT1A enzymes that can glucuronidate them. For instance, UGT1A3 and 1A4 are largely responsible for glucuronidating tertiary amines (Vashishtha $et\ al$., 2001). For UGT1A1 and 1A4, the site of glucuronidation is always adjacent to a hydrophobic region of the substrate, with another hydrophobic region 6–8 Å from the position that is glucuronidated (Smith $et\ al$., 2004). UGT1A9 is similar,

except that the distal hydrophobic region also contains a hydrogen-bond acceptor (Smith $et\ al$., 2004). In a series of twenty four 4-substituted phenols, a methyl or ether in any position increases the rate of glucuronidation compared with phenol itself. UGT1A9 catalyzed the glucuronidation of all 24 substrates, whereas UGT1A6 tended only to glucuronidate less bulky phenolic substrates (Smith $et\ al$., 2004).

In addition to the typical conjugation reactions above, UGTs can form unusual conjugates: (1) bisglucuronides (e.g., bilirubin and morphine), where two different functional groups on the same molecule are glucuronidated; (2) diglucuronides (e.g., 5α-dihydrotestosterone), where two glucuronides are attached in tandem to a single site; (3) N-carbamoyl glucuronides (e.g., sertraline and varenicline), where carbonate is incorporated in the glucuronide; and (4) glycosidation with UDP–sugars other than UDP–glucuronic acid (e.g., glucosidation of barbiturates). Two examples are shown in Fig. 6-52. These reactions will be covered in greater detail later in this chapter. In addition to numerous xenobiotics, substrates for glucuronidation include several endogenous compounds, such as bilirubin, steroid hormones, and thyroid hormones. Table 6-16 provides examples of marker substrates for the major human UGTs. A listing of over 350 UGT substrates is available at http://arjournals.annualreviews.org/doi/suppl/10.1146/annurev.pharmtox.40.1.581 (Tukey and Strassburg, 2000). A review by Kiang and colleagues (2005) also provides an extensive table of UGT substrates along with corresponding K_m and V_{max} values.

Glucuronide conjugates of xenobiotics and endogenous compounds are polar, water-soluble metabolites that are eliminated from the body in urine or bile. Whether glucuronides are excreted from the body in bile or urine depends, in part, on the size of the aglycone (parent compound or unconjugated metabolite). In rat, glucuronides are preferentially excreted in urine if the molecular weight of the aglycone is less than 250, whereas glucuronides of larger molecules (aglycones with molecular weight >350) are preferentially excreted in bile. Molecular weight cutoffs for the preferred route of excretion vary among mammalian species. The carboxylic acid moiety of glucuronic acid, which is ionized at physiological pH, promotes excretion because (1) it increases the aqueous solubility of the xenobiotic and (2) it is recognized by the biliary and renal organic anion transport systems, which enable glucuronides to be secreted into urine and bile.

The cofactor for glucuronidation, UDPGA, is synthesized from glucose-1-phosphate, and the linkage between glucuronic acid and UDP has an α-configuration, as shown in Fig. 6-50. This configuration protects the cofactor from hydrolysis by β-glucuronidase. However, glucuronides of xenobiotics have a β-configuration. This inversion of configuration occurs because glucuronides are formed by nucleophilic attack by an electron-rich atom (usually O, N, or S) on UDPGA, and this attack occurs on the opposite side of the linkage between glucuronic acid and UDP, as shown in Fig. 6-50. In contrast to the UDPGA cofactor, xenobiotics conjugated with glucuronic acid are substrates for β-glucuronidase. Although present in the lysosomes of some mammalian tissues, considerable β-glucuronidase activity is present in the intestinal microflora. The intestinal enzyme can release the aglycone, which can be reabsorbed and thereby enters a cycle called $enterohepatic\ circulation$, which delays the elimination of xenobiotics. N-Glucuronides are more slowly hydrolyzed by β-glucuronidase than O- or S-glucuronides, whereas O-glucuronides tend to be more stable to acid-catalyzed hydrolysis than N- or S-glucuronides. The potential for glucuronides to be hydrolyzed in the presence of an acid or a base complicates the

The functional group that reacts with or is transferred to the xenobiotic is shown in blue.

analysis of conjugates in urine or feces, and has implications for the tumorigenicity of *N*-glucuronides of compounds such as benzidine (discussed later in this section).

The C-terminus of all UGTs contains a membrane-spanning domain that anchors the enzyme in the endoplasmic reticulum. The enzyme faces the lumen of the endoplasmic reticulum, where it is ideally placed to conjugate lipophilic xenobiotics and their metabolites generated by oxidation, reduction, or hydrolysis. The lumenal orientation of UGT poses a problem because UDPGA is

a water-soluble cofactor synthesized in the cytoplasm. Several nucleotide sugar transporters (NSTs) have been postulated to shuttle UDPGA from the cytoplasm to the lumen of the endoplasmic reticulum, and they may also shuttle UDP (the byproduct of glucuronidation) back into the cytoplasm for synthesis of UDPGA, as shown in Fig. 6-50. Kobayashi and colleagues (2006) showed that, when expressed in V79 cells, three human NSTs, namely hUGTrel1 (SLC35B1), huYEA4 (SLC35B4), and huYEA4S (a transcript variant of SLC35B4), all transported UDPGA into the lumen
Figure 6-50. Synthesis of UDP–glucuronic acid and inversion of configuration ($\alpha \rightarrow \beta$) during glucuronidation of a phenolic xenobiotic (designated RO$^-$).

of microsomes prepared from these Chinese hamster fibroblasts, and they further showed that this microsomal transport was entirely dependent on the presence of UDP-N-acetylgalactosamine (a feature of many NSTs). They also demonstrated that the uptake of UDPGA into rat liver microsomes is partially dependent ($\sim$50%) on the presence of UDP-N-acetylgalactosamine, which suggests that NSTs may only be partially responsible for the transport of UDPGA from the cytoplasm to the lumen of the endoplasmic reticulum of rat liver (although they could be entirely responsible for such transport if 50% of the microsomal vesicles were inside out, which is possible).

In addition to UDPGA, the glucuronide metabolites are transported either across the bile canalicular membrane for excretion in bile or back across the endoplasmic reticulum and across the sinusoidal membrane into the blood for excretion in urine. Transport of glucuronides across the sinusoidal membrane into the blood is mediated by MRP1 (ABCC1), MRP3 (ABCC3), and MRP4 (ABCC4). The transport of glucuronides across the canalicular membrane into bile is mediated by MRP2 (ABCC2) and BCRP (ABCG2). Glucuronides can also be taken up by hepatocytes through the action of OATP1B1 (OATP2) and OATP1B3 (OATP8) on the sinusoidal membrane (Giacomini and Sugiyama, 2006). In rats, the hepatic uptake of estradiol-17β-glucuronide is mediated by OATP1A1, 1A4, and 1B2, whereas the biliary excretion of estradiol 3-sulfate-17β-glucuronide (see below, this section) is mediated by MRP2 and possibly BCRP (Sun *et al.*, 2006). Saturable ATP-independent, bidirectional carrier-mediated transport of estradiol-17β-glucuronide

across rat liver microsomal vesicles has also been demonstrated (Battaglia and Gollan, 2001). Other studies have shown that sulfoconjugates, phenolphthalein glucuronide, and estradiol 3-glucuronide are transported across the rat liver endoplasmic reticulum by facilitated diffusion, whereas 4-nitrophenyl glucuronide and 4-acetamidophenyl glucuronide are not, which suggests the presence of at least three microsomal glucuronide transporters with partially overlapping substrate specificity (Csala *et al.*, 2004).

In vitro, the glucuronidation of xenobiotics by liver microsomes can be stimulated by detergents (e.g., CHAPS and Brij-58), which disrupt the lipid bilayer of the endoplasmic reticulum and allow UGTs free access to UDPGA. High concentrations of detergent can inhibit UGTs, presumably by disrupting their interaction with phospholipids, which are important for catalytic activity. Detergents can inhibit certain UGTs, hence, they can affect UGT activity directly in addition to their indirect effects through interaction with phospholipids. Consequently, detergents, especially nonionic detergents such as Brij-58, can alter the kinetics of UGT reactions (Fisher *et al.*, 2000). Treatment of microsomes with detergents also virtually eliminates CYP activity; hence, detergents cannot be used to study the possible coupling of oxidation reactions catalyzed by cytochrome P450 with conjugation reactions catalyzed by UGT. This is not a limitation of alamethicin, a pore-forming peptide that activates UGT activity, like detergent, but which does not inhibit cytochrome P450. Furthermore, in contrast to certain detergents, alamethicin appears to increase $V_{\max}$ without affecting K_{m}.

O-Glucuronides (ethers)

17β-Estradiol — UGT1A1

26,26,26,27,27,27,-hexafluoro-1α,23,25-trihydroxyvitamin D3 — UGT1A3

Trifluoperazine — UGT1A4

1-Naphthol — UGT1A6

Propofol — UGT1A9

Morphine — UGT2B7, UGT2B7

S-Oxazepam — UGT2B15

Other Examples

Acetaminophen	Estrone	Naloxone	Progesterone	Testosterone
Codeine	Hexobarbital	4-Nitrophenol	Propranolol	Thyroxine
Dextrorphan	Methylphenylcarbinol	Phenolphthalein	Temazepam	Trichloroethanol
Diethystilbestrol				

N-Glucuronides

Aniline

Tripelennamine

Other Examples

Amitryptyline	Cyproheptadine	Meprobamate
Benzidine	N-Hydroxyarylamines	Sulfadimethoxine
Ciclopiroxolamine	Imipramine	Sulfathiazole
Cyclobenzaprine	Lamotrigine	Sulfisoxazole

Acyl-glucuronides
O-Glucuronides (esters)

Tolmetin

Other Examples

Benoxaprofen		
Bilirubin	Etodolac	Naproxen
Diclofenac	Gemfibrozil	Suprofen
Diflunisal	Ketoprofen	Valproic acid
Trifluoperazine	Lopanoic acid	Zomepirac

S-Glucuronides

Diethyldithiocarbamate

Thiophenol

Other Examples: Disulfiram   Methimazole

C-Glucuronides

Phenylbutazone $R = C_4H_9$
Sulfinpyrazone $R = (CH_2)_2SOC_6H_5$ — UGT1A9

Other Examples: Suxibuzone   Ethchlorvynol Δ^6-THC

Figure 6-51. Examples of xenobiotics and endogenous substrates that are glucuronidated.

The arrow indicates the site of glucuronidation, with the UGT enzyme if selective.

Table 6-16

Major Human UDP-Glucuronosyltransferase Enzymes

UGT	PRESENT IN LIVER?	TISSUE	EXAMPLE SUBSTRATES
1A1	Yes	Liver, small intestine, colon	**Bilirubin**, **17β-estradiol (3-glucuronidation)**, raloxifene, ethinyl estradiol, carvedilol, levothyroxine, acetaminophen
1A3	Yes	Liver, small intestine, colon	**Hexafluoro-1α,23(s),25-trihydroxyvitamin D3**, tertiary amines, antihistamines, 17β-estradiol, ketotifen, naproxen, ketoprofen, ibuprofen, fenoprofen, valproic acid, ezetimibe, norbuprenorphine
1A4	Yes	Liver, small intestine, colon	**Trifluoperazine**, tertiary amines, antihistamines, lamotrigine, amitriptyline, cyclobenzaprine, olanzapine
1A5	Yes	Liver	Unknown
1A6	Yes	Liver, small intestine, colon, stomach	**1-Naphthol, serotonin**, 4-nitrophenol, 4-methylumbelliferone, ibuprofen, acetaminophen, SN-38, diclofenac
1A7	No	Esophagus, stomach, lung	Octylgallate, arylamines, 4-hydroxybiphenyl, 4-hydroxyestrone, mycophenolic acid, SN-38
1A8	No	Colon, small intestine, kidney	Entacapone, troglitazone, anthraquinone, 8-hydroxyquinoline, furosemide, raloxifene, niflumic acid, ciprofibric acid, clofibric acid, valproic acid, mycophenolic acid, diflunisal, furosemide
1A9	Yes	Liver, colon, kidney	**Propofol**, thyroid hormones, entacapone, salicylic acid, scopoletin, fenofibrate, acetaminophen, ketoprofen, ibuprofen, fenoprofen, naproxen, furosemide, diflunisal, diclofenac, bumetanide
1A10	No	Stomach, small intestine, colon	1-Naphthol, mycophenolic acid, estrogen, raloxifene, troglitazone, furosemide
2A1	No	Olfactory	Valproic acid, ibuprofen
2A2	Unknown	Unknown	Unknown
2A3	Unknown	Unknown	Unknown
2B4	Yes	Liver, small intestine	Hyodeoxycholate, estriol, codeine, androsterone, carvedilol
2B7	Yes	Kidney, small intestine, colon	**Zidovudine (AZT)**, **morphine (6-glucuronidation[a])**, ibuprofen, ketoprofen, diclofenac, opioids, oxazepam, carvedilol, clofibric acid, naloxone, valproic acid, tiaprofenic, zomepirac, benoxaprofen
2B10	Yes	Liver, ileum, prostate	Unknown
2B11	Yes	Mammary, prostate, others	4-Nitrophenol, naphthol, estriol, 2-aminophenol, 4-hydroxybiphenyl
2B15	Yes	Liver, small intestine, prostate	**S-Oxazepam**, androgens, flavonoids, 4-hydroxytamoxifen, estriol, entacapone, SN-38, tolcapone, diclofenac
2B17	Yes	Liver, prostate	Androgens, eugenol, scopoletin, galangin, ibuprofen
2B28	Yes	Liver, mammary	17β-Estradiol, testosterone

Bold text represents selective substrates (or reactions).

[a] UGT2B7 also catalyzes the 3-glucuronidation of morphine, but this reaction is also catalyzed by other UGTs.

Data adapted from Miners JO, Knights KM, Houston JB, Mackenzie PI: In vitro–in vivo correlation for drugs and other compounds eliminated by glucuronidation in humans: Pitfalls and promises. *Biochem Pharmacol* 71:1531–1539, 2006; Kiang TKL, Ensom MHH, Chang TKH: UDP-glucuronosyltransferases and clinical drug–drug interactions. *Pharmacol Ther* 106:97–132, 2005; Williams JA, Hyland R, Jones BC, *et al.*: Drug–drug interactions for UDP-glucuronosyltransferase substrates: a pharmacokinetic explanation for typically observed low exposure (AUCi/AUC) ratios. *Drug Metab Dispos* 32:1201–1208, 2004; Fisher M, Campanale K, Ackermann B, VandenBranden M, Wrighton S: In vitro glucuronidation using human liver microsomes and the pore-forming peptide alamethicin. *Drug Metab Dispos* 28:560–566, 2000.

From a review of the literature, Miners and colleagues report that alamethicin and nonionic detergents like Brij-58 generally result in the highest UGT activity and that alamethicin is the preferred activator because the effects of detergents are not reproducible between substrates (Miners *et al.*, 2006). However, in incubations designed strictly to measure UGT activity (and not both UGT and cytochrome P450 activity), the zwitterionic detergent, CHAPS, can activate certain UGT activities to a comparable or even greater extent than alamethicin.

The in vitro activity of UGT enzymes is highly dependent not only on the substance used to activate the microsomal membranes, but also on incubation conditions. The kinetic properties of UGTs have been demonstrated to vary with the concentration of cofactor, membrane composition, type of buffer, ionic strength, and pH (Miners *et al.*, 2006). In vitro intrinsic clearance (CL_{int}) values (measured as V_{max}/K_m) for zidovudine (AZT) glucuronidation in human liver microsomes were shown to vary sixfold depending on incubation conditions, but even under conditions that produced the greatest CL_{int}, the in vivo clearance rate was under-predicted by three- to fourfold (Miners *et al.*, 2006). This in vitro under-prediction of the in vivo rate of clearance of drugs that are glucuronidated is typical when human liver microsomal kinetic data are used to assess CL_{int}, and is likely due to a number of factors including the presence or absence of albumin, correction for nonspecific binding, atypical in vitro kinetics, active uptake into hepatocytes, and significant extrahepatic expression of various UGTs (Miners *et al.*, 2006). The prediction of the in vivo clearance of drugs that are glucuronidated by hepatocytes appears to be more accurate than for predictions made with microsomes, but under-prediction is still the likely outcome. The case of zidovudine appears to be an exception to this rule, as in
Figure 6-52. Examples of unusual glucuronide conjugates.

vivo clearance values were well-predicted with hepatocytes (Miners *et al*., 2006). The use of either microsomes or recombinant UGT2B7 also appears to under-predict the in vivo magnitude of the *inhibitory* interaction between fluconazole and zidovudine by five- to tenfold (Miners *et al*., 2006). However, when 2% bovine serum albumin (BSA) is added to either systems, there is a decrease in the K_i value of 85% which results in a much improved prediction of the in vivo interaction (Miners *et al*., 2006). The effect of BSA is not due to nonspecific binding; it may involve the removal of inhibitory fatty acids or some as yet unidentified mechanism.

The kinetic properties of UGTs are possibly influenced by the formation of homo- and heterodimers among UGT enzymes and by the formation of heterodimers with other microsomal enzymes such as various CYP enzymes or epoxide hydrolase (Miners *et al*., 2006). For instance, it has been demonstrated that the ratio of morphine 3-glucuronide to morphine 6-glucuronide formed by UGT2B7 is altered by the presence of CYP3A4 (Miners *et al*., 2006). It is not known whether dimerization between UGT2B7 and CYP3A4, if it occurs, also alters the substrate specificity of other individual UGTs, which would have implications for studies designed to determine the substrate specificity of recombinant enzymes, which are invariably expressed individually. Additionally, there is currently no universally accepted method to quantify UGTs in a recombinant preparation, which precludes the accurate determination of relative activity factors, as for recombinant CYP enzymes. Finally, posttranslational modifications to UGTs that occur in vivo in humans (e.g., phsophorylation and N-glycosylation) may not occur in the cell expression system chosen to produce the recombinant UGTs (i.e., bacterial systems), which can impact activity in a substrate-dependent manner (Miners *et al*., 2006). All of these findings suggest that the use of recombinant human UGT enzymes may not provide accurate indications of the extent to which a given UGT can glucuronidate a given substrate.

Cofactor availability can limit the rate of glucuronidation of drugs that are administered in high doses and are conjugated exten-

sively, such as aspirin and acetaminophen. In experimental animals, the glucuronidation of xenobiotics can be impaired in vivo by factors that reduce or deplete UDPGA levels, such as diethyl ether, borneol, and galactosamine. The lowering of UDPGA levels by fasting, such as might occur during a severe toothache or oral cancer, is thought to predispose individuals to the hepatotoxic effects of acetaminophen, although even then hepatotoxicity only occurs with higher-than-recommended doses of this analgesic (Whitcomb and Block, 1994; Rumack, 2004).

The existence of multiple forms of UGT was first suggested by the observation that in rats developmental changes in glucuronidation rates were substrate-dependent, and the glucuronidation of xenobiotics could be differentially affected by the treatment of rats with chemicals known to induce CYP. Based on their ontogeny and inducibility, the UGT activities in rat liver microsomes were categorized into four groups. The activity of enzyme(s) in the first group peaks 1 to 5 days *before* birth, and it is inducible by 3-methylcholanthrene and other CYP1A enzyme inducers. Substrates for the group 1 enzyme(s) tend to be planar chemicals, such as 1-naphthol, 4-nitrophenol, and 4-methylumbelliferone. The activity of enzyme(s) in the second group peaks $\sim$5 days *after* birth and is inducible by phenobarbital and other CYP2B enzyme inducers. Substrates for the group 2 enzyme(s) tend to be bulky chemicals, such as chloramphenicol, morphine, 4-hydroxybiphenyl, and monoterpenoid alcohols. The activity of enzyme(s) in the third group peaks around the time of puberty ($\sim$1 month) and is inducible by PCN and other CYP3A enzyme inducers. Substrates for the group 3 enzyme(s) include digitoxigenin monodigitoxoside (dt_1), a metabolite of digitoxin formed by CYP3A (see Fig. 6-47), and possibly bilirubin. The activity of enzyme(s) in the fourth group also peak around the time of puberty ($\sim$1 month) and is inducible by clofibrate and other CYP4A enzyme inducers. Substrates for the group 4 enzyme(s) include bilirubin but not dt_1, which distinguishes group 3 from group 4 UGTs.

Although this classification system still has some practical value, it has become evident that the four groups of UGTs do

not simply represent four independently regulated enzymes with different substrate specificities. This realization stems from various studies, including those conducted with Gunn rats that are hyperbilirubinemic due to a genetic defect in bilirubin conjugation. The glucuronidation defect in Gunn rats is substrate-dependent in a manner that does not match the categorization of UGTs into the four aforementioned groups. For example, in Gunn rats the glucuronidation of the group 2 substrates, morphine and chloramphenicol, is not impaired, whereas the glucuronidation of 1-naphthol, dt_1 and bilirubin (group 1, 3, and 4 substrates), is low or undetectable. The induction of UGT activity by 3-methylcholanthrene, PCN, and clofibric acid is impaired in Gunn rats, whereas the induction by phenobarbital is normal. (Although phenobarbital does not induce the conjugation of bilirubin in Gunn rats, it does so in normal Wistar rats.)

Only when the UGTs were cloned did it become apparent why the genetic defect in Gunn rats affects three of the four groups of UGTs that are otherwise independently regulated as a function of age and xenobiotic treatment (Owens and Ritter, 1992). It is now apparent that the UGTs expressed in rat liver microsomes belong to two large gene families, UGT1 and UGT2. The former gene family contains at least eight enzymes, all of which belong to the same subfamily designated UGT1A. The individual members of the rat UGT1A subfamily are UGT1A1, 1A2, 1A3, 1A5, 1A6, 1A7, 1A8, and 1A10. Rat UGT1A4 and 1A9 are pseudogenes and are not a member of the rat UGT1A subfamily, although additional members may yet be identified. Additional members of the rat UGT1A subfamily are thought to exist, including the one that glucuronidates digitoxigenin monodigitoxoside (dt_1), a metabolite of digitoxin. The second UGT gene family in rats is divided into two subfamilies, UGT2A and UGT2B; the former contains at least three members (UGT2A1, 2A2, and 2A3) whereas the second contains at least seven members (UGT2B1, 2B2, 2B3, 2B6, 2B8, 2B12, and 2B34). Unlike the UGT1 enzymes (see below), members of the gene family 2 are composed of six exons that are not shared between members, with the exception of UGT2A1, and 2A2. UGT2A1, and 2A2 are encoded by six exons, and the two enzymes arise by differential splicing of the variable first exon to the same set of five exons that lie downstream, similar to UGT1A enzymes (Mackenzie *et al.*, 2005). In contrast, members of family 1 are formed from a single gene with multiple copies of the first exon, each of which can be connected in cassette fashion with a common set of exons (exons 2–5). This arrangement is illustrated in Fig. 6-53 for the human UGT1 gene locus, and will be discussed later in this section. A simplified view of the UGT1A gene locus is that the multiple UGT1A enzymes are constructed by linking different substrate binding sites (encoded by multiple copies of exon 1) to a constant portion of the enzyme (encoded by exons 2–5). This constant region is involved in cofactor binding and membrane insertion. This method of generating multiple forms of an enzyme from a single gene locus is economical, but it is also the genetic equivalent of putting all of one's eggs in the same basket. Whereas a mutation in any one of the UGT2 enzymes affects a single enzyme, a mutation in the constant region of the UGT1 gene affects all enzymes encoded by this locus. In the Gunn rat, a mutation at codon 415 introduces a premature stop signal, so that all forms of UGT encoded by the UGT1 locus are truncated and functionally inactive. The UGTs known to be encoded by the rat UGT1 locus include the 3-methylcholanthrene-inducible enzyme that conjugates planar molecules such as 1-naphthol (UGT1A6 and UGT1A7), the phenobarbital- and clofibric acid-inducible enzyme that conjugates bilirubin (UGT1A1), and the PCN-inducible enzyme that conjugates dt_1. All these UGT1 enzymes are defective in Gunn rats.

As mentioned previously, the second family of rat UGTs, which share less than 50% of amino acid sequence identity with the first family, are divided into two subfamilies (UGT2A and UGT2B). UGT2A1 is expressed specifically in olfactory epithelium where it conjugates a wide variety of substrates. Members of the rat UGT2B subfamily are expressed in liver and various extrahepatic tissues. Members of the UGT2B subfamily are named in the order they are cloned, regardless of the species of origin (much like the nomenclature system for most of the CYP enzymes). UGT2B enzymes have been cloned from rat (forms 1, 2, 3, 6, 8, 12, and 34), humans (forms 4, 7, 10, 11, 15, 17, and 28), mouse (forms 1, 5, 34, 35, 36, 37, and 38), and rabbits (forms 13, 14, and 16). A rabbit UGT has been classified as UGT2C1; however, UGT2C genes in other mammalian species have not been identified.

In rats, at least one UGT2B enzyme (UGT2B1) is inducible by phenobarbital. The gene encoding this enzyme is not defective in Gunn rats; therefore, treatment of Gunn rats with phenobarbital induces the glucuronidation of substrates for UGT2B1. However, UGT2B1 does not conjugate bilirubin (a reaction mainly catalyzed by UGT1A1 and/or UGT1A4), which is why phenobarbital cannot induce the conjugation of bilirubin in Gunn rats. UGT2B1 is the main enzyme responsible for catalyzing the 3-O-glucuronidation of morphine, which is markedly increased by treating of rats with phenobarbital. Whereas Gunn rats are genetically defective in all UGT1A enzymes, LA rats are selectively defective in UGT2B2, which allowed this enzyme to be identified as the principal enzyme responsible for glucuronidating androsterone and triiodothyronine (T_3) in rats (Burchell, 1999).

The mammalian UGT gene superfamily contains four families, UGT1, UGT2, UGT3, and UGT8. To date, at least 22 human UGT enzymes have been identified. The current UGT nomenclature may be found at: http://som.flinders.edu.au/FUSA/ClinPharm/UGT/index.html. Families 1 and 2 preferentially utilize UDPGA as the cofactor, but may use other UDP sugars such as UDP-glucose and UDP-xylose (Mackenzie *et al.*, 2005). UGT3A1 and 3A2 were identified in the human genome, and are ~30% similar to UGT1 and 2 sequences (Mackenzie *et al.*, 2005). The sugar specificity, localization, and activity of UGT3A1 and 3A2 are currently unknown and these enzymes will not be covered in this chapter. Likewise, UGT2A2 and 2A3 have not yet been characterized beyond their gene structure. UGT8A1 utilizes UDP-galactose and is involved in the synthesis of membrane components, which is therefore beyond the scope of this chapter.

The multiple forms of the major drug-metabolizing human UGT are products of either a single UGT1A gene locus (see Fig. 6-52) or multiple UGT2 genes (with the exception of UGT2A1 and 2A2, see below). The human UGT1A locus contains two unique first exons, 1A1 and 1A6, with two clusters of additional exons, 1A2–5 and 1A7–1A13. The polypeptides encoded by the first exons, 1A1 and 1A6, are ~50% identical to one another and to the other polypeptides encoded by the remaining exons, whereas the polypeptides within a cluster are 75–92% identical and this arrangement has been conserved in the rat (Mackenzie *et al.*, 2005). This arrangement allows for 13 potential transcripts (i.e., UGT1A1, 1A2, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, 1A10, 1A11, 1A12, and 1A13), but only nine are translated in vivo into functional enzymes. The genes that are not translated into functional enzymes lack an open reading frame, and are therefore pseudogenes (i.e., UGT1A2, 1A11, 1A12, and 1A13).

The UGT2 genes expressed in humans are UGT2A1, 2A2, 2A3, 2B4, 2B7, 2B10, 2B11, 2B15, 2B17, and 2B28. UGT2B24–27 and 2B29 are pseudogenes. The UGT2 genes are made up of six exons each, which are not shared between subfamily members, with the exception of UGT2A1 and 2A2, and these two genes are >70% similar (Mackenzie *et al.*, 2005). UGT2A1 and 2A2 share five exons with a variable first exon, similar to the UGT1A enzymes, whereas UGT2A3 is made up of six unique exons.

A summary of the current understanding of the tissue distribution and substrate specificity of the human UGT1 and UGT2 enzymes can be found in Table 6-16. Suffice it to say that these enzymes are expressed in a wide variety of tissues, and some enzymes—including UGT1A7, 1A8, 1A10, and 2A1—are expressed only in extrahepatic tissues, which has implications for the common practice of using human liver microsomes to investigate the role of glucuronidation in drug metabolism. Of the hepatically expressed UGT enzymes, UGT1A1, 1A3, 1A4, 1A6, 1A9, 2B7, and 2B15 are considered to be the UGT enzymes most important for hepatic drug metabolism because UGT1A5, 2B4, 2B10, 2B11, 2B17, and 2B28 are reported to have low or negligible activity toward xenobiotics (Miners *et al.*, 2006). UGT1A7, 1A8, and 1A10 expressed in the gastrointestinal tract may also be important for prehepatic elimination of various orally administered drugs. Numerous UGT1 and UGT2 enzymes are expressed throughout the gastrointestinal tract, where they contribute significantly to the first pass elimination of numerous xenobiotics. Several UGT2B enzymes are expressed in steroid-sensitive tissues, such as prostate and mammary gland, where they presumably terminate the effects of steroid hormones.

Probe drugs have been identified for some but not all of the human UGTs, including UGT1A1 (17β-estradiol 3-glucuronidation and bilirubin), UGT1A3 (hexafluoro-1α,25-trihydroxyvitamin D3), UGT1A4 (trifluoperazine), UGT1A6 (serotonin and 1-naphthol), UGT1A9 (propofol), UGT2B7 (morphine 6-glucuronidation and zidovudine [AZT]), and UGT2B15 (*S*-oxazepam) (Miners *et al.*, 2006). The glucuronidation of morphine by UGT2B7 involves conjugation of the phenolic 3-hydroxyl and the alcoholic 6-hydroxyl group in a 7:1 ratio. The 6-*O*-glucuronide is 600 times more potent an analgesic than the parent drug, whereas the 3-*O*-glucuronide is devoid of analgesic activity. UGT2B7 is present in the brain, where it might facilitate the analgesic effect of morphine through formation of the 6-*O*-glucuronide, which presumably does not readily cross the blood–brain barrier and may be retained in the brain longer than morphine (Tukey and Strassburg, 2000). Only UGT2B7 catalyzes the 6-glucuronidation of morphine, whereas several UGTs including UGT1A1, 1A3, 1A6, 1A8, 1A9, 1A10 as well as 2B7 can catalyze the 3-glucuronidation (Stone *et al.*, 2003). Selective probe inhibitors have only been characterized for UGT1A4 (hecogenin) and 2B7 (fluconazole) (Miners *et al.*, 2006).

Drug–drug interactions that are at least partly due to inhibition of UGTs have been reported. For instance, plasma levels of indomethacin are increased about twofold upon coadministration of diflunisal, and in vitro studies indicate that this interaction is due in part to inhibition of indomethacin glucuronidation in the intestine (Gidal *et al.*, 2003; Mano *et al.*, 2006). Valproic acid coadministration increases the AUC of lorazepam and lamotrigine by 20% and 160%, respectively (Williams *et al.*, 2004). In contrast to the situation with CYP enzymes, there are fewer inhibitory drug–drug interactions caused by the inhibition of UGT enzymes, and AUC increases are rarely greater than twofold (Williams *et al.*, 2004), whereas dramatic AUC increases have been reported for CYP enzymes, such as the 190-fold increase in AUC reported for the

CYP1A2 substrate ramelteon (Rozerem^{TM}) upon coadministration of fluvoxamine (Rozerem^{TM} prescribing information, 2005). The low magnitude of UGT-based inhibitory interactions is partly due to the fact that most drugs that are primarily cleared by glucuronidation are metabolized by several UGTs. Drug–drug interactions due to induction of UGT enzymes have also been observed. Rifampin coadministration increases mycophenolic acid clearance by 30%, and increases the AUC of its acyl glucuronide (formed by UGT2B7) and its 7-*O*-glucuronide (formed by various UGT1 enzymes) by more than 100% and 20%, respectively (Naesens *et al.*, 2006).

As mentioned above and as shown in Fig. 6-52, UGTs can form unusual conjugates including bisglucuronides, diglucuronides, *N*-carbamoyl glucuronides, *N*-glucosides, and other glycoside conjugates. Bisglucuronides (i.e., a glucuronide in which two separate functional groups on the aglycone are glucuronidated) are more common than diglucuronides, and include the bisglucuronides of bilirubin, morphine, octylgallate, diosmetin, phenolphthalein, and hydroxylated polycyclic aromatic hydrocarbons (such as hydroxylated chrysene and benzo[*a*]pyrene) (Murai *et al.*, 2006). A diglucuronide is a glucuronide in which a single functional group on the aglycone is conjugated twice resulting in two glucuronosyl groups in tandem (Murai *et al.*, 2006). Diglucuronides of the xenobiotics nalmefene and 4-hydroxybiphenyl, and of the endogenous steroids androsterone, 5α-dihydrotestosterone, 17β-estradiol, estriol, estrone, and testosterone have previously been detected in dogs. Rat liver microsomes do not form diglucuronides of these steroids, whereas monkey liver microsomes form detectable levels of the 5α-dihydrotestosterone, testosterone, and 17β-estradiol diglucuronides, with human liver microsomes forming only the diglucuronide of 5α-dihydrotestosterone (see Fig. 6-52) (Murai *et al.*, 2005). In all cases, it is the 2$'$-hydroxyl group of the first glucuronide moiety that is subject to additional glucuronidation. In the case of 5α-dihydrotestosterone, only human UGT1A8 (an intestinal UGT) has been found to produce the diglucuronide from 5α-dihydrotestosterone itself, although UGT1A4, 2B15, and 2B17 can produce the monoglucuronide, and UGT1A1 and 1A9 can produce the diglucuronide when the monoglucuronide is the substrate (Murai *et al.*, 2006). Human intestinal microsomes form the diglucuronide more efficiently than human liver microsomes, reflecting the fact that UGT1A8, an extrahepatic UGT, is the predominant enzyme involved in the diglucuronidation of 5α-dihydrotestosterone.

N-Carbamoyl glucuronidation has been reported for relatively few primary amines, or the demethylated metabolites of secondary and tertiary amines, and includes drugs such as sertraline (Fig. 6-52), carvedilol, varenicline, mofegiline, garenoxacin, tocainide, and sibutramine (Gipple *et al.*, 1982; Tremaine *et al.*, 1989; Beconi *et al.*, 2003; Hayakawa *et al.*, 2003; Link *et al.*, 2006; Obach *et al.*, 2006). Marked species difference have been found in the formation of *N*-carbamoyl glucuronides, and humans have only been found to produce these conjugates from even fewer drugs, including sertraline, varenicline, and mofegiline. To form this type of conjugate in vitro, the incubation must be performed under a CO_2 atmosphere, in a carbonate buffer. Although not directly demonstrated, it has been hypothesized that a transient carbamic acid intermediate is formed by the interaction of the amine with the dissolved CO_2, followed by glucuronidation (Obach *et al.*, 2005). Because the intermediate is not stable, the hypothesis that UGT also catalyzes the formation of the carbamic acid cannot be disproved. However, in the case of sertraline, and varenicline it is predominantly UGT2B7 that forms the *N*-carbamoyl glucuronide, which also conjugates various carboxylic acids (Obach *et al.*, 2005, 2006). Given that the in vitro

Note that these microsomal enzymes face the lumen of the endoplasmic reticulum.

formation of *N*-carbamoyl glucuronides occurs only under special incubation conditions that are not typically employed, it is possible that many other primary and secondary amines or their oxidative metabolites can be converted to such conjugates but have not been detected because of the unusual incubation conditions required to support the formation of *N*-carbamoyl glucuronides.

Finally, although human UGTs typically are highly selective in the use of UDPGA as a sugar donor, they can accommodate the use of other sugar donors such as UDP-glucose, UDP-galactose, and UDP-xylose in an aglycone-dependent manner, as mentioned previously (Tang and Ma, 2005). For instance, recombinant human UGT1A1 can utilize UDPGA, UDP-xylose, or UDP-glucose to form glycosides, but only with bilirubin (Tang and Ma, 2005). It has also been demonstrated that recombinant human UGT2B7 can glycosidate an endothelin ET_A receptor antagonist with UDPGA, UDP-glucose, and UDP-galactose, but can glycosidate diclofenac with only UDPGA (Tang and Ma, 2005). In the case of an aldose-reductase inhibitor (AS-3201), Toide and colleagues (2004) found that UGT2B4, 2B7, and especially 2B15 all *preferentially* utilize UDP-glucose over UDPGA. Several other compounds have been found to be glucosidated in mammals, including 5-aminosalicylic acid, bromfenac, pranoprofen, pantothenic acid, hyodeoxycholic acid, mycophenolic acid, sulphadimidine, sulphamerazine, sulphamethoxazole, and various barbiturates (e.g., phenobarbital and amobarbital) (Tang and Carro-Ciampi, 1980; Nakano *et al*., 1986; Arima, 1990; Kirkman *et al*., 1998; Toide *et al*., 2004; Picard *et al*., 2005). In the case of the carboxyl-containing amine, bromfenac, the aglycone was observed in rat bile after base hydrolysis, and it was concluded that it was formed by hydrolysis of an acyl glucuronide (Kirkman *et al*., 1998). In later studies to characterize the stability of the putative acyl glucuronide, an *N*-glucoside was detected (Kirkman *et al*., 1998). 5-Aminosalicylic acid is structurally similar to bromfenac in that both NSAIDs contain a primary amine near the carboxyl group, and both are converted to *N*-glucosides (Kirkman *et al*., 1998). In the human metabolism of barbiturates, *N*-glucosides are the major metabolites found in urine, and glucuronides have not been detected. Accordingly, it was theorized that enzymes other

than UGTs may be involved in the conjugation of barbiturates in humans (Toide *et al*., 2004). This latter theory is interesting because liver homogenates from cats, which lack UGT activity, can *N*-glucosidate amobarbital (however, it should be noted that glucose conjugates can sometimes form nonenzymatically) (Carro-Ciampi *et al*., 1985). However, Toide and colleagues (2004) have demonstrated that the N-glucosidation of amobarbital in human liver microsomes correlates highly with the N-glucosidation of AS-3201, but not its N-glucuronidation, indicating that UGT2B15 is probably the predominant human UGT responsible for the glucosidation of amobarbital.

In humans, Crigler–Najjar syndrome (type I and II) and Gilbert disease are congenital defects in bilirubin conjugation. The diseases have historically been differentiated largely on the basis of the severity of symptoms and total plasma concentrations of bilirubin (e.g., Crigler–Najjar Type I: 310–855 μM, Crigler–Najjar Type II: 100–430 μM, and Gilbert disease: 20–100 μM). The major bilirubin-conjugating enzyme in humans is UGT1A1. Genetic polymorphisms in exons 2-5 (which affect all enzymes encoded by the UGT1A locus), in exon 1 (which affect only UGT1A1), in the promoter regions, and in introns 1 and 3 have been identified in patients with Crigler–Najjar syndrome or Gilbert disease. More than 60 genetic polymorphisms are associated with these diseases. A current list of all UGT polymorphisms and phenotypes (when known) can be found at http://galien.pha.ulaval.ca/alleles/alleles.html. Some polymorphisms cause the introduction of a premature stop codon in one of the exons 2-5 (which causes a loss of all UGT1A enzymes, analogous to the Gunn rat) and are associated with type I Crigler–Najjar syndrome, a severe form of the disease characterized by a complete loss of bilirubin-conjugating activity and marked hyperbilirubinemia. Type I Crigler–Najjar syndrome is also associated with various frameshifts and deletions in exons 1-5, and in at least three cases, with changes in introns 1 and 3 that affect splice donor or acceptor sites. Other polymorphisms are associated with the less severe type II Crigler–Najjar syndrome (i.e., UGT1A1*7–9, 12, 26, 30, 33–38, 42, 48, 51, 52, 59, and 64). Individuals with Gilbert disease have an occasionally transient, and generally mild hyperbilirubinemia which

is often caused by the addition of one "TA" segment in the TATA promoter region (i.e., UGT1A1*28: A(TA)$_6$**TAA** → **A(TA)**$_7$TAA). There is some overlap between Crigler–Najjar Type II and Gilbert disease, not only in terms of the plasma concentrations of bilirubin, but also in the type of polymorphism that underlies the disease. In addition to the *28 allele, the *6, *27, *29, *60, and *62 alleles are associated with Gilbert disease, and some of these polymorphisms affect coding regions of the UGT1A1 gene. In addition, the UGT1A1*37 allele produces a A(TA)$_8$TAA promoter defect which results in Crigler–Najjar Type II. A Korean individual heterozygous for three UGT1A1 alleles associated with Gilbert disease (i.e., likely *6, *28, and *60), was found to have total bilirubin concentrations as high as 193 μM (Seok Seo *et al.*, 2007), which is a concentration typically associated with Crigler–Najjar Type II. Crigler–Najjar Type II and Gilbert disease (in contrast to Crigler–Najjar Type I) typically respond to some extent to phenobarbital treatment, which stimulates bilirubin conjugation presumably by inducing UGT1A1. Type I Crigler–Najjar syndrome is also associated with impaired glucuronidation of propofol, ethinylestradiol, and various phenolic substrates for UGT1A enzymes. Polymorphisms that might affect the other UGT1A enzymes have not been thoroughly characterized in vivo, but there are data to suggest that polymorphisms in these enzymes may modify the risk of developing certain types of cancer (Nagar and Remmel, 2006).

The UGT1A1*28 allele has received widespread attention in recent years due to the impact this variant has on the toxicity of the topoisomerase I inhibitor, irinotecan, that is used primarily to treat colorectal cancer. The disposition of irinotecan is complex, with conversion to the active metabolite, SN-38, occurring mainly in the liver by hydrolysis by carboxylesterase. The active metabolite SN-38 is subsequently glucuronidated primarily by UGT1A1, with potential contribution from UGT1A6, 1A7, 1A9, and 1A10 (Nagar and Blanchard, 2006). The UGT1A1*28 variant has now been referenced in the Camptosar® prescribing information, which notes that patients with reduced UGT1A1 activity have a higher exposure to SN-38 (which is 50–100 times more toxic than the glucuronide), and that the dose of irinotecan should be adjusted downward accordingly (Nagar and Blanchard, 2006). The toxicity of SN-38 primarily manifests as severe diarrhea and myelosuppression (in the form of leucopenia, severe thrombocytopenia, severe anemia, or grade 3–4 neutropenia) (Nagar and Blanchard, 2006). Several studies have demonstrated grade 3–4 neutropenia and/or grade 3–4 diarrhea upon irinotecan administration in patients with at least one UGT1A1*28 or *27 allele, and one study implicated *high* activity variants of UGT1A7 and 1A9 with diarrhea (Nagar and Blanchard, 2006). In at least one study, the UGT1A1*28 allele has also been reported to increase the risk of invasive breast cancer in premenopausal women by 1.8-fold, which was attributed to decreased glucuronidation of estradiol, but other studies appear to contradict this finding (Nagar and Remmel, 2006).

Polymorphisms have been identified in UGT2B4, 2B7, 2B15, and 2B28. For example, oxazepam is glucuronidated by UGT2B15, which preferentially glucuronidates *S*-oxazepam over its *R*-enantiomer. Ten percent (10%) of the population appear to be poor glucuronidators of *S*-oxazepam, and one study has implicated the low activity UGT2B15*2 allele as a possible determinant of such variation (Nagar and Remmel, 2006). Such polymorphisms also appear to be the underlying cause of alterations in hyodeoxycholate glucuronidation in gastric mucosa (Tukey and Strassburg, 2000).

Human UGT1A6 glucuronidates acetaminophen and the glucuronidation of acetaminophen in humans is enhanced by cigarette smoking and dietary cabbage and Brussels sprouts, which suggests that human UGT1A6 is inducible by polycyclic aromatic hydrocarbons and derivatives of indole 3-carbinol (Bock *et al.*, 1994). Ligands for the *Ah* receptor, such as those present in cigarette smoke, induce CYP1A2, which would be expected to enhance the hepatotoxicity of acetaminophen. Increased acetaminophen glucuronidation may explain why cigarette smoking does not enhance the hepatotoxicity of acetaminophen. Conversely, decreased glucuronidation may explain why some individuals with Gilbert's syndrome are predisposed to the hepatotoxic effects of acetaminophen (de Morais *et al.*, 1992). Low rates of glucuronidation predispose newborns to jaundice and to the toxic effects of chloramphenicol; the latter was once used prophylactically to prevent opportunistic infections in newborns until it was found to cause severe cyanosis and even death (gray baby syndrome).

Glucuronidation generally detoxifies xenobiotics and potentially toxic endobiotics, such as bilirubin, for which reason glucuronidation is generally considered a beneficial process. However, steroid hormones glucuronidated on the D-ring (but not the A-ring) cause cholestasis, and induction of UGT activity has been implicated as an epigenetic mechanism of thyroid tumor formation in rodents (McClain, 1989; Curran and DeGroot, 1991). Inducers of UGTs cause a decrease in serum thyroid hormone levels, which triggers a compensatory increase in thyroid stimulating hormone (TSH). During sustained exposure to the enzyme-inducing agent, prolonged stimulation of the thyroid gland by TSH (>6 months) results in the development of thyroid follicular cell neoplasia. Glucuronidation followed by biliary excretion is a major pathway of thyroxine biotransformation in rodents whereas deiodination is the major pathway (up to 85%) of thyroxine metabolism in humans. In contrast to the situation in rodents, prolonged stimulation of the thyroid gland by TSH in humans will result in malignant tumors only in exceptional circumstances and possibly only in conjunction with some thyroid abnormality. Therefore, chemicals that cause thyroid tumors in rats or mice by inducing UGT activity are unlikely to cause such tumors in humans. In support of this conclusion, extensive epidemiological data in epileptic patients suggest that phenobarbital and other anticonvulsants do not function as thyroid (or liver) tumor promoters in humans (Parkinson *et al.*, 2006).

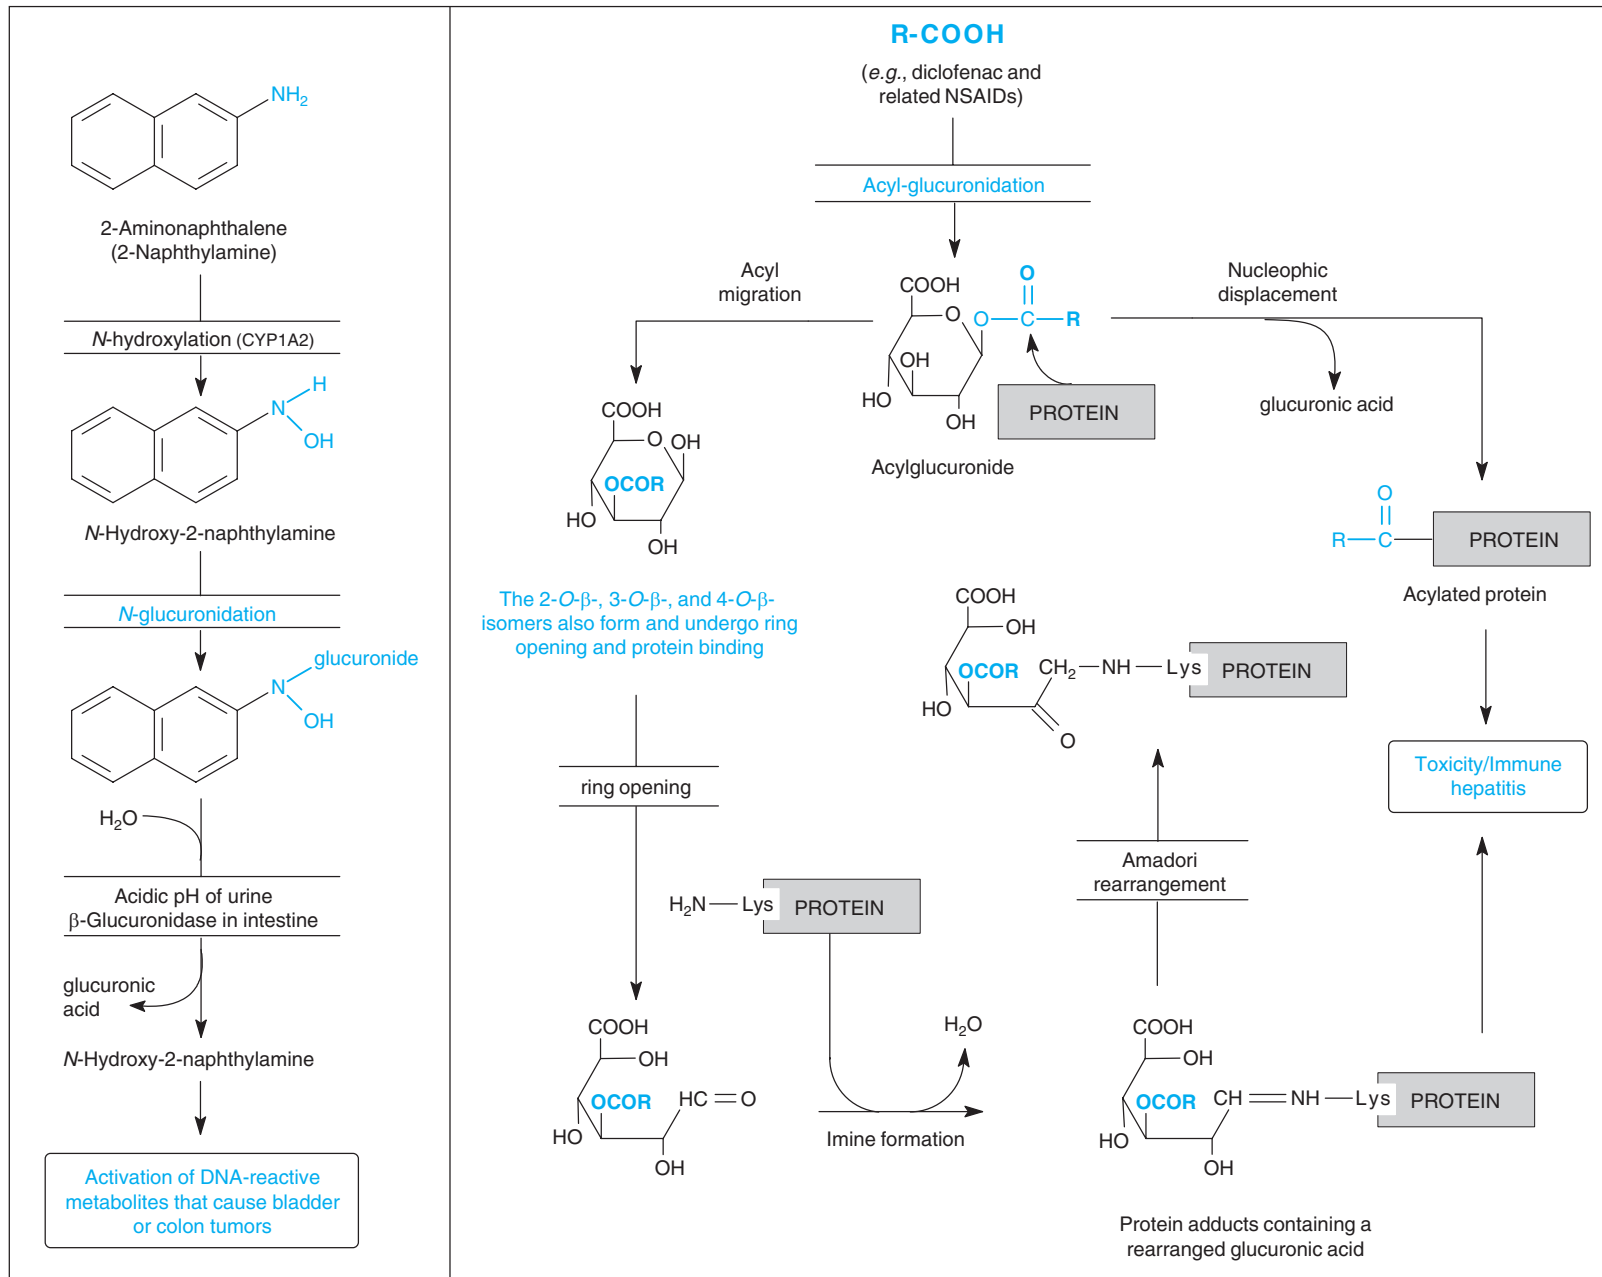
In some cases, glucuronidation represents an important event in the toxicity of xenobiotics. For example, the aromatic amines that cause bladder cancer (such as benzidine, 2-aminonaphthalene, and 4-aminobiphenyl) undergo N-hydroxylation in the liver followed by N-glucuronidation of the resultant *N*-hydroxyaromatic amine, although direct N-glucuronidation also occurs, and is a competing pathway of hepatic metabolism. In the case of 4-aminobiphenyl, the competing pathways of ring hydroxylation and O-esterification (i.e., O-glucuronidation, O-sulfonation, or O-acetylation) are detoxication pathways, whereas N-esterification catalyzed by UGTs, SULTs, or NATs represent activating pathways (see section entitled *Acetylation*) (Cohen *et al.*, 2006). Benzidine and 2-aminonaphthalene are particularly tumorigenic; with accumulating data which demonstrates that the risk of bladder cancer may increase by up to 100-fold in workers exposed to these substances in the course of their occupation in various manufacturing processes (Al-Zoughool *et al.*, 2006). The *N*-glucuronides of such carcinogens, which accumulate in the urine of the bladder, are unstable in acidic pH and thus are hydrolyzed to the corresponding unstable, tumorigenic *N*-hydroxyaromatic amine, as shown in Fig. 6-54. *N*-Hydroxyaromatic amines can give rise to highly electrophilic aromatic nitrenium ions that can bind to DNA and other macromolecules, or they can be


Figure 6-54. *Role of glucuronidation in the activation of xenobiotics to toxic metabolites.*

converted to reactive acetoxy metabolites directly in the bladder epithelium via NAT-mediated O-acetylation, which also leads to the formation of aromatic nitrenium ions (Al-Zoughool *et al.*, 2006). Because N-glucuronidation of aromatic amines can also occur directly without a prior oxidation, this reaction competes with oxidation, and therefore a decrease in UGT activity in the liver would favor N-hydroxylation, with subsequent O-acetylation by NAT and spontaneous formation of aromatic nitrenium ions in the liver, rather than the bladder. In contrast, decreased acetylation with normal UGT activity would lead to a greater accumulation of *N*-hydroxyaromatic amines in the bladder with increased bladder tumor formation. Concordant with this scenario, benzidine has been shown to induce predominantly liver tumors in rats (fast acetylators) but bladder cancer in dogs (poor acetylators) (Al-Zoughool *et al.*, 2006). In humans, there are sex differences in aromatic amine carcinogenicity. Irrespective of ethnicity or race, men are 2.5–5 times more likely to develop bladder cancer than women in general, and in particular male smokers, hairdressers, dye and textile workers who are exposed to aromatic amines have several times increased risk relative to their female counterparts. Male mice, which *N*-glucuronidate 4-aminobiphenyl faster than females, were found during the treatment with this carcinogen to have a 2.2-fold higher rate of DNA-adduct formation, and increased rates of bladder tumor formation relative to females, and female mice were found to have tumors only in the liver (Al-Zoughool *et al.*, 2006). In mice, coadministration of 4-aminobiphenyl with hecogenin, which in humans has been found to inhibit hepatic UGT1A4 (Uchaipichat *et al.*, 2006), was found to increase DNA-adduct formation in a statistically significant manner in the livers of male mice, and to slightly decrease adduct formation in the bladders of both male and female mice (Al-Zoughool *et al.*, 2006). The available literature regarding sex differences in human UGT activity is conflicting. On the one hand, glucuronidation of temazepam, oxazepam, propranolol, and salicylic acid were 20–60% higher in men than in women (Al-Zoughool *et al.*, 2006), whereas 4-methyumbelliferone glucuronidation in cryopreserved human hepatocytes was found to be an average of 40% higher in female samples ($n = 33$), than in male samples ($n = 31$). The carcinogenicity of aromatic amines is multifactorial, and involves not only hepatic N-glucuronidation but also hepatic oxidation, hepatic and bladder acetylation, and possibly peroxidation of *N*-hydroxy-*N*-acetyl aromatic amines in the bladder (Al-Zoughool *et al.*, 2006). Therefore, sex differences in UGT activity alone may not fully explain the sex differences observed in the carcinogenicity of aromatic amines. A similar mechanism may be involved in colon tumor formation by aromatic amines, although in this case hydrolysis of the *N*-glucuronide is probably catalyzed by β-glucuronidase in intestinal microflora.

Some acylglucuronides are reactive intermediates that bind covalently to protein by mechanisms that may or may not result in cleavage of the glucuronic acid moiety, as shown in Fig. 6-54. Several drugs, including the NSAIDs benoxaprofen, bromfenac, diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, indoprofen, ketoprofen, ketorolac, loxoprofen, sulindac, suprofen (very similar to the diuretic, tienilic acid), tiaprofenic acid, tolmetin, and zomepirac, contain a carboxylic acid moiety that can be glucuronidated to form a reactive acylglucuronide that can form covalent adducts with proteins. Acyl glucuronides vary widely in their reactivity, from the highly reactive zomepirac and tolmetin acyl glucuronides to the less reactive acyl glucuronides of ibuprofen and salicylic acid (Shipkova *et al.*, 2003). A relationship between the reactivity of acyl glucuronides and the substitution near the carboxylic acid has been found. In general, α-unsubstituted acetic acid

derivatives such as zomepirac, tolmetin, and diclofenac exhibit the highest degree of covalent binding, while mono-α-substituted acetic acids such as fenoprofen show intermediate levels, and fully substituted α-acetic acids such as furosemide, ketoprofen, ibuprofen, and suprofen exhibit lower levels of covalent binding (Bolze *et al.*, 2002). However, a direct correlation between the ability of acyl glucuronides to give rise to covalent adducts with proteins such as albumin and their ability to cause drug-related toxicity has not been firmly established, and other mechanisms may come into play. For instance, diclofenac is still a widely used drug in spite of the fact that its acyl glucuronide is very reactive, whereas zomepirac, which is less reactive than these other drugs, was withdrawn from the market in 1983 (Chen *et al.*, 2006).

Neoantigens formed by binding of acylglucuronides to protein might be the cause of rare cases of NSAID-induced immune hepatitis. Covalent adducts with proteins in the liver, kidneys, colon, small intestine, skeletal muscle, and bladder were detected in rats administered diflunisal, and in the liver, lungs, and spleen of rats administered diclofenac of UGT activity (Shipkova *et al.*, 2003). Covalent binding of acyl glucuronides appears to be selective, with diclofenac acyl glucuronide forming adducts with dipeptidyl peptidase in rat liver, and with aminopeptidase *N* and sucrase-isomaltase in rat intestine (Shipkova *et al.*, 2003). Human and rat liver UGTs are themselves targets of adducts formed by ketoprofen acyl glucuronide, which may cause nonspecific irreversible inhibition (Shipkova *et al.*, 2003). Binding of acyl glucuronides to protein can involve isomerization reactions that lead to the retention of a rearranged glucuronide moiety (Fig. 6-54). Formation of a common neoantigen (i.e., one that contains a rearranged glucuronic acid moiety) might explain the allergic cross reactivities (cross sensitization) observed among different NSAIDs (Spahn-Langguth and Benet, 1992; Kretz-Rommel and Boelsterli, 1994). There are reports of the detection of antibodies to acyl glucuronide–protein adducts in rats administered diflunisal, and in humans treated with valproic acid (Shipkova *et al.*, 2003). The inherent reactivity of acyl glucuronides (covered above) can be investigated by determining the rate of disappearance of the acyl glucuronide in aqueous buffers at various pH levels (determination of hydrolysis and intramolecular rearrangement), by including human serum albumin to assess the formation of covalently bound adducts, or by the use of a lysine–phenylalanine dipeptide (Lys-Phe) to assess adduct formation. The use of the lysine–phenylalanine dipeptide allows for the rapid quantitative LC/MS/MS analysis of adducts produced by Schiff's base formation (Wang *et al.*, 2004). The rank order of the reactivity of the acyl glucuronides of some carboxylic acid-containing drugs determined by this approach is as follows: tolmetin > zomepirac > diclofenac > ketoprofen > fenoprofen > ibuprofen > furosemide (Wang *et al.*, 2004).

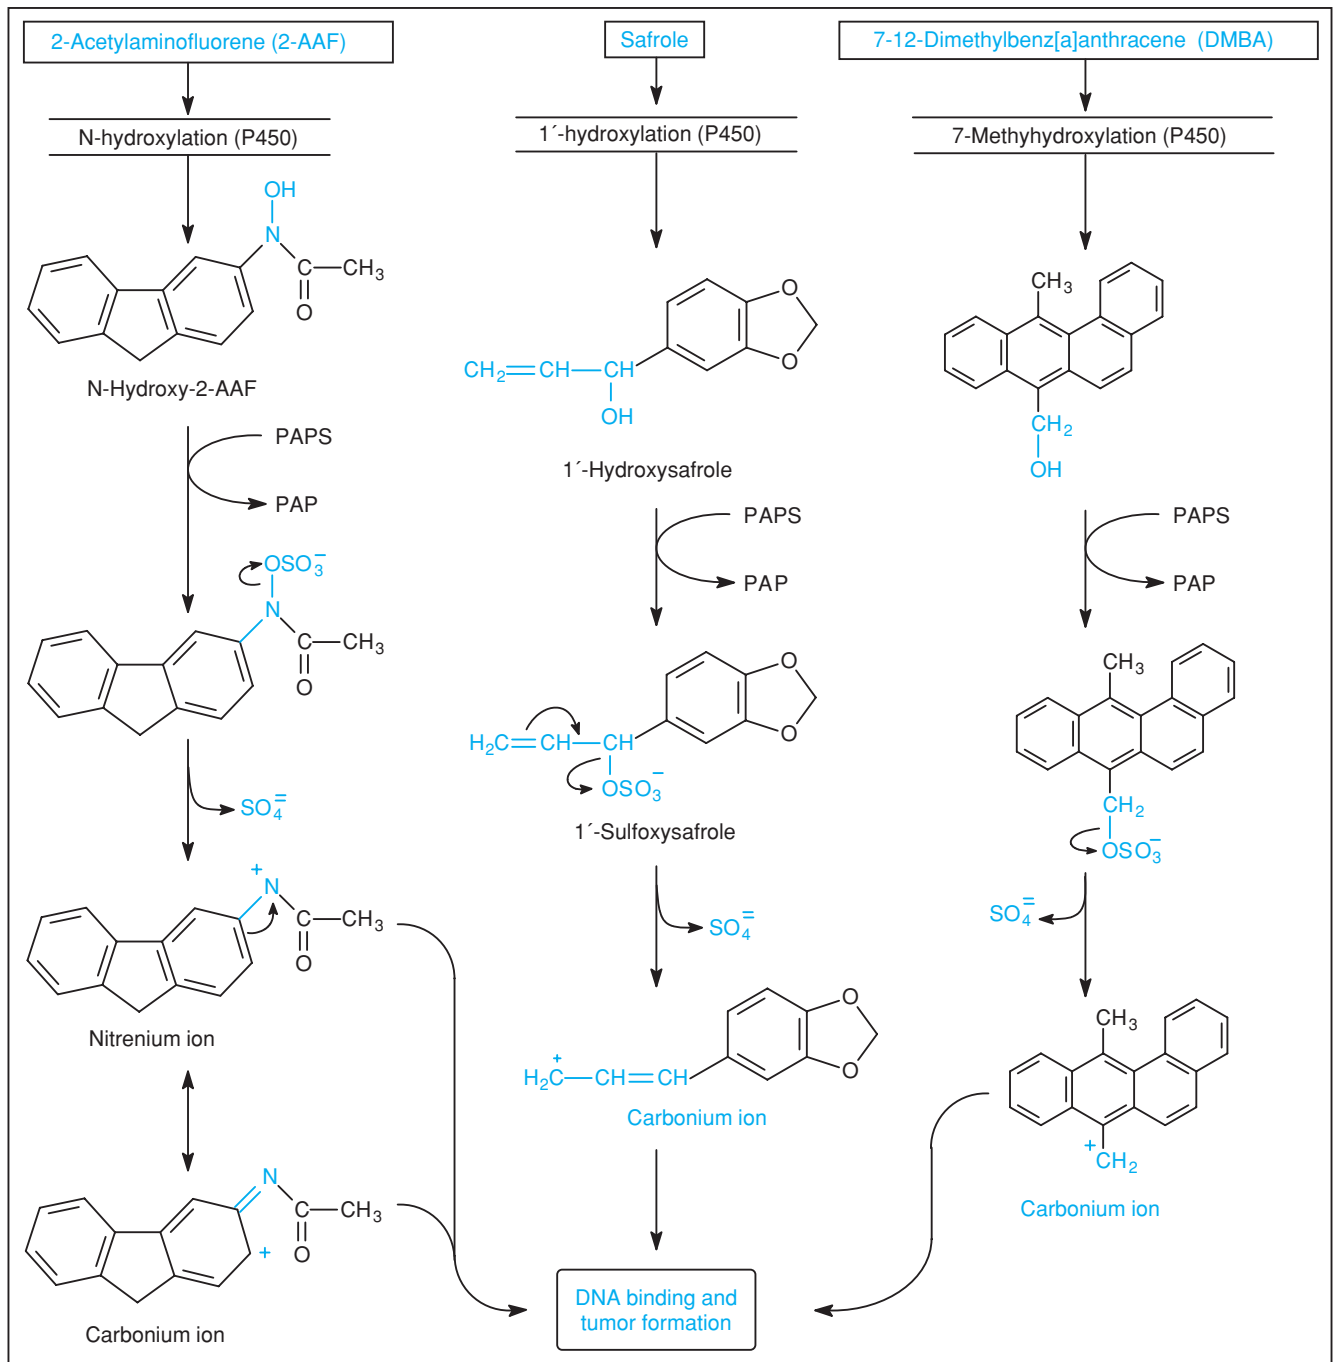
Some glucuronide conjugates have been found to act as substrates for further biotransformation by oxidation or even by further conjugation. For instance, in male Wag/Rij rats, estradiol 17β-glucuronide can be sulfonated by one or more SULTs to estradiol 3-sulfate-17β-glucuronide (Sun *et al.*, 2006). In addition, the acyl glucuronide of 4′-hydroxydiclofenac can be formed either by glucuronidation of the oxidative metabolite of diclofenac, 4′-hydroxydiclofenac (an example of conjugation following oxidation, as historically conceptualized), or the acyl glucuronide of the parent can be 4′-hydroxylated by CYP2C8 (Kumar *et al.*, 2002), (an example of oxidative metabolism occurring after conjugation). Glucuronidation has been shown to convert several other CYP2C9 substrates into CYP2C8 substrates or inhibitors. For instance, CYP2C8 has been shown to catalyze the oxidation of several glucuronides, the aglycones of which are CYP2C9 substrates, including


Figure 6-55. Role of sulfonation in the generation of tumorigenic metabolites (nitrenium or carbonium ions) of 2-acetylaminofluorene, safrole, and 7,12-dimethylbenz[a]anthracene (DMBA).

estradiol 17β-glucuronide and the acyl glucuronides of naproxen, the PPAR-α/agonist MRL-C, and gemfibrozil (Delaforge *et al*., 2005; Kochansky *et al*., 2005; Ogilvie *et al*., 2006). In the case of gemfibrozil, the CYP2C8-mediated hydroxylation of its 1-O-β-glucuronide can apparently lead to the formation of a reactive product that causes irreversible inhibition of this enzyme (Ogilvie *et al*., 2006). The formation of a hydroxylated gemfibrozil acyl glucuronide by CYP2C8 leads to the irreversible inactivation of this enzyme, which leads to significant drug–drug interactions with drugs such as repaglinide and cerivastatin (Ogilvie *et al*., 2006). Kumar and colleagues demonstrated that formation of the acyl glucuronide of 4′-hydroxydiclofenac leads to an underestimation of

hepatic clearance of diclofenac when it is not accounted for. It may also be that oxidation of glucuronide metabolites can lead to toxicity. A case report described the formation of an IgM antibody that bound erythrocytes, but only in the presence of the 4′-hydroxydiclofenac acyl glucuronide in a patient that developed hemolysis during diclofenac treatment (Shipkova *et al*., 2003). A determination of the absolute amount of diclofenac acyl glucuronide formed in vivo relative to the amount of 4′-hydroxydiclofenac formed in vivo would be confounded by the rapid hydrolysis of the glucuronide to the aglycone, and it would therefore be likely that detection of 4′-hydroxydiclofenac acyl glucuronide would be attributed to oxidative metabolism occurring prior to conjugation. Two recent reports

suggest that direct glucuronidation with subsequent oxidation (by a combination of UGT2B7 and CYP2C8 in humans) may be the major determinants of diclofenac clearance in humans (possibly as high as 75%) and monkeys (>90%) (Kumar *et al.*, 2002; Prueksaritanont *et al.*, 2006), as opposed to earlier in vivo data that suggested oxidative metabolism by CYP2C9 alone is the major determinant of clearance (Stierlin and Faigle, 1979; Stierlin *et al.*, 1979). Prueksaritanont and colleagues (2006) further note that there are no clinical reports that implicate pharmacokinetic interactions between diclofenac and potent CYP2C9 inhibitors or inducers. Taken together, these observations suggest that the CYP-mediated oxidation of glucuronide metabolites has implications not only for the prediction of in vivo drug–drug interactions from in vitro data (i.e., gemfibrozil), but also for the prediction of in vivo clearance (i.e., diclofenac), and possibly also toxicity, as in the case of immune-mediated toxicity of diclofenac.

Sulfonation

Many of the xenobiotics and endogenous substrates that undergo O-glucuronidation also undergo sulfonation, as illustrated in Fig. 6-34 for acetaminophen (Mulder, 1981; Paulson *et al.*, 1986). Sulfonation generally produces a highly water-soluble sulfuric acid ester. The reaction is catalyzed by sulfotransferases (SULT), a large multigene family of enzymes found primarily in the liver, kidney, intestinal tract, lung, platelets, and brain. In mammals, there are two major classes of SULTs: (1) membrane-bound SULTs in the Golgi apparatus, and (2) soluble SULTs in the cytoplasm (Gamage *et al.*, 2006). The membrane-bound SULTs are responsible for the sulfonation of glycosaminoglycans, proteins, and peptides such as cholecystokinin, factors V and VIII, α-2-glycoprotein, gastrin, and p-selective glycoprotein ligand-1, thereby modulating their structure and function. At least five different Golgi-resident N-acetylglucosamine 6-O-sulfotransferases have been identified in humans. They are important for many biological processes including cell–cell adhesion, axon function, T-cell response, cell proliferation, and modulation of viral and bacterial infection (reviewed by Grunwell and Bertozzi, 2002), but they have no activity toward xenobiotics (Wang and James, 2006). Brachymorphic mice are undersized because the defect in PAPS synthesis prevents the normal sulfonation of glycosaminoglycans and proteoglycans, such as heparin and chondroitin, which are important components of cartilage. These particular sulfonation reactions are catalyzed by membrane-bound sulfotransferase, which are thought not to play a role in xenobiotic sulfonation. This section will focus on the cytosolic SULTs, which are known for the sulfonation of various drugs, mutagens, flavonoids, and other xenobiotics, as well as endogenous substrates such as bile acids, thyroid hormones, catecholamine neurotransmitters, and steroids.

The cofactor for the sulfonation reaction is $3'$-phosphoadenosine-$5'$-phosphosulfate (PAPS), the structure of which is shown in Fig. 6-49. The sulfonation of aliphatic alcohols and phenols, R-OH, proceeds as follows:

$$R{-}OH \; + \; \underset{adenosine}{phospho\text{-}} {-}O{-}\overset{O^-}{\underset{O}{P}}{-}O{-}\overset{O}{\underset{O}{S}}{-}O^- \; \longrightarrow$$

$$R{-}O{-}\overset{O}{\underset{O}{S}}{-}O^- \; + \; \underset{adenosine}{phospho\text{-}} {-}O{-}\overset{O^-}{\underset{O}{P}}{-}O^- \; + \; H^+$$
Sulfonation involves the transfer of sulfonate not sulfate (i.e., SO_3^- not SO_4^-) from PAPS to the xenobiotic. SULTs are single α/β

globular proteins that contain a PAPS-binding site which is present on a characteristic five-stranded β-sheet along with the core of the catalytic site. The central β-sheet is surrounded by α-helices (Wang and James, 2006). The sulfonate donor PAPS is synthesized from inorganic sulfate (SO_4^{2-}) and ATP in a two-step reaction. The first reaction is catalyzed by ATP sulfurylase, which converts ATP and SO_4^{2-} to adenosine-$5'$-phosphosulfate (APS) and pyrophosphate. The second reaction is catalyzed by APS kinase, which transfers a phosphate group from ATP to the $3'$-position of APS. The major source of sulfate required for the synthesis of PAPS appears to be derived from cysteine through a complex oxidation sequence. Because the concentration of free cysteine is limited, the cellular concentrations of PAPS (4–80 μM) are considerably lower than those of UDP-glucuronic acid (200–350 μM) and glutathione (5–10 mM). This topic has been thoroughly reviewed, and is outside the scope of this chapter (Klaassen and Boles, 1997). The relatively low concentration of PAPS limits the capacity for xenobiotic sulfonation. In general, sulfonation is a high-affinity but low-capacity pathway of xenobiotic conjugation, whereas glucuronidation is a low-affinity but high-capacity pathway. Acetaminophen is one of the several xenobiotics that are substrates for both sulfotransferases and UDP-glucuronosyltransferases (see Fig. 6-34). The relative amount of sulfonate and glucuronide conjugates of acetaminophen is dependent on dose. At low doses, acetaminophen sulfonate is the main conjugate formed due to the high affinity of sulfotransferases. As the dose increases, the proportion of acetaminophen conjugated with sulfonate decreases, whereas the proportion conjugated with glucuronic acid increases. In some cases, even the absolute amount of xenobiotic conjugated with sulfonate can decrease at high doses apparently because of substrate inhibition of sulfotransferase.

Sulfonation is not limited to phenols and aliphatic alcohols (which are often the products of oxidative or hydrolytic biotransformation), although these represent the largest groups of substrates for sulfotransferases. Certain aromatic amines, such as aniline and 2-aminonaphthalene, can undergo sulfonation to the corresponding sulfamates. The primary amines in cisapride and DPC423 can also be directly N-sulfonated. The N-oxide group in minoxidil and the N-hydroxy group in N-hydroxy-2-aminonaphthalene and N-hydroxy-2-acetylaminofluorene can also be sulfonated. In all cases, the conjugation reaction involves nucleophilic attack of oxygen or nitrogen on the electrophilic sulfur atom in PAPS with cleavage of the phosphosulfate bond. Table 6-17 lists some examples of xenobiotics and endogenous compounds that are sulfonated without prior biotransformation by oxidative enzymes. An even greater number of xenobiotics are sulfonated after a hydroxyl group is exposed or introduced during oxidative or hydrolytic biotransformation.

Carboxylic acids can be conjugated with glucuronic acid but not with sulfonate. However, a number of carboxylic acids, such as benzoic acid, naphthoic acid, naphthylacetic acid, salicylic acid, and naproxen, are competitive inhibitors of sulfotransferases (Rao and Duffel, 1991). Pentachlorophenol and 2,6-dichloro-4-nitrophenol are potent sulfotransferase inhibitors because they bind to the enzyme but cannot initiate a nucleophilic attack on PAPS due to the presence of electron-withdrawing substituents in the *ortho*- and *para*-positions on the aromatic ring.

Sulfonate conjugates of xenobiotics are excreted mainly in urine. Those excreted in bile may be hydrolyzed by aryl sulfatases present in gut microflora, which contributes to the enterohepatic circulation of certain xenobiotics. Sulfatases are also present in the endoplasmic reticulum and lysosomes, where they primarily hydrolyze sulfonates of endogenous compounds presumably in a

Table 6-17

Properties of the Human Cytosolic Sulfotransferases (SULTs)

HUMAN SULT	MAJOR TISSUE DISTRIBUTION	MAJOR SUBSTRATES[a]
SULT1A1	Liver (very high), platelets. placenta, adrenals, endometrium, colon, jejunum, brain leukocytes	**4-Nitrophenol**, 4-ethylphenol, 4-cresol, 2-naphthol, other phenols, acetaminophen, minoxidil, *N*-hydroxy-PhIP, T2, T3, 17β-estradiol (and other phenolic steroids), dopamine, benzylic alcohols, 2-nitropropane, aromatic amines, hydroxylamines, hydroxamic acids, apomorphine, troglitazone,
SULT1A2	Liver, bladder tumors	4-Nitrophenol, *N*-hydroxy-2-acetylaminofluorene, 2-naphthol, aromatic hydroxylamines, hydroxamic acids
SULT1A3	Jejunum and colon mucosa (very high), platelets, placenta, brain, leukocytes	**Dopamine**, 4-nitrophenol, 1-hydroxymethylpyrene, norepinephrine, salbutamol, dobutamine
SULT1A4	Liver, pancreas, colon, brain[b]	Not characterized. Likely similar to SULT1A3
SULT1B1	Colon (highest), liver, leukocytes	4-Nitrophenol, T2, T3, r-T3, T4, dopamine, benzylic alcohols
SULT1C2	Fetal lung and kidney, kidney, stomach, thyroid gland	4-Nitrophenol, *N*-hydroxy-2-AAF, aryl hydroxylamines, thyroid hormones
SULT1C4	Kidney, ovary, spinal cord, fetal kidney, fetal lung	4-Nitrophenol, *N*-hydroxy-2-AAF, 17β-estrone, bisphenol-A, 4-octylphenol, nonylphenol, diethylstilbestrol, 1-hydroxymethylpyrene
SULT1E1	Liver (highest), endometrium, jejunum, adrenals, mammary epithelial cells, fetal liver	**17β-Estradiol**, estrone, ethinyl estradiol, 17β-estrone, equilenin, 2-hydroxy-estrone, 2-hydroxy-estradiol, 4-hydroxy-estrone, 4-hydroxy-estradiol, diethylstilbestrol, tamoxifen, thyroid hormones, 4-hydroxylonazolac, pregnenolone, dehydroepiandrosterone, 1-naphthol, naringenin
SULT2A1	Liver (highest), adrenals, jejunum, brain	**Dehydroepiandrosterone (DHEA)**, 1-hydroxymethylpyrene, 6-hydroxymethylbenzo[*a*]pyrene, hycanthone, bile acids, pregnenolone, testosterone, androgens, estrone, 17β-estradiol, other hydroxysteroids, budenoside
SULT2B1_v1	Placenta (highest), prostate, trachea, skin	Dehydroepiandrosterone, pregnenolone, oxysterols, other hydroxysteroids
SULT2B1_v2		**Cholesterol**, dehydroepiandrosterone, other hydroxysteroids
SULT4A1_v1	Brain: cortex, globus pallidus, islands of Calleja, septum, thalamus, red nucleus, substantia nigra and pituitary	Endogenous: 4 unidentified compounds from mouse brain homogenate.[c] Other: T3, T4, estrone, 4-nitrophenol, 2-naphthylamine, 2-naphthol[d]
SULT4A1_v2		

Substrates in bold are reported to be selective probe substrates for the SULT listed (Coughtrie and Fisher, 2005).

[a] T4 is thyroxine. T2 and T3 are di- and tri-iodothyronine.

[b] Data from Bradley, Benner (2005).

[c] Sakakibara *et al*.: Reported that recombinant human SULT4A1 expressed in *E. coli* (and subsequently purified) sulfonated four distinct endogenous substances from mouse brain homogenate (2002).

[d] Sakakibara *et al*.: Reported that recombinant human SULT4A1 expressed in *E. coli* (and subsequently purified) sulfonated these prototypical SULT substrates (2002).

Adapted from Gamage N, Barnett A, Hempel N, *et al*.: Human sulfotransferases and their role in chemical metabolism. *Toxicol Sci* 90:5–22, 2006; Wang LQ, James MO: Inhibition of sulfotransferases by xenobiotics. *Curr Drug Metab* 7:83–104, 2006; Blanchard RL, Freimuth RR, Buck J, Weinshilboum RM, Coughtrie MW: A proposed nomenclature system for the cytosolic sulfotransferase (SULT) superfamily. *Pharmacogenetics* 14:199–211, 2004.

manner analogous to that described for microsomal β-glucuronidase (Dwivedi *et al*., 1987) (see comments on egasyn in section "Carboxylesterases"). Sulfonation facilitates the deiodination of thyroxine and triiodothyronine and can determine the rate of elimination of thyroid hormones in some species. Inhibition of SULTs can occur with exposure to drugs such as mefenamic acid, salicylic acid, clomiphene, danazol, environmental chemicals, such as hydroxylated PCBs, hydroxylated PAHs, pentachlorophenol, triclosan, and bisphenol A, and dietary constituents, such as catechins, colorants, phytoestrogens, and flavonoids. Adverse effects on human health can potentially result from SULT inhibition, such as the thyroid hormone disruption that occurs with exposure to hydroxylated PCBs (Wang and James, 2006). In contrast, given that some sulfonate conjugates are chemically reactive, inhibition of their formation may be protective. There are a few reports of drug–drug interactions due to SULT inhibition. It has been reported that the sulfonation rates of both acetaminophen and salicylamide are decreased when these drugs are coadministered, and dapsone and lamivudine have been found to decrease acetaminophen sulfonation (Wang and James, 2006). Coadministration of acetaminophen with ethinyl estradiol increases its AUC by up to 54% and decreases the AUC of ethinyl estradiol sulfate by ~40%, indicating that acetaminophen may directly inhibit one or more SULTs (Rogers *et al*., 1987). Drug–drug interactions involving induction of SULT are detailed later in this section.

Sulfonation may represent a benign metabolic pathway compared with competing pathways that can lead to the activation of promutagens and procarcinogens. For instance, sulfonation of hydroquinones, phenols, and aminophenols can prevent or reduce the formation of reactive quinones, semiquinones, and quinone amines. Sulfonation of aromatic amines such as 2-amino-3,8-dimethylimidazo-[4,5-f]quinoxaline (MelQx), which leads to sulfamate formation can compete with activation by N-O-acetylation or sulfonation (Wang and James, 2006).

Like glucuronide conjugates, some sulfonate conjugates are substrates for further biotransformation. For instance, the 7- and 4-sulfates of daidzein and genistein can be sulfonated by SULT1E1 to disulfates (Nakano *et al.*, 2004). Other examples include the oxidation of sulfonate conjugates of testosterone and estrogens. Dehydroepiandrosterone-3-sulfate is 16α-hydroxylated by CYP3A7, the major CYP enzyme expressed in human fetal liver (Ingelman-Sundberg *et al.*, 1975; Kitada *et al.*, 1987; Ohmori *et al.*, 1998). CYP2C12, which is expressed in female but not male rats, catalyzes the oxidation of a steroid *di*-sulfate (namely, 5α-androstane-3α,17β-diol-3,17-disulfate) (Ryan *et al.*, 1984).

Multiple sulfotransferases have been identified in all mammalian species examined. An international workshop approved the abbreviation "SULT" for sulfotransferase (although ST remains a common abbreviation) and developed a nomenclature system based on amino acid sequences (and, to some extent, function). SULT nomenclature is available on line at: http://www.fccc.edu/research/labs/blanchard/sult/accessions.html. The SULTs are arranged into gene families that share at least 45% amino acid sequence identity. The nine gene families identified to date (vertebrate: SULT1–SULT6; insect: SULT101; and plant: SULT201–SULT202) are subdivided into subfamilies that are at least 60% identical (Blanchard *et al.*, 2004; Gamage *et al.*, 2006). For example, SULT1 is divided into five subfamilies designated SULT1A–SULT1E. Two SULTs that share more than 60% similarity are considered individual members of the same subfamily. For example, SULT1A1, SULT1A2, SULT1A3, and SULT1A4 are four individual members of the human SULT1A subfamily. In general, the first published sequence in a subfamily is designated as enzyme 1 and subsequent enzymes within that subfamily are assigned on the basis of percentage amino acid identity relative to the "1" enzyme (Blanchard *et al.*, 2004). Exceptions to this rule have been made to maintain historical use of a name (e.g., SULT2A1). Variant forms with different amino acid sequences encoded by the same gene are designated by "vn" at the end. For instance, the SULTs initially referenced as SULT2B1a and SULT2B1b are now called SULT2B1_v1 and SULT2B1_v2. Although nine SULT gene families have been identified, these have not been identified in all mammalian species. Currently, SULT1 and SULT2 are the only gene families subdivided into multiple subfamilies (five in the case of SULT1 [SULT1A–1E]; two in the case of SULT2 [SULT2A and SULT2B]).

Most of the SULTs cloned belong to one of the two families, SULT1 and SULT2. These two families are functionally different; the SULT1 enzymes catalyze the sulfonation of phenols, isoflavones, the procarcinogen *N*-OH-2-acetylaminofluorene, endogenous compounds such as 17β-estradiol (including its glucuronide conjugate; see section "Glucuronidation"), and other steroids, iodothyronines, endogenous catecholamines, and eicosanoids. The SULT2 enzymes catalyze the sulfonation of the 3β-hydroxy groups of steroids with unsaturated A rings, bile acids, benzylic alcohols of polycyclic aromatic hydrocarbons, and other primary and secondary alcohols. A sulfotransferase that catalyzes the sulfonation of heterocyclic amines such as 2-naphthylamine, desipramine, and aniline (to form sulfamates) has been cloned from rabbit and mouse (SULT3A1).

SULT4A1 has been identified in rat, mouse, and human. These enzymes are expressed in the cerebral cortex, cerebellum, pituitary, and brainstem and do not sulfonate typical SULT substrates (Blanchard *et al.*, 2004; Gamage *et al.*, 2006). These SULTs share ~97% amino acid sequence identity across species, which suggests that SULT4A1 likely serves a critical endogenous function. The SULT4A1 sequence has also been identified as SULT5A1,

but the 4A1 nomenclature has been retained. A separate gene, SULT5A1, has been cloned from mouse, but no information on its function is available. SULT6A1 has been cloned from chicken liver, and the recombinant enzyme was found to sulfonate 17β-estradiol and corticosterone (Blanchard *et al.*, 2004). SULT201 and 202 represent two families of plant SULTs. SULTT101A1 is an insect SULT cloned from *Spodoptera frugiperda* and converts retinol to anhydroretinol via a retinyl sulfate intermediate (Blanchard *et al.*, 2004). SULT101A also exhibits sulfotransferase activity toward ethanol, dopamine, vanillin, 4-nitrophenol, serotonin, and hydroxybenzylhydrazine (Blanchard *et al.*, 2004). Thirteen cytosolic SULTs have been cloned from rat, and they belong either to the SULT1, SULT2, or SULT4 gene families. The individual rat enzymes are SULT1A1, 1B1, 1C1, 1C2, 1C3, 1D1, 1E1, 1E2, 2A1, 2A2, 2A3, 2A4, and 4A1.

Eleven genes encoding 13 cytosolic SULTs have been identified in humans, and they belong either to the SULT1, SULT2, or SULT4 gene families. The individual human enzymes are listed in Table 6-17. Various single-nucleotide polymorphisms have been reported in most of the SULT genes with rare single-base deletions in SULT1A2 and 4A1 (Glatt and Meinl, 2004). With a few exceptions, the functional consequences of most of these polymorphisms remain unknown. Several of the human SULT genes have multiple initiation sites for transcription, which produces different mRNA transcripts. Consequently, in some cases, different versions of the same human SULT gene have been cloned several times. For example, there are three alternative first exons (exons 1a, 1b, and 1c) in the human SULT1A3 gene (none of which contains a coding region), and five SULT1A3 cDNAs have been cloned from various human tissues, each with a unique 5′-region (Nagata and Yamazoe, 2000).

Historically, human liver cytosol was found to contain two phenol sulfotransferase activities (PST) that could be distinguished by their thermal stability; hence, they were known as TS-PST (*thermally stable*) and TL-PST (*thermally labile*) (Weinshilboum, 1992a; Weinshilboum *et al.*, 1997). It is now known that TS-PST actually reflects the activity of two SULTs, namely, SULT1A1 and SULT1A2 which share 93% identity, whereas TL-PST reflects the activity of SULT1A3 (and likely SULT1A4), which is 60% similar to both SULT1A1 and 2 (Gamage *et al.*, 2006). Hence, the four members of the SULT1A gene subfamily in human were represented functionally by TS-PST and TL-PST activity. SULT1A1 and SULT1A2 function as homo- and heterodimers, and are coregulated. Although these two individual SULTs are not catalytically identical, they are sufficiently similar to consider them as the single activity traditionally known as TS-PST. Because of differences in their substrate specificity, SULT1A1/2 and 1A3 were also known as phenol-PST and monoamine-PST, respectively. SULT1A3 preferentially catalyzes the sulfonation of dopamine, epinephrine, and levodopa, whereas SULT1A1 and 1A2 preferentially catalyze the sulfonation of simple phenols, such as phenol, 4-nitrophenol, minoxidil, and acetaminophen. SULT1A1 and 1A2 also catalyze the *N*-sulfonation of 2-aminonaphthalene. SULT1A1/2 and SULT1A3 can also be distinguished by differences in their sensitivity to the inhibitory effects of 2,6-dichloro-4-nitrophenol.

The expression of SULT1A1 and 1A2 in human liver is largely determined by genetic factors, which also determines the corresponding sulfotransferase activity in blood platelets. Inherited variation in platelet SULT1A1 and 1A2 largely reflects genetic polymorphisms in these enzymes. One allelic variant of SULT1A1 known as SULT1A1*2 ($Arg_{213} \rightarrow His_{213}$) is associated with decreased activity

in platelets but not liver, and decreased thermal stability (Glatt and Meinl, 2004). This particular genetic polymorphism is common in both Caucasians and Nigerians (with an allele frequency of 0.31 and 0.37, respectively), and is correlated with interindividual variation in the sulfonation of acetaminophen. Low SULT1A1 and 1A2 activity predisposes individuals to diet-induced migraine headaches, possibly due to impaired sulfonation of unidentified phenolic compounds in the diet that cause such headaches. A fourth member of the human SULT1A subfamily, SULT1A4, has been recently described, which appears to be a duplication of SULT1A3, and these two enzymes share >99% sequence identity (Bradley and Benner, 2005; Gamage *et al*., 2006). The genes for both of these SULTs lie on chromosome 16p, which contains a segmental duplication that results in two nearly identical, transcriptionally active copies of SULT1A3 and SULT1A4. Each copy shares exons with an adjacent copy of SULT1A1. Four nonsynonymous SNPs were reported for these genes, which show different enzyme activities (Gamage *et al*., 2006).

Human SULT1B1, like the corresponding enzyme in other species, catalyzes the sulfonation of thyroid hormones, 2-naphthol, and dopamine. SULT1B1 levels in human liver cytosol vary widely, possibly due to polymorphisms (e.g., $Glu_{186} \rightarrow Gly_{186}$ and $Glu_{204} \rightarrow Asp_{204}$) (Glatt and Meinl, 2004). SULT1B1 is also expressed in human colon, small intestine, and blood leukocytes. Humans have two SULT1C enzymes (SULT1C2 and SULT1C4). Their function has not been determined, although the corresponding rat enzyme (SULT1C1) catalyzes the sulfonation of *N*-hydroxy-2-acetylaminofluorene (see Fig. 6-55). SULT1C2 is expressed at high levels in the thyroid, stomach, and kidneys (Blanchard *et al*., 2004). High levels of SULT1C4 are expressed in fetal liver and kidney, with hepatic levels declining in adulthood, but it is also present in adult ovary and brain.

Human SULT1E1 has been identified as a high affinity estrogen sulfotransferase. SULT1A1 also catalyzes the sulfonation of estrogens, such as 17β-estradiol, but it does so with a much lower affinity than does SULT1E1. The sulfonation of ethinyl estradiol in human hepatocytes is inducible by rifampin (Li *et al*., 1999), which raises the possibility that SULT1E1 is an inducible enzyme. In addition to human liver, SULT1E1 is expressed in placenta, breast, brain, testes, adrenal glands, and uterine tissue. SULT1E1 has been studied in SULT1E1-deficient mice, and it was shown that these mice had spontaneous fetal loss caused by placental thrombosis, which was reversible by administration of antiestrogens (Gamage *et al*., 2006).

SULT2A1 is the human alcohol sulfotransferase, long known as DHEA-ST (for its ability to sulfonate dehydroepiandrosterone). In addition to DHEA, substrates for SULT2A1 include steroid hormones, bile acids, and cholesterol. Furthermore, SULT2A1 converts several procarcinogens to electrophilic metabolites, including hydroxymethyl polycyclic aromatic hydrocarbons, *N*-hydroxy-2-acetylaminofluorene, and 1′-hydroxysafrole, as shown in Fig. 6-55. The thermal stability of SULT2A1 is intermediate between that of the four phenol SULTs (SULT1A1/2 and 1A3/4), and the enzyme is resistant to the inhibitory effects of 2,6-dichloro-4-nitrophenol. SULT2A1 is not expressed in blood platelets, but the activity of this enzyme has been measured in human liver cytosol. SULT2A1 is also expressed in adrenal cortex, brain, and intestine (Blanchard *et al*., 2004). SULT2A1 is bimodally distributed, possibly due to a genetic polymorphism that apparently lies outside of the coding region, and perhaps outside of the *SULT2A1* gene itself, with a high activity group composed of ~25% of the population (Glatt and Meinl,

2004). Several SULT2A1 SNPs have been identified, but the underlying basis for the high activity group remains to be determined as these polymorphisms appear to be too rare to explain the bimodal distribution.

Human SULT2B1 is also a DHEA-sulfotransferase. It is expressed in placenta, prostate, and trachea. The SULT2B1 gene can be transcribed from one of the two exons, both of which contain coding sequences, hence, two forms of SULT2B1 (known as 2B1_v1 and 2B1_v2) with different N-terminal amino acid sequences can be transcribed by alternate splicing of precursor mRNA. This situation is analogous to the alternative splicing of multiple exons 1 in the UGT1 gene family (see Fig. 6-53). SULT2B1_v1 appears to catalyze the sulfonation of pregnenolone, and SULT2B1_v2 can catalyze the sulfonation of both pregnenolone and cholesterol (Blanchard *et al*., 2004).

The SULT enzymes were previously categorized into five classes based on their catalytic activity. These five functional classes were: *Arylsulfotransferase*, which sulfonates numerous phenolic xenobiotics; *alcohol sulfotransferase*, which sulfonates primary and secondary alcohols including nonaromatic hydroxysteroids (for which reason these enzymes are also known as hydroxysteroid SULTs); *estrogen sulfotransferase*, which sulfonates estrone and other aromatic hydroxysteroids; *tyrosine ester sulfotransferase*, which sulfonates tyrosine methyl ester and 2-cyanoethyl-*N*-hydroxythioacetamide, and *bile salt sulfotransferase*, which sulfonates conjugated and unconjugated bile acids. The *arylsulfotransferase* and *estrogen sulfotransferase* are composed largely of SULT1 enzymes, which catalyze the sulfonation of phenolic xenobiotics, catechols, and aromatic (phenolic) steroids. The *alcohol sulfotransferase* and *bile salt sulfotransferase* are composed largely of SULT2 enzymes, which catalyze the sulfonation of a variety of primary and secondary alcohols, bile acids, and hydroxysteroids (such as dehydroepiandrosterone or DHEA).

In rats, sulfotransferase activity varies considerably with the sex and age. In mature rats, phenol sulfotransferase activity (SULT1A activity) is higher in males, whereas alcohol sulfotransferase and bile acid sulfotransferase activities (SULT2 activities) are higher in females. Sex differences in the developmental expression of individual sulfotransferases are the result of a complex interplay between gonadal, thyroidal, and pituitary hormones, which similarly determine sex differences in CYP enzyme expression. However, compared with CYP enzymes, the SULTs are refractory or only marginally responsive to the enzyme-inducing effects of 3-methylcholanthrene and phenobarbital, although one or more individual SULT2 enzymes are inducible by PCN. Likewise, SULT1A1, 2A1, or 2E1 expressed in Caco-2 cells are refractory to various polycyclic aromatic hydrocarbons, and 3-methylcholanthrene has no effect on SULT1A1 and 1A3 mRNA levels in primary human hepatocytes (Gamage *et al*., 2006). From rodent studies, it is generally held that AhR agonists have suppressive effects on SULT regulation. 2-AAF, TCDD, 3-methylcholanthrene, and β-naphthoflavone markedly suppress SULT1A1 and 2A activities and mRNA levels in rat livers (Gamage *et al*., 2006). In contrast, there is evidence that the rat liver hydroxysteroid SULTs (SULT2s) may be inducible by tamoxifen and estrogens (Gamage *et al*., 2006). For mouse SULT2A2, a functional nuclear response element responsive for CAR has been reported (Gamage *et al*., 2006). Human SULT2A1 has been reported to be regulated by FXR, PXR, VDR, and PPARα, whereas SULT1A1, 2A1, and 2A9 genes in mice are regulated by CAR (Tirona and Kim, 2005; Gamage *et al*., 2006). There are conflicting data regarding the influence of CAR ligands on

SULT1A1 and 1A3. One study reports an 11-fold increase in SULT1A1 mRNA in primary human hepatocytes by the CAR ligand, CITCO, whereas another study could not reproduce these results for either SULT1A1 or 1A3 (Gamage *et al.*, 2006). The glucocorticoid, dexamethasone, has been reported to induce both murine and human SULT2A1 through PXR and GR activation (Gamage *et al.*, 2006). Human SULT2A1 mRNA and protein have also been reported to be induced by rifampin, vitamin D$_3$, phenobarbital, TCPOBOP, and the PPARα-agonist, ciprofibrate (Runge-Morris and Kocarek, 2005).

Induction of SULTs by rifampin, on the other hand, may be clinically relevant. Rifampin (600 mg q.d.) has been reported to cause up to a 190% increase in the clearance of ethinyl estradiol (35 μg q.d.) (Barditch-Crovo *et al.*, 1999). The interaction between ethinyl estradiol-containing oral contraceptives and antibiotics such as rifampin is often attributed to the induction of CYP3A4, which is the major CYP involved in the *oxidative* metabolism of ethinyl estradiol (e.g., Ortho-Evra® prescribing information, 2005). Several lines of evidence suggest that induction of CYP3A4 is not the predominant mechanism by which rifampin increases the clearance of ethinyl estradiol. First, Li and colleagues (1999) reported that treatment of primary cultures of human hepatocytes with rifampin (33.3 μM) caused up to a 3.3-fold increase in ethinyl estradiol 3-*O*-sulfate formation. Second, SULTs 1A1, 1A2, 1A3, 1E1, and 2A1 catalyze the 3-*O*-sulfonation of ethinyl estradiol with K_m values ranging from 6.7 to 4500 nM, nearer the pharmacologically relevant concentrations (Schrag *et al.*, 2004). Finally, it is known that ethinyl estradiol is predominantly excreted in bile and urine as the 3-sulfate and, to a lesser extent, the 3-glucuronide (Li *et al.*, 1999), which suggests that 3-sulfonation is the major pathway of ethinyl estradiol metabolism. Taken together, these data suggest that induction of SULTs can be clinically relevant at least for low-dose drugs that can be sulfonated with high affinity.

Extrapolation of animal data with regard to biotransformation by SULTs is confounded by the number of SULTs, the expression pattern of SULTs and pronounced sexual dimorphisms in many rodents (Gamage *et al.*, 2006). For instance, expression of SULTs in humans appears to have a largely extrahepatic pattern, whereas rodent SULT expression is predominantly hepatic. For instance, based on RT-PCR measurements of mRNA levels in human tissues, SULT1A3 is expressed at the greatest level in the small intestine, 1B1 in the colon, 2B1 in the placenta, and 4A1 in the brain (Nishimura and Naito, 2006). Of the SULTs that have been characterized by RT-PCR in various human tissues, only SULT1A1, 1E1, and 2A1 are predominantly expressed in the liver (Nishimura and Naito, 2006).

Additionally, humans have four members of the SULT1A subfamily whereas rodents have only one. In contrast, rats have four members of the SULT2A subfamily, whereas humans have only a single SULT2A gene. Human equivalents of mouse SULT3A1 and 5A1 have not yet been identified in humans (Gamage *et al.*, 2006). There are also significant differences between other mammalian species. For instance, sulfotransferase activity is low in pigs but high in cats. The high sulfotransferase activity in cats offsets their low capacity to conjugate xenobiotics with glucuronic acid.

In general, sulfonation is an effective means of decreasing the pharmacological and toxicological activity of xenobiotics. There are cases, however, in which sulfonation increases the toxicity of foreign chemicals because certain sulfonate conjugates are chemically unstable and degrade to form potent electrophilic species. As shown in Fig. 6-55, sulfonation plays an important role in the acti-

vation of aromatic amines, methyl-substituted polycyclic aromatic hydrocarbons, and safrole to tumorigenic metabolites. To exert its tumorigenic effect in rodents, safrole must be hydroxylated by CYP to 1′-hydroxysafrole, which is then sulfonated to the electrophilic and tumor-initiating metabolite, 1′-sulfooxysafrole (Boberg *et al.*, 1983). 1′-Hydroxysafrole is a more potent hepatotumorigen than safrole. Two lines of evidence support a major role for sulfonation in the hepatotumorigenic effect of 1′-hydroxysafrole. First, the hepatotumorigenic effect of 1′-hydroxysafrole can be inhibited by treating mice with the sulfotransferase inhibitor, pentachlorophenol. Second, the hepatotumorigenic effect of 1′-hydroxysafrole is markedly reduced in brachymorphic mice, which have a diminished capacity to sulfonate xenobiotics because of a genetic defect in PAPS synthesis. The sulfo-conjugates of benzylic and allylic alcohols, aromatic hydroxylamines, and hydroxamic acids (including those in cooked meat) are short-lived electrophiles capable of reacting with nucleophilic substances including proteins and DNA (Wang and James, 2006). Sulfonation can also convert procarcinogens and promutagens to electrophilic nitrenium or carbocation intermediates such as *N*-hydroxy-2-acetylaminofluorene (N-OH-AAF), 1-hydroxymethylpyrene (1-HMP), 1′-hydroxysafrole, and the cooked food mutagen *N*-hydroxy-2-amino-1-methyl-6-phenylimidazo(4,5-b)pyridine (N-OH-PhIP) (Wang and James, 2006).

Some drugs must be converted to a sulfonate conjugate to exert their desired effect, including triamterene, cicletanine, and minoxidil (Wang and James, 2006). Sulfonation (as well as glucuronidation) converts morphine to more potent analgesics than the parent, with morphine 6-sulfate being 30 times more potent and with morphine-6-glucuronide being 45–800 times more potent than morphine itself in rats (Wang and James, 2006). Similarly, several sulfonated steroids such as pregnenolone sulfate and DHEA sulfate interact directly with neurotransmitter receptors. It has been found that pregnenolone sulfate and DHEA sulfate enhance memory in mice. Prevention of hydrolysis of these sulfates by the steroid sulfatase inhibitor, (*para*-*O*-sulfamoyl)-*N*-tetradecanoyl tyramine, increases the memory enhancement caused by DHEA sulfate in rats, which suggests there is an important role of these sulfates in the central nervous system (Wang and James, 2006).

Polymorphisms with consequences for the bioactivation of xenobiotics have been reported. For instance, the human SULT1A*Arg (*1) allelozyme expressed in *Salmonella typhinurium* is 12- to 350-fold more active in the sulfonation of 2-acetylamino-4-hydroxyaminotoluene, 2-nitropropoane, 2,4-dinitrobenzylalcohol, (–)-1-(α-hydroxyethyl) pyrene, and 1-hydroxymethylpyrene to mutagens than are cells expressing SULT1A1*His (Gamage *et al.*, 2006). Enantioselective sulfonation of promutagens has been reported, as in the case of 1-(α-hydroxyethyl) pyrene, for which SULT2A1 exhibits a 15-fold preference for the (+)-enantiomer, and SULT1E1 exhibits a 160-fold preference for the (–)-enantiomer (Gamage *et al.*, 2006).

Methylation

Methylation is a common but generally minor pathway of xenobiotic biotransformation. Methylation differs from most other conjugation reactions because it generally decreases the water solubility of xenobiotics and masks functional groups that might otherwise be metabolized by other conjugating enzymes. One exception to this rule is the N-methylation of pyridine-containing xenobiotics, such as nicotine, which produces quaternary ammonium ions that

are water soluble and readily excreted. Another exception is the S-methylation of thioethers to form positively charged sulfonium ions, a reaction catalyzed by thioether methyltransferase (TEMT), which has only been identified in mice (Weinshilboum *et al.*, 1999). The cofactor for methylation is *S*-adenosylmethionine (SAM), the structure of which is shown in Fig. 6-49. The methyl group bound to the sulfonium ion in SAM has the characteristics of a carbonium ion and is transferred to xenobiotics and endogenous substrates by nucleophilic attack from an electron-rich heteroatom (*O*, *N*, or *S*). Consequently, the functional groups involved in methylation reactions are phenols, catechols, aliphatic and aromatic amines, *N*-heterocyclics, and sulfhydryl-containing compounds. The conversion of benzo[*a*]pyrene to 6-methylbenzo[*a*]pyrene is a rare example of C-methylation. Another reaction that appears to involve C-methylation, the conversion of cocaine to ethylcocaine, is actually a transesterification reaction, as shown in Fig. 6-4. Metals can also be methylated. Inorganic mercury and arsenic can both be dimethylated, and inorganic selenium can be trimethylated. The selenium atom in ebselen is methylated following the ring opening of this antiinflammatory drug. Some examples of xenobiotics and endogenous substrates that undergo O-, N-, or S-methylation are shown in Fig. 6-56. During these methylation reactions, SAM is converted to *S*-adenosyl-L-homocysteine (SAH). This section will cover the following methyltransferases: AS3MT, COMT, GNMT, HNMT, INMT, NNMT, PNMT, POMT (TMT), TEMT, and TPMT. Other methyltransferases that have been implicated as drug metabolizing enzymes include GAMT and PEMT (Nishimura and Naito, 2006).

The O-methylation of phenols and catechols is catalyzed by two different enzymes known as catechol-*O*-methyltransferase (COMT) and the enzyme historically termed phenol *O*-methyltransferase (POMT) (Weinshilboum, 1989, 1992b). POMT is a microsomal enzyme that methylates phenols but not catechols, and COMT is both a cytosolic and microsomal enzyme with the converse substrate specificity, i.e., an absolute requirement for catechol substrates (Weinshilboum, 2006). COMT plays a greater role in the biotransformation of catechols than POMT plays in the biotransformation of phenols. It should be noted that there is strong evidence to suggest that the membrane-bound POMT is the same enzyme as TMT (Weinshilboum, 2006). COMT was originally described as a cytosolic, Mg^{2+}-requiring, monomeric enzyme (Mr 25,000). However, in rats and humans, the enzyme is encoded by the COMT gene (on chromosome 22 in humans) with two different promoters and transcription initiation sites. Transcription at one site produces a cytosolic form of COMT, whereas transcription from the other site produces a membrane-bound form by adding 50 hydrophobic amino acids to the N-terminal of the microsomal COMT, which targets this form to the endoplasmic reticulum (Weinshilboum *et al.*, 1999; Weinshilboum, 2006). The microsomal COMT is expressed at high levels in the brain and lymphocytes (Weinshilboum, 2006). The cytosolic form of COMT is present in virtually all tissues, including erythrocytes, but the highest concentrations are found in liver and kidney. The membrane-bound form is more highly expressed in brain.

Substrates for COMT include several catecholamine neurotransmitters, such as epinephrine, norepinephrine, and dopamine; and catechol drugs, such as the anti-Parkinson's disease agent L-dopa (3,4-dihydroxyphenylalanine) and the antihypertensive drug methyldopa (*α*-methyl-3,4-dihydroxyphenylalanine). Catechol estrogens, which are formed by 2- or 4-hydroxylation of the steroid A-ring, are substrates for COMT, as are drugs that are converted

to catechols either by two consecutive hydroxylation reactions (as in the case of phenobarbital and diclofenac), by ring opening of a methylenedioxy group (as in the case of stiripentol and 3,4-methylenedioxymethamphetamine), or by hydrolysis of vicinal esters (as in the case of ibopamine). Formation of catechol estrogens, particularly 4-hydroxyestradiol, has been suggested to play an important role in estrogen-induced tumor formation in hamster kidney, rat pituitary, and mouse uterus (Zhu and Liehr, 1993) (see section "CYP1B1"). These tissues contain high levels of epinephrine or dopamine, which inhibit the O-methylation of 4-hydroxyestradiol by COMT. Nontarget tissues do not contain high levels of catecholamines, which suggests that 4-hydroxyestradiol induces tumor formation in those tissues that fail to methylate and detoxify this catechol estrogen. These observations in animals are especially intriguing in view of subsequent epidemiological evidence demonstrating that low COMT activity appears to increase the risk of breast cancer, with odds ratios ranging from 1.7 to 3.0 (Weinshilboum, 2006).

In the 1970s, when COMT levels in erythrocytes (predominantly the cytosolic form) were measured in human subjects, it was apparent that there was a subpopulation that displayed low levels of this enzyme. Segregation analysis indicated that erythrocyte COMT activity was an autosomal codominant trait, and that erythrocyte levels correlated with relative COMT levels in liver and lymphocyte cytosol (Weinshilboum, 2006). It was subsequently found that COMT is encoded by a single gene with alleles for a low activity form (COMT^L) and high activity form (COMT^H) (Weinshilboum, 1989, 1992b, 2006; Weinshilboum *et al.*, 1999). This polymorphism results from a single G → A transition in exon 4 that results in the substitution Val^{108}Met in cytosolic COMT and Val^{158}Met in microsomal COMT (Weinshilboum *et al.*, 1999; Weinshilboum, 2006). The presence of methionine at position 108 in the cytosolic enzyme not only decreases the catalytic activity of COMT, but it decreases the thermal stability of the enzyme, which has long been used to differentiate COMT^L (thermolabile) from COMT^H (thermostable). In Caucasians, these allelic variants are expressed with equal frequency, so that 25% of the population is homozygous for either the low or high activity enzyme, and 50% is heterozygous and have intermediate COMT activity. COMT activity is generally higher in Asians and African Americans due to a higher frequency of the COMT^H allele (~0.75 for Asians and African Americans vs. ~0.5 for Caucasians [McLeod *et al.*, 1994]). Subsequent resequencing of the COMT gene has revealed numerous single-nucleotide polymorphisms, with at least eight that occur with a frequency >10% in Caucasians, and 11 such SNPs in African Americans. Several of these SNPs are found in the intronic regions. A list of current COMT (and many other) alleles can be found at http://alfred.med.yale.edu/alfred/index.asp.

The genetically determined levels of COMT in erythrocytes correlate with individual differences in the proportion of L-dopa converted to 3-*O*-methyldopa and the proportion of methyldopa converted to its 3-*O*-methyl metabolite. O-Methylation is normally a minor pathway of L-dopa biotransformation, but 3-*O*-methyldopa is the major metabolite when L-dopa is administered with a dopa decarboxylase inhibitor, such as carbidopa or benserazide, which is common clinical practice. High COMT activity, resulting in extensive O-methylation of L-dopa to 3-*O*-methyldopa, has been associated with poor therapeutic management of Parkinson's disease and an increased incidence of drug-induced toxicity (dyskinesia). A large number of epidemiological studies have been performed to examine the effects of the COMT Val$^{108/158}$Met polymorphism, and there is no evidence that the genetic polymorphism in COMT represents a risk modifier for the development of Parkinson's disease
Figure 6-56. Examples of compounds that undergo O-, N-, or S-methylation.

(Weinshilboum *et al.*, 1999). However, Egan and colleagues have demonstrated that COMT genotype was related in an allele-dosage manner to cognitive performance, with individuals homozygous for Met[108] (COMT[L] phenotype) demonstrating increased executive cognition, as measured by the Wisconsin Card Sorting Test (Egan *et al.*, 2001). The impact of the Met[108] allele was attributed to decreased dopamine catabolism in the prefrontal cortex, which results in enhanced neuronal function. Conversely, those individuals who are homozygous for Val[108] (COMT[H] phenotype) appear to have decreased executive cognition, and may be at a slightly increased risk of developing schizophrenia (Egan *et al.*, 2001).

Several *N*-methyltransferases have been described in humans and other mammals, including phenylethanolamine *N*-methyltransferase (PNMT), which catalyzes the N-methylation of the neurotransmitter norepinephrine to form epinephrine; histamine *N*-methyltransferase (HNMT), which specifically methylates the imidazole ring of histamine and closely related compounds (Fig. 6-56); and nicotinamide *N*-methyltransferase (NNMT), which methylates compounds containing a pyridine ring, such as nicotinamide, or an indole ring, such as tryptophan and serotonin (Weinshilboum, 1989, 1992b; Weinshilboum *et al.*, 1999). PNMT is a cytosolic enzyme expressed at high levels in adrenal medullary chromafin cells, and in neurons of the medulla oblongata, hypothalamus, as well as in sensory nuclei of the vagus nerve and the retina,

and is not thought to play a significant role in the biotransformation of xenobiotics (Ji *et al.*, 2005).

Histamine *N*-methyltransferase is a cytosolic enzyme (Mr 33,000) which is highly expressed in kidney, liver, colon, prostate, ovary, and spinal cord cells (Horton *et al.*, 2005). Its activity (which can be measured in erythrocytes) varies sixfold among individuals due to a genetic polymorphism (C → T) that results in a point mutation, namely Thr[115]Ile. The latter allele (Ile[115]) is quite common in Caucasians and Han Chinese (10% frequency) and encodes a variant of HNMT with decreased catalytic activity and thermal stability. HNMT may influence efficacy of some drugs by a mechanism that is not yet fully understood. For instance, individuals who are heterozygous for the Ile[115] allele have been found to exhibit significantly decreased methylprednisolone-induced cortisol suppression relative to (Thr[115])-homozygous individuals (Hon *et al.*, 2006). Several other polymorphisms in the noncoding region of the HNMT gene have also been identified. HNMT can be inhibited by several antihistamines, quinacrine, amodiaquine, metoprine, and tacrine (Horton *et al.*, 2005).

NNMT is a monomeric, cytosolic enzyme (Mr ~30,000) that appears to be a member of a family of methyltransferases that includes PNMT and TEMT (the thioether *S*-methyltransferase present in mouse lung). NNMT catalyzes the N-methylation of nicotinamide and structurally related pyridine compounds (including pyridine

itself) to form positively charged pyridinium ions. Nicotinic acid (niacin), a commonly used lipid-lowering agent, is converted to nicotinamide in vivo, which is then methylated by NNMT (or it is incorporated into nicotinamide adenine dinucleotide, NAD). In contrast to many other methyltransferases, NNMT is not expressed in erythrocytes.

Nicotinamide N-methyltransferase activity in human liver, like HNMT activity in erythrocytes, varies considerably from one individual to the next, and has a trimodal distribution dependent on variations in mRNA and protein levels, and up to 25% of the general population have high NNMT levels (Souto et al., 2005; Williams et al., 2005). It is not known to what extent genetic polymorphisms account for this variation. However, 10 SNPs in the untranslated regions of the gene have been detected in a Spanish population (Souto et al., 2005). A genome-wide scan for genes associated with plasma homocysteine levels determined that there was a statistically significant association with the NNMT gene, and, moreover that one SNP (dbSNP ID#: rs694539), has a greater statistically significant association with homocysteine levels ($p = 0.017$) (Souto et al., 2005). Homocysteine plasma levels are an independent intermediate risk marker for osteoporotic fractures, congestive heart failure, venous thrombosis, myocardial infarction, stroke, and Alzheimer's disease (Souto et al., 2005). In humans, the only source of homocysteine is from the demethylation of methionine in a multi-step pathway that involves SAM-dependent methyltransferases to form S-adenosylhomocysteine, the immediate precursor to homocysteine. Taken together, these data suggest that high methyltransferase activity could contribute to hyperhomocysteinemia. Of the many SAM-dependent methyltransferase genes examined for an association with homocysteine levels, only NNMT (which is highly expressed in the liver) was found to show a significant association (Souto et al., 2005). NNMT is reported to be expressed in the brain and has been implicated as a component of the etiology of idiopathic Parkinson disease because it can convert 4-phenylpyridine to MPP$^+$, which is known to cause Parkinson's disease symptoms due to its toxic effect on neuronal mitochondria (see section "Monoamine Oxidase, Diamine Oxidase, and Polyamine Oxidase" and Fig. 6-28) (Williams et al., 2005).

There are numerous other human N-methyltransferases (as well as O-, S-, and C-methyltransferases) that appear to play relatively specific roles in the methylation of endogenous compounds, and most have not been well-characterized with regard to their capability to methylate xenobiotics (there are at least 39 SAM-dependent methyltransferases in humans [Souto et al., 2005]). For instance, indolethylamine N-methyltransferase (INMT) catalyzes the N-methylation of tryptamine and structurally related compounds (Thompson et al., 1999). Other such enzymes that were initially thought to play a role only in the N-methylation of endogenous compounds were later found to play a role, albeit a minor one, in the N-methylation of one or more xenobiotics. Amine N-methyltransferase (AMNT, also called arylamine N-methyltransferase or nicotine N-methyltransferase), which is highly expressed in human thyroid and is also found in adrenal gland and lung, exhibits some activity toward tryptamine and has been also found to preferentially methylate the pyridine nitrogen of R-nicotine, which gives rise to nicotine isomethonium ions (Hukkanen et al., 2005). Glycine N-methyltransferase (GNMT) is thought to play an important role in the regulation of methyl group metabolism in the liver and pancreas through regulation of the ratio between S-adenosyl-L-methionine and S-adenosyl-L-homocysteine. Rat data show that the tetrameric form of the GNMT has catalytic activity,

and the dimeric form binds polycyclic aromatic hydrocarbons. There is also evidence that the dimeric form of human GNMT sequesters benzo[a]pyrene, and thereby decreases its cytotoxic effects (Chen et al., 2004b; Lee et al., 2006).

The system that is used to classify human N-methyltransferases may not be appropriate for other species. In guinea pigs, for example, nicotine and histamine are both methylated by a common N-methyltransferase. Guinea pigs have an unusually high capacity to methylate histamine and xenobiotics. The major route of nicotine biotransformation in the guinea pig is methylation, although R-nicotine is preferentially methylated over its S-enantiomer (Cundy et al., 1985). Guinea pigs also methylate the imidazole ring of cimetidine.

S-Methylation is an important pathway in the biotransformation of sulfhydryl-containing xenobiotics, such as the antihypertensive drug captopril, the antirheumatic agent D-penicillamine, the antineoplastic and immunosuppressive drugs 6-mercaptopurine, 6-thioguanine, and azathioprine, metabolites of the alcohol deterrent disulfiram, and the deacetylated metabolite of the antidiuretic, spironolactone. In humans, S-methylation is catalyzed by at least two enzymes, thiopurine methyltransferase (TPMT) and thiol methyltransferase (TMT, which may be the same enzyme as POMT).

TPMT is a cytoplasmic enzyme that preferentially methylates aromatic and heterocyclic compounds such as the thiopurine drugs 6-mercaptopurine, 6-thioguanine, and azathioprine. TMT is a microsomal enzyme that preferentially methylates aliphatic sulfhydryl compounds such as captopril, D-penicillamine, and disulfiram derivatives. TMT has also been found to methylate the heterocyclic thiol-containing leaving groups of some cephalosporins (Wood et al., 2002), the thiazolidinedione drug, MK-0767, a dual α/γ peroxisome proliferator-activated receptor (PPAR) agonist (Karanam et al., 2004; Kochansky et al., 2006), dithiothreitol (Weinshilboum, 2006), and some thiofuran flavoring agents (Lake et al., 2003). Although a gene that encodes TMT has not yet been definitively identified, there is strong evidence to suggest that the membrane-bound POMT is the same enzyme as TMT, which means that TMT could also catalyze the O-methylation of phenols (Weinshilboum, 2006).

Both TMT and TPMT are present in erythrocytes at levels that reflect the expression of TPMT and TMT in liver and other tissues. Although TPMT and TMT are independently regulated, their expression in erythrocytes is largely determined by genetic factors. TPMT is encoded by a single gene with alleles for a low activity form (TPMT^L) and for a high activity form (TPMT^H). The allele frequency of TPMT^L and TPMT^H are 0.06 and 0.94, respectively, which produces a tri-modal distribution of TPMT activity with low, intermediate, and high activity expressed in 0.3, 11.1, and 88.6% of Caucasians, respectively. At least 21 separate genetic polymorphisms are associated with low TPMT activity, with the *2, *3A, and *3C alleles accounting for greater than 95% of the TPMT^L phenotype (Weinshilboum, 2006). In Caucasians, the allele that is most commonly associated with the TPMT^L phenotype is TPMT*3A (5%), which contains two nonsynonymous single-nucleotide polymorphisms: Ala$_{154}$Thr and Tyr$_{240}$Cys (Weinshilboum, 2006). These amino acid changes (and those in the TPMT*3B and *3C variants) lead to aggregation and rapid degradation of expressed TPMT by a ubiquitin/proteasome-dependent mechanism (Wang et al., 2005a).

Cancer patients with low TPMT activity are at increased risk for thiopurine-induced myelotoxicity, in contrast to the potential need for higher-than-normal doses to achieve therapeutic levels of

thiopurines in patients with high TPMT activity (Weinshilboum, 1989, 1992b). The thiopurine drugs metabolized by TPMT have a relatively narrow therapeutic index, and are used to treat life-threatening illnesses such as acute lymphoblastic leukemia or organ-transplant patients. The thiopurines are also oxidized by xanthine oxidase, but since there is extensive variation in TPMT activity and xanthine oxidase is not present in hematopoietic tissues, TPMT activity in these tissues is more important in the avoidance of life-threatening myelosuppression at standard doses (Weinshilboum, 2006). Phenotyping for the TPMT genetic polymorphism represents one of the first examples in which testing for a genetic variant has entered standard clinical practice (Weinshilboum *et al.*, 1999). The clinical relevance of TPMT polymorphisms is reflected by the inclusion of TPMT as a "valid biomarker" for pharmacogenomics, along with CYP2D6 polymorphisms, in the FDA's 2005 "Guidance for Pharmacogenomic Data Submission." TPMT can be inhibited by benzoic acid derivatives, which also complicates therapy with drugs that are metabolized by TPMT. Patients with inflammatory bowel disorders such as Crohn disease are often treated with thiopurine drugs, which are metabolized by TPMT, and with sulfasalazine or olsalazine, which are potent TPMT inhibitors. The combination of these drugs can lead to thiopurine-induced myelosuppression.

A genetic polymorphism for TMT also has been described, but its pharmacological and toxicological significance remain to be determined. The molecular basis for the polymorphism has not been determined, but studies have shown that 98% of the five-fold individual variation in erythrocyte TMT activity is due to inheritance, with an allele for high TMT activity having a frequency of 0.12. TMT is relatively specific for aliphatic sulfhydryl compounds such as 2-mercatoethanol, captopril, D-penicillamine, and *N*-acetylcysteine. TMT also rapidly methylates a dihydro-metabolite of ziprasidone that is formed by aldehyde oxidase as shown in Fig. 6-3 (Obach and Walsky, 2005). TMT is present at high levels in the colonic mucosa and is also expressed in liver microsomes and erythrocyte membranes. TMT is not inhibited by benzoic acid derivatives, but it is inhibited by the cytochrome P450 inhibitor proadifen (a.k.a. SKE-525A) (Weinshilboum *et al.*, 1999).

Some of the hydrogen sulfide produced by anaerobic bacteria in the intestinal tract is converted by *S*-methyltransferases to methane thiol and then to dimethylsulfide. Another source of substrates for *S*-methyltransferases is the thioethers of glutathione conjugates. Glutathione conjugates are hydrolyzed to cysteine conjugates, which can either be acetylated to form mercapturic acids or cleaved by cysteine-conjugate β-lyase (CCBL1). This β-lyase pathway converts the cysteine conjugate to pyruvate, ammonia, and a sulfhydryl-containing xenobiotic, which is a potential substrate for S-methylation.

Methylation can also lead to increased toxicity. A recently characterized methyltransferase, AS3MT (previously called Cyt19), methylates inorganic arsenic to form methylarsonic and dimethylarsonic acids, which are more cytotoxic and genotoxic than arsenate and arsenite (Wood *et al.*, 2006). As many as 27 polymorphisms have been identified in this gene, with two rare alleles that cause markedly decreased activity and immunoreactive protein levels, and one frequent allele (i.e., ~10% in both African Americans and Caucasians) that causes increased activity and immunoreactive protein levels (Wood *et al.*, 2006). Up to 1% of African Americans and Caucasians would be expected to be homozygous for the allele that encodes the high activity AS3MT, and this may potentially lead to increased arsenic toxicity in such individuals.

Acetylation

N-Acetylation is a major route of biotransformation for xenobiotics containing an aromatic amine ($R–NH_2$) or a hydrazine group ($R–NH–NH_2$), which are converted to aromatic amides ($R–NH–COCH_3$) and hydrazides ($R–NH–NH–COCH_3$), respectively (Evans, 1992). Xenobiotics containing primary aliphatic amines are rarely substrates for N-acetylation, a notable exception being cysteine conjugates, which are formed from glutathione conjugates and converted to mercapturic acids by N-acetylation in the kidney (see section "Glutathione Conjugation"). Like methylation, N-acetylation masks an amine with a nonionizable group, so that many *N*-acetylated metabolites are less water soluble than the parent compound. Nevertheless, N-acetylation of certain xenobiotics, such as isoniazid, facilitates their urinary excretion.

The N-acetylation of xenobiotics is catalyzed by *N*-acetyltransferases (NATs) and requires the cofactor acetyl-coenzyme A (acetyl-CoA), the structure of which is shown in Fig. 6-49. The reaction occurs in two sequential steps according to a *ping-pong Bi–Bi* mechanism (Hein, 1988). In the first step, the acetyl group from acetyl-CoA is transferred to a cysteine residue in the NAT active site with release of coenzyme A (E-SH + CoA-S-COCH$_3$ → E-S-COCH$_3$ + CoA-SH). In the second step, the acetyl group is transferred from the acylated enzyme to the amino group of the substrate with regeneration of the enzyme. For strongly basic amines, the rate of N-acetylation is determined by the first step (acetylation of the enzyme), whereas the rate of N-acetylation of weakly basic amines is determined by the second step (transfer of the acetyl group from the acylated enzyme to the acceptor amine). In certain cases (discussed below), *N*-acetyltransferases can catalyze the O-acetylation of xenobiotics.

N-Acetyltransferases are cytosolic enzymes found in liver and many other tissues of most mammalian species, with the notable exception of the dog and fox, which are unable to acetylate xenobiotics. In contrast to other xenobiotic-biotransforming enzymes, the number of *N*-acetyltransferases known to play a role in xenobiotic metabolism is limited (Vatsis *et al.*, 1995; Boukouvala and Fakis, 2005). NAT activities are distinguishable from other *N*-acetyltransferases such as those involved in melatonin synthesis and serotonin metabolism (arylalkylamine *N*-acetyltransferases) but are indistinguishable from the group of bacterial enzymes termed *N*-hydroxyarylamine *O*-acetyltransferases (Boukouvala and Fakis, 2005). Rabbits and hamsters express only two *N*-acetyltransferases, known as NAT1 and NAT2, whereas mice and rats express three enzymes, namely, NAT1, NAT2, and NAT3. The Human Genome Organisation (HUGO) Gene Nomenclature Committee (http://www.gene.ucl.ac.uk/nomenclature) has designated NAT as the official symbol for arylamine *N*-acetyltransferases. The two well-known and characterized xenobiotic-acetylating human enzymes are NAT1 and NAT2, which are encoded by two highly polymorphic genes located on chromosome 8. Other HUGO-approved human NAT gene symbols include NAT5–6 and NAT8–14, located on other chromosomes. The activities and expression pattern of these enzymes have not yet been definitively characterized, although some of these genes have been associated with atopic dermatitis or psoriasis (NAT9) and nasopharyngeal cancer (NAT6) (Helms *et al.*, 2003; Bowcock and Cookson, 2004; Duh *et al.*, 2004; Yamada and Ymamoto, 2005; Morar *et al.*, 2006). Individual NATs and their allelic variants were named in the order of their description in the literature, which makes for a somewhat confusing nomenclature system (Vatsis *et al.*, 1995). For example, in humans, the

"wild-type" NAT1 and NAT2 alleles are designated NAT1*4 and NAT2*4, respectively, because they are the most common alleles in some but not all ethnic groups (Hein, 2006).For NAT enzymes, the term "wild-type" may be somewhat arbitrary because it depends on the particular ethnic group that is studied. The official website for maintaining and updating NAT allele nomenclature is http://www.louisville.edu/medschool/pharmacology/NAT.html. The frequency of some SNPs and alleles in various ethnic groups is available online from the National Cancer Institute's SNP500Cancer database (http://snp500cancer.nci.nih.gov).

In each species examined, NAT1 and NAT2 are closely related proteins (79–95% identical in amino acid sequence) with an active site cysteine residue (Cys_{68}) in the N-terminal region (Grant *et al.*, 1992; Vatsis *et al.*, 1995). Human NAT1 and NAT2 genes are composed of intronless open reading frames of 870 bp on the same chromosome with a NAT pseudogene (NATP1) between them, and encode proteins of 290 amino acids that share 87% homology in the coding region (Boukouvala and Fakis, 2005; Hein, 2006). In spite of this apparently simple structure, NAT genes are fairly complex. For instance, comparisons of genomic and cDNA clones of the human NAT2 gene performed in the early 1990s revealed that the 5′ untranslated region is contained in a "noncoding exon," 8 kb upstream of the coding region (Boukouvala and Fakis, 2005). A similar type of unusual structure was later revealed for NAT2 genes in rabbit, hamster, mouse, and rat. More recent sequence alignments of expressed sequence tags with genomic sequences reveal that the presence of one or more upstream "noncoding exons" is typical for all vertebrate NAT genes, with the contiguous coding region contained in a single exon in the 3′ untranslated region (Boukouvala and Fakis, 2005). Furthermore, the splice site nearest the coding region appears to be universally conserved at position-6, relative to the first codon. The primary transcript of both NAT1 and 2 genes are also subject to alternative intron splicing in human, rat, and possibly chicken, whereas alternative splicing for NAT2 has been observed in rabbit and hamster. Alternative splicing in the case of NATs generates mRNAs with variable 5′ untranslated regions. The presence of "noncoding exons" lying upstream of higher eukaryotic genes (especially intronless genes) is common, and their transcription is likely required for transport of the entire transcript to the cytoplasm (Boukouvala and Fakis, 2005). The differential transcription of upstream noncoding exons has been frequently associated with cell-specific regulation of transcription and translation, and recent studies show that certain noncoding NAT exons are present to different extents in different tissues (Boukouvala and Fakis, 2005). There is also evidence of differential utilization of multiple tandem poly-adenosine repeats in the 3′ untranslated regions in different species, but the precise effect of polyadenylation of NATs remains unknown (Boukouvala and Fakis, 2005).

Despite their coexistence on the same chromosome, NAT1 and NAT2 are independently regulated proteins. For instance, human NAT1 protein and/or mRNA has been detected in every tissue examined (e.g., liver, gastrointestinal tract, leukocytes, erythrocytes, bladder, uroepithelial cells, mammary, lung, placenta, kidney, pineal gland, skeletal muscle, heart, brain, and pancreas) and are present from the blastocyst stage, whereas NAT2 is thought to be mainly expressed in liver and intestine. However, most (but not all) of the tissues that express NAT1 also appear to express low levels of NAT2, at least at the level of mRNA (Debiec-Rychter *et al.*, 1999). Hein has also challenged the hypothesis that NAT2 is expressed mainly in the liver and intestine, and noted that the O-acetylation of *N*-hydroxy-4-aminobiphenyl in human urinary bladder cytosol did not correlate with NAT1 activity (4-aminobenzoic acid N-acetylation) consistent with acetylation by both enzymes (Hein, 2006). Regulation of human NAT1 is complex, and involves a promoter region composed of an AP1-box flanked by two TCATT boxes (Boukouvala and Fakis, 2005). The 3′ TCATT box is required for expression whereas the 5′-box attenuates promoter activity. Transcription factors such as c-Fos/Fra, c-Jun, and YY1 bind to the NAT1 promoter (Boukouvala and Fakis, 2005). In addition, because transcription of human NAT1 can begin with different upstream "noncoding exons," it is likely that there are additional promoters that regulate expression.

NAT1 and NAT2 also have different but overlapping substrate specificities, although no substrate is exclusively *N*-acetylated by one enzyme or the other. Substrates preferentially *N*-acetylated by human NAT1 include 4-aminobenzoic acid (PABA), 4-aminosalicylic acid, sulfamethoxazole, and sulfanilamide, whereas substrates preferentially *N*-acetylated by human NAT2 include isoniazid, hydralazine, procainamide, dapsone, aminoglutethimide, and sulfamethazine. Some investigators have used 4-aminobenzoic acid as a selective probe substrate for wild-type NAT1, and either sulfamethazine or sulfadiazine as selective probe substrates for wild-type NAT2 (Winter and Unadkat, 2005). Some xenobiotics, such as the carcinogenic aromatic amine, 2-aminofluorene, are *N*-acetylated equally well by NAT1 and NAT2. Other drugs that are substrates for either NAT1 or NAT2 include acebutolol, amantadine, amonafide, amrinone, benzocaine, declopramide, metamizole, and phenelzine (Gonzalez and Tukey, 2006; Sirot *et al.*, 2006).

Several drugs are *N*-acetylated following their biotransformation by hydrolysis, reduction, or oxidation. For example, caffeine is *N*3-demethylated by CYP1A2 to paraxanthine (Fig. 6-44), which is then *N*-demethylated to 1-methylxanthine and *N*-acetylated to 5-acetylamino-6-formylamino-3-methyluracil (AFMU) by NAT2. Other drugs converted to metabolites that are *N*-acetylated by NAT2 include sulfasalazine, nitrazepam, and clonazepam. Examples of drugs that are *N*-acetylated by NAT1 and NAT2 are shown in Fig. 6-57. It should be noted, however, that there are species differences in the substrate specificity of *N*-acetyltransferases. For example, 4-aminobenzoic acid is preferentially *N*-acetylated by NAT1 in humans and rabbits but by NAT2 in mice and hamsters.

Genetic polymorphisms for N-acetylation have been documented in humans, hamsters, rabbits, and mice (Evans, 1992; Grant *et al.*, 1992; Vatsis *et al.*, 1995; Hirvonen, 1999; Hein *et al.*, 2000). A series of clinical observations in the 1950s established the existence of *slow* and *fast acetylators* of the antitubercular drug isoniazid. In general, ~50% of patients treated with isoniazid have adverse events such as peripheral neuropathy and hepatotoxicity. Slow acetylators also exhibit a higher incidence of adverse events with clonazepam, hydralazine, procainamide, and sulfonamides (Sirot *et al.*, 2006). The incidence of the slow acetylator phenotype is high in Middle Eastern populations (e.g., ~92% in Egyptians), intermediate in Caucasian and African populations (e.g., ~50–59% in Caucasian Americans, Australians, and Europeans; ~41% in African Americans; ~50–60% in black Africans), and low in Asian populations (e.g., <20% in Chinese; ~8–10% in Japanese) (Sirot *et al.*, 2006). Many studies have demonstrated the typical bimodal distribution of fast and slow acetylators with drugs such as isoniazid, but the use of other drugs such as caffeine or sulfamethazine exhibit slow, intermediate, and fast acetylators (Hein, 2006). Parkin and colleagues (1997) also demonstrated that isoniazid elimination is trimodal, and that phenotype and genotype were concordant.

The slow acetylator phenotype is caused by various mutations in the NAT2 gene that either decrease NAT2 activity or enzyme
Figure 6-57. Examples of substrates for the human N-acetyltransferases, NAT1, and the highly polymorphic NAT2.

stability (at least 36 allelic variants of human NAT2 have been documented). For example, a point mutation $T^{341}C$ (which causes the amino acid substitution $Ile^{114}Thr$) decreases V_{max} for N-acetylation without altering the K_m for substrate binding or the stability of the enzyme. This mutation (which is the basis for the NAT2*5 allele) is the most common cause of the slow acetylator phenotype in Caucasians (e.g., frequency >50% in the U.K.) but is rarely observed in Koreans (i.e., <5%) (Hein, 2006). (Note: There are 10 known NAT2*5 alleles, designated NAT2*5A through NAT*5J.) The alleles containing only the $Ile^{114}Thr$ substitution are NAT2*5A (which also contains a silent $C^{481}T$ nucleotide change) and NAT2*5D. The others contain this and at least one other nucleotide and/or amino acid substitution, and NAT2*5B confers the "slowest acetylator" phenotype (Patin *et al*., 2006). The NAT2*7 allele is more prevalent in Asians than Caucasians or Africans (Hein, 2006), and involves either a point mutation $G^{857}A$ (i.e., NAT2*7A) or both this change and $C^{282}T$ (i.e., NAT2*7B). Both of these changes cause the amino acid substitution $Gly^{286}Glu$, which decreases the stability, rather than the activity, of NAT2. NAT2*6 (more common in southern India) and NAT2*14 (present mainly in Africa and Spain) also result in one or more amino acid changes that lead to decreased NAT2 activity, whereas the amino acid change in NAT2*12 (present mainly in Africa and Spain) does not decrease activity (Hein, 2006). Within the slow NAT2 acetylator phenotype there is considerable variation in rates of xenobiotic N-acetylation. This is partly because different

mutations in the NAT2 gene have different effects on NAT2 activity and/or enzyme stability, heterozygotes retain moderate NAT2 activity, and because the N-acetylation of "NAT2-substrates" by NAT1 becomes significant in slow acetylators.

The slowest acetylator haplotype (NAT2*5B, which has the strongest association with bladder cancer) appears to have been positively selected for in only the last 6500 years in western and central Eurasians, which suggests that slow acetylation conferred an evolutionary advantage within this population, contrary to much of the recent epidemiological data (Patin *et al*., 2006). Moreover, because most of the NAT2 polymorphisms that lead to slow acetylation are present at high frequencies in various populations, it would seem that varied rates of acetylation may be an important human adaptation to environmental variables. Because acetylation can be so important in the determination of the interaction between human populations and many xenobiotics in their particular environment (e.g., through different diets and lifestyles), it is not surprising that they are recent targets for natural selection.

NAT1 and NAT2 used to be referred to as *monomorphic* and *polymorphic N*-acetyltransferases because only the latter enzyme was thought to be genetically polymorphic. However, at least 26 allelic variants have now been documented for the human NAT1 gene, although these variants are less prevalent than the NAT2 allelic variants, hence, there is less genetically determined variation in the metabolism of "NAT1 substrates." Nevertheless, there is evidence that phenotypic differences in the N-acetylation of 4-aminosalicylic acid are distributed bimodally, consistent with the existence of low and high activity forms of NAT1. Furthermore, an extremely slow acetylator of 4-aminosalicylic acid has been identified with mutations in both NAT1 alleles; one that decreases NAT1 activity and stability and one that encodes a truncated and catalytically inactive form of the enzyme. It has also been demonstrated that NAT1*16 but not NAT1*10 or NAT1*11 cause a 50% decrease in NAT1 activity and NAT1 protein levels in COS-1 cell cytosol (Soucek *et al*., 2004). The incidence and pharmacological/toxicological significance of genetic polymorphisms in NAT1 that produce phenotypically discernible alterations in NAT1 activity remain to be determined. Cascorbi and colleagues (2001) found that individuals who express NAT1*10 and NAT2*4 (i.e., low NAT1 activity and normal NAT2 activity) were at a significantly lower risk of bladder cancer, especially when exposed to environmental carcinogens. It is therefore likely that the interplay between NAT1 and NAT2 phenotypes is relevant to the susceptibility to certain carcinogens.

Genetic polymorphisms in NAT2 have a number of pharmacological and toxicological consequences for drugs that are *N*-acetylated by this enzyme. The pharmacological effects of the antihypertensive drug hydralazine are more pronounced in slow NAT2 acetylators. Slow NAT2 acetylators are predisposed to several drug toxicities, including nerve damage (peripheral neuropathy) from isoniazid and dapsone, systemic lupus erythematosus from hydralazine and procainamide, and the toxic effects of coadministration of the anticonvulsant phenytoin with isoniazid. Slow NAT2 acetylators that are deficient in glucose-6-phosphate dehydrogenase are particularly prone to hemolysis from certain sulfonamides. HIV-infected individuals of the slow acetylator phenotype suffer more often from adverse drug events and, among patients with Stevens–Johnson syndrome, the overwhelming majority are slow acetylators. Fast NAT2 acetylators are predisposed to the myelotoxic effects of amonafide because N-acetylation retards the clearance of this antineoplastic drug.

Some epidemiological studies suggest that rapid NAT2 acetylators are at increased risk for the development of isoniazid-induced liver toxicity, although several other studies contradict these findings and provide convincing evidence that slow NAT2 acetylation is a risk modifier for isoniazid-induced hepatotoxicity. Following its acetylation by NAT2, isoniazid can be hydrolyzed to isonicotinic acid and acetylhydrazine (CH_3CO–$NHNH_2$). This latter metabolite can be N-hydroxylated by FMO or CYP to a reactive intermediate, as shown in Fig. 6-37a. The generation of a reactive metabolite from acetylhydrazine would seem to provide a mechanistic basis for enhanced isoniazid hepatotoxicity in fast acetylators. However, acetylhydrazine can be further acetylated to diacetlyhydrazine (CH_3CO–$NHNH$–$COCH_3$), and this detoxication reaction is also catalyzed by NAT2. Therefore, acetylhydrazine is both produced and detoxified by NAT2, hence slow acetylation, not fast acetylation, becomes the risk modifier for isoniazid-induced hepatotoxicity, just as it is for isoniazid-induced peripheral neuropathy. Rifampin and alcohol have been reported to enhance the hepatotoxicity of isoniazid. These drug interactions are probably the result of increased N-hydroxylation of acetylhydrazine due to CYP induction rather than to an alteration in NAT2 activity. Isoniazid is an antitubercular drug, and its inactivation by NAT2 is interesting from the perspective that several organisms, including *M. tuberculosis*, express a NAT2-like enzyme, which has implications for isoniazid-resistance in tuberculosis.

Aromatic amines can be both activated and deactivated by N-acetyltransferases (Kato and Yamazoe, 1994; Hirvonen, 1999; Hein *et al*., 2000). The N-acetyltransferases detoxify aromatic amines by converting them to the corresponding amides because aromatic amides are less likely than aromatic amines to be activated to DNA-reactive metabolites by CYP, PHS, and UGTs. However, NATs can activate aromatic amines if they are first N-hydroxylated by CYP because N-acetyltransferases can also function as O-acetyltransferases and convert N-hydroxyaromatic amines (hydroxylamines) to acetoxy esters. As shown in Fig. 6-11, the acetoxy esters of N-hydroxyaromatic amines, like the corresponding sulfonate esters (Fig. 6-55), can break down to form highly reactive nitrenium and carbonium ions that bind to DNA. N-Acetyltransferases catalyze the O-acetylation of N-hydroxyaromatic amines by two distinct mechanisms. The first reaction, which is exemplified by the conversion of N-hydroxyaminofluorene to N-acetoxyaminofluorene, requires acetyl-CoA and proceeds by the same mechanism previously described for N-acetylation. The second reaction is exemplified by the conversion of 2-acetylaminofluorene to N-acetoxyaminofluorene, which does not require acetyl-CoA but involves an intramolecular transfer of the N-acetyl group from nitrogen to oxygen. These reactions are shown in Fig. 6-58.

Genetic polymorphisms in NAT2 have been reported to influence susceptibility to aromatic amine-induced bladder and colon cancer (see section "Glucuronidation") (Evans, 1992; Kadlubar, 1994; Hirvonen, 1999; Hein *et al*., 2000). Bladder cancer is thought to be caused by bicyclic aromatic amines (benzidine, 2-aminonaphthalene, and 4-aminobiphenyl), whereas colon cancer is thought to be caused by heterocyclic aromatic amines, such as the products of amino acid pyrolysis (e.g., 2-amino-6-methylimidazo[4,5-*b*]pyridine or PhIP, and others listed in Table 6-12). Epidemiological studies suggest that slow NAT2 acetylators are more likely than fast NAT2 acetylators to develop bladder cancer from cigarette smoking and from occupational exposure to bicyclic

aromatic amines. The possibility that slow NAT2 acetylators are at increased risk for aromatic amine-induced cancer is supported by the finding that dogs, which are poor acetylators, are highly prone to aromatic amine-induced bladder cancer. By comparison, fast NAT2 acetylators appear to be at increased risk for colon cancer from heterocyclic aromatic amines.

looseness1The influence of acetylator phenotype on susceptibility to aromatic amine-induced cancer can be rationalized on the ability of N-acetyltransferases to activate and detoxify aromatic amines and by differences in the substrate specificity and tissues distribution of NAT1 and NAT2 (recall that NAT1 is expressed in virtually all tissues, whereas NAT2 is expressed mainly in the liver and intestinal tract). Both NAT1 and NAT2 catalyze the O-acetylation (activation) of N-hydroxy bicyclic aromatic amines, whereas the O-acetylation of N-hydroxy heterocyclic aromatic amines is preferentially catalyzed by NAT2. Bicyclic aromatic amines can also be N-acetylated (detoxified) by NAT1 and NAT2, but heterocyclic aromatic amines are poor substrates for both enzymes. Therefore, the fast acetylator phenotype protects against aromatic amine-induced bladder cancer because NAT2 (as well as NAT1) catalyzes the N-acetylation (detoxication) of bicyclic aromatic amines in the liver. In slow acetylators, a greater proportion of the bicyclic aromatic amines are activated through N-hydroxylation by CYP1A2. These N-hydroxylated aromatic amines can be activated by O-acetylation, which can be catalyzed in the bladder itself by NAT1. Recent evidence suggests that a high level of NAT1 in the bladder is a risk modifier for aromatic amine-induced bladder cancer. In addition, the fast acetylator phenotype potentiates the colon cancer-inducing effects of heterocyclic aromatic amines. These aromatic amines are poor substrates for NAT1 and NAT2, so that high levels of NAT2 in the liver do little to prevent their N-hydroxylation by CYP1A2. The N-hydroxylated metabolites of heterocyclic aromatic amines can be activated by O-acetylation, which can be catalyzed in the colon itself by NAT2. The presence of NAT2 (and NAT1) in the colons of fast acetylators probably explains why this phenotype is a risk modifier for the development of colon cancer.

Whether fast acetylators are protected from or predisposed to the cancer-causing effects of aromatic amines depends on the nature of the aromatic amine (bicyclic vs. heterocyclic) and on other important risk modifiers. For example, CYP1A2 plays an important role in the N-hydroxylation of both bicyclic and heterocyclic amines, and high CYP1A2 activity has been shown to be a risk modifier for aromatic amine-induced bladder and colon cancer. A single nucleotide polymorphism in intron 1 of CYP1A2 is associated with high inducibility, and this allelic variant is a risk modifier for bladder cancer in smokers or in people who are slow NAT2 acetylators (Brockmöller *et al*., 1998). The activation of aromatic amines by N-glucuronidation and the activation of N-hydroxy aromatic amines by sulfonation are both suspected of playing an important role in the incidence of bladder and colon cancer. These and other risk modifiers may explain why some epidemiological studies, contrary to expectation, have shown that slow NAT2 acetylators are at increased risk for aromatic amine-induced bladder cancer, as was demonstrated for benzidine manufacturers in China (Hayes *et al*., 1993).

The N-acetylation of aromatic amines (a detoxication reaction) and the O-acetylation of N-hydroxy aromatic amines (an activation reaction) can be reversed by a microsomal enzyme called arylacetamide deacetylase (gene symbol AADAC) (Probst *et al*.,
Figure 6-58. Role of N-acetyltransferase in the O-acetylation of N-hydroxy-2-aminofluorene (N-hydroxy-2AF) and the intramolecular rearrangement of N-hydroxy-2-acetylaminofluorene (N-hydroxy-2-AAF).

1994). This enzyme is similar to but distinct from the microsomal carboxylesterases that hydrolyze esters and amides. Arylacetamide deacetylase can potentially alter the overall balance between detoxication and activation of aromatic amines.

Overall, it would appear that low NAT2 activity increases the risk of bladder, breast, liver and lung cancers, and decreases the risk of colon cancer, whereas low NAT1 activity increases the risk of bladder and colon cancers and decreases the risk of lung cancer (Hirvonen, 1999). The individual risks associated with particular NAT1 and/or NAT2 acetylator genotypes are small, but they increase when considered in conjunction with other susceptibility genes and/or exposure to carcinogenic aromatic and heterocyclic amines. Because of the relatively high frequency of allelic variants of NAT1 and NAT2, the attributable risk of cancer in the population may be high (Hein *et al.*, 2000).

Amino Acid Conjugation

There are two principal pathways by which xenobiotics are conjugated with amino acids, as illustrated in Fig. 6-59. The first involves conjugation of xenobiotics containing a carboxylic acid group with the *amino group* of amino acids such as glycine, glutamine, and taurine (see Fig. 6-49). This pathway involves activation of the xenobiotic by conjugation with CoA, which produces an acyl-CoA thioether that reacts with the *amino group* of an amino acid to form an amide linkage. The second pathway involves conjugation of xenobiotics containing an aromatic hydroxylamine (*N*-hydroxy aromatic amine) with the *carboxylic acid group* of such amino acids as serine and proline. This pathway involves activation of an amino acid by aminoacyl-tRNA-synthetase, which reacts with an aromatic hydroxylamine to form a reactive *N*-ester (Kato and Yamazoe, 1994).
Figure 6-59. Conjugation of xenobiotics with amino acids.

The conjugation of benzoic acid with glycine to form hippuric acid (see Fig. 6-1) was discovered in 1842, making it the first biotransformation reaction discovered (Paulson *et al*., 1986). The first step in this conjugation reaction involves activation of benzoic acid to an acyl-CoA thioester. This reaction requires ATP and is catalyzed by acyl-CoA synthetase (ATP-dependent acid:CoA ligase). The second step is catalyzed by acyl-CoA:amino acid *N*-acyltransferase, which transfers the acyl moiety of the xenobiotic to the amino group of the acceptor amino acid. The reaction proceeds by a *ping-pong Bi–Bi* mechanism, and involves transfer of the xenobiotic to a cysteine residue in the enzyme with release of coenzyme A, followed by transfer of the xenobiotic to the acceptor amino acid with regeneration of the enzyme. The second step in amino acid conjugation is analogous to amide formation during the acetylation of aromatic amines by *N*-acetyltransferase. Substrates for amino acid conjugation are restricted to certain aliphatic, aromatic, heteroaromatic, cinnamic, and arylacetic acids.

The ability of xenobiotics to undergo amino acid conjugation depends on steric hindrance around the carboxylic acid group, and by substituents on the aromatic ring or aliphatic side chain. In rats, ferrets, and monkeys, the major pathway of phenylacetic acid biotransformation is amino acid conjugation. However, due to steric hindrance, diphenylacetic acid cannot be conjugated with an amino acid, so the major pathway of diphenylacetic acid biotransformation in these three species is acylglucuronidation. Bile acids are endogenous substrates for glycine and taurine conjugation. However, the activation of bile acids to an acyl-CoA thioester is catalyzed by a microsomal enzyme, cholyl-CoA synthetase, and conjugation with glycine or taurine is catalyzed by bile acid-CoA:amino acid *N*-acyltransferase (BACAT, gene symbol BAAT) (Falany *et al*., 1994). BACAT is expressed at high levels in the liver, kidney, gallbladder, and intestine, with lower levels in the adrenal gland, muscle, lung, and brain, which suggests that it may have substrates other than bile acids (O'Byrne *et al*., 2003). In vitro studies show that BACAT can form glycine conjugates of long-chain fatty acids, and also possesses thioesterase activity toward the same substrates (O'Byrne *et al*., 2003). In contrast to bile acids, the activation of xenobiotics occurs mainly in mitochondria, which appear to contain multiple acyl-CoA synthetases. The second step in the conjugation of xenobiotics with amino acids is catalyzed by cytosolic and/or mitochondrial forms of *N*-acyltransferase. Amino acid conjugation is apparently catalyzed by separate *N*-acyltransferases specific for each amino acid (Gopaul *et al*., 2003). Glycine-*N*-acyltransferase and glutamine-*N*-phenylacetyltransferase have been isolated from human hepatic mitochondria (Gopaul *et al*., 2003). Another important difference between the amino acid conjugates of xenobiotics and bile acids is their route of elimination: Bile acids are secreted into bile whereas amino acid conjugates of xenobiotics are eliminated primarily in urine. The addition of an endogenous amino acid to xenobiotics may facilitate this elimination by increasing their ability to interact with the tubular organic anion transport system in the kidney.

In addition to glycine, glutamine, and taurine, acceptor amino acids for xenobiotic conjugation include ornithine, arginine, histidine, serine, aspartic acid, and several dipeptides, such as glycylglycine, glycyltaurine, and glycylvaline. The acceptor amino acid used for conjugation is both species- and xenobiotic-dependent. For benzoic, heterocyclic, and cinnamic acids, the acceptor amino acid is glycine, except in birds and reptiles, which use ornithine. Arylacetic acids are also conjugated with glycine except in primates, which use glutamine. In mammals, taurine is generally an alternative acceptor to glycine. Taurine conjugation is well developed in nonmammalian species and carnivores. Whereas most species conjugate bile acids with both glycine and taurine, cats and dogs conjugated bile acids only with taurine.

Conjugation of carboxylic acid-containing xenobiotics is an alternative to glucuronidation. Conjugation with amino acids is a detoxication reaction, whereas the glucuronidation of carboxylic acid-containing xenobiotic produces potentially toxic acylglucuronides (see Fig. 6-54). Amino acid conjugation of ibuprofen and related *profens* (2-substituted propionic acid NSAIDs) is significant for two reasons: It limits the formation of potentially toxic acylglucuronides, and it leads to chiral inversion (the interconversion of *R*- and *S*-enantiomers) (Shirley *et al*., 1994). This latter reaction requires conversion of the profen to its acyl-CoA thioester, which undergoes chiral inversion by 2-arylpropionyl-CoA epimerase (this involves the intermediacy of a symmetrical, conjugated enolate anion). Chiral inversion explains why the *R*- and *S*-enantiomers of several profen NSAIDs have comparable anti-inflammatory effects in vivo, even though the *S*-enantiomers are considerably more potent than their antipodes as inhibitors of cyclooxygenase (the target of NSAID therapy). In general, amino acid conjugation is a high affinity–low capacity reaction, whereas glucuronidation is a high capacity–low affinity reaction. At low substrate concentrations, amino acid conjugation would presumably be the more important reaction.

In contrast to amino acid conjugation of carboxylic acid-containing xenobiotics, which is a detoxication reaction, amino acid conjugation of *N*-hydroxy aromatic amines (hydroxylamines) is an activation reaction because it produces *N*-esters that can degrade to form electrophilic nitrenium and carbonium ions (Anders, 1985; Kato and Yamazoe, 1994). Conjugation of hydroxylamines with amino acids is catalyzed by cytosolic aminoacyl-tRNA synthetases and requires ATP (Fig. 6-59). Hydroxylamines activated by aminoacyl-tRNA synthetases include *N*-hydroxy-4-aminoquinoline 1-oxide, which is conjugated with serine, and *N*-hydroxy-Trp-P-2, which is conjugated with proline. (*N*-hydroxy-Trp-P-2 is the *N*-hydroxylated metabolite of Trp-P-2, a pyrolysis product of tryptophan [see Table 6-12]). It is now apparent that the hydroxylamines formed by the cytochrome P450-dependent N-hydroxylation of aromatic amines can potentially be activated by numerous reactions, including N-glucuronidation by UGTs (Fig. 6-54), O-acetylation by *N*-acetyltransferase (Fig. 6-11), O-sulfonation by sulfotransferase (Fig. 6-55), and conjugation with amino acids by seryl- or prolyl-tRNA synthetase (Fig. 6-59).

Various amino acid conjugates of valproic acid, including glutamine-, glutamate-, and glycine-conjugates, have been detected in the urine, serum, and cerebrospinal fluid of patients administered this antieplieptic (Gopaul *et al*., 2003). CSF concentrations of the glutamine and glutamate conjugates of valproic acid were five and nine times higher than in serum, which suggests that these conjugation reactions in the brain decrease levels of the excitatory neurotransmitter glutamic acid and decrease the incidence of seizure (Gopaul *et al*., 2003). Taken together, these data suggest that amino acid conjugation in the brain may play a role in the mechanism of action of valproic acid.

Glutathione Conjugation

The preceding section described the conjugation of xenobiotics with certain amino acids, including some simple dipeptides, such as glycyltaurine. This section describes the conjugation of xenobiotics

with the tripeptide glutathione (GSH), which is composed of glycine, cysteine, and glutamic acid (the latter being linked to cysteine via the γ-carboxyl group, not the usual α-carboxyl group, as shown in Fig. 6-49). Glutathione transferase activity was first discovered as the enzyme-catalyzed conjugation of glutathione with halogenated compounds such as chloronitrobenzenes and bromosulfophthalein (Mannervik *et al.*, 2005). The activity was initially designated GSH *S*-aryltransferase, and glutathione transferase activities toward other substrates such as alkyl halides and epoxides were called *S*-alkyl and *S*-epoxide transferases. The original names were later replaced with letter designations once the overlapping substrate specificity was described, especially toward 1-chloro-2,4-dinitrobenzene (Mannervik *et al.*, 2005). Although the abbreviation "GST" has survived, the term "glutathione transferase" is technically incorrect because the glutathionyl group is transferred rather than a single sulfur atom (Mannervik *et al.*, 2005) (the correct term is glutathione transferase). GSTs function endogenously as part of a defense mechanism against reactive oxygen species which reduces the formation of hydroperoxides of fatty acids, phospholipids, cholesterol, and against the redox-cycling of some quinone-containing compounds, by conjugation with glutathione (Hayes *et al.*, 2005). GSTs also play a role in other endogenous functions such as the degradation of aromatic amino acids, steroid hormone synthesis, eicosanoid synthesis and inactivation, and modulation of signaling pathways (Hayes *et al.*, 2005). Conjugation of xenobiotics with glutathione is fundamentally different from their conjugation with other amino acids and dipeptides (Mantle *et al.*, 1987; Sies and Ketterer, 1988). Substrates for glutathione conjugation include an enormous array of electrophilic xenobiotics, or xenobiotics that can be biotransformed to electrophiles. In contrast to the amides formed by conjugation of xenobiotics to other amino acids, glutathione conjugates are thioethers, which form by nucleophilic attack of glutathione thiolate anion (GS$^-$) with an electrophilic carbon atom in the xenobiotic. Glutathione can also conjugate xenobiotics containing electrophilic heteroatoms (O, N, and S).

The synthesis of glutathione involves formation of the peptide bond between cysteine and glutamic acid, followed by peptide bond formation with glycine. The first reaction is catalyzed by γ-glutamylcysteine synthetase (γ-GCL); the second by glutathione synthetase. At each step, ATP is hydrolyzed to ADP and inorganic phosphate. The first reaction is inhibited by buthionine-*S*-sulfoximine, which can be used in vivo to decrease glutathione levels in experimental animals.

The conjugation of xenobiotics with glutathione is catalyzed by glutathione transferases (GSTs), found in cytosolic, microsomal (i.e., the MAPEG family), and mitochondrial cell fractions (Hayes *et al.*, 2005). Most GSTs were originally found in the soluble cell fraction, and those GSTs that are found in the cytoplasm are referred to as cytosolic or soluble GSTs, even though they may also be found in the nucleus or peroxisomes (Mannervik *et al.*, 2005). The only mitochondrial GST found to date has traditionally been referred to as Kappa GST, and although it dimerizes (as do the cytosolic GSTs), Kappa GST has a structure that is distinct from the cytosolic GSTs and is also present in peroxisomes, which suggests that it is involved in fatty acid β-oxidation (Hayes *et al.*, 2005; Mannervik *et al.*, 2005). The microsomal GSTs are an independent group of proteins termed "membrane-associated proteins in eicosanoid and glutathione metabolism" (MAPEG), and are integral microsomal and mitochondrial membrane components. It should also be noted that some GSTs have nonenzymatic functions such as binding of zeaxanthin in the retina and c-Jun N-terminal kinase1 by GST P1-1, and

were initially designated by other names (Mannervik *et al.*, 2005). There are also other proteins that are homologous to some GSTs but are not yet known to serve as detoxication enzymes, such as the chloride intracellular channels (CLIC) (Mannervik *et al.*, 2005). Hence, proteins that are already characterized and named may eventually be designated as GSTs, as was the case with glutathione-dependent prostaglandin D_2 synthase, now determined to be GST S1-1 due to similarities with the Sigma class GSTs expressed in nonmammalian organisms. The GSTs are present in most tissues, with high concentrations in the liver, intestine, kidney, testis, adrenal, and lung.

Substrates for glutathione transferase share three common features: they are hydrophobic, they contain an electrophilic atom, and they react nonenzymatically with glutathione at some measurable rate. The mechanism by which glutathione transferase increases the rate of glutathione conjugation involves deprotonation of GSH to GS$^-$ by an active site tyrosine or serine, which functions as a general base catalyst (Atkins *et al.*, 1993; Dirr, 1994). In the case of the Omega class GSTs, the active site contains a cysteine residue (Mukherjee *et al.*, 2006). The concentration of glutathione in liver is extremely high ($\sim$5–10 mM); hence, the nonenzymatic conjugation of certain xenobiotics with glutathione can be significant. However, some xenobiotics are conjugated with glutathione stereoselectively, indicating that the reaction is largely catalyzed by glutathione transferase. Like glutathione, the glutathione transferases are themselves abundant cellular components, accounting for up to 10% of the total cellular protein. These enzymes bind, store, and/or transport a number of compounds that are not substrates for glutathione conjugation. The cytoplasmic protein formerly known as ligandin, which binds heme, bilirubin, steroids, azo-dyes and polycyclic aromatic hydrocarbons, and thyroid hormones is an Alpha class GST.

As shown in Fig. 6-60, substrates for glutathione conjugation can be divided into two groups: those that are sufficiently electrophilic to be conjugated directly, and those that must first be biotransformed to an electrophilic metabolite prior to conjugation. The second group of substrates for glutathione conjugation includes reactive intermediates produced during conjugation and other biotransformations such as oxiranes (arene oxides and alkene epoxides), nitrenium ions, carbonium ions, and free radicals. The conjugation reactions themselves can be divided into two types: *displacement reactions*, in which glutathione displaces an electron-withdrawing group, and *addition reactions*, in which glutathione is added to an activated double bond or strained ring system. Table 6-18 provides examples of typical substrates for each of the characterized GSTs.

The displacement of an electron-withdrawing group by glutathione typically occurs when the substrate contains halide, sulfate, sulfonate, phosphate, or a nitro group (i.e., good *leaving groups*) attached to an allylic or benzylic carbon atom. Displacement of an electron-withdrawing group from aromatic xenobiotics is decreased by the presence of other substituents that donate electrons to the aromatic ring (–NH$_2$, –OH, –OR, and –R). Conversely, such displacement reactions are increased by the presence of other electron-withdrawing groups (–F, –Cl, –Br, –I, –NO$_2$, –CN, –CHO, and –COOR). This explains why 1,2-dichloro-4-nitrobenzene and 1-chloro-2,4-dinitrobenzene, each of which contains three electron-withdrawing groups, are commonly used as substrates for measuring glutathione transferase activity in vitro, and one or more members of all three GST families can catalyze this conjugation (Hayes *et al.*, 2005). Glutathione transferase can catalyze the O-demethylation of dimethylvinphos and other methylated organophosphorus compounds. The reaction is analogous to the

Table 6-18

Human Glutathione Transferase Enzymes

GST FAMILY	CLASS	GENE	EXAMPLE ENZYMES	EXAMPLE SUBSTRATES
Cytosolic	Alpha	GSTA1	GST A1-1	Δ^5-ADD, BCDE, BPDE, busulfan, chlorambucil, DBADE, DBPDE, BPhDE, *N*-a-PhIP
		GSTA2	GST A2-2	CuOOH, DBPDE, 7-chloro-4-nitrobenz-2-oxa-1,3-diazole
		GSTA3	GST A3-3	Δ^5-ADD, Δ^5-pregnene-3,20-dione, DBPDE
		GSTA4	GST A4-4	COMC-6, EA, 4-hydroxynonenal, 4-hydroxydecenal
		GSTA5	GST A5-5	Unknown
	Mu	GSTM1	GST M1-1	*trans*-4-Phenyl-3-buten-2-one, BPDE, CDE, DBADE, *trans*-stilbene oxide, styrene-7,8-oxide
		GSTM2	GST M2-2	COMC-6, 1,2-dichloro-4-nitrobenzene, aminochrome, dopa *O*-quinone, $PGH_2 \rightarrow PGE_2$
		GSTM3	GST M3-3	BCNU, $PGH_2 \rightarrow PGE_2$
		GSTM4	GST M4-4	CDNB
		GSTM5	GST M5-5	CDNB
	Pi	GSTP1	GST P1-1	Acrolein, base propenals, BPDE, CDE, Chlorambucil, COMC-6, EA, Thio-TEPA
	Sigma	PGDS	GST S1-1[a]	$PGH_2 \rightarrow PGD_2$
	Theta	GSTT1	GST T1-1	BCNU, butadiene epoxide, CH_2Cl_2, EPNP, ethylene oxide
		GSTT2	GST T2-2	CuOOH, menaphthyl sulfonate
	Zeta	GSTZ1	GST Z1-1	Dichloroacetate, fluoroacetate, 2-chloropropionate, maleylacetoacetate
	Omega	GSTO1	GST O1-1	Monomethylarsonic acid, dehydroascorbic acid
		GSTO2	GST O2-2	Monomethylarsonic acid, dehydroascorbic acid

		LTC4S	LTC_4S	$LTA_4 \rightarrow LTC_4$
	gp II	MGST3	MGST3	CDNB, $LTA_4 \rightarrow LTC_4$, (*S*)-5-hydroperoxy-8,11,14-*cis*-6-*trans*-eicosatetraenoic acid
	gp IV	MGST1	MGST1	CDNB*, CuOOH, hexachlorobuta-1,3-diene
		PTGEs	PGES1	$PGH_2 \rightarrow PGE_2$

[a]GST S1-1 is also the glutathione-dependent prostaglandin D$_2$ synthase.

Δ^5-ADD, Δ^5-androstene-3,17-dione; BCDE, benzo[*g*]chrysene diol epoxide; BCNU, 1,3-*bis*(2-chloroethyl)-1-nitrosourea; BPDE, benzo[*a*]pyrene diol epoxide; BPhDE, benzo[*c*]phenanthrene diol epoxide; CDE, chrysene-1,2-diol 3,4-epoxide; CDNB, 1-chloro-2,4-dinitrobenzene; COMC-6, crotonyloxymethyl-2-cyclohexenone; CuOOH, cumene hydroperoxide; DBADE, dibenz[*a*,*h*]anthracene diol epoxide; DBPDE, dibenzo[*a*,*l*]pyrene diol epoxide; EA, ethacrynic acid; EPNP, 1,2-epoxy-3-(*p*-nitrophenoxy)propane; *N*-a-PhIP, *N*-acetoxy-2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine.

Data adapted from Hayes JD, Flanagan JU, Jowsey IR: Glutathione transferases. *Annu Rev Pharmacol Toxicol* 45:51–88, 2005; Mannervik B, Board PG, Hayes JD, Listowsky I, Pearson WR: Nomenclature for mammalian soluble glutathione transferases. *Methods Enzymol* 401:1–8, 2005.

interaction between methyliodide and glutathione, which produces methylglutathione and iodide ion ($GS^- + CH_3I \rightarrow GS\text{-}CH_3 + I^-$). In this case, iodide is the leaving group. In the case of dimethylvinphos, the entire organophosphate molecule (minus the methyl group) functions as the leaving group.

The addition of glutathione to a carbon–carbon double bond is also facilitated by the presence of a nearby electron-withdrawing group; hence, substrates for this reaction typically contain a double bond attached to –CN, –CHO, –COOR, or –COR. The double bond in diethyl maleate is attached to two electron-withdrawing groups and readily undergoes a Michael addition reaction with glutathione, as shown in Fig. 6-60. Diethyl maleate reacts so well with glutathione that it is often used in vivo to decrease glutathione levels in experimental animals. The loop diuretic, ethacrynic acid, contains an α/β-unsaturated ketone that readily reacts with glutathione and other sulfhydryls by Michael addition. The conver-

sion of acetaminophen to a glutathione conjugate involves addition of glutathione to an activated double bond, which is formed during the CYP-dependent dehydrogenation of acetaminophen to *N*-acetylbenzoquinoneimine, as shown in Fig. 6-34.

Arene oxides and alkene epoxides, which are often formed by CYP-dependent oxidation of aromatic hydrocarbons and alkenes, are examples of strained ring systems that open during the addition of glutathione (Fig. 6-60). In many cases, conjugation of arene oxides with glutathione proceeds stereoselectively, as shown in Fig. 6-61 for the 1,2-oxides of naphthalene. The glutathione conjugates of arene oxides may undergo rearrangement reactions, which restore aromaticity and possibly lead to migration of the conjugate to the adjacent carbon atom (through formation of an episulfonium ion), as shown in Fig. 6-61. Conjugation of quinones and quinoneimines with glutathione also restores aromaticity, as shown in Fig. 6-34 for *N*-acetylbenzoquinoneimine, the reactive
Figure 6-60. *Examples of glutathione conjugation of xenobiotics with an electrophilic carbon.*

GS^- represents the anionic form of glutathione.

metabolite of acetaminophen. Compared with glucuronidation and sulfonation, conjugation with glutathione is a minor pathway of acetaminophen biotransformation, even though the liver contains high levels of both glutathione and glutathione transferases. The relatively low rate of glutathione conjugation reflects the slow rate of formation of N-acetylbenzoquinoneimine, which is catalyzed by CYP (Fig. 6-34).

Glutathione can also conjugate xenobiotics with an electrophilic heteroatom (O, N, and S), as shown in Fig. 6-62. In each of the examples shown in Fig. 6-62, the initial conjugate formed between glutathione and the heteroatom is cleaved by a second molecule of glutathione to form oxidized glutathione (GSSG). The initial reactions shown in Fig. 6-62 are catalyzed by glutathione transferase, whereas the second reaction (which leads to GSSG formation) generally occurs nonenzymatically. Analogous reactions leading to the reduction and cleavage of disulfides have been described previously (see Fig. 6-13). Some of the reactions shown in

Fig. 6-62, such as the reduction of hydroperoxides to alcohols, can also be catalyzed by glutathione peroxidase, which is a selenium-dependent enzyme. For their role in the reduction of hydroperoxides, the glutathione transferases are sometimes called nonselenium-requiring glutathione peroxidases. For instance, one or more members of the mammalian cytosolic, microsomal, and mitochondrial GSTs exhibit glutathione peroxidase activity toward cumene hydroperoxide (Hayes *et al.*, 2005). The Omega class GSTs also play a role in the reduction of monomethyl arsenate from an oxidation state of +V to +III, which represents the rate-limiting step in arsenic biotransformation in humans as it occurs after methylation of inorganic arsenic (Mukherjee *et al.*, 2006). Cleavage of the nitrate esters of nitroglycerin releases nitrite, which can be converted to the potent vasodilator, nitric oxide. The ability of sulfhydryl-generating chemicals to partially prevent or reverse tolerance to nitroglycerin suggests that glutathione-dependent denitration may play a role in nitroglycerin-induced vasodilation.
Figure 6-61. *Stereoselective conjugation of naphthalene 1,2-oxide and rearrangement of 2-naphthyl to 1-naphthyl conjugates.*

Cytosolic or mitochondrial glutathione transferases catalyze two important isomerization reactions, namely, the conversion of the endoperoxide, PGH_2, to the prostaglandins PGD_2 and PGE_2, and the conversion of Δ^5 steroids to Δ^4 steroids, such as the formation of androstenedione from androst-5-ene-3,17-dione. Another physiological function of glutathione transferase is the synthesis of leukotriene C_4, which is catalyzed by the microsomal GSTs, namely, MGST2, MGST3, and LTC_4S (see Table 6-18).

Glutathione conjugates formed in the liver can be effluxed into bile by MRP2, into the blood by MRP3 and 4, and they can be converted to mercapturic acids in the kidney and excreted in urine (Giacomini and Sugiyama, 2006). As shown in Fig. 6-63, the conversion of glutathione conjugates to mercapturic acids involves the sequential cleavage of glutamic acid and glycine from the glutathione moiety, followed by N-acetylation of the resulting cysteine conjugate. The first two steps in mercapturic acid synthesis are catalyzed by γ-glutamyltransferase (GGT1) and membrane alanyl aminopeptidase (ANPEP). The glutathione conjugate, leukotriene C_4, is similarly hydrolyzed by γ-glutamyltransferase to form leukotriene D_4, which is hydrolyzed by membrane alanyl aminopeptidase to form leukotriene E_4.

Cytosolic glutathione transferases are dimers, typically composed of identical subunits (Mr 23–29 kDa), although some forms are heterodimers. Each subunit contains 199–244 amino acids and one catalytic site. Mitochondrial GSTs are also dimeric with 226 amino acids per subunit. The microsomal GSTs vary in their ability to form complex aggregates across the three groups of human MAPEGs. Numerous subunits have been cloned and sequenced, which forms the basis of a nomenclature system for naming the glutathione transferases (Mannervik *et al.*, 1992, 2005; Hayes and Pulford, 1995; Whalen and Boyer, 1998; Hayes *et al.*, 2005), as shown in Table 6-18. Each cytosolic and mitochondrial enzyme is assigned a two-digit number to designate its subunit composition. For example, the homodimers of subunits 1 and 2 are designated

1-1 and 2-2, respectively, whereas the heterodimer is designated 1-2. The soluble glutathione transferases were initially arranged into four classes designated A, M, P, and T (which refer to Alpha, Mu, Pi, and Theta). More recently, four additional classes have been identified, namely, K (Kappa; the mitochondrial form), S (Sigma), Z (Zeta), and O (Omega) (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange *et al.*, 2000; Hayes *et al.*, 2005). None of these eight gene classes corresponds to the microsomal glutathione transferases, which appear to have evolved independently. By definition, the subunits in the different classes share less than 50% amino acid sequence identity. Generally, the subunits within a class are ~70% identical, but can share up to 90% sequence identity, and can form heterodimers, whereas the subunits in different classes are generally only ~30% identical. Members of the Alpha and Mu classes can also form heterodimers with each other (Hayes *et al.*, 2005). Affinity labeling studies with rat Alpha GSTs demonstrated the presence of a high-affinity, nonsubstrate binding sites within the cleft between the two subunits of the dimer. Presumably, the cleft in heterodimers would be different from that in homodimers, which suggests the possibility that there is an evolutionary reason that the formation of heterodimers between Alpha and Mu subunits has been conserved (Hayes *et al.*, 2005).

The rat genome database (http://rgd.mcw.edu) indicates that rats express at least three GSTA genes, GSTA3, GSTA4, and Yc_2 (provisional). Humans express five subunits belonging to the Alpha class of glutathione transferases, designated GSTA1–GSTA5. Human GSTA1 and 2 are polymorphic, with at least two and five alleles identified, respectively, which affect the amount or the activity of expressed protein (Hayes *et al.*, 2005). Members of the alpha class of glutathione transferases have basic isoelectric points. They are the major glutathione transferases in liver and kidney.

A single Kappa subunit (the mitochondrial GST) is expressed in mouse, rat, and humans. The three-dimensional structure of
Figure 6-62. *Examples of glutathione conjugation of electrophilic heteroatoms.*

the Kappa subunit is more similar to bacterial GSH-dependent and disulfide-bond-forming oxidoreductase, than to the cytosolic GSTs (Hayes *et al*., 2005). GSTK1 appears to be widely and uniformly expressed in humans, whereas in mice and rats it is present at high levels in the liver, kidney, stomach, and heart.

Rats express at least six functional Mu subunits, designated GSTM1–6. Humans express five subunits belonging to the Mu class of glutathione transferases, designated GSTM1. Human GSTM1, 3, and 4 are known to be polymorphic. In the case of GSTM1, the *A and *B allelic variants differ by a single amino acid; *A is a "basic variant" with lysine at residue 173, whereas *B is an "acidic variant" with asparagine at the corresponding site. There is also a GSTM1 deletion (*0) and a duplication (*1×2) (Hayes *et al*., 2005).

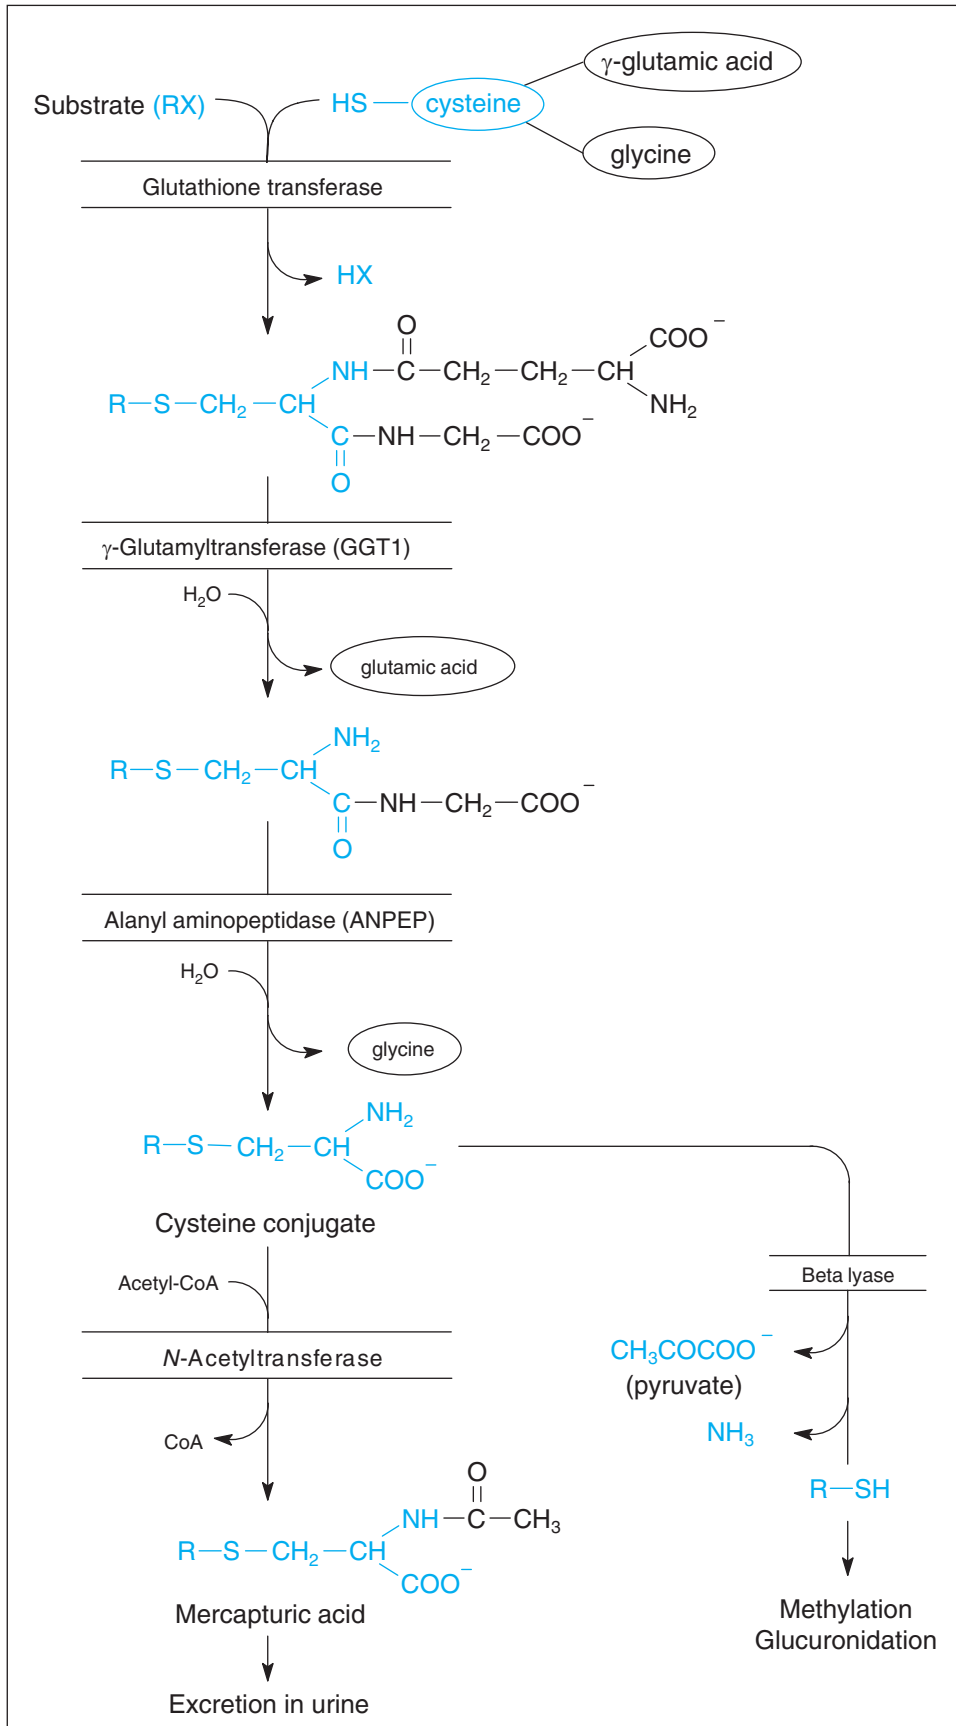
The incidence of the GSTM1 deletion is high in Pacific Islander and Malaysian populations (i.e., 62–100%), intermediate in several other populations (i.e., 35–62% in those of European descent; 32–53% for those of Asian descent; 40–53% for those of Hispanic descent), and low in those of African descent (i.e., 23–41%) (Geisler and Olshan, 2001). GSTM1*0 appears to have only a modest effect on the incidence of lung, head, and neck cancers consistent with its high prevalence in various populations. The GSTM1*0 polymorphism has been linked to an increased susceptibility to certain inflammatory diseases (e.g., asthma) (Hayes *et al*., 2005). At least two allelic variants of GSTM3 and 4 have also been identified. Members of the Mu class of glutathione transferases have neutral isoelectric points. Human GSTM2 and M3 are expressed in muscle and brain, respectively.


Figure 6-63. Glutathione conjugation and mercapturic acid biosynthesis.

Humans express one subunit belonging to the Pi class of glutathione transferases, GSTP1, and whereas rats are also known to express only one subunit (GSTP1), five other GSTP-like sequences have been mapped. The human Pi enzyme is polymorphic, with at least four allelic variants reported (Hayes *et al.*, 2005). The subunit encoded by GSTP1*B is seven times more active than that encoded by GSTP1*A in conjugating diol epoxides of polycyclic aromatic hydrocarbons (Strange *et al.*, 2000). GSTP polymorphisms are known to influence susceptibility to carcinogens (including some pesticides), affect the response to chemotherapy used in the treatment of metastatic colon cancer and multiple myeloma, and to modify the risk of acute myeloid leukemia which results from the successful treatment of Hodgkin's disease, non-Hodgkin's lymphoma, breast, and ovarian cancer (Hayes *et al.*, 2005; Liu *et al.*, 2006b). GSTP polymorphisms that result in decreased activity have also been implicated in an increased susceptibility to certain inflammatory diseases (e.g., asthma) (Hayes *et al.*, 2005). Members of the Pi class of glutathione transferases have acidic isoelectric points. They are expressed in the placenta, lung, gut, and other extrahepatic tissues. In rats, GSTP1 is one of several proteins (so-called preneoplastic antigens) that are overexpressed in chemical-induced tumors.

Rats also express a single GSTS-like protein (GSTS1) from the gene PTGDS2 (glutathione-dependent prostaglandin D_2 synthase) (Mannervik *et al.*, 2005). Humans appear to express one subunit that belongs to the Sigma class of glutathione transferases (GSTS1, also known as the glutathione-dependent prostaglandin D_2 synthase). At least two allelic variants of GSTS have been identified, but their functional significance remains to be elucidated (Hayes *et al.*, 2005).

Humans appear to express two subunits belonging to the Theta class of glutathione transferases (GSTT1 and GSTT2), and rats also appear to express two subunits, with a third GSTT-like sequence mapped. A GSTT1 deletion has been identified (GSTT1*0), which appears to have a modest effect on the incidence of lung, head, and neck cancers, and has also been implicated in an increased susceptibility to certain inflammatory diseases (e.g., asthma) (Hayes *et al.*, 2005).

A single Zeta subunit is expressed in mice and humans (GSTZ1), with a GSTZ-like sequence identified in rats. GSTZ1-1 has maleylacetoacetate isomerase activity and, as such, it catalyzes the penultimate step in tyrosine and phenylalanine catabolism (Hayes *et al.*, 2005). At least four GSTZ alleles have been identified, although their significance in humans is unknown. However, GSTZ1 knockout mice have increased levels of GSTA1, A2, M1, P1, P2, and NQO1 in the liver, and undergo rapid weight loss which results in death when provided 2% phenylalanine in drinking water (Hayes *et al.*, 2005).

Two Omega subunits have been identified in mice, rats, and humans (GSTO1 and 2). The GSTOs differ from the other cytosolic GSTs in that they do not display the typical activity toward substrates such as 1-chloro-2,4-dinitrobenzene, dichloromethane, or ethacrynic acid, but have some characteristics of glutaredoxins (GLRXs) (Mukherjee *et al.*, 2006). Additionally, whereas most GSTs have a tyrosine or serine at the active site, GSTOs have a cysteine and an additional 19 amino acids at the N-terminus (Mukherjee *et al.*, 2006). Many polymorphisms have been detected in both GSTO1 and 2, with five and four polymorphisms that result in amino acid changes, respectively (Mukherjee *et al.*, 2006). A wide variation in expression of these alleles was found, with potential implications for the toxicity of arsenic because of the role played by Omega GSTs, role in the metabolism of arsenic.

The microsomal glutathione transferases are distinct from the soluble enzymes. Six human microsomal glutathione transferases divided into three groups have been identified (see Table 6-18), which differ in their ability to form aggregates. For instance, MGST1 exists as a trimer, as does the other group IV MAPEG, namely, PT-GEs, whereas the group I MAPEGs can function as monomers, dimers, trimers, or more complex aggregates (Hayes *et al.*, 2005). MGST1 conjugates xenobiotics with glutathione and probably functions solely as a detoxication enzyme, whereas MGST2 and 3 contribute to detoxication and synthesis of leukotriene C_4 (Hayes *et al.*, 2005). 5-Lipoxygenase-activating protein (FLAP) does not have catalytic activity, but binds arachidonic acid and is essential for leukotriene synthesis. LTC$_4$S and PGES1 do not appear to be involved in xenobiotic metabolism (Hayes *et al.*, 2005). Many SNPs have been identified in MGST1 and FLAP as well as diallelic variants in MGST3 in certain populations, but the biological significance has not yet been determined (Hayes *et al.*, 2005).

The conjugation of certain xenobiotics with glutathione is catalyzed by most classes of glutathione transferase. For example, members of the Alpha, Kappa, Mu, and Pi classes of human cytosolic GSTs, as well as several of the MAPEG GSTs all catalyze the conjugation of 1-chloro-2,4-dinitrobenzene. Other reactions are fairly specific for one class of enzymes (Hayes and Pulford, 1995). For example, the Alpha glutathione transferases preferentially isomerize Δ^5 steroids to Δ^4 steroids and reduce linoleate and cumene hydroperoxide to their corresponding alcohols. The Mu glutathione transferases preferentially conjugate certain arene oxides and alkene epoxides, such as styrene-7,8-epoxide. The Pi glutathione transferases preferentially conjugate ethacrynic acid. (For additional examples, see Table 6-18.) However, individual members within a class of glutathione transferases can differ markedly in their substrate specificity. In mice, for example, the Alpha glutathione transferases composed of Yc subunits can rapidly conjugate aflatoxin B_1 8,9-epoxide, whereas those composed of Ya subunits are virtually incapable of catalyzing this reaction (Eaton and Gallagher, 1994).

In rodents, individual members of the Alpha and Mu class of glutathione transferases are inducible (generally two- to threefold) by 3-methylcholanthrene, phenobarbital, corticosteroids, oltipraz, and various antioxidants (such as ethoxyquin and butylated hydroxyanisole). Several glutathione transferase substrates (i.e., Michael acceptors) are glutathione transferase inducers, as are certain nonsubstrates, such as hydrogen peroxide and other reactive oxygen species (Rushmore *et al.*, 1991; Daniel, 1993; Nguyen *et al.*, 1994; Hayes and Pulford, 1995; Hayes *et al.*, 2005). Induction is usually associated with increased levels of mRNA due to transcriptional activation of the gene encoding a subunit of glutathione transferase. Not all subunits are induced to the same extent.

The enhancer regions of the genes encoding some of the rodent glutathione transferases (such as rat GSTA2-2) have been shown to contain a xenobiotic (dioxin)-responsive element (XRE), a putative phenobarbital-responsive element, a glucocorticoid-responsive element (GRE), and an antioxidant responsive element (ARE, which is also known as the electrophile-responsive element [see Point 8]). Accordingly, in rodents, certain glutathione transferase subunits are regulated by both *monofunctional* and *bifunctional* agents, as described previously for DT-diaphorase (see sections "Quinone Reduction—NQO1 and NQO2" and "Induction of Cytochrome P450"). Induction of glutathione transferases by the monofunctional agent sulforaphane, which induces one or more GSTs in mice, is thought to be responsible, at least in part, for the anticancer effects

of broccoli (Zhang *et al*., 1992). GSTA4 is induced in mice administered α-angeliclactone, butylated hydroxyanisole, ethoxyquin, indole-3-carbinol, limettin, and oltipraz (Hayes *et al*., 2005). In addition to inducing one or more GSTs, activation of Nrf-2 by oxidative stress or exposure to electrophiles induces. -GCL, which increases GSH levels in response to an initial decrease in GSH levels (see "Point 8").

Factors that regulate the expression of glutathione transferases in rodents may have similar effects in humans, but some differences have been noted. For example, the 5′ promoter region of Alpha glutathione transferase in humans (GSTA1) lacks the ARE and XRE consensus sequences through which the corresponding rat enzyme is induced. However, such sequences appear to be present in the promoter region of human GSTM4 and GSTP1 genes (Hayes and Pulford, 1995; Whalen and Boyer, 1998). (A functional ARE is also present in the promoter region of human DT-diaphorase [NQO1].) Therefore, certain subunits of glutathione transferases are inducible by a variety of mechanisms in rats, and other subunits appear to be inducible by similar mechanisms in humans. Species differences in glutathione transferase regulation may also stem from differences in xenobiotic biotransformation, especially differences in the formation of electrophiles, Michael acceptors, and/or the production of oxidative stress. For example, coumarin is thought be an inducer of GSTP1 in rats because it is converted in rat liver to reactive metabolites, namely, coumarin 3,4-epoxide and *ortho*-hydroxyphenylacetaldehyde (see Fig. 6-42). In contrast, the major route of coumarin biotransformation in humans is by 7-hydroxylation, which would not be expected to be associated with glutathione transferase induction.

Conjugation with glutathione represents an important detoxication reaction because electrophiles are potentially toxic species that can bind to critical nucleophiles, such as proteins and nucleic acids, and cause cellular damage and genetic mutations. All the enzymes involved in xenobiotic biotransformation have the potential to generate reactive intermediates, most of which are detoxified to some extent by conjugation with glutathione. Glutathione is also a cofactor for glutathione peroxidases (GPXs), which play an important role in protecting cells against lipid and hemoglobin peroxidation. Resistance to toxic compounds is often associated with an over-expression of glutathione transferase. Examples include the resistance of insects to DDT (see Fig. 6-20), of corn to atrazine, and of cancer cells to chemotherapeutic agents.

Glutathione transferase is the major determinant of certain species differences in chemical-induced toxicity. For example, low doses of aflatoxin B_1 cause liver toxicity and tumor formation in rats but not mice, even though rats and mice convert aflatoxin B_1 to the highly reactive 8,9-epoxide at similar rates (this reaction is shown in Fig. 6-33). This species difference arises because mice express high levels of an Alpha class glutathione transferase (Yc) enabling them to conjugate aflatoxin B_1 8,9-epoxide with glutathione up to 50 times faster than rats (or humans, which are also considered a susceptible species) (Eaton and Gallagher, 1994). Mice become sensitive to the adverse effects of aflatoxin B_1 following treatment with chemicals that decrease glutathione levels, such as diethyl maleate (which depletes glutathione) or buthionine-*S*-sulfoximine (which inhibits glutathione synthesis). Conversely, treatment of rats with inducers of certain GSTs, such as ethoxyquin, BHA, oltipraz, and phenobarbital, protects them from the hepatotoxic/tumorigenic action of aflatoxin B_1 (Hayes *et al*., 1994).

The conjugation of aflatoxin B_1 8,9-epoxide with glutathione provides an interesting example of the stereospecificity with which

certain glutathione conjugation reactions can occur. CYP converts aflatoxin B_1 to a mixture of *exo-* and *endo*-8,9-epoxides (only a generic 8,9-epoxide is shown in Fig. 6-33; meaning the figure does not indicate whether the oxygen atom is above or below the plane of the ring system). Both enantiomeric epoxides are formed by liver microsomes from mice, rats, and humans, but only the *exo*-epoxide binds extensively to DNA (where it binds to the N^7 position of guanine). One or more mouse Alpha GSTs rapidly conjugate the *exo*-epoxide, which accounts for the resistance of this species to aflatoxin-induced hepatotoxicity and tumorigenicity (as described above). Rat and human GSTAs do not rapidly conjugate either the *exo-* or the *endo*-epoxide (with the exception of the inducible rat glutathione transferase, which is not constitutively expressed in rats to any great extent). However, human GSTM1-1 can conjugate aflatoxin B_1 8,9-epoxide, but it preferentially conjugates the relatively innocuous *endo*-isomer (Wang *et al*., 2000).

Species differences in the detoxication of aflatoxin B_1 8,9-epoxide suggest that individual differences in glutathione transferase may determine susceptibility to the toxic effects of certain chemicals. In support of this interpretation, a genetic polymorphism for GSTM1 has been identified, and individuals who are homozygous for the null allele (i.e., those with low glutathione transferase activity due to complete deletion of the GSTM1 gene) appear to be at a moderately increased risk for cigarette smoking-induced lung cancer, head and neck, and possibly bladder cancer (Hayes and Pulford, 1995; Whalen and Boyer, 1998; Strange *et al*., 2000; Hayes *et al*., 2005). Depending on the ethnic group, 22 to 100% of the population is homozygous for the GSTM1 null genotype, which results in a complete lack of GSTM1 activity in all tissues. On the other hand, there is evidence that GSTM1 confers significant protection from breast cancer in individuals homozygous for a functional GSTM1 allele (Hayes *et al*., 2005). GSTT1 activity is absent from 11 to 58% of the population (depending on ethnicity) due to deletion of the GSTT1 gene, which appears to increase susceptibility to development of astrocytoma, meningioma, and myelodysplasia. When examined for their individual effect, these null genotypes generally have a small effect on susceptibility, with an odds ratio of 2 or less. However, the odds ratio can increase dramatically when these null glutathione transferase genotypes are examined in conjunction with other genotypes or with environmental factors (such as exposure to carcinogens). For example, when the GSTM1 null genotype is combined with cigarette smoking and a particular CYP1A1 allele, the odds ratio can increase to 8.9 (in one study) or 21.9 (in another study). Polymorphisms that result in amino substitutions have been reported for most human glutathione transferase genes; some of which alter glutathione transferase function. Some of these polymorphisms may also be risk modifiers for certain diseases in an analogous manner to the GSTM1 and GSTT1 null genotypes.

In some cases, conjugation with glutathione enhances the toxicity of a xenobiotic (Monks *et al*., 1990; Dekant and Vamvakas, 1993). Five mechanisms of glutathione-dependent activation of xenobiotics have been identified, with the first four shown in Fig. 6-64. These mechanisms are (1) formation of glutathione conjugates of haloalkanes, organic thiocyanates, and nitrosoguanides that release a toxic metabolite; (2) formation of glutathione conjugates of vicinal dihaloalkanes that are inherently toxic because they can form electrophilic sulfur mustards; (3) formation of glutathione conjugates of halogenated alkenes that are degraded to toxic metabolites by β-lyase in the kidney, (4) formation of glutathione conjugates of quinones, quinoneimines, and isothiocyanates that are

degraded to toxic metabolites by γ-glutamyltransferase and alanyl aminopeptidase (ANPEP) in the kidney, and (5) cyclical glutathione conjugation which leads to glutathione depletion.

The first mechanism is illustrated by dichloromethane, which is conjugated with glutathione to form the highly unstable *S*-chloromethyl-glutathione, which then breaks down to formaldehyde. Both formaldehyde and the glutathione conjugate are reactive metabolites, and either or both may be responsible for dichloromethane-induced tumorigenesis in sensitive species. The rate of conjugation of dichloromethane with glutathione is considerably faster in mice, which are susceptible to dichloromethane-induced tumorigenesis, than in rats or hamsters, which are resistant species.

The second mechanism accounts for the toxicity of dichloroethane and dibromoethane. These vicinal dihaloalkanes are converted to glutathione conjugates that can rearrange to form mutagenic and nephrotoxic episulfonium ions (sulfur half-mustards) (Fig. 6-64). Dichloroethane and dibromoethane can also be oxidized by CYP to chloroacetaldehyde and bromoacetaldehyde (by reactions analogous to those shown in Fig. 6-48). Either pathway can potentially account for the toxic and tumorigenic effects of these dihaloalkanes. However, the toxicity and DNA-binding of dihaloalkanes are increased by factors that decrease their oxidation by CYP and increase their conjugation with glutathione.

The third mechanism accounts for the nephrotoxicity of several halogenated alkenes. Several halogenated alkenes, such as hexachlorobutadiene, cause damage to the kidney tubules in rats, which leads to carcinoma of the proximal tubules. These nephrotoxic halogenated alkenes are conjugated with glutathione and transported to the kidney for processing to mercapturic acids. The cysteine conjugates, which form by removal of glutamic acid and glycine, are substrates for *N*-acetyltransferase, which completes the synthesis of mercapturic acids, and cysteine-conjugate β-lyase, which removes pyruvate and ammonia from the cysteine conjugate to produce thionylacyl halides, thiiranes, thiolactones, and thioketenes. The early damage to renal mitochondria caused by halogenated alkenes is probably because cysteine-conjugate β-lyase is a mitochondrial enzyme.

The fourth mechanism accounts for the nephrotoxicity of bromobenzene, which causes damage to the proximal tubules in rats. Bromobenzene is oxidized by CYP in the liver to bromohydroquinone, which is conjugated with glutathione and transported to the kidney (Fig. 6-64). The glutathione conjugate is converted to the cysteine derivative by γ-glutamyltransferase and membrane alanyl aminopeptidase. Substitution of bromohydroquinones with cysteine lowers their redox potential and thereby facilitates their oxidation to toxic quinones. The cysteine conjugates of bromohydroquinone are thought to undergo redox cycling and cause kidney damage through the generation of reactive oxygen species. 4-Aminophenol is thought to cause kidney damage by a similar mechanism, except a benzoquinoneimine is involved in conjugation with glutathione and subsequent damage to proximal tubules of the kidney. Treatment of rats with the glutathione depletor, buthionine-*S*-sulfoximine, protects them against the nephrotoxic effects of 4-aminophenol, which implicates glutathione conjugation in the activation of this compound.

The fifth mechanism occurs with moderately toxic allyl-, benzyl-, and phenethyl-isothiocyantes as well as sulforaphane formed from plant glucosinolates. These compounds are reversibly conjugated with glutathione to form thiocarbamates which spontaneously degrade to their isothiocyanates upon export from the cell, which releases glutathione. The isothiocyanate is then taken up by the cells again and the cycle can repeat until intracellular glutathione is depleted. Once glutathione levels are low, the compounds will tend to thiocarbamylate proteins, which can lead to cell death (Hayes *et al.*, 2005).

The ability of GSTs to form reactive metabolites has been exploited with the development of cancer therapies that specifically target cells that overexpress GSTP1-1, which is often associated with a poor prognosis and chemotherapeutic resistance in ovarian, nonsmall cell lung, breast, and colorectal cancers. For instance, Telcyta™ (TLK286: Confosfamide (not yet approved)) is a modified glutathione analog that can be metabolized by GSTP1-1, which results in the release of two electrophilic fragments, glutathione vinyl sulfone, and a tetrakis (chloroethyl) phosphorodiamidate which leads to apoptosis (Townsend and Tew, 2003; Rosen *et al.*, 2004; Gonzalez and Tukey, 2006). Other drugs have also been recently developed to take advantage of activation by GSTP1-1, which is present in some tumor cells at 2–4 times the level found in normal cells.

Thiosulfate Sulfurtransferase (Rhodanese)

Cyanide forms naturally in leucocytes and neural cells, and also as a result of vitamin B12 metabolism, and is also encountered as a xenobiotic in plants containing cyanogenic glycosides, such as cassava, and tobacco smoke (Billaut-Laden *et al.*, 2006). Thiosulfate sulfurtransferase is a mitochondrial enzyme encoded by the TST gene that converts cyanide to the far less toxic metabolite, thiocyanate. The reaction involves transfer of sulfur from thiosulfate (or another sulfur donor) as follows:

$$CN^- \;+\; S_2O_3{}^{2-} \;\rightarrow\; SCN^- \;+\; SO_3{}^{2-}$$
$$\text{cyanide}\quad\text{thiosulfate}\quad\text{thiocyanate}\quad\text{sulfite}$$
The sulfite produced by this reaction can be converted to sulfate by the molybdozyme, sulfite oxidase. Cyanide can also be "detoxified" by binding to methemoglobin (the oxidized or ferric form of hemoglobin). 4-Dimethylaminophenol is used to induce methemoglobinemia as an antidote to cyanide poisoning because methemoglobin competes with cytochrome oxidase for the cyanide ion. However, 4-dimethylaminophenol is nephrotoxic to rats, presumably by a mechanism similar to that described above for the structural analog, 4-aminophenol (see preceding section and "Peroxidase-Dependent Cooxidation").

In humans, TST is expressed at high levels in the colon, where it plays a major role in the detoxification of hydrogen sulfide (which can reach concentrations of 3.4 mM) produced by anaerobic bacteria (Billaut-Laden *et al.*, 2006). TST is also widely distributed in the central nervous system. Six allelic variants of TST have been identified, namely, TST*1B–*1F and TST*2, with the latter showing significantly reduced intrinsic clearance for thiocyanate formation (Billaut-Laden *et al.*, 2006). TST polymorphisms that decrease cyanide and hydrogen sulfide detoxification may ultimately become important in understanding certain diseases, such as ulcerative colitis and amyotrophic lateral sclerosis (ALS). For instance, hydrogen sulfide release has been found to be 3–4 times higher in patients with ulcerative colitis when compared with normal subjects, and is positively correlated with disease severity (Billaut-Laden *et al.*, 2006). Finally, it has been postulated that individuals with ALS display a disorder in cyanide metabolism because of the higher blood and urine levels of cyanide
Figure 6-64. Role of glutathione conjugation in the activation of xenobiotics to toxic metabolites.

(Billaut-Laden *et al.*, 2006). Mimori and colleagues (1984) also reported significantly decreased TST activity in cervical and thoracic spinal cords of patients with ALS, compared with normal subjects.

Phosphorylation—The Dog That Did Not Bark

Some drugs are intentionally designed to be phosphorylated by intracellular enzymes. For example, the anti-HIV drug zidovudine (AZT) is converted to a triphosphate nucleoside by enzymes in the salvage pathway (nucleoside kinase, nucleoside monophosphate kinase or NMK, and nucleoside diphosphate kinase or NDK). However, phosphorylation of xenobiotics is the exception rather than the rule. All conjugation reactions ultimately require ATP, either to activate the xenobiotic for conjugation with glutathione or amino acids, or to synthesize high-energy cofactors such as UDPGA and

PAPS. The process is inefficient in that several ATP molecules (or their equivalent) are used to synthesize each cofactor molecule. The question arises: Why is ATP not used directly by conjugating enzymes? In other words, why are xenobiotics never phosphorylated directly (with the exception of drugs such as zidovudine), which would require less ATP and would achieve the goal of converting xenobiotics to water-soluble conjugates? It is difficult to be certain why this does not occur, but four reasons suggest themselves. First, if xenobiotics could be phosphorylated, high intracellular levels of a xenobiotic might consume so much ATP as to jeopardize cell viability, whereas UDPGA and PAPS can be depleted without killing cells. Second, phosphorylation of endogenous substrates, such as glucose, is a mechanism for trapping endogenous substrates inside a cell. This works because the plasma membrane of all cells is a barrier to the passage of polar compounds by virtue of its hydrophobic properties (lipid bilayer) and its general lack of transporters that pump phosphorylated compounds out

of the cell. The same is true for the phosphorylated metabolites of zidovudine and related antiviral drugs; they are retained inside the cell that forms them. A lipid bilayer is also a physical barrier to other water-soluble conjugates, such as glucuronides and sulfonates, but these are transported out of the cell by various transporters. Third, phosphorylation of both small molecules (such as inositol) and proteins (such as membrane-bound receptors and various transcription factors) plays an important role in intracellular and intranuclear signaling. It is possible that some xenobiotics, if they were phosphorylated, might interfere with these regulatory systems and thereby disrupt cellular homeostasis. Fourth, even if xenobiotics were phosphorylated in the liver and excreted in bile, they would be rapidly hydrolyzed by high levels of alkaline phosphatase lining the surface of enterocytes in the small intestine, which would promote reabsorption of the xenobiotic (by the very process exploited in the design of phosphorylated prodrugs like fosamprenavir). Whatever the reason, there appears to be strong evolutionary pressure against the conjugation of xenobiotics with phosphoric acid.

CHAPTER 7

TOXICOKINETICS

Danny D. Shen

INTRODUCTION

Toxicokinetics is the quantitative study of the movement of an exogenous chemical from its entry into the body, through its distribution to organs and tissues via the blood circulation, and to its final disposition by way of biotransformation and excretion. The basic kinetic concepts for the absorption, distribution, metabolism, and excretion of chemicals in the body system initially came from the study of drug actions or pharmacology; hence, this area of study is traditionally referred to as pharmacokinetics. Toxicokinetics represents extension of kinetic principles to the study of toxicology and encompasses applications ranging from the study of adverse drug effects to investigations on how disposition kinetics of exogenous chemicals derived from either natural or environmental sources (generally refer to as xenobiotics) govern their deleterious effects on organisms including humans.

The study of toxicokinetics relies on mathematical description or modeling of the time course of toxicant disposition in the whole organism. The classic approach to describing the kinetics of drugs is to represent the body as a system of one or two compartments even though the compartments do not have exact correspondence to anatomical structures or physiologic processes. These empirical compartmental models are almost always developed to describe the kinetics of toxicants in readily accessible body fluids (mainly blood) or excreta (e.g., urine, stool, and breath). This approach is particularly suited for human studies, which typically do not afford organ or tissue data. In such applications, extravascular distribution, which does not require detail elucidation, can be represented simply by lumped compartments. An alternate and newer approach, physiologically based toxicokinetic modeling attempts to portray the body as an elaborate system of discrete tissue or organ compartments that are interconnected via the circulatory system. Physiologically based models are capable of describing a chemical's movements in body tissues or regions of toxicological interest. It also allows a priori predictions of how changes in specific physiological processes affect the disposition kinetics of the toxicant (e.g., changes in respiratory status on pulmonary absorption and exhalation of a volatile compound) and the extrapolation of the kinetic model across animal species to humans.

It should be emphasized that there is no inherent contradiction between the classic and physiologic approaches. The choice of modeling approach depends on the application context, the available data, and the intended utility of the resultant model. Classic compartmental model, as will be shown, requires assumptions that limit its application. In comparison, physiologic models can predict tissue concentrations; however, it requires much more data input and often the values of the required parameters cannot be estimated accurately or precisely, which introduces uncertainty in its prediction.

We begin with a description of the classic approach to toxicokinetic modeling, which offers an introduction to the basic kinetic concepts for toxicant absorption, distribution, and elimination. This will be followed by a brief review of the physiologic approach to toxicokinetic modeling that is intended to illustrate the construction and application of these elaborate models.

CLASSIC TOXICOKINETICS

Ideally, quantification of xenobiotic concentration at the site of toxic insult or injury would afford the most direct information on exposure–response relationship and dynamics of response over time. Serial sampling of relevant biological tissues following dosing can be cost-prohibitive during in vivo studies in animals and is nearly impossible to perform in human exposure studies. The most accessible and simplest means of gathering information on absorption, distribution, metabolism, and elimination of a compound is to examine the time course of blood or plasma toxicant concentration over time. If one assumes that the concentration

One Compartment Model

Two Compartment Model
Figure 7-1. Compartmental toxicokinetic models.

Symbols for one-compartment model: k_a is the first-order absorption rate constant, and k_{el} is the first-order elimination rate constant. Symbols for two-compartment model: k_a is the first-order absorption rate constant into the central compartment (1), k_{10} is the first-order elimination rate constant from the central compartment (1), k_{12} and k_{21} are the first-order rate constants for distribution between central (1) and peripheral (2) compartment.

of a chemical in blood or plasma is in some describable dynamic equilibrium with its concentrations in tissues, then changes in plasma toxicant concentration should reflect changes in tissue toxicant concentrations and relatively simple kinetic models can adequately describe the behavior of that toxicant in the body system.

Classic toxicokinetic models typically consist of a central compartment representing blood and tissues that the toxicant has ready access and equilibration is achieved almost immediately following its introduction, along with one or more peripheral compartments that represent tissues in slow equilibration with the toxicant in blood (Fig. 7-1). Once introduced into the central compartment, the toxicant distributes between central and peripheral compartments. Elimination of the toxicant, through biotransformation and/or excretion, is usually assumed to occur from the central compartment, which should comprise the rapidly perfused visceral organs capable of eliminating the toxicant (e.g., kidneys, lungs, and liver). The obvious advantage of compartmental toxicokinetic models is that they do not require information on tissue physiology or anatomic structure. These models are useful in predicting the toxicant concentrations in blood at different doses, in establishing the time course of accumulation of the toxicant, either in its parent form or as biotransformed products during continuous or episodic exposures, in defining concentration–response (vs. dose–response) relationships, and in guiding the choice of effective dose and design of dosing regimen in animal toxicity studies (Rowland and Tozer, 1995).

One-Compartment Model

The most straightforward toxicokinetic assessment entails quantification of the blood or more commonly plasma concentrations of a toxicant at several time points after a bolus intravenous (iv) injection.

Often, the data obtained fall on a straight line when they are plotted as the logarithms of plasma concentrations versus time; the kinetics of the toxicant is said to conform to a one-compartment model (Fig. 7-2). Mathematically, this means that the decline in plasma concentration over time profile follows a simple exponential pattern as represented by the following mathematical expressions:

$$C = C_0 \times e^{-k_{el} \times t} \qquad (7\text{-}1)$$

or its logarithmic transform

$$\text{Log}\, C = \text{Log}\, C_0 - \frac{k_{el} \times t}{2.303} \qquad (7\text{-}2)$$

where C is the plasma toxicant concentration at time t after injection, C_0 is the plasma concentration achieved immediately after injection, and k_{el} is the exponential constant or elimination rate constant with dimensions of reciprocal time (e.g., min^{-1} or hr^{-1}). The constant 2.303 in Equation (7-2) is needed to convert natural logarithm to base-10 logarithm. It can be seen from Equation (7-2) that the elimination rate constant can be determined from the slope of the log C versus time plot (i.e., $k_{el} = -2.303 \times$ slope).

The elimination rate constant k_{el} represents the overall elimination of the toxicant, which includes biotransformation, exhalation, and/or excretion pathways. When elimination of a toxicant from the body occurs in an exponential fashion, it signifies a first-order process; that is, the rate of elimination at any time is proportional to the amount of toxicant remaining in the body (i.e., body load) at that time. This means that following an iv bolus injection, the absolute rate of elimination (e.g., mg of toxicant eliminated per minute) continually changes over time. Shortly after introduction of the dose, the rate of toxicant elimination will be at the highest. As elimination proceeds and body load of the toxicant is reduced, the elimination rate will decline in step. As a corollary, it also means that at multiple levels of the toxicant dose, the absolute rate of elimination at corresponding times will be proportionately more rapid at the higher doses. This mode of elimination offers an obvious advantage for the organism to deal with increasing exposure to a toxicant. First-order kinetics occur at toxicant concentrations that are not sufficiently high to saturate either metabolic or transport processes.

In view of the nature of first-order kinetics, k_{el} is said to represent a constant fractional rate of elimination. Thus, if the elimination rate constant is, for example, 0.3 h^{-1}, the percentage of plasma concentration remaining in the body ($C/C_0 \times 100$) and the percentage of the dose eliminated from the body after 1 hour, i.e., $1 - (C/C_0 \times 100)$, are 74% and 26%, respectively, regardless of the dose administered (Table 7-1). The percentage of the total dose eliminated at 1 hour is said to be independent of dose. It also means that the fractional rate of elimination of the toxicant remains constant over time after iv injection or any acute exposure. Because a constant percentage of toxicant present in the body is eliminated over a given time period regardless of dose or the starting concentration, it is more intuitive and convenient to refer to an elimination half-life ($T_{1/2}$); that is, the time it takes for the original blood or plasma concentration to fall by 50% or to eliminate 50% of the original body load. By substituting $C/C_0 = 0.5$ into Equation (7-1), we obtain the following relationship between $T_{1/2}$ and k_{el}:

$$T_{1/2} = \frac{0.693}{k_{el}} \qquad (7\text{-}3)$$

One Compartment Model

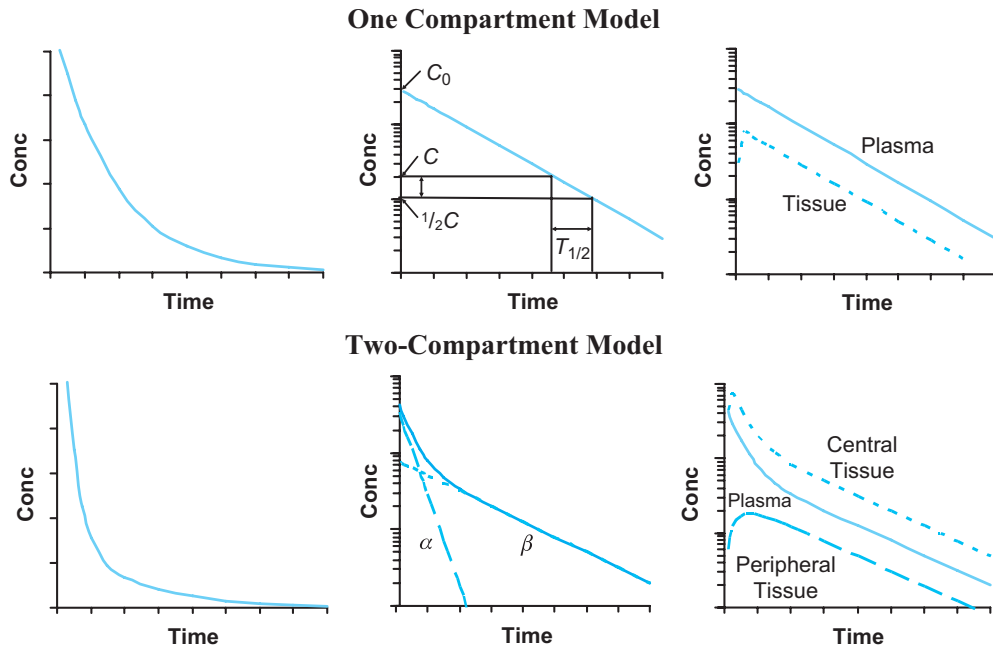
Two-Compartment Model


Figure 7-2. Plasma concentration versus time curves of toxicants exhibiting kinetic behavior conforming to a one-compartment model (top row) and a two-compartment model (bottom row) following intravenous bolus injection. Left and middle panels show the plots on a rectilinear and semilogarithmic scale, respectively. Right panels illustrate the relationship between tissue (dash lines) and plasma (solid line) concentration over time.

The right panel for the one-compartment model shows a typical tissue with a higher concentration than plasma. Note that tissue concentration can be higher, nearly the same, or lower than plasma concentration. Tissue concentration peaks almost immediately, and thereafter declines in parallel with plasma concentration. The right panel for the two-compartment model shows typical tissues associated with the central (1) and peripheral (2) compartments as represented by short and long dash lines, respectively. For tissues associated with the central compartment, their concentrations decline in parallel with plasma. For tissues associated with peripheral compartment, toxicant concentration rises, while plasma concentration declines rapidly during the initial phase; it then reaches a peak and eventually declines in parallel with plasma in the terminal phase. Elimination rate constant k_{el} for one-compartment model and the terminal exponential rate constant β are determined from the slope of the log-linear concentration versus time curve. Half-life ($T_{1/2}$) is the time required for plasma toxicant concentration to decrease by one-half. C_0 is the concentration of a toxicant for a one compartment model at $t = 0$ determined by extrapolating the log-linear concentration time curve to the Y-axis.

where 0.693 is the natural logarithm of 2. Simple calculations reveals that it would take about four half-lives for >90% (exactly 93.8%) of the dose to be eliminated, and about seven half-lives for >99% (exactly 99.2%) elimination. Thus, given the elimination $T_{1/2}$ of a toxicant, the length of time it takes for near complete washout of a toxicant after discontinuation of its exposure can easily be estimated. As will be seen in next section, the concept of $T_{1/2}$ is applicable to toxicants that exhibit multi-exponential kinetics.

We can infer from the mono-exponential decline of blood or plasma concentration that the toxicant equilibrates very rapidly between blood and the various tissues relative to the rate of elimination, such that extravascular equilibration is achieved nearly instantaneously and maintained thereafter. Depiction of the body system by a one-compartment model does not mean that the concentration of the toxicant is the same throughout the body, but it does assume that the changes that occur in the plasma concentration reflect proportional changes in tissue toxicant concentrations (Fig. 7-2 upper, right panel). In other words, toxicant concentrations in tissues are expected to decline with the same elimination rate constant or $T_{1/2}$ as in plasma.

Two-Compartment Model

After rapid iv administration of some toxicants, the semi-logarithmic plot of plasma concentration versus time does not yield a straight line but a curve that implies more than one dispositional phase (Fig. 7-2). In these instances, it takes some time for the toxicant to be taken up into certain tissue groupings, and to then reach an equilibration with the concentration in plasma; hence, a multi-compartmental model is needed for the description of its kinetics in the body (Fig. 7-1). The concept of tissue groupings with distinct uptake and equilibration rates of toxicant becomes apparent when we consider the factors that govern the uptake of a lipid-soluble, organic toxicant. Table 7-2 presents data on the volume and blood perfusion rate of various organs and tissues in a standard size human. From these data and assuming reasonable partitioning ratios of a typical lipid-soluble, organic compound in the various tissue types, we can estimate the uptake equilibration half-times of the toxicant in each organ or tissue region during constant, continuous exposure. The results suggest that the tissues can be grouped into rapid-equilibrating visceral organs, moderately slow-equilibrating lean body tissues (mainly skeletal muscle), and very slow-equilibrating body fat; these

Table 7-1
Elimination of a Toxicant that Follows First-Order Kinetics ($k_{el} = 0.3$ h^{-1}) by 1 Hour After IV Administration at Four Different Dose Levels

DOSE (mg)	TOXICANT REMAINING (mg)	TOXICANT ELIMINATED (mg)	TOXICANT ELIMINATED (% of dose)
10	7.4	2.6	26
30	22	8	26
90	67	23	26
250	185	65	26

groupings give rise to three distinct uptake phases; that is, half-times of <2 minutes for the rapid-equilibrating tissues, several tens of minutes for the moderately slow-equilibrating lean body tissues, and hours for the very slow-equilibrating body fat. By inference, three distinct phases of washout should also be evident following a brief exposure to the toxicant, such as after a bolus iv injection. The relative prominence of these distributional phases will vary depending on the average lipid solubility of the toxicant in each tissue grouping and any other sequestration and removal mechanisms of a toxicant in particular tissues (e.g., tight binding to tissue proteins, active influx into, or efflux out of the tissue cell types), as well as the competing influence of elimination from the visceral organs. For example, very rapid metabolism or excretion at the visceral organs would limit distribution into the slow or very slow tissue groupings. Also, there are times when equilibration rates of a toxicant into visceral organs overlaps with lean body tissues, such that the distribution kinetics of a toxicant into these two tissue groupings become indistinct with respect to the exponential decline of plasma concentration, in which case two instead of three tissue groupings may be observed. The concept of tissue groupings with respect to uptake or washout kinetics serves to justify the seemingly simplistic, yet pragmatic, mathematical description of extravascular distribution by the classic two- or three-compartment models.

Plasma concentration-time profile of a toxicant that exhibits multi-compartmental kinetics can be characterized by multi-exponential equations. For example, a two-compartment model can be represented by the following bi-exponential equation.

$$C = A \times e^{-\alpha \times t} + B \times e^{-\beta \times t} \qquad (7\text{-}4)$$

where A and B are coefficients in units of toxicant concentration, and α and β are the respective exponential constants for the initial and terminal phases in units of reciprocal time. The initial (α) phase is often referred to as the distribution phase, and terminal (β) phase as the post-distributional or elimination phase. The lower, middle panel of Fig. 7-2 shows a graphical resolution of the two exponential phases from the plasma concentration-time curve. It should be noted that the α constant is the slope of the residual log linear plot and not the initial slope of the decline in the observed plasma toxicant concentration; that is, the initial rate of decline in plasma concentration approximates, but is not exactly equal, the α rate constant in Equation (7-4).

It should be noted that distribution into and out of the tissues and elimination of the toxicant are ongoing at all times; that is, elimination does occur during the "distribution" phase, and distribution between compartments is still ongoing during the "elimination" phase. As illustrated in Fig. 7-3, the dynamics of a

Table 7-2
Prediction of Equilibration Half-Times for Tissues in the Groupings of Highly Perfused Visceral Tissues, Poorly Perfused Lean Tissues, and Adipose Tissues for a Lipid-Soluble, Organic Toxicant with Assumed Typical Tissue-to-Blood Partitioning Ratios (P)[a]

GROUPING	TISSUE	PERFUSION (L/min)[b]	VOLUME (L)[b]	EQUILIBRATION $T_{1/2}$ (min)[c]

Adipose tissue, $P = 5$	—	0.20	14	243

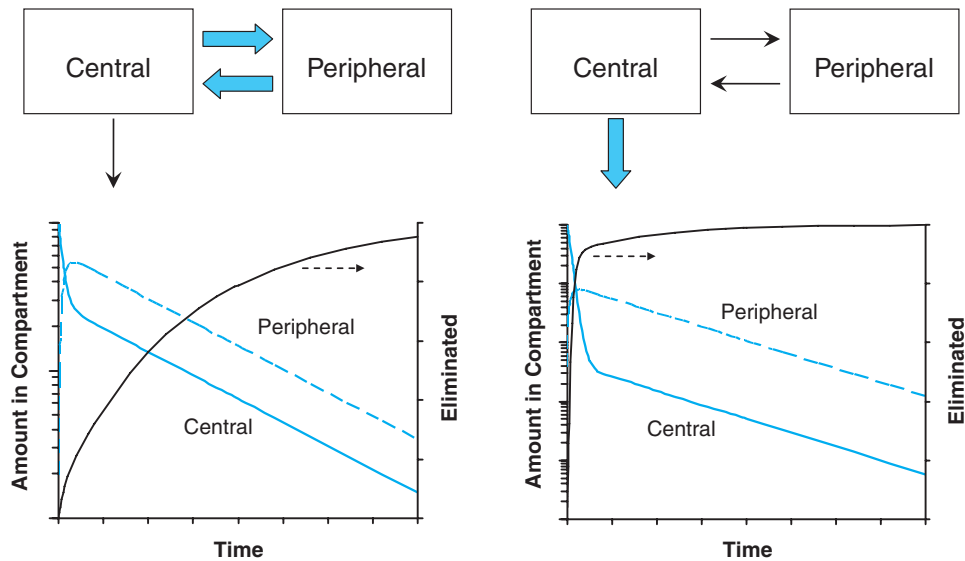
[a] Adapted from Rowland and Tozer (1995).
[b] Data taken from the compilation of Rowland and Tozer (1995), Table 10-1 on p. 138.
[c] Equilibration half-time is the predicted time it takes to achieve 50% of the eventual equilibrated concentration in a tissue when arterial toxicant concentration is held constant and assuming that distribution is perfusion rate-limited. It is calculated by $0.693 \times (V/Q)$, where Q = blood perfusion rate of the tissue, and V = tissue volume.
Note that the equilibration half-times for the highly perfused visceral tissues are predicted to be very short, <2 min. The equilibration half-times for poorly perfused lean tissues are estimated to be around 10–20 min. The equilibration half-time predicted for fat is the order of at least several hours. This tissue grouping in equilibration kinetics gives rise to multiphasic toxicokinetics that are describable by two or three compartment models.


Figure 7-3. Effects of interplay between kinetics of distribution and elimination processes on time course of exchange between body compartments and elimination from the body for toxicants whose disposition conforms to a two-compartment model.

Left panel depicts the more common scenario of rapid distribution between compartments relative to elimination, in which case elimination from the body occurs largely during the terminal phase when a dynamic equilibration between the central and peripheral compartment has been reached. Accordingly, half-life of the terminal phase is an appropriate measure of elimination. Right panel depicts the scenario of very slow distribution relative to elimination, in which case a substantial (>90% of dose) loss of toxicant occurs during the initial phase. The terminal phase reflects the slow redistribution of the toxicant sequestered in the peripheral site to the central site where it can be eliminated (i.e., washout is rate-limited by redistribution). Under this scenario, the initial phase reflects elimination kinetics, whereas the terminal phase reflects tissue distribution kinetics. (Adapted from Tozer and Rowland, 2006.)

multi-compartmental system is such that the governing factor, that is, be it inter-compartmental distribution or elimination, for each of the phases depends on the relative magnitude of the rate constants for inter-compartmental exchange and the elimination process. In the usual case, that of rapid distribution and relatively slow elimination (left panel of Fig. 7-3), the initial rapid phase indeed reflects extravascular distribution, and the later, slow phase reflects elimination after a dynamic equilibration between tissue and blood is attained. There are cases where distribution into some tissue group is much slower than elimination. Then, the initial phase is governed largely by elimination, and the later phase reflects the slow redistribution of the toxicant from the tissues associated with the peripheral compartment to the central compartment, where it is eliminated (i.e., washout in the terminal phase is rate-limited by redistribution from the peripheral compartment). The aminoglycoside antibiotic gentamicin is a case in point (Schentag and Jusko, 1977). Following an iv injection of gentamicin in patients with normal renal function, serum gentamicin concentration exhibits biphasic kinetics. Serum concentration of gentamicin initially falls very quickly with a half-life of around 2 hours; a slow terminal phase does not emerge until serum concentration has fallen to less than 10% of initial concentration. The terminal half-life of serum gentamicin is in the range of 4 to 7 days. This protracted terminal half-life reflects the slow turnover of gentamicin sequestered in the kidneys. In fact, repeated administration of gentamicin leads to accumulation of gentamicin in the kidneys, which is a risk factor for its nephrotoxicity. Because of the complication arising from the interplay of distribution and elimination kinetics, it has been recommended that multiphasic dis-

position should be simply described as consisting of early and late or rapid and slow phases; mechanistic labels of distribution and elimination should be applied with some caution. Lastly, the initial phase may last for only a few minutes or for hours. Whether multiphasic kinetics becomes apparent depends to some extent on how often and when the early blood samples are obtained, and on the relative difference in the exponential rate constants between the early and later phases. If the early phase of decline in toxicant concentration is considerably more rapid than the later phase or phases, the timing of blood sampling becomes critical in the ability to resolving two or more phases of washout.

Sometimes three or even four exponential terms are needed to fit a curve to the plot of log C versus time. Such compounds are viewed as displaying characteristics of three- or four-compartment open models. The principles underlying such models are the same as those applied to the two-compartment open model, but the mathematics is more complex and beyond the scope of this chapter.

Apparent Volume of Distribution

For a one-compartment model, a toxicant is assumed to equilibrate between plasma and tissues immediately following its entry into the systemic circulation. Thus, a consistent relationship should exist between plasma concentration and the amount of toxicant in each tissue and, by extension, to the entire amount in the body or body burden. The apparent volume of distribution (V_d) is defined as the proportionality constant that relates the total amount of the toxicant in the body to its concentration in plasma, and typically has units

of liters or liters per kilogram of body weight (Rowland and Tozer, 1995). V_d is the apparent fluid space into which an amount of toxicant is distributed in the body to result in a given plasma concentration. As an illustration, envision the body as a tank containing an unknown volume (L) of well mixed water. If a known amount (mg) of dye is placed into the water, the volume of that water can be calculated indirectly by determining the dye concentration (mg/L) that resulted after the dye has equilibrated in the tank; that is, by dividing the amount of dye added to the tank by the resultant concentration of the dye in water. Analogously, the apparent volume of distribution of a toxicant in the body is determined after iv bolus administration, and is mathematically defined as the quotient of the amount of chemical in the body and its plasma concentration. V_d is calculated as

$$V_d = \frac{Dose_{iv}}{\beta \times AUC_0^\infty} \tag{7-5}$$

where $Dose_{iv}$ is the intravenous dose or known amount of chemical in body at time zero; β is the elimination rate constant; and AUC_0^∞ is the area under the toxicant concentration versus time curve from time zero to infinity. AUC_0^∞ is estimated by numerical methods, the most common one being the trapezoidal rule (Gibaldi and Perrier, 1982). The product, $\beta \times AUC_0^\infty$, in unit of concentration, is the theoretical concentration of toxicant in plasma if dynamic equilibration were achievable immediately after introduction of the toxicant into the systemic circulation. For a one-compartment model, immediate equilibration of the toxicant between plasma and tissues after an acute exposure does hold true, in which case V_d can be calculated by a simpler and more intuitive equation

$$V_d = \frac{Dose_{iv}}{C_0} \tag{7-6}$$

where C_0 is the concentration of toxicant in plasma at time zero. C_0 is determined by extrapolating the plasma disappearance curve after iv injection to the zero time point (Fig. 7-2).

For the more complex multi-compartmental models, V_d is calculated according to Equation (7-5) that involves the computation of area under the toxicant concentration-time curve. Moreover, the concept of an overall apparent volume of distribution is strictly applicable to the terminal exponential phase when equilibration of the toxicant between plasma and all tissue sites are attained. This has led some investigators to refer to the apparent volumes of distribution calculated by Equation (7-5) as V_β (for a two-compartment model) or V_z (for a general multi-compartmental model); the subscript designation refers to the terminal exponential phase (Gibaldi and Perrier, 1982). It should also be noted that when Equation (7-6) is applied to the situation of a multi-compartmental model, the resultant volume is the apparent volume of the central compartment, often times referred to as V_c. By definition, V_c is the proportionality constant that relates the total amount of the toxicant in the central compartment to its concentration in plasma. It has limited utility; for example, it can be used to calculate an iv dose of the toxicant to target an initial plasma concentration.

V_d is appropriately called the *apparent* volume of distribution because it does not correspond to any real anatomical volumes. The magnitude of the V_d term is toxicant-specific and represents the extent of distribution of toxicant out of plasma and into extravascular sites (Table 7-3). Equation (7-7) provides a more intuitive interpretation of an apparent volume of distribution:

$$V_d = V_p + \sum P_{t,i} \times V_{t,i} \tag{7-7}$$

where V_p is the plasma volume and the $\sum$-term represents the summation of the apparent volume of each tissue region as represented by the product of $P_{t,i}$ (i.e., partition ratio or tissue-to-plasma concentration ratio at dynamic equilibrium) and $V_{t,i}$ (i.e., anatomical volume of tissue). At one extreme, a toxicant that predominantly remains in the vasculature will have a low V_d that approximates the volume of blood or plasma; that is, the minimum V_d for any toxicant is the plasma volume. For toxicants that distribute extensively into extravascular tissues, V_d exceeds physiological fluid spaces, such as plasma or blood volume, interstitial fluid or extracellular fluid. A toxicant that is highly sequestered in tissues (i.e., high $P_{t,i}$) can have a volume of distribution larger than average body size (>1 L/kg). The mechanisms of tissue sequestration include partitioning of a toxicant into tissue fat, high affinity binding to tissue proteins, trapping in specialized organelles (e.g., pH trapping of amine compounds in acidic lysozomes), and concentrative uptake by active transporters. In fact, the equation below is an alternate form of Equation (7-7), which features the interplay of binding to plasma and tissue proteins in determining the partitioning of a toxicant in that only free or unbound drug can freely diffuse across membrane and cellular barriers.

$$V_d = V_p + \sum \left(\frac{f_{up}}{f_{ut,i}} \right) \times V_{t,i} \tag{7-8}$$

where f_{up} is the unbound fraction of toxicant in plasma (Table 7-3) and $f_{ut,i}$ is the effective unbound fraction in a tissue region. Here, $P_{t,i}$ is governed by the ratio $f_{up}/f_{ut,i}$. Thus, a toxicant that has high affinity for plasma proteins (e.g., albumin and/or α_1-acid glycoprotein) relative to tissue proteins has a restricted distribution volume; for example, the anticoagulant warfarin with a plasma-bound fraction of 0.995 or an f_{up} of 0.005 (Table 7-3). On the other hand, a toxicant that has a high affinity for tissue proteins and lesser affinity for plasma proteins can have a very high V_d. For example, the tricyclic antidepressant nortriptyline has a good affinity for plasma proteins with a bound fraction of 0.92 or an f_{up} of 0.08; however, binding of nortriptyline to tissues constituents is so much higher such that it has a V_d of 18 times the body weight in adult humans.

Table 7-3

Volume of Distribution (V_d) and Unbound or Free Fraction in Plasma (f_{up}) for Several Drugs that are of Clinical Toxicological Interest.[a] Volumes of Body Fluid Compartments in Healthy Human Adults are Included for Comparison.

CHEMICAL	V_d (L/kg)	f_{up}
Chloroquine	~200	~0.45
Nortriptyline	18	0.080
Oxycodone	2.0	0.55
	Body size = 1.0	
Acetaminophen	0.95	<0.20
	Total body water = 0.60	
Phenytoin	0.64	0.11
	Extracellular fluid = 0.27	
Warfarin	0.14	0.005
Epoetin alfa	0.05	–
	Plasma volume = 0.045	

[a] V_d and f_{up} values taken from Thummel *et al.* (2006).

In addition to its value as a parameter to indicate the extent of extravascular distribution of a toxicant, V_d also has practical utility. Once the V_d for a toxicant is known, it can be used to estimate the amount of toxicant remaining in the body at any time when the plasma concentration at that time is known; that is,

$$X_B = V_d \times C \qquad (7\text{-}9)$$

where X_B is the amount of toxicant in the body or body burden, and C is the plasma concentration at a given time.

Clearance

Toxicants are cleared from the body via various routes; for example, excretion by the kidneys into urine or via bile into the intestine, biotransformation by the liver, or exhalation by the lungs. Clearance is an important toxicokinetic parameter that relates the rate of toxicant elimination from the whole body in relation to plasma concentration (Wilkinson, 1987). Whereas terminal $T_{1/2}$ is reflective of the rate of removal of a toxicant from plasma or blood, as was explained earlier, it is also subject to the influence of distributional processes, especially for toxicants exhibiting multi-compartmental kinetics. Clearance, on the other hand, is a parameter that solely represents the rate of toxicant elimination.

A formal definition of total body clearance is the ratio of overall elimination rate of a toxicant divided by plasma concentration at any time after an acute exposure or during repetitive or continuous exposure (i.e., elimination rate/C); in effect, clearance expresses the overall efficiency of the elimination mechanisms. Because this measure of elimination efficiency is in reference to blood or plasma toxicant concentration, it is also named blood or plasma clearance. High values of clearance indicate efficient and generally rapid removal, whereas low clearance values indicate slow and less efficient removal of a toxicant from the body. By definition, clearance has the units of flow (e.g., mL/min or L/hr). In the classic compartmental context, clearance is portrayed as the apparent volume containing the toxicant that is cleared per unit of time. After intravenous bolus administration, total body clearance (Cl) is calculated by

$$Cl = \frac{Dose_{iv}}{AUC_0^\infty} \qquad (7\text{-}10)$$

Clearance can also be calculated if the volume of distribution and elimination rate constants are known; that is, $Cl = V_d \times k_{el}$ for a one-compartment model and $Cl = V_d \times \beta$ for a two-compartment model. It should be noted that the relationship is a mathematical derivation and does not imply that clearance is dependent upon the distribution volume (see later section for further commenting). A clearance of 100 mL/min can be visualized as having a 100 mL of blood or plasma completely cleared of toxicant in each minute during circulation.

The biological significance of total body clearance is better appreciated when it is recognized that it is the sum of clearances by individual eliminating organs (i.e., organ clearances):

$$Cl = Cl_r + Cl_h + Cl_p + \cdots \qquad (7\text{-}11)$$

where Cl_r depicts renal, Cl_h hepatic, and Cl_p pulmonary clearance. Each organ clearance is in turn determined by blood perfusion flow through the organ and the fraction of toxicant in the arterial inflow that is irreversibly removed, i.e., the extraction fraction (E_i). Various

organ clearance models have been developed to provide quantitative description of clearance that is related to blood perfusion flow (Q_i), free fraction in blood (f_{ub}), and intrinsic clearance ($Cl_{int,i}$) (Wilkinson, 1987). For example, for hepatic clearance (Cl_h), if the delivery of the toxicant to its intracellular site of removal is rate-limited by liver blood flow (Q_h) and the toxicant is assumed to have equal, ready access to all the hepatocytes within the liver (i.e., the so-called well-stirred model):

$$Cl_h = Q_h \times E_h = \frac{Q_h \times f_{ub} \times Cl_{int,h}}{f_{ub} \times Cl_{int,h} + Q_h} \qquad (7\text{-}12)$$

where $Cl_{int,h}$ is the hepatic intrinsic clearance that embodies a combination of factors that determines the access of the toxicant to the enzymatic sites (e.g., plasma protein binding and sinusoidal membrane transport) and the biochemical efficiency of the metabolizing enzymes (e.g., $\frac{V_{max}}{K_M}$ for an enzyme obeying Michaelis kinetics). Equation (7-12) dictates that hepatic clearance of a toxicant from the blood is bounded by either liver blood flow or intrinsic clearance (i.e., $f_{ub} \times Cl_{int,h}$). Note that when $f_{ub} \times Cl_{int,h}$ is very much higher than Q_h, E_h approaches unity (i.e., near complete extraction during each passage of toxicant through the hepatic sinusoid or high extraction) and Cl_h approaches Q_h. Put in another way, hepatic clearance cannot exceed the hepatic blood flow rate even if the maximum rate of metabolism in the liver is more rapid than the rate of hepatic blood flow, because the rate of overall hepatic clearance is limited by the delivery of the toxicant to the metabolic enzymes in the liver via the blood. At the other extreme, when $f_{ub} \times Cl_{int,h}$ is very much lower than Q_h, E_h becomes quite small (i.e., low extraction) and Cl_h nearly equals $f_{ub} \times Cl_{int,h}$ In this instance, the intrinsic clearance is relatively inefficient; hence, alteration in liver blood flow would have little, if any, influence on liver clearance of the toxicant. Thus, the concept of clearance is grounded in the physiological and biochemical mechanisms of an eliminating organ.

Relationship of Elimination Half-Life to Clearance and Volume

Elimination half-life ($T_{1/2}$) is probably the most easily understood pharmacokinetic concept and is an important parameter as it determines the persistence of a toxicant following discontinuation of exposure. As will be seen in a later section, elimination half-life also governs the rate of accumulation of a toxicant in the body during continuous or repetitive exposure. Elimination half-life is dependent upon both volume of distribution and clearance. $T_{1/2}$ can be calculated from V_d and Cl:

$$T_{1/2} = \frac{0.693 \times V_d}{Cl} \qquad (7\text{-}13)$$

The above relationship among $T_{1/2}$, V_d, and Cl is another illustration that care should be exercised in interpretation of data when relying upon $T_{1/2}$ as the sole representation of elimination of a chemical in toxicokinetic studies, since $T_{1/2}$ is influenced by both the volume of distribution for the chemical and the rate by which the chemical is cleared from the blood. For a fixed V_d, $T_{1/2}$ decreases as Cl increases, because the chemical is being removed from this fixed volume faster as clearance increases (Fig. 7-4). Conversely, as the V_d increases, $T_{1/2}$ increases for a fixed Cl since the volume of
Figure 7-4. The dependence of $T_{1/2}$ on V_d and Cl.

Renal *Cl* values of 60, 130, and 650 mL/min represent partial reabsorption, glomerular filtration, and tubular secretion, respectively. Values for V_d of 3, 18, and 40 L represent approximate volumes of plasma water, extracellular fluid and total body water, respectively, for an average-sized person.

fluid that must be cleared of chemical increases but the efficiency of clearance does not.

Absorption and Bioavailability

For most chemicals in toxicology, exposure occurs by extravascular routes (e.g., inhalation, dermal, or oral), and absorption into the systemic circulation is often incomplete. The extent of absorption of a toxicant can be experimentally determined by comparing the plasma AUC_0^∞ after intravenous and extravascular dosing. Because intravenous dosing assures full (100%) delivery of the dose into the systemic circulation, the AUC ratio should equal the fraction of extravascular dose absorbed and reaches the systemic circulation in its intact form, and is called *bioavailability* (F). In acute toxicokinetic studies, bioavailability can be determined by using different iv and non-iv doses according to the following equation, provided that the toxicant does not display dose-dependent or saturable kinetics.

$$F = \left(\frac{AUC_{\text{non-iv}}}{Dose_{\text{non-iv}}} \right) \bigg/ \left(\frac{AUC_{\text{iv}}}{Dose_{\text{iv}}} \right) \qquad (7\text{-}14)$$

where $AUC_{\text{non-iv}}$, AUC_{iv}, $Dose_{\text{non-iv}}$, and $Dose_{\text{iv}}$ are the respective area under the plasma concentration versus time curves and doses for non-iv and iv administration. Bioavailabilities for various chemicals range in value between 0 and 1. Complete availability of chemical to the systematic circulation is demonstrated by $F = 1$. When $F < 1$, less than 100% of the dose is able to reach the systemic circulation. Because the concept of bioavailability is judged by how much of the dose reaches the systemic circulation, it is often referred to as systemic availability. Systemic availability is determined by how well a toxicant is absorbed from its site of application and any intervening processes that could remove or inactivate the toxicant between its point of entry and the systemic circulation. Specifically, systemic availability of an orally administered toxicant is governed by its absorption at the gastrointestinal barrier, metabolism within the intestinal mucosa, and metabolism and biliary excretion during its first transit through the liver. Metabolic inactivation and excretion of the toxicant at the intestinal mucosa and the liver prior to its entry into the systemic circulation is called pre-systemic extraction or first-pass effect. The following equation accounts for the action

of absorption and sequential first-pass extraction at the intestinal mucosa and the liver as determinants of the bioavailability of a toxicant taken orally:

$$F = f_{\text{g}} \times (1 - E_{\text{m}}) \times (1 - E_{\text{h}}) \qquad (7\text{-}15)$$

where f_{g} is the fraction of the applied dose that is released and absorbed across the mucosal barrier along the entire length of the gut, E_{m} is the extent of loss due to metabolism within the gastrointestinal mucosa, and E_{h} is the loss due to metabolism or biliary excretion during first-pass through the liver. Note that E_{h} in this equation is same as the hepatic extraction E_{h} defined in Equation (7-12), which refers to hepatic extraction of a toxicant during recirculation. This means that poor oral bioavailability of a chemical can be attributed to multiple factors. The chemical may be absorbed to a limited extent because of low aqueous solubility preventing its effective dissolution in the gastrointestinal fluid or poor permeability across the brush-border membrane of the intestinal mucosa. Extensive degradation by metabolic enzymes residing at the intestinal mucosa and the liver may also hinder entry of the chemical in its intact form into the systemic circulation.

The rate of absorption of a toxicant via an extravascular route of entry is another critical determinant of outcome, particularly in acute exposure situations. As shown in Fig. 7-5, slowing the absorption rate of a toxicant, while maintaining the same extent of absorption or bioavailability, leads to a delay in time to peak plasma concentration (T_{p}) and a decrease in the maximum concentration (C_{max}) (compare case 2 to case 1). The converse is true; accelerating absorption shortens T_{p} and increases C_{max}. The dependence of T_{p} and C_{max} on absorption rate has obvious implication in the speed of onset and maximum toxic effects following exposure to a chemical. Case 3 in Fig. 7-5 illustrates the peculiar situation when the absorption rate is so much slower than the elimination rate (e.g., $k_{\text{a}} \ll k_{\text{el}}$ for a one-compartment model). The terminal rate of decline in plasma concentration reflects the absorption rate constant, instead of the elimination rate constant; that is, the washout of toxicant is rate-limited by slow absorption until the applied dose is completely absorbed or removed, beyond which time the toxicant remaining in the body will be cleared according the elimination rate-constant. This means that continual absorption of a chemical can affect the persistence of toxic effect following an acute exposure, and that it is important to institute decontamination procedure quickly after overdose or accidental exposure to a toxicant. This is especially a consideration in occupational exposure via dermal absorption following skin contact with permeable industrial chemicals.

Metabolite Kinetics

The toxicity of a chemical is in some cases attributed to its biotransformation product(s). Hence, the formation and subsequent disposition kinetics of a toxic metabolite is of considerable interest. As expected, the plasma concentration of a metabolite rises as the parent drug is transformed into the metabolite. Once formed, the metabolite is subject to further metabolism to a nontoxic byproduct or undergoes excretion via the kidneys or bile; hence at some point in time, the plasma metabolite concentration peaks and falls thereafter. Figure 7-6 illustrates the plasma concentration time course of a primary metabolite in relation to its parent compound under contrasting scenarios. The left panel shows the case when the elimination rate constant of the metabolite is much greater than
Figure 7-5. Influence of absorption rate on the time to peak (T_p) and maximum plasma concentration (C_{max}) of a toxicant that exhibit one-compartment kinetics.

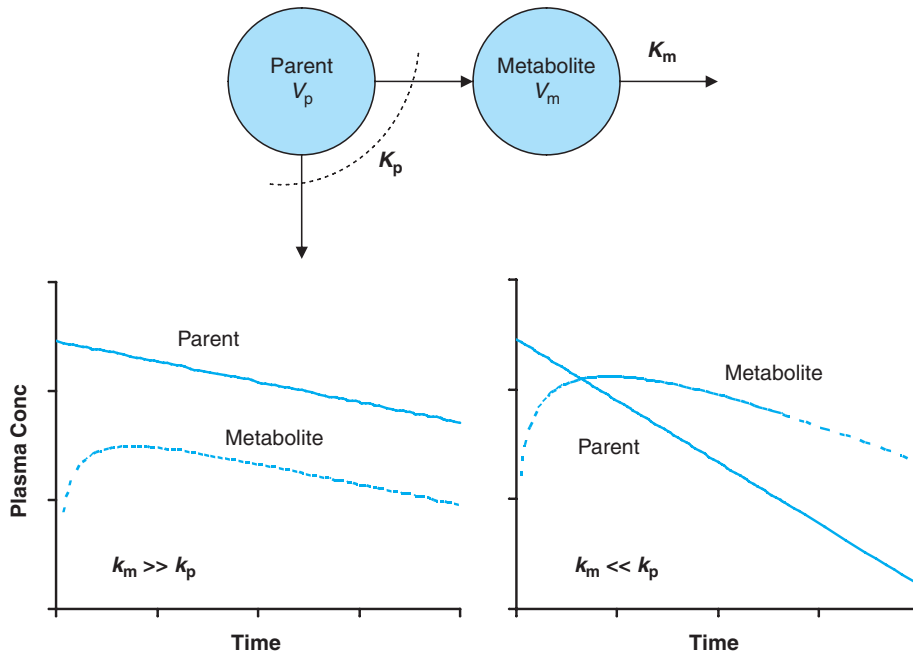
The left panel illustrates the change in plasma concentration-time curves as the first-order absorption rate constant (k_a) decreases, while keep the extent of absorption or bioavailability (F), hence the AUC, constant. The right panel displays the same curves in a semi-logarithmic plot. Time to peak plasma concentration shows a progressive delay as k_a decreases, along with a decrease in C_{max}. In case 1 and 2, the terminal decline in plasma concentration is governed by elimination half-life; hence, the parallel decline in the semi-logarithmic plot. In case 3 where $k_a \ll k_{el}$, the absorption becomes so slow that decline in plasma concentration in the terminal phase reflects the absorption half-life; that is, washout of toxicant is rate-limited by absorption. Accordingly, the terminal decline is slower than in case 1 and 2.


Figure 7-6. Plasma concentration time course of a primary metabolite and its parent compound under contrasting scenarios: when elimination of the metabolite is much more rapid than its formation ($k_m \gg k_p$, lower left panel) and when elimination of the metabolite is much slower than its formation ($k_m \ll k_p$, lower right panel). Semi-logarithmic plots are shown to compare the slope of the terminal decline of parent compound and its metabolite.

The top panel shows the model for conversion of the parent compound to a single metabolite. Note that the elimination rate constant for the parent compound (k_p) includes both the rate constant for metabolism and extra-metabolic routes of elimination. k_m is the elimination rate constant for the derived metabolite. When $k_m \gg k_p$, the terminal decline of the metabolite parallels that of the parent compound; i.e., metabolite washout is rate-limited by its formation. When $k_m \ll k_p$, the terminal decline of metabolite concentration is much slower than that of parent compound; i.e., metabolite washout is rate-limited by its elimination.

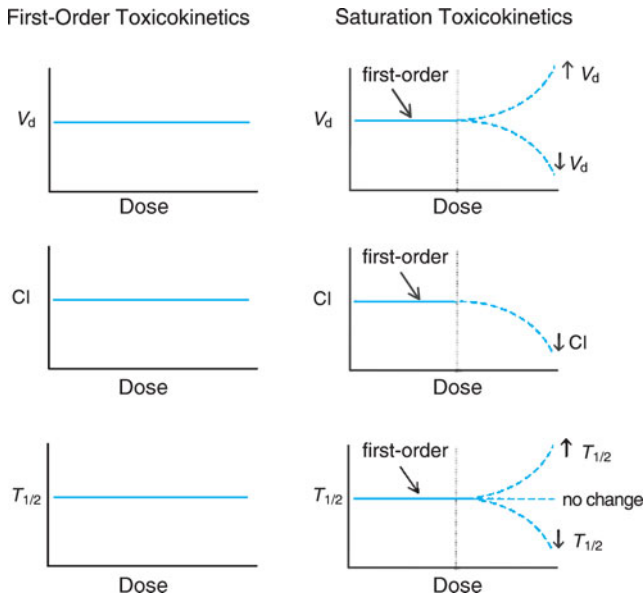
First-Order Toxicokinetics   Saturation Toxicokinetics


Figure 7-7. *Changes in V_d, Cl and $T_{1/2}$ following first-order toxicokinetics (left panels) and following saturable toxicokinetics (right panels).*

Vertical dashed lines represent point of departure from first-order to saturation toxicokinetics. Pharmacokinetic parameters for toxicants that follow first-order toxicokinetics are independent of dose. When plasma protein binding or elimination mechanisms are saturated with increasing dose, pharmacokinetic parameter estimates become dose-dependent. **V_d** may increase, for example, when protein binding is saturated, allowing more free toxicant to distribute into extravascular sites. Conversely, **V_d** may decrease with increasing dose if tissue protein binding saturates. Then, chemical may redistribute more freely back into plasma. When chemical concentrations exceed the capacity for biotransformation by metabolic enzymes, overall clearance of the chemical decreases. These changes may or may not have effects on **$T_{1/2}$** depending upon the magnitude and direction of changes in both **V_d** and **Cl**.

the overall elimination rate constant of the parent compound (i.e., $k_m \gg k_p$). The terminal decline of the metabolite parallels that of the parent compound; the metabolite is cleared as quickly as it is formed or its washout is rate-limited by conversion from the parent compound. The right panel shows the opposite case when the elimination rate constant of the metabolite is much lower than the overall elimination rate constant of the parent compound (i.e., $k_m \ll k_p$). The slower terminal decline of the metabolite compared to the parent compound simply reflects a longer elimination half-life of the metabolite. It should also be noted that the AUC_0^∞ of the metabolite relative to the parent compound is dependent on the partial clearance of the parent drug to the metabolite and clearance of the derived metabolite. A biologically active metabolite assumes toxicological significance when it is the major metabolic product and is cleared much less efficiently than the parent compound.

Saturation Toxicokinetics

As already mentioned, the distribution and elimination of most chemicals occurs by first-order processes. Under first-order elimination kinetics, the elimination rate constant, apparent volume of distribution, clearance and half-life are expected not to change with increasing or decreasing dose (i.e., dose independent). As a result, a semi-logarithmic display of plasma concentration versus time over a range of doses shows a set of parallel plots. Furthermore, plasma

concentration at a given time or the AUC_0^∞ is strictly proportional to dose; for example, a twofold change in dose results in an exact twofold change in plasma concentration or AUC_0^∞. However, for some toxicants, as the dose of a toxicant increases, its volume of distribution and/or clearance may change, as shown in Fig. 7-7. This is generally referred to as non-linear or dose-dependent kinetics. Biotransformation, active transport processes, and protein binding have finite capacities and can be saturated. For instance, most metabolic enzymes operate in accordance to Michaelis–Menten kinetics (Gibaldi and Perrier, 1982). As the dose is escalated and concentration of a toxicant at the site of metabolism approaches or exceeds the K_M (substrate concentration at one-half V_{max}, the maximum metabolic capacity), the increase in rate of metabolism becomes less than proportional to the dose and eventually approaches a maximum at exceedingly high doses. The transition from first-order to saturation kinetics is important in toxicology because it can lead to prolonged persistence of a compound in the body after an acute exposure and excessive accumulation during repeated exposures. Some of the salient characteristics of nonlinear kinetics include the following: (1) the decline in the levels of the chemical in the body is not exponential; (2) AUC_0^∞ is not proportional to the dose; (3) V_d, Cl, k_{el} (or β), or $T_{1/2}$ change with increasing dose; (4) the composition of excretory products changes quantitatively or qualitatively with the dose, and (5) dose–response curves show an abruptly steeper change in response with an increasing dose, starting at the dose at which saturation effects become evident.

Inhaled methanol provides an example of a chemical whose metabolic clearance changes from first-order kinetics at low level exposures to zero-order kinetics at near toxic levels (Burbacher et al., 2004). Figure 7-8 shows predicted blood methanol concentration-time profiles in female monkeys followed a 2-hour controlled exposure in an inhalation chamber at two levels of methanol vapor, 1200 ppm and 4800 ppm. Blood methanol kinetics at 1200 ppm exposure follows typical first-order kinetics. At 4800 ppm, methanol metabolism is fully saturated, such that the initial decline in blood methanol following the 2-hour exposure occurs at a constant rate (i.e., a fixed decrease in concentration per unit time independent of blood concentration), rather than a constant fractional rate. As a result, a rectilinear plot of blood methanol concentration versus time yields an initial linear decline, whereas a convex curve is observed in the semi-logarithmic plot (compare left and right panels of Fig. 7-8). In time, methanol metabolism converts to first-order kinetics when blood methanol concentration falls below K_M (i.e., the Michaelis constant for the dehydrogenase enzyme); at which time, blood methanol shows an exponential decline in the rectilinear plot and a linear decline in the semi-logarithmic plot. Moreover, Fig. 7-8 shows the greater than proportionate increase (i.e., > fourfold) in C_{max} and AUC_0^∞ as the methanol vapor concentration is raised from 1200 ppm to 4800 ppm. It should be noted that a constant $T_{1/2}$ or k_{el} does not exist during the saturation regime; it varies depending upon the saturating methanol dose.

In addition to the complication of dose-dependent kinetics, there are chemicals whose clearance kinetics changes over time (i.e., time-dependent kinetics). A common cause of time-dependent kinetics is auto-induction of xenobiotic metabolizing enzymes; that is, the substrate is capable of inducing its own metabolism through activation of gene transcription. The classic example of auto-induction is with the antiepileptic drug, carbamazepine. Daily administration of carbamazepine leads to a continual increase in clearance and shortening in elimination half-life over the first few weeks of therapy (Bertilsson et al., 1986).
Figure 7-8. Predicted time course of blood methanol concentration following a 120-minute exposure to 1200 and 4800 ppm of methanol vapor in the female monkey based on the toxicokinetic model reported by Burbacher et al. (2004) that features a saturable (Michaelis–Menten type) metabolic clearance.

The left panel is a rectilinear plot of the simulated blood methanol concentration–time curves at the two exposure levels. The right panel shows the same simulation in a semi-logarithmic plot. The washout of blood methanol following the 120-min inhalation exposure at 1200 ppm follows a typical concave or exponential pattern in the rectilinear plot (left panel) and is linear in a semi-logarithmic plot (right panel). The post exposure profile at 4800 ppm shows a linear segment during the first 120 min of washout and becomes exponential thereafter in the rectilinear plot (left panel). The linear segment reflects saturation of alcohol dehydrogenase, which is the principal enzyme responsible for the metabolism of methanol. The in vivo K_M for this simulation was set at 32.7 μg/mL. At concentrations above K_M, the kinetics approach zero-order kinetics. At concentrations below K_M, washout kinetics become first-order with a half-life of about 60 min. The right panel shows a characteristic convex semi-logarithmic plot for the initial phase of zero-order kinetics and becomes linear as expected for first-order kinetics when the concentration falls below K_M. It should also be noted that the maximum blood methanol following 4800 ppm exposure is predicted to be 5.9-times higher than that following 1200 ppm. Also, the area under the blood concentration-time curve (AUC) from time zero to 480 min at 4800 ppm exposure is eightfold higher than at 1200 ppm. Under linear kinetics, the increase in maximum blood methanol and AUC ought to be proportionate to the dose increase, i.e., a fourfold increment. Here, we observe a more than proportionate increase in blood methanol concentration in relation to the dose, which is another hallmark of saturation kinetics.

Accumulation During Continuous or Intermittent Exposure

It stands to reason that continual or chronic exposure to a chemical leads to its cumulative intake and accumulation in the body. For a chemical that follows first-order elimination kinetics, the elimination rate increases as the body burden increases. Therefore, at a fixed level of continuous exposure, accumulation of a toxicant in the body eventually reaches a point when the intake rate of the toxicant equals its elimination rate, from thereon the body burden stays constant. This is referred to as the steady state. Figure 7-9 illustrates the rise of toxicant concentration in plasma over time during continuous exposure and the eventual attainment of a plateau or the steady-state. Steady-state concentration of a toxicant in plasma (C_{ss}) is related to the intake rate (R_{in}) and clearance of the toxicant.

$$C_{ss} = \frac{R_{in}}{Cl} \qquad (7\text{-}16)$$

For a one-compartment model, an exponential rise in plasma concentration is expected during continuous exposure and the time it takes for a toxicant to reach steady state is governed by its elimination half-life. It takes one half-life to reach 50%, four half-lives to reach 93.8%, and seven half-lives to reach 99.2% of steady state.

Time to attainment of steady state is not dependent on the intake rate of the toxicant. The left panel of Fig. 7-9 shows the same time to 50% steady state at three different rates of intake; on the other hand, the steady-state concentration is strictly proportional to the intake rate. Change in clearance of a toxicant often leads to a corresponding change in elimination half-life (see right panel of Fig. 7-9), in which case both the time to reach and magnitude of steady-state concentration are altered. The same steady-state principle applies to toxicants that exhibit multi-compartmental kinetics; except that, accumulation occurs in a multi-phasic fashion reflective of the multiple exponential half-lives for inter-compartmental distribution and elimination. Typically, the rise in plasma concentration is relatively rapid at the beginning, being governed by the early (distribution) half-life, and becomes slower at later times when the terminal (elimination) half-life takes hold.

The concept of accumulation applies to intermittent exposure as well. Figure 7-10 shows a typical occupational exposure scenario to volatile chemicals at the workplace over the course of a week. Whether accumulation occurs from day to day and further from week to week depends on the intervals between exposure and the elimination half-life of the chemicals involved. For a chemical with relatively short half-life compared to the interval between work shifts and the "exposure holiday" over the weekend, little accumulation is expected. In contrast, for a chemical with elimination
Figure 7-9. Accumulation of plasma toxicant concentration over time during constant, continuous exposure as a function of exposure level (left panel) and elimination half-life (right panel).

These simulations are based on a one-compartment model at a constant apparent volume of distribution. Case 1 serves as the reference with an elimination half-life set equal to one arbitrary time unit. In the left panel, which illustrates accumulation of toxicant as a function of exposure level, exposure level is raised by twofold in Case 2 and lowered by 50% in Case 3. The changes in eventual steady state concentration are proportional to the changes in exposure level, i.e., increased by twofold in Case 2 and decreased by 50% in Case 3. During continuous exposure, 50% of steady state is achieved in one half-life. Near plateau or steady-state (>90%) is reached after four half-lives. Since the elimination half-life is constant across Cases 1–3 in the left panel, the time it takes to attain 50% of steady-state concentration (see arrows) is the same, i.e., one time unit. Right panel illustrates the influence of elimination half-life and clearance on accumulation at a fixed constant rate of exposure. Case 4 represents a 50% decrease in clearance and a corresponding twofold increase in elimination half-life compared to Case 1. Case 5 represents a twofold increase in clearance and a corresponding 50% decrease in elimination half-life. Changes in both the time to attain steady-state and the steady-state concentration are evident. In Case 4, the steady-state concentration increased by twofold as a result of a 50% reduction in clearance, and the time to achieved 50% of steady state increased by twofold as a result of the prolonged elimination half-life. In Case 5, the steady-state concentration is reduced by 50%, while the time to reach 50% steady state is shortened by 50%.

half-life approaching or exceeding the between-shift intervals (>12 to 24 hours), progressive accumulation is expected over the successive workdays. Washout of the chemical may not be complete over the weekend and result in a significant carry forward of body burden into the next week. It should also be noted that the overall exposure as measured by the AUC over the cycle of a week is dependent on the toxicant clearance.

Conclusion

For many chemicals, blood or plasma chemical concentration versus time data can be adequately described by a one- or two-compartment, classic pharmacokinetic model when basic assumptions are made (e.g., instantaneous mixing within compartments and first-order kinetics). In some instances, more sophisticated models with increased numbers of compartments will be needed to describe blood or plasma toxicokinetic data; for example, if the chemical is preferentially sequestered and turns over slowly in select tissues. The parameters of the classic compartmental models are usually estimated by statistical fitting of data to the model equations using nonlinear regression methods. A number of software packages are available for both data fitting and simulations with classic compartmental models; examples include WinNonlin (Pharsight Corp., Palo Alto, CA), SAAM II (SAAM Institute, University of Washington, Seattle, WA), ADAPT II (University of Southern California, Los Angeles, CA), and PK Solutions (Summit Research Services, Montrose, CO).
Figure 7-10. Simulated accumulation of plasma concentration from occupational exposure over the cycle of a work week compared between two industrial chemicals with short and long elimination half-lives.

Shading represents the exposure period during the 8-hour workday, Monday through Friday. Intake of the chemical into the systemic circulation is assumed to occur at a constant rate during exposure. Exposure is negligible over the weekend. For the chemical with the short elimination half-life of 8 hours, minimal accumulation occurs from day to day over the work days. Near complete washout of the chemical is observed when work resumes on Monday (see arrow). For the chemical with the long elimination half-life of 24 hours, progressive accumulation is observed over the five work days. Washout of the longer half-life chemical over the weekend is incomplete; a significant residual is carried into the next work week. Because of its lower clearance, the overall AUC of the long half-life chemical over the cycle of a week is higher by threefold.

Knowledge of toxicokinetic data and compartmental modeling are useful in deciding what dose or dosing regimen of chemical to use in the planning of toxicology studies (e.g., targeting a toxic level of exposure), in choosing appropriate sampling times for biological monitoring, and in seeking an understanding of the dynamics of a toxic event (e.g., what blood or plasma concentrations are achieved to produce a specific response, how accumulation of a chemical controls the onset and degree of toxicity, and the persistence of toxic effects following termination of exposure).

PHYSIOLOGIC TOXICOKINETICS

The primary difference between physiologic compartmental models and classic compartmental models lies in the basis for assigning the rate constants that describe the transport of chemicals into and out of the compartments (Andersen, 1991). In classic kinetics, the rate constants are defined by the data; thus, these models are often referred to as data-based models. In physiologic models, the rate constants represent known or hypothesized biological processes, and these models are commonly referred to as physiologically based models. The concept of incorporating biological realism into the analysis of drug or xenobiotic distribution and elimination is not new. For example, one of the first physiologic models was proposed by Teorell (1937). This model contained all the important determinants in chemical disposition that are considered valid today. Unfortunately, the computational tools required to solve the underlying equations were not available at that time. With advances in computer science, the software and hardware needed to implement physiological models are now well within the reach of toxicologists.

The advantages of physiologically based models compared with classic models are that (1) these models can describe the time course of distribution of toxicants to any organ or tissue, (2) they allow estimation of the effects of changing physiologic parameters on tissue concentrations, (3) the same model can predict the toxicokinetics of chemicals across species by allometric scaling, and (4) complex dosing regimes and saturable processes such as metabolism and binding are easily accommodated (Gargas and Andersen, 1988). The disadvantages are that (1) much more information is needed to implement these models compared with classic models, (2) the mathematics can be difficult for many toxicologists to handle, and (3) values for parameters are often ill defined in various species, strains, and disease states. Nevertheless, physiologically based toxicokinetic models are conceptually sound and are potentially useful tools for gaining rich insight into the kinetics of toxicants beyond what classic toxicokinetic models can provide.

Basic Model Structure

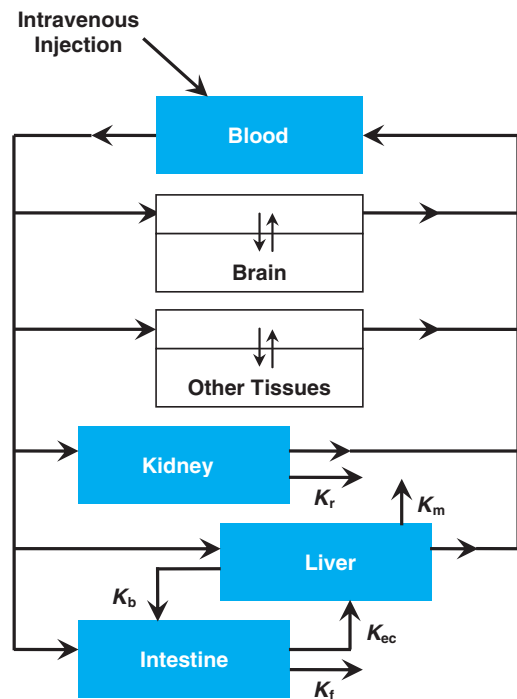
Physiologic models are fundamentally complex compartmental models; it generally consists of a system of tissue or organ compartments that are interconnected by the circulatory network. If necessary, each tissue or organ compartments can further be divided into extracellular and intracellular compartments to describe movement of toxicant at the cellular level. The exact model structure, or how the compartments are organized and linked together, depends on both the chemical and the organism being studied. For example, a physiologic model describing the disposition of a chemical in fish would require a description of the gills (Nichols *et al.*, 1994), whereas a model for the same chemical in mammals would require a lung compartment (Ramsey and Andersen, 1984). Model structures can also vary with the chemicals being studied. For


Figure 7-11. Physiologic model for a hypothetical toxicant that is soluble in water, has a low vapor pressure (not volatile), and has a relatively large molecular weight (MW > 100).

This hypothetical chemical is eliminated through metabolism in the liver (K_m), biliary excretion (K_b), renal excretion (K_r) into the urine, and fecal excretion (K_f). The chemical can also undergo enterohepatic circulation (K_{ec}). Perfusion-limited compartments are noted in blue and diffusion-limited compartments are noted in white.

example, a model for a non-volatile, water-soluble chemical, which might be administered by intravenous injection (Fig. 7-11), has a structure different from that of a model for a volatile organic chemical for which inhalation is the likely route of exposure (Fig. 7-12). The route of administration is not the only difference between these two models. For example, the first model has a compartment for the intestines, because biliary excretion, fecal elimination, and enterohepatic circulation are presumed important in the disposition of this chemical. The second model has a compartment for fat because fat is an important storage organ for organics. However, the models are not completely different. Both contain a liver compartment because the hepatic metabolism of each chemical is an important element of its disposition. It is important to realize that there is no generic physiologic model. Models are simplifications of reality and should contain elements believed to represent the essential disposition features of a chemical.

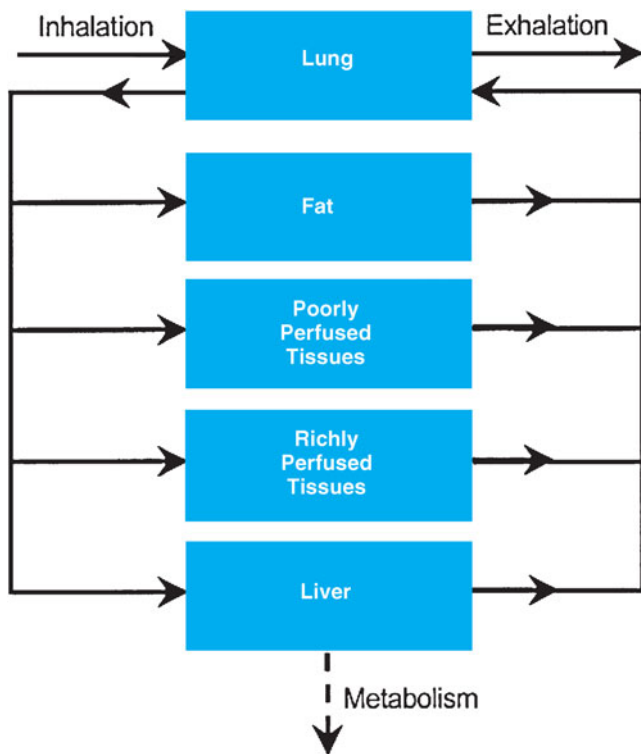
In view of the fact that physiologic modeling requires more effort than does classic compartmental modeling, what then accounts for the popularity of this approach among toxicologists? The answer lies in the potential predictive power of physiologic models. Toxicologists are constantly faced with the issue of extrapolation in risk assessments—from laboratory animals to humans, from high to low doses, from occasional to continuous exposure, and from single chemicals to mixtures. Because the kinetic constants in physiologic models represent measurable biological or chemical processes, the resultant physiologic models have the potential for extrapolation from observed data to predicted scenarios.


Figure 7-12. Physiological model for a typical volatile organic chemical.

Chemicals for which this model would be appropriate have low molecular weights ($MW < 100$), are soluble in organic solvents, and have significant vapor pressures (volatile). Transport of chemical throughout the body by blood is depicted by the black arrows. Elimination of chemical as depicted by the model includes metabolism (*dashed arrow*) and exhalation (*black arrow*). All compartments are perfusion-limited.

One of the best illustrations of the predictive power of physiologic models is their ability to extrapolate kinetic behavior from laboratory animals to humans. For example, physiologic models developed for styrene and benzene correctly simulate the concentration of each chemical in the blood of both rodents and humans (Ramsey and Andersen, 1984; Travis *et al.*, 1990). Simulations are the outcomes or results (such as a chemical's concentration in blood or tissue) of numerically solving the model equations over a time period of concern, using a set of initial conditions (such as intravenous dose) and parameter values appropriate for the species (such as organ weights and blood flow). Both styrene and benzene are volatile organic chemicals; thus, the model structures for the kinetics of both chemicals in rodents and humans are identical to that shown in Fig. 7-12. However, the parameter values for rodents and humans are different. Humans have larger body weights than rodents, and thus weights of organs such as the liver are larger. Because humans are larger, they also breathe more air per unit of time than do rodents, and a human heart pumps a larger volume of blood per unit of time than does that of a rodent, although the rodent's heart beats more times in the same period. The parameters that describe the chemical behavior of styrene and benzene, such as solubility in tissues, are similar in the rodents and human models. This is often the case because the composition of tissues in different species is similar.

For both styrene and benzene, there are experimental data for humans and rodents and the model simulations can be compared with the actual data to see how well the model has performed

(Ramsey and Andersen, 1984; Andersen *et al.*, 1984; Travis *et al.*, 1990). The conclusion is that the same model structure is capable of describing the chemicals' kinetics in two different species. Because the parameters underlying the model structure represent measurable biological and chemical determinants, the appropriate values for those parameters can be chosen for each species, forming the basis for successful interspecies extrapolation. Even though the same model structure is used for both rodents and humans, the simulated and the observed kinetics of both chemicals differ between rats and humans. The terminal half-life of both organics is longer in the human compared with the rat. This longer half-life for humans is due to the fact that clearance rates for smaller species are faster than those for larger ones. Even though the larger species breathes more air or pumps more blood per unit of time than does the smaller species, blood flows and ventilation rates per unit of body mass are greater for the smaller species. The smaller species has more breaths per minute or heartbeats per minute than does the larger species, even though each breath or stroke volume is smaller. The faster flows per unit mass result in a more efficient delivery of a chemical to organs responsible for elimination. Thus, a smaller species can eliminate the chemical faster than a larger one can. Because the parameters in physiologic models represent real, measurable values, such as blood flows and ventilation rates; the same model structure can resolve such disparate kinetic behaviors among species.

Compartments

The basic unit of the physiologic model is the lumped compartment, which is often depicted as a box in a graphical scheme (Fig. 7-13). A compartment represents a definable anatomical site or tissue type in the body that acts as a unit in effecting a measurable kinetic process (Rowland, 1984, 1985). A compartment may represent a particular structure or functional portion of an organ, a segment of blood vessel with surrounding tissue, an entire discrete organ such as the liver or kidney, or a widely distributed tissue type such as fat or skin. Compartments usually consist of three individual well-mixed regions, or sub-compartments, that correspond to specific physiologic spaces or regions of the organ or tissue. These sub-compartments are: (1) the vascular space through which the compartment is perfused with blood, (2) the interstitial space that forms the matrix for the cells, and (3) the intracellular space consisting of the cells in the tissue (Gerlowski and Jain, 1983).

As shown in Fig. 7-13, the toxicant enters the vascular sub-compartment at a certain rate in mass per unit of time (e.g., mg/h). The rate of entry is a product of the blood flow rate to the tissue (Q_t in L/h) and the concentration of the toxicant in the blood entering the tissue (C_{in} in mg/L). Within the compartment, the toxicant moves from the vascular space to the interstitial space at a certain net rate ($Flux_1$) and moves from the interstitial space to the intracellular space at different net rate ($Flux_2$). Some toxicants can bind to cell components; thus, within a compartment there may be both free and bound toxicants. The toxicant leaves the vascular space at a certain venous concentration (C_{out}). C_{out} is equal to the concentration of the toxicant in the vascular space assuming a well-mixed compartment.

Parameters

The most common types of parameters, or information required, in physiologic models are anatomic, physiologic, thermodynamic, and transport.
Figure 7-13. Schematic representation of a lumped tissue compartment in a physiologic model.

The blood capillary and cell membranes separating the vascular, interstitial, and intracellular sub-compartments are depicted in heavy black lines. The vascular and interstitial sub-compartments are often combined into a single extracellular sub-compartment. Q_t is blood flow, C_{in} is chemical concentration into the compartment, and C_{out} is chemical concentration out of the compartment.

Anatomic Anatomic parameters are used to describe the physical size of various compartments. The size is generally specified as a volume (milliliters or liters), because a unit density is assumed even though weights of organs and tissues are most frequently obtained experimentally. If a compartment contains sub-compartments such as those in Fig. 7-13, those volumes also must be known. Volumes of compartments often can be obtained from the literature or from specific toxicokinetic experiments. For example, kidney, liver, brain, and lung can be weighed. Obtaining precise data for volumes of compartments representing widely distributed tissues such as fat or muscle is more difficult. If necessary, these tissues can be removed by dissection and weighed. Among the numerous sources of general information on organ and tissue volumes across species, Brown *et al.* (1997) is a good starting point.

Physiologic Physiologic parameters encompass a wide variety of processes in biological systems. The most commonly used physiologic parameters are blood flows and lung ventilation. The blood flow rate (Q_t in volume per unit time, such as mL/min or L/h) to individual compartments must be known. Additionally, information on the total blood flow rate or *cardiac output* (Q_c) is necessary. If inhalation is the route for exposure to the chemical or is a route of elimination, the alveolar ventilation rate (Q_p) also must be known. Blood flow rates and ventilation rates can be taken from the literature or can be obtained experimentally.

Parameters for renal excretion and hepatic metabolism are another subset of physiologic parameters, and are required, if these processes are important in describing the elimination of a chemical. For example, glomerular filtration rate and renal tubular transport parameters are required to describe renal clearance. If a chemical is known to be metabolized via a saturable process, both V_{max} (the maximum rate of metabolism) and K_M (the concentration of chemical at one-half V_{max}) for each of the enzymes involved must be obtained so that elimination of the chemical by metabolism can be described in the model. In principle, these parameters can be determined from in vitro metabolism studies with cultured cells, tissue homogenates, or cellular fractions containing the metabolic enzymes (e.g., microsomes for cytochrome P450 enzymes and UDP-GTs), along with appropriate in vitro-in vivo scaling techniques (Iwatsubo *et al.*, 1997; MacGregor *et al.*, 2001; Miners *et al.*, 2006). Although there have

been examples of remarkable success with quantitative prediction of in vivo metabolic clearance based on in vitro biochemical data, there are also notable failures. Unfortunately, estimation of metabolic parameters from in vivo studies is also fraught with difficulties, especially when multiple metabolic pathways and enzymes are present. Estimation of metabolic parameters remains a challenging aspect of physiologically based toxicokinetic modeling.

Thermodynamic Thermodynamic parameters relate the *total* concentration of a chemical in a tissue (C_t) to the concentration of *free* chemical in that tissue (C_f). Two important assumptions are that (1) total and free concentrations are in equilibrium with each other, and (2) only free chemical can be exchanged between the tissue sub-compartments (Lutz *et al.*, 1980). Most often, total concentration is measured experimentally; however, it is the free concentration that is available for passage across membrane barriers, binding to proteins, metabolism, or carrier-mediated transport. Various mathematical expressions describe the relationship between these two entities. In the simplest situation, the toxicant is a freely diffusible water-soluble chemical that does not bind to any molecules. In this case, free concentration of the chemical is equal to the total concentration of the chemical in the tissue: total = free, or $C_t = C_f$. The affinity of many chemicals for tissues of different composition varies. The extent to which a chemical partitions into a tissue is directly dependent on the composition of the tissue and independent of the concentration of the chemical. Thus, the relationship between free and total concentration becomes one of proportionality: total = free × partition coefficient, or $C_t = C_f \times P_t$. In this case, P_t is called a tissue partition coefficient, which is most often determined from tissue distribution studies in animals, ideally at steady-state during continuous intravenous infusion of the chemical. Estimation of P_t based on in vitro binding studies with human or animal tissues or tissue fractions has proven successful in some cases (Lin *et al.*, 1982; MacGregor *et al.*, 2001). Knowledge of the value of P_t permits an indirect calculation of the free concentration of toxicant in the tissue or $C_f = C_t/P_t$.

Table 7-4 compares the partition coefficients for a number of toxic volatile organic chemicals. The larger values for the fat/blood partition coefficients compared with those for other tissues suggests that these chemicals distribute into fat to a greater extent than they distribute into other tissues. This has been observed experimentally. Fat and fatty tissues, such as bone marrow, contain higher concentrations of benzene than do tissues such as liver and blood. Similarly, styrene concentrations in fatty tissue are higher than styrene concentrations in other tissues. It should be noted that lipophilic organic compounds often can bind to plasma proteins and/or blood cell constituents, in which case the observed tissue/blood partition coefficients will be a function of both the tissue and blood partition coefficient (i.e., P_t/P_b). Hence, partitioning or binding to blood

Table 7-4

Partition Coefficients for Four Volatile Organic Chemicals in Several Tissues

CHEMICAL	BLOOD/AIR	MUSCLE/BLOOD	FAT/BLOOD
Isoprene	3	0.67	24
Benzene	18	0.61	28
Styrene	40	1	50
Methanol	1350	3	11

constituents (P_b) must be known in order to estimate the true thermodynamic partitioning coefficient for a tissue or the free toxicant concentration at equilibrium. P_b can be determined from in vitro studies of blood cells to plasma distribution and plasma protein binding of the chemical.

A more complex relationship between the free concentration and the total concentration of a chemical in tissues is also possible. For example, the chemical may bind to saturable binding sites on tissue components. In these cases, nonlinear functions relating the free concentration in the tissue to the total concentration are necessary. Examples in which more complex binding has been used are physiologic models for dioxin and *tertiary*-amyl methyl ether (Andersen *et al.*, 1993; Collins *et al.*, 1999).

Transport Passage of a chemical across a biological membrane may occur by passive diffusion, carrier-mediated transport involving either facilitated or active transporters, or a combination thereof (Himmelstein and Lutz, 1979). The simplest of these processes—passive diffusion is a first-order process described by Fick's law of diffusion. Diffusion of a chemical occurs during its passage across the blood capillary membrane (*Flux*$_1$ in Fig. 7-13) and across cell membrane (*Flux*$_2$ in Fig. 7-13). *Flux* refers to the rate of transfer of a chemical across a boundary. For simple diffusion, the net flux (mg/h) from one side of a membrane to the other is governed by the barrier permeability and the chemical concentration gradient.

$$Flux = PA \times (C_1 - C_2) = PA \times C_1 - PA \times C_2 \qquad (7\text{-}17)$$

The term *PA* is often called the *permeability-area product* for the membrane or cellular barrier in flow units (e.g., L/h), and is a product of the barrier permeability coefficient (*P* in velocity units, e.g., μm/h) for the chemical and the total barrier surface area (*A*, in μm^2). The permeability coefficient takes into account the diffusivity of the specific chemical and the thickness of the cell membrane. C_1 and C_2 are the respective *free* concentrations of the chemical in the originating and receiving compartments. Diffusional flux is enhanced when the barrier thickness is small, the barrier surface area is large, and a large concentration gradient exists. Membrane transporters offer an additional route of entry into cells, and allow more effective tissue penetration for chemicals that have limited passive permeability. Alternately, the presence of efflux transporters at epithelial or endothelial barriers can limit toxicant penetration into critical organs, even for highly permeable toxicant (e.g., P-glycoprotein mediated efflux functions as part of the blood–brain barrier). For both transporter-mediated influx and efflux processes, the kinetics is saturable and can be characterized by T_{max} (the maximum transport rate) and K_T (the concentration of toxicant at one-half T_{max}) for each of the transporters involved. In principle, kinetic parameters for passive permeability or carrier-mediated transport can be estimated from in vitro studies with cultured cell systems. However, the predictability and applicability of such in vitro approaches for physiologic modeling has not been systematically evaluated (MacGregor *et al.*, 2001). At this time, the transport parameters have to be estimated from in vivo data, which are at times difficult and carry some degree of uncertainty.

There are two limiting conditions for the uptake of a toxicant into tissues: perfusion-limited and diffusion-limited. An understanding of the assumptions underlying the limiting conditions is critical because the assumptions change the way in which the model equations are written to describe the movement of a toxicant into and out of the compartment.

Perfusion-Limited Compartments

A perfusion-limited compartment, alternately referred to as blood flow-limited or simply flow-limited compartment, describes the situation when permeability across the cellular or membrane barriers (*PA*) for a particular toxicant is much greater than the blood flow rate to the tissue (Q_t), i.e., $PA \gg Q_t$. In this case, uptake of toxicant by tissue sub-compartments is limited by the rate at which the toxicant is presented to the tissue via the arterial inflow, and not by the rate at which the toxicant penetrates through the vascular endothelium, which is fairly porous in most tissues, or gains passage across the cell membranes. As a result, equilibration of a toxicant between the blood in the tissue vasculature and the interstitial sub-compartment is maintained at all times, and the two sub-compartments are usually lumped together as a single extracellular compartment. An important exception to this vascular-interstitial equilibrium relationship is in the brain, where the capillary endothelium with its tight junctions poses a diffusional barrier between the vascular space and the brain interstitium. Furthermore, as indicated in Fig. 7-13, the cell membrane separates the extracellular compartment from the intracellular compartment. The cell membrane is the most crucial diffusional barrier in a tissue. Nonetheless, for molecules that are very small (molecular weight < 100) or lipophilic (log P > 2), cellular permeability generally does not limit the rate at which a molecule moves across cell membranes. For these molecules, flux across the cell membrane is fast compared with the tissue perfusion rate ($PA \gg Q_t$), and the molecules rapidly distribute throughout the sub-compartments. In this case, free toxicant in the intracellular compartment is always in equilibrium with the extracellular compartment, and these tissue sub-compartments can be lumped as a single compartment. Such a flow-limited tissue compartment is shown in Fig. 7-14. Movement into and out of the entire tissue compartment can be described by a single equation.

$$V_t \times \frac{dC_t}{dt} = Q_t \times (C_{in} - C_{out}) \qquad (7\text{-}18)$$

where V_t is the volume of the tissue compartment, C_t is the toxicant concentration in the compartment ($V_t \times C$ equals the amount of toxicant in the compartment), $V_t \times dC_t/dt$ is the change in the amount of toxicant in the compartment with time, expressed as mass per unit of time, Q_t is blood flow to the tissue, C_{in} is the toxicant concentration entering the compartment, and C_{out} is the toxicant
Figure 7-14. Schematic representation of a tissue compartment that features blood flow–limited uptake kinetics.

Rapid exchange of toxicant between the extracellular space (*blue*) and intracellular space (*light blue*), unhindered by a significant diffusional barrier as symbolized by the dashed line, allows equilibrium to be maintained between the two sub-compartments at all times. In effect, a single compartment represents the tissue distribution of the toxicant. Q_t is blood flow, C_{in} is the chemical concentration entering the compartment via the arterial inflow, and C_{out} is the chemical concentration leaving the compartment in the venous outflow.

concentration leaving the compartment. Equations of this type are called mass-balance differential equations. Differential refers to the term dC_t/dt. Mass balance refers to the requirement that the rate of change in the amount of toxicant in a compartment (left-hand side of Equation (7-18)) equals the difference in the rate of entry via arterial inflow and the rate of departure via venous outflow (right-hand side of Equation (7-18)).

In the perfusion-limited case, the concentration of chemical in the venous drainage from the tissue is equal to the free concentration of chemical in the tissue (i.e., $C_{out} = C_f$) when the chemical is not bound to blood constituents. As was noted previously, C_f (or C_{out}) can be related to the total concentration of chemical in the tissue through a simple linear partition coefficient, $C_{out} = C_f = C_t/P_t$. In this case, the differential equation describing the rate of change in the amount of a chemical in a tissue becomes

$$V_t \times dC_t/dt = Q_t \times [C_{in} - C_t/P_t] \tag{7-19}$$

In the event the chemical does bind to blood constituents, blood partitioning coefficient needs to be recognized in the mass balance equation.

$$V_t \times dC_t/dt = Q_t \times [C_{in} - C_t/(P_t/P_b)] \tag{7-20}$$

The physiologic model shown in Fig. 7-12, which was developed for volatile organic chemicals such as styrene and benzene, is a good example of a model in which all the compartments are described as flow-limited. Distribution of a toxicant in all the compartments is described by using equations of the type noted above. In a flow-limited compartment, the assumption is that the concentrations of a toxicant in all parts of the tissue are in equilibrium. For this reason, the compartments are generally drawn as simple boxes (Fig. 7-12) or boxes with dashed lines that symbolize the equilibrium between the intracellular and extracellular sub-compartments (Fig. 7-14). Additionally, with a flow-limited model, estimates of fluxes between sub-compartments are not required to develop the mass balance differential equation for the compartment. Given the challenges in measuring flux across the vascular endothelium and cell membrane, this is a simplifying assumption that significantly reduces the number of parameters required in the physiologic model.

Diffusion-Limited Compartments

When uptake of a toxicant into a compartment is governed by its diffusion or transport across cell membrane barriers, the model is said to be diffusion-limited or barrier-limited. Diffusion-limited uptake or release occurs when the flux, or the transport of a toxicant across cell membranes, is slow compared with blood flow to the tissue. In this case, the permeability-area product is small compared with blood flow, i.e., $PA \ll Q_t$. The distribution of large polar molecules into tissue cells is likely to be limited by the rate at which the molecules pass through cell membranes. In contrast, entry into the interstitial space of the tissue through the leaky capillaries of the vascular space is usually rapid even for large molecules. Figure 7-15 shows the structure of such a compartment. The toxicant concentrations in the vascular and interstitial spaces are in equilibrium and make up the extracellular sub-compartment, where uptake from the incoming blood is flow-limited. The rate of toxicant uptake across the cell membrane from the extracellular space into the intracellular space is limited by membrane permeability, and is thus diffusion-limited. Two mass balance differential equations are necessary to
Figure 7-15. Schematic representation of a tissue compartment that features membrane-limited uptake kinetics.

Perfusion of blood into and out of the extracellular compartment is depicted by thick arrows. Transmembrane transport (flux) from the extracellular to the intracellular sub-compartment is depicted by thin double arrows. Q_t is blood flow, C_{in} is chemical concentration entering the compartment, and C_{out} is chemical concentration leaving the compartment.

describe the events in these two sub-compartments:

$$\textit{Extracellular: } V_{t1} \times dC_{t1}/dt = Q_t \times (C_{in} - C_{out})$$
$$- PA_t \times (C_{t1}/P_{t1}) + PA_t \times (C_{t2}/P_{t2}) \tag{7-21}$$
$$\textit{Intracellular: } V_{t2} \times dC_{t2}/dt = PA_t \times (C_{t1}/P_{t1})$$
$$- PA_t \times (C_{t2}/P_{t2}) \tag{7-22}$$

Q_t is blood flow, and C is the chemical concentration in entering blood (in), exiting blood (out), tissue extracellular space (t1), or tissue intracellular space (t2). The subscript (t) for the PA term acknowledges the fact that PA, reflecting either via passive diffusion or carrier-mediated processes, can differ between tissues. Both equations feature fluxes or transfers across the cell membrane that are driven by free concentration. Hence, partition coefficients are needed to convert extracellular and intracellular tissue concentration to their corresponding free concentration. The physiologic model in Fig. 7-11 is composed of two diffusion-limited compartments each of which contain two sub-compartments—extracellular and intracellular space, and several perfusion-limited compartments.

Specialized Compartments

Lung The inclusion of a lung compartment in a physiologic model is an important consideration because inhalation is a common route of exposure to many volatile toxic chemicals. Additionally, the lung compartment serves as an instructive example of the assumptions and simplifications that can be incorporated into physiologic models while maintaining the overall objective of describing processes and compartments in biologically relevant terms. For example, although lung physiology and anatomy are complex, Haggard (1924) developed a simple approximation that sufficiently describes the uptake of many volatile chemicals by the lungs. A diagram of this simplified lung compartment is shown in Fig. 7-16. The assumptions inherent in this compartment description are as follows: (1) ventilation is continuous, not cyclic; (2) conducting airways (nasal passages, larynx, trachea, bronchi, and bronchioles) function as inert tubes, carrying the vapor to the pulmonary or gas exchange region; (3) diffusion of vapor across the lung cell and capillary walls is rapid compared with blood flow through the lung; (4) all chemicals disappearing from the inspired air appears in the arterial blood (i.e., there is no hold-up of chemical in the lung tissue and insignificant lung mass); and (5) vapor in the alveolar air and arterial blood within the lung compartment are in rapid equilibrium and are related by $P_{b/a}$, the
Figure 7-16. Simple model for exchange of volatile chemicals in the alveolar region of the respiratory tract.

Rapid exchange in the lumped lung compartment between the alveolar gas (*blue*) and the pulmonary blood (*light blue*) maintains the equilibrium between them as symbolized by the dashed line. Q_p is alveolar ventilation (L/h); Q_c is cardiac output (L/h); C_{inh} is inhaled vapor concentration (mg/L); C_{art} is concentration of vapor in the arterial blood; C_{ven} is concentration of vapor in the mixed venous blood. The equilibrium relationship between the chemical in the alveolar air (C_{alv}) and the chemical in the arterial blood (C_{art}) is determined by the blood/air partition coefficient $P_{b/a}$, i.e., $C_{alv} = C_{art}/P_{b/a}$.

blood/air partition coefficient (e.g., $C_{alv} = C_{art}/P_{b/a}$). $P_{b/a}$ is a thermodynamic parameter that quantifies the equilibrium partitioning of a volatile chemical between blood and air.

In the lung compartment depicted in Fig. 7-16, the rate of inhalation of a volatile chemical is controlled by the ventilation rate (Q_p) and the inhaled concentration (C_{inh}). The rate of exhalation of the chemical is a product of the ventilation rate and the chemical's concentration in the alveoli (C_{alv}). Chemical also can enter the lung compartment via venous blood returning from the heart, at a rate represented by the product of cardiac output (Q_c) and the concentration of chemical in venous blood (C_{ven}). Chemical leaving the lungs via the blood at a rate determined by both cardiac output and the concentration of chemical in arterial blood (C_{art}). Putting these four processes together, a mass balance differential equation can be written for the rate of change in the amount of chemical in the lung compartment (L):

$$\frac{dL}{dt} = Q_p \times (C_{inh} - C_{alv}) + Q_c \times (C_{ven} - C_{art}) \qquad (7\text{-}23)$$

Because of these assumptions, at steady-state the rate of change in the amount of chemical in the lung compartment becomes zero ($dL/dt = 0$). C_{alv} can be replaced by $C_{art}/P_{b/a}$, and the differential equation can be solved for the arterial blood concentration:

$$C_{art} = (Q_p \times C_{inh} + Q_c \times C_{ven})/(Q_c + Q_p/P_{b/a}) \qquad (7\text{-}24)$$

This algebraic equation is incorporated into physiologic models for many volatile organics. Because the lung is viewed here as a portal of entry and not as a target organ, the concentration of a chemical delivered to other organs by the arterial blood is of primary interest. The assumptions of continuous ventilation, dead space, rapid equilibrium with arterial blood, and no hold-up of vapor in the lung tissues have worked extremely well with many volatile organics, especially relatively lipophilic volatile solvents. Indeed, the use of these assumptions simplifies and speeds model calculations and may be entirely adequate for describing the chemical behavior of relatively inert vapors with low water solubility.

Inspection of the equation for calculating the arterial concentration of the inhaled organic vapor indicates that the term $P_{b/a}$, the blood/air partition coefficient of the chemical, becomes an important term for simulating the uptake of various volatile organics. As the value for $P_{b/a}$ increases, the maximum concentration of the

chemical in the blood increases. Additionally, the time to reach the steady-state concentration and the time to clear the chemical also increase with increasing $P_{b/a}$. Fortunately, $P_{b/a}$ is readily measured by using in vitro techniques in which a volatile chemical in air is equilibrated with blood in a closed system, such as a sealed vial (Gargas and Andersen, 1988).

Liver The liver is almost always featured as a distinct compartment in physiologic models because biotransformation is an important route of elimination for many toxicants and the liver is considered the major organ for biotransformation of xenobiotics. A simple compartmental structure for the liver is depicted in Fig. 7-17, where uptake into the liver compartment is assumed to be flow-limited. This liver compartment is similar to the general tissue compartment in Fig. 7-14, except that the liver compartment contains an additional process for metabolic elimination. Under first-order elimination, the rate of hepatic metabolism (R) by the liver can be presented as:

$$R = Cl_l \times C_f \qquad (7\text{-}25)$$

where C_f is the free concentration of toxicant in the liver (mg/L), and Cl_l is the clearance of free toxicant within the liver (L/h). The latter parameter is conceptually the same as the intrinsic hepatic clearance term ($Cl_{int,h}$) in Equation (7-12). In the case of a single enzyme mediating the biotransformation and Michaelis–Menten kinetics are obeyed, Cl_l is related to the maximum rate of metabolism, V_{max} (in mg/h) and the Michaelis constant, K_M (in mg/L) (Andersen, 1981). As a result, the rate of hepatic metabolism can be expressed in terms of the Michaelis parameters.

$$R = [V_{max}/(K_M + C_f)] \times C_f \qquad (7\text{-}26)$$

Under non-saturating or first-order condition (i.e., $C_f \ll K_M$), Cl_l becomes equal to the ratio of V_{max}/K_M. Because many chemicals at toxic levels display saturable metabolism, the above equation is a key factor in the success of physiologic models for simulation of chemical disposition across a wide range of doses.

Other, more complex expressions for metabolism also can be incorporated into physiologic models. Bi-substrate second-order
Figure 7-17. Schematic representation of a flow-limited liver compartment in which metabolic elimination occurs.

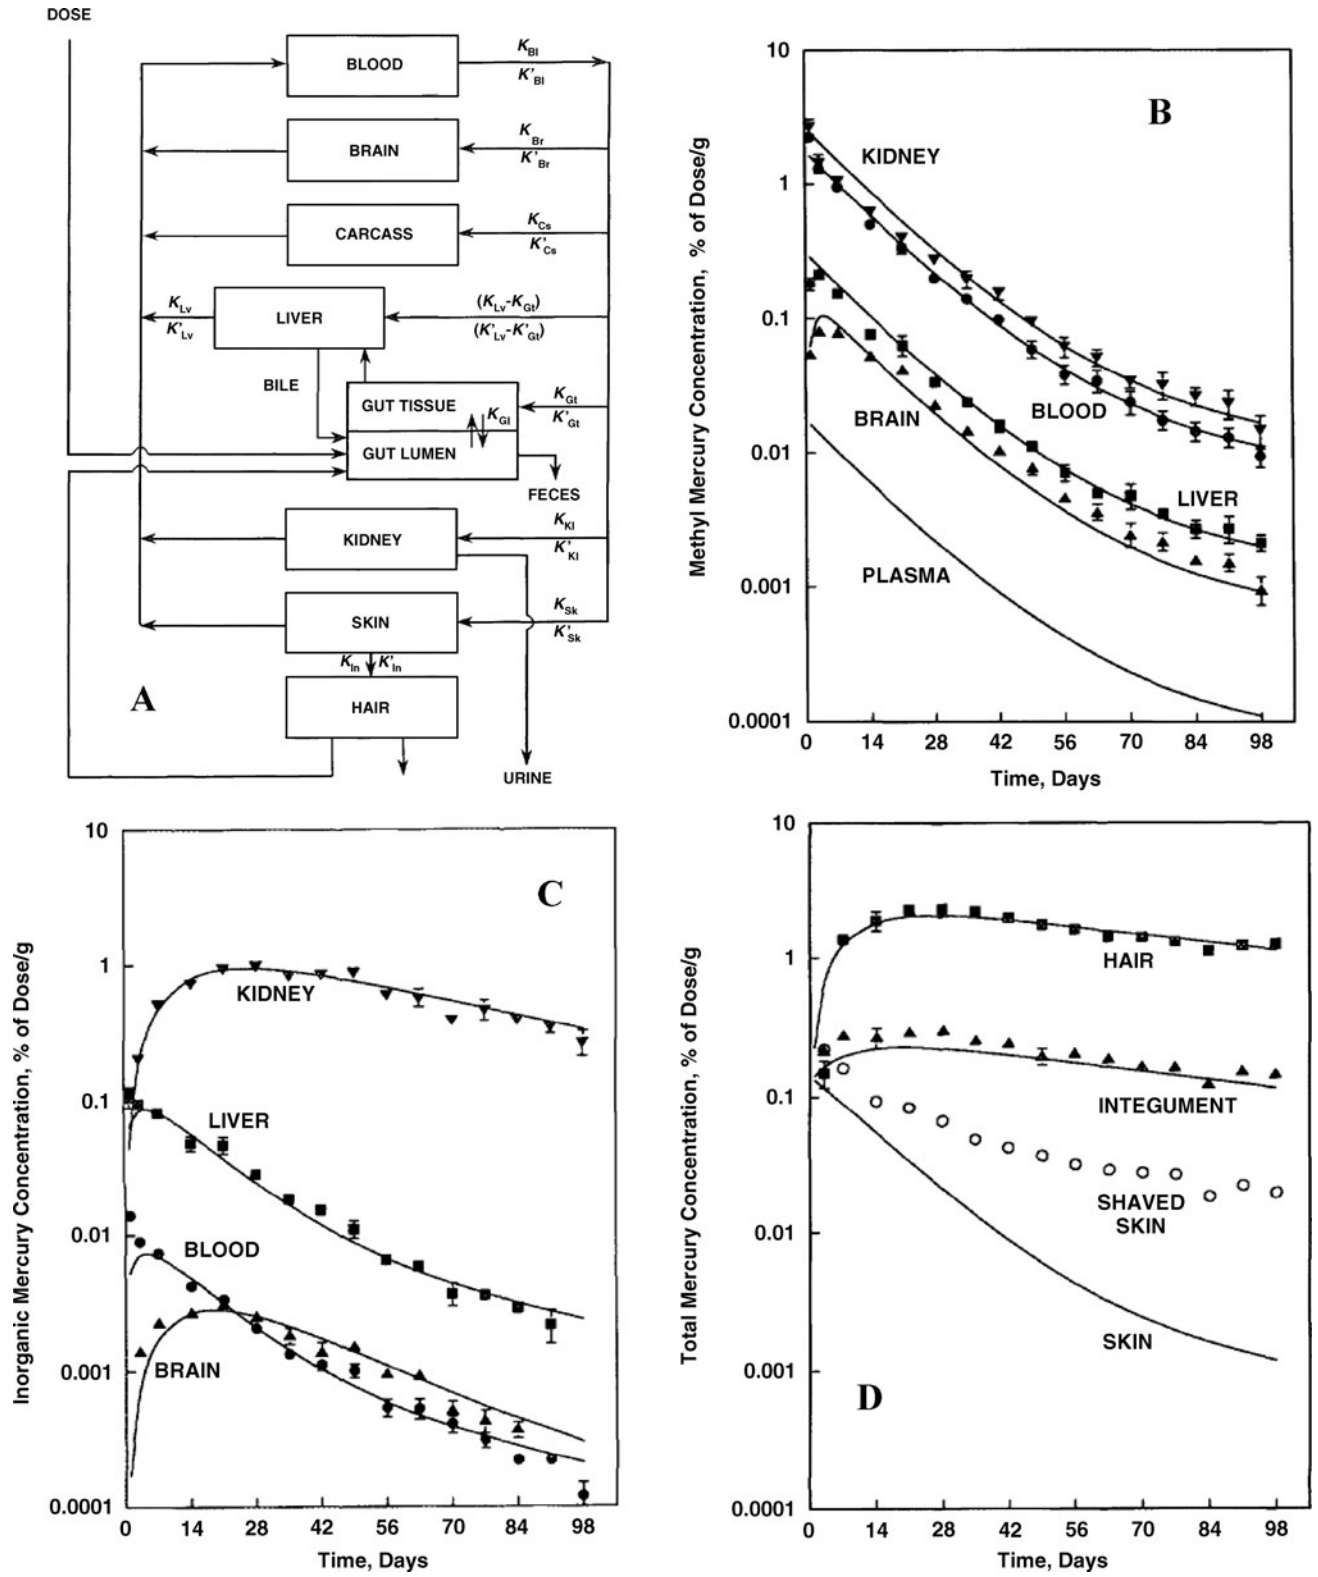
R, in milligrams per hour, is the rate of metabolism. Q_l is hepatic blood flow, C_{in} is chemical concentration entering the liver compartment, and C_{out} is chemical concentration out of the liver compartment. It should be noted that the liver receives blood from two sources, arterial inflow via hepatic artery and outflow from the upper mesentery via portal vein. This dual inflow is featured in the physiologic model featuring enterohepatic circulation in Fig. 7-11. Inflow via hepatic artery is often ignored, as in this case and in the physiologic model shown in Fig. 7-12, because of its relatively small flow rate compared to portal flow.


Figure 7-18. Model simulations compared with experimental data obtained in growing adult rats dosed orally with ^{203}Hg-labelled methylmercury chloride.

Panel A shows the physiologic model for methylmercury and its demethylated product, inorganic mercury. Primed symbols denote the parameters for inorganic mercury. Panels B and C show the respective time course of methylmercury and inorganic mercury concentration in blood, liver, kidneys and the brain. Panel C shows the slow accumulation of total mercury in hair and skin, or the integument (skin plus hair). Reprinted from Farris FF, Dedrick RL, Allen P, *et al*.: Physiological model for the pharmacokientics of methyl mercury in the growing rat. *Toxciol Appl Pharmacol* 119:74–90, 1993. With permission from Elsevier.

reactions, reactions involving the destruction of enzymes, inhibition of enzymes, or the depletion of cofactors, have been simulated using physiologic models. Metabolism can be also included in other compartments in much the same way as described for the liver.

Blood   In a physiologic model, the tissue compartments are linked together by the circulatory network. Figures 7-11 and 7-12 represent different approaches toward describing the circulating blood in physiologic models. In general, the arterial system delivers a chemical into various tissues. Exceptions are the liver, which receives arterial and portal blood, and the lungs, which receive mixed venous blood from the right cardiac ventricle. In the body, the venous blood supplies draining from tissue compartments eventually merge in the vena cava and heart chambers to form mixed venous blood. In Fig. 7-11, a blood compartment is created in which the input is the sum of the toxicant outflow from each compartment ($Q_t \times C_{vt}$). Outflow from the blood compartment is a product of the blood concentration in the compartment and the total cardiac output ($Q_c \times C_{bl}$). The mass-balance differential equation for the blood compartment in Fig. 7-11 is as follows:

$$V_{bl} \times dC_{bl}/dt = (Q_{br} \times C_{vbr} + Q_{ot} \times C_{vot} + Q_k \times C_{vk} + Q_l C_{vl})$$
$$- Q_c \times C_{bl}, \tag{7-27}$$

where V_{bl} is the volume of the blood compartment; C is concentration; Q is blood flow; bl, br, ot, k, and l represent the blood, brain, other tissues, kidney, and liver compartments, respectively; and vbr, vot, vk, and vl represent the venous blood leaving the organs. Q_c is the total blood flow equal to the sum of the venous blood flows from each organ.

In contrast, the physiologic model in Fig. 7-12 does not feature an explicit blood compartment. For simplicity, the blood volumes of the heart and the major blood vessels that are not within organs are assumed to be negligible. The venous concentration of a chemical returning to the lungs is simply the weighted average of the concentrations in the venous blood emerging from the tissues.

$$C_v = (Q_l \times C_{vl} \times Q_{rp} \times C_{vrp} + Q_{pp} \times C_{vpp} + Q_f \times C_{vf})/Q_c$$
$$\tag{7-28}$$

where C is concentration; Q is blood flow; v, l, rp, pp, and f represent the venous blood entering the lungs, liver, richly perfused, poorly perfused, and fat tissue compartments, respectively; and vl, vrp, vpp, and vf represent the venous blood leaving the corresponding organs. Q_c is the total blood flow equal to the sum of the blood flows exiting each organ.

In the physiologic model in Fig. 7-12, the blood concentration entering each tissue compartment is the arterial concentration (C_{art}) that was calculated above for the lung compartment (Equation (7-24)). The decision to use one formulation as opposed to another to describe blood in a physiologic model depends on the role the blood plays in disposition and the type of application. If the toxicokinetics after intravenous injection is to be simulated or if binding to or metabolism by blood components is suspected, a separate compartment for the blood that incorporates these additional processes is required. A blood compartment is obviously needed if the model were developed to explain a set of blood concentration–time data for a toxicant. On the other hand, if blood is simply a conduit to the other compartments, as in the case for inhaled volatile organics shown in Fig. 7-12, the algebraic solution is acceptable.

Figure 7-18 shows the application of physiologic modeling in elucidating the disposition fate of methylmercury and its demethylated product, inorganic mercury following a single peroral administration in the growing adult rat (Farris *et al.*, 1993). The model scheme presented in Panel A for both the organic and inorganic forms of mercury has the following unique features: (1) increase in compartment size due to growth over the long duration of the tissue washout experiment; (2) mercury enters the gut lumen via biliary excretion and secretory transport from gut tissue to lumen, some of which is reabsorbed; (3) uptake of methylmercury from blood into tissues, except for the brain, is assumed to be rate-limited by plasma flow because of sequestration of mercury in rat erythrocytes and its slow release; (4) uptake of methylmercury across the blood brain barrier is rate-limited by transport; (5) uptake of inorganic mercury into all tissues, except the liver, is limited by permeability/transport; (6) mercury is transferred from skin into hair, where it is irreversibly bound; and (7) mercury in hair is either shed or ingested by the animal during grooming. The model simulations displayed in Panels B, C, and D show two prominent features of methylmercurcy disposition: (1) methylmercury is rapidly demethylated to inorganic mercury, which is slowly eliminated from the brain and the kidneys, two major sites of methylmercury toxicities; and (2) a significant portion of mercury is sequestered in hair and the ingestion of hair by the animal contributes to the remarkable persistence of mercury in the rat. This example illustrates the capability of physiologic models to deal with the varied and complex disposition kinetics of toxicants from a wide range of sources under a multitude of experimental and environmental exposure scenarios.

Conclusions

The second section provides an introduction to the simpler elements of physiologic models and the important assumptions that underlie model structures. For more detailed aspects of physiologic modeling, the readers can consult several in-depth and well-annotated reviews on physiologically based toxicokinetic models (Clewell and Anderson, 1994, 1996; O'Flaherty, 1998; Krishnan and Anderson, 2001; Krishnan *et al.*, 2002; Anderson, 2003). Computer softwares are available for numerically integrating the system of differential equations that form the models. Investigators have successfully used Advanced Continuous Simulation Language (Pharsight Corp., Palo Alto, CA), Simulation Control Program (Simulation Resources, Inc., Berrien Springs, MI), MATLAB (The MathWorks, Inc., Natick, MA), and SAS software applications to name a few. Choice of software depends on prior experience, familiarity with the computer language used, and cost of the software package.

The field of physiologic modeling is evolving as toxicologists and pharmacologists develop increasingly more sophisticated applications. Three-dimensional visualizations of xenobiotic transport in fish and vapor transport in the rodent nose, physiologic models of a parent chemical linked in series with one or more active metabolites, models describing biochemical interactions among xenobiotics, and more biologically realistic descriptions of tissues previously viewed as simple lumped compartments are just a few of the more sophisticated applications. Finally, physiologically based toxicokinetic models are beginning to be linked to biologically based toxicodynamic models to simulate the entire exposure → dose → response paradigm that is basic to the science of toxicology.

CHEMICAL CARCINOGENESIS

James E. Klaunig and Lisa M. Kamendulis

OVERVIEW

Cancer is a disease of cellular mutation, proliferation, and aberrant cell growth. It ranks as one of the leading causes of death in the world. In the United States, cancer ranks as the second leading cause of death, with over one million new cases of cancer diagnosed and more than one half million Americans die from cancer annually. Multiple causes of cancer have been either firmly established or suggested, including infectious agents, radiation, and chemicals. Estimates suggest that 70–90% of all human cancers have a linkage to environmental, dietary, and behavioral factors (Fig. 8-1). While our understanding of the biology of the progression from a normal cell to a malignant one has advanced considerably in the past several decades, many aspects of the causes, prevention, and treatment of human cancers remain unresolved.

HISTORICAL BACKGROUND

A strong historical foundation for the linkage of the induction of cancer by chemicals has been documented (Table 8-1). In 1775, Percival Pott described a linkage between the increased occurrence of scrotal and nasal cancer among chimney sweepers and their profession. Pott (1775) concluded that chimney soot was the causative agent for cancer induction in these individuals. Other investigators also recognized an association between exposure to chemicals and the
Figure 8-1. Major causes of Human Cancers.

Adapted from *Harvard Reports on Cancer Prevention volume* 1 (1996).

induction of human cancer. Thiersch (1875) described a relationship between sunlight exposure and skin cancer in humans. A linkage between an increased incidence of lung cancer and uranium mining was noted by Harting and Hesse (1879). Butlin, in a follow-up of Potts' observations, noted that scrotal cancer in chimney sweepers in the European continent was relatively rare compared to that seen in England (Butlin, 1892). He attributed this difference to better hygiene practices by the European sweepers as well as to the use of younger boys as sweeps in England, suggesting that the age of exposure and the duration of exposure influence the formation of the cancer. Rehn (1895) reported a linkage between the manufacturer of aniline dyes and the induction of bladder cancer in dye workers. Due to the increase in demand for synthetic dyes in the 19th century, production of the aniline-based dyes increased, as did the development of skin and bladder cancer in exposed workers. The specific chemicals in the dyes related to the cause of skin and bladder cancer were later determined to be the aromatic compounds 2-naphthylamine and benzidine (Hueper *et al*., 1938). Exposure of workers to metals such as chromium (Alwens and Jonas, 1932), nickel (Stephens, 1932), as well as asbestos (Wood and Gloyne, 1934) was shown to be associated with an increased incidence of lung cancers in workers.

Based on these human observations, further investigations in the first half of the 20th century were performed to examine the role of these chemical mixtures and individual chemical compounds in the mixtures using animal models. Initial studies by Yamagiwa and Ichikawa (1915) examined the linkage between exposure to coal tar and its derivatives on cancer induction in humans by painting coal tar on rabbit ears. This resulted in skin cancer in the rabbits. Subsequently, Kennaway and Hieger (1930) purified the compound dibenz(*a,h*)anthracene from the coal tar extract, and determined that dibenz(*a,h*)anthracene was at least one compound in the coal tar mixture that was responsible for inducing skin cancer in mice. Cook *et al*. (1933) similarly isolated another polyaromatic hydrocarbon, benzo(*a*)pyrene, from the coal tar and showed this to also function as a carcinogen in rodents. In similar approaches with aromatic amines, Hueper *et al*. (1937) reported that 2-naphthylamine induced bladder tumors in dogs, and Yoshida and Kinosita (1936) found that feeding aminoazotoluene or aminoazobenzene to rodents induced liver cancer. Studies with the aromatic amine compounds in animal models correlated with the human epidemiological studies that had revealed an association between bladder cancer in humans and exposure to aniline dyes, and helped to define the specific chemicals in the dyes responsible for the cancer induction. These

Table 8-1
Historical Events in Chemically Induced Cancer

DATE	INVESTIGATOR(S)	CAUSATIVE AGENT(S)
1775	Pott	Soot and chimney sweeps
1822	Ayrton	Arsenic-containing metal
1875	Thiersch	Sunlight
1876	Manourriez	Coal tar
1879	Harting and Hesse	Lung cancer and uranium
1892	Butlin	Soot and chimney sweeps
1895	Rehn	Manufacture of aniline dyes
1902	Frieben	X-rays
1915	Davis	Pipe smokers and betel nut chewers
1915	Yamagiwa, Ichikawa, and Tsusui	Induction of skin cancer in rabbits and mice by coal tar
1920	Leitch and Seguina	Radium radiation
1928	Delore and Bergamo	Benzene
1930	Kennaway and Hieger	Tumor induction by dibenz[*a,h*] anthracene
1932	Stephens	Nickel
1932	Alwens	Chromium compounds
1933	Cook, Hewett, and Hieger	Isolation of the carcinogen benzo[*a*]pyrene from coal tar
1936	Yoshida and Kinosita	Induction of liver cancer in rats by *o*-aminoazotoluene
1934	Wood and Gloyne	Arsenicals, beryllium, and asbestos
1934	Neitzel	Mineral oil mists and radiation
1936	Kawahata	Coal tar fumes
1938	Hueper, Wiley, and Wolfe	Induction of urinary cancer in dogs by 2-naphthylamine
1941	Berenblum, Rous, MacKenzie, and Kidd	Initiation and promotion stages in skin carcinogenesis with benzo[*a*]pyrene
1951	Miller and Miller	Carcinogen binding to cellular macromolecule

epidemiological and experimental studies have shown a clear relationship between the induction of cancer in humans and rodents by a specific chemical or chemical mixture. In addition, this experimental work, demonstrated that animal models could be used as surrogates for humans in the study of chemical carcinogenesis.

Definitions

An understanding of the cellular and molecular aspects of the cancer process requires an understanding of the pathology and scientific terms involved in defining neoplasia (Table 8-2). Neoplasia is often defined as new growth or autonomous growth of tissue. The resulting neoplastic lesion is referred to as a neoplasm. Both benign and malignant neoplasms can be induced by chemical carcinogens. Benign neoplasms are lesions characterized by expansive growth, frequently exhibiting slow rates of proliferation that do not invade surrounding tissue or other organs. In contrast, a malignant neoplasm demonstrates invasive growth characteristics, capable of spreading throughout the organ of origin, and through metastasis to other tissues and organs. Metastases are

Table 8-2
Terminology

Neoplasia	New growth or autonomous growth of tissue
Neoplasm	The lesion resulting from the neoplasia
Benign	Lesions characterized by expansive growth, frequently exhibiting slow rates of proliferation that do not invade surrounding tissues
Malignant	Lesions demonstrating invasive growth, capable of metastases to other tissues and organs
Metastases	Secondary growths derived from a primary malignant neoplasm
Tumor	Lesion characterized by swelling or increase in size, may or may not be neoplastic
Cancer	Malignant neoplasm
Carcinogen	A physical or chemical agent that causes or induces neoplasia
Genotoxic	Carcinogens that interact with DNA resulting in mutation
Nongenotoxic	Carcinogens that modify gene expression but do not damage DNA

Table 8-3

Neoplasm Nomenclature

TISSUE OF ORIGIN	BENIGN NEOPLASM	MALIGNANT NEOPLASM
Connective tissue		
Bone	Osteoma	Osteosarcoma
Fibrous	Fibroma	Fibrosarcoma
Fat Lipid	Lipoma	Liposarcoma
Blood cells and related cells		
Hematopoietic cells		Leukemias
Lymphoid tissue		Lymphomas
Muscle		
Smooth	Leiomyoma	Leiomyosarcoma
Striated	Rhabdomyoma	Rhabdomyosarcoma
Endothelium	Hemangioma	Angiosarcoma
Mesothelium		Mesothelioma
Epithelial		
Squamous	Squamous cell papilloma	Squamous cell or carcinoma
Respiratory	Bronchial adenoma	Bronchogenic carcinoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Liver cells	Liver cell adenoma	Hepatocellular carcinoma
Urinary epithelium	Transitional cell papilloma	Transitional cell carcinoma
Testicular epithelium		Seminoma
Melanocytes		Malignant melanoma

secondary growths derived from the cells of the primary malignant neoplasm.

The term "tumor" describes a lesion that may or may not be neoplastic, and is characterized by swelling or an increase in size. In classifying neoplasms, the nomenclature reflects both the tissue or cell of origin, and the characteristics of the type of tissue involved (Table 8-3). For benign neoplasms, the tissue of origin is frequently followed by the suffix "oma"; for example, a benign fibrous neoplasm would be termed *fibroma*, and a benign glandular epithelium termed an *adenoma*. Malignant neoplasms from epithelial origin are called *carcinomas* while those derived from mesenchymal origin are referred to as *sarcoma*. Thus, a malignant neoplasm of fibrous tissue would be a *fibrosarcoma*, whereas that derived from bone would be an *ostoesarcoma*. Similarly, a malignant neoplasm from the liver would be a *hepatocellular carcinoma*, whereas that derived from skin would be referred to as a *squamous cell carcinoma*. Preneoplastic lesions have also been observed in a number of target organs in both animal models and humans, and reflect an early reversible lesion in neoplasm progression. The characterization and study of preneoplastic cells has led to a further understanding of the process of cancer formation.

The term "cancer" describes the subset of neoplasia that represents malignant neoplasms. A *carcinogen* is an agent, chemical or physical, that causes or induces neoplasia. This definition has been more thoroughly defined as an agent whose administration to previously untreated animals leads to a statistically significant increased incidence of neoplasia of one or more histogenetic types, as compared with the incidence of the appropriate untreated control animals (Pitot, 1986). Thus, the induction of both benign and malignant neoplasms is included in this definition.

Carcinogens can be chemicals, viruses, hormones, radiation, or solid materials. Carcinogens either produce new neoplastic growth in a tissue or organ or increase the incidence and/or multiplicity of background spontaneous neoplastic formation in the target tissue.

Table 8-4

Features of Genotoxic and Nongenotoxic Carcinogens

Genotoxic carcinogens
Mutagenic
Can be complete carcinogens
Tumorigenicity is dose responsive
No theoretical threshold
Nongenotoxic carcinogens
Nonmutagenic
Threshold, reversible
Tumorigenicity is dose responsive
May function at tumor promotion stage
No direct DNA damage
Species, strain, tissue specificity

Carcinogens may be *genotoxic*, meaning that they interact physically with DNA to damage or change its structure. Other carcinogens may change how DNA expresses information without modifying or directly damaging its structure, or may create a situation in a cell or tissue that makes it more susceptible to DNA damage from other sources. Chemicals belonging to this latter category are referred to as *nongenotoxic* carcinogens. Common features of genotoxic and nongenotoxic carcinogens are shown in Table 8-4.

This knowledge has led to continued efforts, using both epidemiological information and experimental animal models, to assess chemical carcinogenicity of occupational, industrial, and environmental agents, to gain an understanding of the mechanisms of action for these agents, and to determine the relevance of human exposure to cancer risk.
Figure 8-2. Multistage model of carcinogenesis.

MULTISTAGE CARCINOGENESIS

Through extensive experimental studies with animal models and evaluation of human cancers, it has been shown that the carcinogenesis process involves a series of definable and reproducible stages. Operationally, these stages have been defined as initiation, promotion, and progression (Fig. 8-2). These steps follow a temporal sequence of events that have been observed in a wide variety of target tissues. The defining characteristics of each of these stages are outlined in Table 8-5.

Initiation

The first stage of the cancer process involves initiation, a process that is defined as a stable, heritable change. This stage is a rapid, irreversible process that results in a carcinogen-induced mutational event. Chemical and physical agents that function at this stage are

referred to as initiators or initiating agents. Initiating agents lead to genetic changes including mutations and deletions. Chemical carcinogens that covalently bind to DNA and form adducts that result in mutations are initiating agents. Included among chemicals classified as initiating carcinogens are compounds such as polycyclic hydrocarbons and nitrosamines, biological agents such as viruses, and physical agents such as X-rays and UV light. Most chemical carcinogens that function at the initiation stage of the cancer process are indirect-acting genotoxic compounds that require metabolic activation in the target cell to produce the DNA-damaging event. For indirect-acting genotoxic compounds, the chemical must be taken into the target site and metabolized. The ultimate form of the carcinogen is then able to bind to nuclear DNA, resulting in adduct formation. The initiating event becomes "fixed" when the DNA adducts or other damage to DNA are not correctly repaired or are incompletely repaired prior to DNA synthesis. This event can lead to inappropriate base pairing and/or formation of a mutation.

Initiation by itself does not appear to be sufficient for neoplastic formation. Once initiated cells are formed, their fate has multiple potential outcomes: (1) the initiated cell can remain in a static nondividing state through influences by growth control via either normal surrounding cells or through endocrine influence; (2) the initiated cell may possess mutations incompatible with viability or normal function and be deleted through apoptotic mechanisms; or (3) the cell, through stimuli such as intrinsic factors or from chemical exposure, may undergo cell division resulting in the growth in the proliferation of the initiated cell. In some instances, typically following relatively high doses and/or repeated exposure to the genotoxic carcinogen, a chemical carcinogen may function as a complete carcinogen, i.e., it is capable of progressing through all stages of the cancer process.

Promotion

Derived from either endogenous or exogenous stimuli of cell growth, the second stage of the carcinogenesis process involves the selective clonal expansion of initiated cells to produce a preneoplastic lesion. This is referred to as the promotion stage of the carcinogenesis process. Both exogenous and endogenous agents that function at this stage are referred to as tumor promoters. Tumor promoters are not mutagenic and generally are not able to induce tumors by themselves; rather they act through several mechanisms involving gene expression changes that result in sustained cell proliferation, either through increases in cell proliferation and/or the inhibition of apoptosis. Nongenotoxic carcinogens frequently function at the tumor promotion stage. The growth of preneoplastic lesions requires repeated applications of or continuous exposure to tumor-promoting

Table 8-5
Characteristics of the Stages of the Carcinogenesis Process

Initiation
  DNA modification
  Mutation
  Genotoxic
  One cell division necessary to lock in mutation
  Modification is not enough to produce cancer
  Nonreversible
  Single treatment can induce mutation
Promotion
  No direct DNA modification
  Nongenotoxic
  No direct mutation
  Multiple cell divisions necessary
  Clonal expansion of the initiated cell population
  Increase in cell proliferation or decrease in cell death (apoptosis)
  Reversible
  Multiple treatments (prolonged treatment) necessary
  Threshold
Progression
  DNA modification
  Genotoxic event??
  Mutation, chromosome disarrangement
  Changes from preneoplasia to neoplasia benign/malignant
  Irreversible
  Number of treatments needed with compound unknown (may require only single treatment)

compounds. While initial exposure to tumor promoters may result in an increase in cell proliferation and/or DNA synthesis in all tissues of the organ, this is usually a transient effect and with repeated applications of the tumor promoter only the initiated cells continue to clonally expand and divide (Fig. 8-2). Promotion is a reversible phenomenon whereby upon removal of the promoting agent, the focal cells may return to single initiated cell thresholds. In addition, these agents demonstrate a well-documented threshold for their effects, below a certain dose or frequency of application, tumor promoters are unable to induce cell proliferation. Multiple chemical compounds as well as physical agents have been linked to the tumor promotion stage of the cancer process. Tumor promoters in general show organ-specific effects, e.g., a tumor promoter of the liver, such as phenobarbital will not function as a tumor promoter in the skin or other tissues.

Progression

The final stage of the carcinogenesis process, progression, involves the conversion of benign preneoplastic lesions into neoplastic cancer. In this stage, due to increase in DNA synthesis cell proliferation in the preneoplastic lesions, additional genotoxic events may occur resulting in additional DNA damage including chromosomal aberrations and translocations. These events result in the transfer from preneoplastic, clonally derived cell populations into neoplastic cell populations. Chemicals that impact on the progression stage are usually genotoxic agents. By definition, the progression stage is an irreversible stage in that neoplasm formation, whether benign or malignant, occurs. With the formation of neoplasia, an autonomous growth and/or lack of growth control is achieved. Spontaneous progression can occur from spontaneous karyotypic changes that occur in mitotically active initiated cells during promotion. An accumulation of nonrandom chromosomal aberrations and karyotypic instability are hallmarks of progression. As such, chemicals that function as progressor agents are usually clastogenic and are capable of causing chromosomal abnormalities. Complete carcinogens have the ability to function at the initiation, promotion, and progression stages and hence by definition have genotoxic properties. In addition, a number of model systems are available to test for carcinogenicity and/or to study the multistep mechanisms involved in chemical carcinogenesis. The models are described in a later section of this chapter.

MECHANISMS OF ACTION OF CHEMICAL CARCINOGENS

The development of neoplasia requires two major events: the formation of an initiated, mutated cell and the selective proliferation of the mutated cell to form a neoplasm. Both these events can be induced or acted upon by chemical carcinogens. Chemicals that induce cancer have been broadly classified into one of two categories—genotoxic or DNA reactive, and nongenotoxic or epigenetic carcinogens—based on their relative abilities to interact with genomic DNA.

Genotoxic Carcinogens

Genotoxic carcinogens initiate tumors by producing DNA damage. Experimental and epidemiological observations made in the middle of the 20th century identified a number of chemicals that could cause cancer in humans or experimental animals. Coal tar carcinogens including benzo(*a*)pyrene, pesticides such as 2-acetylaminofluorine,

Table 8-6
Examples of Genotoxic Carcinogens

Direct-acting carcinogens
Nitrogen or sulfur mustards
Propane sulfone

N-Nitrosoamines
Azo dyes
Hydrazines
Cycasin
Safrole
Chlorinated hydrocarbons
Aflatoxin
Mycotoxin
Pyrrolizidine alkaloids
Bracken fern
Carbamates

and azo dyes such as diaminobenzamide were among the first chemical carcinogens to be studied. DNA reactive carcinogens can be further subdivided according to whether they are active in their parent form (i.e., direct-acting carcinogens—agents that can directly bind to DNA without being metabolized) and those that require metabolic activation (i.e., indirect-acting carcinogens—compounds that require metabolism in order to react with DNA). Examples of direct-acting and indirect-acting carcinogens are listed in Table 8-6.

Direct-Acting (Activation-Independent) Carcinogens A variety of carcinogens do not require metabolic activation or chemical modification to induce cancer, and are termed direct acting or activation-independent carcinogens. These chemicals are also defined as ultimate carcinogens. Examination of the chemical structure of these agents reveals that they are highly reactive electrophilic molecules that can interact with and bind to nucleophiles, such as cellular macromolecules including DNA. Common electrophilic species are shown in Fig. 8-3. Generally, chemicals containing these moieties are highly reactive and frequently result in tumor formation at the site of chemical exposure.

Direct-acting carcinogens include epoxides, imines, alkyl and sulfate esters, and mustard gases (Fox and Scott, 1980; Sontag, 1981). Direct-acting electrophilic carcinogenic chemicals typically test positive in the Ames test without additional bioactivation with a liver metabolic fraction. The relative carcinogenic strength of direct-acting carcinogens depends in part on the relative rates of interaction between the chemical and genomic DNA, as well as competing reactions with the chemical and other cellular nucleophiles. The relative carcinogenic activity of direct-acting carcinogens is dependent upon such competing reactions and also on detoxification reactions. Chemical stability, transport, and membrane permeability determine the carcinogenic activity of the chemical. Direct-acting

1. Carbonium ions

2. Nitrenium ions

carcinogens are typically carcinogenic at multiple sites and in all species examined. A number of direct-acting alkylating agents, including a number of chemotherapeutic chemicals, are carcinogenic in humans (Vainio *et al.*, 1991).

Indirect-Acting Genotoxic Carcinogens An important discovery in the understanding of chemical carcinogenesis came from the investigations of the Millers who established that many carcinogens are not intrinsically carcinogenic, but require metabolic activation to be carcinogenic. They demonstrated that azo dyes covalently bind to proteins in liver, leading to the conclusion that carcinogens may bind to proteins that are critical for cell growth control (Miller and Miller, 1947). Subsequent work with benzo(*a*)pyrene showed covalent binding of benzo(*a*)pyrene or the metabolites of benzo(*a*)pyrene in rodents (Miller, 1951). Additional investigations with other indirect-acting genotoxic carcinogens confirmed that metabolism of the parent compound was necessary to produce a metabolite (activation) that was able to interact with DNA (Miller, 1970).

It has since been shown that the majority of DNA reactive carcinogens are found as parent compounds, or procarcinogens. Procarcinogens are stable chemicals that require subsequent metabolism to be carcinogenic (Miller and Miller, 1981; Weisburger and Wiliams, in Becker, 1981; Conney, 1982; Miller *et al.*, 1983). The terms procarcinogen, proximate carcinogen, and ultimate carcinogen have been coined to define the parent compound (procarcinogen) and its metabolite form, either intermediate (proximate carcinogen) or final (ultimate carcinogen) that reacts with DNA (Fig. 8-4). The ultimate form of the carcinogen is most likely the chemical species that results in mutation and neoplastic transformation. The ultimate form of certain carcinogenic chemicals is not known, whereas for other chemicals there may be more than one ultimate carcinogenic metabolite depending on the metabolic pathway followed. It is important to note that besides activation of the procarcinogen to a DNA

reactive form, detoxification pathways may also occur resulting in inactivation of the carcinogen.

Indirect-acting genotoxic carcinogens usually produce their neoplastic effects, not at the site of exposure (as seen with direct-acting genotoxic carcinogens) but at the target tissue where the metabolic activation of the chemical occurs. Indirect-acting genotoxic carcinogens include the polycyclic aromatic hydrocarbons (PAHs), nitrosamines, aromatic amines, and aflatoxin B1. Figure 8-4 shows the parent (procarcinogen) and metabolites for several representative indirect-acting genotoxic carcinogens.

Mutagenesis

The reaction of a carcinogen with genomic DNA, either directly or indirectly, may result in DNA adduct formation or DNA damage, and frequently produces a mutation. Several mechanisms of mutagenesis are known to occur. Modification of DNA by electrophilic carcinogens can lead to a number of products. Modified DNA are dependent upon when in the cell cycle the adducts are formed; where the adducts are formed; and, the type of repair process used in response to the damage.

Transitions are a substitution of one pyrimidine by the other, or one purine by the other (changes within a chemical class), whereas a transversion occurs when a purine is replaced by a pyrimidine, or a pyrimidine is replaced by a purine (changes across a chemical class). Carcinogens can induce transitions and transversions several ways. In one scenario, when adducts (or apurinic or apyrmidinic sites) are encountered by the DNA replication processes, they may be misread. The polymerase may preferentially insert an adenine (A) in response to a noninformative site. Thus, the daughter strand of an A, C, G, or T adduct will have an adenine (A) and this change is fixed (mutation) and resistant to subsequent DNA repair. A second outcome, a shift in the reading frame (resulting in a frame-shift mutation) may also result from carcinogen–DNA adducts formation. Most frame-shift mutations are deletions and occur more frequently when the carcinogen–DNA adduct is formed on a nucleotide. In a third scenario, DNA strand breaks can also result from carcinogen DNA adducts. These may arise either as a result of excision–repair mechanisms that are incomplete during DNA replication or via direct alkylation of the phosphodiester backbone leading to backbone cleavage. Strand scission can lead to double-strand breaks, recombination, or loss of heterozygosity.

Damage by Alkylating Electrophiles

As noted above, most chemical carcinogens require metabolic activation to exert a carcinogenic effect. The ultimate carcinogenic forms of these chemicals are frequently strong electrophiles (Fig. 8-3) that can readily form covalent adducts with nucleophilic targets. Because of their unpaired electrons, S:, O:, and N: atoms are nucleophilic targets of many electrophiles. The extent of adducts formed is limited by the structure of DNA, where bulky electrophilic chemicals can bind, and size of the ultimate carcinogenic form. In general, the stronger electrophiles display a greater range of nucleophilic targets (i.e., they can attack weak and strong nucleophiles), whereas weak electrophiles are only capable of alkylating strong nucleophiles (e.g., S: atoms in amino acids). In addition, the metabolic capability of a target cell will dictate the extent and types of electrophiles generated from the procarcinogenic parent.

An important and abundant source of nucleophiles is contained not only in the DNA bases, but also in the phosphodiester
Figure 8-4. Structures of representative indirect-acting carcinogens and their metabolic derivatives.

The proximate (Px) and ultimate (Ut) carcinogenic forms result from the metabolism of the procarcinogenic form (Pr).

backbone (Fig. 8-5). Whereas carcinogen DNA adducts may be formed at all sites in DNA, the most common sites of alkylation include the N^7 of guanine, the N^3 of adenine, the N^1 of adenine, the N^3 of guanine, and the O^6 of guanine. Alkylations of phosphate may also occur at a high frequency. Selective examples of carcinogen

interactions with proteins and nucleic acids are shown in Fig. 8-6. Different electrophilic carcinogens will often display different preferences for nucleophilic sites in DNA and different spectra of damage. Dimethylnitrosamine and diethylnitrosamine, for example, are metabolized by P450 oxidation to yield a methyl carbonium ion
Figure 8-5. Examples of cellular nucleophiles and sites of possible adduct formation.

(CH_3^+) and an ethyl carbonium ion ($CH_3CH_2^+$), respectively. Despite the structural similarities of the ultimate electrophiles, they display significant differences in alkylation profiles (Pegg, 1984). The relative proportions of methylated bases present in DNA following reaction with carcinogen-methylating agents are shown in Table 8-7 (Pegg, 1984). The predominant adduct formed following exposure to methylating chemicals such as methylmethane sulfonate is 7-methylguanine. In contrast, ethylating agents produce adducts predominately in the phosphate backbone of DNA. The carcinogenic potential of the type of adducts formed is often debated; some believe that O^6-alkylguanine is the most carcinogenic adduct, while others report that O^4-alkylthymine is more important in the carcinogenic process, due to its persistence relative to other adducts (Pegg, 1984; Swenberg *et al.*, 1984).

Another common modification to DNA is the hydroxylation of DNA bases. Oxidative DNA adducts have been identified in all four DNA bases (Fig. 8-7); however, 8-hydroxyguanine is among the most prevalent oxidative DNA adduct (Floyd, 1990). The source of oxidative DNA damage is typically formed from free radical reactions that occur endogenously in the cell or from exogenous sources (Floyd, 1990; Ames and Shigenaga, 1993; Klaunig and Kamendulis, 2004). Although a relatively large amount of oxidative DNA adducts have been proposed to be formed per day, repair mechanisms exist that maintain the cellular level at a low rate and keep endogenous mutations to a relatively low level. The role of oxidative

damage and oxidative stress is discussed in greater detail later in this chapter.

Methylation of deoxycytidine residues is a well-studied DNA adduct. This reaction occurs by the transfer of a methyl group from *S*-adenosylmethionine by DNA methyltransferases (Holliday, 1990). Methylation of DNA results in heritable expression or repression of genes, with hypomethylation associated with active transcription of genes, while hypermethylated genes tend to be rarely transcribed. Chemical carcinogens may inhibit DNA methylation by several mechanisms including forming covalent adducts, single strand breaks in the DNA, alteration of methionine pools, and inactivation of the DNA methyltransferase responsible for methylation (Riggs and Jones, 1983). The importance of DNA methylation in chemical carcinogenesis is discussed later in this chapter.

Although a large number of adducts can be formed following exposure to chemicals, whether a particular DNA adduct will result in mutation and participate in the carcinogenesis process is dependent in part on the persistence of the adduct through the process of DNA replication, which is also in part dependent upon DNA repair.

DNA Repair

Following the formation of a carcinogen DNA adduct, the persistence of the adduct is a major determinant of the outcome. This

persistence depends on the ability of the cell to repair the altered DNA. The detection of unique DNA adducts has proven to be important in understanding the mechanism of action of specific carcinogens and has been correlated with carcinogenesis (Goth and Rajewsky, 1974; Kadlubar *et al.*, 1981; Becker and Shank, 1985; Swenberg *et al.*, 1985). However, the presence of a DNA adduct is not sufficient for the carcinogenesis process to proceed. The relative rates or persistence of particular DNA adducts may be an important determinant of carcinogenicity, for example, O^4-ethylthymine is relatively stable in DNA while O^6-ethylguanine does not persist in DNA after continuous exposure to diethylnitrosamine (Swenberg *et al.*, 1984). The persistence of DNA adducts of trans-4-aminostilbene does not correlate with organ carcinogenicity and/or tissue susceptibility. While the liver and kidney exhibited the greatest burden and persistence of the adduct and the Zymbals gland showed the least amount of DNA adducts, the latter tissue was more susceptible to carcinogenesis by this chemical (Neumann, 1983). As such, differences in susceptibility to carcinogenesis are likely the result of a number of factors, including DNA replication within a tissue and repair of a DNA adduct.

The quantification of covalent DNA adducts in tissues has been used to demonstrate exposure of humans to carcinogenic chemicals and to assess the relative risk from exposure to carcinogenic chemicals. For example, DNA adducts of carcinogenic polyaromatic hydrocarbons have been demonstrated at relatively high levels in tissues and blood of smokers and foundry workers compared with nonexposed individuals (Perera *et al.*, 1991). In addition, DNA adducts of aflatoxin B1 were seen in samples of human placenta and cord blood in individuals in Taiwan, an area that has a high incidence of liver cancer (Hsieh and Hsieh, 1993). The presence of macromolecular carcinogen adducts may be important to their mechanism of carcinogenicity, the presence and persistence of the adducts is only one factor in the process of cancer development.

Experimental and epidemiological evidence indicates that the development of cancer following exposure to chemical carcinogens is a relatively rare event. This can be explained by the ability of a cell to recognize and repair damaged DNA. During the DNA repair, the DNA region containing the adduct is removed and a new patch of DNA is synthesized, using the opposite intact strand as a template. The new DNA segment is then spliced into the DNA molecule in

DNA damage can lead to the insertion of an incorrect base during DNA replication, followed by transcription and translation of the mutated templates, ultimately leading to the synthesis of altered protein. Mutations in an oncogene, tumor-suppressor gene, or gene that controls the cell cycle can result in a clonal cell population with a survival advantage. The development of a cancer requires many such events, occurring over a long period of time, and for this reason human cancer induction often takes place within the context of chronic exposure to chemical carcinogens.

A number of structural alterations may occur in DNA as a result of interaction with reactive chemicals or radiation, and the more frequent types of damage are depicted in Fig. 8-8. The reaction of chemical species with DNA can produce adducts within the bases, sugar, and phosphate backbone of DNA. In addition, bi-functional alkylating agents (such as mustards) may cause DNA crosslinking between two opposing bases. Other structural changes such as pyrimidine dimer formation are specific for exposure to UV light, while double-stranded breaks in DNA are more commonly associated with ionizing radiation. A variety of mechanisms have evolved to effectively remediate and repair DNA damage. The more common types of DNA repair mechanisms seen in mammalians are listed in Table 8-8.

In addition to the proofreading activity of DNA polymerases that can correct miscopied bases during replication, cells have several mechanisms for repairing DNA damage. Repair of DNA

place of the defective one. To be effective in restoring a cell to normal, repair of DNA must occur prior to cell division; if repair is not complete prior to replication, the presence of the adducts can give rise to mispairing of bases and other genetic effects such as rearrangements and translocations of DNA segments. Thus, a chemical that alters the repair process or the rate of cell division can itself affect the frequency of neoplastic transformation.

DNA Repair Mechanisms

Although cells possess mechanisms to repair many types of DNA damage, these are not always completely effective, and residual

Figure 8-8. Common Forms of DNA Damage.

damage does not always occur prior to cell replication, and in addition, repair of DNA damage by some chemicals is relatively inefficient, as such, exposure to chemicals that cause DNA damage can increase the probability of acquiring mutations that ultimately lead to cancer development.

Mismatch Repair of Single-Base Mispairs Spontaneous mutations may occur through normal cellular DNA replication errors. Many spontaneous mutations are point mutations, a change in a single base pair in the DNA sequence. The issue for mismatch repair is determining which is the normal DNA and which is the damaged DNA strand, and therefore repairing the mutated strand such that the correct base pairs are restored. Depurination is a fairly common occurrence and a spontaneous event in mammals, and results in the formation of apurinic sites. If these lesions are left unrepaired, mutations are generated during DNA replication since the DNA synthetic machinery is unable to determine the appropriate base with which to pair. All mammalian cells possess apurinic endonucleases that function to cut DNA near apurinic sites. The cut is then extended by exonucleases, and the resulting gap repaired by DNA polymerases and ligases.

Excision Repair DNA regions containing chemically modified bases, or DNA chemical adducts, are typically repaired by excision repair processes. DNA adducts cause a distortion in the normal shape of DNA. Proteins that slide along the surface of a double-stranded DNA molecule recognize the irregularities in the shape of the double helix, and affect the repair of the lesion. DNA lesions that are repaired by excision repair processes include thymine–thymine dimers, produced following exposure to UV light; dimers that interfere with both replication and transcription of DNA. The repair

of DNA regions containing bases altered by the attachment of large chemical adducts such as benzo(*a*)pyrene are also effectively repaired by excision repair processes (Fig. 8-9).

End-Joining Repair of Nonhomologous DNA A cell that has double-strand breaks can be repaired by joining the free DNA ends. The joining of broken ends from different chromosomes, however, will lead to the translocation of DNA pieces from one chromosome to another, translocations that have the potential to enable abnormal cell growth by placing a proto-oncogene next to, and therefore under the control of, another gene promoter. Double-strand breaks can be caused by ionizing radiation, and drugs such as anticancer drugs. Double-strand breaks are correctly repaired only when the free ends of DNA rejoin exactly. The repair of double-stranded DNA is therefore confounded by the absence of single-stranded regions that can signal the correct base pairing during the rejoining process. Homologous recombination is one of two mechanisms responsible for the repair of double-strand breaks. In this process, the double-strand break on one chromosome is repaired using the information on the homologous, intact chromosome.

The predominant mechanism for double-stranded DNA repair in multicellular organisms is nonhomologous repair, and involves the rejoining of the ends of the two DNA molecules. Although this process yields a continuous double-stranded molecule, several base pairs are lost at the joining point. This type of deletion may produce a possibly mutagenic coding change.

Classes of Genotoxic Carcinogens

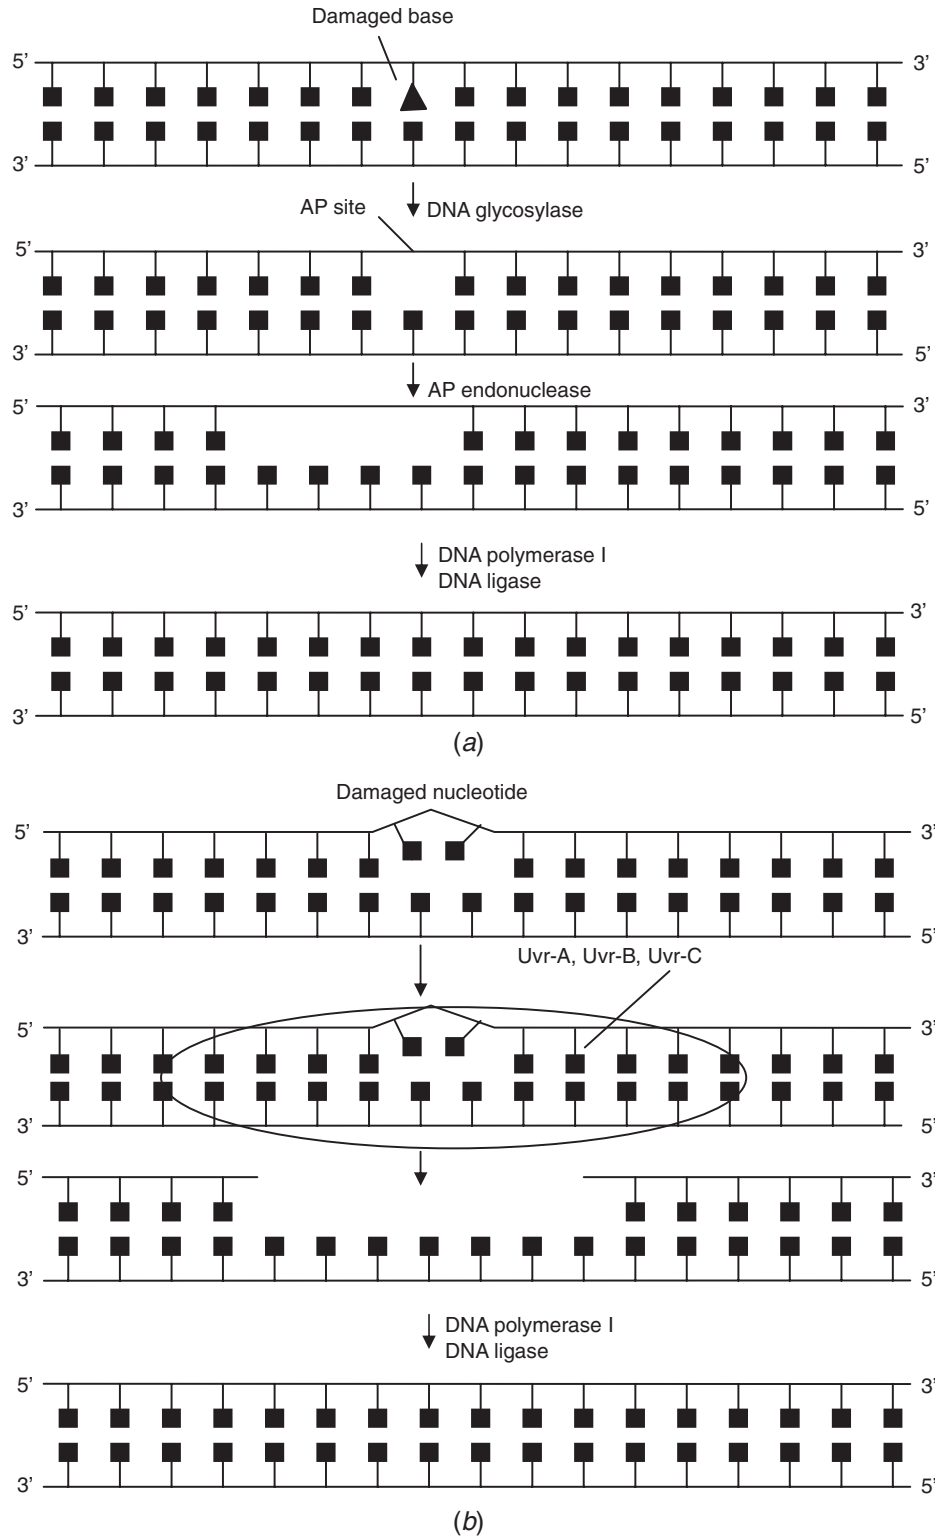
Polyaromatic Hydrocarbons Polyaromatic hydrocarbons are found at high levels in charcoal broiled foods, cigarette smoke,


Figure 8-9. (A) DNA repair by base excision. (B) DNA repair by nucleotide excision.

and in diesel exhaust. Representative chemicals belonging to this class are shown in Fig. 8-10a. Benzo(*a*)pyrene is a representative polycyclic hydrocarbon that has been studied extensively. The metabolism and pathways that lead to tumor formation have been characterized through the work of a number of laboratories (Conney, 1982). The ultimate carcinogen is a diol epoxide of benzo(*a*)pyrene,

formed following three separate enzymatic reactions (Sims *et al*., 1974). Benzo[*a*]pyrene is first oxidized by cytochrome P4501A1 to form benzo[*a*]pyrene 7,8-oxide, further metabolized by epoxide hydrolase, yielding the 7,8-dihydrodiol. And then further metabolism by cytochrome P4501A1 to yield the ultimate carcinogen, the 7,8-dihydrodiol-9,10-epoxide (Yang *et al*., 1976; Lowe and
Figure 8-10. *(A) Chemical structures of selected carcinogenic polycyclic hydrocarbons. (B) Role of epoxide hydrolase in the activation of benzo[a]pyrene 4,5-oxide and in the conversion of benzo[a]pyrene to its tumorigenic bay-region diole poxide.*

Silverman, 1994). The Bay region or K region of the benzo(*a*)pyrene molecule is the site of metabolic targeting and DNA interaction (Fig. 8-10b). The importance of the bay region (K region) of the benzo(*a*) pyrene molecule was demonstrated from the understanding of the metabolism of the benzo(*a*)pyrene to its ultimate DNA reactive form. Similar regions (to the Bay region) have been iden-

tified in other carcinogenic polycyclic hydrocarbons and used to access and predict carcinogenic potential of other PAHs.

Alkylating Agents   Alkylating chemicals represent an important class of chemical carcinogens. Whereas some alkylating chemicals are direct-acting genotoxic agents, many require

metabolic activation to produce electrophilic metabolites that can react with DNA. Alkylating agents can be classified into several groups including the direct-acting alkylalkanesulfonates (methyl- and ethyl methanesulfonate) and nitrosamides (*N*-methyl-*N*-nitrosourea,

N-ethyl-*N*-nitrosourea, *N*-methyl-*N*-nitro-*N*-nitrosoguanidine, and the indirect-acting nitrosamides (dimethyl- and diethylnitrosamines) (Fig. 8-11). The alkylating compounds (or in the case of diethylnitrosamine and dimethylnitrosamine; their metabolites)

readily react with DNA at more than 12 sites. The N[7] position of guanine and the N[3] position of adenine are the most reactive sites in DNA for alkylating chemicals. DNA methylation reactions occur more readily and thus exhibit >20 more adducts than with ethylation reactions. However, ethylation reactions have a greater affinity for oxygen centers, an event that appears to correlate with the mutagenicity and carcinogenicity of these compounds. Nitrosamines were initially used as solvents in chemistry. Their toxic effects were identified when workers using the nitrosamines solvents developed jaundice and liver damage. Subsequent studies in animal models revealed that dimethylnitrosamine and diethyl-nitrosamine were highly hepatotoxic and hepatocarcinogenic.

Other alkylating chemicals including the nitrogen mustards (e.g., chlorambucil, cyclophosphamide) have been used in cancer chemotherapy. They produce DNA adducts as well as induce the formation of DNA strand breaks. The alkylation of DNA by nitrogen mustards requires the formation of highly reactive *N*-alkylazirdinium ions (Fig. 8-12). Nitrogen mustards can produce a wide spectrum of mutations including base pair substitutions (AT and GC) and deletions. In addition, nitrogen mustards are potent clastogens causing chromosomal aberrations and sister chromatid exchanges (SCEs), predominantly in GC-rich regions.

Ethylene oxide and propylene oxide are other examples of mutagenic and carcinogenic alkylating agents (Fig. 8-13). Ethylene oxide is a direct-acting alkylating carcinogen in rodents, and perhaps of human concern (Hogstedt *et al.*, 1986). Ethylene oxide is mutagenic in short term in vitro assays, and produces chromosomal aberrations and SCEs in eukaryotic cells (Ehrenberg and Hussain, 1981). Propylene oxide is also a mutagenic rodent carcinogen inducing nasal tumors in rodents following inhalation exposure (NTP, 1985). Alkylation of DNA by ethylene and propylene oxide occurs predominantly at the N[7] position of guanine, yielding 7-(2-hydroxyethyl)guanine and 7-(2-hydroxypropyl)guanine adducts, respectively. These adducts represent the major adducts formed following either in vitro or in vivo exposure (Walker *et al.*, 1992).

Vinyl chloride is another known rodent and human carcinogen, producing angiosarcomas in the liver and tumors in the lung and hematopoetic system in humans (Doll, 1985). Limited evidence also suggests that vinyl chloride exposure results in brain tumors. Vinyl chloride is mutagenic and is metabolized by cytochrome P450 to form chloroethylene oxide, which rearranges nonenzymatically to produce chloroacetaldehyde, both of which can alkylate DNA. Vinyl chloride and metabolites form several DNA adducts including

7-(2′-oxoethyl)guanine, N^2, 3-ethenoguaine, 3,N^4-ethenocytosine, and 1,N^6-ethenoadenine (Guengerich, 1994).

Aromatic Amines and Amides   Aromatic amines and amides encompass a class of chemicals with varied structures (aromatic amines, e.g. aniline dyes, 2-naphthylamine, benzidine, 2-acetylaminofluorene) (Fig. 8-14). Because of their use in the dye industry and other industrial processes their carcinogen potential in humans was realized as early as the late 19th century. While proper industrial hygiene processes have considerably reduced the human exposure to aromatic amines and amides in the workplace, exposure to these chemicals still occurs through cigarette smoke and environmental sources. The aromatic amines undergo both phase-I and phase-II metabolism. Phase-I reactions occur mainly by cytochrome P450-mediated reactions, yielding hydroxylated metabolites that are often associated with adduct formation in proteins and DNA, and produce liver and bladder carcinogenicity (Miller *et al.*, 1964). For example, metabolism of 2-acetylaminofluorene (AAF) results in the formation of N-hydroxy-AAF, which is a metabolite responsible for the liver tumorigenicity. Similarly, 1-napthylamine exhibits carcinogenic activity only in test systems capable of producing the N-hydroxy metabolite of naphthylamine. Aromatic amines are capable of forming adducts with several DNA bases.

Inorganic Carcinogens

Several metals exhibit carcinogenicity in experimental animals and/or exposed humans. Table 8-9 provides a listing of some common metals and their corresponding carcinogenicity in animals and humans. Additional details are provided below.

Arsenic   Arsenic compounds are poorly mutagenic in both bacterial and mammalian cell assays (Lofroth and Ames, 1978). Metallic arsenic, arsenic trioxide, sodium arsenite, sodium arsenate, potassium arsenite, lead arsenate, calcium arsenate, and pesticide mixtures containing arsenic have been tested for carcinogenicity in experimental animals (IARC, 1980, 1987). In the majority of studies in experimental animals—including oral exposure studies in mice, rats, and dogs; dermal exposure studies in mice; inhalation exposure studies in mice; injection studies in mice and rats; and intramedullary injection studies in rats and rabbits—no tumors were observed or the results were inconclusive, and thus it has previously been concluded that limited evidence exists for the carcinogenicity of inorganic arsenic compounds in experimental animals (IARC, 1987).

In contrast, inorganic arsenic compounds are known human carcinogens, based on sufficient evidence of carcinogenicity in humans. Epidemiological studies of humans exposed to arsenic compounds demonstrated that exposure to inorganic arsenic compounds increases the risk of cancer in the skin, lung, digestive tract, liver, bladder, kidney, and lymphatic and hematopoietic systems (IARC, 1973, 1980). Several of the epidemiological studies have reported dose–response relationships between arsenic in drinking water and several types of cancer, including bladder, kidney, lung, and skin cancer (Cantor, 1997; Ferreccio *et al.*, 2000). The mechanisms for cancer formation are unclear but possibly involve the induction of oxidative stress, altered cell signaling, modulation of apoptosis, and/or altered cell cycle (Harris and Shi, 2003; Quian and Shi, 2003; Hughes and Kitchin, 2006). The latency period in humans of arsenic-related carcinogenesis is considered to be 30–50 years. The first signs of chronic exposure, frequently seen in water supplies contaminated with arsenic, are skin pigmentation, depigmentation, hyperkeratosis of palms and soles, and skin lesions. A unique

peripheral vascular disease associated with chronic arsenic exposure is black foot disease, starting with numbness and ulceration of extremities and ending in gangrene and spontaneous amputations (Chen *et al.*, 1988).

Beryllium   Beryllium and its salts are not mutagenic and do not appear to induce cellular transformation (IARC, 1993). Mechanistically, beryllium salts bind to nucleoproteins and inhibit enyzmes involved in DNA synthesis, resulting in infidelity of DNA synthesis and also induce gene mutations in cultured cells (Leonard and Lauwerys, 1987). Studies in animal models have consistently reported increases in lung tumors in rodents and nonhuman primates exposed to beryllium or beryllium compounds (IARC, 1993; Finch *et al.*, 1996; NTP, 1998). Beryllium metal and several beryllium compounds (e.g., beryllium–aluminum alloy, beryllium ore, beryllium chloride, beryllium hydroxide, beryllium sulfate tetrahydrate, and beryllium oxide) induced lung tumors in rats. Beryllium oxide and beryllium sulfate produced lung cancer (anaplastic carcinoma) in monkeys after intrabronchial implantation or inhalation. In rabbits, osteosarcomas were reported after exposure to beryllium metal, beryllium carbonate, beryllium oxide, beryllium phosphate, beryllium silicate, or zinc beryllium silicate (IARC, 1993).

Beryllium and beryllium compounds have been classified as human carcinogens based on animal studies and evidence of carcinogenicity in humans. Epidemiological studies indicate an increased risk of lung cancer in occupational groups exposed to beryllium or beryllium compounds (Steenland and Ward, 1991; Ward *et al.*, 1992). Further, an association with lung cancer has consistently been observed in occupational populations exposed to beryllium or beryllium compounds. Acute beryllium pneumonitis, a marker for exposure to beryllium has been shown to be associated with higher lung cancer rates (Steenland and Ward, 1991).

Cadmium   Animal studies have shown that cadmium and cadmium compounds induce tumor formation at various sites in multiple species of experimental animals, following multiple exposure routes, including the induction of prostate tumors in rats, testicular tumors in rats and mice, lymphoma in mice, adrenal-gland tumors in hamsters and mice, and lung and liver tumors in mice (IARC, 1993; Waalkes *et al.*, 1994, 1999). It has been suggested that ionic cadmium, or compounds that release ionic cadmium, is the cause of genetic damage and thus the carcinogenic species. Increased frequencies of chromosomal aberrations (changes in chromosome structure or number) have been observed in lymphocytes of workers occupationally exposed to cadmium. Many studies of cultured mammalian cells have shown that cadmium compounds cause genetic damage, including gene mutations, DNA strand breaks, chromosomal damage, cell transformation, and disrupted DNA repair (IARC, 1993).

Cadmium and cadmium compounds have been classified as known human carcinogens based on evidence of carcinogenicity in humans, including epidemiological and mechanistic information that indicate a causal relationship between exposure to cadmium and cadmium compounds and human cancer (IARC, 1993). Epidemiological studies of cadmium workers found that exposure to various cadmium compounds increased the risk of death from lung cancer (IARC, 1993). Follow-up analysis of some of these cohorts has confirmed that cadmium exposure is associated with elevated lung cancer risk under some industrial circumstances (Sorahan *et al.*, 1995; Sorahan and Lancashire, 1997). Some epidemiological evidence has also suggested an association between cadmium exposure and prostate cancer (Shigematsu *et al.*, 1982; van der Gulden *et al.*,

1995), kidney (Mandel *et al.*, 1995), and bladder (Siemiatycki *et al.*, 1994).

Chromium   Chromium has multiple oxidation states: from -2 to $+6$; however, the most common forms are the trivalent (III) and hexavalent (VI) forms. With regard to carcinogenicity, chromium III does not exhibit carcinogenicity in laboratory animals whereas chromium VI has been tested to be positive for genotoxicity and carcinogenicity in a variety of bioassays (Langard, 1988; IARC, 1990). Chromium VI compounds cause genetic damage including gene mutations and DNA damage in bacteria. Several chromium VI compounds also caused mutations in yeast and insects. Many chromium VI compounds caused genetic damage in cultured human and other animal cells and in experimental animals exposed in vivo, including SCE, chromosomal aberrations, and cell transformation. Chromosomal aberrations, SCE, and aneuploidy were observed in workers exposed to chromium VI compounds (IARC, 1990). Chromium VI (calcium chromate, chromium trioxide, sodium dichromate, lead chromates, strontium chromate, or zinc chromates) exposure in rats following inhalation, intrabronchial, intrapleural, intratracheal, intramuscular, or subcutaneous administration resulted in benign and malignant lung tumors in rats in a number of studies. In mice, calcium chromate caused benign lung tumors and chromium trioxide caused malignant lung tumors. Exposure of hamsters, guinea pigs, and rabbits to chromium VI compounds by intratracheal instillation did not cause lung tumors (IARC, 1980, 1990). While the mechanisms for chromium VI carcinogenicity remain unresolved, it has been speculated that the reduction of chromium VI by glutathione is involved (Connett and Whtterhahn, 1985; Kortenkamp and O'Brien, 1994).

Hexavalent chromium (chromium VI) compounds have been classified as known human carcinogens based on data from animal studies and human epidemiological studies. Human epidemiological studies have consistently reported increased risks of lung cancer among chromate workers. Chromate workers are exposed to a variety of chromium compounds, including chromium VI and trivalent (III) compounds. In addition, an increased risk of a rare cancer of the sinonasal cavity was observed in these workers (IARC, 1990). Some studies suggested that exposure to chromium among workers, such as chromium-exposed arc welders, chromate pigment workers, chrome platers, and chromium tanning workers, may be associated with leukemia and bone cancer (Costa, 1997).

Nickel   Many studies in cultured rodent and human cells have shown that a variety of nickel compounds, including both soluble and insoluble forms of nickel, exhibit genotoxicity, producing DNA strand breaks, mutations, chromosomal damage, cell transformation, and modulation of DNA repair. Soluble nickel salts can be complete carcinogens and/or initiators of carcinogenesis (Kasprzak *et al.*, 1990; Diwan *et al.*, 1992). In rats and mice, inhalation or intratracheal instillation of nickel subsulfide or nickel oxide produced dose-related increases of benign and malignant lung tumors (IARC, 1990; NTP, 1996). Inhalation of nickel compounds also caused malignant and benign pheochromocytoma in rats (NTP, 1996). Short-term intraperitoneal exposure during gestation to soluble nickel salt induced malignant pituitary tumors in the offspring. Additionally, exposure to nickel acetate through the placenta followed by exposure of the offspring to barbital (a known tumor promoter) produces kidney tumors (renal cortical and pelvic tumors) (Diwan *et al.*, 1992). In adult rats, injection of soluble nickel salts followed by exposure to a promoting carcinogen resulted in kidney cancer (renal cortical

adenocarcinomas) that frequently metastasized to the lung, liver, and spleen (Kasprzak *et al.*, 1990). The carcinogenic properties of metallic nickel are believed to be due to ionic nickel, which can slowly dissolve in the body from nickel compounds.

Nickel compounds are classified as known human carcinogens (IARC, 1990) based on animal data and sufficient evidence of carcinogenicity from human studies. The IARC (1990) evaluation of nickel and nickel compounds concluded that nickel compounds are carcinogenic to humans based on sufficient evidence in the nickel refining industry and very strong evidence of carcinogenicity of a variety of nickel compounds in experimental studies in rodents. Several cohort studies of workers exposed to various nickel compounds showed an elevated risk of death from lung and nasal cancers (IARC, 1990). An excess risk of lung and nasal cancer was seen in nickel refinery workers exposed primarily to soluble nickel compounds (Anderson *et al.*, 1996).

Lead   Lead compounds do not appear to cause genetic damage directly, but may do so through several indirect mechanisms, including inhibition of DNA synthesis and repair, oxidative damage, and interaction with DNA-binding proteins and tumor-suppressor proteins (NTP, 2003). Lead has exhibited conflicting results concerning its genotoxicity; it does not cause mutations in bacteria, but does cause chromosomal aberrations in vitro and in vivo, and causes DNA damage in vivo and in cell-free systems, whereas in mammalian systems, conflicting results were observed. Lead also inhibits the activity of DNA and RNA polymerase in cell-free systems and in mammalian cell cultures. Conflicting results were observed for SCE and micronucleus formation in mammalian test systems.

In studies with laboratory animals, carcinogenicity has been observed for soluble (lead acetate and lead subacetate) and insoluble (lead phosphate, lead chromate) inorganic lead compounds as well as for tetraethyl lead (an organic lead compound), following exposure via oral, injection, and in offspring exposed via the placenta or lactation. Although kidney tumors (including adenomas, carcinomas, and adenocarcinomas) were most frequently associated with lead exposure, tumors of the brain, hematopoietic system, and lung were reported in some studies (IARC, 1980, 1987; Waalkes *et al.*, 1995). Lead also appears to function as a tumor promoter, leading to increased incidence in kidney tumors initiated by *N*-ethyl-*N*-hydroxyethylnitrosamine and *N*-(4′-fluoro-4-biphenyl)acetamide (IARC, 1980, 1987). The mechanisms by which lead causes cancer are not understood.

Lead and lead compounds are classified as reasonably anticipated to be human carcinogens based on limited evidence from studies in humans and sufficient evidence from studies in experimental animals. Lead exposure has been associated with increased risk of lung, stomach, and bladder cancer in diverse human populations (Fu and Boffetta, 1995; Steenland and Boffetta, 2000; NTP, 2003). Epidemiological studies link lead exposure to increased risk for lung and stomach cancer. However, most studies of lead exposure and cancer reviewed had limitations, including poor exposure assessment and failure to control for confounding factors.

Nongenotoxic (Epigenetic) Carcinogens

A number of chemicals that produce tumors in experimental animals following chronic treatment appear to act via mechanisms not involving direct binding, damage, or interaction of the chemical or its metabolites with DNA (Williams and Whysner, 1996). Based on the lack of genotoxicity, yet their ability to induce tumors in rodent models, these agents have been labeled nongenotoxic carcinogens. The

organ and tissue targets induced by nongenotoxic carcinogens are many times in tissues where a significant incidence of background, spontaneous tumors is seen in the animal model. Prolonged exposure to relatively high levels of chemicals is usually necessary for the production of tumors. In addition, with nongenotoxic carcinogens, tumors are not theoretically expected to occur at exposures below a threshold at which relevant cellular effects are not observed. In contrast to DNA-reactive genotoxic effects, non-DNA reactive mechanisms may be unique to the rodent species used for testing. Certain chemical carcinogens have been well studied and provide examples for the use of mechanistic information in risk assessment. Further, the biochemical modes of action for non-DNA reactive carcinogens are diverse. Examples include agents that function via sustained cytotoxicity, receptor-mediated (e.g., CAR, PPARα, AhR) effects, hormonal perturbation, as well as the induction of oxidative stress and modulation of methylation status (Table 8-10). Each of these potential mechanisms is discussed in greater detail in the following sections.

Cytotoxicity   Cytotoxicity and consequent regenerative hyperplasia is a well-documented mode of action for a variety of non-DNA reactive chemical carcinogens (Dietrich and Swenberg, 1991). Chloroform-induced liver and kidney tumors and melamine-induced bladder tumors are classic examples of chemical carcinogens that are classified as functioning via a cytolethal mode of action (Bull *et al.*, 1986; Butterworth, 1990; Larson *et al.*, 1994; Pereira, 1994; Andersen *et al.*, 1998). Chemicals that function through this mechanism produce sustained cell death, often related to metabolism of

Table 8-10

Proposed Modes of Action for Selected Nongenotoxic Chemical Carcinogens

MODE OF ACTION	EXAMPLE
Cytotoxicity	Chloroform
	Melamine
α_{2u}-*Globulin-binding*	D-limonene,
	1,4-dichlorobenzene
Receptor mediated CAR	Phenobarbital
PPARα	Trichloroethylene
	Perchloroethylene
	Diethylhexylphthalate
	Fibrates (e.g., clofibrate)
AhR	TCDD
	Polychlorinated biphenyls (PCBs)
	Polybrominated biphenyls (PBBs)
Hormonal	Biogenic amines
	Steroid and peptide hormones
	DES
	Phytoestrogens (bisphenol-A)
	Tamoxifen
	Phenobarbital
Altered methylation	Phenobarbital
	Choline deficiency
	Diethanolamine
Oxidative stress inducers	Ethanol
	TCDD
	Lindane
	Dieldrin
	Acrylonitrile

the chemical, that is accompanied by persistent regenerative growth, resulting in the potential for the acquisition of "spontaneous" DNA mutations and allowing mutated cells to accumulate and proliferate. This process then gives rise to preneoplastic focal lesions that upon further expansion can lead to tumor formation. Chloroform has been shown to induce mouse liver tumors only at doses that produce liver necrosis, thus demonstrating an association between necrosis with compensatory hyperplasia and the resulting tumorigenicity, and also supports that a threshold for the induction of tumors is likely at doses that do not produce toxicity. It is important to note that the induction of cytotoxicity may be observed with many carcinogens both genotoxic and nongenotoxic when high toxic exposures occur. Thus, the induction of cytotoxicity with compensatory hyperplasia may contribute to the observed tumorigenicity of many carcinogenic chemicals at high doses.

α_{2u}-Globulin-Binding Chemicals   The carcinogens D-limonene, 1,4-dichlorobenzene, and trimethylpentane (Fig. 8-15) induce renal tumors selectively in the male rat, and provide excellent examples of species, sex, and tissue specificity of non-DNA reactive carcinogens. The mechanism for the species and sex specificity is related to the ability of these compounds to bind to α_{2u}-globulin, a protein synthesized by the male rat liver at the onset of puberty, as the mechanism of tumorigenesis. α_{2u}-Globulin is filtered through the glomerulus, and only partially excreted (∼50%) in the urine. The reabsorbed fraction accumulates in the lysosomes of the P2 segment of the proximal tubules, where it is hydrolyzed to amino acids (Melnick *et al.*, 1996). Chemicals with the ability to bind to α_{2u}-globulin prevent the digestion of α_{2u}-globulin and result in the accumulation in lysosomes, dysfunction of this organelle, and subsequent release of digestive enzymes and cell necrosis. The greater loss of tubule cells leads to increased cell proliferation in the P2 segment, which may be responsible for the tumor development and malignant transformation (Dietrich and Swenberg, 1991).

Receptor Mediated
P450 Inducers: Phenobarbital-like Carcinogens   Phenobarbital is a commonly studied non-DNA reactive compound that is known to cause tumors by a nongenotoxic mechanism involving liver hyperplasia (Williams and Whysner, 1996). One feature seen following phenobarbital exposure is the induction of P450 enzymes, particularly CYP2B (Nims and Lubet, 1996). Because a number of diverse chemicals are known to induce various members of the P450 system (e.g., dieldrin, ethanol, TCDD), the specificity of this effect to carcinogenesis has been questioned. Recent evidence has shown that the induction of CYP2B is mediated by activation of the constitutive androstane receptor (CAR), a member of the nuclear receptor family (Honkakoski *et al.*, 1998; Ueda *et al.*, 2002; Kodama *et al.*, 2004). CAR-null mice show no induction of CYP2B following phenobarbital exposure (Wei *et al.*, 2000). Other phenobarbital responses that are critical for tumor formation include increased cell proliferation, inhibition of apoptosis, inhibition of gap junctional communication, hypertrophy, and development of preneoplastic focal lesions in the liver (Whysner *et al.*, 1996), effects that have all been shown to be CAR-dependent (Wei *et al.*, 2000; Kodama *et al.*, 2004) (Fig. 8-16).

Peroxisome Proliferator Activated Receptor α (PPARα)   A wide array of chemicals are capable of increasing the number and volume of peroxisomes in the cytoplasm of cells. These chemicals, termed peroxisome proliferators, include chemicals such as herbicides, chlorinated solvents (e.g., trichloroethylene and perchloroethylene), plasticizers (e.g., diethylhexylphthalate and other phthalates), lipid lowering fibrate drugs (e.g., ciprofibrate, clofibrate), and natural products. In addition, many of these chemicals produce liver enlargement and hepatocellular carcinoma in rats and mice through non-DNA reactive mechanisms (Lake, 1995; Reddy and Rao, 1997). Two additional tumor types are also associated with exposure to peroxisome proliferating compounds: Leydig cell tumors and pancreatic acinar-cell tumors in the rat. Studies conducted either in vivo or in vitro in primary hepatocyte cultures have shown important interspecies differences in the hepatic peroxisome proliferation responses to chemicals within the class of compounds. The rat and mouse were clearly responsive species, whereas primates and the guinea pig proved to be nonresponders. The Syrian hamster exhibits an intermediate response (Bentley *et al.*, 1993; Lake, 1995). Due to the wide structural diversity of this chemical class, the mechanism(s) involved in peroxisome proliferation and tumorigenesis went unrecognized for years. The currently accepted mode of action for this class of chemicals involves agonist binding to the nuclear hormone receptor, peroxisome proliferator-activated receptor alpha (PPARα). Largely through the use of PPARα knockout mice, the activation of PPARα by agonists is needed for these chemicals to induce peroxisome proliferation and tumorigenesis in rodents (Issemann and Green, 1990; Lee *et al.*, 1995; Peters *et al.*, 1998, reviewed in Klaunig *et al.*, 2003). PPARα is highly expressed in cells that have active fatty acid oxidation capacity (e.g., hepatocytes, cardiomyocytes, enterocytes).

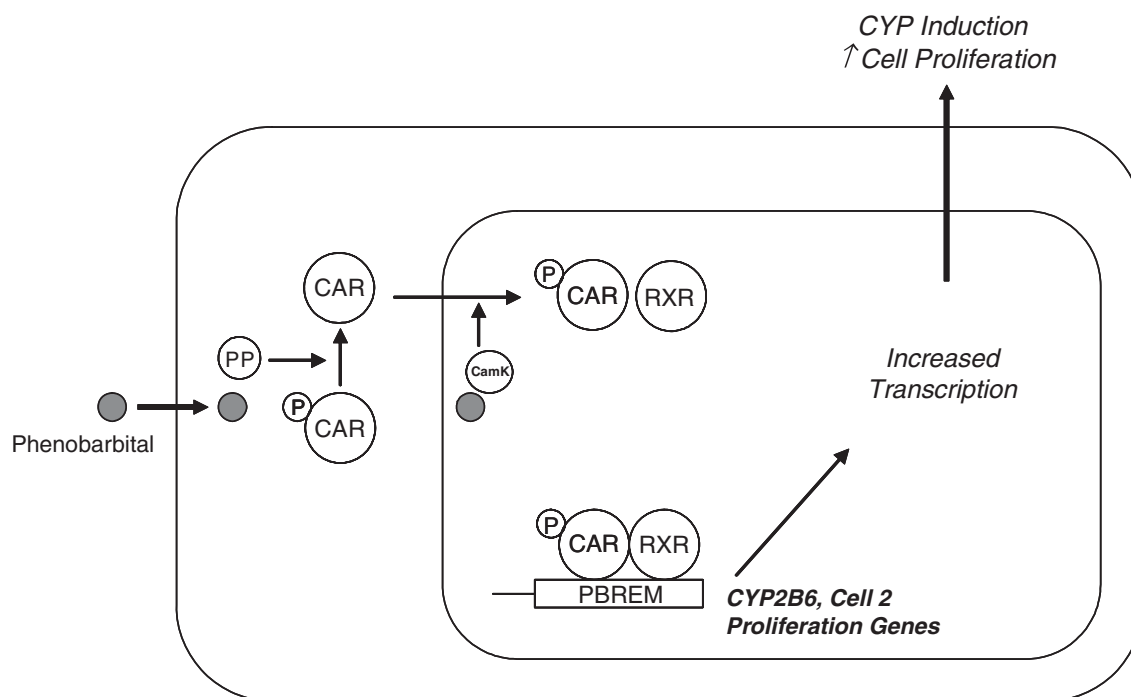
It is well documented that PPARα plays a central role in lipid metabolism and acts as a transcription factor to modulate gene expression following ligand activation. This latter effect arises through the heterodimerization of PPAR and RXRα, which results in binding


Figure 8-16. Proposed mechanism for the involvement of the constitutive androstane receptor (CAR) in phenobarbital-induced gene expression changes.

PP, protein phosphatase; CamK, CaM Kinase; RXR, retinoic acid receptor; PBREM, phenobarbital response element. Following dephosphorylation of CAR by protein phosphatase, CAR crosses the cell membrane and becomes phosphorylated by CaM kinase. CAR then forms a dimer with RXR and binds to PBREMs, resulting in increased gene expression.
Figure 8-17. Mechanism for altered gene expression by peroxisome proliferator activated receptor α (PPARα) agonist binding.

Following agonist binding to PPARα, the receptor dimerizes with the retinoic acid receptor (RXR). This complex then binds to PPREs, resulting in enhanced gene transcription.

to response elements (PPREs) and subsequent modulation of target gene transcription (Fig. 8-17). Following this event is the induction of cell proliferation and suppression of apoptosis (Marsman *et al.*, 1988; James and Roberts, 1996; Burkhardt *et al.*, 2001). Both these events would then be expected to affect tumor development as these effects would enhance the rate of fixation of DNA damage in the genome, leading to changes in gene expression such as the silencing of tumor suppressor genes or increased expression of oncogenes,

or suppress apoptosis that may normally remove DNA-damaged, potentially tumorigenic, cells.

Because humans are exposed to a number of chemicals that are PPARα ligands, the relevance of this mode of action to humans has been evaluated (Klaunig *et al.*, 2003). Although the same events would be expected to occur in exposed humans, several species differences have been noted, including a lack of induction of cell proliferation in nonhuman primates (Pugh *et al.*, 2000), and the finding that the amount of PPARα in human liver is at least ten-fold lower compared with the rat or mouse (Palmer *et al.*, 1998; Tugwood *et al.*, 1998). Based on these kinetic and dynamic differences between species, it has been concluded that tumors are not likely to occur in humans (Klaunig *et al.*, 2003).

Aryl Hydrocarbon Receptor (AhR)   Agonists of the AhR including TCDD and selective members of the polychlorinated- and brominated-biphenyl (PCBs and PBBs) class of compounds (Fig. 8-18) have been linked to tumor development, and appear to function as hepatic tumor promoters (Pitot *et al.*, 1982; IARC, 1997). The tumor response has been determined to be AhR dependent (Knutson and Poland, 1982) (Fig. 8-19). Upon ligand binding to the AhR, the ligand-bound AhR translocates to the nucleus, dimerizes with the Ah receptor nuclear translocator (ARNT), and binds to aryl hydrocarbon response elements [AREs also known as dioxin response elements (DRE) and xenobiotic response elements (XRE)] (for review see Nebert *et al.*, 2000). AhR-ARNT-dependent genes include cytochrome P450 family members, NAD(P)H:quinine oxidoreductase, a cytosolic aldehyde dehydrogenase 3, a UDP-glucuronosyltransferase, and a glutathione transferase (Nebert *et al.*, 2000), genes that are involved in metabolic

activation as well as detoxification of chemicals. It has been hypothesized that there are additional AhR-ARNT-dependent genes (Nebert *et al.*, 2000). AhR knockout mice showed a diminished response to tumor induction by AhR ligands (Nakatsuru *et al.*, 2004), conversely, constitutively overexpressed AhR resulted in an increased incidence of liver tumors (Moennikes *et al.*, 2004). As seen with

other promoting chemicals, TCDD does inhibit apoptosis in hepatic foci (Stinchcombe *et al.*, 1995).

Hormonal Mode of Action   Hormonally active chemicals include biogenic amines, steroids, and peptide hormones that cause tissue-specific changes through interaction with a receptor. In addition, a number of non-DNA reactive chemicals can induce neoplasms in rodents through receptor-mediated mechanisms, and/or perturbation of hormonal balance. Trophic hormones are known to induce cell proliferation at their target organs. This action may lead to the development of tumors when the mechanisms of hormonal control are disrupted and some or other hormone shows persistently increased levels. Several well-studied examples include the induction of ovarian neoplasms via decreased estradiol and increased LH levels (Capen *et al.*, 1995) and the induction of thyroid tumors in rats by phenobarbital-type P450 inducers (McClain, 1995; Williams, 1995).

Estrogenic agents can induce tumors in estrogen-dependent tissue. Selective estrogenic chemicals (agonists and antagonists) are shown in Fig. 8-20. Oral administration of 17β-estradiol to female mice increases the incidence of mammary tumors (Highman *et al.*, 1977; Welsch *et al.*, 1977), whereas subcutaneous administration of estradiol to young female mice produced tumors of the cervix and vagina (Pan and Gardner, 1948). Evidence that estrogenic chemicals are carcinogenic to humans comes from epidemiological data on breast and ovarian cancer, which indicates that individuals with higher circulating estrogen levels and those with exposure to the potent estrogenic agent diethylstilbesterol (DES) are at increased risk of cancer development. DES was first shown to induce mammary tumors in male mice following subcutaneous administration of the hormone. DES has been causally associated to the higher incidence of adenocarcinomas of the vagina and cervix in daughters of women treated with the hormone during pregnancy (Herbst and Scully, 1970; Herbst *et al.*, 1972; Noller *et al.*, 1972). The mechanism of action for DES is believed to function through its ability to induce

ARNT, AhR nuclear transporter; XRE, xenobiotic response element. Non-ligand bound AhR is maintained in the cytoplasm via association with chaperone proteins (e.g., AIP, Hsp90). Following ligand binding, chaperone proteins dissociate and AhR translocates to the nucleus where it binds with ARNT. The heterodimer binds to XREs resulting in an increase in gene transcription.

aneuploidy (Li *et al*., 1997; Tsutsui *et al*., 1997). The effects of steroidal chemicals on the cell cycle (Sutherland *et al*., 1995) and on microtubule assembly (Metzler *et al*., 1996) may be important in the aneuploidy inducing effects of some hormonal agents (Li *et al*., 1996).

Chronic exogenous administration of hormonally active chemicals, including synthetic estrogens and anabolic steroids, can increase hepatic adenoma incidence in rats (Li *et al*., 1992) and in humans (IARC, 1997). Women of child-bearing age are sensitive to hepatic adenoma formation, which can be exacerbated by oral contraceptive use. These adenomas will regress upon hormone cessation (Edmondson *et al*., 1977) and can progress with continued administration (Christopherson *et al*., 1978). Chronic administration (>8 years) is required to detect this increased liver tumor risk from oral contraceptives (Tavani *et al*., 1993).

Many substances in plants (phytoestrogens) have been described. These include compounds such as genestein, daidzein, glycetein, equol, and their metabolites found in soy products and various lignan derivatives (Adlercreutz and Mazur, 1997). In addition, a number of environmental nonsteroidal synthetic compounds have been identified that demonstrate apparent estrogenic activity (e.g., nonyl-phenol, bisphenol-A, chlorinated hydrocarbons) (Soto *et al*., 1997). The potential for these chemicals to induce cancer in humans is an area of current investigation.

Species and tissue specificity in response to receptor and hormone-mediated carcinogenesis is often observed. As an example, tamoxifen is antiestrogenic in the chick oviduct, estrogenic in the mouse uterus with acute administration, but antiestrogenic with chronic administration in the same tissue, while it is estrogenic in the rat uterus. Whereas this may be in part due to tissue and species differences in coactivator and corepressor levels and availability,

many other pharmacokinetic and pharmacodynamic properties are likely to participate (Carthew *et al*., 1995). To further exemplify the complexity of the role of estrogen in cancer development, estrogens have also been shown to be protective in prostate cancer.

Induction of ovarian tumors by dietary administration of nitrofurantoin in mice is an example of a tumorigenic effect secondary to drug-induced hormonal disturbance. Nitrofurantoin treatment resulted in ovarian atrophy with absence of graafian follicles and sterility. The reduction of follicles induced a reduction of sex steroids by the ovary, resulting in increased production of gonadotrophins, notably LH, presumably due to the decreased negative feedback on the hypothalamus–pituitary axis by estrogens. Persistent stimulation by LH of the ovary cells resulted in development of tumors (Capen *et al*., 1995). A similar effect is known to occur with dopamine agonists. The induction of hypoprolactinemia changes the number of LH receptors and leads to enhanced sensitivity to LH and a higher stimulation by LH, similar to nitrofurantoin.

A number of chemicals that reduce thyroid hormone concentrations (T4 and/or T3) and increase thyroid-stimulating hormone (TSH) have been shown to induce neoplasia in the rodent thyroid. TSH demonstrates proliferative activity in the thyroid, with chronic drug-induced TSH increases leading to progression of follicular cell hypertrophy, hyperplasia, and eventually neoplasia. Inducers of metabolic enzymes in the liver, a classic and well-studied example being phenobarbital (Hood *et al*., 1999), result in increased thyroid hormone metabolism and as such lead to increases in TSH levels (Fig. 8-21). It is this latter event that is associated with the development of thyroid tumors in rodents. Recent evidence suggests that the enhancement of metabolism and excretion of thyroid hormones by xenobiotics (via induction of Phase II enzymes) is a consequence of CAR (and presumably PXR) activation. Qualitatively, thyroid gland
Figure 8-21. Mechanism for phenobarbital-induced thyroid tumors.

Through alteration of gene expression, phenobarbital enhances metabolism of thyroid hormone (T3) resulting in enhanced TSH production. Increased TSH then leads to increased cell proliferation in the thyroid.

function in rodents is much more susceptible to disturbances of the thyroid hormone levels than it is in humans. In contrast to humans, rodents lack the thyroid-binding globulin, which is the predominant plasma protein responsible for thyroxin binding and transport in humans (McClain, 1995). A relatively higher level of functional activity is present in rat thyroid compared to humans.

DNA Methylation and Carcinogenesis   Post-DNA synthetic methylation of the 5-position on cytosine (5-methylcytosine, 5mC) is a naturally occurring modification to DNA in higher eukaryotes that influences gene expression (Holliday, 1990) (Fig. 8-22). Under normal conditions, DNA is methylated symmetrically on both strands. Immediately following DNA replication, the newly synthesized double-stranded DNA contains hemimethylated sites that signal for DNA maintenance methylases to transfer methyl groups from *S*-adenosylmethionine to cytosine residues on the new DNA strand (Hergersberg, 1991). The degree of methylation within a gene inversely correlates with the expression of that gene; hypermethylation of genes is associated with gene silencing, whereas hypermethylation results in an enhanced expression of genes. Several chemical carcinogens are known to modify DNA methylation, methyltransferase activity, and chromosomal structure. During carcinogenesis, both hypomethylation and hypermethylation of the genome have been observed (Counts and Goodman, 1995; Baylin, 1997). Increased methylation of CpG islands have been observed in bladder cancer and tumor suppressor genes such as the retinoblastoma gene, $p16^{ink4a}$, and $p14^{ARF}$ have been reported to be hypermethylated in tumors (Stirzaker *et al*., 1997; Belinsky *et al*., 1998; Myöhänen *et al*., 1998; Salem *et al*., 2000; Esteller *et al*., 2001). Hypomethylation has been associated with increased mutation rates. Most metastatic neoplasms in humans have significantly lower 5MeC than normal tissue (Gama-Sosa *et al*., 1983); furthermore, many oncogenes are hypomethylated and their expression amplified.

Choline and methionine, which can be derived from dietary sources, provide a source of methyl groups used in methylation reactions. Rats exposed to choline and/or methionine-deficient
Figure 8-22. Substrates and products involved in DNA methylation.

Methylation of DNA occurs through an enzymatic reaction catalyzed by DNA methyltransferases (DNMTs). DNA is methylated at the 5-position of cytosine and requires the cofactor *S*-adenosyl methionine.

diets resulted in hepatocellular proliferation and neoplasia (Abanobi *et al.*, 1982; Wainfan and Poirier, 1992) (Table 8-11). In rodents fed choline or methyl donor groups deficient diets, the hepatic neoplasia is thought to arise from hypomethylation of *c-myc*, *c-fos*, and *c-H-ras* proto-oncogenes, due to the decreased availability of *S*-adenosyl-methionine (Newberne *et al.*, 1982; Wainfan and Poirier, 1992). Chemicals such as diethanolamine result in hepatic neoplasia, in part via mechanisms involving choline depletion, altered methylation, and modulation of gene expression (Kamendulis and Klaunig, 2005; Carnell *et al.*, 2006). Reactive oxygen species have also been shown to modify DNA methylation, resulting in changes in DNA methylation profiles through interfering with the ability of methyltransferases to interact with DNA leading to hypomethylation of CpG sites (Weitzman *et al.*, 1994; Turk *et al.*, 1995). Also, the presence of 8-OHdG in DNA can lead to hypomethylation of DNA, because this adduct if present in CpCpGpGp sequences will inhibit the methylation of adjacent C residues. Thus, oxidative DNA damage may be an important contributor to the carcinogenesis process brought about by the loss of DNA methylation, allowing the expression of normally quiescent genes. Also, the abnormal methylation pattern observed in cells transformed by chemical oxidants may contribute to an overall aberrant gene expression and promote the tumor process.

Oxidative Stress and Chemical Carcinogenesis   Experimental evidence has shown that increases in reactive oxygen in the cell, through either physiological modification or through chemical carcinogen exposure, contribute to the carcinogenesis processes (Vuillaume, 1987; Trush and Kensler, 1991; Witz, 1991; Guyton and Kensler, 1993). Reactive oxygen species encompass a series of reactive compounds including the superoxide anion ($^\bullet O_2$-), hydroperoxyl radical ($HO_2^\bullet$.), hydrogen peroxide (H_2O_2), and the hydroxyl radical ($^\bullet OH$), all derived through the reduction of molecular oxygen (Table 8-12). Oxygen radicals can be produced by both endogenous and exogenous sources and are typically counterbalanced by antioxidants (Table 8-13). Antioxidant defenses are both enzymatic (e.g., superoxide dismutase, glutathione peroxidase, and catalase) and nonenzymatic (e.g., vitamin E, vitamin C, β-carotene, glutathione (Betteridge, 2000; Abuja and Albertini, 2001). Importantly, many of these antioxidants are provided through dietary intake (Clarkson and Thompson, 2000).

Endogenous sources of reactive oxygen species include oxidative phosphorylation, P450 metabolism, peroxisomes, and inflammatory cell activation (Table 8-13). Within the mitochondria, a small percentage of oxygen is converted into the superoxide anion via one-electron reduction of molecular oxygen. Superoxide can be dismutated by superoxide dismutase to yield hydrogen peroxide (Barber

Table 8-12
Pathways for Intercellular Oxidant Generation

$$HO_2^\bullet + e^- + H \rightarrow H_2O_2 \text{ (hydrogen peroxide)}$$
$$H_2O_2 + e^- \rightarrow OH^- + {}^\bullet OH \text{ (hydroxyl radical)}$$
A series of oxygen radicals are produced by the reduction of molecular oxygen. Of the radicals produced, the hydroxyl radical, hydroperoxyl radical, and the superoxide anion are sufficiently reactive and may interact with biomolecules.

and Harris, 1994). In the presence of partially reduced metal ions, hydrogen peroxide is converted to the highly reactive hydroxyl radical through Fenton and Haber-Weiss reactions (Betteridge, 2000). Neutrophils, eosinophils, and macrophages represent another intracellular source of reactive oxygen species. Activated macrophages, through "respiratory burst" elicit a rapid increase in oxygen uptake that gives rise to a variety of reactive oxygen species including superoxide anion, hydrogen peroxide, and nitric oxide. The release of cytokines and reactive oxygen intermediates from activated Kupffer cells (the resident macrophage of the liver) has been implicated in hepatotoxicological and hepatocarcinogenic events (Rose *et al.*, 1999; Rusyn *et al.*, 1999); in particular, recent studies show that Kupffer cells may function at the promotion stage of carcinogenesis. Reactive oxygen species can also be produced by cytochrome P450-mediated mechanisms including: (1) redox cycling in the presence of molecular oxygen, (2) peroxidase-catalyzed single-electron drug oxidations, and (3) "futile cycling" of cytochromes P450 (Parke, 1994; Parke and Sapota, 1996). Ethanol, phenobarbital, and a number of chlorinated and nonchlorinated compounds such as dieldrin, TCDD, and lindane are among the xenobiotics shown to increase in reactive oxygen species through P450-mediated mechanisms (Eksrom and Ingleman-Sundberg, 1989; Rice *et al.*, 1994; Klaunig *et al.*, 1997). Chemicals classified as peroxisome proliferators activated receptor α (PPARα) agonists (e.g., clofibrate, phthalate esters) represent chemicals that induce cytochrome P4504A, and increase the formation of peroxisomes. As such, an increase in H_2O_2 production often accompanies exposure to chemicals that stimulate the number and activity of peroxisomes (Rao and Reddy, 1991; Wade *et al.*, 1992). Through these or other currently unknown mechanisms, a number of chemicals that induce cancer (e.g., chlorinated compounds, radiation, metal ions, barbiturates, and some PPARα agonists) induce reactive oxygen species formation and/or oxidative stress (Rice-Evans and Burdon, 1993; Klaunig *et al.*, 1997; Kamendulis and Klaunig, 2005).

Oxidants > Antioxidants	Oxidative Damage (DNA, RNA, Lipid, Protein)

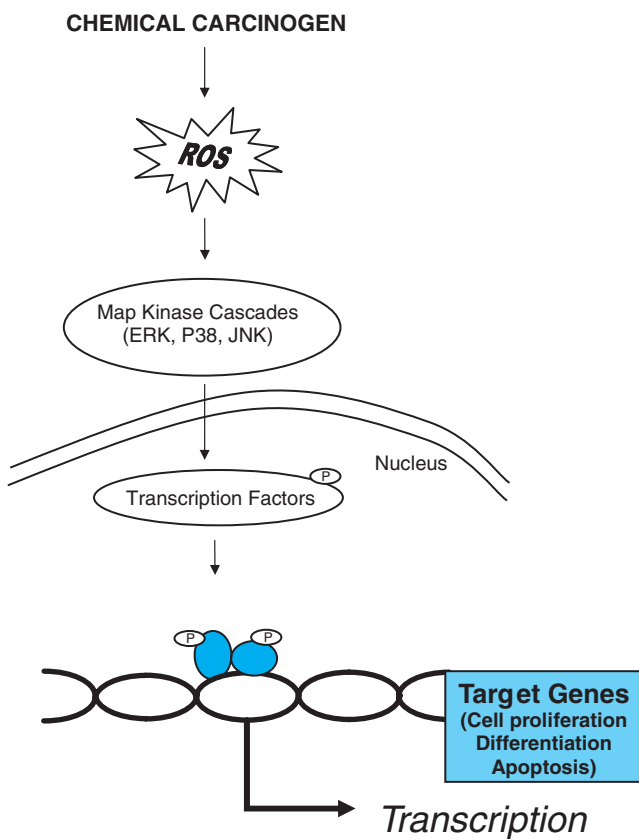
Oxidants can be produced via both endogenous and exogenous sources. Antioxidants function to maintain the cellular redox balancing. However, excess production of oxidants and or inadequate supplies of antioxidants result in damage to cellular biomolecules and may impact on neoplastic development.


Figure 8-23. Role of reactive oxygen species (ROS) on altered gene expression.

Many chemical carcinogens increase ROS and activate signaling cascades, such as the mitogen activated (MAP) kinase family. These serene/threonine kinases activate transcription factors, leading to DNA binding and gene expression changes.

Oxidative Damage and Carcinogenesis   Reactive oxygen species left unbalanced by antioxidants can result in damage to cellular macromolecules. In DNA, reactive oxygen species can produce single- or double-stranded DNA breaks, purine, pyrimidine, or deoxyribose modifications, and DNA crosslinks (von Sonntag, 1987; Dizdaroglu, 1992; Demple and Harrison, 1994). Persistent DNA damage can result in either arrest or induction of transcription, induction of signal transduction pathways, replication errors, and genomic instability, events that are potentially involved in carcinogenesis. Oxidation of guanine at the C8 position results in the formation of 8-hydroxydeoxyguanosine (8-OHdG; see Fig. 8-7). This oxidative DNA adduct is mutagenic in bacterial and mammalian cells, produces dose-related increases in cellular transformation, and causes $G \rightarrow T$ transversions which are commonly observed in mutated oncogenes and tumor suppressor genes (Shibutani *et al.*, 1991; Moriya, 1993; Hussain and Haris, 1998; Zhang *et al.*, 2000). During DNA replication, 8-OHdG in the nucleotide pool can incorporate into the DNA template strand opposite dC or dA resulting in A:T to C:G transversions (Cheng *et al.*, 1992; Demple and Harrison, 1994). Oxidative damage to mitochondrial DNA and mutations in mitochondrial DNA have been identified in a number of cancers (Schumacher *et al.*, 1973; Horton *et al.*, 1996; Cavalli and Liang, 1998; Tamura *et al.*, 1999). Compared to nuclear DNA, mitochondrial genome is relatively susceptible to oxidative base damage due to (1) close proximity to the electron transport system, a major source of reactive oxygen species (Barber and Harris, 1994); (2) mitochondrial DNA is not protected by histones; and (3) DNA repair capacity is limited in the mitochondria (Bohr and Dianov, 1999; Sawyer and Van Houten, 1999). Although many pathways exist that enable the formation of oxidative DNA damage, mammalian cells also possess specific repair pathways for the remediation of oxidative DNA damage (Tchou and Grollman, 1993; Fortini *et al.*, 1999).

Apart from oxidized nucleic acids, oxygen radicals can damage cellular biomembranes resulting in lipid peroxidation. Peroxidation of biomembranes generates a variety of products, including reactive electrophiles, such as epoxides and aldehydes, including

CHEMICAL CARCINOGENS
Figure 8-24. *Interaction between reactive oxygen species (ROS) and NFkB-induced gene expression.*

A number of chemicals that increase ROS have been shown to activate NF*k*B. It is proposed that ROS enhance the dissociation of IkB from the NF*k*B/IkB complex leading to active NF*k*B. NF*k*B can then translocate into the nucleus where it binds DNA and increases gene transcription.

malondialdehyde (MDA) (Janero, 1990). MDA is a highly reactive aldehyde and exhibits reactivity toward nucleophiles and can form MDA–MDA dimers. Both MDA and the MDA–MDA dimers are mutagenic in bacterial assays and the mouse lymphoma assay (Riggins and Marnett, 2001).

Oxidative Stress and Cell Growth Regulation Reactive oxygen species production and oxidative stress can affect both cell proliferation and apoptosis (Cerutti, 1985; Burdon, 1995; Slater *et al.*, 1995). H_2O_2 and superoxide anion can induce cell proliferation in several mammalian cell types (D'Souza *et al.*, 1993). Conversely, high concentrations of reactive oxygen species can initiate apoptosis (Dypbukt *et al.*, 1994). It has clearly been demonstrated that low levels of reactive oxygen species influence signal transduction pathways and alter gene expression (Fiorani *et al.*, 1995). Many xenobiotics, by increasing cellular levels of oxidants, alter gene expression through activation of signaling pathways including cAMP-mediated cascades, calcium-calmodulin pathways, and transcription factors such as AP-1 and NF-kB as well as signaling through mitogen-activated protein (MAP) kinases, extracellular signal-regulated kinases (ERK), c-Jun N-terminal kinases (JNK), and the p38 kinases (Kerr, 1992; Muller *et al.*, 1997; Timblin *et al.*, 1997). Activation of these signaling cascades by reactive oxygen species induced by chemical carcinogens ultimately leads to altered gene expression for a number of genes including those affecting proliferation, dif-

ferentiation, and apoptosis (Hollander and Fornace, 1989; Amstad *et al.*, 1992; Pinkus, 1993; Zawaski, 1993; Brown *et al.*, 1998; Chang and Karin, 2001; Martindale and Holbrook, 2002) (Fig. 8-23). Activation of NFkB, a ubiquitously expressed transcription factor, is regulated, in part, by reactive oxygen species and the cellular redox status, and has been observed to occur following a wide variety of extracellular stimuli, including exposure to chemical carcinogens such as PPARα agonists (Rusyn *et al.*, 2003) and PCBs (Beauerle *et al.*, 1988; Li and Karin, 1998; Schulze-Oshoff *et al.*, 1998; Pahl, 1999; Nebreda and Porrai, 2000; Molina *et al.*, 2001; Glauert *et al.*, 2002) (Fig. 8-24).

Gap Junctional Intercellular Communication and Carcinogenesis

Cells within an organism communicate in a variety of ways including through gap junctions, which are aggregates of connexin proteins that form a conduit between two adjacent cells (Lowenstein *et al.*, 1981) (Fig. 8-25). Gap junctional intercellular communication appears to play an important role in the regulation of cell growth and cell death, in part through the ability to exchange small molecules (<1 kDa) between cells through gap junctions. Loss of gap junctions or decreased cell-to-cell communication is seen during liver regeneration following partial hepatectomy, a situation in which gap junction expression remains decreased until liver mass and
Figure 8-25. *Schematic diagram of a gap junction.*

Gap junctions consist of connexin hexamers that form a pore between neighboring cells through which molecules <1 kDa can pass.

lobular conformation are restored. Aberrant growth control is an essential feature of cancer cells, and since the absence or reduction in cell-to-cell communication has been observed between cancer cells, between cancer and normal cells, and in transformed cells, it has been speculated that altered gap junctional cell communication is involved in carcinogenesis (Trosko and Chang, 1984). If cell communication is blocked between tumor and normal cells, the exchange of growth inhibitory signals from normal cells would be prevented from acting on initiated cells, thus allowing the potential for unregulated growth and clonal expansion of initiated cell populations. This would therefore allow for the acquisition of additional genetic changes that may lead to neoplastic transformation (Klaunig and Ruch, 1989).

Intercellular communication is also decreased by growth factor administration and following exposure to a variety of tumor-promoting compounds (e.g., phenobarbital, phthalates, dieldrin, phorbol esters). Tumor-promoting chemicals inhibit gap junctional intercellular communication in a number of cell types following exposure both in vivo and in vitro (Klaunig and Ruch, 1989). The ability of a tumor-promoting compound to block cell-to-cell communication in cultured cells correlates with its ability to induce rodent tumors (Klaunig and Ruch, 1987). In addition, the inhibition of gap junctional intercellular communication by tumor promotors appears to be tissue and species specific; they produce inhibition in target

organs and sensitive species, while they do not inhibit cell-to-cell communication in nontarget tissues for carcinogenicity (Klaunig and Ruch, 1987). The mechanisms by which tumor promoters inhibit intercellular communication are not clear but may be due to decreased synthesis and/or enhanced degradation of gap junction proteins in the cell, reducing the number of channels in cell membranes, or other changes that modulate gap junction function and/or protein expression (Sugie *et al.*, 1987; Klaunig and Ruch, 1989).

Modifiers of Chemical Carcinogenic Effects

Genetic and environmental factors have a significant impact on the way in which individuals and/or organisms respond to carcinogen exposure. As with most genes, enzymes that metabolize carcinogens are expressed in a tissue-specific manner. Within tissues, the enzymatic profile can vary with cell type or display differential localization within cells. Further, carcinogen-metabolizing enzymes are differentially expressed among species. These differences may represent an underlying factor explaining the differential responses to chemical carcinogens across species.

The expression of many carcinogen-metabolizing enzymes is highly inducible by foreign chemicals. For example, compounds such as benzo(*a*)pyrene highly induce P450 isozymes CYP1A1 and 1A2, enzymes which display catalytic activity toward a number of polycyclic aromatics. A number of other enzymes, e.g., GST isozymes, UDPGTs are also induced by PAHs, thus the net result is enhanced metabolism of PAHs. Numerous other chemical carcinogens are potent inducers of drug-metabolizing enzymes; examples include chemicals such as phenobarbital, DDT, ethanol, 17β-estradiol, PPARα agonists, each of which results in the upregulation of a distinct set of phase I and phase II enzymes. Many chemicals produce inhibitory effects on drug metabolism enzymes, and could either increase the half-life of a chemical carcinogen or prevent or delay the formation of active metabolites of carcinogens.

Polymorphisms in Carcinogen Metabolism and DNA Repair

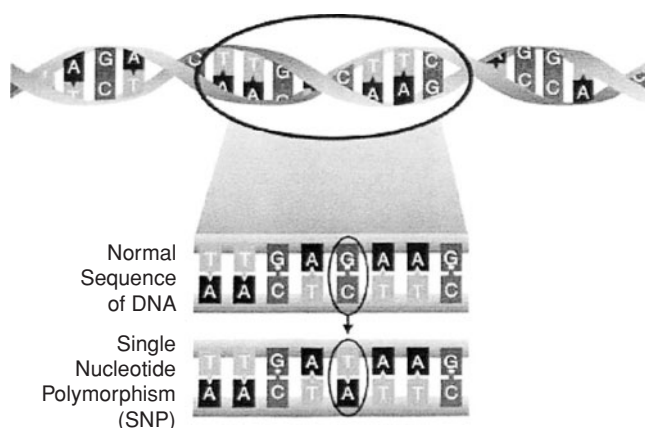
Genetic polymorphisms arise from human genetic variability. A genetic polymorphism is when a gene has more than one allele. In assessing variability in the human genome project, it was found that base variations occurred at approximately once in every 1000 base pairs. Therefore, more than 1 million genetic variations may be seen between any two individuals. A single nucleotide polymorphism (SNP) is a variant in DNA sequence found in greater than 1% of the population (Fig. 8-26). Thus, the definition of shift changes in DNA sequence goes from mutation to polymorphism when a unique genotype is seen in over 1% of the population. Over 3 million candidate SNPs have been identified to date with up to 10 million being estimated to be present within the human genome. In carcinogenesis, genetic polymorphisms may account for the susceptibility of some individuals to certain cancers. In particular, SNPs of genes involved in carcinogen metabolism (activation and detoxification) and DNA repair have, to date, received considerable attention. A number of polymorphisms have been described in carcinogen-metabolizing enzymes, with certain alleles linked to altered risk of selective cancers (Boddy and Ratain, 1997). Glutathione-*S*-transferases (GSTs), which are involved in detoxification of many chemical carcinogens and also in the remediation of oxidative stress, are highly polymorphic in humans. Polymorphisms of the GSTM1 phenotype have been related to bladder, gastric, and lung cancer in humans (Welfare


Figure 8-26. *Example of a single nucleotide polymorphism in DNA.*

Single nucleotide polymorphisms are instances in which a single nucleotide is changed within a DNA sequence.

Table 8-14

Carcinogen Exposure and Cancer Risk in Humans

EXPOSURE	SUSCEPTIBILITY (GENOTYPE)	RESULT (DISEASE)
↓	↓	Low risk
↑	↓	Low risk
↓	↑	Mod risk
↑	↑	High risk

et al., 1999; Tsuchida and Sato, 1992). Individuals expressing the GSTM1 null genotype have a 1.5-fold higher risk for bladder cancer and 1.7-fold increased risk for gastric cancer, compared to individuals expressing the common genotype (Risch *et al.*, 2001; Ates *et al.*, 2005). The GSTM1 isoform is of particular importance in carcinogenesis, because this isoform exhibits the highest reactivity toward epoxides. GSTT1 null isoform individuals show a 3-fold increased risk in breast cancer, a 1.6-fold increased risk in gastric cancer, and a 4-fold increased risk in liver cancer compared to individuals having the common genotype (Bosch *et al.*, 2006).

Similarly in women (nonsmokers) with lung cancer, a higher level of PAH DNA adducts have been detected. Higher DNA adduct levels are also found to be associated with the expression of the

cytochrome $P4501A1$ (CYP1A1) gene (Han *et al.*, 2003). This enzyme causes bioactivation of the carcinogen benzopyrene, and increased DNA adduct levels correlate with increased expression of CYP1A1. SNPs of DNA repair genes, in particular oxidative DNA repair, OGG1, involved in the repair of 8-OHdG-induced damage, have been linked to increase in lung cancer in individuals with lower OGG1 expression (Goode *et al.*, 2002).

In the case of prostate cancer, studies have suggested roles for a number of candidate SNPs. Recent evidence suggests that the presence of a genetic variant which is more prevalent in African-American men is less effective of clearing reactive oxygen species. Examples of candidate genes which likely contribute to prostate cancer carcinogenesis include the androgen receptor gene, steroid synthesis, and metabolism genes (*CYP17, CYP1B1, CYP3A4, CYP3A5, CYP3A43, SD5A2, HSD3B1, HSD3B2, CYP19*), transmembrane drug efflux genes (*ABCG2*), and reactive oxygen species metabolizing genes (*MnSOD, APE1, XRCC1, GSTP1*) (Dong, 2005). Individually, polymorphisms in each of these genes have been associated with an increased risk of prostate cancer.

The importance of SNPs, cancer susceptibility, and cancer risk are illustrated in Table 8-14. If exposure to a chemical carcinogen is low and the genetic susceptibility for genes related to the carcinogenic activity is low, then the risk for cancer will also be low. If exposure to a chemical carcinogen is high but the genetic susceptibility is low, then the risk for cancer development is likely to be low. However, if the genetic susceptibility is high, then exposure to a chemical carcinogen will result in a higher risk for cancer development.

Proto-Oncogenes and Tumor-Suppressor Genes

Proto-oncogenes and tumor-suppressor genes play a key role in cancer induction. These genes encode a wide array of proteins that function to control cell growth and proliferation. Common characteristics of oncogenes and tumor suppressor genes are shown in Table 8-15. Mutations in both oncogenes and tumor suppressor genes contribute to the progressive development of human cancers. Accumulated damage to multiple oncogenes and/or tumor suppressor genes can result in altered cell proliferation, differentiation, and/or survival of cancer cells.

Retroviruses Evidence that specific genes (oncogenes) could cause cancer, first came from studies showing sarcomas could be produced in healthy chickens by injecting them with cell-free

Table 8-15

Characteristics of Proto-Oncogenes, Cellular Oncogenes, and Tumor Suppressor Genes

PROTO-ONCOGENES	ONCOGENES	TUMOR SUPPRESSOR GENES
Dominant	Dominant	Recessive
Broad tissue specificity for cancer development	Broad tissue specificity for cancer development	Considerable tissue specificity for cancer development
Germ line inheritance rarely involved in cancer development	Germ line inheritance rarely involved in cancer development	Germ line inheritance frequently involved in cancer development
Analogous to certain viral oncogenes	No known analogues in oncogenic viruses	No known analogues in oncogenic viruses
Somatic mutations activated during all stages of carcinogenesis	Somatic mutations activated during all stages of carcinogenesis	Germ line mutations may initiate, but mutation to neoplasia occurs only during progression stage

extracts derived from chicken tumors (Rous, 1911). The transforming agent in the filtrate eventually was shown to be an RNA-type tumor virus, the *Rous sarcoma virus* (RSV) that is capable of transforming a normal cell and producing sarcomas within weeks of injection (Temin and Rubin, 1958). The genome of RSV and other retroviruses consists of two identical copies of mRNA, which is then reverse transcribed into DNA and incorporated into the host-cell genome. Oncogenic transforming viruses like RSV contain the v-*src* gene, a gene required for cancer induction. It was later demonstrated that normal cells from chickens and other species contain a gene closely related to v-*src* in RSV; the normal "proto-oncogene" commonly is distinguished from the viral gene by the prefix "c" (c-*src*; Oppermann *et al.*, 1979). This discovery showed that cancer may be induced by the action of normal, or nearly normal, genes.

DNA Viruses   Six major classes of DNA tumor viruses have been identified: simian virus 40 (SV40), polyoma virus, hepatitis B virus, papilloma viruses, adenoviruses, herpes viruses, and poxviruses. Unlike retroviral oncogenes, which are derived from normal cellular genes and have no function for the virus, the known oncogenes of DNA viruses are integral parts of the viral genome required for viral replication. SV40 or polyoma viruses are not capable of inducing tumors in their natural host species (monkey and mice, respectively). Infection by small DNA viruses is lethal to most nonhost

animal cells; however, a small proportion integrates the viral DNA into the host-cell genome. The cells that survive infection become permanently transformed due to the presence of one or more oncogenes in the viral DNA. For example, SV40 codes for the large T antigen, which alone is capable of inducing transformation (Fried and Prives, 1986). Both SV40 and polyoma viruses use the host cells DNA synthetic apparatus for their own replication. Papilloma viruses can infect and cause tumors in rabbits, cows, and humans (Lancaster and Olson, 1982). Of the human papilloma viruses, types 6, 10, and 11 are associated with genital warts whereas types 16, 18, 31, and 33 are associated with human cervical cancers (Vousden, 1989). Herpes viruses are complex, and are capable of producing tumors in frogs, chickens, monkeys, and humans (Rapp, 1974). Included among this class is the Epstein–Barr virus, a causative agent in the development of Burkett's B-cell lymphomas and in nasopharyngeal carcincoma (de-Thé *et al.*, 1978), and is mediated by genes encoding *EBNA-1*, *EBNA-2*, and *latent membrane protein* (Fahreus *et al.*, 1990). Adenoviruses affect host and nonhost cells differently; in host cells, infection causes lysis, whereas in nonhost cells, infection results in transformation via *E1A* and *E1B* genes (Pettersson and Roberts, 1986). Hepatitis B viruses specifically infect the liver of ducks, woodchucks, and squirrels and is strongly associated with liver cancer development in humans; infected individuals exhibit a >100-fold risk for cancer development (Snyder *et al.*, 1982). Hepatitis B gene X is thus far the main gene

implicated in the transformation process (Kim *et al*., 1991). Poxviruses (e.g., Yaba monkey virus, Shope fibroma virus) replicate in the cytoplasm of infected cells and produce benign tumors (Niven *et al*., 1961).

Proto-Oncogenes   An oncogene is a gene encoding a protein that is capable of transforming cells in culture or inducing cancer in animals. Of the known oncogenes, the majority appear to have been derived from normal genes (i.e., proto-oncogenes), and are involved in cell signaling cascades (Table 8-16). Because most proto-oncogenes are essential for maintaining viability, they are highly conserved evolutionarily. It has been clearly demonstrated that altered expression of these genes results in unregulated control of cell growth. Activation of proto-oncogenes arises through mutational events occurring within proto-oncogenes (Alitalo and Schwab, 1986; Bos, 1989). It has been recognized that a number of chemical carcinogens are capable of inducing mutations in proto-oncogenes (Balmain and Pragnell, 1983).

Several oncogene products are associated with growth factors. The *sis* oncogene encodes for platelet-derived growth factor (PDGF), which consists of types A and B chains. Active PDGF can consist of homo- or heterodimers of the A and B chains. Only cells that express the PDGF receptor are susceptible to transformation by the *sis* oncogene (Doolittle *et al*., 1983). Fibroblast growth factor (FGF), epidermal growth factor (EGF), and the *wnt* family also have oncogenes that encode for their production (Burgess and Maciag, 1989; Nusse and Varmus, 1992). Enhanced expression of these growth factor genes leads to transformation of cultured cells. In addition, lung carcinomas and astrocytomas in humans express both PDGF and its receptor.

In order for the growth factors listed above to induce cell growth, the cell must also express the appropriate growth factor receptors. Ligand binding to receptors in many cases results in the activation of signaling cascades, of which a number have protein kinase activity. Protein kinases can phosphorylate at tyrosine, serine, or threonine residues. Several oncogene products have been identified that have tyrosine kinase activity (e.g., *src*, *fps*, *fgr*, *fms*, *kit*, and *ros*) (Collett and Erickson, 1978). Growth factor receptors including EGF, PDGF, insulin, insulin-like growth factor, and FGF have tyrosine activity (Wells, 1999). An extensive number of protein kinases are serine or threonine kinases, some of which can be activated in tumor cells and lead to transformation. The protein kinase C family consists of serine/threonine kinases (Nishizuka, 1988). This family of proteins participates in the inositol-phospholipid second messenger pathway and can be activated by calcium and diacylglycerol, as well as phorbol ester tumor promoters. The *raf* and *mos* oncogenes are other examples of serine threonine kinases, that interact with mitogen-activated kinase pathways, leading to enhanced expression of "immediate-early" genes such as Myc and Fos/Jun heterodimers, which ultimately leads to enhanced cell growth (Su and Karin, 1996).

Guanine nucleotide-binding proteins are a subset of the GTP superfamily. The primary oncogenic members of this family are the *ras* genes (e.g., *Ha-*, *Ki-*, and *n-ras*), which were initially found in murine retroviruses, and are frequently activated in human tumors and in chemically induced tumors in rodent models (McCormick, 1994). The three ras forms differ by only 20 amino acids, and have a conserved cytosine-186, which is a site for posttranslational modification by a farnesyl, isoprenyl group, a modification that is needed for membrane localization (Hancock *et al*., 1989). Mutations in *ras*

affect the association of the Ras with GTP, and because Ras is active when GTP is bound, constitutive Ras activation is often seen with mutated forms of *ras*. Many mutation sites are associated with activation of *ras* and include codons 12, 13, 61, 116, 117, 119, and 146 (de Vos *et al*., 1988). Although a dominant gain-of-function mutation in the *ras* gene converts it into an oncogene, a recessive loss-of-function mutation in the *NF1* gene also leads to constitutive Ras activation. *NF1* encodes a GTPase-activating enzyme (GAP) that accelerates hydrolysis of GTP and the conversion of active GTP-bound Ras to inactive GDP-bound Ras. The loss of GAP leads to sustained Ras activation of downstream signal transduction proteins. Individuals with neurofibromatosis have inherited a single mutant *NF1* allele; subsequent somatic mutation in the other allele leads to formation of neurofibromas.

In addition to acting at the receptor level, some oncogene products are nuclear transcription factors and thus alter gene expression. One of the first to be identified was the erbA oncogene product, which is an altered form of the thyroid hormone receptor (Damm *et al*., 1989). This altered form is unable to bind thyroid hormone and allows the oncogene protein to act in a dominant-negative manner, functioning as a constitutive repressor of normal expression of genes regulated by thyroid hormone. Another family of oncogenes encode for the AP-1 transcription factor, a complex consisting of *jun* and *fos*, as well as Jun family members with homology to c-jun (Jun B and Jun D) (Chiu *et al*., 1988; Vogt, 2001). Phorbol esters and several other tumor-promoting compounds are able to rapidly induce gene expression of both *fos* and *jun*. Activation of both *fos* and *jun* results in the constitutive expression of the transcription factors and sustained stimulation of cell growth signals. The *myc* family (*c-myc*, N-*myc*, and L-*myc*) encodes for transcription factors that are found activated in a number of tumor types (Marcu *et al*., 1992).

Tumor Suppressor Genes
Retinoblastoma (Rb) Gene   In contrast to oncogenes, the proteins encoded by most tumor suppressor genes act as inhibitors of cell proliferation or cell survival (Table 8-17). The prototype tumor suppressor gene, *Rb*, was identified by studies of inheritance of retinoblastoma. Loss or mutational inactivation of *Rb* contributes to the development of a wide variety of human cancers. In its unphosphorylated form, Rb binds to the *E2F* transcription factors preventing E2F-mediated transcriptional activation of a number of genes whose products are required for DNA synthesis. In addition, the Rb–E2F complex acts as a transcriptional repressor for many of these same genes (Chellappan *et al*., 1991). During the early G1 phase of the cell

Table 8-17

Examples of Tumor Suppressor Genes and Cancer Association

TUMOR SUPPRESSOR	DISORDER	NEOPLASM
Rb1	Retinoblastoma	Small-cell lung carcinoma
p53	Li-Fraumeni syndrome	Breast, Colon, Lung Cancers
BRCA1	Unknown	Breast carcinoma
WT-1	Wilm's tumor	Lung cancer
p16	Unknown	Melanoma

cycle, Rb is in an unphosphorylated state, but becomes phosphorylated during the late G1, causing dissociation from E2F—a process that allows E2F to induce synthesis of DNA replication enzymes, resulting in a commitment to the cell cycle. Rb phosphorylation is initiated by an active Cdk4–cyclin D complex, and is completed by other cyclin-dependent kinases (Sherr, 1993; Weinberg, 1995). Most tumors contain an oncogenic mutation of one of the genes in this pathway, such that cells enter the S phase of the cell cycle in the absence of the proper extracellular growth signals that regulate Cdk activity. In addition, Rb is bound and inactivated by the E1A protein of the adenoviruses (Whyte *et al.*, 1988) and also by the large T antigen of SV40 and the E7 protein of the papilloma virus, suggesting that the elimination of Rb function may be an important mechanism in tumor development by viruses and/or mutations induced by chemical carcinogens.

p53 Gene   The p53 protein is a tumor suppressor gene that is essential for checkpoint control and arrests the cell cycle in G_1 in cells with damaged DNA. Cells with functional p53 arrest in G_1 when exposed to DNA damaging agents such as irradiation, whereas cells lacking functional p53 are unable to block the cell cycle. p53 is activated by a wide array of stressors including ultraviolet light, γ irradiation, heat, and several carcinogens. DNA damage by γ irradiation or by other stresses leads to the activation of certain kinases, including ATM, which is encoded by the gene mutated in ataxia telangiectasia, and a DNA-dependent protein kinase. Phosphorylation of p53 by these and other kinases results in stabilization of p53 and an increase in cell content of this protein (Finlay *et al.*, 1989). The active form of p53 is a tetramer of four identical subunits. A missense point mutation in one *p53* of the two alleles in a cell can abrogate almost all p53 activity, because virtually all the oligomers will contain at least one defective subunit, and such oligomers cannot function as a transcription factor. Oncogenic *p53* mutations thus act as "dominant negatives," in contrast to tumor-suppressor genes such as *Rb* (Levine *et al.*, 1991).

Virtually all p53 mutations abolish its ability to bind to specific DNA sequences and activate gene expression (El-Deiry *et al.*, 1992). The transcription of cyclin-kinase inhibitor p21, which binds to and inhibits mammalian G_1 Cdk–cyclin complexes, is induced by p53. As a result, cells with damaged DNA are arrested in G_1 until the damage is repaired and the levels of p53 and p21 fall; the cells then can progress into the S phase. In most cells, accumulation of p53 also leads to induction of proteins that promote apoptosis, and therefore would prevent proliferation of cells that are likely to accumulate multiple mutations. When the p53 checkpoint control does not operate properly, damaged DNA can replicate, producing mutations and DNA rearrangements that contribute to the development of transformed cells. Proteins that interact with and regulate p53 are also altered in many human tumors. The gene encoding one such protein, MDM2, is amplified in many sarcomas and other human tumors that maintain functional p53 (Leach *et al.*, 1993). Under normal conditions, MDM2 binds the N-terminus of p53, repressing the ability of p53 to activate transcription of *p21* and genes mediating p53 degradation. Thus, MDM2 normally inhibits the ability of p53 to block at G1 or induce apoptosis. Enhanced MDM2 levels in tumor cells therefore results in decreased functional p53 and prevents p53 from growth arrest in response to irradiation or chemical carcinogens. For example, benzo(*a*)pyrene produces inactivating mutations at codons 175, 248, and 273 of the *p53* gene in cultured cells; these same positions are mutational hot spots in human lung cancer (Nakayama *et al.*, 1984). Aflatoxin exposure induces a G to T transversion at codon 249 of

p53, and methyl-N'-nitro-N-nitrosoguanidine (MNNG) can alter methylation of DNA leading to inactivation of p53 (Burns *et al.*, 1987).

BRCA1 Gene   Genetic analysis of breast tumors has revealed an hereditary predisposition for breast cancer is linked to *BRCA1*, a tumor-suppressor gene. Mutation of a single *BRCA1* allele has a 60% probability of developing breast cancer by age 50. In families transmitting the mutant BRCA1 allele, the normal allele is often absent in tumors. A number of investigators have shown that germ line mutations lead to loss of function of the BRCA1 gene, perhaps by acting as a transcription factor through binding at a zinc finger domain. However, no mutations have been observed in sporadic breast cancers (Futreal *et al.*, 1994), suggesting that BRCA1 gene silencing may occur through nonmutational mechanisms.

Wilm's Tumor Gene (WT1)   Wilm's tumor occurs in the developing kidney at a rate of approximately 1 per 10,000 children. The WT1 gene is believed to be responsible for tumor development and is thought to function as a transcription factor (Hastie, 1994). The DNA-binding region of the WT1 gene contains four zinc finger domains, and binds a consensus sequence shared with EGR1; however, WT1 acts as a transcriptional repressor at this site (Rauscher *et al.*, 1990). Similar to p53, WT1 mutant alleles act in a dominant negative manner.

p16 Gene   The group of proteins that function as cyclin-kinase inhibitors play an important role in cell cycle regulation. Mutations, especially deletions of the *p16* gene, that inactivate the ability of p16 to inhibit cyclin D-dependent kinase activity are common in several human cancers including a high percentage of melanomas (Kamb *et al.*, 1994). Loss of p16 would mimic cyclin D1 overexpression, leading to Rb hyperphosphorylation and release of active E2F transcription factor. Thus p16 normally acts as a tumor suppressor. As with the BRCA1 gene, relatively few mutations have been found in this gene, and some researchers have speculated that epigenetic mechanisms such as gene silencing by DNA methylation may occur during tumorigenesis (Merlo *et al.*, 1995).

Hormesis and Carcinogenesis

Hormesis is defined as a dose–response curve in which a U, J, or inverted U-shaped dose–response is observed; with low-dose exposures often resulting in beneficial rather than harmful effects (Calabrese, 2002) (Fig. 8-27). One of the first reports establishing an hormetic response was observed with ionizing radiation, in which it was hypothesized to be due to adaptation to background radiation exposure, as well as enhanced metabolism and
Figure 8-27. Hormesis curve.

Table 8-18
Classes of Chemopreventive Agents

INHIBITORS OF CARCINOGEN FORMATION	EXAMPLES
Reductive acids	Ascorbic acid
Phenols	Cafeic acid, ferulic acid, gallic acid
Sulfhydryl compounds	N-Acetylcysteine
Amino acids	Praline, thioproline
Blocking agents	
Inhibition of cytochrome P450	Dithiocarbamates, ellagic acid, diallyl sulfide, isothiocyanates
Induction of cytochrome P450	Indole-3-carbinol, B-naphthoflavone
Induction of phase II enzymes	
Glutathione S-transferase	Allyl sulfides, dithiolethiones, isothiocyanates
UDP-glucuronyltransferase	Polyphenols
Glutathione peroxidase	Selenium
Scavenge electrophiles	Ellagic acid, N-acetylcysteine
Scavenge free radicals	Sodium thiosulfate, polyphenols, vitamin E
Increase overall levels of DNA repair	Vanillin
Increase poly(ADP-ribosyl) transferase	N-acetylcysteine
Suppress error-prone DNA repair	Protease inhibitors
Suppressing agents	
Inhibit polyamine metabolism	DRv10, polyphenols, substituted putrescines
Induce terminal cell differentiation	Calcium, retinoids, vitamin D_3
Modulate signal transduction	Glycyrrhetinic acid, NSAIDS, polyphenols, retinoids
Modulate hormonal/growth factor activity	NSAIDs, retinoids, tamoxifen
Inhibit oncogene activity	Genistein, NSAIDs, monoterpenes
Promote intracellular communication	Carotenois, polyphenols, retinoids
Restore immune response	NSAIDs, selenium, vitamin E
Induce apoptosis	Butyric acid, genistein, selenium, sulindac sulfone, retinoids
Correct DNA methylation imbalances	Folic acid, choline, methionine
Inhibit basement membrance degradation	Protease inhibitors
Inhibit arachidonic acid metabolism	Glycyrrhetinic acid, N-acetylcysteine, NSAIDs, polyphenols

detoxification (Calabrese, 2002; Parsons, 2003). Numerous examples exist that provide evidence for U- and J-shape dose relationships to different biomarkers of carcinogenesis, both for initiating and promoting carcinogens. For example, low-dose styrene treatment resulted in a decrease of chromosomal aberrations (Camurri *et al*., 1983). A reduction in DNA strand breaks in human keratinocytes was seen following low-dose exposure to N-methyl-N'-nitro-N-nitrosoguanidine, while high doses markedly increased DNA strand breaks (Kleczkowska and Althaus, 1996). Several chronic bioassays for carcinogenicity in rats and mice have demonstrated a negative correlation between proliferative hepatocellular lesions and lymphomas at low and medium dose levels (Young and Gries, 1984). TCDD at hepatocarcinogenic doses caused dose-dependent reduction in mammary and uterine tumors (Kociba *et al*., 1978). TCDD has also been shown to reduce tumor incidence after exposure to low doses of radiation and selenium (Nordberg and Andersen, 1981; Pollycove and Feinendegen, 2001). Evidence for a U-shaped dose–response curve has also been demonstrated for phenobarbital (Kitano *et al*., 1998; Ito *et al*., 2003; Kinoshita *et al*., 2003). These investigators have shown that phenobarbital promoted the growth of diethylnitrosamine-induced hepatic lesions at doses between 60 and 500 ppm, while doses between 1 and 7.5 ppm decreased lesion growth, hepatocellular carcinoma, and tumor multiplicity.

Adaptive responses have been proposed to explain the hormetic effects observed by chemical carcinogens. When experimental an-

imals are exposed to chemicals, the initial response is an adaptive response to maintain homeostasis (Calabrese, 2002). Adaptive responses usually involve actions of the chemical on cellular signaling pathways that lead to changes in gene expression, resulting in enhanced detoxification and excretion of the chemical, as well as preserving the cell cycle and programmed cell death. It has been proposed that following very low doses of chemicals, the upregulation of these mechanisms overcompensates for cell injury such that a reduction in tumor promotion and/or tumor development is seen, and would explain the U- or J-shaped response curves obtained following carcinogen exposure.

A common feature of chemical carcinogens for which hormetic effects have been proposed is the formation of reactive oxygen species and the induction of cytochrome P450 isoenzymes. Inhibition of carcinogenesis by low levels of phenobarbital has been postulated to involve the suppression of 8-OHdG generation and cellular proliferation within areas of GST-P positive foci, possibly related to enhanced expression of the gene encoding the enzyme oxoguanine glycosylase 1 (Ogg1), which is involved in the repair of 8-OHdG lesions (Kinoshita *et al*., 2003). Another explanation for the suppressive effect of low level phenobarbital on the development of preneoplastic lesions involves the stimulation of hepatic drug-metabolizing enzymes, which detoxify carcinogens (Pitot *et al*., 1987). In a low-dose phenobarbital study, cDNA microarray analysis showed a suppression in mRNA expression MAP

Table 8-19
General Methods for Identification of Potential Carcinogens

METHOD	TIME FRAME
Short term	
Mutagenesis assays	Several wks
Transformation in cell culture	1–3 months
Medium term	
Qualitative and quantitative analysis of preneoplasia	2–8 months
Long term	
Chronic bioassay in animals	18–24 months

kinase p38, JNK1,2, and other intracellular kinases (Kinoshita *et al.*, 2003). Thus, suppression of gene expression of signal transduction modulators appears to be involved in the inhibitory effect of phenobarbital on cell proliferation.

Chemoprevention

The study of chemicals that prevent, inhibit, or slow down the process of cancer is referred to as chemoprevention. A number of chemicals, including drugs, antioxidants, foodstuffs, and vitamins have been found to inhibit or retard the components of the cancer process (Table 8-18) in both in vitro and in vivo models. Cancer chemopreventive agents may function at one or more of the steps in the carcinogenesis process. Cancer chemoprevention involves the administration or inclusion in the diet of natural or synthetic chemicals in an attempt to prevent, halt, or reverse the process of carcinogenesis. A basic assumption in chemoprevention is that treating early stages of malignant process will halt or delay the progression to neoplasia. Chemopreventive agents may function via one or several mechanisms; inhibitors of carcinogen formation, blocking agents, and/or as suppressing agents (Table 8-18). Blocking agents serve to prevent the metabolic activation of genotoxic or nongenotoxic carcinogens by either inhibiting its metabolism or by enhancing the detoxification mechanisms. In the case of reactive oxygen species generation by a carcinogen, antioxidants, such as, *N*-acetylcysteine, or vitamins E, A, and C serve as blocking agents by trapping the oxidative species before it can induce cellular damage. The drug oltipraz induces the phase II enzymes, in particular glutathione-*S*-transferase, has been shown to reduce the carcinogenicity of aflatoxin B1 by enhancing its detoxification (Jacobson *et al.*, 1997). Chemopreventive agents that increase tissue resistance function on the target tissue, usually an early preneoplastic lesion, by increasing tissue maturation and/or decreasing cell proliferation. Suppressing agents induce tissue differentiation, may counteract oncogenes, enhance tumor suppressor gene activities, inhibit proliferation of premalignant cells, or modify the effect of the carcinogen on the target tissue. Retinoic acid is a classic chemical that functions by inducing target tissue differentiation. Similarly, viral vectors containing wild-type p53 have been shown to negate the effects of tumor growth driven via p53 mutation. Extensive experimental evidence exists showing the inhibition or retardation of the cancer process by chemopreventive agents. These studies have been performed in animal models and cell systems. Whereas the human results of chemoprevention interventions are less convincing than the experimental models, considerable epidemiological evidence demonstrates an inverse relationship of some nutrient factors with cancer risks.

TEST SYSTEMS FOR CARCINOGENICITY ASSESSMENT

Numerous in vivo and in vitro experimental systems are available to assess the potential carcinogenicity of chemicals. The types of tests available to identify chemicals with carcinogenic potential can be classified into general categories, based on the duration required to conduct the test (Table 8-19). Short-term tests are typically of the duration of days to a few weeks, intermediate-term tests last from weeks up to a year, while chronic long-term tests usually encompass 6 months to 2 years exposure to a chemical. These bioassays use bacterial and mammalian targets.

Short-term Tests for Mutagenicity

Short-term tests for mutagenicity were developed to identify potentially carcinogenic chemicals based on their ability to induce mutations in DNA either in vivo or in vitro. A variety of in vivo and in vitro short-term tests are available to test the potential carcinogenicity of a chemical (Table 8-20). The majority of these tests measure the mutagenicity of chemicals as a surrogate for carcinogenicity. Therefore, while they are usually very predictive of indirect acting and direct acting (if a metabolic source is provided), these tests routinely fail to detect nongenotoxic carcinogens.

In Vitro Gene Mutation Assays The most widely used short-term test is the Ames assay (Ames *et al.*, 1975). The relative simplicity and low cost of the test make it a valuable screening tool for mutagenic carcinogens. *Salmonella typhimurium* strains, deficient in DNA repair and unable to synthesize histidine, are used. In the presence of a mutagenic chemical, the defective histidine gene can be mutated back to a functional state (*back mutation*), resulting in a restoration of bacterial growth in a medium lacking histidine. The mutant colonies, which can make histidine, are referred to as "revertants." The Ames test in basic form can detect direct-acting genotoxic carcinogens. With the inclusion of a metabolic source, specifically the 9000g supernatant (S9) of a rat liver homogenate to promote metabolic conversion of the chemical, the Ames test can also detect indirect-acting genotoxic carcinogens. Figure 8-28 describes the standard method used for performing the Ames assay.

Genetically unique strains of the *S. typhimurium* bacterium have been developed for determining specific mutational targets. Strains TA100 and TA1535 are able to detect point mutations, whereas strains TA98, TA1537, and TA1538 are able to detect frameshift mutations. Chemicals are typically tested at several dose levels (usually five or more) and the mutation frequency (number of revertants) is calculated. Activation-independent (e.g., sodium azide and methyl methanesulfonate) and activation-dependent (e.g., 2-aminoanthracene) positive controls are included in each assay.

The mouse lymphoma assay is a mutagenicity assay used to determine whether a chemical is capable of inducing mutation in eukaryotic cells. Typically, mouse lymphoma L5178Y cells are used, and the ability of the cell cultures to acquire resistance to trifluorothymidine (the result of forward mutation at the thymidine kinase locus) is quantified. Another mammalian cell mutation assay, the Chinese hamster ovary (CHO) test, is also commonly used to assess the potential mutagenicity of chemicals. This assay uses the

hypoxanthine-guanine phosphoribosyltransferase (HGPRT) gene as the end point. The basis for these assays is shown in Fig. 8-29. Cells are treated with the test chemical and then placed into suspension with selective medium for replication and fixation of induced mutations. Cells are then plated for colony growth, and after several days, colony numbers and colony size are recorded. The number of mutant colonies is a measure of the ability of the test chemical to induce a genetic change at the thymidine kinase or HGPRT loci in these transformed cells.

As with the Ames assay, these assays are frequently performed in the presence of an exogenous metabolic source (e.g., irradiated epithelial cell feeder layer). Because not all carcinogens are mutagens and/or directly damage the DNA, the concordance with the chronic in vivo bioassay for these mutagenicity assays is relatively low.

In Vivo Gene Mutation Assays For the assessment of the carcinogenic potential of chemicals, in vivo genotoxicity tests are important complement to in vitro mutagenicity tests. The in vivo tests have advantages over the in vitro test systems in that they take into account the whole animal processes such as absorption, tissue distribution, metabolism, and excretion of chemicals and their metabolites. The commonly used in vivo models include transgenic rodent mutation assay systems based on the genes of the *lac* operon, Muta™Mouse (Gossen *et al.*, 1989), and Big Blue® (Kohler *et al.*, 1991a,b).

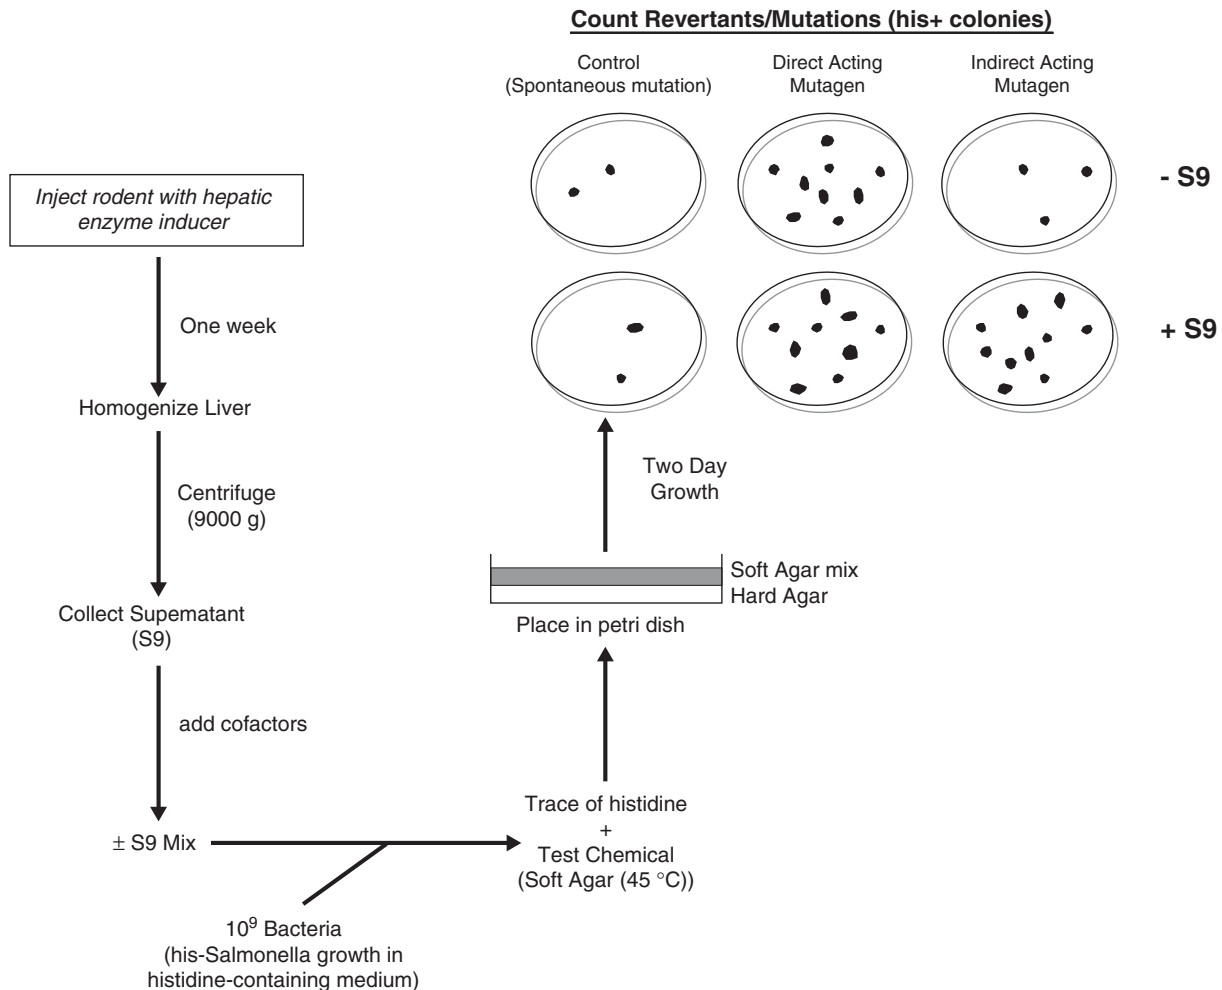
The Muta™Mouse is a transgenic mouse in which a vector prepared from bacteriophage λDNA (λgt10) has been stably inserted into the genome and exists within every cell. Within the λDNA sequence, the bacterial gene *lacZ*, which encodes for β-galactosidase, was inserted at the single *Eco*RI restriction site. The entire vector contains ~47,000 bp, of which the *lacZ* gene comprises 3126 bp. The construction and analysis of Muta™Mouse have been previously described (Gossen *et al.*, 1989). The Big Blue® transgenic mouse was developed using a 47.6 kb λshuttle vector containing the bacterial *lacI* gene (1080 bp), which encodes the repressor protein of the *lacZ* gene. As with the Muta™Mouse, this vector is stably inserted into the genome and exists in every cell. Details on the Big Blue® system are described elsewhere (Kohler *et al.*, 1991a,b).


Figure 8-28. Ames tests for mutagenesis of chemicals in Salmonella typhimurium bacteria.

To detect mutations, following exposure of mice to test chemicals, mutations are analyzed in high molecular DNA isolated from the tissue under investigation. The next step is to isolate a viable λphage for the analysis of mutations in the *lacZ* or *lacI* genes from the mouse. The infectious λparticles are detected as plaques that form on a bacterial (*Escherichia coli* strain) lawn grown on an agar surface. In the case of Muta™Mouse, a positive selection system is used that involves the scoring of clear plaques on titration plates to determine the total number of plaque forming units and on selection plates to determine the number of mutants (Gossen and Vijg, 1993). For Big Blue®, a nonselectable color screening assay is used, scoring blue mutant plaques among the nonmutant clear plaques (Kohler *et al*., 1991a). In each case the ratio of mutants to the total population will provide a mutation frequency for each chemical and each organ tested. As with the other short-term tests that have been discussed, it is unlikely that in vivo genotoxicity test systems will identify nongenotoxic/non-DNA reactive compounds.

Chromosomal Alterations   Chromosomal alterations are quite common in malignant neoplasms, as such the detection of chromosomal abnormalities by test chemicals is considered an excellent test for the assessment of carcinogenic potential. Both in vivo and in vitro assays are available to assess chromosomal alterations. In mammalian cell lines, most of the test systems used the same lines as used in the mutation assay (Galloway *et al*., 1985). To assess induction of chromosomal alterations, cells are harvested in their first mitotic division after the initiation of chemical exposure. Cells are stained with Giemsa and scored for completeness of karyotype (21 +/− 2 chromosomes). The classes of aberrations recorded include breaks and terminal deletions, rearrangements and translocations, as well as despiralized chromosomes, and cells containing 10 or more aberrations.

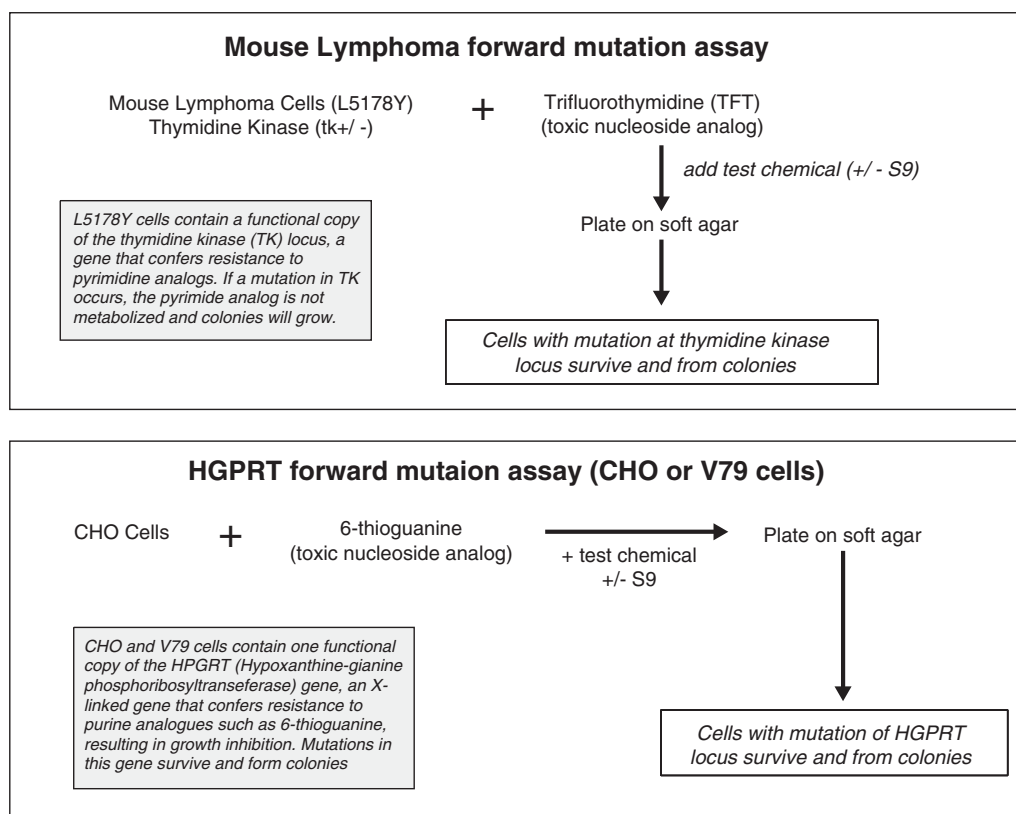
SCEs are a measure of DNA damage and increased levels of DNA damage, events that are associated with mutation induction and cancer. During metaphase, sister chromatids, each encompassing a complete copy of one chromosome, are bound together through specific protein interactions. SCEs are a reflection of an interchange of DNA between different chromatids at homologous loci within a replicating chromosome (Latt, 1981). Differential staining of chromatids is therefore used to assess SCEs. Typically, 5-bromodeoxyuridine (BrdU) is added along with the test chemical for one cell replication followed by replacement of the medium with a medium containing BrdU and colcemid, without test chemical.


Figure 8-29. In vitro approaches for assessing forward mutations using the TK and HGPRT Assays.

Cells are then harvested, stained, and second-division metaphase cells scored to determine the frequency of SCE/cell for each dose level.

In vivo analysis of chromosomal alterations have been described since the 1980s (Generosso *et al*., 1980). Disruption of the DNA replication process or damage to chromosomes by chemicals can alter the genetic material distributed to either of the two daughter nuclei. When this occurs, the genetic material that is not incorporated into a new nucleus may form its own "micronucleus," which is clearly visible with a microscope. For this assay, animals are exposed to chemicals and the frequency of micronucleated cells is determined at some specified time after treatment. Micronucleus tests must be performed on cells that are dividing, most typically in cells from bone marrow samples (Heddle *et al*., 1983). As with other short-term tests, the micronucleus test provides complementary information to gene mutation data but the tests neither enhance the ability to detect genotoxic carcinogens nor are capable of detecting non-DNA reactive carcinogens. However, this assay does provide information on the ability of a chemical to disrupt mammalian chromosome structure and function.

DNA Damage   Primary DNA damage represents possible premutational events that can be detected, either directly or indirectly, by a number of techniques using mammalian cells in culture or using rodent tissue. Unscheduled DNA synthesis (UDS) is a commonly used assay that measures the ability of a chemical to induce DNA lesions by measuring the increase in DNA repair. Among the available techniques is the measurement of DNA strand breaks both in vivo and in vitro (Miyamae *et al*., 1997). Whereas a wide array of assays are available to assess DNA damage, the Comet Assay, or single-cell gel electrophoresis has become one of the standard methods for assessing DNA damage and repair at the individual cell level. Since its introduction in 1988, the alkaline comet assay has been modified to increase the utility of this technique for detecting various forms of DNA damage (e.g., single- and double-strand breaks, oxidative DNA base damage, and DNA-DNA/DNA-protein/DNA-drug crosslinking) and DNA repair in virtually any eukaryotic cell. Through the use of lesion-specific endonucleases, the levels of ultraviolet (UV)-induced pyrimidine dimers, oxidized bases, and alkylation damage can be assessed in biological samples (Collins, 2004).

Transformation Assays   A variety of in vitro test systems have been developed to assess the carcinogenic potential of chemicals. The C3H/10T$^{1/2}$ cell line has been widely used in the transformation assays. It was originally derived from fibroblasts taken from the prostate of a C3H mouse embryo. The cells are approximately tetraploid but the chromosome number in the cells varies widely. As such, these cells are chromosomally abnormal and have already passed through some of the stages that might be involved in the production of a cancerous cell. Upon plating these cells, they will stop growing when their density is sufficiently high (contact growth inhibition). However, the contact inhibition can fail, resulting in cell piling forming a transformed colony. Therefore, following exposure to xenobiotics, this assay

assesses carcinogenic potential based on the percentage of colonies that are transformed (Reznikoff *et al.*, 1973).

The most frequently used endpoint for cell transformation is morphological transformation of mammalian cell fibroblasts in culture. Transformation assays using BALB3T3 and Syrian Hamster Embryo (SHE) cells are available for the assessment of the carcinogenic potential of chemicals. BALB/3T3 transformation assay, however, has not gained full acceptance as a carcinogenic screening assay, mainly due to issues regarding its relatively low sensitivity, low reproducibility, and relatively long test period (Schectman *et al.*, 1985; Sakai *et al.*, 1989). The Syrian hamster embryo (SHE) cell assay, a diploid cell transformation assay, measures carcinogenic potential of xenobiotics by assessing transformed colonies based on morphological criteria. The SHE cell assay has several features that make it an appealing method to evaluate the carcinogenic potential of xenobiotics: (1) The assay has a >85% concordance with the 2-year rodent bioassay; (2) the stages involved in the clonal transformation of SHE cells (e.g., morphological transformation, immortalization, and tumorigenicity) closely resemble those associated with the classic defined stages of carcinogenesis (e.g., initiation, promotion, and progression); and (3) nongenotoxic/non-DNA reactive carcinogens elicit a positive response on morphological transformation in the SHE cell assay (Barrett and Lamb, 1985; LeBeouf *et al.*, 1990; Isfort *et al.*, 1994, 1996). The SHE assay offers an alternative, regulatory approved, means to check the validity of the positive result before embarking on potentially unnecessary and expensive chronic or subchronic testing protocols.

Chronic Testing for Carcinogenicity

The majority of in vivo carcinogenicity testing is performed in rodent models. The administration of chemicals in the diet, often for extended periods, for assessment of their safety and/or toxic-

ity began in the 1930s (Sasaki and Yoshida, 1935). Animal testing today remains a standard approach for determining the potential carcinogenic activity of xenobiotics. In addition to the lifetime exposure rodent models, organ-specific model systems, multistage models, and transgenic models are being developed and used in carcinogen testing (Table 8-21).

Chronic (2-Year) Bioassay   Two-year studies in laboratory rodents remain the primary method by which chemicals or physical agents are identified as having the potential to be hazardous to humans. The most common rodents used are the rat and mouse. Typically the bioassays are conducted over the lifespan of the rodents (2 years). Historically, selective rodent strains have been used in the chronic bioassay; however, each strain has both advantages and disadvantages. For example, the National Toxicology Program (NTP) typically uses Fisher 344 (F344) rats and B6C3F1 mice. The F344 rat has a high incidence of testicular tumors and leukemias, whereas the B6C3F1 mouse is associated with a high background of liver tumors (Table 8-22).

In the chronic bioassay, two or three dose levels of a test chemical and a vehicle control are administered to 50 males and 50 females (mice and rats), beginning at 8 weeks of age, continuing throughout their lifespan. The route of administration can be via oral (gavage), dietary (mixed in feed), or inhalation (via inhalation chambers) exposure. Typically a number of short-term in vivo tests are conducted prior to the chronic bioassay to determine acute toxicity profiles, appropriate route of administration, and the maximum tolerated dose (MTD). Generally, the MTD is used to set the high dose in the chronic study. The use of the MTD as the upper dose level has been questioned by many investigators, as it is recognized that the doses selected often represent doses that are considered unrealistically high for human exposure. Pharmacokinetics and metabolism at high dose are frequently unrepresentative of those at lower doses; in

addition, a general relationship between toxicity and carcinogenicity cannot be drawn for all classes of chemicals. During the study, food consumption and bodyweight gain should be monitored, and the animals observed clinically on a regular basis, and at necropsy the tumor number, location, and pathological diagnosis for each animal is thoroughly assessed.

Organ-Specific Bioassays and MultiStage Animal Models
Many tissue-specific bioassays have been developed with the underlying goal being to produce a sensitive and reliable assay that could be conduced in a time frame shorter in duration than the 2-year chronic bioassay. These assays are commonly used to detect carcinogenic activity of chemicals in various target organs (Weisburger and Williams, 1984). Of the many models available, three models, the liver, skin, and lung models are more widely used.

Carcinogenicity Testing in the Liver   The liver represents a major target organ for chemical carcinogens. It has been estimated that nearly half of the chemicals tested in the 2-year chronic bioassay by the National Toxicology Program showed an increased incidence of liver cancer. The rodent liver has been used as an animal model for carcinogenesis since the 1930s. Early pioneering work by Peraino and Pitot as well as Farber showed the multistaged process that occurs in the liver. The multistage nature of carcinogenesis is paralleled in the animal models; the system is characterized by well-defined changes including the formation of initiated cells by genotoxic agents that then progress to preneoplastic focal lesions, some of which subsequently convert into neoplasms. The use of preneoplastic lesions as endpoints in carcinogenicity testing may shorten the experiment from 2 years to a few months. Several rodent liver focus assays have been developed to assess the ability of a chemical to induce liver cancer, and study the mechanisms involved in tumor development (Williams, 1982; Bannasch, 1986a; Ito *et al*., 1989). Liver carcinogenesis assays have been developed to study and distinguish chemicals that affect the initiation or promotion stage of hepatocarcinogenesis. During the assay for initiating activity of a chemical, the test substance is given prior to exposure to a promoting chemical. Although a single initiating dose can result in the induction of focal lesions, exposure over several weeks is often used to increase

the sensitivity of the model (Williams, 1982; Parnell *et al*., 1988). Phenobarbital is a commonly used tumor promoter; however, a wide range of chemicals have also been used as promoting agents (Solt and Farber, 1976; Oesterle and Deml, 1988). To assess the promoting activity of a chemical, the liver is initiated with a genotoxic chemical, often diethylnitrosamine. The test chemical is then administered for a duration of weeks to several months, and chemical substances with promoting activity may stimulate the proliferation of initiated cells or may inhibit the proliferation of the surrounding putatively normal cells. The dose of the initiating carcinogen should represent a dose that will not itself induce liver tumors during the course of the experiment.

Another method commonly used was developed in Japan by Ito and coworkers (Ogiso *et al*., 1990; Ito *et al*., 1994; Shirai *et al*., 1999). The entire assay takes only 8 weeks to perform. Rats are initiated with a single dose of diethylnitrosamine, followed by a 2-week recovery period, after which point the animals are exposed to the test compound for 8 weeks. After 1 week of exposure to the test substance, the animals are given a 2/3 partial hepatectomy. The control group receives the same initiation and partial hepatectomy, but is not exposed to the test chemical. Hepatic focal lesions, while individually are clonal in nature express a number of phenotypic alterations in various enzyme markers. A common endpoint assessed is the formation of liver lesions that stain for glutathione-S-transferase pi (GST-P), a marker that stains many focal lesions in the rat. Using this assay, these investigators have demonstrated a significant correlation between the results obtained using this assay and the medium- and long-term study results (Ogiso *et al*., 1990). This group has also modified the original procedure to enable the detection of promoting agents. In this protocol, carcinogens are given over a 4-week period to initiate the formation of focal lesions, after which, test chemicals are administered for an additional 24- to 36-week period (Ito *et al*., 1996). In this manner, the ability of the test chemical to promote the growth of preneoplastic lesions can be assessed. The newborn mouse model originally described by Shubik and coworkers (Pietra *et al*., 1959) has also been used as a model for hepatocarcinogenesis (Vesselinovitch *et al*., 1978; Fujii, 1991). In this model, a single dose of diethylnitrosamine is administered to infant mice to initiate focal lesions. This step is then followed by exposure to test chemicals for several weeks to assess their potential to promote focal lesion development in the liver.

Identification of hepatic foci in H&E-stained sections is regarded as the most reliable approach for the diagnosis and quantification of preneoplastic liver lesions in rodents. Preneoplastic lesions are obligatory precursor lesions that can lead to liver tumors and will progress to benign and malignant liver cell tumors without further chemical exposure, and are used as endpoints in carcinogenicity testing (Pitot *et al*., 1987; Pereira and Herren-Freund, 1988; Ito *et al*., 1989; Maronpot *et al*., 1989; Williams, 1989). In addition to the sensitive detection of these preneoplastic lesions in conventional H&E staining, a number of histochemically detectable phenotypic alterations have been used for their quantification; however, these markers are only useful in the rat model, as focal lesions in mice to not exhibit these same phenotypic markers.

Carcinogenicity Testing in the Skin   The Mouse Skin model is one of the most extensively studied and used models for understanding multistage carcinogenesis. This model of carcinogenesis is an assay that has been used to dissect mechanisms of carcinogenesis and also is purported to be a useful intermediate-term cancer bioassay. The skin was the target organ of the first experimental induction
Figure 8-30. *Experiments demonstrating the initiation and promotion phases of carcinogens in mice.*

Group 2: Application of promoter repeated at twice-weekly intervals for several months. Group 3: Application of promoter delayed for several months and then applied twice weekly. Group 6: Promoter applied at monthly intervals.

of chemical carcinogenesis (Yamagiwa and Ichikawa, 1915). The early studies by Friedwald and Rous (1944) and Berenblum and Shubik (1947) introduced the two-stage concept of carcinogenesis in the skin (Fig. 8-30). This model exploits many of the unique properties of the mouse skin; one major being that the development of neoplasia can be followed visually. In addition, the number and relative size of papillomas and carcinomas can be quantified as the tumors progress.

Both initiating and promoting activities of chemical carcinogens can be assessed using this model. In the promotion assay, a number of chemical carcinogens have been used to initiate cells in the mouse skin including urethane, UV light, benzo(a)pyrene, and dimethylbenzanthracene, with the latter of more common usage. The requirement for all initiating agents is to induce a genotoxic event that upon failure to repair DNA damage results in the formation of a mutated cell. Grossly, initiated cells of the skin appear identical to normal skin. Initiation in skin is frequently linked with the mutation of the CHr gene. Since the terminally differentiated cells in the skin are no longer capable of undergoing cell division, only initiated cells retain their proliferative capacity and thus represent the cell populations that give rise to tumors. To assess promotion by a chemical, an initiating chemical is applied first and is followed by the administration of a test substance for several weeks on the shaved skin of mice (Slaga, 1984). The promotion of initiated karatinocytes is commonly assessed using the phorbol ester TPA, which is routinely included as a positive control in this assay. The current hypothesis is that during the initiation stage the expansion of initiated cells occurs as a result of inflammation and hyperplasia from either TPA or through mechanical wound healing mechanisms. Upon repeated application of tumor promoters, selective clonal expansion of initiated keratinocytes occurs, resulting in skin papillomas, which over time can progress to carcinomas. In the standard two-stage protocol for mouse skin, malignant progression is relatively rare with approximately 5% of the papillomas progressing to the carcinoma stage. For the detection of initiating activity,

the test substance is applied to skin prior to promotion with phorbol esters. Several mouse models are available, including hairless mice, SENCAR mice, both of which have enhanced sensitivity to induction of skin cancer (Brown and Balmain, 1995; Sundberg *et al*., 1997).

Carcinogenicity Testing in the Lung Strain A mice are genetically susceptible to the development of lung tumors, with lung tumors being observed in control animals as early as 3–4 weeks of age, with a steady increase to nearly 100% by 24 months of age (Shimkin and Stoner, 1975). Chemically induced tumors appear to be derived from hyperplastic lesions that progress to adenoma, carcinoma within adenoma, and ultimately, to carcinomas (Stoner *et al*., 1993). In this model, carcinogenicity is typically assessed as an acceleration of tumor development, rather than an increase in the tumor incidence. The protocol currently used is that the chemical is administered for a period of 8 weeks, after which the animals remain on test for 4 additional months without chemical exposure. The strain A mouse lung tumor assay is sensitive to particular classes of chemicals, such as polycyclic aromatic hydrocarbons, nitrosamines, nitrosoureas, carbamates, aflatoxin, certain metals, and hydrazines (Stoner and Shimkin, 1985; Maronpot *et al*., 1986; Stoner, 1991).

Carcinogenicity Testing in Other Organs Test systems to examine the ability of a chemical to promote neoplastic development at organ sites other than liver, skin, and lung have also been developed. The available systems include animal models directed at examining carcinogenicity in the kidney, bladder, pancreas, stomach, colon, small intestine, and oral cavity. These models vary in the initiating carcinogen used, and frequency, duration, and site of application, as well as the duration of promoting chemical exposure. Table 8-23 provides an overview of the animal models available for these target organs.

Table 8-23

ORGAN	SPECIES	INITIATING CARCINOGEN	INITIATOR DURATION	CARCINOGEN (PROMOTER) DURATION	REFERENCES
Kidney	Rat[1]	N-ethyl-N-hydroxyethylnitrosamine	Single exposure	20 wks	Hiasa et al., 1991
Bladder	Rat	N-nitrosobutyl(4-hydroxybutyl)amine	4 wks	32 wks	Fukushima et al., 1983
Pancreas	Rat, Syrian Hamsters	N-nitrosobis(2-oxopropyl)amine, N-nitroso(2-hydroxypropyl)(2-oxopropyl)amine	Single exposure		Longnecker et al., 1984, 1985
Stomach (forestomach)	Rat	Benzo(a)pyrene	1–2x/week, 4 wks	40 wks	Silva et al., 1995
Stomach (glandular)	Rat	N-methyl-N'-nitro-N-nitronitrosoguanidine	Single exposure	40 wks	Takahashi et al., 1986
Colon	Rat	Azoxymethane	2 exposures	12 wks	Yamashita et al., 1994
Small intestine	Rat Mice	1,2-Dimethylhydrazine N-ethyl-N'-nitro-N-nitrosoguanidine	2–9 wks 4 wks	16–20 wks	Lindenschmidt et al., 1987; Jagadeesan et al., 1994
Oral cavity (lip, oral, nasal)	Rat	4-Nitroquinoline N-oxide	4 wks[2]		Johansson et al., 1989
Oral cavity (tongue)	Rat	4-Nitroquinoline N-oxide	8 wks[3]		Tanaka et al., 1995
Buccal cells (squamous cell carcinoma)	Syrian Hamster	—	—	Repeated application[4] 10–16 wks	Solt et al., 1987
Buccal cells (squamous cell carcinoma)	Syrian Hamster	dimethylbenz[a]anthracene	Single exposure	45 wks	Gimenez-Conti and Slaga, 1993

Transgenic Animals in Carcinogenicity Assessment

Due to the development of animal models with genetic alterations that invoke a susceptibility to carcinogenesis by chemical agents, the use of transgenic and knockout animals in carcinogenicity assessment is gaining more popularity. The common models that have been used include the Tg.AC and rasH2 transgenic mice, and p53$^{+/-}$ and XPA$^{-/-}$ knockout mice (Gulezian et al., 2000). Recently, the feasibility of the use of these animal models as alternative assays for the 2-year chronic bioassay was assessed by the Health and Environmental Sciences Institute (HESI) branch of the International Life Sciences Institute (ILSI). In this assessment, 21 chemicals were evaluated, encompassing genotoxic, nongenotoxic, and noncarcinogenic chemicals. The conclusions drawn from the scientific review suggested that these models appear to have usefulness as screening models for assessment of chemical carcinogenicity; however, they do not provide definitive proof of potential human carcinogenicity. Further the scientific panel suggested that these models could be used in place of the mouse 2-year bioassay (Tennant et al., 1998; Cohen et al., 2001). Coupled with information on genotoxicity, particularly DNA reactivity, structure–activity relationships, results from other bioassays, and the results of other mechanistic investi-

gations including toxicokinetics, metabolism, and mechanistic information, these alternate mouse models for carcinogenicity appear to be useful models for assessing the carcinogenicity of chemical agents.

CHEMICAL CARCINOGENESIS IN HUMANS

A number of factors have been implicated in the induction of cancer in humans. Infectious agents, lifestyle, medical treatments, environmental and occupational exposure account either directly or indirectly for the majority of cancers seen in humans. Of these, the component that contributes the most to human cancer induction and progression is lifestyle: tobacco use, alcohol use, and poor diet (Fig. 8-1 and Table 8-24). Tobacco usage either through smoking tobacco, chewing tobacco, or tobacco snuff-type products is estimated to be responsible for 25–40% of all human cancers. In particular a strong correlation between tobacco usage and mouth, larynx, lung, esophageal, and bladder cancer exists. It has been estimated (Doll and Peto, 1981) that 85–90% of all lung cancer cases in the United States are a direct result of tobacco use. The induction of pancreatic cancer also appears to have a linkage to tobacco use. Alcohol

Table 8-24
Carcinogenic Factors Associated with Lifestyle

CHEMICAL(S)	NEOPLASM(S)
Alcohol beverage	Esophagus, liver, oropharynx, and larynx
Aflatoxins	Liver
Betel chewing	Mouth
Dietary intake (fat, protein, calories)	Breast, colon, endometrium, gallbladder
Tobacco smoking	Mouth, pharynx, larynx, lung, esophagus, bladder

Table 8-25
Occupational Human Carcinogens

AGENT	INDUSTRIAL PROCESS	NEOPLASMS
Asbestos	Construction, asbestos mining	Peritoneum, bronchus
Arsenic	Mining and smelting	Sking, bronchus, liver
Alkylating agents (mechloro-ethamine hydrochloride and bis[chloromethyl]ether)	Chemical manufacturing	Bronchus
Benzene	Chemical manufacturing	Bone marrow
Benzidine, beta-naphthylamine	Dye and textile	Urinary bladder
Chromium and chromates	Tanning, pigment making	Nasal sinus, bronchus
Nickel	Nickel refining	Nasal sinus, bronchus
Polynuclear aromatic hydrocarbons	Steel making, roofing, chimney cleaning	Skin, scrotum, bronchus
Vinyl chloride monomer	Chemical manufacturing	Liver
Wood dust	Cabinet making	Nasal sinus
Beryllium	Aircraft manufacturing, electronics	Bronchus
Cadmium	Smelting	Bronchus
Ethylene oxide	Production of hospital supplies	Bone marrow
Formaldehyde	Plastic, textile, and chemical	Nasal sinus, bronchus
Polychlorinated biphenyls	Electrical-equipment production and maintenance	Liver

Table 8-26
Human Carcinogenic Chemicals Associated with Medical Therapy and Diagnosis

CHEMICAL OR DRUG	ASSOCIATED NEOPLASMS
Alkylating agents (cyclophospamide, melphalan)	Bladder, leukemia
Azathioprine	Lymphoma, reticulum cell sarcoma, skin, Kaposi's sarcoma (?)
Chloramphenicol	Leukemia
Diethylstilbestrol	Vagina (clear cell carcinoma)
Estrogens	Liver cell adenoma, endometrium, skin
Phenacetin	Renal pelvis (carcinoma)
Phenytoin	Lymphoma, neuroblastoma
Thorotrast	Liver (angiosarcoma)

consumption contributes anywhere from 2 to 4% of cancers of the esophagus, liver, and larynx.

Poor diets whether high fat, low protein, high calories, or diets lacking in needed antioxidants and minerals account for anywhere from 10 to 70% of human cancers. Diet contaminated by molds such as Aspergillus flavis (which produces aflatoxin B1) have been linked epidemiologically to a higher incidence of liver cancer. It also appears that aflatoxin B1 exposure coupled with hepatitis B virus infection produces an increased incidence of liver cancer compared to aflatoxin B1 or hepatitis B exposure individually. Mold contaminated food stuffs have also been shown to produce nitroso compounds.

There is substantial evidence that over nutrition either through excess calories and/or high fat diets contribute to a number of human cancers (Doll and Peto, 1981). In particular high fat and high calorie diets have been linked to breast, colon, and gall bladder cancer in humans. Diets poor in antioxidants and/or vitamins such as vitamin A and vitamin E probably also contribute to the onset of cancer. The method of cooking may also influence the production of carcinogens produced in the cooking process. Carcinogenic heterocyclic amines and polycyclic aromatic hydrocarbons are formed during broiling and grilling of meat. Acrylamide, a suspected human carcinogen has been found in fried foods at low concentrations.

A number of occupations have been associated with the development of specific cancers (Table 8-25). As noted earlier, the linkage between chimney sweepers who as young boys in England were exposed to polyaromatic hydrocarbons through constant exposure to soot, developed scrotal cancer. The linkage between occupational

Table 8-27
IARC Classification of the Evaluation of Carcinogenicity for Human Beings

GROUP	EVIDENCE
1. Agent is carcinogenic to humans	Human data strong
	Animal data strong
2A. Agent is probably carcinogenic to humans	Human epidemiology data suggestive
	Animal data positive
2B. Agent is possibly carcinogenic to humans	Human epidemiology data weak
	Animal data positive
3. Agent is not classifiable as to carcinogenicity to humans	Human and animal data inadequate
4. Agent is probably not carcinogenic to humans	Human and animal data negative

exposure to asbestos and the development of bronchiogenic carcinoma and as well as malignant mesothelioma has been clearly established. The appearance of bronchiogenic carcinoma was much higher in shipyard workers who were exposed to both asbestos as well as cigarette smoking. Muscat and Wynder (1991) noted no association between cigarette smoking and mesothelioma formation. Similarly, asbestos exposure by itself (without smoking) does not seem to increase the risk of bronchiogenic carcinoma. Aromatic amines used in the chemical and dye industries have been shown to produce or induce bladder cancer in humans. Prolonged high exposure to benzene in an occupational setting has been linked to the formation of acute myelogenous leukemia in humans.

A number of medical therapy and medical diagnostic tools have also been linked to the induction of human cancer (Table 8-26). Cancer chemotherapeutic drugs, such as the alkylating agent cyclophos-

phamide, have been associated with bladder tumors and leukemia in patients receiving these treatments. The administration of the synthetic estrogenic compound diethylstilbestrol to pregnant women, in order to improve embryo implantation and prevent spontaneous abortion, has been shown to result in the formation of clear cell carcinomas of the vagina in the female offspring of mothers treated with diethylstilbestrol during pregnancy. The use of oral contraceptives containing synthetic estrogens as their major or only component has been implicated in the induction of liver cell adenomas. In addition, an association exists between prolonged use of estrogenic oral contraceptives and an increased incidence of premenopausal breast cancer. Androgenic steroids and synthetic testosterone compounds have been implicated in hepatocellular carcinoma induction. Therapeutic immunosuppression given to transplant patients or arising secondary to selective diseases such as acquired immune deficiency syndrome (AIDS) result in an increase in a variety of different neoplasms. These results further support the role of the immune system in identifying and removing early preneoplastic cells from the body. In addition, the previously used diagnostic tracer Thorotrast has been sufficiently linked to the formation of hemangiosarcomas in the liver.

Classification Evaluation of Carcinogenicity in Humans

The assessment and designation of a chemical or a mixture of chemicals as carcinogenic in humans is evaluated by various agencies worldwide. The evaluation usually encompasses both epidemiological and experimental animal and in vitro data utilizing assays as described earlier in this chapter. One of the first devised schemes for the classification of an agent's carcinogenicity was devised by the International Agency for Research on Cancer (IARC) (Table 8-27). The IARC approach assigns the chemical or mixture to one of five groupings based upon strength of evidence for the
