CHAPTER 18

TOXIC RESPONSES OF THE HEART AND VASCULAR SYSTEM

Y. James Kang

INTRODUCTION

Cardiovascular toxicology is concerned with the adverse effects of extrinsic and intrinsic stresses on the heart and vascular system. Extrinsic stress involves exposure to therapeutic drugs, natural products, and environmental toxicants. Intrinsic stress refers to exposure to toxic metabolites derived from nontoxic compounds such as those found in food additives and supplements. The intrinsic exposures also include secondary neurohormonal disturbance such as overproduction of inflammatory cytokines derived from pressure overload of the heart and counter-regulatory responses to hypertension. These toxic exposures result in alterations in biochemical pathways, defects in cellular structure and function, and pathogenesis of the affected cardiovascular system. The manifestations of toxicologic response of the heart include cardiac arrhythmia, hypertrophy, and overt heart failure. The responses of the vascular system include changes in blood pressure and lesions in blood vessels in the form of atherosclerosis, hemorrhage, and edema.

This chapter is divided into two parts: the heart and the vascular system. For a better understanding of the toxic manifestations of the cardiovascular system, an overview of the physiology and biochemistry of the heart and the vascular system is presented in relation to toxicologic concerns. The toxicologic responses of the heart and the vascular system and the mechanisms of these responses are the major focus of this chapter. This chapter also presents a brief discussion of chemicals that affect the heart and the vascular system.

OVERVIEW OF THE HEART

Overview of Cardiac Structural and Physiological Features

Cardiac muscle, along with nerve, skeletal muscle, and smooth muscle, is one of the excitable tissues of the body. It shares many bioelectrical properties with other excitable tissues, but also has unique features associated with cardiac structural and physiological specificities. Figure 18-1 illustrates the basic anatomy of the heart. With regard to cardiac toxicology, this section will only review some features of cardiac physiology and structures. There are many textbooks of cardiac anatomy and physiology that provide extensive knowledge basis of cardiac physiology and structural properties, which will not be repeated in this section.

Review of Cardiac Structure   The primary contractile unit within the heart is the cardiac muscle cell, or cardiac myocyte. Cardiac myocytes are composed of several major structural features and organelles, as illustrated in Fig. 18-2. A primary component is the contractile elements known as the myofibril. Each myofibril consists of a number of smaller filaments (the thick and thin myofilaments). The thick filaments are special assemblies of the protein myosin, whereas the thin filaments are made up primarily of the protein actin. Cardiac myosin is a hexamer composed of one pair of myosin heavy chains (MHCs) and two pairs of myosin light chains (MLC). Two isoforms of MHC, α and β, are expressed in cardiac muscle; the expression of these is under developmental control and may be altered by a variety of physiologic, pathologic, and pharmacologic stimuli (Martin *et al.*, 1996; Metzger *et al.*, 1999). In addition, the predominant isoform expressed in normal adult cardiac tissue also depends on the species examined. Similarly, two isoforms of actin are expressed in the heart (cardiac and skeletal α-actin), and, as with MHC, actin isoform expression is influenced by developmental, physiologic, pathologic, and pharmacologic stimuli, and the primary isoform of actin found in normal adult cardiac muscle also depends on the species examined.

Under electron microscopy, these essential structural components of myocardial contractile proteins display alternating dark bands (A bands, predominantly composed of myosin) and light bands (I bands, predominantly composed of actin). Visible in the middle of the I band is a dense vertical Z line. The area between two Z lines is called a sarcomere, the fundamental unit of muscle contraction. Although cardiac and skeletal muscle share many similarities, a major difference lies in the organization of cardiac myocytes into a functional syncytium where cardiac myocytes are joined end-to-end by dense structures known as intercalated disks. Within these, there are tight gap junctions that facilitate action potential propagation and intercellular communication. About 50% of each cardiac myocyte is composed of myofibrils. The rest of the intracellular space contains the remaining major components of the cell: mitochondria (33%), one or more nuclei (5%), the sarcoplasmic reticulum (SR) (2%), lysosomes (very low), glycogen granules, a Golgi network, and cytosol (12%) (Opie, 1996).

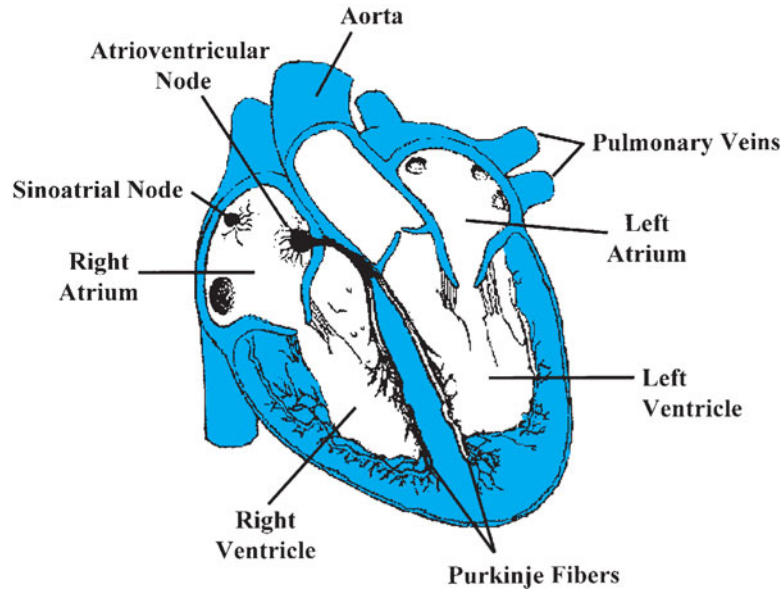
Cardiac myocyte is the largest cell in the heart and contributes to the majority of cardiac mass. However, cardiac myocytes make


Figure 18-1. Diagram illustrating the basic anatomy of the heart.

up only about one-quarter of all the cells in the heart. Cardiac fibroblasts, vascular cells, Purkinje cells, and other connective tissue cells make up the majority of cell number in the heart. Cardiac fibroblasts make up approximately 90% of these "nonmuscle" cells. Cardiac myocytes are generally considered to be terminally differentiated, although this view has been challenged recently (Anversa *et al.*, 2006). These cells may be multinucleated, but they may not divide after birth unless under certain circumstances in some species such as mice (Anversa *et al.*, 2006). The heart undergoes a significant increase in size and mass throughout growth of the organism, but the increase in heart size and mass is produced by enlargement (or hypertrophy) of preexisting cardiac myocytes (Li *et al.*, 1996). With regard to this developmental period, cardiac hypertrophy is considered to be a normal physiological process. Under pathological conditions, hypertrophy of remaining cardiac myocytes is a hallmark of cardiac remodeling following myocardial injuries, such as myocardial infarction. Cardiac fibroblasts may continue to proliferate after birth, particularly in response to injury. Cardiac fibroblasts also contribute to cardiac remodeling following myocardial infarction and are believed to promote fibrosis and scarring of injured cardiac tissue. Thus, from a toxicologic perspective, the heart is vulnerable to injury because of limited proliferative capacity of cardiac myocytes, and promotion of cardiac fibroblast proliferation and remodeling following injury.

Electrophysiology   The electrophysiology of the heart is concerned with bioelectricity and its related cardiac physiological function. Bioelectricity is the result of charge generated from the movement of positively and negatively charged ions in tissues. In cardiac myocytes, three major positively charged ions make a significant contribution to the bioelectricity of the heart; calcium (Ca^{2+}), sodium (Na^+), and potassium (K^+). Each of the ions has specific channels and transporters (pumps) on the membrane of cardiac myocytes. Through the movement of these ions across the cell membrane, an action potential is generated and propagated from one cell to another, so that electric conductance is produced in the heart.
Figure 18-2. Structural organization of cardiac muscle tissue.

Action Potential   Cardiac myocytes produce an action potential when activated. In the resting state, the resting potential of a myocyte is about -60 to -90 mV relative to the extracellular fluid potential. A sudden depolarization changes the membrane potential from negative inside to positive inside, followed by a repolarization
Figure 18-3. Characteristic cardiac action potential recorded from sinoatrial node and Purkinje fibers as indicated. (From Berne RM, Levy MN (eds.), Physiology pp. 454–457, 1983. With permission from Elsevier.)

to reset the resting potential. The process of an action potential from depolarization to the completion of repolarization is divided into five phases in cardiac Purkinje fibers as shown in Fig. 18-3. Phase 0 represents a rapid depolarization due to the inward current of Na^+. Phase 1 is associated with an immediate rapid repolarization, during which the Na^+ inward current is inactivated and a transient K^+ outward current is activated, followed by an action potential plateau or phase 2, which is dominated by slowly decreasing inward Ca^{2+} current and a slow activation of an outward K^+ current. Phase 3 reflects a fast K^+ outward current and inactivation of the plateau Ca^{2+} inward current, and phase 4 is the diastolic interval for the resetting of resting potential.

Automaticity A group of specialized cells in the heart are capable of repetitively spontaneous self-excitation, which generate and distribute each impulse through the heart in a highly coordinated manner to control the normal heart beat. These cells include the sinus node P cells and Purkinje fibers in the ventricles. Other cells such as atrial-specialized fibers under normal conditions do not have automaticity, but can become automatic under abnormal conditions. The sinus node P cells or pacemaker cells have only three distinct phases of action potential (Fig. 18-3): phase 0, rapid depolarization; phase 3, plateau and repolarization; and phase 4, slow depolarization or often referred to as *pacemaker potential*. It is the pacemaker potential that brings the membrane potential to a level near the threshold for activation of the inward Ca^{2+} current, which triggers the phase 0 rapid depolarization and makes the pacemaker cells of automaticity. In pacemaker cells, phase 0 is mediated almost entirely by increased conductance of Ca^{2+} ions.

Contractility Cardiac myocytes like other muscle cells have a unique functional feature, contractility. Myocyte contraction occurs when an action potential causes the release of Ca^{2+} from the SR

as well as the entry of extracellular Ca^{2+} into the cell. This action potential-triggered Ca^{2+} increase in the plasma and myocyte contraction is called *excitation–contraction coupling* (Fig. 18-4). The increase in Ca^{2+} concentrations in the cell allows Ca^{2+} to bind to troponin and tropomysin leading to some conformational change in the contractile unit of the cardiac myocyte, thin filament. This conformational change permits interaction between the actin and myosin filaments through the crossbridges (myosin heads). ATP is hydrolyzed by ATPase present in the crossbridges to release energy for the movement of the crossbridges in a ratchet-like fashion. This action increases the overlap of the actin and myosin filaments, resulting in shortening of the sarcomeres and contraction of the myocardium.

Electrotonic Cell-to-Cell Coupling Myocardium as a whole has to synchronize the contraction and relaxation of individual myocytes in order to perform its pump function. This is achieved by a special structural feature of cell-to-cell interaction, electrotonic cell-to-cell coupling via the gap junction. Through the gap junction, major ionic fluxes between adjacent cardiomyocytes are spread, thus allowing electrical synchronization of contraction. Each single gap junction is composed of 12 connexin 43 (Cx43) units, assembled in two hexametric connexons (hemichannels) that are contributed, one each, by the two participating cells. The connexins interact with other proteins within the cell so that connexons are not only important for cell-to-cell coupling, but also involved in cell signaling and volume regulation. An important feature of the connexon-controlled electrotonic cell-to-cell coupling is the electrotonic current flow that attenuates the differences in action potential duration of individual cardiac myocytes.

Electrocardiograph The electrophysiological features of cardiac myocytes and the electrotonic cell-to-cell coupling give rise to
Figure 18-4. Overview of excitation–contraction coupling in cardiac myocytes.

Upon rapid depolarization (rapid influx of Na^+ through fast channels; phase 0 of the action potential), L-type Ca^{2+} channels are opened allowing a slower but sustained influx of Ca^{2+} down the electrochemical gradient (phase 2 of the action potential). During the process of Ca^{2+}-induced Ca^{2+} release (CICR), slight elevation in intracellular-free Ca^{2+} stimulates Ca^{2+} release from the sarcoplasmic reticulum (SR) through ryanodine receptors (RyR). The SR provides the majority of Ca^{2+} required for contraction. The mitochondria provide energy for contraction in the form of ATP. Repolarization of the cell occurs largely by activation of K^+ channels and efflux of K^+ (phase 3 of the action potential). For relaxation, the SR Ca^{2+} ATPase (SERCA) actively pumps Ca^{2+} back into the SR, although some Ca^{2+} may be removed by the Na^+/Ca^{2+} exchanger or by sarcolemmal Ca^{2+} pumps.

charge at any given locus in the heart with a magnitude and a direction. Therefore, at any given moment in the cardiac cycle, there is a complex pattern of electrical charges across the membranes of myriad cells in the heart. The sum of all the individual cells that exist at any given time within the heart is the *resultant cardiac vector*. The changes in the resultant cardiac vector throughout the cardiac cycle can be recorded as a *vector cardiograph*. Lead systems are used to record certain projections of the resultant cardiac vector. The potential difference between two recoding electrodes represents the projection of the vector on the line between the two leads. Components of vectors projected on such lines eliminate their directions and have a sum of magnitude, being scalar quantities. Thus, a recording of the changes with time in the potential differences between two points on the surface of the skin is the so-called *scalar electrocardiograph*.

In general, the pattern of the scalar electrocardiograph consists of P, QRS, and T waves, as shown in Fig. 18-5. The PR interval is a measure of the time from the onset of atrial activation to the onset of ventricular activation. The QRS complex represents the conduction pathways through the ventricles. The ST segment is the interval during which the entire ventricular myocardium is depolarized, and lies on the isoelectric line under normal conditions. The QT interval is sometimes referred to as the period of "electrical systole" of the ventricles, and reflects the action potential duration. The QT interval prolongation is recognized as a major life-threatening factor of drug cardiac toxicity, which is brought about by a reduction of outward currents and/or enhanced inward currents during phase 2 and 3 of the action potential.

Neurohormonal Regulation   Although the heartbeat is governed by the automaticity of the sinus node P cells, neurohormonal regu-
Figure 18-5. A typical electrocardiogram (ECG) with the illustration of important deflections and intervals.

lation of cardiac electrophysiology and contraction controls cardiac function under normal and abnormal conditions. Toxicants often exert their effects on the cardiac system through interference with the neurohormonal regulation, thus this regulatory system is of significant relevance to cardiac toxicology. There are many neurohormonal systems that have significant impact on the heart. A detailed description of the regulatory system will be provided in the following sections in association with specific discussion of cardiac functional regulation, compensatory and maladaptive responses to toxic exposures.

Overview of Cardiac Energy Metabolism and Biochemistry

ATP and the Heart   It is easy to understand that the need of energy for the heart is high. The chemical energy in the form of ATP is absolutely needed to support the systolic and diastolic work of the heart (Ventura-Clapier *et al.*, 2004). In the heart, the primary ATP-utilizing reactions are catalyzed by actomyosin ATPase in the myofibril, the Ca^{2+}-ATPase in the SR, and the Na^+,K^+-ATPase in the sarcolemma (Ingwall and Weiss, 2004). ATP is also needed for molecular synthesis and degradation in the heart as in other organ systems. ATP synthesis by oxidative phosphorylation in the mitochondria is usually sufficient to support the normal needs of the heart, even when the work output of the heart increases three- to fivefold (Ingwall and Weiss, 2004). In addition, the glycolytic pathway and the tricarboxylic acid cycle also make small contributions to ATP synthesis. The concentration of ATP does not define the energetic state of the heart. The amount of ATP made and used at any given time is many times greater than the size of the measurable ATP pool (Ingwall and Weiss, 2004). Thus, cardiac myocytes contain high concentrations of mitochondria, which ensure that ATP remains constant through oxidation of a variety of carbon-based fuels for ATP synthesis under different conditions.

Phosphocreatine and the Heart   A unique feature in energy metabolism of the heart is the use of energy reserve systems, such as phosphocreatine (PCr), to maintain a high phosphorylation potential to drive ATPase reactions under highly demanding conditions (Ingwall *et al.*, 1985). PCr exists in the heart at twice the ATP concentration (Bittl and Ingwall, 1985). The enzyme creatine kinase (CK) transfers the phosphoryl group between ATP and PCr at a rate about 10 times faster than the rate of ATP synthesis by oxidative phosphorylation. The reaction catalyzed by CK is: PCr + ADP + H^+ ↔ creatine + ATP. Under the conditions when ATP demand exceeds ATP supply, the use of PCr is a major pathway to maintain a constant supply of ATP. The CK reaction is also important to maintain low ADP and Pi concentrations, thereby retaining high phosphorylation potential (Saupe *et al.*, 2000). Creatine is not made in the heart but accumulates against a large concentration gradient facilitated by a creatine transporter. In the normal heart, about two-thirds of the total creatine pool is phosphorylated through the CK reaction to form PCr (Wallimann *et al.*, 1998; Neubauer *et al.*, 1999).

Metabolic Pathways   The continuous synthesis of ATP via mitochondrial oxidative phosphorylation is mandatory for the work of the heart (Huss and Kelly, 2005). Under normal conditions, the oxidation of fatty acid (FA) is the major pathway, providing about 65% of the total energy demand. In contrast, the oxidation of glucose provides about 30% of the total energy demand (Shipp *et al.*, 1961; Wisneski *et al.*, 1987). In hypertrophic and failing hearts, there is a metabolic shift from FA- to glucose-dependent energy supply. Thus, decreased FA oxidation and increased glucose utilization in association with depressed FA deposition and increased glucose uptake are observed in hypertrophic and failing hearts (van Bilsen *et al.*, 2004). This shift enhances the glycolytic pathway, and thus increases the anaerobic metabolism. However, it remains debated whether this metabolic shift to the so-called "fetal phenotype" is adaptive or maladaptive. It is important to note that the "shift" is only partial, and even when the proportion of ATP synthesized from glucose increases many fold, aerobic metabolism still remains dominant (van Bilsen *et al.*, 2004). With regard to the concern of cardiac toxicology, the metabolic shift is often observed with mitochondrial dysfunction. In response to toxic exposure, mitochondrial damage leads to impaired oxidative phsphorylation and a metabolic shift from aerobic to anaerobic and a reliance on glucose utilization.

Calcium and Calcineurin   The role of calcium in cardiac toxic responses has been extensively investigated. However, our understanding of the role of calcium in cardiac toxicity remains superficial. When carefully examining the current literature, one can find that there are very few mechanistic studies that specifically probe the role of calcium in cardiac toxicity, although numerous studies have implicated intracellular Ca^{2+} as a signal for cardiac responses to environmental toxic insults (Shier *et al.*, 1992; Toraason *et al.*, 1997; Buck *et al.*, 1999). In response to myocardial stress by environmental toxic exposures, calcium concentrations are increased in the myocardial cells (Sleight, 1996). This is consistent with the speculation that Ca^{2+} coordinates physiological responses to stresses. There are many other speculations that are derived from the studies examining the role of calcium in toxicologic responses in other systems. The unique action of calcium in cardiac toxicity, however, has to be studied specifically.

The role of calcium in mediating myocardial hypertrophic signals has been extensively studied (Stemmer and Klee, 1994). A sustained increase in intracellular Ca^{2+} concentrations activates calcineurin. Calcineurin is a ubiquitously expressed serine/threonine phosphatase that exists as a heterodimer, comprises a 59-kDa calmodulin (CaM)-binding catalytic A subunit and a 19-kDa Ca^{2+}-binding regulatory B subunit (Molkentin *et al.*, 1998). Activation of calcineurin is mediated by binding of Ca^{2+} to the regulatory subunit and CaM to the catalytic subunit (Fig. 18-6). Of toxicologic relevance is that calcineurin is activated by a sustained increase in Ca^{2+} concentration and is insensitive to transient Ca^{2+} fluxes, such as in response to cardiomyocyte contraction (Stemmer and Klee, 1994).

Numerous studies have demonstrated important roles for Ras, mitogen-activated protein kinase (MAPK), and protein kinase C (PKC) signaling pathways in myocardial responses to hypertrophic stimuli (Jalili *et al.*, 1999). All of these signal transduction pathways are associated with increase in intracellular Ca^{2+} concentrations (Ho *et al.*, 1998). The coordinating role of calcium in cardiac hypertrophic response has been demonstrated (Stemmer and Klee, 1994) as follows. Hypertrophic stimuli, such as angiotensin II and phenylephrine, cause an elevation of intracellular Ca^{2+} that results in activation of calcineurin. A series of reactions occur through activated calcineurin, including dephosphorylation of nuclear factor of activated T-cell (NFAT) and its translocation to nucleus, where it interacts with GATA4 (Fig. 18-6). Calcineurin also acts through an NFAT-independent mechanism to regulate hypertrophic gene expression.

AMP-Activated Protein Kinase   Activation of AMP-activated protein kinase (AMPK) often occurs when the myocardial metabolic phenotype shifts to the fetal form. Activation of AMPK occurs with changes in high-energy phosphate metabolism in hypertrophic and failing hearts. The increase in AMP/ATP ratio occurs when the PCr/ATP ratio decreases due to a decrease in PCr, with or without a concomitant decrease in ATP. The decrease in PCr/ATP ratio is an index of decreased energy reserve and correlates with the severity of heart failure and is of prognostic value (Neubauer *et al.*, 1997).
Figure 18-6. Calcineurin signal transduction pathways in regulation of transcription factors involved in hypertrophic growth of cardiac myocytes.

Sustained increases in intracellular Ca^{2+} concentrations, along with calmodulin (CaM), activate calcineurin, which in turn causes dephosphorylation of nuclear factor of activated T cells (NFAT), enabling NFAT to translocate to the nucleus where it interacts with GATA4 to regulate gene expression. Phosphorylation of NFAT is stimulated by glycogen synthase kinase 3β (GSK3β), whose activity is inhibited by activation of the phosphoinositide 3-kinase (PI3K)/Akt pathway. Calcineurin also regulates CaM activation of CaM-dependent kinase (CaMK), which activates GATA transcription factor. CaMK also phosphorylates histone deacetylases (HDAC), leading to HDAC translocation from nucleus to cytoplasm. Otherwise, HDAC in the nucleus inhibits myocyte-enhancer factor 2 (MEF2) transcription activity. Cyclosporine A (CsA) and modulatory calcineurin-interacting protein (MCIP) inhibit calcineurin activation.

Activation of AMPK leads to translocation of the insulin-dependent glucose transporter (GLUT4) from intracellular stores to the sarcolemma (Russell *et al.*, 1999). Mice overexpressing an active form of AMPK suffer from pathological cardiac glucogen accumulation (Arad *et al.*, 2003). Furthermore, the AMPK-dependent phosphorylation of the enzyme 6-phosphofructo-2-kinase stimulates glycolysis (Marsin *et al.*, 2000). These pathways indicate the importance of AMPK activation for the cardiac metabolic shift to the energy supply reliance on glucose metabolism.

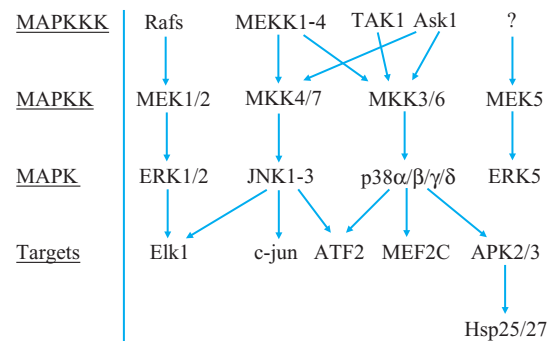
Mitogen-Activated Protein Kinases   MAPKs play a major role in cardiac response to toxic insults. A generalized diagram for MAPK signaling is presented in Fig. 18-7. The MAPKs consist of a series of successively acting kinases and three major branches are involved in the classic MAKP signaling pathway. These branches are divided based on their terminal effector kinases: the extracellular signal-regulated protein kniases (ERK), the c-jun NH2-terminal kinases (JNK), and p38 MAPKs (Sugden and Clerk, 1998). Each branch of the MAPKs has a hierarchy control system beginning at the MAPK kinase kinase (MAPKKK), as shown in Fig. 18-7. Among the MAPKs, p38 MAPKs have been extensively studied in myocardial apoptosis. This subfamily consists of p38α, p38β, p38γ, and p38δ (Sugden and Clerk, 1998). Several studies have identified p38 MAPKs as an important group of signaling molecules that mediate environmental stress responses in various cell types (Tibbles and Woodgett, 1999). In noncardiac cells, p38 MAPKs have been implicated in gene expression, morphological changes, and cell death in response to endotoxin, cytokines, physical stress, and chemical


Figure 18-7. Schematic representation of the hierarchy constituents of the MAPK signaling pathways.

MAPK, mitogen-activated protein kinase; MAPKK, MAPK kinase; MAPKKK, MAPK kinase kinase.

insults (Tan *et al.*, 1996; Wang and Ron, 1996). In cardiac cells, p38 MAPKs are associated with the onset of apoptosis in ischemia–reperfusion (Yin *et al.*, 1997). In particular, transfection experiments using primary cultures of neonatal rat cardiomyocytes have shown that p38α is critically involved in myocyte apoptosis (Wang *et al.*, 1998).

Adriamycin is a cardiac toxicant and two observations indicate that the p38 MAPK is involved in Adriamycin-induced myocyte apoptosis (Kang *et al.*, 2000a). First, a time–course analysis revealed that p38 MAPK activation preceded the onset of apoptosis. As early as 30 minutes after Adriamycin administration, myocyte apoptosis occurs, detected by a sensitive method of fluorescein isothiocyanate (FITC) conjugation of Annexin V (Annexin V-FITC). However, p38 MAPK activation detected by the FITC-conjugated anti-phospho-p38 antibody and confocal microscopy is observed 20 minutes after Adriamycin treatment (Kang *et al.*, 2000a). Second, SB203580, a specific inhibitor of p38 MAPKs, inhibits Adriamycin-induced myocyte apoptosis (Kang *et al.*, 2000a). Because SB203580 acts as a specific inhibitor of p38α and p38β, but not p38γ and p38δ, the involvement of the former specific isoforms of the p38 MAPK in the Adriamycin-induced myocyte apoptosis are implicated. p38α is involved in apoptosis of neonatal rat cardiomyocytes in primary cultures and p38β mediates hypertrophy of these cells (Wang *et al.*, 1998).

Protein Kinase C   PKC is among the most extensively studied signaling molecules in the heart. Many cardiac toxicologic studies have examined the role of PKC in mediating toxic signals. Several excellent reviews on PKC in myocardial signaling pathways leading to cardiac hypertrophy and heart failure are available (Puceat and Vassort, 1996). PKC is a ubiquitously expressed serine/threonine kinase, which is activated predominantly by G_q/G_{11}-coupled receptors. The PKC family consists of 11 isoforms, which are divided into three subgroups: conventional PKCs (cPKCs) including α, β (I and II), and γ, novel PKCs (nPKCs) including ε, δ, η, ζ, and θ, and atypical PKCs (aPKCs) including ι, λ, and μ (Newton, 1995). The cPKCs are activated by Ca^{2+} and diacylglycerol (DAG), as well as phorbol esters. The nPKCs do not bind Ca^{2+}, but respond to DAG and phorbol ester stimulation. The aPKCs do not respond to either Ca^{2+}, DAG, or phorbol esters. PKC has been demonstrated to participate in the regulation of transcription, the maintenance of cell growth and membrane structure, and modulation of immune responses. Disturbances in PKC signaling pathways

lead to cardiac hypertrophy and heart failure, which is of toxicologic significance.

Transcription Factors   Transcription factors activate or deactivate myocardial gene expression, which affects the function and phenotype of the heart. Many transcription factors have been studied in myocardial tissue. Several of them are of toxicologic significance as described below:

Activator Protein-1   AP-1 is a transcription factor composed of *Jun* and *Fos* gene family members (McMahon and Monroe, 1992). The AP-1-binding site is the TRE (12-*O*-tetradecanoyl phorbol 13-acetate response element), and the binding of AP-1 to the TRE initiates transcription of the target genes (Diamond *et al.*, 1990). Elevated levels of c-Jun are seen in cardiomyocytes with ischemia–reperfusion (Brand *et al.*, 1992). In volume-overload hypertrophy, AP-1 plays an important role in the regulation of Fas and FasL activities (Wollert *et al.*, 2000). Over-stretching of myocardium induces Fas expression (Cheng *et al.*, 1995). Subsequently, Fas-dependent signaling pathways can lead to myocardial cell apoptosis. However, there are other studies that indicate activation of AP-1 is not associated with the induction of apoptosis (Lenczowski *et al.*, 1997). AP-1 has been implicated in transcriptional regulation of several genes associated with a hypertrophic response (Paradis *et al.*, 1996).

Myocyte-Enhancer Factor-2   MEF-2 is a transcription factor that binds to A-/T-rich DNA sequences within the promoter regions of a number of cardiac genes, including muscle CK gene, β-MHC, MLC1/3, MLC2v, skeletal α-actin, SR Ca^{2+}-ATPase, cardiac troponin T, C, and I, desmin, and dystrophin (Black and Olsen, 1998). MEF2 is critically involved in the regulation of inducible gene expression during myocardial hypertrophy. The activation of MEF2 involves phosphorylation of the transcription factor by p38 MAPK or ERK5-MAPK. The ERK5-MEF2 pathway has been observed in the generation of cardiac hypertrophy. An important function of MEF2 is the convergence in the binary downstream pathway of Ca^{2+} signaling. Increased intracellular Ca^{2+} binds to and activates Ca^{2+}-binding proteins including CaM, which regulates calcineurin and Ca^{2+}/CaM-dependent protein kinase (CaMKs). Activation of either calcineurin or CaMKs induces cardiac hypertrophy. CaMKs stimulate MEF2 through phosphorylation of the transcriptional suppressor, histone deacetylases (HDACs). CaMK is considered as HDAC kinase whose activity is enhanced by calcineurin. Thus, MEF2 converges the stimulating signaling of both CaMKs and calcineurin leading to activation of hypertrophic gene expression (Fig. 18-6).

Nuclear Factor of Activated T Cells 3   NFAT3 is a member of a multigene family that contains four members, NFATc, NFATp, NFAT3, and NFAT4 (Rao *et al.*, 1997). These transcription factors bind to the consensus DNA sequence GGAAAAT as monomers or dimers through a Rel homology domain (Rooney *et al.*, 1994). Unlike the other three members that are restricted in their expression to T cells and skeletal muscle, NFAT3 is expressed in a variety of tissues including the heart. NFAT3 plays a major role in cardiac hypertrophy (Pu *et al.*, 2003). Hypertrophic stimuli, such as angiotensin II and phenylephrine, cause an increase in intracellular Ca^{2+} levels in myocardial cells. This elevation in turn results in activation of calcineurin. NFAT3 is localized within the cytoplasm and is dephosphorylated by the activated calcineurin. This dephosphorylation enables NFAT3 to translocate to the nucleus where it interacts with GATA4 (Fig. 18-6). NFAT3 can also activate some hypertrophic responsive genes through mechanisms independent of GATA4.

GATA   GATA factors are a family of nuclear transcriptional regulatory proteins that are related structurally within a central DNA-binding domain, but are restricted in expression to distinct sets of cell types (Yamamoto *et al.*, 1990). Currently, six different family members have been characterized in vertebrate species. They are GATA1, 2, 3, 4, 5, and 6. Each protein contains two similar repeats of a highly conserved zinc finger of the form $CXNCX_6LWRRX_7CNAC$. The c-terminal repeat constitutes a minimal DNA-binding domain sufficient for sequence-specific recognition of a "GATA" *cis*-element, usually (A/T)GATA(A/G) or a related DNA sequence, present in promoters and/or enhancers of target genes (Evans *et al.*, 1988). It has been shown that GATA-1/2/3 regulate various aspects of hematopoiesis (Orkin, 1992), whereas GATA 4/5/6 regulates cardiogenesis (Yamamoto *et al.*, 1990). The significance of GATA-4 in regulation of hypertrophic response in myocardial cells has been demonstrated (Evens, 1997). Cardiac hypertrophy induced by angiotensin II is mediated by an angiotensin II type$_{1\alpha}$ receptor ($AT_{1\alpha}R$). A GATA motif exists in the $AT_{1\alpha}R$ promoter. Mutations introduced to the consensus-binding site for GATA factor abolished the pressure overload response (Evens, 1997). Moreover, interactions between AP-1 and GATA-4, and between NFAT3 and GATA-4 are essential in myocardial hypertrophic responses.

CARDIAC TOXIC RESPONSES

Basic Concepts and Definitions

The ultimate functional effect of cardiac toxic manifestations is decreased cardiac output and peripheral tissue hypoperfusion, resulting from alterations in biochemical pathways, energy metabolism, cellular structural and function, electrophysiology, and contractility of the heart. These morphological and functional alterations induced by toxic exposure are referred to as toxicologic cardiomyopathy. The critical cellular event leading to toxicologic cardiomyopathy is myocardial cell death and extracellular matrix (ECM) remodeling. The recognition of the role of apoptosis in the development of heart failure during the last decade has significantly enhanced our knowledge of myocardial cell death (James, 1994; Haunstetter and Izumo, 1998; Sabbah and Sharov, 1998).

Manipulation of genes responsible for cardiac function began in the mid-1990s (Robbins, 2004). The most important conclusion of these studies is that a sustained expression of any single mutated functional gene, either in the form of gain-of-function or loss-of-function, can lead to a significant phenotype, often in the form of cardiac hypertrophy and heart failure (Robbins, 2004; Olson, 2004). However, it is difficult to apply this knowledge to patients: first, acquired cardiac disease such as heart failure is the result of interaction between environmental factors and genetic susceptibility, indicating the role of polymorphisms. Second, extrinsic and intrinsic stresses produce lesions that cannot be explained by a single gene or a single pathway, suggesting complexity between deleterious factors and the heart. Cardiac toxicity is the critical link between environmental factors and myocardial pathogenesis.

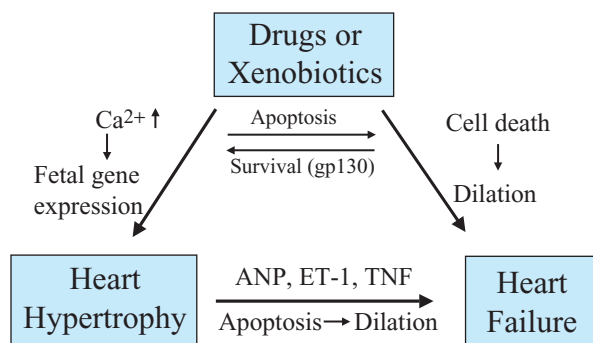
For a better understanding of cardiac toxicology, a triangle model of cardiac toxicity is presented in Fig. 18-8. In this model, complexity of the interaction between environmental stresses and the heart, and the balance between myocardial protection and


Figure 18-8. Triangle analytical model of cardiac responses to drugs and xenobiotics.

Drugs or xenobiotics can directly cause both heart failure and heart hypertrophy. Under severe acute toxic insults, myocardial cell death becomes the predominant response leading to cardiac dilation and heart failure. In most cases, myocardial survival mechanisms can be activated so that myocardial apoptosis is inhibited. The survived cardiomyocytes often become hypertrophy through activation of calcium-mediated fetal gene expression and other hypertrophic program. If toxic insult continues, the counter-regulatory mechanisms against heart hypertrophy such as activation of cytokine-mediacted pathways eventually lead to myocardial cell death through apoptosis or necrosis, dilated cardiomyopathy, and heart failure.

deleterious dose and time effects are considered. First, it is important to recognize that chemicals can lead to heart failure without heart hypertrophy. Second, a chemical can lead to activation of both protective and destructive responses in the myocardium. Third, long-term toxicologic responses often result in maladaptive hypertrophy, which primes the heart for malignant arrhythmia, leading to sudden death or transition to heart failure.

In the study of cardiac toxicology, the manifestations of cardiac toxicity in human patients and animal models are critical parameters serving as indices of cardiac toxicity. These manifestations are expressed in the forms of cardiac arrhythmia, hypertrophy, and heart failure. These abnormal changes reflect myocardial functional alterations resulting from both acute and chronic cardiac toxicity. Although some changes, such as cardiac hypertrophy, was viewed as a compensatory response to hemodynamic changes in the past, more recent studies suggest that cardiac hypertrophy is a maladaptive process of the heart in response to intrinsic and extrinsic stresses (van Empel *et al.*, 2004; Berenji *et al.*, 2005; Dorn and Force, 2005). Cardiac hypertrophy is a risk factor for sudden cardiac death and has a high potential to progress to overt heart failure. Therefore, a distinction between compensatory and maladaptive responses is critical for treatment of patients with toxicologic cardiomyopathy.

Cardiac Arrhythmia   Cardiac rhythms under physiological conditions are set by pacemaker cells that are normally capable of developing spontaneous depolarization and responsible for generating the cardiac rhythm, the so-called automatic rhythm. A cardiac rhythm that deviates from the normal automatic rhythm is called cardiac arrhythmia, often manifested in the form of tachycardia (fast heart rate). There are several classes of tachycardia, including sinus tachycardia, atrial tachycardia, ventricular tachycardia, and torsade de pointes (TdP) (a life-threatening ventricular tachycardia). In addition, subclasses such as atrial fibrillation, atrial flutter, and accelerated idioventricular rhythm provide further description of the manifestations of arrhythmia. Mechanisms for different classes

of arrhythmia will be discussed in the section of QT-prolongation and sudden cardiac death. According to the cause of the tachycardia, it is divided into abnormal automatic arrhythmia and triggered arrhythmia, which will be discussed in other sections.

Cardiac Hypertrophy   There are two basic forms of cardiac hypertrophy: concentric hypertrophy, which is often observed during pressure overload and is characterized by new contractile-protein units assembled in parallel resulting in a relative increase in the width of individual cardiac myocytes (De Simone, 2003). By contrast, eccentric hypertrophy is characterized by the assembly of new contractile-protein units in series resulting in a relatively greater increase in the length than in the width of individual myocytes, occurring in human patients and animal models with dilated cardiomyopathy (Kass *et al.*, 2004). Toxicologic cardiomyopathy is often manifested in the form of eccentric hypertrophy. The development of cardiac hypertrophy can be divided into three stages: Developing hypertrophy, during which period the cardiac workload exceeds cardiac output; compensatory hypertrophy, in which the workload/mass ratio is normalized and normal cardiac output is maintained; decompensatory hypertrophy, in which ventricular dilation develops and cardiac output progressively declines, and overt heart failure occurs (Richey and Brown, 1998).

Heart Failure   A traditional definition of heart failure is the inability of the heart to maintain cardiac output sufficient to meet the metabolic and oxygen demands of peripheral tissues. This definition has been modified recently to include changes in systolic and diastolic function that reflect specific alterations in ventricular function and abnormalities in a variety of subcellular processes (Piano *et al.*, 1998). Therefore, a detailed analysis to distinguish right ventricular from left ventricular failure can provide a better understanding of the nature of the heart failure and predicting the prognosis.

Acute Cardiac Toxicity   Acute cardiac toxicity is referred to as cardiac response to a single exposure to a high dose of cardiac toxic chemicals. It is often manifested by cardiac arrhythmia. However, myocardial apoptosis is also involved in acute cardiac toxicity. It is not difficult to define acute cardiac toxicity; however, it sometimes is technically difficult to measure acute cardiac toxicity. In particular, the impact of acute cardiac toxicity on the ultimate outcome of cardiac function is not often easily recognized. For instance, a single high dose of arsenic can lead to cardiac arrhythmia and sudden cardiac death, which is easy to measure (Goldsmith and From, 1980). However, that a single oral dose of monensin (20 mg/kg) leads to a diminished cardiac function progressing to heart failure in calves requires a long-term observation; often a few months for clinical signs of heart failure (van Vleet, *et al.*, 1983; Litwak *et al.*, 2005), which is difficult to measure. As shown in Fig. 18-8, toxic exposure can directly lead to heart failure, which is different from an often-observed hypertrophic response, which may or may not progress to heart failure.

Chronic Cardiac Toxicity   Chronic cardiac toxicity is the cardiac response to long-term exposure to chemicals, which is often manifested by cardiac hypertrophy and the transition to heart failure. About 25% of human patients with cardiomyopathy are categorized as having idiopathic cardiomyopathy. At least a portion of these patients with idiopathic cardiomyopathy are due to chemical exposure. Environmental exposure to particulate matter (PMs) in the air

can lead to cardiomyopathy, which has only been recognized recently (Dockery, 2001; Gordon and Reinman, 2002). Recognition of chronic cardiac toxicity in the pathogenesis of cardiomyopathy is of clinical relevance, and this knowledge can be used to prevent and treat patients with toxicologic cardiomyopathy.

Myocardial Degeneration and Regeneration

Myocardial degeneration is the ultimate response of the heart to toxic exposure, which can be measured by both morphological and functional degenerative phenotypes. However, myocardial degeneration should not be considered an irreversible toxic response. In the past, the heart has been considered incapable of regenerating, so that cardiac injury in the form of cell loss or scar tissue formation was considered permanent damage to the heart. However, evidence now indicates myocardial regeneration and recovery from cardiomyopathy. Cardiac toxic responses or damage are now divided into reversible and irreversible.

Myocardial Degenerative Responses   Myocardial cell death, fibrosis (scar tissue formation), and contractile dysfunction are considered as degenerative responses, which can result in cardiac arrhythmia, hypertrophy, and heart failure. If acute cardiac toxicity does not affect the capacity of myocardial regeneration, the degenerative phenotype is reversible. Both acute and chronic toxic stresses can lead to irreversible degeneration, depending on whether or not the cardiac repair mechanisms are overwhelmed. Cell death is the most common phenotype of myocardial degeneration. Both apoptosis and necrosis occur in the process of myocardial cell death, which will be discussed in the next section. Myocardial cell death is accompanied by hypertrophy of the remaining cardiac myocytes so that in the hypertrophic heart, the total number of cardiac myocytes is reduced but the size or volume of individual cells is increased.

During myocardial remodeling after cell death, not only is there an increase in the size of cardiac myocytes, but also cardiac fibrosis occurs. Myocardial fibrosis results from excess accumulation of ECM, which is mainly composed of collagens. The net accumulation of ECM connective tissue results from enhanced synthesis or diminished break down of the matrix, or both. Collagen, predominately type I and III, are the major fibrous proteins in ECM and their synthesis may increase in response to toxic insults. The degradation of ECM is dependent on the activity of matrix metalloproteinases (MMPs). According to their substrate specificity, MMPs fall into five categories: collagenases (MMP-1, MMP-8, and MMP-13), gelatinases (MMP-2 and MMP-9), stromelysins (MMP-3, MMP-7, MMP-10, and MMP-11), membrane-type MMPs (MMP-14, MMP-15, MMP-16, MMP-17, MMP-24, and MMP-25), and metalloelastase (MMP-12). These MMPs are organ specific so that not all are present in the heart. The activities of these enzymes are altered during the processes of fibrogenesis and fibrinolysis. Under toxic stress condition, the imbalance between fibrogenesis and fibrinolysis leads to enhanced fibrogenesis and excess collagen accumulation—fibrosis.

Toxic Effect on Myocardial Regeneration   The mainstay of cardiac medicine and therapy has centered on the concept that the heart is a terminally differentiated organ and that cardiac myocytes are incapable of proliferating. Thus, cell death would lead to a permanent loss of the total number of cardiac myocytes. However, this view has been challenged recently due to the identification of cardiac progenitor cells (Anversa *et al.*, 2006). These cells are characterized and proposed to be responsible for cardiac repair because these cells can make myocytes and vascular structures. These cells possess the fundamental properties of stem cells, therefore, they are also called cardiac stem cells. They are self-renewing, clonogenic, and multipotent, as demonstrated by reconstitution of infarcted heart by intramyocardial injection of cardiac progenitor cells or the local activation of these cells by growth factors. It is important to note that toxicologic studies of the cardiac progenitor cells have not been done and it is important to determine the potential of cardiac stem cells to help recover from toxic insults. The effect of chemicals on the cardiac progenitor cells is unknown. One speculation is that when severe damage to cardiac progenitor cells occurs, the potential for recovery from severe cardiac injury would be limited.

The removal of scar tissue or fibrosis in the myocardium in the past has been considered impossible. Although there are no studies that have shown scar tissue is removable, there are observations in animal models of hypertensive heart disease that myocardial fibrosis is recoverable (Weber, 2005).

Myocardial vascularization is required for myocardial regeneration. Many toxic insults affect the capacity of angiogenesis in the myocardium, so that cardiac ischemia occurs. The combination of cardiac ischemia and the direct toxic insults to cardiomyocytes constitute synergistic damage to the heart. During regeneration, coronary arterioles and capillary structures are formed to bridge the dead tissue (scar tissue) and supply nutrients for the survival of the regenerated cardiomyocytes. There is an orderly organization of myocytes within the myocardium and a well-defined relationship between the myocytes and the capillary network. This proportion is altered under cardiac toxic conditions; either toxicologic hypertrophy or diminished capillary formation can lead to hypoperfusion of myocytes in the myocardium. Unfortunately, our understanding of the toxic effects on myocardial angiogenesis is limited.

Reversible and irreversible toxic response. Cardiomyopathy was viewed not to be recoverable in the past, but there is cumulative evidence that demonstrates reversibility of cardiomyopathy. The issue related to whether or not toxicologic cardiac lesions are reversible has not been explored. However, it can be speculated that there would be reversible and irreversible manifestations of the cardiac response to toxic insults.

Myocardial Cell Death and Signaling Pathways

Apoptosis and Necrosis   Toxic insults trigger a series of reactions in cardiac cells leading to measurable changes. Mild injuries can be repaired. However, severe injuries will lead to cell death in the modes of apoptosis and necrosis. If the cell survives the insults, structural and functional adaptations will take place.

Apoptosis was found to be involved in cardiomyopathy in 1994 (Gottlieb *et al.*, 1994). The loss of cardiac myocytes is a fundamental part of myocardial injury, which initiates or aggravates cardiomyopathy. An important mode of myocardial cell loss is apoptosis, which has been demonstrated in heart failure patients (Olivetti *et al.*, 1997). Myocardial apoptosis has been shown to play an important role in cardiac toxic effects induced by Adriamycin (Kang *et al.*, 2000a; Wang *et al.*, 2001a), an important anticancer drug whose clinical application is limited by its major toxic effect, cardiotoxicity. Exposure of primary cultures of cardiomyocytes to cadmium also induces apoptosis (El-Sherif *et al.*, 2000).

Many in vivo studies have shown that only a very small percentage of myocardial cell populations undergo apoptosis under

pathological conditions. For example, less than 0.5% of cells appeared apoptotic in myocardial tissue under the stress of dietary copper deficiency in mice (Kang *et al.*, 2000b). At first glance, this number seems to be too insignificant to account for myocardial pathogenesis. In a carefully designed time–course study (Kajstura *et al.*, 1996), it was estimated that cardiomyocyte apoptosis is completed in less than 20 hours in rats. Myocytes that undergo apoptosis are lost and may not be replaced under toxicologic conditions. Although the possibility of myocardial regeneration has been identified (Anversa *et al.*, 2006), xenobiotics often cause degenerative effect through apoptosis as well as inhibitory effect on regeneration. Adriamycin-induced cardiomyopathy is a good example for the pathogenesis resulting from both degeneration and inhibition of regeneration. If apoptosis occurs at a constant rate of about 0.5% myocytes a day (Kang *et al.*, 2000b), the potential contribution of apoptosis to the overall loss of myocytes over a long period of time is significant under Adrimaycin toxic exposure.

    Necrosis is a term that had been widely used to describe myocardial cell death in the past. Myocardial infarction, in particular, had been considered as a consequence of necrosis (Eliot *et al.*, 1977). It is now recognized that apoptosis contributes significantly to myocardial infarction (Yaoita *et al.*, 2000). However, the importance of necrosis in myocardial pathogenesis cannot be underestimated. The contribution of necrosis to cardiomyopathy induced by environmental toxicants and pollutants is particularly important. A critical issue is how to distinguish apoptosis from necrosis.

    Apoptosis and necrosis were originally described as two distinct forms of cell death that can be clearly distinguished (Wyllie, 1994). However, these two modes of cell death can occur simultaneously in tissues and cultured cells. The intensity and duration of insults may determine the outcome. Triggering events can be common for both types of cell death. A downstream controller, however, may direct cells toward a programmed execution of apoptosis. If the apoptotic program is aborted before this control point and the initiating stimulus is severe, cell death may occur by necrosis (Leist *et al.*, 1997).

    To distinguish apoptosis from necrosis, specific oligonucleotide probes have been developed to recognize different aspects of DNA damage (Didenko *et al.*, 1998), and have been successfully applied, in combination with confocal microscopy, to identify apoptotic and necrotic cell death in the heart with different pathogenic challenges.

Single-Strand DNA Breaks   A monoclonal mouse anti-ssDNA antibody has been developed that is specifically reactive with ssDNA, but does not recognize dsDNA. An immunohistochemical assay for detection of ssDNA using this antibody in combination with a terminal deoxynucleotidyl-transferase-mediated dUTP nick end labeling(TUNEL) assay can distinguish repairable ssDNA breaks from apoptotic DNA damage in the heart.

    Apoptotic DNA damage produces end products that are fragments of double-strand DNA cleavage with 3′ overhang (Didenko *et al.*, 1998), which can be specifically identified by *Tag* polymerase-generated probe (Didenko *et al.*, 1998). The specificity of this molecular probe to identify apoptosis has been confirmed by other methods such as dual labeling of TdT and caspase-3 (Frustaci *et al.*, 2000). In addition, this apoptotic specific probe in combination with fluorescence labeling of different cellular components allows quantitative detection of apoptotic cells, with the possibility of identifying the origin of the apoptotic cells, such as myocytes (stained with α-sarcomeric actin), endothelial cells (stained with factor VIII),

and fibroblasts (stained with vimentin) in the heart (Anversa, 2000).

    Necrotic DNA damage is characterized by double-strand DNA cleavage with blunt ends. That is because during necrosis, the release of lysosomal proteases degrades histones, resulting in loss of DNA protection and exposure to endonucleases and exonucleases. Endonucleases produce double-strand DNA cleavage with 3′ overhangs, but exonucleases remove terminal nucleotides, leading to a bunt end of the damaged DNA. A probe generated by *pfu* polymerase can specifically recognize these blunt-end DNAs (Anversa, 2000). Its specific reaction with necrotic DNA has been confirmed by other methods such as the permeability of myosin antibody into necrotic cells (Guerra *et al.*, 1999), and the disruption of the sarcolemma by vinculin staining, which can clearly define the continuity of the sarcolemmal surface (Yamashita *et al.*, 2001).

    Proportion of apoptotic and necrotic cell death in the heart can be estimated by the combination of the above procedures. First, a conventional TUNEL procedure can be used to identify the total TUNEL-positive cells. Second, the procedure to define double-strand DNA breaks with blunt ends can be used to quantify the proportion of necrotic cells in the total TUNEL-positive population. Finally, the combination of the procedure to identify double-strand DNA breaks with 3′ overhangs, and the specific antibody to identify total ssDNA breaks can distinguish the proportion of apoptotic cells from those with ssDNA breaks only.

    Distinguishing apoptotic myocytes from non-myocytes in the myocardium is another problem to overcome. An in situ TUNEL assay in combination with a dual immunohistochemical detection of α-sarcomeric actin has been used to distinguish apoptotic myocytes from non-myocytes (Kang *et al.*, 2000a). Apoptotic myocytes are dually stained by TUNEL and α-sarcomeric actin, and apoptotic non-myocytes are stained only by TUNEL. Another procedure is immuno-gold TUNEL and electron microscopic examination of the apoptotic cells (Kang *et al.*, 2000a). The gold standard for identification of apoptotic cells is morphological examination by electron microscopy. The immuno-gold TUNEL and electron microscopic procedure defines cell type and morphological characteristics of apoptotic cells.

Mitochondrial Control of Cell Death   The role of mitochondria in myocardial response to toxicants as well as therapeutic drugs has long been a focus of investigation. Mitochondrial control of cell death is an important topic of apoptotic research during the last decade. Factors affecting mitochondrial control of cell death is presented in Fig. 18-9. These factors have the same target effect: modification of mitochondrial permeability transition (MPT).

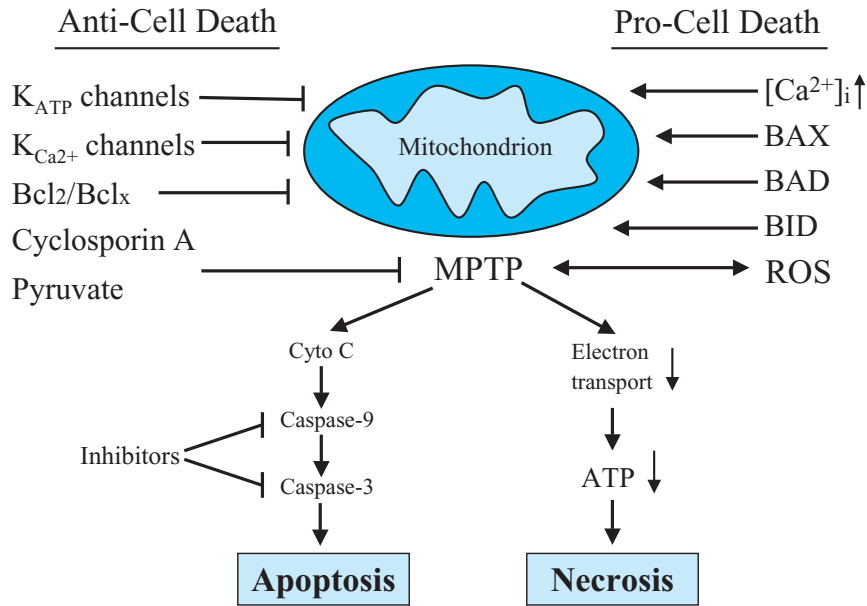
    Mitochondrial permeability transition occurs under toxic insults (Kroemer *et al.*, 1997). This MPT behaves like a membrane pore that allows diffusion of solutes <1500 Da in size. Although MPT can occur as a temporary event, it can rapidly become irreversible, with the resulting loss of mitochondrial homeostasis and high-amplitude mitochondrial swelling. Because the inner membrane has a larger surface area than the outer membrane, mitochondrial swelling can cause the rupture of the outer membrane, releasing intermembrane proteins into the cytosol (Reed *et al.*, 1998). Among the intermembrane proteins is cytochrome *c*. Another possible mechanism that leads to mitochondrial cytochrome *c* release is the action of Bax, a proapoptotic protein of the Bcl-2 family (Adams and Cory, 1998). Overexpression of Bax under oxidative stress conditions has been observed in a number of studies using different


Figure 18-9. Major factors affecting mitochondrial MPTP and myocardial cell death.

Mitochondrial cytochrome *c* release is a critical factor controlling cardiomyocyte apoptosis. Mitochondrial permeability transition pore (MPTP) opening is a determinant factor for cytochrome *c* release, as well as for electron transport collapsing leading to decreases in ATP production. The factors affecting MPTP thus are classified as pro-cell death and anti-cell death. Many other factors also affect cell death programs such as apoptosis inducing factor (AIF) released from mitochondria, but the involvement of MPTP is not evidenced.

tissues including the heart (Cook *et al.*, 1999). It has been shown that Bax is translocated from cytosol to mitochondria and forms pores in mitochondrial outer membranes, leaving the inner membranes intact (Jurgensmeier *et al.*, 1998). This mechanism implies that Bax-mediated cytochrome *c* release is independent of MPT (Saikumar *et al.*, 1998). The release of cytochrome *c* from mitochondria into the cytosol is a critical initiation step in myocardial apoptosis. Cytochrome *c* aggregates with apoptotic protease activating factor-1 (apaf-1, another factor released from mitochondria under oxidative stress), procaspase-9, and dATP, and subsequently activates caspase-9, which activates caspase-3. The apoptotic pathway involving mitochondrial cytochrome *c* release and caspase-3 activation is presented in Fig. 18-10. To determine the significance of the caspase-3-activated apoptotic pathway in the pathogenesis of toxicologic cardiomyopathy, a caspase-3-specific inhibitor, Ac-DEVD-cmk, is often used. For instance, treatment of cultured cardiomyocytes isolated from neonatal mice with Ac-DEVD-cmk efficiently suppressed caspase-3 activity and reduced the number of apoptotic cells in cultures under treatment with Adriamycin (Wang *et al.*, 2001a).

Defective mitochondrial oxidative phosphorylation has been extensively investigated ever since the identification of mitochondrial oxidative phosphorylation. The link between defective oxidative phosphorylation and pathogenesis of cardiomyopathy has been revealed recently. The early phase of defects in oxidative phosphorylation increases mitochondrial outer membrane permeability, leading to cytochrome *c* release, thus resulting in cytochrome *c*-mediated caspase-9 activation and thereby caspase-3 activation, leading to apoptosis (Fosslien, 2001). The defective oxidative phosphorylation also leads to depletion of cellular ATP levels, resulting in necrosis
Figure 18-10. Mitochondrial control of myocardial apoptotic pathway.

Exposure to drugs or xenobiotics can cause mitochondrial MPTP opening and cytochrome *c* release, which in association with apaf-1 and in the presence of dATP, activates caspase-9. Caspase-9 consequently activates caspase-3 leading to apoptosis. Factors regulating the apoptotic pathway include those listed in Fig. 18-9, such as Bax and Bcl-2. Ac-DEVD-cml is a selective inhibitor of caspase-3.
Figure 18-11. *Diagram of the electron-transferring complexes I, II, III, and IV and the ATPase (V) present in the inner mitochondrial membrane.*

The respective complexes are I, NADH: ubiquinone oxidoreductase; II, succinate: ubiquinone oxidoreductase; III, ubiquinol: ferrocytochrome *c* oxidoreductase; IV, ferrocytochrome *c*: oxygen oxidoreductase; V, ATP synthesase. UQ 5 ubiquinone or coenzyme Q. The mitochondrial electron transport chain is coupled at three points so that the electron transfer between carriers is sufficiently exergonic to drive the transport of protons and to establish an electrochemical proton gradient upon which ATP formation depends. Various inhibitors and their sites are also noted.

(Fosslien, 2001). Figure 18-11 presents a generalized mitochondrial oxidative phosphorylation process, including electron-transferring complexes and ATP production. Detection of mutated or otherwise defective components in oxidative phosphorylation is important for understanding the myocardial cell death by xenobiotics.

Abnormal mitochondrial biosynthesis is also linked to myocardial pathogenesis. Nuclear DNA encodes mitochondrial proteins, and thus nuclear DNA damage can lead to mutated products and abnormal mitochondrial biosynthesis. However, mitochondrial DNA encodes essential elements for mitochondrial function. Mitochondrial DNA is subjected to far more oxidative injury than nuclear DNA due to the lack of histones and high exposure to reactive oxygen species (ROS) generated by the electron transport chain. Mitochondrial DNA repair exists, although the repair is not as efficient as that of nuclear DNA repair. Due to these unique characteristics of mitochondrial DNA, cumulative mitochondrial DNA damage under oxidative stress conditions such as Adriamycin treatment, leads to irreversible mitochondrial dysfunction in the heart (Zhou *et al.*, 2001). This cumulative and relatively irreversible oxidative mitochondrial dysfunction concept has an important impact on our understanding of chronic as well as late-onset cardiomyopathy of anthracyclines. These drugs cause cardiomyopathy sometimes months to years after cessation of the drug therapy. During this time period, subtle pathological changes that may not be detectable but may continue to accumulate and lead to an overt toxic event. The cumulative and irreversible mitochondrial dysfunction might explain such a phenomenon, and may contribute to the delayed myocardial pathogenesis by Adriamycin.

Generation of reactive oxygen species has been ascribed as an "unwanted" function of mitochondria. Drugs and other chemicals have been studied individually to determine how they produce ROS; however, debate continues regarding the importance of each identified pathway as well as the site of ROS generation in mitochondria. In general, it is accepted that changes in mitochondrial membrane potential are critically involved in ROS generation. There are two important potassium channels that play important roles in mitochondrial membrane permeability. The first is the mitochondrial ATP-sensitive potassium channel (Akao *et al.*, 2001), and the second is the Ca^{2+}-activated potassium channel in the cardiac inner mitochondrial membrane (Xu *et al.*, 2002). It has been shown that diazoxide opens mitochondrial ATP-sensitive potassium channels and preserves mitochondrial integrity, as well as suppresses hydrogen peroxide-induced apoptosis in cardiomyocytes (Akao *et al.*, 2001). The Ca^{2+}-activated potassium channels, in contrast, contribute to mitochondrial potassium uptake of myocytes, and opening of these channels protects the heart from infarction (Xu *et al.*, 2002).

Death Receptors and Signaling Pathways   Death receptor-mediated apoptotic signaling pathway has been one of the focuses of cardiotoxicity research. In this regard, cytokines that trigger the death receptor signaling pathways have been studied. Among these cytokines is tumor necrosis factor-α (TNF-α) (Kubota *et al.*, 2001), the most studied cytokine in myocardial cell death signaling pathways. The pathway leading to TNF-α-induced myocardial apoptosis is mediated by TNF receptors, TNFR1, and TNFR2. TNF-α-binding of these receptors leads to activation of caspase 8, which in turn cleaves BID, a BH3 domain-containing proapoptotic Bcl2 family member. The truncated BID is translocated from cytosol to mitochondria, inducing first the clustering of mitochondria around the nuclei and release of cytochrome *c*, and then the loss of mitochondrial membrane potential, cell shrinkage, and nuclear condensation,
Figure 18-12. Simplified presentation of death receptors-mediated myocardial apoptosis.

The cardiotoxicity-related death receptors include Fas and tumor necrotic factor receptor 1 (TNFR1), as shown. Other death receptors such as DR3 and DR4/5 are not included in the figure. Both Fas- and TNFR1-activated apoptotic pathways can be altered by drugs and xenobiotics directly or indirectly through changes in the production of Fas ligand (FasL) or TNF-α. Fas activation activates caspase-8 through Fas-associated death domain (FADD). TNFR1 activates TNF-R1-associated death domain (TRADD), leading to activation of FADD. TNFR1 also activates a receptor-interacting protein (RIP), which activates caspase-2 through the adaptor protein, RIP-associated ICH-1/CED-3 homologous protein with a death domain (RAIDD). Both caspase-8 and caspase-3 activate the apoptosis executor proteins, caspase-3, -6 and -7.

i.e., apoptosis. Caspase 8 also directly activates caspase-3, leading to apoptosis (Fig. 18-12). Besides TNF-α, Fas ligand is also able to induce apoptosis of cardiomyocytes through the death receptor-mediated signaling pathway (Hayakawa *et al.*, 2002).

The death receptor-mediated apoptosis thus can be divided into mitochondrion-dependent and mitochondrion-independent signaling pathways. There is a bewildering diversity of programmed cell death paradigms related to the mitochondrion-controlled process, eventually leading to caspase-3 activation and apoptosis. Under chronic toxic insults, the relative importance of mitochondrial MPT pore opening, cytochrome *c* release, and electron transport defects needs to be critically examined in order to understand the process or mode of cell death.

There are two important questions that need to be carefully addressed. First, how important is apoptosis in the overall pathogenesis of cardiomyopathy under different conditions? It essentially is a universal observation that apoptosis is involved in the cardiotoxicity of drugs and chemicals; however, there is very limited information regarding its significance in a quantitative manner in contribution to cardiomyopathy. This concern is followed by the second important question: can caspase inhibitors offer long-term protection against myocardial cell death leading to prevention of cardiomyopathy? It is important to note that apoptosis and necrosis are linked phenomena sharing common triggers, such as MPT pore opening, as depicted in Fig. 18-13. For instance, some studies have shown that caspase inhibitors effectively inhibit apoptosis, but cell death occured by necrosis instead of apoptosis (Suzuki *et al.*, 2001). It is thus important to define the most efficient approach to blocking myocardial cell
Figure 18-13. Interchange between apoptotic and necrotic cell death pathways regulated by mitochondrial MPTP.

Mitochondrial MPTP opening leads to cytochrome *c*-mediated activation of apoptotic pathway, which is ATP dependent. However, MPTP formation also leads to electron transport collapse and reduced ATP production, which eventually leads to necrosis. Inhibition of caspase-3 also potentially switches the cell death program from apoptotic to necrotic if the exposure to drugs or xenobiotics is persistent.

death rather than inhibiting a particular cell death program (Kang, 2001).

It is important to note that apoptosis is an energy-dependent process and that the switch in the decision between apoptosis and necrosis depends on ATP concentrations (Eguchi *et al.*, 1997), as depicted in Fig. 18-13. In particular, conditions causing ischemia by many drug and chemical exposures to myocardial cells result in significant reduction and eventual depletion of adenine nucleotides. Loss of more than 70% of the total ATP pool present in myocardial cells results in a switch from apoptosis to necrosis (Leist *et al.*, 1999). This extent of ATP depletion is observed in myocardial infarction.

Cardiac Hypertrophy and Heart Failure

Adaptive and Maladaptive Responses   Myocardial adaptation refers to the general process by which the ventricular myocardium changes in structure and function. This process is often referred to as "remodeling." During maturation, myocardial remodeling is a normal feature for adaptation to increased demands. However, in response to pathological stimuli, such as exposure to environmental toxicants, myocardial remodeling is adaptive in the short term, but is maladaptive in the long term, and often results in further myocardial dysfunction. The central feature of myocardial remodeling is an increase in myocardial mass associated with a change in the shape of the ventricle (Frey and Olson, 2003).

At the cellular level, the increase in myocardial mass is reflected by cardiac myocyte hypertrophy, which is characterized by

enhanced protein synthesis, heightened organization of the sarcomere, and the eventual increase in cell size. At the molecular level, the phenotype changes in cardiac myocytes are associated with reintroduction of the so-called fetal gene program, characterized by the patterns of gene expression mimicking those seen during embryonic development. These cellular and molecular changes are observed in both adaptive and maladaptive responses, thus distinguishing adaptive from maladaptive responses is difficult.

Adaptive Response   There is both physiological hypertrophy and pathological hypertrophy of the heart. Physiological hypertrophy is considered an adaptive response, which is an adjustment of cardiac function for an increased demand of cardiac output. Such an adaptive hypertrophy is the increase in cardiac mass after birth and in response to exercise. A biochemical distinction of the adaptive hypertrophy is that myocardial accumulation of collagen does not accompany the hypertrophy. Functionally, the increased mass is associated with enhanced contractility and cardiac output. In response to toxicologic stresses, the heart also often increases its mass, which has been viewed as an adaptive response as well. However, most recent evidence suggests that cardiac hypertrophy is a maladaptive process of the heart in response to intrinsic and extrinsic stresses.

Maladaptive Response   Although toxic stress-induced hypertrophy can normalize wall tension, it is a risk factor for sudden death and has a high potential to progress to overt heart failure. A distinction between adaptive and maladaptive hypertrophy is whether the hypertrophy is necessary for the compensatory function of the heart under physiological and pathological stress conditions. Many studies using genetically manipulated mouse models, either in the form of gain-of-function or loss-of-function, have supported the hypothesis that cardiac hypertrophy is neither required nor necessarily compensatory. For instance, forced expression of a dominant-negative calcineurin mutant confers protection against hypertrophy and fibrosis after abdominal aortic construction (Zou *et al.*, 2001). Also, the elimination of hypertrophy in animals by calcineurin suppression did not cause compromised hemodynamic changes over a period of several weeks (Hill *et al.*, 2000). Therefore, in these experimental approaches, hypertrophic growth could be abolished in the presence of continuous pressure overload, but the compensatory response could not be compromised. An interesting observation is that an almost complete lack of cardiac hypertrophy in response to aortic banding in a transgenic mouse model was accompanied with a significant slower pace of deterioration of systolic function (Esposito *et al.*, 2002). These observations indicate that cardiac hypertrophy in response to extrinsic and intrinsic stress is not a compensatory response. However, cardiac hypertrophy increases the risk for malignant arrhythmia and heart failure, and thus is now viewed as a maladaptive response.

Hypertrophic Signaling Pathways   Extrinsic and intrinsic stresses activate signaling transduction pathways leading to fetal gene program activation, enhanced protein synthesis of adult cardiomyocytes, and the eventual hypertrophic phenotype. The signaling pathways include several components: G-protein-coupled receptors, protein kinases including MAPK, PKC, and AMPK, calcium and calcineurin, and phosphoinositide 3-kinase (PI3K)/glycogen synthase kinase 3β (GSK3β), and transcription factors. Activation of each of the components is sufficient to induce myocardial hypertrophic growth. These components also affect each other through crosstalk. The diagram presented in Fig. 18-14 briefly summaries these pathways and their interactions. Among these pathways, protein kinases, calcium/calcineurin, and transcription factors have been discussed above. A brief summary for the G-protein-coupled receptors and the PI3K/GSK3 pathway is presented as follows:

G-Protein-Coupled Receptors   Myocardial adrenergic, angiotensin, and endothelin (ET-1) receptors belong to G-protein-coupled receptors, which are coupled to three major classes of heterotrimeric GTP-binding proteins, $G_{\alpha s}$, $G_{\alpha q}/G_{\alpha 11}$, and $G_{\alpha i}$. Activation of $G_{\alpha q}$-coupled receptors is sufficient to induce myocyte hypertrophy in vitro (Adams *et al.*, 1998). Cardiac-specific ablation of $G_{\alpha q}/G_{\alpha 11}$ in adult animals causes an almost complete lack of cardiac hypertrophy in response to aortic banding (Wettschureck *et al.*, 2001). Overexpression of a dominant-negative mutant of $G_{\alpha q}$ in transgenic mouse hearts suppresses pressure–overload hypertrophy (Akhter *et al.*, 1998). Cardiac overexpression of $G_{\alpha s}$, the downstream effector of β1-adenergic receptors in the heart, initially increases contractility, but eventually results in cardiac hypertrophy, fibrosis, and heart failure (Bisognano *et al.*, 2000).

Phosphoinositide 3-Kinase/Glycogen Synthase Kinase3β Pathway   Activation of PI3K is found in both physiological and pathological hypertrophy. Insulin-like growth factor (IGF) is involved in the growth of the heart after birth (Shioi *et al.*, 2002). Overexpression of IGF induces cardiac hypertrophy (Delaughter *et al.*, 1999). IGF signals through PI3K to the serine/threonine kinase Akt or protein kinase B. Both PI3K and the Akt induce hypertrophic growth of adult hearts. Overexpression of constitutively active PI3K mutant in the heart leads to increased heart size in mice, and expression of dominant-negative PI3K results in a small heart (Shioi *et al.*, 2000). Overexpression of Akt induces cardiac hypertrophy in transgenic mice without adverse effects on systolic function (Matsui *et al.*, 2002). Akt phsophorylates GSK3β, thus inhibits the activation of GSK3β. Otherwise, the activated GSK3β phosphorelates transcription factors of the NFAT family (Fig. 18-14). As discussed above, activation of calcineurin dephosphorylates NFAT3 in the cytoplasm, which enables NFAT3 to translocate to the nucleus where it can activate hypertrophic gene expression dependent on or independent of GATA4. Phosphorylation of NFAT3 in the nucleus by GSK3β promotes NFAT3 translocation to the cytoplasm, becoming inactive. Hypertrophic stimuli such as β-adrenergic agonist isoproterenol, ET-1, and phenylepherine all induce GSK3β phosphorylation in a PI3K-dependent fashion, indicating possible requirement of inactivation of GSK3β through phosphorylation in hypertrophic growth of the heart.

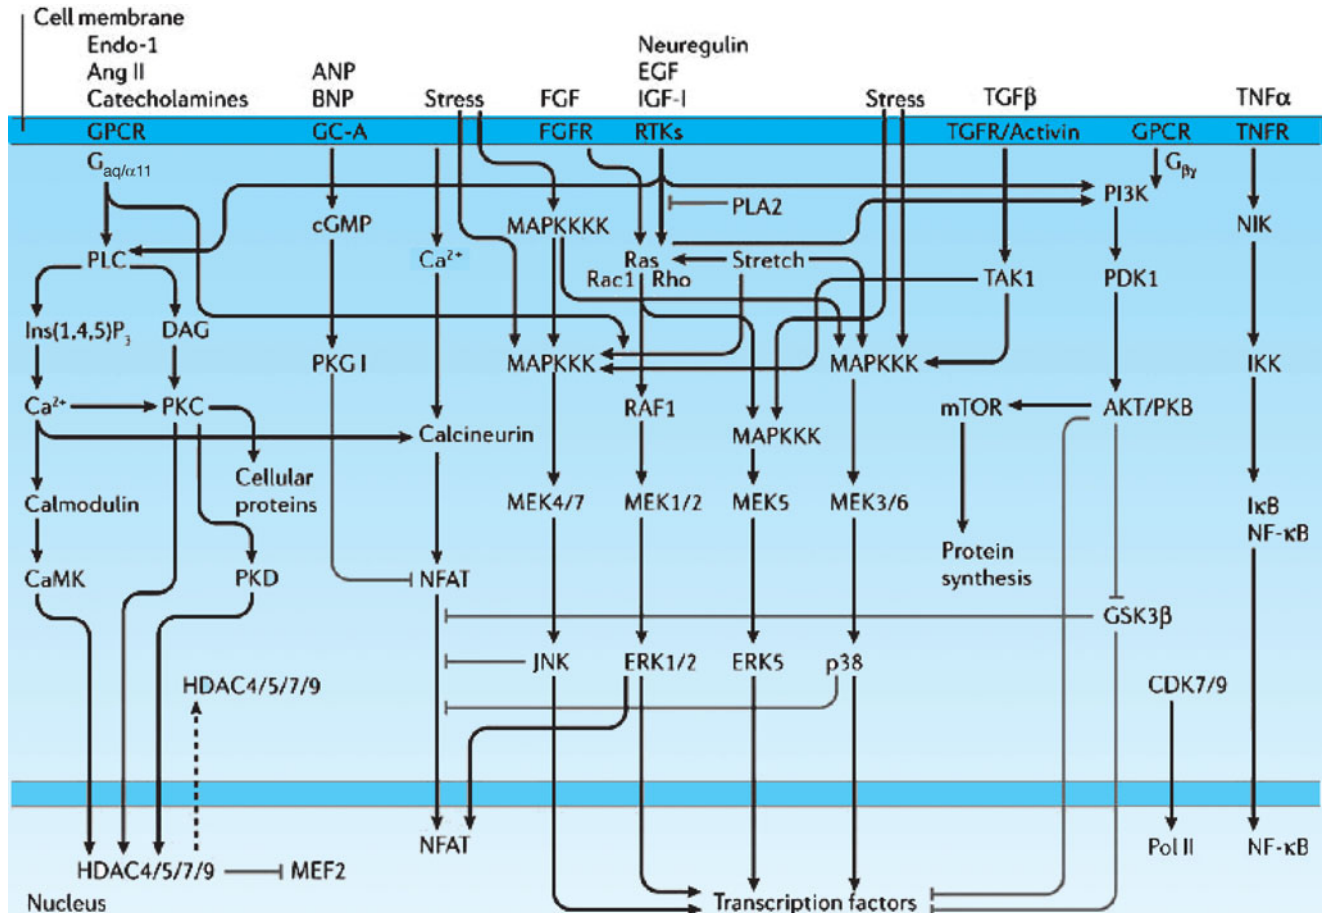
Transition from Cardiac Hypertrophy to Heart Failure   Pathological hypertrophy is a risk factor for malignant arrhythmia and heart failure. The link of heart hypertrophy to malignant arrhythmia will be discussed in the next section. The critical cellular event of this transition is myocardial apoptosis triggered by inflammatory cytokines, such as TNF-α, and neurohormonal factors, such as atrial natriuretic peptide (ANP), leads to dilated cardiomyopathy and deterioration of cardiac function. Toxicologic exposures may cause dilated cardiomyopathy or heart failure without an intermediate hypertrophic stage. Myocardial cell death also plays an essential role in direct cardiac dilation pathogenesis. Figure 18-15 illustrates the process of xenobiotic-induced transition from cardiac hypertrophy to heart failure.


Figure 18-14. *Overview of signaling transduction pathways involved in cardiac hypertrophic growth and their cross-talk interactions.*

The signalling that occurs at the sarcolemmal membrane is shown at the top and the intermediate transduction of signals by various kinases and phosphatases is shown in the middle. The nucleus is shown at the bottom. ANP, atrial natriuretic peptide; Ang II, angiotensin II; BNP, B-type natriuretic peptide; CaMK, calmodulin-dependent kinase; CDK, cyclin-dependent kinase; DAG, diacylglycerol; EGF, epidermal growth factor; Endo-1, endothelin-1; ERK, extracellular signal-regulated kinase; FGF, fibroblast growth factor; FGFR, FGF receptor; GC-A, guanyl cyclase-A; GPCR, G-protein-coupled receptors; GSK3β, glycogen synthase kinase-3β; HDAC, histone deacetylases; IκB, inhibitor of NF-κB; IGF-I, insulin-like growth factor-I; IKK, inhibitor of NF-κB kinase; Ins(1,4,5)P₃, inositol-1,4,5-trisphosphate; JNK, c-Jun N-terminal kinase; MAPKKK, mitogen-activated protein kinase kinase kinase; MAPKKKK, MAPKKK kinase; MEF, myocyte-enhancer factor; MEK, mitogen-activated protein kinase kinase; mTOR, mammalian target of rapamycin; NFAT, nuclear factor of activated T cells; NF-κB, nuclear factor-κB; NIK, NF-κB-inducing kinase; PDK, phosphoinositide-dependent kinase; PI3K, phosphatidylinositol 3-kinase; PKB, protein kinase B; PKC, protein kinase C; PKD, protein kinase D; PLA2, phospholipase A2; PLC, phospholipase C; Pol II, RNA polymerase II; RTK, receptor tyrosine kinase; TAK, TGFβ-activated kinase; TGF-β, transforming growth factor-beta; TGFR, TGF receptor; TNFα, tumour necrosis factor-α; TNFR, TNFα receptor. (Copied from *Nature Reviews of Molecular Cell Biology*, 7:589–600, 2006).

Alterations of biochemical reactions in the myocardium are often seen soon after exposure to environmental toxicants. These include alterations in ionic homeostasis, such as changes in intracellular calcium concentrations, which occur in most exposures to environmental toxicants (Symanski and Gettes, 1993). Aberrant energy metabolism is another early response to environmental toxicants in the heart, resulting in decreased production and/or enhanced consumption of ATP (Abas *et al.*, 2000). Alterations in enzymatic reactions are often described in cardiac toxic responses (Depre and Taegtmeyer, 2000). The early signaling pathways leading to myocardial toxic responses are the focus of current cardiac toxicology research (Piano, 1994). Detailed descriptions of these pathways and their role in cardiotoxicity are yet to be explored. It is likely that activation of signaling pathways is a critical response of myocardial cells to environmental toxic insults (Cheng *et al.*, 1999a). The crosstalk between signaling pathways determines the ultimate outcome of myocardial responses to chemicals.

Physiological alterations occur both as early responses to environmental toxicants and as subsequent events in the late development of cardiomyopathy. The most obvious myocardial dysfunction that occurs in the early responses to toxicants is cardiac arrhythmia (Peters *et al.*, 2000), which often results from the changes in intracellular calcium concentrations and other biochemical alterations, leading to miscommunication between cells and misconduction of electricity (Rosen, 1995). These changes, if not accompanied by cardiomyopathy, do not involve myocardial cell death and are reversible. In contrast, the late phase of cardiac dysfunction and arrhythmia, however, often result from cardiomyopathy.

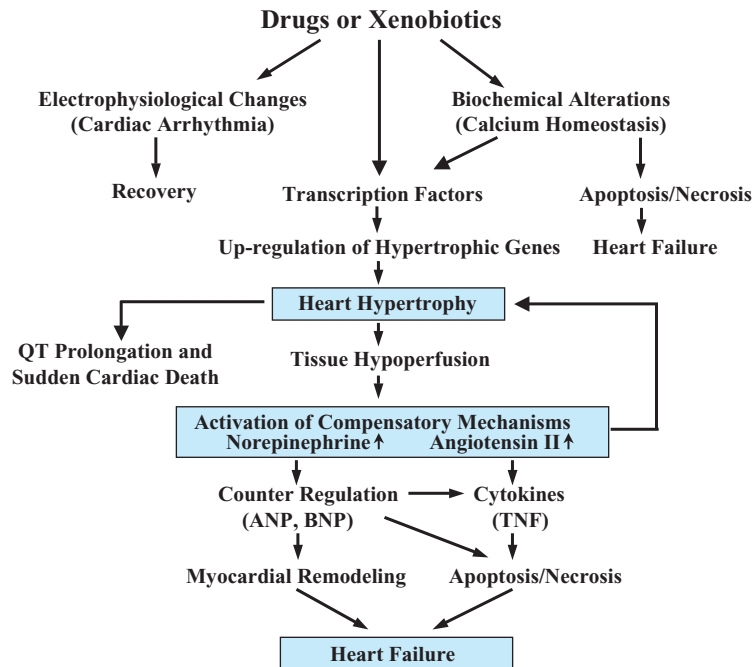
Changes in myocardial morphology take place when extensive toxic insults are imposed on the heart and/or toxic exposures persist (He *et al.*, 1996). Cardiac hypertrophy is often observed as a


Figure 18-15. Acute and chronic toxic exposure-induced heart failure and the transition from heart hypertrophy to heart failure.

Acute exposure to drugs or xenobiotics can cause cardiac arrhythmia, which is often observed. But if the toxic insult is so severe, myocardial apoptosis and necrosis become predominant leading to dilated cardiomyopathy and heart failure. However, the heart often survives from toxic insults through adaptive mechanisms involving upregulation of hypertrophic genes and heart hypertrophy. Heart hypertrophy increases the risk for QT prolongation and sudden cardiac death, and also activates neurohormonal regulatory mechanisms including elevation of plasma concentration of sympathetic neural transmitters and angiotensins. These compensatory mechanisms in turn activate counter-regulatory mechanisms such as ANP, BNP, and TNF-α. A long-term action of the counter-regulatory mechanisms leads to myocardial remodeling and the transition from heart hypertrophy to heart failure.

consequence of long-term toxic insults. From cardiac hypertrophy to heart failure, activation of compensatory mechanisms, including the sympathetic nervous system and the renin–angiotensin system occurs (Holtz, 1993). The compensatory response in turn activates counter-regulatory mechanisms such as upregulation of ANP expression (Francis and Chu, 1995) and increase in cytokines, such as TNF-α production. Extensive biochemical, physiological, and molecular changes result in myocardial remodeling (Swynghedauw, 1999) and remarkable cell death, ultimately leading to heart failure.

QT prolongation and Sudden Cardiac Death

Recognition of QT prolongation and its associated adverse effects on the heart has been a major focus in drug discovery and development during the last decade. A number of drugs have been found to cause QT prolongation and Torsade de pointes (TdP), and thus were removed from the market or relabeled for restricted use. It has been known for a long time that quinidine causes sudden cardiac death; however, the severe and lethal side effect of QT prolongation did not draw sufficient attention until the last decade, due to the lack of knowledge and experimental approaches to obtain a comprehensive understanding of QT prolongation. Knowledge on QT prolongation has accumulated and regulatory guidelines for a battery of preclinical tests to assess QT liability of a potential drug are recommended.

Definition of QT Prolongation   A simple definition for QT prolongation is that the length of QT interval observed from a typical electrocardiogram is prolonged. Clinically, long QT syndrome is defined when the QT interval is longer than 460 mseconds. However, TdP occurs with an average increase in QT interval by approximately 200 mseconds (a normal QT interval is about 300 mseconds). A human study has found that TdP does not occur with a QT interval shorter than 500 mseconds (Joshi *et al.*, 2004). In general, the long QT syndrome can be divided into two classes: congenital and acquired. Congenital long QT syndrome is rare and acquired is the major concern of drug cardiac toxicity in pharmaceutical discovery and development.

Molecular Basis of QT Prolongation   Prolongation of the QT interval on the electrocardiogram is caused by prolongation of the action potential of ventricular myocytes. In cardiac action potential, phase 0 represents depolarization of myocytes and the depolarization of all ventricular myocytes is measurable as the QRS complex on the electrocardiogram. Phase 1 of the cardiac action potential is recognized as a partial repolarization of the membrane due to inactivation of cardiac sodium channels, and activation of transit outward potassium channels. Phase 2 of the action potential is generated primarily by slowly decreasing inward calcium currents through

L-type calcium channels, and gradually increasing outward currents through several types of potassium channels. This phase is sensitive to small changes in ion currents and is a critical determinant of the duration of the action potential. At this point, the cardiac cycle of the electrocardiogram has returned to baseline. Phase 3 of the cardiac action potential represents myocardial cell repolarization due to outward potassium currents. There are two critical potassium channels that terminate the plateau phase (phase 2) and initiate the final repolarization phase 3: I_{kr} and I_{ks}. I_{kr} is the rapidly activating delayed rectifier potassium current, and I_{ks} is the slowly activating delayed rectifier potassium current. The repolarization phase correlates with the T wave on the electrocardiogram. Therefore, the duration of the QT interval is related to the length of the ventricular action potentials.

A reduction in net outward current and/or an increase in inward current are potential contributors to the prolongation of cardiac action potential, thereby QT prolongation on the electrocardiogram. Although many channels are potentially involved in the prolongation of the cardiac action potential, current studies have identified three important channels that play a critical role in the plateau phase (phase 2) of the cardiac action potential, sodium inward channels, and potassium outward channels (I_{kr} and I_{ks}).

Sodium channel dysfunction in congenital long QT syndrome is related to mutations in *SCN5A* gene that encodes the α-subunits of sodium channels. Mutational analyses have found 14 distinct mutations of *SCN5A* associated with long QT syndrome (Splawski *et al.*, 2000). It has been hypothesized that gain-of-function mutations in *SCN5A* would cause long QT syndrome because reopening of the sodium channels during the plateau phase of action potential, even in a small inward current, would lengthen the duration of the cardiac action potential. Sodium channel inactivation immediately following depolarization (phase 1) is important for the transition to phase 2 of the action potential. A mutation of *SCN5A* has been found to destabilize the inactivation gate (Bennett *et al.*, 1995). Activation of these mutant sodium channels is normal and the rate of inactivation appears slightly faster than normal, but these mutant channels can reopen during the plateau phase of the action potential, leading to a prolonged plateau phase.

The I_{kr} potassium channels critically affect the length of the plateau phase of the cardiac action potential. The human *ether-à-go-go*-related gene (*HERG*) is expressed primarily in the heart and encodes the α-subunit of the cardiac I_{kr} potassium channel. There are 94 mutations of *HERG*, which have been identified to represent 45% of the total number of mutations related to long QT syndrome to date (Splawski *et al.*, 2000). The HERG α-subunits assemble with MiRP1 β-subunits to form cardiac I_{kr} channels. The I_{kr} potassium channel is one of the two channels that are primarily responsible for termination of the plateau phase of the action potential. During the repolarization of the action potential, the I_{kr} channels open, resulting in an increase in the magnitude of I_{kr} current during the first-half of phase 3 repolarization. Many *HERG* mutations occur around the membrane-spanning domains and the pore region of the channel. Most of these mutations have a loss-of-function effect and many long QT syndrome-associated mutations in *HERG* are missense mutations, which lead to a dominant-negative effect on I_{kr} channels because the functional I_{kr} potassium channels are composed of heteromultimers including several HERG subunits. Therefore, the loss-of-function mutations in *HERG* make a critical contribution to the long QT syndrome due to the prolonged plateau phase of cardiac potential.

The I_{ks} potassium channel is the other one of the two channels primarily responsible for the termination of the plateau phase of the action potential. The I_{ks} potassium channel is assembled from KVLQT1 α-subunits and the minK β-subunits. There are two molecular mechanisms that possibly account for reduced KVLQT1 function in the long QT syndrome (Wollnik *et al.*, 1997). First, intragenic deletions of one *KVLQT1* allele result in synthesis of abnormal α-subunits that do not assemble with normal subunits, leading to a 50% reduction in the number of the functional channels. Second, missense mutations result in synthesis of KVLQT1 subunits with structural abnormalities, which can assemble with normal subunits. Channels formed from the mutant KVLQT1 subunits have reduced or no function. Both of these mutations result in a dominant-negative effect. Interestingly, both *KVLQT1* and *minK* are expressed in the inner ear, in which the channels function to produce a potassium-rich fluid known as endolymph that bathes the organ of Corti, the cochlear organ responsible for hearing. Individuals with Jervell and Lange–Nielsen syndrome have homozygous mutations of *KVLQT1* or minK, thus having no functional I_{ks} channels. These individuals have severe arrhythmia susceptibility and congenital neural deafness.

Therefore, the molecular basis of the QT prolongation on the electrocardiogram is the prolongation of cardiac action potential. In this regard, the inward sodium channels and outward potassium channels play an important role in increasing the length of the plateau phase of action potentials. Congenital long QT syndrome is related to gain-of-function mutations in sodium channels and/or loss-of-function mutations in potassium channels. Acquired long QT syndrome is also related to altered function of these channels; however, many other factors that affect the phenotype of long QT syndrome and the clinical manifestations.

Torsade De Pointes and Sudden Cardiac Death   The abnormalities of different channels in different regions of the heart at varying levels result in channel dysfunction with regional variability. The regional abnormalities of cardiac repolarization or conductance provide a substrate for arrhythmia. Under these conditions, arrhythmia is induced if a trigger mechanism is implanted. The trigger for arrhythmia in the long QT syndrome is believed to be spontaneous secondary depolarization that arises during or just following the plateau of the action potential. This small action potential is the so-called early afterdepolarization, which occurs preferentially in M cells and Purkinje cells due to reactivation of the L-type calcium channels and/or activation of the sodium–calcium exchange current. When the spontaneous depolarization is accompanied by a marked increase in dispersion of repolarization, the likelihood to trigger an arrhythmia is increased. Once triggered, the arrhythmia is maintained by a regenerative circuit of electrical activity around relatively inexcitable tissue, a phenomenon known as reentry. The development of multiple reentrant circuits within the heart causes ventricular arrhythmia, or TdP, leading to sudden cardiac death. Drugs causing TdP are considered severe cardiac toxic agents. There are several drugs that were removed from the market due to their TdP effect. These drugs include those recently removed cyclo-oxygenase-2 (COX-2) inhibitors, Vioxx and Bextra, which will be discussed in the "Cardiac Toxic Chemicals" section. QT prolongation effect is now a required test by the U.S. Food and Drug Administration for drug development.

Parameters Affecting QT Prolongation and Torsadogenesis
Alterations in the function of cardiac channels, or "cardiac channelopathies" occur at the cellular level. However, electrotonic cell-to-cell coupling influences the dispersion of repolarization. If myocardial cells with intrinsically different duration of action potential are well coupled, electrotonic current flow attenuates the differences in action potential duration in individual cardiomyocytes. Therefore, torsadogenesis results from not only cardiomyocytes, but also other types of cells and the interaction among these cells. There are many factors that affect the clinical manifestations of QT prolongation and torsadogenesis. Genetic polymorphisms and female gender are two distinct risk factors. The mechanism of the polymorphisms and the rationale for high susceptibility of females to QT prolongation and torsadogenesis are yet to be determined. The following factors are more descriptable.

Drugs and Environmental Toxicants   Drug-induced QT prolongation is a major acquired long QT syndrome. Selective blockers of potassium channels, including the drugs so-called class III antiarrhythmics, have been developed for the treatment of various atrial arrhythmias. However, these drugs predictably produce long QT syndrome, which is sufficient to cause TdP in 5–7% of recipients. Environmental exposure to PM pollution in air is a risk factor for QT prolongation in elders, children, and individuals with compromised hearts.

Disturbances in Ion Homeostasis   Hypokalemia in combination with torsadogenic drugs is a most recognized risk factor for QT prolongation and TdP. It is also shown that sodium supplementation can diminish the long QT syndrome due to the gain-of-function mutations in sodium channels. Stress-induced Ca^{2+} overload in myocardial cells increases the likelihood of arrhythmia. The electrode imbalance exerts more effect on compromised hearts.

Abnormal Gap Junction   Gap junction-mediated intercellular communication is essential in the propagation of electrical impulse in the heart. The gap junction is composed of connexons, as described in the cardiac physiology and structural features section. Under normal conditions, the gap junction electrotonic current flow attenuates the differences in action potential duration of myocardial cells. Toxicologic exposures cause damage to connexons leading to disruption of electrotonic cell-to-cell coupling, thus the differences in the action potential duration would be dominant, in particular under the influence of torsadogenic drugs or conditions.

Myocardial Ischemic Injury   Acute myocardial ischemia can cause immediate arrhythmia due to disturbance in ionic homeostasis, which is often transient. However, acute ischemia induces myocardial infarction can lead to block of cardiac conductance. Under the myocardial infarction, the areas separated by the scar tissue would be uncoupled, making the differences in the duration of action potential of myocardial cells in different regions apparent. The infarct heart thus is more susceptible to drug-induced QT prolongation and TdP.

Cardiac Hypertrophy   Purkinje fibers are derived from myogenic precursors during embryonic development. The normal distribution of Purkinje fibers in the myocardium is proportional to the mass of the heart. Cardiac hypertrophy resulting from the hypertrophic growth of cardiac myocytes would lead to unbalanced distribution of Purkinje fibers in the remodeling heart. The conduction of pacemaker potentials would thus be interrupted.

Myocardial Fibrosis   Dilated cardiomyopathy in alcoholics often involves myocardial fibrosis, which simulates the effect of myocardial infarction on the electrical conduction in the heart and the block of cardiac conductance.

Heart Failure   Most individuals with failing hearts die suddenly of cardiac arrhythmias. Heart failure presents a common, acquired form of the long QT syndrome. In human heart failure, selective downregulation of two potassium channels, I_{to1} and I_{k1}, has been shown to be involved in action potential prolongation. The I_{to1} current is involved in phase 1 of action potential and opposes the depolarization. The increase in depolarization may be adaptive in the short term because it provides more time for excitation–contraction coupling, mitigating the decrease in cardiac output. However, downregulation of potassium channels becomes maladaptive in the long term because it predisposes the individual to early afterdepolarization, inhomogeneous repolarization, and polymorphic ventricular tachycardia.

Biomarkers for Cardiac Toxicity

Myocardial injury can be divided into two major classes: structural and nonstructural injuries. The structural damage of the heart includes cell death and the associated histopathological changes such as myocardial infarction. Functional deficits often accompany the structural injury. Nonstructural damage represents functional deficits without apparent structural alterations. Myocardial adaptation to intrinsic and extrinsic stress leading to myocardial structural changes such as hypertrophy should be in the category of structural damage because the progression of hypertrophy leads to heart failure in which cell death is a major determinant factor. Myocardial structural changes and functional alterations can be indirectly measured by echocardiography and electrocardiogram in combination with stress testing. The data generated from these measurements can be considered in a broad sense as biomarkers. However, in clinical practice and experimental approach, biomarkers are referred to as indexes of myocardial injury measured from blood samples. The fundamental principle of the biomarkers is that molecules that are released from the myocardium under various injury conditions are readily detectable from blood samples.

Validation of Biomarkers   For a biomarker to be indicative of myocardial damage, an important question needs to be addressed is what characteristics are required for a valid biomarker. In 2000, an Expert Working Group (EWG) on biomarkers of drug-induced cardiac toxicity was established under the Advisory Committee for Pharmaceutical Sciences of the Center for Drug Evaluation and Research of the U.S. Food and Drug Administration. The report from this EWG has summarized the characteristics of ideal cardiac toxic injury biomarkers (Wallace *et al.*, 2004). These characteristics include cardiac specificity, sensitivity, predictive value, robust, bridge preclinical to clinical, and noninvasive procedure/accessibility. These characteristics are adapted as a standard for development and validation of a biomarker of myocardial injury.

Availability of Biomarkers   Currently validated biomarkers that are included in clinical diagnostic testing guidelines are all related to myocardial structural injury. Developing biomarkers for non-structural injury is most challenging and demands implantation of more advanced technologies such as functional genomics and proteomics. In addition, currently available biomarkers have limitations, although they are useful.

Creatine Kinase   There are three major CK isoenzymes identified; CK-MM is the principal form in skeletal muscle, CK-MB presents in myocardium in which CK-MM is also found, and CK-BB is the predominant form in brain and kidney. Elevation of serum CK-MB is considered a reasonably specific marker of acute myocardial infarction.

Myoglobin   Myoglobin is found in all muscle types and its value as a biomarker of myocardial injury is based on the fact that serum concentrations of myoglobin increase rapidly following myocardial tissue injury, with peak values observed 1–4 hours after acute myocardial infarction. Elevation of serum myoglobin is likely reflective of the extent of myocardial damage.

B-Type Natriuretic Peptide   BNP is a cardiac neurohormone secreted by the ventricular myocardium in response to volume and pressure overload, and the release of BNP appears to be directly correlated with the degree of ventricular wall tension. BNP is now accepted as a biomarker for congestive heart failure and is included in the European guideline for the diagnosis of chronic heart failure.

C-Reactive Protein   The acute phase reactant CRP is a marker of systemic and vascular inflammation, which appears to predict future cardiac events in asymptomic individuals. In particular, inflammation has been shown to play a pivotal role in the inception, progression, and destabilization of atheromas. A predictive value of CRP for the prognosis of coronary heart disease is thus proposed. The measurement of CRP appears to provide additional prognostic information when cTnT is measured at the same time.

Cardiac Troponins   Cardiac troponin T (cTnT) and I (cTnI) are constituents of the myofilaments and expressed exclusively in cardiomyocytes. It is thus of absolute myocardial tissue specificity. In healthy persons, serum cTnT or cTnI are rarely detectable. Therefore, any measurable concentrations of serum cTnT or cTnI reflect irreversible myocardial injury such as myocardial infarction. The clinical experience has arrived at a recommendation that cTn measurement becomes the "gold standard" for diagnosis of acute myocardial infarction.

Biomarker Applications and Limitations   All the biomarkers described above have been used as indices of myocardial injury in clinical practice and experimental studies. The major concern of most of the biomarkers is their specificity. CK-MB is present in small quantities in skeletal muscle and other tissues, thus elevations of CK-MB occur in some diseases involving skeletal muscle injury. Myoglobin is found in all muscle types and its concentrations vary significantly between species and even within species. BNP has been proposed to use as a prognostic indicator of disease progression and outcome of congestive heart failure. However, the actual utility of this biomarker is untested. BNP is involved in the counter-regulation of heart hypertrophy, thus the changes in serum BNP concentrations

as a function of time in the transition from cardiac hypertrophy to heart failure needs to be understood comprehensively. Higher levels of BNP may not necessarily indicate more severity of the heart disease, indicating that more scrutiny to analysis is needed. CRP is a biomarker of inflammation and its use in myocardial injury is more supplementary to other tests than having independently predictive value.

Considering all of the limitations above, more reliable biomarkers are needed. A significant advance in the development and validation of biomarkers for myocardial injury is the promising clinical experience with cTn, which has absolute myocardial tissue specificity and high sensitivity. It is now accepted by the clinical community that cTn as the biomarker of choice for assessing myocardial damage in humans. Its preclinical value for monitoring drug cardiac toxicity and in drug development need to be evaluated.

CARDIAC TOXIC CHEMICALS

Many substances can cause cardiac toxic responses directly or indirectly. However, only chemicals that primarily act on the heart or whose cardiac toxicity is the primary concern should be categorized as cardiac toxic chemicals. Clinically, the most recognized toxicologic cardiomyopathy is found in alcoholic heart muscle disease, which is often referred to as alcoholic cardiomyopathy (ACM). In this section, ACM will be discussed as a prototype of toxicologic cardiomyopathy. However, cardiomyopathy induced by therapeutic drugs is also well recognized, but it is often referred to as cardiomyopathy induced by specific chemicals, such as anthracycline cardiomyopathy. In this context, the chemicals that cause cardiac toxicity can be classified in multiple ways, however, this chapter will category them into (1) pharmaceutical chemicals, (2) natural products, and (3) environmental and industrial chemicals. Because general mechanisms of cardiotoxicity have been discussed above, these cardiac toxic chemicals will be briefly discussed.

Alcohol and Alcoholic Cardiomyopathy

ACM has been recognized for a long time (Klatsky, 1998) and the prevalence of ACM in selected populations ranges from 23% to 40% (Fauchier *et al.*, 2000; Mckenna *et al.*, 1998). Alcohol is believed to be the causal chemical in up to 40% of all patients with nonischemic, dilated cardiomyopathy (Gavazzi *et al.*, 2000). ACM is characterized by an increase in myocardial mass, dilation of the ventricles, wall thinning, ventricular dysfunction, and heart failure (Piano, 2002).

The pathogenesis of ACM is not completely understood. However, it is clear that the duration of heavy alcohol use in patients is a critical factor. Clinical data have shown that ACM typically is seen after a long term of consistent consumption of at least 80 g of alcohol per day (Regan, 1990; Lazarevic *et al.*, 2000). In general, asymptomatic ACM patients with changes in cardiac structure and function had a history of consuming >90 g/d of alcohol for more than 5 years (Lazarevic *et al.*, 2000). For the symptomatic ACM, some limited data have shown that more than 10 years of excessive alcohol consumption in alcoholics produces congestive heart failure (Mathews *et al.*, 1981).

The pathogenesis of heart failure begins after an index event such as alcohol-induced cardiac muscle injury that produces an initial decline in pumping capacity of the heart. Following this initial decline, a variety of compensatory mechanisms are activated, including the adrenergic nervous system, the renin–angiotensin

system, and the cytokine system. Some of these compensatory changes have been detected in alcoholic patients (Adams and Hirst, 1986). However, with time, the sustained activation of these systems can lead to secondary end-organ damage within the ventricle by activating and accelerating the left ventricle remodeling and subsequent cardiac decompensation, resulting in the transition from asymptomatic to symptomatic heart failure (Mathews *et al.*, 1981).

It was proposed that the metabolite acetaldehyde is responsible for some of the cardiac injury associated with ethanol consumption. The metabolic enzyme responsible for the conversion of ethanol to acetaldehyde is alcohol dehydrogenase, which is absent in cardiac myocytes. Studies have indicated that the impaired liver function of alcoholics may be sufficient to generate quantities of acetaldehyde that can reach the heart. The direct effects of acetaldehyde on the myocardium include inhibition of protein synthesis, inhibition of Ca^{2+} sequestration by the SR, alterations in mitochondrial respiration, and disturbances in the association of actin and myosin. The exact mechanism of ACM is unresolved. It has been suggested that a combination of multiple factors is involved, including malnutrition, cigarette smoking, systemic hypertension, and beverage additives, in addition to a long-term consumption of alcohol in the ACM patients (Ahmed and Regan, 1992).

The generation of reactive oxidative metabolites from the biotransformation of ethanol has been suggested to be a major contributing factor for ACM, because these metabolites lead to lipid peroxidation of cardiac myocytes or oxidation of cytosolic and membraneous protein thiols (Ribiere *et al.*, 1992; Kannan *et al.*, 2004). Most experimental approaches involve alcohol-containing liquid diet feeding to rodent models of ACM for several weeks to several months. However, a key factor for the development of ACM in humans is the duration of excessive consumption of alcohol. The simulation of daily excessive amount of alcohol consumption in rodents without disturbances in the food intake to produce nutritional deficiency is a constant challenge. One of the difficulties in using rodent models is that the short life span of the animals does not allow a sufficient long period of alcohol exposure to produce some of the critical pathological changes such as myocardial fibrosis observed in humans.

A recent study using a mouse model in which alcohol-induced heart hypertrophy and fibrosis were all produced, may have been a breakthrough. In this mouse model, a zinc-regulatory protein, metallothionein (MT), is genetically deleted and when zinc was exogenously added to the alcohol-containing liquid diet, alcohol-induced cardiac fibrosis, but not heart hypertrophy, in the MT knockout (MT-KO) mice was prevented (Wang *et al.*, 2005). Zinc deficiency is an important feature in alcoholic patients and animal models (McClain and Su, 1983; Bogden *et al.*, 1984). Zinc homeostasis within the cell is dependant on MT, which under physiological conditions binds 7 atoms of zinc (Kagi, 1991). The role of MT in the regulation of zinc homeostasis has been revealed only recently (Maret, 2000; Kang, 2006). The most important feature of MT is that under oxidative stress conditions, it releases zinc (Maret, 2000; Kang, 2006). In the MT-KO mice, alcohol-induced myocardial pathological changes are either accelerated or severely altered relative to those in WT mice. These pathological changes, in particular the myocardial fibrosis, resemble the pathology observed in patients with ACM.

There are several interesting clues that have been provided from the MT-KO mouse studies. First, the link between the deficiency in endogenously stored zinc due to the lack of MT and the alcohol-induced myocardial fibrosis is suggested by the fact that supplementation with zinc inhibits alcoholic myocardial fibrosis.

Second, the dissociation between alcohol-induced heart hypertrophy and myocardial fibrosis is suggested by the fact that supplementation with zinc only inhibits fibrosis but heart hypertrophy. Third, possible involvement of oxidative stress in the fibrogenesis is suggested by the fact that MT functions as an antioxidant (Kang, 1999) and zinc release from MT is an essential response of MT to oxidative stress (Maret, 2000; Kang, 2006), suggesting that oxidative stress is involved in the fibrogenesis. Further studies following the same direction will provide more comprehensive insights into the pathogenesis of ACM.

Pharmaceutical Chemicals

Cardiac toxicity of pharmaceutical chemicals is a major problem in drug development and their clinical application. The pharmaceutical chemicals that cause cardiac toxic responses can be simply classified as drugs that are used to treat cardiac disease, and others that are used to treat noncardiac disease. In the category of drugs used to treat cardiac disease, cardiac toxicity is often produced by overexpression of the principal pharmaceutical effects. Although overdosing of these drugs can be a major factor for untoward effects, cardiac toxicity is often inevitable for this group of drugs. Drugs such as digitalis, quinidine, and procainamide often cause acute cardiac toxicity in the form of arrhythmia, which is reversible upon cessation of their use. Other cardiac drugs that may cause cardiac toxicity by mechanisms different from that of the therapeutic action. For instance, catecholamines may cause cardiac toxicity through oxidative stress, rather than by their pharmaceutical action on the sympathetic nervous system. The other category is noncardiac drugs that produce cardiac toxicity. For instance, anthracyclines, such as Adriamycin, are effective anticancer drugs, but their ability to produce severe cardiac toxicity limits their use in cancer patients. Vioxx is a selective COX-2 inhibitor used as an anti-inflammatory drug, but it causes QT prologation and increases the risk for sudden cardiac death.

Antiarrhythmic Agents   Antiarrhythmic drugs have historically been classified based upon a primary mechanism of action: Na^+ channel blockers (class I), β-adrenergic blockers (class II), drugs that prolong action potential duration, especially K^+ channel blockers (class III), and Ca^{2+} channel blockers (class IV). However, this classification is artificial because most of the drugs have multiple mechanisms of action.

Class I antiarrhythmic agents are primarily Na^+ channel blockers, including disopyramide, encainide, flecainide, lidocaine, mexiletine, moricizine, phenytoin, procainamide, propafenone, quinidine, and tocainide. Blockade of cardiac Na^+ channels results in reduction of conduction velocity, prolonged QRS duration, decreased automaticity, and inhibition of triggered activity from delayed afterdepolarizations or early afterdepolarizations (Roden, 1996). The primary concern of Na^+ channel blocker toxicity is that proarrhythmic effects are seen at a much higher incidence in those patients with a previous history of myocardial infarction or with acute myocardial ischemia (Nattel, 1998). The proarrhythmic effects of these drugs would also be more prevalent in patients with other cardiac complications.

Class II antiarrhythmic drugs are β-adrenergic receptor-blocking drugs, including acebutolol, esmolol, propranolol, and sotalol. The catecholamines increase contractility, heart rate, and conduction through activation of β-adrenergic receptors in the heart. These effects can be explained by increased adenylyl cyclase

activity, increased cyclic AMP, activation of protein kinase A, and phosphorylation and activation of L-type Ca^{2+} channels, thereby increasing intracellular Ca^{2+}, and particularly the amplitude of the Ca^{2+} transient. Therefore, antagonists of β-adrenergic receptors in the heart lead to effects that are opposite that of catecholamines, and are useful for the treatment of supraventricular tachycardia. The main adverse cardiovascular effect of β-adrenergic receptor antagonists is hypotension. These drugs may also exacerbate AV conduction deficits (e.g., heart block) and promote arrhythmias during bradycardia.

Class III antiarrhythmic drugs are primarily K^+ channel blockers. These drugs include amiodarone, bretylium, dofetilide, ibutilide, quinidine, and sotalol. Blockade of K^+ channels increases action potential duration and increases refractoriness. Prolonged action potential duration contributes to the development of early afterdepolarizations and promotion of tachycardia, especially polymorphic ventricular tachycardia (torsades de pointes). The most noticeable adverse effect of these drugs is QT prolongation and torsadogenesis. Most of the drugs in this class also affect other ion channels and/or receptors. Amiodarone and quinidine also block Na^+ channels, whereas sotalol inhibits β-adrenergic receptors in the heart. Amiodarone prolongs action potential duration and effective refractory period of Purkinje fibers and ventricular myocytes, and the most common adverse cardiovascular effect of amiodarone is bradycardia. Amiodarone may also have cardiotoxic effects by stimulating excessive Ca^{2+} uptake, especially in the presence of procaine (Gotzsche and Pedersen, 1994).

Class IV antiarrhythmic drugs are Ca^{2+} channel blockers and include diltiazem and verapamil. The dihydropyridine Ca^{2+} channel blockers are not used to treat arrhythmias because they have a greater selectivity for vascular cells; however, these drugs may also alter cardiac ion homeostasis when plasma concentrations of the drugs are elevated. The dihydropyridines interact with Ca^{2+} channels in the inactivated state of the channel, and because vascular smooth muscle resting potentials are lower than cardiac cells, the time spent in the inactivated state is relatively longer in vascular smooth muscle, thus providing some preference of dihydropyridines for the vasculature (Galan *et al.*, 1998). Bepridil, verapamil, and diltiazem exert negative inotropic and chronotropic effects. These drugs also exert a negative chronotropic effect, thus they may produce bradycardia. In contrast, the dihydropyridine Ca^{2+} channel blockers typically induce a reflex tachycardia subsequent to peripheral vascular dilation and baroreceptor reflex leading to increased sympathetic outflow from the medulla.

Inotropic Drugs   Drugs involved in this category include the cardiac glycosides, Ca^{2+} sensitizing agents, catecholamines, and other sympathomimetic drugs. As with the antiarrhythmic drugs, inotropic drugs may exert cardiotoxic effects through extensions of their pharmacologic action.

Cardiac glycosides (digoxin and digitoxin) are inotropic drugs used for the treatment of congestive heart failure. Ouabain is a cardiac glycoside commonly used in the laboratory for electrophysiological experiments in cardiac myocytes. The mechanism of inotropic action of cardiac glycosides involves inhibition of Na^+, K^+-ATPase, elevation of intracellular Na^+, activation of Na^+/Ca^{2+} exchange, and increased availability of intracellular Ca^{2+} for contraction. Consequently, cardiotoxicity may result from Ca^{2+} overload, potentially including reduction in resting membrane potential (less negative), delayed afterdepolarizations, and premature ven-

tricular contraction or ectopic beats. Cardiac glycosides also exhibit parasympatho-mimetic activity through vagal stimulation and facilitation of muscarinic transmission; however, at higher doses, sympathomimetic effects may occur as sympathetic outflow is enhanced. The principal adverse cardiac effects of cardiac glycosides include slowed AV conduction with potential block, ectopic beats, and bradycardia. During overdose, when the resting membrane potential is significantly altered and ectopic beats are prevalent, ventricular tachycardia may develop and can progress to ventricular fibrillation. A wide variety of drug interactions with digoxin have been reported, including both pharmacokinetic interactions (drugs that alter serum concentrations of digoxin) and pharmacodynamic interactions (drugs that alter the cardiac effects of digoxin).

Ca^{2+}-sensitizing drugs including adibendan, levosimendan, and pimobendan are useful as inotropic drugs for the treatment of heart failure. In contrast to the main mechanism by which many other inotropic drugs act through elevating intracellular-free Ca^{2+} ($[Ca^{2+}]_i$) during the Ca^{2+} transient (i.e., increase the amplitude of the Ca^{2+} transient), these Ca^{2+}-sensitizing drugs increase Ca^{2+} sensitivity of cardiac myocytes, thereby avoiding Ca^{2+} overload (Lee and Allen, 1997). Although cardiotoxicity resulting from Ca^{2+} overload would not be expected following administration of these new drugs, some experimental data suggest that they may still exert proarrhythmic effects (Lee and Allen, 1997). The possibility that such Ca^{2+}-sensitizing drugs interfere with diastolic function (relaxation) requires further investigation but may contribute to the ventricular arrhythmias associated with these drugs. Other Ca^{2+}-sensitizing drugs include the xanthine oxidase inhibitors allopurinol and oxypurinol, which have been shown to increase contractile force but decrease Ca^{2+} transient amplitude (Perez *et al.*, 1998).

Catecholamines and sympathomimetics Catecholamines represent a chemical class of neurotransmitters synthesized in the adrenal medulla (epinephrine and norepinephrine) and in the sympathetic nervous system (norepinephrine). These neurotransmitters exert a wide variety of cardiovascular effects. Because of their ability to activate α- and β-adrenergic receptors, especially in the cardiovascular system, a number of synthetic catecholamines have been developed for the treatment of cardiovascular disorders and other conditions such as asthma and nasal congestion. Inotropic and chronotropic catecholamines used to treat bradycardia, cardiac decompensation following surgery, or to increase blood pressure (e.g., hypotensive shock) include epinephrine, isoproterenol, and dobutamine, and these drugs typically display nonselective activation of adrenergic receptors. More selective $β_2$-adrenergic receptor agonists used for bronchodilatory effects in asthma include albuterol, bitolterol, fenoterol, formoterol, metaproterenol, pirbuterol, procaterol, salmeterol, and terbutaline. High oral doses of albuterol or terbutaline or inhalation doses (i.e., enhanced delivery to the stomach instead of the lungs with subsequent systemic absorption) of these drugs may lead to nonselective activation of $β_1$-adrenergic receptors in the heart with subsequent tachycardia.

Sympathomimetic drugs that are more selective for α-adrenergic receptors include the nasal decongestants ephedrine, phenylephrine, phenylpropanolamine, and pseudoephedrine. As with the asthma drugs, at high doses these nasal decongestants can produce tachycardia, and a number of deaths have been reported. Of particular interest is the high concentration of ephedra alkaloids that may be present in some herbal remedies or "neutraceuticals," especially in products containing ma huang (Gurley *et al.*, 1998). Tachycardia may occur from the consumption of large amounts of

ephedra alkaloids, which may predispose the myocardium to ventricular arrhythmias.

High circulating concentrations of epinephrine (adrenaline) and norepinephrine (noradrenaline) and high doses of synthetic catecholamines, such as isoproterenol, may cause cardiac myocyte death. Many of the catecholamines and related drugs have been shown to induce cardiac myocyte hypertrophic growth in vitro. Catecholamine-induced cardiotoxicity involves pronounced pharmacologic effects, including increased heart rate, enhanced myocardial oxygen demand, and an overall increase in systolic arterial blood pressure.

Other possible mechanisms for the cardiotoxicity of high concentrations of catecholamines include coronary insufficiency resulting from coronary vasospasm, decreased levels of high-energy phosphate stores caused by mitochondrial dysfunction, increased sarcolemmal permeability leading to electrolyte alterations, altered lipid metabolism resulting in the accumulation of FAs, and intracellular Ca^{2+} overload (Dhalla *et al.*, 1992).

Central Nervous System Acting Drugs   Some of central nervous system (CNS)-acting drugs have considerable effects on the cardiovascular system, including tricyclic antidepressants (TCAs), general anesthetics, some of the opioids, and antipsychotic drugs.

TCAs including amitriptyline, desipramine, doxepin, imipramine, and protriptyline have significant cardiotoxic effects, particularly in cases of overdose. The effects of TCAs on the heart include ST segment elevation, QT prolongation, supraventricular and ventricular arrhythmias (including torsades de pointes), and sudden cardiac death. In addition, as a result of peripheral α-adrenergic blockade, TCAs cause postural hypotension—the most prevalent cardiovascular effect. Although many of these adverse effects are related to the quinidine-like actions, anticholinergic effects, and adrenergic actions of these drugs, the tricyclics also have direct actions on cardiac myocytes and Purkinje fibers, including depression of inward Na^+ and Ca^{2+} and outward K^+ currents (Pacher *et al.*, 1998). Furthermore, the risk of TCA-induced cardiotoxicity is significantly enhanced in children and by concomitant administration of other drugs that alter ion movement or homeostasis in the heart (e.g., the Na^+ channel-blocking class I antiarrhythmic agents), or use in patients with cardiovascular disease.

Antipsychotic drugs include the phenothiazines (acetophenazine, chlorpromazine, fluphenazine, mesoridazine, perphenazine, thioridazine, and trifluoperazine), chlorprothixene, thiothixene, and other heterocyclic compounds (clozapine, haloperidol, loxapine, molindone, pimozide, and risperidone). As with TCAs, the most prominent adverse cardiovascular effect of antipsychotic drugs is orthostatic hypotension. However, the phenothiazines (e.g., chlorpromazine and thioridazine) may exert direct effects on the myocardium, including negative inotropic actions and quinidine-like effects (Baldessarini, 1996). Some ECG changes induced by these drugs include prolongation of the QT and PR intervals, blunting of T waves, and depression of the ST segment. Through anticholinergic actions, clozapine can produce substantial elevations in heart rate (tachycardia).

General anesthetics as exemplified by enflurane, desflurane, halothane, isoflurane, methoxyflurane, and sevoflurane have adverse cardiac effects, including reduced cardiac output by 20–50%, depression of contractility, and production of arrhythmias (generally benign in healthy myocardium but more serious in cardiac dis-

ease). These anesthetics may sensitize the heart to the arrhythmogenic effects of endogenous epinephrine or to β-receptor agonists. Halothane has been found to block the L-type Ca^{2+} channel by interacting with dihydropyridine-binding sites, to disrupt Ca^{2+} homeostasis associated with the SR, and to modify the responsiveness of the contractile proteins to activation by Ca^{2+} (Bosnjak, 1991). Propofol is an intravenously administered general anesthetic that also decreases cardiac output and blood pressure. In addition, propofol causes a negative inotropic effect by its direct action on cardiac myocytes. Propofol has been shown to antagonize β-adrenergic receptors, inhibit L-type Ca^{2+} current, and reduce Ca^{2+} transients (Zhou *et al.*, 1997, 1999; Guenoun *et al.*, 2000).

Local Anesthetics   In general, local anesthetics have few undesirable cardiac effects. However, when high systemic concentrations of cocaine and procainamide are attained, these chemicals may have prominent adverse effects on the heart.

Cocaine acts as a local anesthetic agent by blocking conduction in nerve fibers through reversibly inhibiting Na^+ channels and stopping the transient rise in Na^+ conductance. In the heart, cocaine decreases the rate of depolarization and the amplitude of the action potential, slows conduction speed, and increases the effective refractory period. The other major pharmacologic action of cocaine is its ability to inhibit the reuptake of norepinephrine and dopamine into sympathetic nerve terminals (sympathomimetic effect). Cocaine also, indirectly through its actions on catecholamine reuptake, stimulates β- and α-adrenergic receptors, leading to increased cyclic AMP and inositol triphosphate levels. These second messengers will, in turn, provoke a rise in cytosolic Ca^{2+}, which causes sustained action potential generation and extrasystoles. The net effect of these pharmacologic actions is to elicit and maintain ventricular fibrillation. In addition, cocaine causes cardiac myocyte death and myocardial infarction, but the mechanism of action remains to be elucidated.

Other local anesthetic drugs include benzocaine, bupivacaine, etidocaine, lidocaine, mepivacaine, pramoxine, prilocaine, procaine, procainamide, proparacaine, ro-pivacaine, and tetracaine. Lidocaine and procainamide are also used as antiarrhythmic drugs. Extremely high doses of these drugs cause decreases in electrical excitability, conduction rate, and force of contraction likely through inhibition of cardiac Na^+ channels (Catterall and Mackie, 1996).

Anthracyclines and Other Antineoplastic Agents   Cardiotoxicity is recognized as a serious side effect of chemotherapy for malignant cancers, especially with well-known antitumor agents such as doxorubicin, daunorubicin, 5-fluorouracil, and cyclophosphamide (Havlin, 1992).

Anthracyclines (doxorubicin or Adriamycin and daunorubicin) are widely used antineoplastic drugs for the treatment of breast cancer, leukemias, and a variety of other solid tumors. Unfortunately, the clinical usefulness of these drugs is limited because of acute and chronic cardiotoxic effects. The acute effects mimic anaphylactic-type responses, such as tachycardia and various arrhythmias. These effects are usually manageable and most likely are due to the potent release of histamine from mast cells sometimes observed in acute dosing. In addition, large acute doses can also cause left ventricular failure. The greatest limiting factor of the anthracyclines is associated with long-term exposure, which usually results in the development of cardiomyopathies and, in severe cases, congestive heart failure (Havlin, 1992).

Two new anthracyclines were introduced to the U.S. market in 1999, and a lipid formulation of doxorubicin (liposomal doxorubicin) is under development. *Valrubicin* is a semisynthetic derivative of doxorubicin approved for treatment of carcinoma in situ of the bladder. It is administered locally for bladder cancer and therefore induces only mild systemic toxicities; however, systemic absorption from the bladder may occur, but valrubicin seems to exhibit a lower propensity for cardiotoxicity than doxorubicin (Hussar, 2000). *Epirubicin* is a semisynthetic derivative of daunorubicin approved for treatment of breast cancer. Like doxorubicin, epirubicin is given systemically and may induce cardiotoxicity. However, epirubicin is more lipophilic than doxorubicin and is biotransformed by the conjugative pathways in the liver, resulting in a shorter half-life and a lower incidence of cardiotoxicity than with doxorubicin (Hussar, 2000).

Several major hypotheses have been suggested to account for the onset of anthracycline-induced cardiomyopathy: (1) oxidative stress from redox cycling or mitochondrial Ca^{2+} cycling, (2) defects in mitochondrial integrity and subsequent deterioration of myocardial energetics, (3) alterations in both SR Ca^{2+} currents and mitochondrial Ca^{2+} homeostasis, and (4) altered cardiac myocyte gene expression and induction of apoptosis. The cause-and-effect relationships of the proposed mechanisms of cardiotoxicity have not been determined, and no single theory adequately explains the exact mechanism for anthracycline-induced cardiomyopathy.

The free radical hypothesis has received the most attention in the understanding of anthrocycline-induced cardiotoxicity. The formation of ROS by doxorubicin (Fig. 18-16) has been attributed to redox cycling of the drug (Powis, 1989). Doxorubicin can undergo futile redox cycling that results in the production of oxygen free radicals; these ROS may then oxidize proteins, lipids, and nucleic acids and potentially cause DNA strand scission. The quinone-like structure of doxorubicin permits this molecule to accept an electron and form a semiquinone radical. Oxidation of the semiquinone back to the parent quinone by molecular oxygen results in the formation of superoxide radical ions that are believed to initiate oxidative stress. The enzymatic reduction that is believed to be responsible for the generation of superoxide by doxorubicin has been proposed to occur between complexes I and III of the mitochondrial respiratory chain. Doxorubicin has high affinity for cardiolipin, a phospholipid found on the inner mitochondrial membrane, where NADH dehydrogenase converts the drug to a semiquinone radical (Marcillat *et al.*, 1989). In the presence of oxygen, this radical is responsible for the generation of ROS, which then may peroxidize unsaturated membrane lipids and initiate myocardial cell injury.

Several alternate hypotheses to explain the cardiotoxicity of doxorubicin have been proposed and tested. For example, several studies have tested the hypothesis that doxorubicin induces a cycling of mitochondrial Ca^{2+} that is associated with the production of ROS and dissipation in the mitochondrial membrane potential, which in turn may result in depletion of cellular ATP (Chacon and Acosta, 1991; Solem *et al.*, 1994). It is important to note that the observed changes in ROS accumulation, disruption of Ca^{2+} homeostasis, and mitochondrial damage are not isolated, but rather these changes occur sequentially or simultaneously. It is extremely difficult to dissect the sequences of these changes, leading to several alternate hypotheses, which may in fact occur sequentially. One of the ultimate consequences of these changes is myocardial cell death. Many studies have demonstrated that anthracycline-induced cardiotoxicity includes induction of apoptosis (Kang *et al.*, 2000a; Wang *et al.*,
Figure 18-16. *Production of superoxide anions by oxidation-reduction cycling of doxorubicin at the level of the mitochondria.*

NADH dehydrogenase (NAD-DH), which is located within complex I, has been proposed as the enzyme that catalyzes the one-electron reduction of doxorubicin (1) to a semiquinone radical (2). The semiquinone then may be reoxidized back to the parent compound by means of the reduction of molecular oxygen (O_2) to the superoxide anion (O_2^-).

2001a; Sawyer *et al.*, 1999; Andrieu-Abadie *et al.*, 1999; Arola *et al.*, 2000).

5-Fluorouracil Clinical evidence of 5-fluorouracil cardiotoxicity ranges from mild precordial pain and ECG abnormalities (ST segment elevation, high peaked T waves, T-wave inversions, and sinus tachycardia) to severe hypotension, atrial fibrillation, and abnormalities of ventricular wall motion. The mechanism of cardiotoxicity of fluorouracil is unknown, but it may relate to impurities present in commercial products of the drug, one of which is metabolized to fluoroacetate, a compound that might participate in fluorouracil-induced cardiotoxicity.

Cyclophosphamide High doses of cyclophosphamide given to cancer or transplant patients may lead to severe hemorrhagic cardiac necrosis. The mechanism of the cardiotoxicity of this drug is not clear, but there is suggestive evidence that the toxic metabolite of cyclophosphamide, 4-hydroperoxycyclophosphamide, may alter the ion homeostasis in cardiac myocytes, resulting in increased Na^+ and Ca^{2+} content and reduced K^+ levels (Levine *et al.*, 1993).

Antimicrobial and Antiviral Agents   Cardiotoxicity associated with the clinical use of antimicrobial and antiviral drugs is often observed in overdosage and in patients with preexisting cardiovascular dysfunction.

Aminoglycosides include amikacin, gentamicin, kanamycin, netilmicin, streptomycin, and tobramycin. Gentamicin is a representative aminoglycoside and has an inhibitory action on slow inward Ca^{2+} channels in heart muscle. Aminoglycosides inhibit the uptake or binding of Ca^{2+} at sarcolemmal sites, thus reducing the concentration of membrane-bound Ca^{2+} available for movement into the myoplasm during depolarization of the sarcolemma. The principle mechanism of cardiodepression by gentamicin is the dislocation of Ca^{2+} from slow-channel-binding sites on the external surface of the sarcolemma, which results in a blockade of the channels (Hino *et al.*, 1982).

Macrolides include azithromycin, clarithromycin, dirithromycin, and erythromycin. Erythromycin is associated with QT prolongation and cardiac dysrhythmias characterized by polymorphic ventricular tachycardia (torsades de pointes). These effects occur primarily in patients with underlying cardiac disease.

Fluoroquinolones are a group of rapid growing antibacterial chemicals in terms of numbers of new drugs released into the market in the United States. Fluoroquinolone antibacterial drugs include ciprofloxacin, enoxacin, gatifloxacin, gemifloxacin, grepafloxacin, levofloxacin (levo-rotatory isomer of ofloxacin), lomefloxacin, moxifloxacin, norfloxacin, ofloxacin, sparfloxacin, and trovafloxacin (Pickerill *et al.*, 2000). Grepafloxacin, moxifloxacin, and sparfloxacin are associated with QT prolongation in perhaps a higher incidence than macrolides. In fact, grepafloxacin was voluntarily removed from the U.S. market because of the relatively high incidence of QT prolongation and risk of torsades de pointes.

Tetracycline and chloramphenicol have been reported to depress myocardial contractility by direct cardiac myocyte interaction or an indirect effect that lowers Ca^{2+} concentrations in the plasma or extracellular spaces. Tetracylcines are Ca^{2+} chelating agents, which explain the action of tetracyclines on myocardial contractility.

Antifungal agents, such as amphotericin B, may depress myocardial contractility by blocking activation of slow Ca^{2+} channels and inhibiting the influx of Na^+. Ventricular tachycardia and cardiac arrest have been reported in patients treated with amphotericin B. Flucytosine is another antifungal drug that has been associated with cardiotoxicity. In fungal cells, flucytosine is converted to 5-fluorouracil, which then exerts antifungal effects. However, flucytosine may be converted to 5-fluorouracil by gastrointestinal microflora in humans, which then may be absorbed systemically and induce cardiotoxicity as discussed above. Cardiac arrest has been reported in individuals receiving flucytosine.

Antiviral drugs that are potentially cardiotoxic include the nucleoside analog reverse transcriptase inhibitors used for the treatment of human immunodeficiency virus (HIV) infections. Clinical studies of direct cardiotoxicity of these drugs in HIV patients are complicated by cardiomyopathy related to disease progression. The direct evidence for cardiotoxicity of zidovudine (AZT) has been obtained from a study using transgenic mice expressing replication-incompetent HIV (Lewis *et al.*, 2000). AZT-induced cardiotoxicity in this model is related to alteration in Ca^{2+} homeostasis and/or mitochondrial toxicity. The mitochondrial toxicity of AZT has also been shown in skeletal muscle biopsy samples from AIDS patients (Dalakas, *et al.*, 1990).

Although cardiotoxicity of individual antiviral drugs is rare in clinical setting, the combination of several antiviral drugs for highly active anti-retroviral therapy (HAART) has generated a major concern of cardiotoxicity (Bozkurt, 2004). HAART has dramatically improved the life expectancy of patients with HIV. The majority of the studies examining the incidence of cardiac effects demon-

strated an increase in cardiac adverse event rate with HAART in the HIV-infected population. Overall, the cardiotoxicity risk appears to be greater in the HIV-infected population than in the general population, and the increased cardiac risk is associated with HAART, particularly with protease inhibitor use. However, there is general consensus that the benefits of HAART far outweigh toxicity-related risks of the treatment with HAART.

Anti-Inflammatory Agents   Nonsteroidal anti-inflammatory drugs (NSAIDs) include aspirin, Motrin, and Naprosyn, which are classified as nonselective NSAIDs because they are inhibitors for both COX-1 and COX-2. Inhibition of COX-1 is associated with gastrointestinal toxicity because COX-1 exerts a protective effect on the lining of the stomach. A newer class of NSAIDs has been developed; including rofecoxib (Vioxx), celecoxib (Celebrex), and valdecoxib (Bextra), witch are selective inhibitors of COX-2. In September 2004, Vioxx was voluntarily withdrawn from the market based upon the data from a clinical trial that showed after 18 months of use Vioxx increased the relative risk for cardiovascular events, such as heart attack and stroke (Arellano, 2005). In April 2005, Bextra was removed from the market based on the potential increased risk for serious cardiovascular adverse events and increased risk of serious skin reactions (e.g., toxic epidermal necrolysis, Stevens–Johnson syndrome, erythema multiforme) (Talhari *et al.*, 2005). Emerging information indicates the risk of cardiovascular events may be increased in patients receiving Celebrex (Solomon *et al.*, 2005). The cardiovascular events induced by COX-2 inhibitors are presumably related to thrombotic events. Studies have also indicated the link of Vioxx to long QT syndrome and the increased risk for TdP and sudden cardiac death (Arellano 2005; Fitzgerald 2004).

Antihistamines   The most severe adverse effect of the second-generation histamine H_1 receptor antagonists (antihistamines) is their association with life-threatening ventricular arrhythmias and sudden cardiac death (Simons, 1994). Terfenadine and astemizole cause altered repolarization, notched inverted T waves, prominent TU waves, prolonged QT interval, first- and second-degree AV block, ventricular tachycardia or fibrillation, and torsades de pointes. These antihistamines produce cardiac arrhythmias by blocking the delayed rectifier K^+ channel and prolonging action potential duration in cardiac myocytes. The prolonged action potential duration promotes early afterdepolarizations and predisposes the myocardium to ventricular arrhythmias. However, terfenadine also inhibits L-type Ca^{2+} channels in rat ventricular myocytes at concentrations near or below that required to inhibit delayed rectifier K^+ current (Liu *et al.*, 1997). Therefore, both inhibition of Ca^{2+} and inhibition of K^+ current likely contribute to the cardiotoxic actions of terfenadine. As a result of cardiotoxicity, both astemizole and terfenadine have been removed from the United States market. However, the understanding of astemizole- and terfenadine-induced cardiotoxicity continues to be an important consideration in drug development, and other drugs have demonstrated similar clinical limitations (e.g., cisapride and fluoroquinolone antibacterial agents).

Immunosuppressants   Rapamycin and tacrolimus may produce adverse cardiovascular effects, including hypertension, hypokalemia, and hypomagnesemia. Rapamycin and tacrolimus (FK506) interact with a protein that associates with ryanodine receptors (RyRs), and the protein carries the tacrolimus- or FK506-binding protein (FKBP). When rapamycin or tacrolimus binds to

FKBP in cardiac myocytes, RyR becomes destabilized, resulting in Ca^{2+} leak from the SR (Marks, 1997). Tacrolimus has been shown to be associated with hypertrophic cardiomyopathy in pediatric patients, a condition that was reversed by discontinuation of tacrolimus and administration of cyclosporin A; some of these patients developed severe heart failure (Atkison *et al.*, 1995).

Miscellaneous Drugs   Several drugs that are not included in the categories discussed above have significant cardiotoxic concerns and are briefly discussed below, including cisapride, methylxanthines, and sildenafil.

Cisapride is a chemical that has been used as a prokinetic drug for gastrointestinal hypomotility. However, cisapride has been removed from the U.S. market because of risk of potentially life-threatening arrhythmias (torsades de pointes) associated with its use. Like astemizole and terfenadine, cisapride inhibits delayed rectifier K^+ current, prolongs action potential duration, prolongs the QT interval, and predisposes the heart to ventricular arrhythmias.

Methylxanthines (including caffeine, theobromine, and theophylline), can be found in significant quantities in coffee, tea, chocolate, soft-drinks, and other foods. Theophylline has been used for many decades for the treatment of asthma, although the mechanism of action has not been fully understood. Overdose of theophylline or rapid intravenous administration of therapeutic doses of aminophylline (theophylline complexed with ethylenediamine to increase water solubility) may produce life-threatening ventricular arrhythmias; these effects may in part be explained by direct actions of theophylline on cardiac myocyte SR or by inhibition of phosphodiesterase and elevation of cyclic AMP. The cardiac effects of methylxanthines observed in vivo (including increases in cardiac output and heart rate) may also be explained by elevated catecholamines, as theophylline has been shown to increase plasma epinephrine concentrations (Vestal *et al.*, 1983). High concentrations of caffeine stimulate massive release of Ca^{2+} from the SR, an effect that is often utilized experimentally to determine SR function. Although it rarely occurs, caffeine-associated ventricular arrhythmias have been reported.

Sildenafil is a relatively specific inhibitor of phosphodiesterase 5, which is responsible for the degradation of cyclic GMP (a vasodilatory second messenger). Interestingly, sildenafil was originally developed as a potential drug for treating angina; however, it was not very effective for this purpose and was subsequently developed for treatment of erectile dysfunction, where it produces vasodilation and filling of the corpus cavernosum. The primary concern regarding adverse effects of sildenafil is nonspecific inhibition of PDE3 in the heart and vasculature (Hussar, 1999). In vitro studies have revealed that sildenafil increases cyclic AMP in cardiac tissue without significant effects on cyclic GMP (Stief *et al.*, 2000); however, whether these effects are associated with cardiotoxicity is not known.

Natural Products

Natural products include naturally occurring catecholamines, hormones, and cytokines, as well as animal and plant toxins. Many of these products have been shown to cause cardiac toxic responses. However, it is difficult to define whether or not the cardiac toxicity results directly from the action of these products in vivo, although these products cause deleterious effects on cultured cardiomyocytes. The exposure levels of these chemicals tested in vitro in general are much higher than the concentration reached in cardiac tissue under in vivo exposure conditions. Therefore, extrapolation of in vitro data related to cardiac toxicity of natural products to in vivo conditions is challenging. However, there are some products that have clearly demonstrated cardiac toxic effects, and mechanisms of action of these products have been determined.

Catecholamines   The naturally occurring sympathomimetic amines, such as epinephrine and norepinepherine, are potent and can cause deleterious effects to the heart. The synthetic catecholamine, isoproterenol, is able to cause massive necrotic changes in the myocardium and is often used as a prototype compound for the study of catecholamine cardiotoxicity, which has been discussed in the therapeutic drugs that cause cardiotoxicity.

Steroids and Related Hormones   Estrogens, progestins, androgens, and adrenocortical steroids are major steroid hormones produced by mammals including humans. Myocardial tissue contains steroid receptors; therefore the heart serves as a target organ for steroid effects. It also has been shown that cardiac tissue can synthesize steroid hormones, although the capacity for synthesis may be much lower than more classic steroid synthesizing tissues. There are two major mechanisms of action of the hormones: the first is to alter gene expression and the second is to change signaling transduction pathways.

Estrogens are synthesized in ovaries, testes, and adrenal glands, and estrogen is an active metabolite of testosterone. Endogenous estrogens include 17β-estradiol (E_2), estrone, and estriol. Synthetic estrogens include diethylstilbestrol (nonsteroidal), equilin, esterified versions of E_2, ethinyl estradiol, mestranol, and quinestrol. In addition, many other synthetic chemicals have been shown to exert estrogenic activity, including the pesticides DDT and methoxychlor, the plasticizer bisphenol A, other industrial chemicals including polychlorinated biphenyls, and some compounds found in soybeans and tofu (e.g., phytoestrogens). Estrogens (frequently in combination with progestins) have been used for over 40 years as oral contraceptive drugs. The older versions of estrogenic oral contraceptives that contained high amounts of estrogens were associated with increased risk of coronary thrombosis and myocardial infarction; however, lower doses of estrogens have been found by numerous investigators to impart protective effects on the cardiovascular system, including antiapoptotic effects, and beneficial effects on lipid metabolism such as decreased low-density lipoproteins (LDL cholesterol) and increased high-density lipoproteins (HDL cholesterol). Estrogens alter cardiac fibroblast proliferation, but they can either increase or decrease proliferation of these cells.

Progestins are also synthesized in the ovaries, testes, and adrenal glands. Naturally occurring and synthetic progestins include desogestrel, hydroxyprogesterone, medroxyprogesterone, norethindrone, norethynodrel, norgestimate, norgestrel, and progesterone. As part of hormone replacement therapy, progestins serve an opposing role to estrogens. Unfortunately, estrogen treatment opposed with progestins may negate the cardiovascular benefits of estrogens on lipid metabolism (Kalin and Zumoff, 1990). Very little is known about the direct effects of progestins on the heart. Although progestins could exert deleterious effects on the heart, more studies are required to investigate mechanisms.

Androgens cause adverse cardiovascular effects (Rockhold, 1993; Melchert and Welder, 1995). The principal androgens are testosterone and its active metabolite dihydrotestosterone.

Testosterone is synthesized in the testes, ovaries, and adrenal glands and dihydrotestosterone mediates most androgen actions. Synthetic anabolic-androgenic steroids include the alkylated and orally available drugs danazol, fluoxymesterone, methandrostenolone, methenolone, methyltestosterone, oxandrolone, oxymetholone, and stanozolol. The nonalkylated drugs with poor oral bioavailability include androstenedione and dehydroepiandrosterone (both sold in various "nutraceutical" formulations), boldenone (veterinary product), nandrolone (19-nortestosterone), and testosterone. Nearly all of these chemicals have received significant illicit use, particularly in extremely high doses with attempts to improve physical appearance or performance. Anabolic-androgenic steroids have been associated with alterations in lipid metabolism, including increased LDL cholesterol and decreased HDL cholesterol; therefore these chemicals may predispose individuals to atherosclerosis (Melchert and Welder, 1995). Evidence indicating the direct cardiac toxic effect of anabolic-androgenic steroids includes alteration of Ca^{2+} fluxes in cardiac myocytes induced by testosterone (Koenig *et al.*, 1989), hypertrophic growth of neonatal rat cardiac myocytes stimulated by testosterone and dihydrotestosterone (Marsh *et al.*, 1998), and mitochondrial abnormalities and myofibrillar lesions induced by methandrostenolone given intramuscularly to rats (Behrendt and Boffin, 1977). In humans, high-dose anabolic-androgenic steroid use has been associated with cardiac hypertrophy and myocardial infarction. However, the mechanisms responsible for the cardiotoxic effects of anabolic-androgenic steroids remain poorly understood.

Glucocorticoids and mineralocorticoids are primarily synthesized in the adrenal glands. Naturally occurring glucocorticoids include corticosterone, cortisone, and hydrocortisone (cortisol), and the mineralocorticoid is aldosterone. A large number of synthetic glucocorticoids are used for treatment of various autoimmune and inflammatory diseases. These drugs include alclometasone, amcinonide, beclomethasone, betamethasone, clobetasol, desonide, desoximetasone, dexamethasone, diflorasone, fludrocortisone, flunisolide, fluocinolone, fluocinonide, fluorometholone, flurandrenolide, halcinonide, medrysone, methylprednisolone, mometasone, paramethasone, prednisolone, prednisone, and triamcinolone. Most of these agents are primarily used topically, intranasally, or inhalationally. The primary glucocorticoids used systemically include cortisone, hydrocortisone, dexamethasone, methylprednisolone, prednisolone, and prednisone. The mineralocorticoid aldosterone is not used clinically; however, the aldosterone receptor antagonist spironolactone has been used for years to treat hypertension and is now thought to decrease morbidity and mortality associated with congestive heart failure. Both aldosterone and glucocorticoids appear to stimulate cardiac fibrosis by regulating cardiac collagen expression independently of hemodynamic alterations (Young *et al.*, 1994; Robert *et al.*, 1995). Furthermore, aldosterone and glucocorticoids induce hypertrophic growth and alter expression of Na^+, K^+-ATPase, Na^+/H^+ antiporter, and chloride/bicarbonate exchanger of cardiac myocytes in vitro. Clinically relevant cardiac hypertrophy has been observed in premature infants undergoing dexamethasone treatment. The mechanisms responsible for the direct effects of these chemicals remain poorly understood.

Thyroid hormones include thyroxine (T_4) and triiodothyronine (T_3). These hormones exert profound effects on the cardiovascular system. Hypothyroid states are associated with decreased heart rate, contractility, and cardiac output; whereas hyperthyroid states are associated with increased heart rate, contractility, cardiac output,

ejection fraction, and heart mass. Patients with underlying cardiovascular disease may display arrhythmias under the treatment of thyroid hormones. Thyroid hormones also alter expression of cardiac SR Ca^{2+} handling proteins including increased expression of SR Ca^{2+} ATPase (SERCA) and decreased expression of phospholamban, an inhibitory protein of SERCA (Kaasik *et al.*, 1997).

Cytokines   More than 100 different cytokines have been found, and the cardiovascular effects of these substances can be classified as proinflammatory, anti-inflammatory, or cardioprotective (Pulkki, 1997). Members of the proinflammatory class include TNF-α; interleukin-1β (IL-1β), interleukin-2 (IL-2), interleukin-6 (IL-6), interleukin-8 (IL-8), Fas ligand, and chemokines (e.g., C-C chemokines such as MCP-1, macrophage chemoattractant protein-1; MIP-1α, macrophage inflammatory protein-1α; and RANTES, regulated on activation normally T-cell-expressed and secreted). Members of the anti-inflammatory class typically downregulate expression of proinflammatory cytokines and include interleukin-4 (IL-4), interleukin-10 (IL-10), interleukin-13 (IL-13), and transforming growth factor-beta (TGF-β). The cardioprotective cytokines include cardiotrophin-1 (CT-1) and leukemia inhibitor factor, which have been shown to inhibit cardiac myocyte apoptosis from a number of different stimuli. Many of these cytokines are elevated during cardiovascular diseases such as I/R injury, myocardial infarction, and congestive heart failure.

IL-1β is known to exert negative inotropic actions and induce apoptosis of cardiac myocytes. The effects of IL-1β on cardiac myocytes are likely mediated through induction of nitric oxide synthase (NOS) and/or increased production of nitric oxide (NO) (Arstall *et al.*, 1999). Superoxide anion and peroxynitrite formation was associated with reduced left ventricular ejection fraction in dogs treated with microspheres containing IL-1β, suggesting that involvement of peroxynitrite in IL-1β cardiotoxicity (Cheng *et al.*, 1999b).

TNF-α induces apoptotic cell death in myocardium (Krown *et al.*, 1996). The mechanisms responsible for TNF-α-induced apoptosis of cardiac myocytes are not entirely clear. TNF-α also exerts negative inotropic effects on cardiac myocytes at least potentially through increased production of sphingosine (Sugishita *et al.*, 1999). However, it has been shown TNF-α is essential for the cardiac protective response to stresses such as ischemic cardiac injury (Kurrelmeyer *et al.*, 2000).

IL-6 has been shown to induce negative inotropic effects on cardiac myocytes, possibly through induction of NOS expression and increased NO production (Sugishita *et al.*, 1999).

IL-2 may decrease the mechanical performance and metabolic efficiency of the heart, and these myocardial effects may be related to changes in NO synthesis and Na^+/H^+ exchange.

Interferon may result in cardiac arrhythmias, dilated cardiomyopathy, and signs of myocardial ischemia. Interferon-γ acts synergistically with IL-1β to increase NO formation in the heart, and induce Bax expression and apoptosis in cardiac myocyte cultures (Arstall *et al.*, 1999).

Animal and Plant Toxins   Animal toxins in the venom of snakes, spiders, scorpions, and marine organisms have profound effects on the cardiovascular system. There are also a number of plants—such as foxglove, oleander, and monkshood—that contain toxic constituents and have adverse effects on the cardiovascular system.

Environmental Pollutants and Industrial Chemicals

There are many chemicals classified in this category that cause cardiac toxicity. Metals and metalloids can be found both in environmental pollutants and industrial chemicals. Some heavy metals, such as cadmium, block calcium channels that affect cardiac rhythm leading to arrhythmia, others such as arsenic have high affinity for sulfhydryl groups, and interfere with sulfhydryl-containing proteins, such as receptors, regulatory proteins, and transporters. During the last decade, epidemiological and experimental studies have identified an association of air pollution of PMs (particulate matters) and cardiac toxicity, however, mechanistic insights into cardiac toxicity induced by PM remain elusive. In this section, a brief discussion of selected industrial agents with their prominent cardiotoxic effects and proposed mechanisms of cardiotoxicity is presented. For a more comprehensive review of industrial chemicals and their cardiotoxic potential, the reader is referred to Zakhari (1992).

Particulate Matters   There are several obstacles in the systemic study of cardiac toxicity caused by particulate air pollution. One of the major challenges is the complexity of the particulate components of air pollution. Current consensus in the field is to divide the airborne particulates into classes according to aerodynamic diameters. There are three major classes: coarse (PM_{10}, 2.5–10 μm), fine ($PM_{2.5}$, <2.5 μm), and ultrafine ($PM_{0.1}$, <0.1 μm). However, ambient air PM consists of a mixture of combustive byproducts and resuspended crystal materials, of which the contents are highly related to geographic regions. Thus studying mechanisms by which particulate air pollution causes cardiovascular toxicity is extremely challenging, although attempts have been made to provide insights into the mechanistic link between particulate air pollution and cardiac toxicity. The documented cardiac toxic effects of particulate air pollution have been limited to electrocardiographic changes, including arrhythmia, decreased heart rate variability, and the exacerbation of ST-segment changes in experimental models of myocardial infarction.

Solvents   Industrial solvents can exert adverse effects on the heart directly or indirectly; both are related to their inherent lipohilicity. Solvents may affect cardiac physiological functions such as contraction and energy production by directly dispersing into plasma membranes. However, the effects of solvents on the heart would be more related to their actions on the neuro-hormonal regulation of cardiac function. Solvents may disrupt sympathetic and parasympathetic control of the heart as well as cause release of circulating hormones such as catecholamines, vasopressin, and serotonin, which in turn affects cardiac function.

Alcohols and Aldehydes   On a molar basis, there is a relationship between increased carbon chain length of the alcohol and cardiotoxicity. Metabolic oxidation of alcohols yields aldehydes. Aldehydes have sympathomimetic activity as a result of their effect on releasing catecholamines. Unlike alcohols, the sympathomimetic activity of aldehydes decreases with increased chain length. The acute cardiodepressant effects of alcohols and aldehydes may be related to inhibition of intracellular Ca^{2+} transport and/or generation of oxidative stress. Chronic alcoholic cardiotoxicity is more related to a long-term consumption of alcohol, referred to as ACM,

which was discussed above. The environmental exposure to alcohols is more lated to acute cardiaotoxicity, including a negative dromotropic effect (reduced conductivity) and a decreased threshold for ventricular fibrillation. The common inductrial alcohols include methanol (methyl alcohol or wood alcohol) and isopropyl alcohol (isopropanol). Methanol is metabolized by alcohol dehydrogenase and aldehyde dehydrogenase to formaldehyde and formic acid, and often causes reduction in heart rate. Isopropanol is metabolized to acetone, and both isopropanol and its metabolite are potent CNS depressants. Acetone is metabolized to formic acid and acetic acid, which have the potential to induce mild acidosis. Tachycardia is the most prominent clinical finding of isopropanol exposure.

Halogenated Alkanes   The highly lipophilic nature of halogenated alkanes allows them to cross the blood–brain barrier readily. This action, coupled with their CNS-depressant activity, makes these compounds ideally suited for anesthetics (halothane, methoxyfluorane, and enflurane). Halogenated hydrocarbons depress heart rate, contractility, and conduction. In addition, some of these agents sensitize the heart to the arrhythmogenic effects of β-adrenergic receptor agonists such as endogenous epinephrine. Fluorocarbons (freons) have been reported to have this sensitizing effect on the myocardium. Chronic exposure to halogenated hydrocarbons may cause myocardial degenerative response.

Metals and Metalloids   The most common heavy metals that have been associated with cardiotoxicity are cadmium, lead, and cobalt. These metals exhibit negative inotropic and dromotropic effects and can also produce structural changes in the heart. Chronic exposure to cadmium has been reported to cause cardiac hypertrophy. Lead has an arrhythmogenic sensitizing effect on the myocardium. In addition, lead has been reported to cause degenerative changes in the heart. Cobalt has been reported to cause cardiomyopathy. The cardiotoxic effects of heavy metals are attributed to their ability to form complexes with intracellular macromolecules and their ability to antagonize intracellular Ca^{2+}.

Other metals that have been reported to affect cardiac function are manganese, nickel, and lanthanum. Their mechanism of action appears to block Ca^{2+} channels. However, high concentrations are required to block Ca^{2+} channels (e.g., millimolar range). Barium is another metal that can affect cardiac function. Barium chloride given intravenously in high doses to laboratory animals has been reported to induce arrhythmias. This arrhythmogenic effect of barium chloride has been utilized to screen antirrhythmic agents.

Arsenic is a metalloid, which has been shown to cause cardiotoxicity directly. Arsenic has a high affinity for sulfhydryl proteins, which are involved in multiple cellular metabolism and function. Besides environmental exposure to arsenic such as through drinking water contamination, therapeutic use of arsenic in the form of arsenic trioxide for the treatment of acute promyelocytic leukemia (APL) is another important route of exposure. Clinical reports have shown serious ventricular tachycardia at the therapeutic doses of arsenic trioxide in APL patients. Experimetnal studies using a dose regiment that has been shown to produce plasma concentrations of arsenic within the range of those present in arsenic-treated APL patients have shown that arsenic causes myocardial cell death through apoptosis, and results in decreased systolic and diastolic function of the heart (Li *et al.*, 2002).
Figure 18-17. Schematic diagram of vascular supply to selected organs.

The capillary beds represented by a meshwork connnecting the arteries (right) with the veins (left); the distribution of the vasculature in several organs (liver, kidney, and lung) indicates the importance of the vascular system in toxicology.

OVERVIEW OF VASCULAR SYSTEM

Vascular Physiology and Structural Features

The vascular system consists of blood vessels of varying size and different cellular composition. Blood vessels can be divided into arterial, venous, and capillary systems. In addition, the lymphatic system belongs to the vascular system, but it only carries plasma. Although blood is the content of the vascular system and changes in the status of blood and circulation are associated with the functional alteration and toxicity of the vascular system, the blood is not included in this chapter because Chap. 11 specifically addresses the toxic responses of the blood. The main function of the vascular system is to provide oxygen and nutrients to and remove carbon dioxide and metabolic products from organ systems (Fig. 18-17). In addition, the vascular system is a conduit that delivers hormones and cytokines to target organs. The vascular system also has regulatory functions to manipulate organ system responses under certain toxicologic conditions. For instance, endothelins produced by vascular endothelial cells alter cardiac rhythm and affect myocardial contractility. Many regulatory systems control the physiological function of the vascular system, so that the changes in the vascular system reflect either local action of chemicals or disruption of the regulatory systems, or both. The distinction between primary and secondary vascular toxic responses is challenging. To better understand the toxic responses of the vascular system, the following presents an overview of physiology and regulatory mechanism of the vascular system.

Arterial System and Physiological Function   The arterial system is composed of the aorta, major arteries, and small arterioles. The aorta and major arteries are thick-walled structures with vascular smooth muscle, elastic, and connective tissues (Fig. 18-18). Blood flow within the arterial system is initiated by contraction of the heart and begins at the ascending aorta. The ascending aorta receives all of the output of the heart with the exception of the coronary blood flow. Blood is distributed to the organ systems of the body through the major arteries that branch from the aorta. All these arteries further branch to give rise to smaller arteries and become arterioles that connect to capillaries for the delivery of oxygen and nutrients to target tissues.

The Aorta and Large Arteries   The aorta and the large arteries provide supporting structures and maintain the blood flow from the heart to the target organs. Therefore, these vessels function primarily as conduits. The driving force for the blood flow is derived from the contraction of the heart and the elasticity of the aorta and large arteries under the regulation of the neurohormonal system and the resistance of the target organs. Chemicals can affect directly the arterial systems leading to alterations in blood flow or indirectly act through the regulatory system to change the blood flow.

Arterioles and Vascular Resistance   The arterioles are composed of a tube of endothelial cells, surrounded by connective tissue basement membrane, a single or double layer of vascular smooth muscle cells, and a thin outer adventitial layer. The vascular smooth
Figure 18-18. Cross-sectional representation of the vascular wall of large and medium-size blood vessels.

The tunica intima is composed of endothelial cells, facing the vessel lumen, which rest on a thin basal lamina. The tunica media consists mainly of vascular smooth muscle cells interwoven with collagen and elastin. The tunica adventia is a layer of fibroblasts, collagen, elastin, and glycosaminoglycans.

muscle cells are critical for the regulation of vascular resistance. The tension developed by the vascular smooth muscle cells alters the vessel diameter. Therefore, arterioles are primarily responsible for regulation of peripheral vascular resistance and blood flow. Toxic agents affecting the structure and function of the vascular smooth muscle cells can thus change the physiological regulation of the vascular resistance, leading to excess dilation or restriction.

Coronary Arteries and Circulation Coronary arteries branch from the aorta immediately past the mitral valve. Supply of oxygen and nutrients to the heart is primarily supported by the coronary arteries. The coronary blood flow can increase about four-fold to supply additional oxygen needed by the heart muscle under demanding conditions, such as during exercise. However, even when the body is at rest, the oxygen supply through the coronary arteries to the heart is more than the supply to an equal mass of skeletal muscle during vigorous exercise. Heart tissue extracts most of the oxygen from blood during resting conditions the, and coronary blood flow increases with the workload demands on the heart. Increase in blood flow is the major mechanism of the heart to increase energy production. Coronary vasculature disruption both anatomically and physiologically leads to reduction in cardiac blood flow and cardiac work, which is an important effect of xenobiotics. In fact, pathology of the coronary vasculature is the cause of death in about one-third of the population in industrialized societies. Recent studies indicate that PMs in the air are associated with coronary heart disease (Dockery, 2001; Gordon and Reibman, 2000).

Capillaries and Microcirculation Capillaries directly connect to the distal portion of the arterioles serving as the communication site between blood and tissues, and constitute the major part of the microcirculation where nutrients, water, gases, hormones, cytokines, and waste products are exchanged between blood and tissues. In other parts of the vascular system, blood is separated from tissues by the walls of arterial and venous vessels. In contrast, capillaries are only one cell layer thick. The passage of molecules through the capillary wall can occur both between and through the endothelial cells. Lipid-soluble molecules such as oxygen and carbon dioxide readily pass through the endothelial cell membranes. Water-soluble molecules diffuse between endothelial cells. The other pathway for water-soluble molecules is the cell membrane vesicle formation via pinocytosis (inward) and exocytosis (outward) on both the luminal and the tissue side of the capillary wall. This pathway can transfer even the largest molecules. The endothelial cells are targets of xenobiotics, whose effects can be measured by accumulation of toxic metabolites in the target organs and the pathophysiological changes in the microcirculation.

In general, there is some capillary reserve in tissues so that a particular area of a tissue can be perfused by more than one capillary, but not all of the capillaries open up at any given time. This capillary reserve serves two important functions: one is to meet the increase in metabolic demands. Under the condition that metabolic demands increase, more capillaries can open up. The other is to compensate for lesions or disruption of certain capillaries. For instance, if an occlusion occurs due to a thrombus, capillaries in close proximity can open to provide perfusion to the vulnerable area. However, in the brain, this capillary reserve appears absent so that any occlusion may result in damage.

Venous System and Physiological Function The venous system is composed of venules, veins, and vena cava. The blood flow in the venous system starts from the thin-walled venules that collect the blood from the target tissues of the body. These vessels have a relatively large surface area facilitating the reabsorption of filtered plasma from the tissue. The venules merge to veins and eventually drain into the vena cava, returning blood to the heart. Therefore, the important physiological function of the venous system is collecting blood from organ systems of the body and returning the blood to the heart. The other important function of the venous system is the capacitance of the circulatory system. This is an important protective mechanism of the circulatory system. The large veins contain vascular smooth muscle cells that can increase the blood return to the heart by constriction and increase the capacitance by dilation. If hemorrhage occurs, the circulatory system can rapidly adjust the capacitance and maintain perfusion of the tissues. Xenobiotics can exert adverse effects on the vascular smooth muscle cells so that the capacitance function of the venous system can be compromised.

Lymphatic System and Physiological Function Lymphatic vessels are endothelial tubes within tissues. The lymphatic system begins as blind-ended lymphatic end bulbs that drain into a meshwork of interconnected lymphatic vessels. This is a low-pressure system that collects excess tissue water and plasma proteins that have not been reabsorbed by the venous system. In general, in all organ systems with the exception of the CNS, more fluid is filtered than reabsorbed by the venous system. Therefore, removal of the excess fluid as well as plasma proteins that diffuse into the interstitial spaces by lymphatic system is essential. All the lymphatics ultimately drain into the vena cava. Therefore, the physiological function of the lymphatic system is to maintain a negative interstitial pressure by removing any excess fluid and plasma proteins. Toxic insults to the lymphatic system can lead to elevated interstitial pressures and subsequent tissue edema.

Regulatory Mechanisms of the Vascular System

The vascular system includes conduits and microcirculation. This system under physiological conditions is regulated by the demands of tissue metabolism. The mechanisms controlling vascular physiology can be divided into neural, hormonal, and local controls. However, this categorization is artificial because the performance of the vascular system at any given time is the result of the integration of all three controlling mechanisms, and each of the three mechanisms affects the other two. The controlling mechanisms can be divided into remote or systemic, and local regulation. The remote regulation includes both neural and hormonal mechanisms.

Neurohormonal Regulation Most arteries, arterioles, venules, and veins, with the exception of those of the external genitalia, receive sympathetic innervation only. Norepinephrine is the usual transmitter that binds to α_1-adrenergic receptors. These receptors are distributed to vascular smooth muscle cells, and activation of the receptors leads to contraction of the vascular smooth muscle and thus the constriction of blood vessels. There are also β_2-adrenergic receptors in vascular smooth muscle cells, to which binds the circulating epinephrine released from the adrenal medulla. Activation of the β_2-adrenergic receptors leads to vascular smooth muscle relaxation and vasodilation. Coronary and skeletal muscle arteries are

highly responsive to the epinephrine-induced vasodilation. In addition, the blood vessels of skeletal muscles receive sympathetic cholinergic innervation in addition to their sympathetic adrenergic innervation, whose activation leads to vascular smooth muscle relaxation and vasodilation. The CNS regulates the activity of the autonomic nerves at several levels. Interactions between the central and autonomic nerves take place in the spinal cord, medulla, and hypothalamus. These central nervous regulations are reviewed in many physiology textbooks and not covered in this chapter.

There are many hormones that control the vascular system. Catecholamines, renin–angiotensin–aldosterone, antidiuretic hormone (ADH), and atrial natriuretic peptide (ANP) are important hormones that affect the vascular system and will be briefly reviewed.

Catecholamines are primarily secreted from the adrenal medulla. During the activation of the sympathetic nervous system, the adrenal medulla releases epinephrine ($>90\%$) and norepinephrine ($<10\%$) into the blood. As discussed above, the increase in circulating epinephrine activates the β_2-adrenergic receptors localized in the coronary and skeletal muscle arteries leading to vascular smooth muscle relaxation and vasodilation. This occurs during defense and exercise.

The renin–angiotensin–aldosterone system is critically involved in the regulation of blood pressure and volume. Renin is released from the kidney in response to reduced arterial pressure and blood volume, which catalyzes the conversion of a plasma protein angiotensinogen to angiotensin I. Angiotensin I is further converted to angiotensin II by an angiotensin-converting enzyme. Angiotensin II is a powerful arteriolar vasoconstrictor and also causes the release of aldosterone from the adrenal cortex. One of the important actions of the aldosterone is to reduce renal sodium excretion, resulting in retention of water and increase in blood volume.

ADH is released from the posterior pituitary gland under the control of the hypothalamus. ADH is a vasoconstrictor but is not present in plasma in high concentrations under physiological conditions. However, ADH release is increased under the conditions of hemorrhage, decreased atrial stretch receptor firing, and increased plasma osmolarity. The effect of ADH on the vascular system is to increase the retention of water by the kidney, and thus increasing blood volume.

ANP is released from atrial muscle cells when they are stimulated by stretch. ANP increases the excretion of sodium so that it decreases the blood volume. Therefore, ANP regulation of blood volume is a counter-regulatory mechanism of the renin–angiotensin–aldosterone system and ADH.

Local Metabolic Regulation   The local regulation of the vascular system is primarily referred to as the control of microcirculation. The microcirculation is also controlled by the above neurohormonal system. This section will focus on the local metabolic regulation of microcirculation. In addition, chemicals released from endothelial cells are major local regulators of microcirculation and highly toxicologically relevant.

Oxygen is a major regulator of microcirculation. Oxygen is not stored in the end organs, and has to be replenished constantly from the blood flow. Therefore, change in metabolic rate in the end organ will require a parallel change in oxygen supply from the blood flow. The change in oxygen tension signals vascular muscles to relax or constrict. The vascular smooth muscle is not sensitive enough to respond to changes in oxygen tension except for extremely low or high oxygen tensions. However, decrease in oxygen tension along with increases in metabolic rate causes the release of adenine nucleotides, free adenosine, and Krebs cycle intermediates. In addition, lactic acid accumulates under hypoxia conditions. All these cause vasodilation at physiological concentrations.

An important mechanism of local regulation of microcirculation is the substance released by endothelial cells, endothelium-derived relaxing factor. This substance is NO generated from arginine by NOS. The mechanism of action of the endothelium-derived relaxing factor involves the increase in cyclic guanosine monophosphate (cGMP) and the subsequent activation of intracellular signaling pathways leading to relaxation of vascular smooth muscle cells. The endothelium-derived relaxing factor also suppresses platelet activation and reduces adhesion of leukocytes to endothelial cells.

VASCULAR SYSTEM TOXIC RESPONSES

Mechanisms of Vascular Toxicity

The effects of chemicals on the vascular system have been studied for some time, but the significance of the toxic responses of this system in affecting physiological function and pathogenesis of other organ systems is not fully understood. The potential effects of vascular toxicity on overall health and disease status are most likely underestimated. All chemicals, after absorption, contact the vascular system. Vascular endothelial cells are the immediate targets of the chemicals and are of the most frequent risk for toxic insults. These cells are the major component of the microcirculation system. Vascular smooth muscle cells are the next important targets of the chemicals.

Responses of Vascular Endothelial Cells to Toxic Insults   Vascular endothelial cells play a critical role in both vascular protection from toxic insults and triggering detrimental cascade in response to toxic insults. Damage to vascular endothelial cells is a critical starting point for vascular injury. In response to toxic insults, production of NO and ROS increases in endothelial cells. Substances mimicking agonists activate the receptors on the endothelial cells and trigger intracellular signaling transduction, leading to activation of nuclear factor kappa-B (NFκB) and MAPK activity. The downstream signaling transduction pathways triggered by NFκB, MAPK, NO, and ROS then activate gene expression and regulate posttranslational modification of proteins leading to cytoprotective action against toxic insults, or the production of cytokines, chemokines, and adhesion molecules to protect the circulatory system and the affected organ systems.

Angiogenesis is an adaptive response to damages that follow toxic insults. This process helps form new blood vessels and deliver nutrients and oxygen to damaged tissue to repair the lesion. Vascular endothelial cells are both central to initiating and promoting the formation of new blood vessels and essential for blood vessel formation by forming initial tube-like structures. Xenobiotics can both promote and suppress angiogenesis, and the primary target is the vascular endothelial cell. Apoptosis is a major mechanism for cell death of the vascular endothelial cells and mechanisms and molecular signaling pathways leading to apoptosis are basically the same as described for cardiomyocytes. Until recently, it was thought that preexisting endothelial cells are the sole cellular source for angiogenesis in adults. Recent results indicate the existence of endothelial

progenitor cells. The injured endothelial monolayer can be regenerated by circulating bone marrow-derived endothelial progenitor cells, which accelerates re-endothelialization and limits atherosclerotic lesion formation. These endothelial progenitor cells may be important targets of xenobiotics, although no data are available.

Lesions to endothelial cells can result in atherosclerosis. Injury to endothelial cells results in increased production of endothelin-1 (ET-1) and increased release of prostacyclins. The endothelial cells are also involved in the recruitment of inflammatory cells to the lesion site. Activated lymphocytes secrete cytokines, such as TGF-β, which leads to a cascade of signaling transduction and a series of injurious responses including deposition of collagen.

ET-1 secreted by endothelial cells is a major mediator of vascular toxicity. ET is a peptide composed of 21 amino acids, derived from a large precursor, the big-ET, by the action of the endothelin-converting enzyme family. There are three isoforms of ET that have been identified, ET-1, ET-2, and ET-3. ET-1 is produced mainly by vascular endothelial cells and acts through two receptor subtypes, ET-A and ET-B. The ET receptors belong to the G-protein-coupled family. ET-1 is a potent vasoconstrictive chemical and plays an important role in the maintenance of vascular tone and blood pressure in healthy subjects. ET-1 contributes to the pathogenesis of myocardial disease. In failing hearts, activation of the ET system occurs; myocardial tissue levels of ET-1 are increased along with increased density of ET receptors, mainly in the form of ET-A due to upregulation in the myocardium (Ito *et al.*, 1993). In addition, circulating levels of both ET-1 and big-ET-1 are elevated in the patients with failing hearts. The elevation in serum levels of ET-1 thus has been used as an important marker of heart failure in humans (Monge, 1998). ET-1 mediated myocardial response is involved in air pollution PM-induced cardiac toxicity (Bouthillier *et al.*, 1998).

Responses of Smooth Muscle Cells to Toxic Insults   The consequence of damage to vascular smooth muscle cells involves changes in the vascular tone and atherosclerosis. Receptors localized on the plasma membrane of smooth muscle cells mediate the environmental changes and change the contractility of the blood vessels. The activation of these receptors leads to signaling transduction and changes in calcium conductance. Elevation of intracellular calcium activates the contractile apparatus, leading to alteration of vascular tone. Toxic substances influence calcium homeostasis in multiple ways. Calcium homeostasis is regulated by several regulatory mechanisms as well as affects many downstream actions. Toxic targets include the calcium-binding proteins, the calcium homeostasis regulatory proteins, the calcium-activated proteins such as calcineurin, and calcium storing and releasing process.

Proliferation and migration of medial smooth muscle cells are primarily responsible for the formation of sclerosis. Under certain circumstances, smooth muscle cells lose most of their contractility and become transformed smooth muscle cells. In most cases, this transformation is reversible. These new form of smooth muscle cells synthesize collagen and accumulate low-density lipoproteins along with a loss in the number of myofilaments. This phenotype transformation of the smooth muscle cells occurs in atherosclerosis. The mechanism and factors involved in the transformation are not fully understood, but the involvement of platelet activation has been indicated. Toxic substances affect the phonotype transformation of smooth muscle cells through multiple pathways. However, the growth-promoting effect is apparently a major action involved in the atherosclerotic lesion.

Oxidative Stress and Vascular Injury   Many xenobiotics generate ROS during their biotransformation. Both endothelial and smooth muscle cells are capable of producing ROS and the subsequent oxidative injury (Gurtner and Burke-Wolin, 1991). The mechanism of ROS generation from xenobiotics involves enzymatic and nonenzymatic reactions. Enzymes involved in the generation of ROS in vascular cells include amine oxidase, cytochrome $P450$ monooxygenases and prostaglandin synthetase. These enzymes use a diversity of substrates to produce ROS. The nonenzymatic reaction involves free iron and copper in the circulation system, which catalyze the Fenton' reaction to produce ROS.

Increase in ROS in endothelial cells is related to the stimulation by angiotensin II, as well as other neurohormonal factors and cyctokines. Angiotensin II binds to the AT1 receptor on the plasma membrane of endothelial cells. In response to receptor activation, cGMP production increases, leading to activation of endothelial CaM-dependent NOS and the production of NO. Stimulation of the AT1 receptor also leads to release of superoxide anion ($O_2^{\bullet-}$), through activation of a tyrosine phosphatase pathway. The release of both NO and $O_2^{\bullet-}$ is a major oxidative stress response of endothelial cells. The NO and $O_2^{\bullet-}$ production and release cause damage not only to endothelial cells, but also to other cells in the vascular system.

Vascular smooth muscle cells in response to angiotensin II markedly increase the production of $O_2^{\bullet-}$. The source of $O_2^{\bullet-}$ in these cells likely comes from NADPH oxidase, although NADH is also indicated in the production of $O_2^{\bullet-}$ in these cells. Xenobiotics, as discussed in the "Vascular System Toxic Chemicals" section, can activate the enzyme system and lead to more extensive production of $O_2^{\bullet-}$, or inhibit the antioxidant system including superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase resulting in accumulation of ROS in the cells.

Inflammatory Lesions   Inflammatory lesions of the vascular system are a common response of the vascular system. Inflammatory lesions are also called vasculitis. The pathogenesis of vasculitis has been studied both in vivo and in vitro, but the causes of many types of vasculitis are unknown. The initial injury to endothelial cells and the release of chemicals from the injured cells are responsible for the initiation of the inflammatory response, including recruitment of inflammatory cells to the injured site. Cytokines released from the activated inflammatory cells further propagate the inflammatory response leading to eventual lesion or vasculitis.

Toxic Responses of Blood Vessels

Hypertension and Hypotension   The vasculature pressure change is a major phenotype of vascular injury. Hypertension results from excessive constriction of the arterial vasculatures and/or increased resistance of the microcirculation system. However, the primary problem of sustained hypertension is an elevated vascular resistance in all organs. Once hypertension is established it becomes a disease of the microvasculature, particularly the arteriolar microvasculature. An increased incidence of temporary or, in some cases, permanent closure of small arterioles is associated with increased resistance of the end organs. The vascular smooth muscle cells become hypertrophied. However, the most predominant change is that all vascular smooth muscle cells are exceptionally responsive to norepinephrine. Sustained hypertension is a major complication of primary cardiovascular diseases. Complications include accelerated atherosclerosis and overload of the left ventricular muscle due

to high arterial pressure. Toxic substances may directly or indirectly affect the sympathetic nervous system or alter the turnover of catecholamines in the circulation, resulting in hypertension. However, sustained hypertension by xenobiotics may involve more complicated metabolic changes in the end organs and thus changes in microcirculation also take place. For example, chemicals may enhance the renin–angiotensin system as well as renal toxicity, which may cause hypertension.

Hypotension is practically defined as the symptoms caused by low blood pressure. There are several regulatory mechanisms in the vascular system and the integration of these regulations that maintain blood flow and blood pressure within normal range. Baroreceptors, volume receptors, chemoreceptors, and pain receptors are all involved in the integrated regulatory action to maintain adequate blood pressure. During chemical exposure, these mechanisms may be affected individually or jointly resulting in a disturbance in the integration of the regulatory mechanisms. Both transient and sustained hypotension can be produced by xenobiotics. The most common adverse effect of antihypertension drugs is hypotension. Another major cause of hypotension is hemorrhage. Alcohol overdose also causes hypotension.

Atherosclerosis   The most frequent vascular structural injury is atherosclerosis. The primary problem is the mechanical occlusion of the blood vessels so that blood flow is inadequate for the metabolic demands of the organs. As discussed above, activation of vascular smooth muscle cells is critically involved in atherosclerosis. Once stimulated, the vascular smooth muscle cells proliferate and migrate to the lesion site. These cells undergo phenotype transformation and increase the production of type I and II collagen, dermatan sulfate, proteoglycan, and stromelysins. In addition, the smooth muscle cells produce cytokines including macrophage colony-stimulating factor, TNF-α, and monocyte chemoatractant protein-1. The recruitment of inflammatory cells to the lesion site is the perpetuation process of atherosclerosis.

The classic definition of atherosclerotic plaque is a combination of changes in the intima of arteries consisting of local accumulation of lipids, complex carbohydrates, blood and blood products, fibrous tissue, and calcium deposits. However, this classic definition does not sufficiently describe the advanced atherosclerotic plaques that invade the media and produce bulging or enlarged arteries, cellular infiltration, and neovascularization. During the early development of atherosclerotic plaques, the lipid core has been described as the starting step of atherosclerosis. A lipid core develops and accumulates in the deep layer of the lesions before fibrous plaque formation begins. Inflammation and immune response are involved in both the early deposition of the lipid core and the late stage of fibrous accumulation. The inflammatory response includes cytokines, such as IL-6 and TNF-α. These cytokines are produced by vascular smooth muscle cells and infiltrated inflammatory cells. Many chemicals affect the oxidative metabolism of lipids in the circulatory system to trigger the formation and development of the lipid core of atherosclerosis. Toxic effects on smooth muscle cells can also initiate the formation of atherosclerotic plaques, which may be different from the lipid core mediated atherosclerosis. In addition, macrophages and monocytes are also targets for xenobiotics and have been shown to be importantly involved in the progression of atherosclerosis.

Hemorrhage   A direct mechanical injury to blood vessels causes bleeding. Chemical-induced hemorrhages are seen when damage to capillaries takes place. In addition, toxic effects on blood-clotting increases the probability of hemorrhage. A classic example of chemical-induced hemorrhage is observed in snake venom poisoning. Zinc-dependent metalloproteinases are major components of snake venom and responsible for the hemorrhage. Snake venom metalloproteinases degrade various components of the basement membrane and hydrolyze endothelial cell membrane proteins, such as integrins and cadherins, involved in cell–matrix and cell–cell adhesion. These actions weaken the capillary wall and perturb the interactions between endothelial cells and the basement membrane. Thus the transmural pressure acting on the weakened capillary wall causes distention. As a consequence, endothelial cells become very thin and eventually, the integrity of the capillary wall is lost. In addition, endothelial cells become more susceptible to blood flow-dependent shear stress, further contributing to the capillary wall disruption.

Edema   The capillary exchange of fluid is bidirectional and capillaries and venules may alter the balance of hydrostatic and colloid osmotic pressure. Filtration occurs most likely at the arteriolar end of capillaries, where filtration forces exceed absorption forces. The absorption of water occurs in the venular end of the capillary and small venules. The capillary pressure is determined by both the resistance of, and the blood pressure in arterioles and venules. Xenobiotics can change the pressure gradient and cause more filtration than reabsorption of the extracellular liquid by the capillary system. In addition, more fluid is filtered than is reabsorbed by the venous system under physiological conditions. Therefore, the removal of excess fluid as well as plasma proteins that diffuse into the interstitial space is essential. This is accomplished by the lymphatic system. The lymphatics ultimately drain into the vena cava. Toxic insults to the lymphatic system can lead to elevated interstitial pressures and the subsequent tissue edema.

VASCULAR SYSTEM TOXIC CHEMICALS

Chemicals that cause vascular toxicity can also be classified into pharmaceutical chemicals, natural products, and environmental pollutants and industrial chemicals. Blood vessels are the target organ of these chemicals. However, some of these chemicals affect both the blood vessels and the heart. For instance, blood vessels in the heart belong to the vascular system, so that the toxicity of vascular toxic chemicals may express their toxicity in the form of cardiac toxic manifestations. Endothelial cells are major target cells of the chemicals affecting the vascular system, which are also found in the heart and make a contribution to cardiac toxicity. The same principle applies to other organ systems. Due to the distribution of vascular system in the end organs, vascular toxicity affects the organs in which the vessels are localized and is often accompanied with functional defects of the organ.

Pharmaceutical Chemicals

Vascular toxicity of pharmaceutical chemicals that are used to treat vascular disease or used to treat nonvascular disease is well-known clinically. The major manifestation and mechanisms of action of selected therapeutic agents are briefly discussed below.

Sympathomimetic Amines   The sympathomimetic amines, including epinephrine, norepinephrine, dopamine, and isoproterenol, can damage the arterial vasculature by a variety of mechanisms.

Large doses of norepinephrine produce toxic effects on the endothelium of the thoracic aorta of rabbits, including degenerative changes in the aortic arch in the form of increased numbers of microvilli and many focal areas of unusual endothelial cytoarchitecture. Repeated exposure to catecholamines induces atherosclerotic lesions in several animal species. Experimetnal data suggest that catecholamines cause the proliferative disturbances in vascular cells via α-receptors because prazocin, an α-receptor antagonist, effectively prevents the toxic response (Nakaki *et al.*, 1989). Smooth muscle cells subjected to increased stress by diabetes, hypertension, and balloon injury are more susceptible to the effects of catecholamines. Thus, the formation of arteriosclerotic lesions in certain forms of hypertension may be initiated and/or potentiated by high levels of circulating catecholamines.

Nicotine   Nicotine is an alkaloid found in various plants and mimics the actions of acetylcholine at nicotinic receptors throughout the body. At pharmacologic concentrations, nicotine increases heart rate and blood pressure as a result of stimulation of sympathetic ganglia and the adrenal medulla. Epidemiologic and experimental studies have suggested that nicotine is a causative or aggravating factor in myocardial and cerebral infarction, gangrene, and aneurysm. The effects of nicotine are related to competitive inhibition of cyclooxygenase.

Cocaine   The central actions of cocaine are to increase the circulating levels of catecholamines and cause a generalized state of vasoconstriction. Hypertension and cerebral strokes are common vascular complications. In pregnant women, cocaine-induced vascular changes have been associated with abortions and abruptio placentae. Studies have shown that cocaine enhances leukocyte migration across the cerebral vessel wall during inflammatory conditions. This effect is exerted through a cascade of augmented expression of inflammatory cytokines and endothelial adhesion molecules and may in fact underlie the cerebrovascular complications associated with cocaine abuse (Gan *et al.*, 1999).

Psychotropic Agents   Trifluoperazine and chlorpromazine among the psychotropic drugs have been shown to cause intracellular cholesterol accumulation in cultured cells of the aortic intima (Iakushkin *et al.*, 1992). Enalapril has been shown to cause angioedema in humans. Aside from the atherogenic effects, postural hypotension has been identified as the most common cardiovascular side effect of TCAs.

Antineoplastic Agents   The vasculotoxic responses elicited by antineoplastic drugs range from asymptomatic arterial lesions to thrombotic microangiopathy. Pulmonary veno-occlusive disease has been reported after the administration of various drugs, including 5-fluorouracil, doxorubicin, and mitomycin. Cyclophosphamide causes cerebrovascular and viscerovascular lesions, resulting in hemorrhages. Chronic infusions of 5-fluoro-2-deoxyuridine into the hepatic artery in dogs resulted in gastrointestinal hemorrhage and portal vein thrombosis.

Analgesics and Nonsteroidal Anti-Inflammatory Agents   Aspirin can produce endothelial damage as part of a pattern of gastric erosion. Studies in rats have shown early changes in the basement membrane of endothelial cells of the capillaries and postcapillary venules, leading to obliteration of small vessels and ischemic

infarcts in the large intestine. Regular use of analgesics containing phenacetin has been associated with an increased risk of hypertension and cardiovascular morbidity. NSAIDs may induce glomerular and vascular renal lesions.

Oral Contraceptives   Oral contraceptive steroids can produce thromboembolic disorders. Epidemiologic studies have shown that oral contraceptive users have an increased risk of myocardial infarction relative to nonusers, a correlation that is markedly exacerbated by smoking, and oral contraceptive users experience an increased risk of cerebral thrombosis, hemorrhage, venous thrombosis, and pulmonary embolism (Stolley *et al.*, 1989). However, the mechanism by which oral contraceptives increase the risk of vascular disease is unclear.

Natural Products

Natural products that cause vascular toxicity include those discussed for drugs causing cardiotoxicity. In addition, many other drugs also cause vascular leasions and toxicity such as bacterial endotoxins and homocysteines, which have unique vascular toxic effects.

Bacterial Endotoxins   Bacterial endotoxins are potent toxic agents to vascular system and cause a variety of toxic effects in many vascular beds. In the liver, they cause swelling of endothelial cells and adhesion of platelets to sinusoid walls. In the lung, endotoxins produce increased vascular permeability and pulmonary hypertension. Infusion of endotoxin into experimental animals produces thickening of endothelial cells and the formation of fibrin thrombi in small veins. The terminal phase of the effects of endotoxin on the systemic vasculature results in marked hypotension. The ability of vitamin E to prevent disseminated intravascular coagulation induced by bacterial endotoxins in the rat suggests that that action of these agents is somehow related to oxidative stress mechanisms.

Homocysteine   Moderately elevated levels of homocysteine have been associated with atherosclerosis and venous thrombosis. Conditions including increases in the circulating homocysteine involve cardiac complications such as hypertrophic cardiomyopathy and heart failure. Toxicity may involve oxidative injury to vascular endothelial and/or smooth muscle cells, leading to deregulation of vascular smooth muscle growth, synthesis and deposition of matrix proteins, and adverse effects on anticoagulant systems (Harpel, 1997).

Hydrazinobenzoic Acid   Hydrazinobenzoic acid is a nitrogen–nitrogen bonded chemical that is present in the cultivated mushroom *Agaricus bisporus*. This hydrazine derivative causes smooth muscle cell tumors in the aorta and large arteries of mice when administered over the life span of the animals (McManus *et al.*, 1987). These tumors have the characteristic appearance and immunocytochemical features of vascular leiomyomas and leiomyosarcomas. Smooth muscle cell lysis with vascular perforation apparently precedes malignant transformation.

T-2 Toxin   Trichothecene mycotoxins, commonly classified as tetracyclic sesquiterpenes, are naturally occurring cytotoxic metabolites of *Fusarium* species. These mycotoxins, including T-2 toxin   [4β,15-diacetoxy-8α-(3-methylbutyryloxy)-3α-hydroxy-12,13-epoxytrichothec-9-ene], are major contaminants of foods

and animal feeds and may cause illness in animals and humans. Intravenous infusion of T-2 toxin in rats causes an initial decrease in heart rate and blood pressure, followed by tachycardia and hypertension and finally by bradycardia and hypotension (Mcmanus *et al.*, 1987). Acute T-2 toxin exposure causes extensive destruction of myocardial capillaries, while repeated dosing promotes thickening of large coronary arteries.

Vitamin D   The toxic effects of vitamin D may be related to its structural similarity to 25-hydroxycholesterol, a potent vascular toxin. The manifestions of vitamin D hypervitaminosis include medial degeneration, calcification of the coronary arteries, and smooth muscle cell proliferation in laboratory animals.

β-Amyloid   Accumulation of β-amyloid is a major lesion in the brain of Alzheimer's patients. Studies have shown that administration of β-amyloid produces extensive vascular disruption, including endothelial and smooth muscle damage, adhesion and migration of leukocytes across arteries and venules (Thomas *et al*., 1997). Most importantly, the vascular actions of β-amyloid appear to be distinct from the neurotoxic properties of the peptide. It appears that vascular toxicity of β-amyloid makes contributions to Alzheimer's dementia.

Environmental Pollutants and Industrial Chemicals

The environmental pollutants and industrial chemicals discussed in cardiac toxicity section all have toxic effects on the vascular system. As discussed above, the cardiac effect of some of these agents and pollutants may result primarily from the vascular effect. The byproducts of vascular tissue damage or the secreted substances, such as cytokines derived from vascular injury, can affect the heart either directly because of the residual of the vascular system in the heart, or indirectly through blood circulation. In this context, some of the chemicals discussed in the cardiotoxicity will not be further described. Some unique vascular toxicity will be presented.

Carbon Monoxide   Carbon monoxide induces focal intimal damage and edema in laboratory animals at a concentration (180 ppm) to which humans may be exposed from environmental sources such as automobile exhaust, tobacco smoke, and fossil fuels. However, it is difficult to distinguish the direct effects of carbon monoxide from those of chemicals such as sulfur oxides, nitrogen oxides, aldehydes, and hydrocarbons on humans because most sources of carbon monoxide are complex mixtures of chemicals. Degenerative changes of myocardial arterioles have been produced experimentally in dogs forced to smoke. Similar changes have also been detected in humans who were heavy smokers and died of noncardiac causes (Wald and Howard, 1975). Tobacco smoke not only exerts a direct atherogenic effect (endothelial injury, changes in lipid profiles, and proliferation of smooth muscle cells), but also facilitates thrombosis by modulation of platelet function and vascular spasm.

Short-term exposure to carbon monoxide is associated with direct damage to vascular endothelial and smooth muscle cells. Injury to endothelial cells increases intimal permeability and allows the interaction of blood constituents with underlying components of the vascular wall. This response may account in part for the ability of carbon monoxide to induce atherosclerotic lesions in several animal species. The toxic effects of carbon monoxide have been attributed to its reversible interaction with hemoglobin. As a result of this interaction, carboxyhemoglobin decreases the oxygen-carrying capacity of blood, eventually leading to functional anemia. In addition, carbon monoxide interacts with cellular proteins such as myoglobin and cytochrome *c* oxidase and elicits a direct vasodilatory response of the coronary circulation.

Carbon Disulfide   Carbon disulfide (dithiocarbonic anhydride) occurs in coal tar and crude petroleum and is commonly used in the manufacture of rayon and soil disinfectants. This chemical has been identified as an atherogenic agent in laboratory animals. The mechanism for carbon disulfide-atheroma production may involve direct injury to the endothelium coupled with hypothyroidism, because thiocarbamate (thiourea), a potent antithyroid substance, is a principal urinary metabolite of carbon disulfide. Carbon disulfide also modifies low-density lipoprotein in vitro and enhances arterial fatty deposits induced by a high-fat diet in mice (Lewis *et al.*, 1999).

1,3-Butadiene   Studies have shown that 1,3-butadiene, a chemical used in the production of styrene-butadiene, increases the incidence of cardiac hemangiosarcomas, which are tumors of endothelial origin (Miller and Boorman, 1990). Although hemangiosarcomas have also been observed in the liver, lung, and kidney, cardiac tumors are a major cause of death in animals exposed to this chemical. The toxic effects of 1,3-butadiene are dependent on its metabolic activation by cytochrome $P450$ to toxic epoxide metabolites. The ultimate outcomes of exposure probably are influenced by the rates of glutathione-mediated detoxification of oxidative metabolites.

Metals and Metalloids   The vascular toxicity of food- and waterborne elements (selenium, chromium, copper, zinc, cadmium, lead, and mercury) as well as airborne elements (vanadium and lead) involves reactions of metals with sulfhydryl, carboxyl, or phosphate groups. Metals such as cobalt, magnesium, manganese, nickel, cadmium, and lead also interact with and block calcium channels. Intracellular calcium-binding proteins, such as CaM, are biologically relevant targets of heavy metals, including cadmium, mercury and lead, although the contribution of this mechanism to the toxic effects of metals has been fully understood.

Cadmium effects on the vascular system have been studied in the greatest detail. Although cadmium is not preferentially localized in blood vessels relative to other tissues, when present, cadmium is localized in the elastic lamina of large arteries, with particularly high concentrations at arterial branching points (Perry *et al.*, 1989). A large portion of the cadmium that accumulates in the body is tightly bound to hepatic and renal MT. The low MT levels in vascular tissue may actually predispose a person to the toxic effects of cadmium (Perry *et al.*, 1989). Long-term exposure of laboratory animals to low levels of cadmium has been associated with the development of atherosclerosis and hypertension in the absence of other toxic effects. Selenium and zinc inhibit, whereas lead potentiates the hypertensive effects of cadmium. Calcium has antagonistic effect on cadmium-induced high blood pressure. Cadmium increases sodium retention, induces vasoconstriction, increases cardiac output, and produces hyperreninemia. Any one of these mechanisms could account for the putative hypertensive effects of cadmium.

Lead has been shown from epidemiologic studies to be associated with essential hypertension in a large percentage of patients (Batuman *et al.*, 1983). Elevated blood pressure has also been

observed during childhood lead poisoning. The direct vasoconstrictor effect of lead may be related to the putative hypertensive response. This effect can be complemented by the ability of lead to activate the renin–angiotensin–aldosterone system. Lead also directly affects vascular endothelial and smooth muscle cells. For instance, lead inhibits the repair process in damaged endothelial cells (Fujiwara *et al.*, 1997) and modulates spontaneous release of fibrinolytic proteins from subendothelial cells through intracellular calcium-independent pathways (Yamamoto *et al.*, 1997). Acute lead-induced neuropathy may be due to cerebral capillary dysfunction. Inorganic lead alters arterial elasticity and causes sclerosis of renal vessels.

Mercury produces vasoconstriction of preglomerular vessels and disrupts the integrity of the blood–brain barrier. The opening of the blood–brain barrier results in extravasation of plasma protein across vascular walls into adjoining brain tissues. Mercury added to platelet-rich plasma causes a marked increase in platelet thromboxane B_2 production and platelet responsiveness to arachidonic acid.

Arsenic poisoning causes vasodilation and capillary dilation. These actions have been associated with extravasation, transudation of plasma, and decreased intravascular volume. A severe form of arteriosclerosis, blackfoot disease, in Taiwan has beens shown to be associated with high levels of arsenic in the soil and water. Blackfoot disease is an endemic peripheral vascular occlusive disease that exhibits arteriosclerosis obliterans and thromboangiitis. The ability of arsenic to induce these changes has been attributed to its effects on vascular endothelial cells. Arsenic has been reported to cause noncirrhotic portal hypertension in humans.

Aromatic Hydrocarbons   Aromatic hydrocarbons, including polycyclic aromatic hydrocarbons and polychlorinated dibenzop-dioxins, are persistent toxic environmental contaminants. Aromatic hydrocarbons have been identified as vascular toxins that can initiate and/or promote the atherogenic process in experimental animals (Ou and Ramos, 1992). The atherogenic effect is associated with cytochrome P450–mediated conversion of the parent compound to toxic metabolic intermediates, but aromatic hydrocarbons can also initiate the atherogenic process. However, studies have also shown that treatment with several polycyclic hydrocarbons increases the size but not the frequency of atherosclerotic lesions (Albert *et al.*, 1977; Penn and Synder, 1988), suggesting that polycyclic aromatic hydrocarbons act as promoters of the atherosclerotic process. Although additional studies are required to define the "initiating" versus "promotional" actions of polycyclic aromatic hydrocarbons, their ability to readily associate with plasma lipoproteins may play a critical role in vascular toxicity.

Particulate Air Pollution   Recent epidemiological studies have provided a strong body of evidence that elevated levels of ambient particulate air pollution (PM) are associated with increased cardiovascular and respiratory morbidity and mortality. Besides the PM effects on cardiomyocytes such as alterations in ion channel function leading to cardiac malfunction, available clinical and experimental evidence lends support to the vascular effects of inhaled ambient particles, including endothelial dysfunction and promotion of atherosclerotic lesions. Importantly, these lesions lead to release or secretion of cytokines and chemokines, worsening cardiac complications. For instance, PM exposure significantly increases serum total endothelin concentrations and worsens premature ventricular complexes of the electrocardiograms that occurr in the myocardial infaret rats (Kang *et al.*, 2002). The PM effects on vascular system and the consequences are important health-related topics and further studies are needed to substantiate our current understanding of mechanisms for PM adverse vascular effects.

CHAPTER 19

TOXIC RESPONSES OF THE SKIN

Robert H. Rice and Theodora M. Mauro

As the body's first line of defense against external insult, the skin's enormous surface area (1.5–2 m^2) is exposed routinely to chemicals and may inadvertently serve as a portal of entry for topical contactants. Recognizing the potential hazards of skin exposure, the National Institute of Occupational Safety and Health (NIOSH) characterized skin disease as one of the most pervasive occupational health problems in the United States. In 1982, NIOSH placed skin disease in the top ten leading work-related diseases based on frequency, severity, and the potential for prevention. Data from the Bureau of Labor Statistics indicate that in 2004, skin disease attributed to workplace exposures accounted for nearly 16% of the reported nonfatal occupational disease in private industry; incidence data indicate a rate of 4.4 cases per 10,000 or nearly 39,000 new cases per year. Substantial reduction in the reported incidence has occurred in recent years thanks to workplace cleanup and better personal protective equipment. Nevertheless, improvements in prevention and management are needed for continued progress (Emmett, 2003). Skin conditions resulting from exposures to consumer products or occupational illnesses not resulting in work time loss are poorly recorded and tracked. Hence the incidence of such skin diseases appears greatly underestimated.

SKIN AS A BARRIER

A large and highly accessible human organ, the skin protects the body against external insults to maintain internal homeostasis. Its biological sophistication allows it to perform a myriad of functions above and beyond that of a suit of armor. Physiologically, the skin participates directly in thermal, electrolyte, hormonal, metabolic, and immune regulation, without which a human would perish. Rather than merely repelling noxious physical agents, the skin may react to them with a variety of defensive mechanisms that prevent internal or widespread cutaneous damage. If an insult is severe or

sufficiently intense to overwhelm the protective function of the skin, acute or chronic injury becomes readily manifest in various ways. The specific presentation depends on a variety of intrinsic and extrinsic factors including body site, duration of exposure, and other environmental conditions (Table 19-1).

Skin Histology

The skin consists of two major components: the outer epidermis and the underlying dermis, which are separated by a basement membrane (Fig. 19-1). The junction ordinarily is not flat but has an undulating appearance (rete ridges). In addition, epidermal appendages (hair follicles, sebaceous glands, and eccrine glands) span the epidermis and are embedded in the dermis. In thickness, the dermis comprises approximately 90% of the skin and has mainly a supportive function. It has a high content of collagen and elastin secreted by scattered fibroblasts, thus providing the skin with elastic properties. Separating the dermis from the underlying tissues is a layer of adipocytes, whose accumulation of fat has a cushioning action. The blood supply to the epidermis originates in the capillaries located in the rete ridges at the dermal–epidermal junction. Capillaries also supply the bulbs of the hair follicles and the secretory cells of the eccrine (sweat) glands. The ducts from these glands carry a dilute salt solution to the surface of the skin, where its evaporation provides cooling.

The interfollicular epidermis is a stratified squamous epithelium consisting primarily of keratinocytes. These cells are tightly attached to each other by desmosomes and to the basement membrane by hemidesmosomes. Melanocytes are interspersed among the basal cells and distributed in the papilla of hair follicles. In the epidermis, these cells are stimulated by ultraviolet light to produce melanin granules. The granules are extruded and taken up by the surrounding keratinocytes, which thereby become pigmented. Migrating through the epidermis are numerous Langerhans cells, which

Table 19-1
Factors Influencing Cutaneous Responses

VARIABLE	COMMENT
Body site	
Palms/soles	Thick stratum corneum—good physical barrier
	Common site of contact with chemicals
	Occlusion with protective clothing
Intertriginous areas (axillae, groin, neck, finger webs, umbilicus, genitalia)	Moist, occluded areas
	Chemical trapping
	Enhanced percutaneous absorption
Face	Exposed frequently
	Surface lipid interacts with hydrophobic substances
	Chemicals frequently transferred from hands
Eyelids	Poor barrier function—thin epidermis
	Sensitive to irritants
Postauricular region	Chemical trapping
	Occlusion
Scalp	Chemical trapping
	Hair follicles susceptible to metabolic damage
Predisposing cutaneous illnesses	
Atopic dermatitis	Increased sensitivity to irritants
	Impaired barrier function
Psoriasis	Impaired barrier function
Genetic factors	Predisposition to skin disorders
	Variation in sensitivity to irritants
	Susceptibility to contact sensitization
Temperature	Vasodilation—improved percutaneous absorption
	Increased sweating—trapping
Humidity	Increased sweating—trapping
Season	Variation in relative humidity
	Chapping and wind-related skin changes
Figure 19-1. Diagram of a crosssection of human skin.

The epidermis and pilosebaceous unit are shown in blue.

are important participants in the immune response of skin to foreign agents.

Keratinocytes of the basal layer comprise the germinative compartment. When a basal cell divides, one of the progeny detaches from the basal lamina and migrates outward. As cells move toward the skin surface, they undergo a remarkable program of terminal differentiation. They gradually express new protein markers and accumulate keratin proteins, from which the name of this cell type is derived. The keratins form insoluble intermediate filaments accounting for nearly 40% of the total cell protein in the spinous layer. At the granular layer, the cells undergo a striking morphological transformation, becoming flattened and increasing in volume by nearly 40-fold. Lipid granules fuse with the plasma membrane at the granular layer/stratum corneum interface, filling the intercellular spaces of the stratum corneum with lipid, as opposed to the aqueous intercellular solution in the viable epidermis. Meanwhile, the plasma membranes of these cells become permeable, resulting in the loss of their reducing environment and consequently in extensive disulfide bonding among keratin proteins. Cell organelles are degraded, while a protein envelope is synthesized immediately beneath the plasma membrane. The membrane is altered characteristically by the loss of phospholipid and the addition of sphingolipid.

This program of terminal differentiation, beginning as keratinocytes leave the basal layer, produces the outermost layer of the skin, the stratum corneum. No longer viable, the mature cells

(called *corneocytes*) are ∼80% keratin in content. They are gradually shed from the surface and replaced from beneath. The process typically takes 2 weeks for basal cells to reach the stratum corneum and another 2 weeks to be shed from the surface. In the skin disease psoriasis, the migration of cells to the surface is nearly tenfold faster than normal, resulting in a stratum corneum populated by cells that are not completely mature. In instances in which the outer layer is deficient due to disease or physical or chemical trauma, the barrier to the environment that the skin provides is inferior to that provided by normal, healthy skin.

Percutaneous Absorption

Until a century ago, the skin was thought to provide an impervious barrier to exogenous substances. Gradually, the ability of substances to penetrate the skin, though this process generally is very slow, became appreciated. During the past 50 years, the stratum corneum has been recognized as the primary barrier (Scheuplein and Blank, 1971). Diseases (e.g., psoriasis) or other conditions (e.g., abrasion, wounding) in which this barrier is compromised can permit greatly increased uptake of poorly permeable substances, as does removal of the stratum corneum by tape stripping or organic solvents such as acetone. The viable layer of epidermis provides a much less effective barrier, because hydrophilic chemicals readily diffuse into the intercellular water, while hydrophobic chemicals can partition into cell membranes, and each can diffuse readily to the blood supply in the rete ridges of the dermis.

Probably the best-known biological membrane barrier for this purpose, the stratum corneum, prevents water loss from underlying tissues by evaporation. Its hydrophobic character reflects the lipid content of the intercellular space, ∼15% of the total volume (Elias, 1992). The lipids, a major component being sphingolipids, have a high content of long-chain ceramides, removal of which seriously compromises barrier function as measured by transepidermal water loss. The stratum corneum ordinarily is hydrated (typically 20% water) with the moisture residing in corneocyte protein; however, it can take up a great deal more water upon prolonged immersion, thereby reducing the effectiveness of the barrier to chemicals with a hydrophilic character. Indeed, occlusion of the skin with plastic wrap, permitting the retention of perspiration underneath, is a commonly employed technique to enhance uptake of chemicals applied to the skin surface. Although penetration from the air is generally too low to be of concern, protection from skin uptake may be advisable for some compounds (e.g., nitrobenzene) at concentrations high enough to require respirator use.

Finding the rate at which the uptake of chemicals through the skin occurs is important for estimating the consequences of exposure we encounter in the environment. Indeed, a regulatory strategy permitting bathing in water considered barely unfit for drinking was revised when it was realized that exposure from dermal/inhalation uptake during bathing could be comparable to that from drinking 2 L of the water (Brown *et al*., 1984). Uptake through the skin is now incorporated in pharmacokinetic modeling to estimate potential risks from exposures. The degree of uptake depends upon the details of exposure conditions, being proportional to solute concentration (assuming it is dilute), time, and the amount of skin surface exposed. In addition, two intrinsic factors contribute to the absorption rate of a given compound: its hydrophobicity, which affects its ability to partition into epidermal lipid, and its rate of diffusion through this barrier. A measure of the first property is the commonly used octanol/water partitioning ratio (K_{ow}). This is particularly relevant for exposure to contaminated water, as occurs during bathing or swimming. However, partitioning of a chemical into the skin is greatly affected by its solubility in or adhesion to the medium in which it is applied (including soil). Similarly, very hydrophobic compounds, once in the stratum corneum, may diffuse only very slowly into less hydrophobic regions below. The second property is an inverse function of molecular weight (MW) or molecular volume. Thus, hydrophobic agents of low MW permeate the skin better than those of high MW or those that are hydrophilic. For small molecules, hydrophobicity is a dominant factor in penetration.

Although only small amounts of chemicals may penetrate the stratum corneum, those of high potency may still be very dangerous. For example, hydrophobic organophosphorus and carbamate pesticides can be neurotoxic to humans and domestic animals by skin contact. Children and adolescents harvesting tobacco are especially susceptible to poisoning by contact with nicotine, a natural pesticide present in moisture on the leaves (McKnight and Spiller, 2005). Conditions of topical treatment of livestock for pest control must take into consideration not only the tolerance of the animals but also residues in meat and milk resulting from skin penetration. High-level skin exposure to chemicals considered safe at low levels can be dangerous, evident from the nervous system toxicity and deaths of babies exposed to hexachlorophene mistakenly added to talcum powder for their diapers (Martin-Bouyer *et al*., 1982). Previous findings of *N*-nitrosamines that penetrate skin well (such as *N*-nitrosodiethanolamine) in cutting oils and cosmetics raised concern and led to their monitoring and to reduction of exposure.

Considerable empirical information has been collected on some chemicals of special interest (including pharmaceuticals, pesticides, and pollutants) for use in quantifying structure/penetration relationships. From such information, relations can be obtained for skin penetration (P_{cw}) using empirically derived constants (C_1, C_2, C_3) that have the form shown below (Potts and Guy, 1992). Such relations describe steady-state conditions, in which a chemical

$$\log P_{cw} = C_1 - C_2(MW) + C_3 \log K_{ow}$$

leaves the stratum corneum at the same rate it enters. Because rates of transfer of very hydrophobic agents into the aqueous phase of the spinous layer are slow, saturation of the stratum corneum provides a depot, leading to continued penetration into the body for relatively long time periods after external exposure to a chemical stops. More recent modeling efforts have taken into account vehicles and additives to improve predictability of complex chemical mixtures (Riviere and Brooks, 2005).

Diffusion through the epidermis is considerably faster at some anatomical sites than others. A list in order of decreasing permeability gives the following hierarchy: foot sole > palm > forehead > abdomen (Scheuplein and Blank, 1971). Scrotal skin reportedly has the highest permeability for some topical chemicals (Fisher, 1989). Under ordinary conditions, absorption through the epidermal appendages is generally neglected, despite the ability of chemicals to bypass the stratum corneum by this route, because the combined appendageal surface area is such a small fraction of the total available for uptake. However, because loading of the stratum corneum is slow, penetration through the appendages can constitute an appreciable fraction of the total for short exposures. In some cases, the effects of appendages can even be dominant. For instance, benzo(*a*)pyrene

penetrates the skin of haired mice several-fold faster than that of hairless strains (Kao and Hall, 1987). As indicated below, in some cases these properties have been exploited for therapeutic uses.

Transdermal Drug Delivery The ability of the stratum corneum to serve as a reservoir for exogenously applied chemicals is well illustrated by the recent development of methods for the delivery of pharmaceuticals. Application of drugs to the skin can produce systemic effects, a phenomenon observed unintentionally before the ability of the skin to serve as a delivery system was appreciated. For example, topical exposure of young girls to estrogens has led to reports of pseudoprecocious puberty, whereas in young or adult males, such exposure has produced gynecomastia (Amin et al., 1998). Specially designed patches are currently in use to deliver estradiol, testosterone, nitroglycerin, scopolamine, clonidine, fentanyl, and nicotine for therapeutic purposes, and others are under development. The advantages of this approach over oral dosing include providing a steady infusion for extended periods (typically 1–7 days), thereby avoiding large variations in plasma concentration, preventing exposure to the acidic pH of the stomach, and avoiding biotransformation in the gastrointestinal tract or from first-pass removal by the liver. The contrast in plasma concentration kinetics between different methods of delivery is particularly evident for agents that are rapidly metabolized, such as nitroglycerin, which has a half-life of a few minutes. A variety of chemicals, chosen carefully to minimize irritation or allergenicity, have been incorporated into pharmaceutical preparations to enhance absorption and penetration. In addition, encapsulating a drug in small vesicles of phospholipid or nonionic surfactant can be effective at least in part by targeting hair follicles (Choi and Maibach, 2005).

Measurements of Penetration For many purposes, including risk assessment and pharmaceutical design, the most useful subject for experimentation is human skin. Volunteers are dosed, plasma and/or urine concentrations are quantified at suitable intervals, and amounts excreted from the body are estimated. Previous measurements of penetration often used ^{14}C-labeled agents. This approach is not preferred, but use of isotopic labels now is readily feasible when coupled to ultrasensitive detection by accelerator mass spectrometry (Buchholz et al., 1999). For in vitro work, excised split-thickness skin can be employed in special diffusion chambers, though care is needed to preserve the viability of the living layer of epidermis. The chemical is removed for quantification from the underside by a fluid into which it partitions, thereby permitting continued penetration. Commonly employed is a simpler set up, using cadaver skin with the lower dermis removed. This lacks biotransformation capability but retains the barrier function of the stratum corneum. The phamacokinetic approach with intact subjects is most commonly employed with experimental animals. Without verification using human skin, such measurements are subject to large uncertainties due to species differences in density of epidermal appendages, stratum corneum properties (e.g., thickness, lipid composition), and biotransformation rates. Because penetration through rodent skin is usually faster than through human skin, the former can provide an overestimate for the behavior of the latter. To simplify determination of penetration kinetics, skin flaps may be employed and the capillary blood flow monitored to measure penetration. For this purpose, pig skin has particular utility (Riviere and Brooks, 2005). A promising variation minimizing species differences is to use skin grafts on experimental animals for these measurements. Human skin persists well

on athymic mice and retains its normal barrier properties (Krueger and Pershing, 1993). More recently, penetration of chemicals can be tracked through the skin using confocal microscopy (Alvarez-Roman et al., 2004). In any case, accurate testing of percutaneous absorption of poorly soluble agents from environmental substrates requires attention to details of particle size, component complexes, application rate and skin contact.

Biotransformation

The ability of the skin to metabolize chemicals that diffuse through it contributes to its barrier function. This influences the potential biological activity of xenobiotics and topically applied drugs, leading to their degradation or their activation as skin sensitizers or carcinogens (Hotchkiss, 1998). To this end, the epidermis and pilosebaceous units are the most relevant and, indeed, are the major sources of such activity in the skin. On a body-weight basis, phase I metabolism in this organ usually is only a small fraction ($\sim$2%) of that in the liver, but its importance should not be underestimated. For example, when the epidermis of the neonatal rat is treated with benzo(a)pyrene or Aroclor 1254, the arylhydrocarbon hydroxylase (P450) activity in the skin can exceed 20% of that in the whole body (Mukhtar and Bickers, 1981). As illustrated in this example, cytochrome P4501A1 is inducible in the epidermis by chemicals that are inducers in other tissues—TCDD (tetrachlorodibenzo-p-dioxin), polycyclic aromatic hydrocarbons, PCBs (polychlorinated biphenyls), and crude coal tar, which is used in dermatological therapy. Thus, exposure to such inducers could influence skin biotransformation and even sensitize epidermal cells to other chemicals that are not good inducers themselves, a phenomenon observable in cell culture (Walsh et al., 1995).

Biotransformation of a variety of compounds in the skin has been detected, including arachidonic acid derivatives, steroids, retinoids, and 2-amino-anthracene, suggesting that multiple P450 activities are expressed. With the advent of DNA microarray and real-time polymerase chain reaction technologies, it is now evident that over a dozen distinct isozymes are expressed at widely varying levels. A recent survey of those in the CYP1-4 families indicated that half were expressed at substantially higher levels in differentiating keratinocytes (similar to spinous cells) than in basal-like cells (Du et al., 2006). In addition to influencing our response to the natural environment, these activities are also important in influencing our response to pharmaceuticals used in clinical dermatology inasmuch as a large fraction of the latter are P450 inducers, inhibitors, or substrates (Ahmad and Mukhtar, 2004). Species differences are apparent in the amounts of P450 activities detectable. For example, measured ethoxycoumarin-O-deethylase activity is 20-fold higher in mouse than human (or rat) skin. Differences of such magnitude help rationalize the observation that the rate of penetration of ethoxycoumarin is sufficient to saturate its metabolism in some species (e.g., the human) but not in others (e.g., the mouse or guinea pig) (Storm et al., 1990). To the extent that phase I (and II) metabolism influences sensitization to exogenous chemicals (Merk et al., 2004), they may also help rationalize species differences in allergic response.

Enzymes participating in phase II metabolism are expressed in skin. For example, multiple forms of epoxide hydrolase and UDP-glucuronosyl transferase have been detected in human and rodent skin. In general, this activity occurs at a much lower rate than observed in the liver, but exceptions are evident, as in the case of quinone reductase (Khan et al., 1987). Human and rodent skin

exhibit qualitatively similar phase II reactions, but rodent skin often has a higher level of activity. An additional consideration is that different species express different relative amounts of the various isozymes, which could alter resulting target specificities or degree of responsiveness. Glutathione transferase, for instance, catalyzes the reaction of glutathione with exogenous nucleophiles or provides intracellular transport of bound compounds in the absence of a reaction. It also facilitates the reaction of glutathione with endogenous products of arachidonate lipoxygenation (leukotrienes) to yield mediators of anaphylaxis and chemotaxis, which are elements of the inflammatory response in the skin. Of the first three major transferase forms characterized in the liver, the major form in the skin of humans and rodents is the P isozyme. Human skin also expresses the A isozyme, whereas rat and mouse skin express the M isozyme and, in much smaller amounts, the A isozyme (Raza *et al.*, 1992).

A variety of other metabolic enzyme activities have also been detected in human epidermal cells, including sulfatases, β-glucuronidase, *N*-acetyl transferases, esterases, and reductases (Hotchkiss, 1998). The intercellular region of the stratum corneum has catabolic activities (e.g., proteases, lipases, glycosidases, phosphatases) supplied by the lamellar bodies along with their characteristic lipid (Elias, 1992). The report that cholesterol sulfotransferase is regulated by ligands of LXR and PPAR illustrates the potential for exogenous agents, including pharmaceuticals, to influence such activities and thereby the barrier function of the skin (Jiang *et al.*, 2005), where penetration can be influenced by cell differentiation and biotransformation. For example, methyl salicylate readily diffuses through the epidermis and is detected in the dermis, but only as de-esterified salicylate, illustrating first-pass metabolism (Cross *et al.*, 1997). The influence of hydroxysteroid dehydrogenases and microsomal reductase activities during percutaneous absorption is evident in studies on mouse skin in organ culture. In one study (Kao and Hall, 1987), 8 hours after topical application of testosterone, 59% of the permeated steroid was collected unchanged and the rest was transformed into metabolites. In parallel, estrone was converted substantially to estradiol (67%), while only 23% was collected as the parent compound. By contrast, estradiol was metabolized to a much lower extent (21%).

CONTACT DERMATITIS

In the occupational arena, where records are compiled on large workforces, contact dermatitis is by far the largest category ($\sim$90%) of compensated skin disease. Using eczema of the hand as a sentinel condition, since 80% of the total reported dermatitis occurs at that location (10% on the face), reveals a prevalence of 7–10% among workers. Attributed to better diagnosis, more accurate identification of offending chemicals, and more effective prevention and worker education, the fraction of afflicted workers recovering without impairment has improved nearly to 80% with proper management (Belsito, 2005). However, whereas certain conditions carry a favorable prognosis, others (e.g., chronic cumulative irritant contact dermatitis or contact allergy to nickel, chromate, formaldehyde, or rubber) frequently result in chronic disease in which changing jobs is of limited or no benefit (Emmett, 2003; Belsito, 2005). Overall, contact dermatitis falls into the two major categories of irritant and allergic forms. Both involve inflammatory processes and can have indistinguishable clinical characteristics of erythema (redness), induration (thickening and firmness), scaling (flaking), and vesiculation (blistering) in areas of direct contact with the chemical. Biopsies from affected sites reveal a mixed-cell inflammatory infil-

trate of lymphocytes and eosinophils and spongiosis (intercellular edema), but are insufficient to distinguish the two conditions from each other or from certain other common syndromes.

Irritant Dermatitis

Accounting for $\sim$80% of contact dermatitis cases, this condition arises from the direct action of chemicals on the skin. A chemical in this category is anticipated to give an adverse reaction to anyone if the concentration is high enough and the exposure time long enough. Certain chemicals at sufficient concentration produce an acute irritation, sometimes called a second-degree chemical burn, which can even result in scarring in serious cases. These include strong acids and alkalies and powerful oxidizing and reducing agents that substantially disrupt the cornified layer, produce cytotoxicity directly, and stimulate release of proinflammatory cytokines. More common is chronic cumulative irritation from repeated exposures to mild irritants such as soaps, detergents, solvents, and cutting oils. An example of eczema from cutting oil is shown in Fig. 19-2A. The chronic friction and production of small-scale trauma can wear away the lipid barrier of the stratum corneum, leading gradually to further damage (loss of cohesion, desquamation) that facilitates penetration of exogenous chemicals, and may be detectable as increased transepidermal water loss. In some cases, epidermal thickening occurs without much inflammation. In any case, increased penetrance can facilitate exposure to chemicals that elicit a subsequent allergic reaction. For example, because wet cement is alkaline and often contains chromates (commonly allergenic), chronic exposure can produce a composite response.

The skin at some anatomic sites is more sensitive than at other sites. Eyelids have a thin epidermis and are quite sensitive, for example, and the back is more sensitive than the forearm or the scalp of individuals with male pattern baldness (Zhai *et al.*, 2004). Individuals vary greatly in sensitivity to irritant dermatitis. Figure 19-2B shows an irritant reaction on the inside of the elbow on an atopic person. Comprising up to 20% of school children (Laughter *et al.*, 2000), atopic individuals are the most sensitive to irritants and exhibit a propensity to produce specific IgE antibodies to allergens. They typically suffer from hay fever but do not seem more prone to allergic contact dermatitis (Belsito, 2005). These individuals usually have a poorer prognosis than nonatopics and have a higher frequency of persistent dermatitis. The best preventive measure for atopics and others is to avoid exposure to contact irritants, but in practice this strategy is difficult to implement. Lipid-rich moisturizers and barrier creams containing dimethicone or perfluoropolyethers may be useful in protecting skin from offending agents (Saary *et al.*, 2005).

Information on the irritancy of chemicals toward human skin may be obtained as part of differential diagnosis by patch testing for allergic response. The skin of laboratory animals (mice, rats, rabbits, guinea pigs) can be used for testing, but it is thinner and more sensitive than human skin to irritants. For development of new pharmaceuticals, cosmetics, and other consumer products, a great need exists for an in vitro system to determine the potential for irritant responses. Use of human epidermal cell cultures has been increasing as reconstructed epidermal and skin models come closer to the native differentiated state. For example, a recent study compared 50 chemicals for which data on 30 are available from patch testing (Tornier *et al.*, 2006). The tests provided useful comparative data and, judging by viability (mitochondrial function), histology, and release of inflammatory mediators (IL-1α) suggested a parallel with natural skin. Such models offer advantages in convenience

Figure 19-2. Examples of occupational skin toxicity. (See the colored insert.)

The panels, available at the NIOSH website (http://www.cdc.gov/niosh/ocderm1.html), are a small selection from the 140-slide NIOSH program "Occupational Dermatoses—A Program for Physicians" prepared by Drs. E. Shmunes, M.M. Key, J.B. Lucas, and J.S. Taylor. (A, eczema from cutting oil; B, atopic irritant dermatitis; C, burn from ethylene oxide; D, burn from alkali exposure; E, sensitization to dichromate; F, beryllium granulomas; G, phototoxicity from lime juice; H, acne from cutting oil; I, leukoderma from rubber antioxidants; J, hyperpigmentation from mercaptobenzothiazole.)

and cost, appear applicable to photoxicity as well, and are more uniform in response than skin in the human population. Though advanced, the state of maturation in such culture models is not complete, as seen by histology and barrier function, resulting in their greater sensitivity than the skin (Netzlaff *et al*., 2005). In addition, extrapolation of the models to cumulative insult dermatitis presents a challenge.

Chemical Burns

A chemical that is extremely corrosive can produce immediate coagulative necrosis resulting in considerable tissue damage with ulceration and sloughing. Sometimes referred to as a third-degree chemical burn, the damage does not have a primary inflammatory component and thus may not be classified as an irritant reaction. Examples of burns from ethylene oxide and alkali are shown in Fig. 19-2C and 2D. If the chemical is not quickly and completely removed, damage to the skin may continue and, with increased access to the circulation, systemic injury can occur. Table 19-2 lists some important corrosive compounds giving chemical burns in the occupational area. Certain chemical warfare agents first used in

combat nearly a century ago and intermittently since, such as bis-(2-chloroethyl)sulfide (sulfur mustard) or 2-chlorovinyl dichloroarsine (Lewisite), are potent vesicants upon skin contact and produce considerable damage when inhaled. Exposure today is rare, but the threat of use remains (McManus and Huebner, 2005).

Allergic Contact Dermatitis

Allergic contact dermatitis is a delayed (T-cell mediated) hypersensitive reaction. To induce sensitization through the skin, chemical haptens generally penetrate the lipid barrier and, to be detected by the immune system, become attached to carrier proteins. The complete antigens are then processed by Langerhans cells (resident macrophages) and displayed on their surfaces with major histocompatibility complex II molecules. The Langerhans cells present the processed peptides to T helper type 1 cells in regional lymph nodes, thereby stimulating interleukin release and proliferation of the sensitive T helper cells. Over a 1–3 week period, memory T cells are thus generated and enter the circulation. Upon subsequent exposure to a specific antigen previously encountered, allergen presentation by the Langerhans cells results in a much greater response due to

Table 19-2
Selected Chemicals Causing Skin Burns

CHEMICAL	COMMENT
Ammonia	Potent skin corrosive
	Contact with compressed gas can cause frostbite
Calcium oxide (CaO)	Severe chemical burns
	Extremely exothermic reaction—dissolving in water can cause heat burns
Chlorine	Liquid and concentrated vapors cause cell death and ulceration
Ethylene oxide	Solutions and vapors may burn
	Compressed gas can cause frostbite
Hydrogen chloride (HCl)	Severe burning with scar formation
Hydrogen fluoride (HF)	Severe, painful, slowly healing burns from high concentration
	Lower concentration causes delayed cutaneous injury
	Systemic absorption can lead to electrolyte abnormalities and death
	Calcium-containing topical medications and quaternary ammonium compounds are used to limit damage
Hydrogen peroxide	High concentration causes severe burns and blistering
Methyl bromide	Liquid exposure produces blistering, deep burns
Nitrogen oxides	Moist skin facilitates the formation of nitric acid causing severe yellow-colored burns
Phosphorus	White phosphorus continues to burn on skin in the presence of air
Phenol	Extremely corrosive even in low concentrations
	Systemic absorption through burn sites may result in cardiac arrhythmias, renal disease, and death
Sodium hydroxide	High concentration causes deep burns, readily denatures keratin
Toluene diisocyanate	Severe burns with contact
	Skin contact rarely may result in respiratory sensitization

homing by the memory cells to the skin, their clonal proliferation and their release of cytokines chemotactic for inflammatory cells and stimulatory for their further production. Because this process takes time, the characteristic dermal infiltration and spongiosis result after a delay (latent period) of 0.5–2 days (Mark and Slavin, 2006).

Thousands of chemicals have been reported to give rise to allergic contact dermatitis, many across a variety of occupations and consumer products. Table 19-3 lists some common contact allergens, several of which are shown in Fig 19-3. Because most compounds in the chemical universe are only weakly active or infrequently encountered, much effort has focused on finding the major allergens in the population by systematic patch testing of dermatology patients.

Although not measuring sensitivity in the population at large, the results are quite useful. The panel of compounds tested can vary with geographic location to accommodate local usage, or it can be directed to specific anatomic sites such as the foot (Holden and Gawkrodger, 2005). Panels also are adapted to emerging trends as new products appear and others decline in use. Table 19-4 lists the chemicals (22) giving positive reactions in at least 3% of the subjects in a recent test from the North American Contact Dermatitis Group (Pratt *et al.*, 2004). Other testing groups show similar results but often include some different chemicals or use them at different concentrations, which can affect the measured frequencies (Wetter *et al.*, 2005). A number of these chemicals (nickel, dichromate, *p*-phenylenediamine, formaldehyde) have shown high prevalences

of reactivity for several decades, whereas others (e.g., gold salts), once thought innocuous, have recently become recognized as reactive (Cohen, 2004). An example of contact allergy to dichromate in cement is shown in Fig. 19-2E. Reduction in use of the most prevalent allergenic chemicals and their replacement by less allergenic substitutes is now advocated. Caution in using less characterized agents as replacements must be exercised, however, because their allergenicity may not become evident until they reach large populations of users, as has happened in several prominent cases (Uter *et al.*, 2005). For example, methylchloroisothiazolinone/methylisothiazolinone, used in cosmetics, was replaced with the biocide methyldibromo glutaronitrile, which did not cause allergic contact dermatitis in initial screens. Upon widespread use, however, the latter also was shown to be a potent contact allergen (Kynemund Pedersen *et al.*, 2004).

Unlike contact irritants, where the response is generally proportional to the applied dose and time, contact allergens can elicit reactions at very small doses. Nevertheless, careful analysis from human and animal testing (Boukhman and Maibach, 2001; Arts *et al.*, 2006) shows that a higher dose confers a greater likelihood of sensitization and that doses below a threshold for sensitization can have a cumulative effect. In addition, the dose required to elicit a reaction is lower after sensitization with a higher dose. Moreover, the dose dependence for sensitization displays nonlinearity, suggesting that the response of individual dendritic cells is sublinear, probably sigmoidal. Thus, more stimulation can produce a more than proportionally larger response, although at high doses saturation and sometimes even inhibition of the response become evident. This result emphasizes the importance of minimizing individual exposures. The findings also reveal a wide variation in human

Ethylenediamine di-HCl	Aminophylline, piperazine
Formaldehyde	Arylsulfonamide resin, chloroallyl-hexaminium chloride
Hydroquinone	Resorcinol
Methyl hydroxybenzoate	Parabens, hydroquinone monobenzyl ether
p-Aminobenzoic acid	p-Aminosalicylic acid, sulfonamide
Phenylenediamine	Parabens, p-aminobenzoic acid
Propyl hydroxybenzoate	Hydroquinone monobenzyl ether
Phenol	Resorcinol, cresols, hydroquinone
Tetramethylthiuram disulfide	Tetraethylthiuram mono- and disulfide

response to sensitization, which appears to have at least in part a genetic basis.

Diagnosis and Testing   When a patient exhibits allergic contact dermatitis, finding the responsible chemical is important to avoid continued exposure. For this purpose, patch testing is commonly employed by procedures refined over many years of practice since it was first employed a century ago (Mark and Slavin, 2006). On the washed backs of patients, who are not currently exhibiting contact dermatitis or using corticosteroids or other immunosuppressives, are placed patches each containing a small amount of a potential allergen. Conveniently, many of the materials are commercially available at standardized concentrations too low to produce irritant reactions. Certain chemicals normally are not tested because they induce too strong a response (urushiol from poison ivy) or might produce sensitization (beryllium). After 2–3 days, during which time a maximal reaction usually develops, the patches are removed and sites of exposure are scored for degree of response. Relevance to the pa-

tient's actual environment must be considered so that exposure in daily life can be minimized to appropriate chemicals. Interpretation of the results and environmental modification should take into account the phenomenon of cross-sensitivity, where reactivity to a compound may be evident if it shares functional groups that have provoked sensitization in another compound. Figure 19-4 illustrates the principle with three amine compounds, and Table 19-5 lists some common cross-reacting chemicals.

Animal testing to predict allergenicity has an extended history. A chemical is applied to intact or abraded skin or through intradermal injection with or without adjuvant to enhance sensitization. The reaction of the skin to subsequent challenge with the chemical is then observed and graded. This approach has successfully identified some strong sensitizers relevant to human exposures, but detection of weak sensitizers on a large scale is hampered by the usual difficulties in animal testing, including small animal numbers and limited experiment time to reduce expense. In addition, extrapolation of sensitivity measurements from laboratory animals to humans presents large uncertainties. Nevertheless, the local lymph node assay performed in mice has gained attention as a way to measure the pool of sensitized T cells by their proliferation in draining lymph nodes, illustrated by a comparison of potencies of Disperse Blue 106 and 2,4-dinitrochlorobenzene (Betts *et al*., 2005). Because sensitizers differ in potency by at least four orders of magnitude, a quantitative assay has a distinct advantage. Other steps in the sensitization process (e.g., percutaneous absorption) would be expected to influence the potency, but incorporation of structure–activity data may improve the validity of predictions for certain chemicals (Uter *et al*., 2005). To this end, a structure–activity study to streamline testing of new chemical products has identified

Figure 19-4. Structural formulas of selected para-amino compounds that show cross-reactions in allergic contact sensitization.

15 classes of reactive functional groups, as well as several subject to activation by metabolism, as especially suspect of bestowing allergenicity (Gerner *et al*., 2004). That water solubility, octanol/water partitioning, and molecular weight (<1000) were not found to be diagnostic indicators for this endpoint suggests that the rate of stratum corneum penetration is not a decisive factor. If instead dendritic cell responses to chemicals are critical, the possibility of routine prediction of allergic potential from them is attractive (Ryan *et al*., 2005). A number of parameters need further development such as determining appropriate endpoints, the dynamic range of the measurements and the possible need for interactions with or biotransformation by other cell types (e.g., keratinocytes). Using a minimally deviated continuous dendritic cell line could solve the problem of limited supply of human cells and the variability in responsiveness among donors, while finding the basis of the individual variability itself would be important.

GRANULOMATOUS DISEASE

Foreign body reactions, isolating invading substances that cannot be readily removed, occur infrequently toward a variety of agents introduced into the skin through injection or after laceration or abrasion. These can produce persistent lesions with abundant inflammatory cells resembling chronic infectious conditions (e.g., tuberculosis, leprosy, leishmaniasis, syphilis) and present diagnostic challenges (Del Rosario *et al*., 2005). In the case of silica or talc (a magnesium silicate), a resulting hard nodule may appear after a latent period of months or years as the original large particles disaggregate to assume a colloidal state. Injection of paraffin or mineral oil in the skin or contamination of wounds with starch powder cross linked with epichlorohydrin for use in surgical gloves may also result in granulomatous reactions. Delayed allergic sensitization may occur with beryllium analogous to the reaction in the lung, and skin lesions have even been reported in individuals with life-threatening pulmonary exposure. An example of beryllium granuloma of the skin is shown in Fig. 19-2F. Metallic mercury, zirconium compounds formerly used in deodorants, and tattoo dye constituents (cobalt, chromium compounds) are also known to induce such reactions.

PHOTOTOXICOLOGY

The ultraviolet and visible spectra of solar radiation reaching the earth extend from 290 nm to 700 nm. Wavelengths beyond this range are either filtered by the earth's atmosphere or are insufficiently energetic to cause cutaneous pathology. Adequate doses of artificially produced UVC (<290 nm) or X-rays can produce profound physical and toxicologic skin changes. The protective skin pigment melanin, synthesized in melanocytes, absorbs a broad range of radiation from UVB (290–320 nm) through the visible spectrum. Other chromophores in the skin include amino acids, primarily tryptophan and to a lesser extent tyrosine, and their breakdown products (e.g., urocanic acid), which absorb light in the UVB range. Biologically, the most significant chromophore is DNA, because damage from radiation can have lasting effects on the genetic information in target cells.

Adverse Responses to Electromagnetic Radiation

The most evident acute feature of ultraviolet radiation exposure is erythema (redness or sunburn). The minimal erythema dose (MED), the smallest dose of ultraviolet light needed to induce an erythematous response, varies greatly from person to person. Vasodilation responsible for the color change is accompanied by significant alterations in a variety of inflammatory mediators from injured keratinocytes and local inflammatory cells that may be responsible for some systemic symptoms associated with sunburn such as fever, chills, and malaise. UVB (290–320 nm) is the most effective solar band to cause erythema in human skin. A substantially greater dosage of UVA (320–400) reaches the earth compared to UVB (up to 100-fold); however, its efficiency in generating erythema in humans is about 1000-fold less than that of UVB. Both UVA and UVB have been implicated in the development of melanoma and nonmelanoma skin cancers. Because of its longer wavelength and greater depth of skin penetration, UVA is likely more responsible for long-term UV effects such as wrinkling, skin atrophy, and easy bruisibility. Overt pigment darkening is another typical response to ultraviolet exposure. This may be accomplished by enhanced melanin production by melanocytes or by photooxidation of melanin. Tanning or increased pigmentation usually occurs within 3 days of ultraviolet light exposure, because photooxidation is evident immediately. The tanning response is most readily produced by exposure to UVB and may be induced, along with erythema and DNA repair, by DNA damage. Tanning serves to augment the protective effects of melanin in the skin, but the protection afforded appears insufficient to balance the damage sustained in acquiring it, especially in fair-skinned individuals (Sheehan *et al*., 2002).

Chronic exposure to radiation induces a variety of characteristic skin changes. For ultraviolet light, these changes accelerate or mimic aging, but the rate depends greatly on the baseline skin pigmentation of the individual. Lighter-skinned people suffer from chronic skin changes with greater frequency than darker individuals, and locations such as the head, neck, hands, and upper chest are more readily involved due to their routine exposures. Pigmentary changes such as freckling and hypomelanotic areas, wrinkling, telangiectasias (fine superficial blood vessels), actinic keratoses (precancerous lesions), and malignant skin lesions such as basal and squamous cell carcinomas and malignant melanomas are all consequences of chronic exposure to ultraviolet light exposure. One significant pathophysiologic response of chronic exposure to ultraviolet light is the pronounced decrease of epidermal Langerhans cells. Chronically sun exposed skin may have up to 50% fewer epidermal Langerhan cells compared to photoprotected areas. This decrease may result in lessened immune surveillance of neoantigens on malignant cells and thus allow such transformation to proceed unabated. For these reasons, gaining a tan, either naturally or through tanning salons, is not recommended (Spencer and Amonette, 1998). Exposures to ionizing radiation may produce a different spectrum of disease depending upon the dose delivered. Large acute exposures will result in local redness, blistering, swelling, ulceration, and pain. After a latent period or following subacute chronic exposures, characteristic changes such as epidermal thinning, freckling, telangiectasias, and nonhealing ulcerations may occur. Also, a variety of skin malignancies have been described years after skin exposure to radiation.

Apart from the toxic nature of electromagnetic radiation, natural and environmental exposures to certain bands of light are vital for survival. Ultraviolet radiation is critical for the conversion of 7-dehydrocholesterol to pre-vitamin D3, without which normal endogenous production of vitamin D would not take place. Blue light in the 420–490 nm range can be lifesaving due to its capacity to

photo-isomerize bilirubin (a red blood cell breakdown product) in the skin. Infants with elevated serum bilirubin, potentially neurotoxic, have difficulty clearing this byproduct because of its low water solubility, but treatment with blue light renders bilirubin more water soluble and markedly augments excretion. In addition, the toxic effects of ultraviolet light have been exploited for decades through artificial light sources for treatment of hyperproliferative skin disorders such as psoriasis.

Photosensitivity

An abnormal sensitivity to ultraviolet and visible light, photosensitivity may result from endogenous or exogenous factors. Illustrating the former, a variety of genetic diseases, such as xeroderma pigmentosum, impair the cell's ability to repair ultraviolet light-induced damage. The autoimmune disease lupus erythematosus also features abnormal sensitivity to ultraviolet light. In hereditary or chemically induced porphyrias, enzyme abnormalities disrupt the biosynthetic pathways producing heme, the prosthetic building block for hemoglobin, myoglobin, catalases, peroxidases, and cytochromes, leading to accumulation of porphyrin precursors or derivatives throughout the body, including the skin. These compounds in general fluoresce when exposed to light of 400–410 nm (Soret band), and in this excited state interact with cellular macromolecules or with molecular oxygen to generate toxic free radicals. A "constitutional" sensitivity to light (porphyria cutanea tarda) can be precipitated by alcohol, estrogens, or certain antibiotics in individuals with hereditary abnormalities in porphyrin synthesis, and an "acquired" sensitivity in general by hexachlorobenzene and mixtures of polyhalogenated aromatic hydrocarbons (Kimbrough, 1987; van Birgelen *et al.*, 1996).

Phototoxicity Phototoxic reactions from exogenous chemicals may be produced by systemic or topical administration or exposure. In acute reactions, the skin can become red and blister within minutes to hours after ultraviolet light exposure. In an occupational setting, for example, exposing the skin to coal tar and sunlight can quickly produce a stinging sensation and elicit damage resembling a bad sunburn with hyperpigmentation. Phototoxic chemicals most commonly absorb ultraviolet light in the range of 320–400 nm (UVA), thereby assuming a higher energy excited triplet state and either transfer an electron to another molecule or become reduced to form highly reactive free radicals (DeLeo, 2004; Moan and Peng, 2004). An oxygen-dependent photodynamic reaction commonly occurs as these excited molecules, returning to the ground state, transfer their energy to oxygen to form highly reactive singlet oxygen. These reactive products are capable of damaging cellular macromolecules (notably unsaturated membrane lipids) and causing cell death. The resulting damage stimulates the release of a variety of immune mediators from keratinocytes and local white blood cells that recruit more inflammatory cells to the skin and thus yield the clinical signs of phototoxicity. Chemicals most often associated with phototoxic reactions are listed in Table 19-6.

Psoralens are good examples of agents that produce phototoxicity largely without requiring oxygen radicals. Upon entering cells, they intercalate with the DNA and then form covalent adducts and cross-links when activated by UVA. The result is to inhibit DNA synthesis and repair and cell growth or survival. Psoralens (and other phototoxins) can be encountered in a variety of food plants, including limes and celery, producing phytophotodermatitis in occupational settings where such food is routinely handled. An example

Table 19-6

of phototoxicity from lime juice is given in Fig. 19-2G. Psoralens in combination with UVA (PUVA) are used therapeutically to inhibit the growth of keratinocytes and lymphocytes in hyperproliferative conditions such as psoriasis and T-cell lymphomas. In analogous fashion, though generating reactive oxygen, photodynamic therapy is a new approach that takes advantage of the selective uptake of a photosensitizing agent, usually a porphyrin derivative, into rapidly dividing cells such as in neoplasms. The photosensitizing agent is activated by laser or continuous wave light sources ranging from 400 to 600 nm or more, resulting in selective destruction of the neoplasm (Zeitouni *et al.*, 2003).

Nails often suffer toxic reactions to drugs, most commonly to systemically administered chemicals, such as antibiotics, and less commonly to topically applied chemicals. Whereas various types of nail pathology may result from therapy-induced changes in cell growth or division, changes in pigmentation, or detachment of the various layers of the nail plate from each other (onycholysis) often result from photosensitive reactions, commonly phototoxic and less commonly photoallergic. Chemicals, such as topical or systemic porphyrins, coal tar, and drugs, such as the tetracycline family of antibiotics, produce photodynamic toxicity, which requires generation of oxygen radicals. In contrast, topical or systemic psoralens produce onycholysis by a nonphotodynamic mechanism that does not require oxygen.

Photoallergy A photoallergen elicits an allergic response by forming a complete antigen upon absorbing ultraviolet or visible light. Light stimulates the chemical either to assume an excited state that can bind directly to a carrier protein or to yield a stable photoproduct that becomes conjugated to a carrier. As in the case of allergic contact dermatitis, the complete antigen formed then is processed by Langerhans cells and presented to T cells. Upon recurrent exposure to an exogenous chemical and light, a delayed

hypersensitivity (Type IV) reaction ensues, leading typically to eczema (erythema, vesiculation, itching). Like phototoxins, most photoallergens respond to light in the range of 320–400 nm (UVA). Light sensitivity usually subsides within days but may persist for several weeks if the chemical is retained in the epidermis. Rarely, a person may display chronic actinic dermatitis with continued reaction to sunlight long after removal of the chemical (Goossens, 2004).

Use of halogenated salicylanilides and related antimicrobial chemicals in widely used consumer personal care products, such as soap, led to many thousands of cases of photoallergy in the 1960s and 1970s (Epstein, 1999). When the most active agents were removed from the market, fragrances in cosmetics and sunscreens then became conspicuous sources of photoallergy a decade later. Currently, active ingredients in sunscreens appear to be the most frequently recognized causes. Although of low risk, these chemicals have become widely used as the risks of extensive sun exposure have become appreciated. *p*-Aminobenzoate and derivatives in the original sunscreen formulations have been replaced with chemicals of lower risk, sensitivity to which are now being detected, although proper diagnosis must take into account contact dermatitis from fragrances and preservatives in these products (Cook and Freeman, 2001).

Photoallergy generally is distinguishable from phototoxicity, because the former results from delayed hypersensitivity, and amounts of chemical too low to give a toxic response still suffice to elicit allergy. Chemicals causing phototoxicity, because reactivity is generated upon light exposure, may also be photoallergenic, but the latter type of response is much less common. Among individuals with a history of photosensitivity, an estimated 10–20% exhibit photoallergy (DeLeo, 2004). Diagnosis is best performed by patch testing with and without light exposure of the treated surface to distinguish photocontact from contact allergy. Because the offending chemical may not be obvious from the patient history due to the delay between exposure to the chemical and sunlight and the symptoms, a panel of test chemicals may include some 30 common photoallergens as well as the patient's own sunscreen and personal care products. To assist in predicting risks of photoallergy, efforts have been made to derive important chemical features among existing photoallergens that account for their reactivity toward proteins. This information, coupled with assessment of physical properties such as aqueous/lipid partitioning, is anticipated to streamline testing of new products (Barratt, 2004).

ACNE

Acne is a common affliction of the pilosebaceous units in the face, upper chest, and upper back. Found in many forms, this condition typically arises from blockage of the sebaceous duct leading from the gland to the hair follicle, resulting in retention of sebum, and enlargement of the gland (Toyoda and Morohashi, 2001). In the most common form (acne vulgaris), androgen stimulation at puberty leads to excess sebum production and, likely as a result of the high local fatty acid concentration, excessive cornification of the ductal cells to plug the orifice. Proliferation of resident bacteria and inflammation typically result. Long chain fatty acids can give an acne-like response in animal models and appear to do so in sensitive individuals exposed to them in cosmetics. Likely acting in a similar fashion, petroleum products (oils, coal tar) in the workplace can give rise to acneiform eruptions. Insoluble cutting oils used in machining may have this effect, as illustrated in Fig. 19-2H. Such chemicals appear to stimulate excessive stratification of the ductal cells, preventing their disaggregation and blocking the flow of sebum.

Chloracne

The most disfiguring form of acne in humans, chloracne, is caused by exposure to halogenated aromatic hydrocarbons. Chloracnegenic chemicals such as polychlorinated biphenyls and naphthalenes are often accompanied by the highly potent polychlorinated dibenzofurans and dioxins readily formed during synthesis of these chemicals or chlorinated phenolic pesticides, and can arise from combustion of the latter in fires and explosions. Chloracne is a rare disease; however, its recalcitrant nature and preventability make it an important occupational and environmental illness. Typically, comedones and straw-colored cysts are present behind the ears, around the eyes, shoulders, back, and genitalia. In addition to acne, hypertrichosis (increased hair in atypical locations), hyperpigmentation, brown discoloration of the nail, conjunctivitis, and eye discharge may be present. Because chloracne is a marker of systemic exposure, concurrent effects in the liver and nervous system may accompany the integumentary findings. Chloracne exhibits progressive degeneration of sebaceous units, transition of sebaceous gland cells to keratinizing cells, and prominent hyperkeratosis in the follicular canal.

Since the original recognition of the syndrome a century ago, effects of chloracnegens on humans have been clearly demonstrated over the past five decades through industrial disasters. In 1953 a chemical plant in Ludwigshafen exploded, discharging 2,4,5 trichlorophenol; in 1976 in Seveso, Italy, a reactor explosion liberated tetrachlorodibenzo-*p*-dioxin (TCDD); and in 1968 and 1979 in Japan and Taiwan, respectively, rice cooking oil was contaminated with polychlorinated biphenyls (PCBs), polychlorinated dibenzofurans, and related polychlorinated aromatic hydrocarbons. As in the Seveso accident (Baccarelli *et al.*, 2005), chloracne is noted within months after exposure and, depending on the severity, may either be cleared quickly or remain manifest even decades after exposure ceases, reflecting the high lipid solubility, recalcitrance to metabolic clearance, and thus long half-life in humans of the responsible chemicals. The highly potent TCDD has a half-life in humans of ∼8 years (Geyer *et al.*, 2002), and highly chlorinated dibenzofurans and biphenyls are similarly persistent.

Chlorinated dioxins and dibenzofurans have significant and reproducible effects on cellular function. TCDD is one of the most potent known inducers of CYP1A1 by virtue of its high affinity for the Ah receptor stimulating its expression. The fate of individuals afflicted with chloracne has been of particular interest in view of the suggestion that they may be more prone to other adverse health effects of exposure. So far, however, chloracne has not proven to be such a "sentinel" biomarker (Baccarelli *et al.*, 2005). Because polymorphisms in Ah receptor sequence confer differences in sensitivity to health effects in animals, analogous polymorphisms have been sought in the human population; Ah receptor polymorphisms have been identified, but as yet they have not been shown to affect responses to the receptor ligands (Okey *et al.*, 2005). In mice, skin symptoms analogous to chloracne in humans are dependent on the hr locus, where the (–/–) genotype is susceptible (Poland and Knutson, 1982). An analogous locus has been identified in humans that governs hair loss, where mutations give a phenocopy of the generalized atrichia from loss of vitamin D receptor activity (Miller *et al.*, 2001), but a functional allele does not prevent susceptibility to chloracne.
Figure 19-5. Chemical structure of tyrosine and of selected hypopigmenting and depigmenting agents.

PIGMENTARY DISTURBANCES

Melanocytes help protect the skin from harmful effects of ultraviolet light by producing the insoluble polymeric pigment melanin, starting with the action of tyrosine hydroxylase. As indicated in Table 19-7, a variety of chemicals can interfere with normal pigmentation to yield either excessive or reduced amounts of melanin. A rare acquired condition of generalized pigmentation loss (leukoderma or vitiligo) has a genetic basis but is triggered by environmental influences, largely obscure (Spritz, 2006). Thought likely to be of an autoimmune origin, this condition is characterized by the loss of melanocytes. In the occupational arena, depigmentation is well known to occur through exposure to phenols, catechols, quinones, and related compounds, several of which are shown in Fig 19-5, that appear toxic to melanocytes. An illustration of depigmentation caused by antioxidant exposure in rubber manufacture is given in Fig. 19-2I. In case reports, the cancer chemotherapeutic imatinib mesylate has been found to give pigment loss, probably through its inhibition of c-Kit tyrosine kinase signaling essential for melanocyte survival (Legros *et al.*, 2005). In sub-Saharan Africa and Asia, use of skin lightening creams containing hydroquinone, corticosteroids, or mercurials is common among women. The desired cosmetic effect, often nonuniform, is frequently accompanied by undesirable cutaneous consequences such as facial acne and hypertrichosis and carries the risk of systemic effects (del Giudice and Yves, 2002). By contrast, hyperpigmentation is well known to result from exposure to phototoxic agents including coal tar, coumarin derivatives found in perfumes and certain food such as limes (shown in Fig. 19-2G) and food plants (parsely, celery), dyes in cosmetics, and elements such as lead, bismuth, and arsenic (Table 19-7). An example of excessive pigmentation from mercaptobenzothiazole is shown in Fig. 19-2J.

URTICARIA

For those allergens to which IgE antibodies have been elicited by previous or ongoing exposure, subsequent contact can lead to development of hives, typically in minutes, through an immediate type I hypersensitivity reaction (Lipozencic and Wolfe, 2005). Hives are raised wheals that usually itch or sting and may appear reddish.

        Butylated hydroxytoluene

Generally disappearing within hours and rarely lasting longer than a day or two, the symptoms result from degranulation of cutaneous mast cells by liganded IgE, leading to release of histamine and other vasoactive substances. Food allergies and pharmaceuticals are major causes of acute urticaria, but many other causes are known (Table 19-8). Some chemicals (e.g., opiates) can bring about direct release of histamine from mast cells without antibody mediation, while others (nonsteroidal anti-inflammatories) may do so through effects on arachidonic acid metabolism or by uncertain mechanisms. Responses lasting longer than 6 weeks, if not attributable to allergen exposure, frequently have an autoimmune basis such as development of autoantibodies to IgE.

Contact urticaria in an occupational setting can arise from exposure to plant or animal proteins and appears more common in atopic individuals, who are especially sensitive to irritants. Among the numerous occupations where this response occurs include hairdressers and those involving routine handling of food, plant, or animal products (Doutre, 2005). A major problem in the health care industry involves allergy to latex protein, where the response can range from a mild skin reaction to anaphylaxis and death (Reines and Seifert, 2005). The widespread use of latex rubber in medical supplies and devices, notably in gloves, has resulted in widespread sensitization. In addition, powder used in the gloves can adsorb

Table 19-8

the allergenic proteins and distribute them through the air, a phenomenon leading to use of powderless gloves and those made of nitrile.

A life-threatening response of anaphylactic shock, as from latex allergy, may occur from IgE-mediated massive release of histamine and other vasoactive agents from the mast cells upon systemic exposure to allergens. Certain food allergies (e.g., nuts, fish, and shellfish) are capable of producing this extreme response. Among pharmaceuticals, the best-known example is penicillin, where adverse reactions must be managed carefully to avoid serious consequences (Gruchalla and Pirmohamed, 2006). Other antibiotics that can produce anaphylaxis include cephalosporins, sulfonamides, macrolides, vancomycin, tetracyclines, and fluoroquinolines; all but the last two can also produce toxic epidermal necrolysis. Insect allergens such as those in bee and wasp stings are well known to be capable of giving an anaphylactic response.

TOXIC EPIDERMAL NECROLYSIS

Toxic epidermal necrolysis is a rare life-threatening skin disease with an incidence of ~1 case per million person-years. At the most severe end of a spectrum of adverse cutaneous hypersensitivity reactions to drugs, this syndrome involves detachment of ≥30% of the epidermal surface from the dermis, accompanied by severe erosions of the mucous membranes and often pulmonary, intestinal, and ocular damage. Sepsis and pulmonary manifestations are the most common causes of death, the fate of at least 30% of those afflicted. The Stevens–Johnson (sometimes called Lyell's) syndrome is a milder but still serious version of nearly the same phenomenon with up to 10% of the skin surface area affected and with a proportionally lower fatality rate. The two syndromes overlap when 10–30% of the skin surface is involved. Toxic epidermal necrolysis commonly resembles an upper respiratory tract infection in the first several days (fever, cough, malaise), but prompt diagnosis when the cutaneous lesions become evident several days later improves survival chances. Exposure to the offending drug is stopped and treatment is initiated similar to that for burns, where fluid and electrolyte replacement, protection from infection and nutritional assistance are critical. Responsible for at least 70% of the cases, nearly 100 drugs have been reported to cause this syndrome including sulfonamides and other antibiotics, anticonvulsants, nonsteroidal anti-inflammatories, allopurinol, and nevirapine (Roujeau, 2005; Wolf et al., 2005). Mechanisms leading to this idiosyncratic drug reaction are under scrutiny to prevent its occurrence or at least to optimize treatment. A characteristic feature of the syndrome is the large-scale apoptosis of epidermal keratinocytes. Candidates for mediating apoptosis through cell surface death receptors include tumor necrosis factor and FAS ligand, which appear elevated; alternatively, drug-sensitized cytotoxic T lymphocytes could be responsible for granzyme-induced cytolysis. The rare individuals susceptible to the syndrome may suffer from an autostimulation of death receptor pathways by the action of the cytotoxic T cells. Effective treatment may involve judicious immunosuppression, possibly with cyclosporine (Chave et al., 2005), or blockage of death receptors using intravenous immunoglobulin therapy (French et al., 2006).

SKIN CANCER

Radiation

Skin cancer is the most common neoplasm in humans, accounting for nearly one-third of all cancers diagnosed each year. At present, the major cause of skin cancer (half a million new cases per year in the United States) is sunlight, which damages epidermal cell DNA. UVB (290–320 nm) induces pyrimidine dimers and 8-oxoguanine modifications, thereby eliciting mutations in critical genes (Melnikova and Ananthaswamy, 2005; Nishigori, 2006). The p53 tumor suppressor gene is a major target in which damage occurs early and is detectable in most resulting squamous cell carcinomas. Because the p53 protein arrests cell cycling until DNA damage is repaired and may induce apoptosis, its loss destabilizes the genome of initiated cells and gives them a growth advantage. UV light also has immunosuppressive effects that may help skin tumors survive. Nonmelanoma skin cancer incidence is highest in the tropics and is highest in pale-complexioned whites, particularly at sites on the head and neck that receive the most intense exposure. Individuals with xeroderma pigmentosum, who are deficient in repair of pyrimidine dimers, must scrupulously avoid sun exposure to prevent the occurrence of premalignant lesions that progress with continued exposure. Even when it does not cause cancer in normal individuals, sun exposure leads to premature aging of the skin. For this reason, sunbathing is discouraged and the use of sunblock lotions is encouraged, especially those that remove wavelengths up to 400 nm. Protection from solar (and other) radiation as well as chemical carcinogens is important in the occupational arena (Gawkrodger, 2004).

In the past, ionizing radiation was an important source of skin cancer. With the discovery of radioactive elements at the turn of the

twentieth century came the observation that X-rays can cause severe burns and squamous cell carcinomas of the skin. By the 1920s, basal cell carcinomas were also noted. For several decades thereafter, ionizing radiation was used to treat a variety of skin ailments (acne, atopic dermatitis, psoriasis, and ringworm) and for hair removal. The levels of exposure led to an increased risk of skin cancer and sometimes produced atrophy of the dermis (radiodermatitis) from the death or premature aging of fibroblasts which secrete elastic supporting fibrous proteins.

Polycyclic Aromatic Hydrocarbons

A landmark epidemiological investigation by Percival Pott in 1775 connected soot with the scrotal cancer prevalent among chimney sweepers in England. Since that time, substances rich in polycyclic aromatic hydrocarbons (coal tar, creosote, pitch, and soot) have become recognized as skin carcinogens in humans and animals. The polycyclic aromatic compounds alone are relatively inert chemically, but they would tend to accumulate in membranes and thus perturb cell function if they were not removed. They are hydroxylated by a number of cytochrome P450 isozymes, primarily 1A1 and 1B1 in epidermal cells, and conjugated for disposal from the body. Oxidative biotransformation, however, produces electrophilic epoxides that can form DNA adducts. Phenols, produced by rearrangement of the epoxides, can be oxidized further to electrophilic quinones that generate reactive oxygen species and lead to DNA adducts, oxidized bases, and abasic sites (Park *et al.*, 2006). Occupations at risk of skin cancer from exposure to these compounds (e.g., roofing) often involve considerable sun exposure, an additional risk factor. Concern persists regarding the use of coal tar for pharmaceutical purposes (Thami and Sarkar, 2004). The combination of coal tar and UV light is useful in treating severe psoriasis, because the toxicity reduces the excessive turnover rate of keratinocytes that characterizes this disease. Repeated treatments are necessary, however, and carry with them an elevated risk of nonmelanoma skin cancer. Using longer wave UVA with phototoxic psoralen derivatives (PUVA) in place of coal tar in such protocols is much less messy and avoids UVB but produces DNA adducts and an elevation of nonmelanoma skin cancer risk as well. Although one large study suggested that PUVA also increased the risk of melanoma skin cancer (Stern *et al.*, 1997), these findings have not been replicated in subsequent studies (Lindelof *et al.*, 1999).

As a major regulator of induction of CYP1A1, and to a lesser extent CYP1B1, the aryl hydrocarbon receptor (AhR) plays a critical role in the response of epidermal cells to polycyclic aromatic hydrocarbons (Swanson, 2004). For example, mice in which the AhR gene has been functionally ablated are insensitive to skin cancer from topical application of benzo(*a*)pyrene (Shimizu *et al.*, 2000). By contrast, a constitutively active AhR expressed in mouse epidermal keratinocytes was not seen to induce neoplasia, but it did result in inflammatory skin lesions reminiscent of contact dermatitis elicited by polycyclic aromatic hydrocarbons in humans (Tauchi *et al.*, 2005). A common AhR polymorphism reduces the sensitivity in mice by an order of magnitude to toxic effects of ligands for this receptor, while in the rat an AhR variant with more subtle transactivation properties bestows dramatic resistance to lethal effects of TCDD without altering CYP1A1 inducibility (Okey *et al.*, 2005). Screening efforts in humans have not yet revealed AhR polymorphisms that alter human responses to receptor ligands, but polymorphisms in cytochromes P450 do exist that are regulated by the AhR

and could plausibly affect skin sensitivity or function. An example is CYP2S1, which metabolizes retinoic acid (Saarikoski *et al.*, 2005).

Mouse Skin Tumor Promotion

Through the work of numerous investigators over the past century, initially studying substances rich in polycyclic aromatic hydrocarbons, mouse skin has been developed as an important target for carcinogenicity testing (Rubin, 2001). The observed incidence of squamous cell carcinomas has been helpful in providing a biological basis for conclusions from epidemiological studies. For instance, mouse skin carcinogenicity of tobacco smoke condensate and constituents strongly supported the conclusion that tobacco smoke is carcinogenic in humans. Carcinogenicity in mouse skin is taken as evidence of a carcinogenic risk for humans, although not necessarily for our epidermis. Much has been learned about the pathogenesis of squamous cell carcinomas in mouse skin that does have general applicability to human squamous cell carcinomas of the skin or other anatomic sites, a learning process now augmented with mouse strains engineered for overexpression or ablation of genes of interest.

Initial fractionation of coal tar showed that the carcinogenic polycyclic aromatic hydrocarbons, thereby purified and identified, accounted for only a small fraction of the total carcinogenicity (Rubin, 2001). This puzzling observation led to the realization that other constituents, by themselves not carcinogenic, acted as cocarcinogens. Some chemicals, called tumor promoters, were found effective even when applied to the mouse skin long after a single treatment with a carcinogen applied at a dose too low to give cancer alone. The latter, inducing tumors by itself at sufficiently high doses, was a "complete" carcinogen with the salient property of being genotoxic. One explanation for the commonly observed nonlinear response is that a large dose of a complete carcinogen does more than initiate cancer by damaging the DNA in cells. It is also toxic, killing some cells and thereby stimulating a regenerative response in the surviving basal cells. Tumor promoters are chemicals that do not cause cancer themselves but induce tumor development in skin that has been initiated by a low dose of a carcinogen. Their promoting power generally is parallel to their ability to give sustained hyperplasia of the epidermis with continued treatment. Selective stimulation of tumor growth is envisioned to occur from differential stimulation of initiated cells or due to the insensitivity of initiated cells to toxicity or to terminal differentiation induced in uninitiated cells by the promoter. Continuing efforts to understand the promotion process are envisioned to assist development of short-term tests that predict promoting potential (Curtin *et al.*, 2006).

An advantage of the experimental model of mouse skin carcinogenesis is the ability to separate the neoplastic process into stages of initiation, promotion, and progression, and the analysis can be extended to more complicated multihit, multistage models (Owens *et al.*, 1999). In the simplest model, the skin is treated once with a low dose of an initiator, a polycyclic aromatic hydrocarbon, for example. The skin does not develop tumors unless it is subsequently treated with a promoter, which must be applied numerous times at frequent intervals (e.g., twice per week for 3 months). Application of the promoter need not start immediately after initiation, but if it is not continued long enough, or if it is applied before or without the initiator, tumors do not develop. A consequence of promotion then is a tendency to linearize the dose–response curve for the initiator. Although an important aspect of promotion is its epigenetic nature, papillomas arising from promotion characteristically are aneuploid.

Mutations in the *c-Ha-ras* gene are commonly found in papillomas, particularly those initiated by polycyclic aromatic hydrocarbons. Eventually some of the resulting papillomas become autonomous, continuing to grow without the further addition of the promoter. Genetic damage accumulates in the small fraction of tumors that progress to malignancy.

A number of natural products are tumor promoters, many of which alter phosphorylation pathways. The best-studied example, and one of the most potent, is the active ingredient of croton oil, 12-*O*-tetradecanoylphorbol-13-acetate. This is a member of a diverse group of compounds that give transitory stimulation followed by chronic depletion of protein kinase C in mouse epidermis (Fournier and Murray, 1987). Another group of chemicals, an example of which is okadaic acid, consists of phosphatase inhibitors. Compounds acting by other routes are known, including thapsigargin (calcium channel modulator) and benzoyl peroxide (free radical generator). Sensitivity to tumor promotion is an important factor in the relative sensitivity to skin carcinogenesis among different mouse strains and even among other laboratory animal species. An intriguing example, TCDD is 100-fold more potent than tetradecanoylphorbol acetate in certain hairless mouse strains but virtually inactive in some non-hairless strains (Poland *et al.*, 1982). Much effort is currently being focused on the signal transduction pathways that are perturbed by treatment with such chemicals.

The finding that chromate (a human lung carcinogen) in the drinking water enhances tumor yield from ultraviolet light in mouse skin suggests that generation of reactive oxygen can be effective and raises concern about the Cr(VI) drinking water standard (Davidson *et al.*, 2004).

The desire to reduce the cost and improve the effectiveness of cancer testing in animals has led to development of transgenic mice with useful properties. The Tg.AC strain, for example, exhibits a genetically initiated epidermis (Humble *et al.*, 2005). Integrated in this mouse genome is a v-Ha-ras oncogene driven by part of the ζ-globin promoter, which in this context fortuitously drives expression only in epidermis that is wounded or treated with tumor promoters. The mice display enhanced skin sensitivity to a number of nongenotoxic carcinogens and have low backgrounds of spontaneous tumors over a 26-week treatment period. They also respond to genotoxic carcinogens, which target genes that cooperate with the ras oncogene in neoplastic development (Owens *et al.*, 1995). Tg.AC mice can be employed for testing in combination with a different mouse strain that has one p53 allele inactivated, and thus displays enhanced sensitivity to genotoxic carcinogens in other tissues in addition to the skin. These genetically modified mice promise to speed up testing using fewer animals and to reduce false–positive results arising from either strain/species-specific idiosyncrasies or high doses that could elicit secondary responses not relevant to human exposures. Although replacement of the very expensive 2-year rodent carcinogenesis assay is not yet feasible, these genetically modified mice have reduced the number of such assays and assisted pharmaceutical evaluation (Jacobs, 2005).

Arsenic

An abundant element in the earth's crust, arsenic is encountered routinely in small doses in the air, water, and food. In earlier times, high exposures occurred from medications such as Fowler's solution (potassium arsenite) and from pesticides such as sodium arsenite and lead arsenate; the latter pesticides have been phased out

in the United States but monomethylarsenate is still used in considerable (though decreasing) volumes in agriculture. Around the world, substantial exposures can occur as a result of mining operations to individuals from breathing dust from the ore or fumes from subsequent smelting or to communities encountering leachate from tailings into waterways. Glass manufacture and food dried using coal with high arsenic content can also contribute to high exposures, and the environmental burden is increased by disposal of large volumes of wood preserved with chromated copper arsenate and of litter from poultry fed organic arsenical antibiotics. Well water derived from geological formations with high arsenic content is now recognized as a major health concern, highlighted by populations in the tens of millions at risk in Bangladesh and India (Tapio and Grosche, 2006). Previous studies of populations in southwestern Taiwan revealed an association of high arsenic exposure with altered skin pigmentation and hyperkeratosis of the palms and soles, blackfoot disease from impaired circulation reflecting endothelial cell damage, and carcinomas of the skin and several other organs (bladder, lung, liver). More recent concentration dependence studies in West Bengal, India, show skin hyperpigmentation and keratoses occurring with drinking water concentrations close to 50 ppb (Mazumdur *et al.*, 1998), the former USA drinking water standard. In such regions, reduced lung function in men (von Ehrenstein *et al.*, 2005), stillbirths in women (von Ehrenstein *et al.*, 2006), and bronchiectasis in both sexes (Mazumdur *et al.*, 2005) are found at elevated rates among individuals with arsenic-induced skin lesions. Recognition that carcinomas of the skin and internal organs occur in humans imbibing drinking water with concentrations less than an order of magnitude higher than 50 ppb (Tapio and Grosche, 2006) contributed to reducing the U.S. standard to 10 ppb as of 2006.

Due to continuing debate over the dependence of health effects on arsenic at low concentration, which has regulatory implications (Schoen *et al.*, 2004), much effort is devoted to understanding arsenic action. Numerous mechanisms have been proposed by which arsenic serves as a carcinogen and gives other pathological effects, of which the majority could plausibly involve binding of trivalent forms to protein sulfhydryls (Kitchen and Wallace, 2005). Methylation has been considered a detoxification method, because the observed pentavalent mono- and dimethyl arsenates isolated in urine from exposed humans and animals are much less toxic than the inorganic forms. Wide species differences in methylation capability even among primates have raised the possibility that other detoxification pathways exist, and observations that the methylated forms are also found at low levels in the highly toxic trivalent state in animal tissues and in human urine (Aposhian *et al.*, 2000) have prompted re-evaluation of their roles. Identification of an AsIII-methyltransferase and exploration how it mediates toxic effects in cells where it is expresssed (Drobna *et al.*, 2005) promise to clarify this important issue. For the epidermis, where little methylation occurs, effects of the inorganic forms evidently dominate. As shown by many labs, effects of arsenate (the most common form in drinking water) in vivo or in culture are mediated by reduction to arsenite (Patterson *et al.*, 2003).

Arsenic is a weak mutagen at best in bacteria and mammalian cells, but it does induce DNA deletions and chromosomal aberrations and acts as a co-mutagen, possibly by interfering with DNA repair (Rossman *et al.*, 2004). Arsenic was recently found to be a transplacental carcinogen in mice, leading to an increase in tumors of the liver, adrenal gland, lung, and ovary in adulthood among animals exposed in utero (Waalkes *et al.*, 2004). A lack of epidermal

tumors in these mice suggests species specificity in tissue response, and finding tumors in tissues with a substantial background rate could suggest enhancement of an endogenous carcinogenic process (Rossman, 2003). In mice where the skin is irradiated with ultraviolet light, arsenic acts as a cocarcinogen (Rossman *et al.*, 2004), and in Tg.AC mice, expressing an activated ras oncogene in the epidermis, arsenic enhances phorbol ester tumor promotion (Germolec *et al.*, 1997). Although arsenic is thought to elicit cancer in regions of the skin not receiving high sun exposure (e.g., the palms and soles), careful examination of epidemiological data in Bangladesh indicate sun exposure is a risk factor for arsenical keratoses, precursors for cancer (Chen *et al.*, 2006). High arsenic exposure from drinking water also appears to promote skin lesions in users of betel nut (McCarty *et al.*, 2006), a source of genotoxic nitrosamines known to be activated by cytochrome P450 activities in keratinocytes of the oral cavity (Miyazaki *et al.*, 2005). Among the proposed mechanisms of arsenic action, generation of reactive oxygen in target cells is a likely contributor to such carcinogenic and other pathological effects. This phenomenon has been proposed to result from activation of NADPH oxygenases (Smith *et al.*, 2001), damage to mitochondria (Liu *et al.*, 2005) or, in the case of the methylated forms, (auto)oxidation (Kitchin and Ahmad, 2003). Consequent formation of 8-hydroxyguanine or -guanosine, consistent with low-level mutagenesis, has been detected in vivo and in culture. Reactive oxygen generation could also account for the hyperplastic response of mouse skin to arsenic (Rossman *et al.*, 2004) and the broad effects in target cells (Rea *et al.*, 2003), including central signaling molecules such as focal adhesion kinase (Yancy *et al.*, 2005).

TOXIC RESPONSES OF THE REPRODUCTIVE SYSTEM

Paul M.D. Foster and L. Earl Gray Jr.

INTRODUCTION

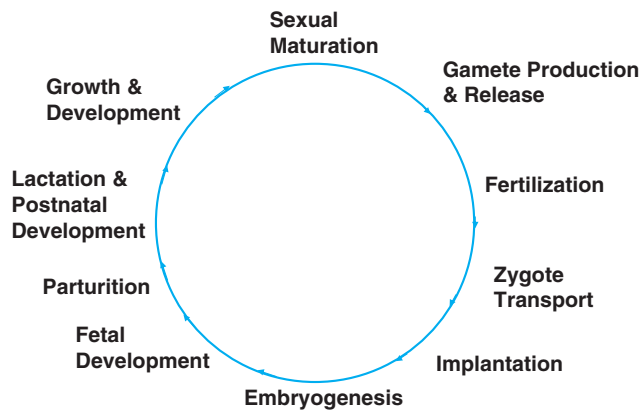
Any evaluation of toxicity to reproduction will have as an important consideration that events may not only be on the adults having impact on their likelihood to have children, but also impact the viability and quality of life of their potential offspring and feasibly even affect later generations. That chemicals can adversely affect reproduction in males and females is not a new concept, one only has to look at the importance of drugs as contraceptives to realize how sensitive the reproductive system can be to external chemical influences to


Figure 20-1. The Reproductive Cycle.

Table 20-1

Examples of reproductive physiology similarities among humans and rats

Steroid hormone control of reproductive function relies on testosterone, dihydrotestosterone, estradiol, and progesterone.

CNS-hypothalamic secretion of GnRH controls pituitary release and synthesis of FSH and LH.

FSH and LH regulate germ cell development after puberty, LH surges induce spontaneous ovulation in the female, LH regulates testis Leydig cell testosterone production.

Placental support of embryos. Placenta and fetal unit also produce hormones critical for pregnancy maintenance after the first week.

Hormonal regulation of uterine function and onset of delivery.

Androgens required to maintain male spermatogenesis and secondary sex characteristics.

Hormone-dependent mating and other sexually dimorphic behavior. "Rough and tumble" play behavior is sexually dimorphic behavior being imprinted by early androgens.

Lactation under complex hormonal regulation.

Dramatic endocrine changes resulting from CNS-HPG maturation responsible for puberty in males and females. Females generally attain puberty at an earlier age than males of the same species.

Key: CNS, central nervous system; GnRH, gonatropin-releasing hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone; HPG, hypothalamic-pituitary-gonadal.

disrupt this process. Of course in these cases, the failure of normal reproduction is a desired outcome in a contraceptive, but unfortunately we have had a number of catastrophes in which such failure has been unintentional. Many of the classic examples in chemical workers, or contamination of groundwater from chemical exposure such as dibromochloropropane (DBCP) or kepone (Chlordecone) have shown the sensitivity of human reproduction to these specific exposures (reviewed in (Cannon *et al.*, 1978; Faroon *et al.*, 1995; Winker and Rudiger, 2006). There have been significant improvements in our ability to test for effects on reproduction for chemicals, agrochemicals and drugs, but unfortunately such adverse episodes continue to occur in, for example, the more recent reports of the effects of 2-bromopropane in chemical workers (both male and female) in Korea (reviewed in Boekelheide *et al.*, 2004).

Recent trends in human fertility, fecundity—changing social influences (age at which women have their first child) and the knowledge that populations in many western countries are no longer self sustaining, coupled with the advent of assisted reproductive techniques (ARTs), where according to a recent paper 5.9% of all live births in Denmark used these ARTs (Andersen *et al.*, 2005), all point to the potential for declines in normal human reproduction. Underlying all these issues with human reproductive performance is the concept that exposure to environmental chemicals and drugs may be contributing to these declines.

The advent of the endocrine disruptor debate provided a major impetus to the examination of the methods used in screening and testing for reproductive (and other) toxicity, and highlighted a number of shortfalls, not least in how we should evaluate the latent effects on adults of in utero exposures. However, this Chapter will not specifically address the emerging issue of the fetal origins of adult disease as proposed by Barker (Barker, 1995, 1999; Barker *et al.*, 1993; Barker *et al.*, 1989).

This chapter will take the reproductive cycle (Fig. 20-1) as the biological basis for the description of toxicity to reproduction rather than an encyclopedic approach. The basic biology of the different lifestages and processes that are requisites for normal reproduction will be discussed and, where possible, the differences between experimental animals and humans highlighted (see Tables 20-1 and 20-2). These processes will then be placed into perspective by reference to a number of case studies of selected chemicals chosen to illustrate a range of modes of action and how they can perturb reproduction.

Special attention will be focused on endocrine disruption, methods proposed for screening and testing and the selection of chemicals with specific pharmacologies (e.g., estrogen or antiandrogen) to illustrate the types of toxicities produced at different lifestages.

The chapter will also provide basic information on testing methodologies for chemicals, pesticides and drugs, but placed into the reproductive cycle framework. Thus, it will examine the lifestages that are exposed and when specific evaluations are undertaken. Lastly, we have included a section on the evaluation of data and weight of evidence, specifically how one looks at concordance of end points with examples of the types of profiles observed (based on the examples used previously). We do not believe that we have seen this anywhere before, or in this context, and hopefully this will be a useful tool for students and professionals alike.

THE REPRODUCTIVE CYCLE

If one considers the purpose of the reproductive system as the production of good quality gametes, capable of fertilization and producing a viable offspring which in turn can successfully reproduce, then it is clear that a large number of complex processes need to be orchestrated in a precise, sequential order for optimal performance at different stages of the lifecycle of the animal, or human. Thus, following fertilization of an egg by a sperm, the resulting zygote must be transported along the oviduct while maturing into an early embryo. This embryo is then required to implant in the uterus successfully, such that the developing conceptus can differentiate, produce a placenta and normal embryogenesis and fetal development occur. Once the fetus has completed in utero growth and differentiation, parturition needs to occur at the correct time and the neonate be born and then proceed successfully through the lactation phase of development and be weaned.

When the male and female offspring enter puberty after infancy, they need to acquire sexual characteristics as young adults

Table 20-2

Examples in which the reproductive strategy of the rat differs from that of the human

1. The rat is a short (22.5 day) gestation species. Pregnancy in humans is 9 month.
2. The rat placenta lacks aromatase; estrogen is produced during pregnancy by the ovary. Human placental tissue expresses high levels of aromatase.
3. In the rat, sexual differentiation of the reproductive tract is perinatal, whereas central nervous system (CNS) sexual differentiation is a postnatal event, regulated to a great degree by aromatization of testosterone to estradiol (play behavior, an exception, is androgen dependent in both rats [Hotchkiss *et al.*, 2002, 2003] and humans [Hines, 2003]). In nonhuman primates and presumably humans, more CNS events are prenatal, and androgens are more important than in rats (Goy and Phoenix, 1972; Goy and Resko, 1972; Goy *et al.*, 1988; Hines, 2003).
4. The rat has a 4- to 5-day estrous cycle, with no functional corporus luteum. The estrous cycle can be monitored easily by examining daily cytology. The female rat displays sexual receptivity only during estrus after "lights out" after a proestrus vaginal smear. This behavior is exquisitely dependent on estrogen followed by progesterone. Humans have a menstrual cycle approximately 28 days in duration and do not display periods of peak behavioral estrus during the cycle. Corpora luteal function is sustained for approximately 10 days by mating-induced cervical stimulatory prolactin surges in rats, whereas the human menstrual cycle has a spontaneous luteal phase of 10 to 14 days after ovulation.
5. Male rat sex behavior can be induced by estrogens and involves multiple series of ejaculations in a single mating. Mating involves approximately 10 mounts, with intromission before each ejaculation, followed by a postejaculatory interval before the onset of the next series. In nonhuman primates and presumably humans, male sex behavior is androgen mediated.
6. Both ovaries spontaneously release several ova in response to a luteinizing hormone surge into separate uterine horns, each with a separate cervix in the rat; whereas in women, a single ovum is typically ovulated during each cycle.
7. Pregnancy is easily disrupted by estrogens in rats, but not in humans. Rats, unlike humans, are a litter-bearing species.
Most strains used for toxicology testing have litters of 10 to 12 pups. Spontaneous reproductive malformations are very rare in the rat, whereas in humans, some malformations such as cryptorchidism occur in 3% of newborn boys.
8. Spermatogenesis begins at approximately 5 days of age in the rat; the spermatogenic cycle is about 53 days of age, and sperm appear in the epididymis at about 55 days of age. In humans, spermatogenesis begins during puberty at 10 to 14 yr of age, and the entire spermatogenic cycle is approximately 75 days in duration.
9. Puberty in the rat (as measured by the age at vaginal opening and the onset of estrous cyclicity) occurs at about 32 days of age in females and 42 days of age (as measured by preputial separation an androgen-dependent event) in male SD and LE rat strains. In humans, puberty occurs at 9 to 12 yr of age in girls, and 10 to 14 yr of age in boys.
10. Fertility begins to decline in the female rat at about 6 mo of age, especially if never mated and allowed to cycle continuously. Fertility begins to decline in women at about 35 yr of age, and at 40 yr of age, approximately 50% of women are infertile.

For a review of reproductive physiology, see Knobil E, Neill JD, eds.: *The Physiology of Reproduction*, 2nd ed, Vol 1 and 2. New York: Raven Press, 1994.

with mature reproductive systems. Acquisition of sexual maturity involves the generation of gametes by the gonads which in turn can result in the production of the next generation. For the parental animals, once their reproductive lifespan has finished, the process of reproductive senescence then occurs. This myriad of processes all involve complex interplay between tissues and cells, the vast majority of these processes being under complex hormonal control that provides the critical signals and precise timing of these events.

Not surprisingly, it is possible to perturb this complex series of events and thus disturb the process and purpose of reproduction. Indeed, all these processes can be targets for the action of specific agents that can disturb these events leading to adverse effects on reproduction, such that the normal production of viable offspring cannot occur. It is thus important to consider in an evaluation of reproductive toxicity that while simple yes/no answers as to whether a particular agent can be a reproductive toxicant are possible, and indeed are used, any description of such toxicity has to be in the context of the lifestage of exposure and effect. There are examples of chemicals that can have different effects on reproduction, at different lifestages, via different modes of action/mechanisms. Indeed it might be useful for this particular aspect of toxicity to modify the adage of Paracelsus to "It is the **timing** of the dose that makes the poison." That is the dose of the toxic chemical and its resultant effects will be dependent on when in the lifestage of the organism that the chemical is administered and evaluated.

The next sections will examine some of the hormonal and other control mechanisms that have been deduced from careful physiological studies in experimental animals and humans (see Table 20-3) to provide more information as to where chemicals may produce their effects. Rather than provide a laundry list of chemicals that can produce effects on reproduction, one or two examples will be mentioned to illustrate the variety of processes that can be affected with referral to more detailed references. While reviewing the mammalian reproductive cycle one could start in any position, we have decided to begin with the development of the reproductive system in utero that occurs with the process of sexual differentiation of the embryo and the move forward around the cycle as depicted in Fig. 20-1.

REPRODUCTIVE DEVELOPMENT AND SEXUAL DIFFERENTIATION

During early human development there is a short period immediately prior to sexual differentiation when the gonad is sexually indifferent and it is not until the seventh week of gestation that male and female morphological characteristics begin to develop. In rodents, the embryo remains sexually indifferent and possesses both male and female reproductive tract primordia until embryonic day 13.5 regardless of its genetic sex.

Table 20-3
Reproductive Parameters for Various Species

			OVULATION		GESTATION	
SPECIES	AGE AT PUBERTY/ PERIOD	SEXUAL CYCLE DURATION (DAYS)	TIME	TYPE	IMPLANTATION (DAYS)	PARTURITION (DAYS)
Mouse	5–6 wk	4	2–3 hr	S	4–5	19 (19–21)
Rat	6–11 wk	4–6	8–11 hr	S	5–6	21–22
Rabbit	6–7 mo	Indefinite	10 hr	I	7–8	31 (30–35)
Hamster	5–8 wk	4	Early estrus	S	5+	16 (15–18)
Guinea Pig	8–10 wk	16–19	10 hr	S	6	67–68
Ferret	8–12 mo	Seasonal	30–36 hr	I	12–13	42
Cat	6–15 mo	Seasonal	24–56 hr	I	13–14	63 (52–69)
Dog	6–8 mo	9	1–3 days	S	13–14	61 (53–71)
Monkey	3 yr	28	9–20 days	S	9	168 (146–180)
Man	12–16 yr	27–28	13–15 days	S	7.5	267 (ovulation)

S = Spontaneous
I = Induced

Gonadogenesis begins with proliferation of the mesodermal (coelomic) epithelium which invades the underlying mesenchyme, resulting in a longitudinal thickening on the medial side of the mesonephros, known as the gonadal ridge (Byskov, 1986). The invading epithelium begins to form primitive sex cords in the gonadal ridge which are surrounded by undifferentiated mesenchyme (Pelliniemi, 1975). Primordial germ cells, or primitive sex cells, are first visible in the fourth week in the caudal region of the yolk sac near the origin of the allantois and migrate along the hindgut, up the dorsal mesentery and into the gonadal ridges (Eddy *et al.*, 1981). The primordial germ cells divide mitotically during migration and continue to proliferate as they migrate under the underlying mesenchyme and are incorporated into the primary sex cords (Moore, 1982). As the primitive cords begin to form, the mesenchyme is invaded by capillaries. The indifferent gonad now consists of an outer cortex and an inner medulla. In the rodent, formation of the gonadal cords is a rapid process that occurs at gestational day 13 via transitory epithelial cell aggregates along the length of the gonadal ridge (Paranko *et al.*, 1983).

Gonadal differentiation is dependent on signals from the Y chromosome which contains the genes necessary to induce testicular morphogenesis. One of these signals is the SRY gene which is the sex-determining region on the short arm of the Y chromosome (Koopman *et al.*, 1990) and acts as a "switch" to initiate transcription of other genes which contribute to testicular organogenesis. In the absence of the SRY protein, the gonad remains indifferent for a short period of time before differentiating into an ovary.

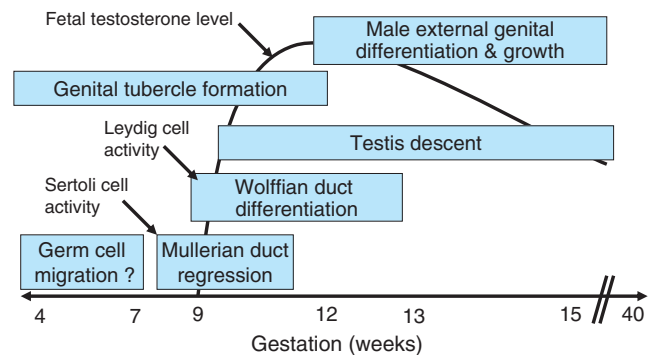
The first morphological sign of testis formation is the aggregation of primordial germ cells and somatic cells (primitive Sertoli cells). These aggregates develop from the gonadal blastema into plate-like structures which then develop into simple arches of elongated testicular cords (Paranko *et al.*, 1983). Throughout differentiation, the testicular cords remain connected to the basal portion of the mesonephric cell mass. The cords gradually transform and extend into the medulla of the gonad, where they branch and anastomose to form a network of cords, known as the rete testis (Moore, 1982). A characteristic and diagnostic feature of testicular development is development of a thick fibrous capsule, the tunica albuginea. As this capsule develops the connection of the prominent testicular (seminiferous) cords with the surface epithelium is disrupted. Gradually the testis separates from the regressing mesonephros, becoming


Figure 20-2. Male sexual differentiation in humans during gestation.

(Reproduced with permission from Klonisch T, Fowler PA, Hombach-Klonisch S: Molecular and genetic regulation of testis descent and external genitalia development. *Dev Biol* 270:1–18, 2004. Elsevier Science.)

suspended by its own mesentery. Concurrent with testicular cord formation, fetal Leydig cells differentiate from loosely packed, undifferentiated mesenchymal cells in the interstitium (Pelliniemi, 1975). These interstitial Leydig cells produce the male sex hormone testosterone, which induces masculine differentiation of the Wolffian duct and external genitalia. Intratesticular vasculature differentiates in the gonadal mesenchyme along with the growth of epithelial components. A testis-specific distribution of blood vessels is obvious from an early phase of testicular development (Pelliniemi, 1975). See Fig. 20-2 for a diagrammatic representation of sexual differentiation in the human male.

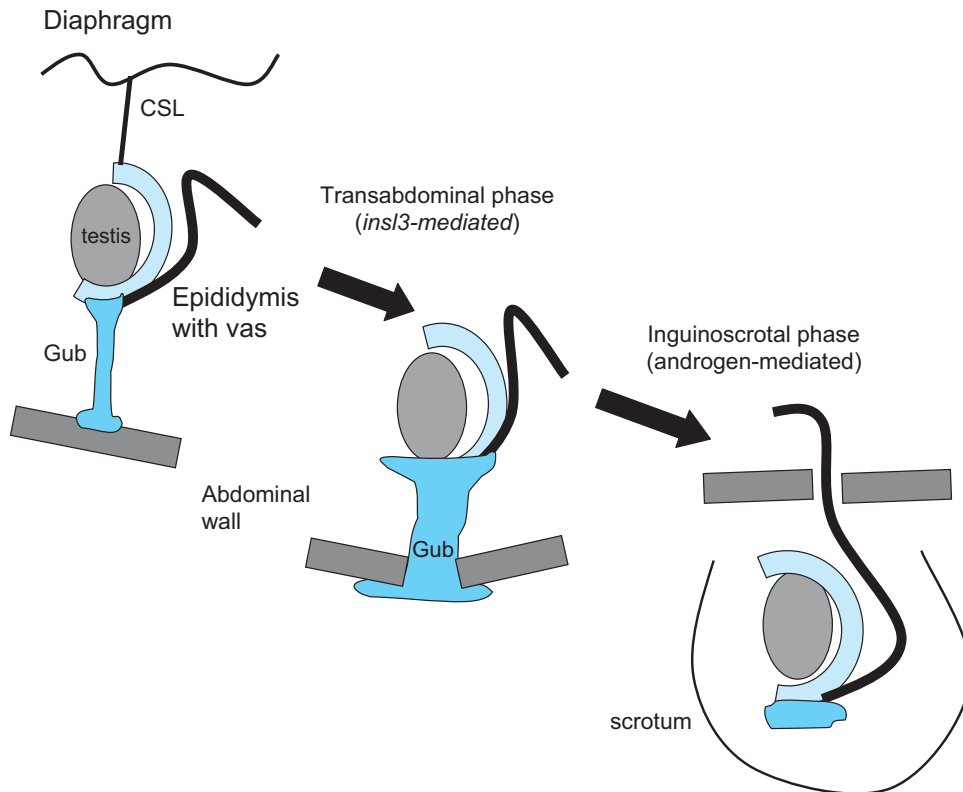
The fetal testis is composed of testicular cords containing supporting immature Sertoli cells and centrally placed spermatogonia, derived from the surface epithelium and primordial germ cells respectively. These cords are surrounded by a highly vascularized interstitium containing fetal Leydig cells and mesenchyme (Pelliniemi and Niei, 1969). The testicular cords remain without a lumen throughout the fetal period. The seminiferous cords turn into tubules when the Sertoli cells undergo terminal differentiation. This occurs after birth when they finish dividing (roughly at the onset of puberty). They develop tight junctions between adjacent cells, and apical secretion of fluid begins as these cells become highly


Figure 20-3. The two distinct phases of testicular descent in mammals.

The first (transabdominal phase) mediated by insl3 from the fetal testis involving the removal of the cranial suspensory ligament (CSL) and development of the gubernaculum (gub). The second (inguinoscrotal phase) being androgen mediated. (Reproduced with permission from Klonisch T, Fowler PA, Hombach-Klonisch S: Molecular and genetic regulation of testis descent and external genitalia development. *Dev Biol* 270:1–18, 2004. Elsevier Science.)

polarized. Thus, the lumen forms as Sertoli cells develop their mature phenotype.

In the rodent and human species, fetal testicular androgen production is not only necessary for proper testicular development and normal male sexual differentiation but also differentiation of the Wolffian ducts into the epididymides, vasa deferentia, and seminal vesicles (Barker *et al.*, 1993; Berman *et al.*, 1995; Imperato-McGinley *et al.*, 1992; Kassim *et al.*, 1997; Roy and Chatterjee, 1995; Silversides *et al.*, 1995; Veyssiere *et al.*, 1982; Wilson and Lasnitzki, 1971).

Androgens derived from the Leydig interstitial cells stimulate the mesonephric (or Wolffian) ducts to form the male genital ducts, while Sertoli cells produce Müllerian Inhibiting Substance (MIS or Anti Müllerian Hormone (AMH)) which suppresses development of the paramesonephric (Müllerian) ducts, or female genital ducts.

There is differential maturation of the mesonephric ducts depending on location. Near the testis, some tubules persisting and are transformed into efferent ductules, which open into the mesonephric duct, forming the ductus epididymis. Distal to the epididymis, the mesonephric ducts acquire a thickening of smooth muscle to become the ductus deferens, or vas deferens (Moore, 1982).

Development of the external genitalia is similar in the two sexes. In the human the external genitalia are indistinguishable until the ninth week of gestation, and not fully differentiated until the twelfth week of development. Development of the external genitalia coincides with gonadal differentiation. Early in the fourth week of

gestation, the sexually undifferentiated fetus develops a genital tubercle at the cranial end of the cloacal membrane. Labioscrotal (genital) swellings and urogenital (urethral) folds then develop on each side of the cloacal membrane. The genital tubercle then elongates forming a phallus. In response to testicular androgens the phallus enlarges and elongates forming the penis while the labioscrotal swellings ultimately form the scrotum. At the end of the sixth week of gestation, the urorectal septum fuses with the cloacal membrane dividing the membrane into a dorsal anal and a ventral urogenital membrane. Approximately a week following, these membranes rupture forming the anus and urogenital orifice, respectively (Moore, 1982).

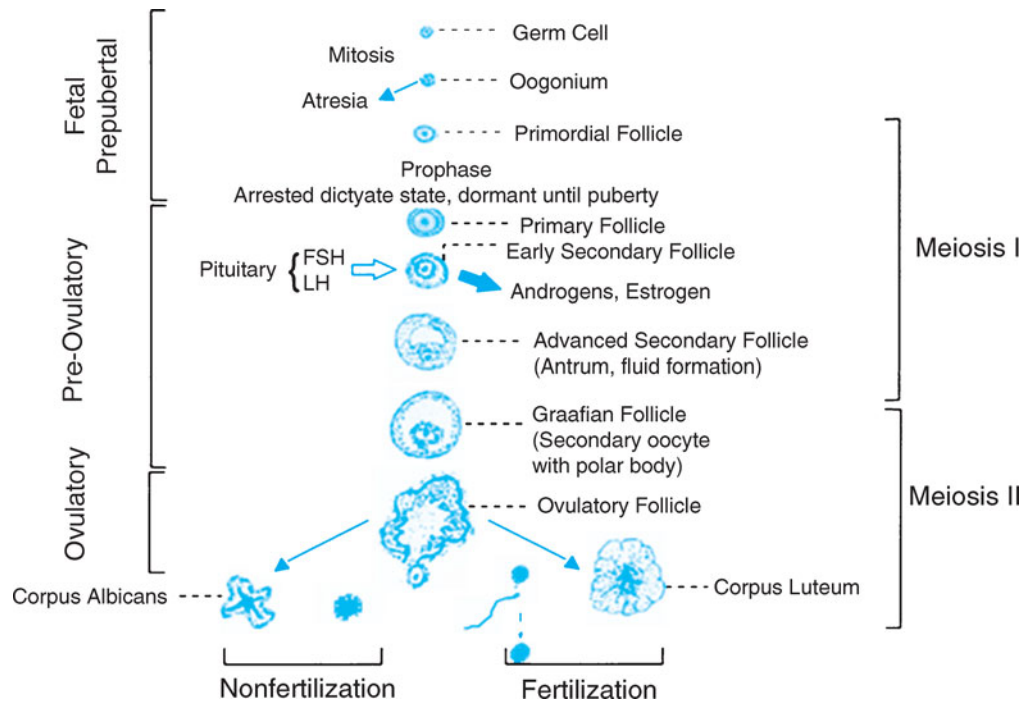
Fetal testicular androgens are responsible for the induction of masculinization of the indifferent external genitalia. The testis remains caudally positioned during the tenth to fifteenth week until entry into the inguinal canal and transabdominal descent. Testicular descent through the inguinal canal begins in the twenty-eighth week and the testes enter the scrotum by the thirty-second week. At birth, the testes reach the bottom of the scrotum (Moore, 1982). There are two critical phases of testis descent, transabdominal and inguinoscrotal, essential to move the testes into the scrotum. Although the precise mechanisms of testicular descent, and causes of cryptorchidism, remain unclear the insulin-like peptide hormone INSL3 and fetal testicular androgens are known to play a critical role (Klonisch *et al.*, 2004)—see Fig. 20-3. Cryptorchidism or undescended testes occurs in about 3% of full-term and 30% of preterm males making it the most common human birth defect (Boisen *et al.*,


Figure 20-4. Development of the Oocyte.

2004). However, a comparative study of the prevalence of cryptorchidism in cohorts of children in Denmark and Finland, a higher prevalence of cryptorchidism was observed in Denmark, with a 9% incidence rate in full-term males reported at birth (Boisen *et al.*, 2004). These data add further evidence to the concept that there is a significant geographical difference in male reproductive health in two neighboring countries, and therefore potential exposure to similar environmental effects. As the major difference was found in the milder forms of cryptorchidism, an environmental rather than a genetic basis for effect is favored. If correct, there is a need to determine the nature of the environmental agents responsible, because similar agents may well be implicated in the trends noted in other geographically diverse countries where an increasing frequency of cryptorchidism and testicular cancer has been found (Boisen *et al.*, 2004).

Thus male, but not female, reproductive tract development is totally hormonally dependent and thus inherently more susceptible to endocrine disruption (see section "Endocrine Disruption" including "Screening and Puberty"). It is also of note to mention that the early development and triggers of the testis are mediated by direct hormone action before the establishment of the hypothalamic-pituitary-gonadal (HPG) axis.

GAMETOGENESIS

Formation and production of gametes in mammals begins in early embryonic life with the development of primordial germ cells in the genital ridge and movement of these cells into what will become the gonads (see section on sex differentiation). The critical feature in the production of gametes is the process of meiosis.

The basic features of meiosis—two cell divisions with no intervening DNA replication, results in a halving of the chromosome complement—is conserved throughout evolution. Thus, it is not surprising that the general outline applies to both mammalian males and females. However, the strategies employed are remarkably dif-

ferent between the sexes. The mammalian oocyte begins meiosis during fetal development but arrests partway through meiosis I and does not complete the first division until ovulation; the second division is completed only if the egg is fertilized (see Fig. 20-4). Oogenesis therefore requires several start and stop signals and, in some species (e.g., the human), may last for more than 10 years. In contrast, male meiosis begins at puberty and is a continuous process, with spermatocytes progressing from prophase through the meiotic second division in little more than a week. This difference in strategy has implications for the action of toxicants and critical time periods when these cells may be vulnerable to attack (see section on male and female reproductive system). Critical to this is the understanding that the complement of oocytes available to the mammalian female is complete at birth, whereas in the male there is significant stem cell (spermatogonial) renewal to maintain the significantly higher number of germ cells available in males.

NEONATAL DEVELOPMENT

At birth, or even late in gestation, male rats display longer anogenital distances (AGD) than do female rats with neonatal male AGD being more than twice as long as females (Gray *et al.*, 1999). There are homologous sex differences in humans (Longnecker *et al.*, 2007; Swan *et al.*, 2005). Administration of androgen receptor (AR) antagonists or inhibitors of testosterone synthesis can demasculinize male AGD whereas androgen administration during this period lengthens female AGD (Gray *et al.*, 1994, 1999; Hotchkiss *et al.,* 2007; Wolf *et al.*, 2002).

In addition, in many mammalian species, including humans and rats, males of the species engage in more aggressive play than do females (Hines, 2003; Hotchkiss *et al.*, 2003). In the rat, play behavior is displayed for a period of a few weeks around 35 days of age and males engage in more rough and tumble aggressive play than do females. This behavior differentiates during neonatal life

and exposure to antiandrogens like flutamide or vinclozolin shortly after birth demasculinizes this behavior such that treated males engage in female-like play at about 35 days of age. In contrast, neonatal androgen treatments masculinize female rat play behavior such that they will engage in male-like levels of rough and tumble play. In humans, sexually dimorphic play behaviors are displayed fairly early in life. Congenital adrenal hyperplasia (CAH) daughters, exposed to high levels of adrenal androgens in utero display male-like play (Hines and Kaufman, 1994). Normally in the rat, the development of this behavior differentiates under the influence of a neonatal surge in testosterone in the first few days of pregnancy, after which fetal testis Leydig cells regress and testosterone production declines to very low levels for a few weeks until the emergence of the adult Leydig cells occurs in the testis prior to puberty (Huhtaniemi and Pelliniemi, 1992). In rodents but not humans, interestingly the first wave of spermatogenesis is initiated at about 4 days of age.

INFANTILE DEVELOPMENT

Later in lactation, during the infantile period of development, several key events occur in the reproductive system of rats including emergence of the nipple buds and areolae in females and maturation of the hypothalamic-pituitary axis. Emergence of the nipple buds is an event most visible around 13 days of age which is prevented in males by prenatal androgen-induced atrophy of the nipple anlagen. It is noteworthy that male rats with the shortest AGD and highest numbers of female-like nipples have a very high likelihood of displaying reproductive tract lesions like hypospadias or epididymal agenesis (Barlow *et al.*, 2004; Hotchkiss *et al.*, 2007). Similarly, prenatally androgen treated females with the longest AGDs and reduced infant nipple numbers are more likely to display reproductive tract malformations (retained male tissues or vaginal agenesis) than less affected females (Hotchkiss *et al.*, 2007). In addition, the effects on AGD are permanent in both sexes (Barlow *et al.*, 2004; Hotchkiss *et al.*, 2004, 2007) with nipple buds being permanent in males.

PUBERTAL DEVELOPMENT

Scientific evidence increasingly supports the concerns about environmentally induced alterations of pubertal events in girls and boys. In addition, experimental animal data are consistent with a potential role of environmental factors in inducing altered pubertal maturation in humans. Puberty is the stage of life when an individual matures from a child, through adolescence to full maturity. The process is marked by dramatic development of hormone dependent sexual characteristics, somatic growth, and sexual and social behaviors eventually resulting in full sexual maturity and reproductive capacity. The stages of puberty in boys and girls are determined using approaches including the Tanner Stages (Marshall and Tanner 1969, 1970) for breast and pubic hair development in girls and gonadal and pubic hair development in boys. Puberty in girls is also assessed using the age at menarche as a marker. Alternatively, increasing levels of estradiol or androgens in the serum prior to some of the development of some of the early physical markers can be used to determine the onset of puberty in girls and boys respectively.

Puberty is initiated by activation of the HPG and hypothalamic-pituitary-adrenal (HPA) axes (Ojeda and Heger, 2001; Ojeda *et al.*, 2003) (see Fig. 20-5). At the onset, the HPG axis releases gonadotropin releasing hormone (GnRH) pulses with increasing frequency and amplitude which induces complimentary pulsatile secretions of luteinizing hormone (LH) and follicle-stimulating hormone

(FSH) from the anterior pituitary (Ojeda *et al.*, 2003). In turn, LH and FSH stimulate the gonads inducing gonadarche characterized by the onset of gonadal hormone production. In the female, secretion of androgens from theca cells and estradiol from granulosa cells of maturing follicles prior to ovulation, followed by secretion of progesterone from the corpus luteum after ovulation, whereas in the male, LH stimulates testicular synthesis and secretion of androgens and insulin-like 3 peptide hormone from the Leydig cells of males. Interestingly, in most mammals including humans and rodents, puberty in the female normally precedes the age of puberty in the male.

In humans, adrenarche, the maturation of adrenal endocrine function, occurs early in pubertal development resulting in the growth of pubic hair, acne, and other secondary sex traits (Auchus and Rainey, 2004). These physical changes result from increasing adrenal synthesis and secretion of steroids including dehydroepiandrosterone (DHEA), dehydroepiandrosterone sulfate (DHEAS), and androstenedione, steroids with weak androgenic activities. Adrenarche is independent of gonadarche and typically occurs between 6 and 8 years of age in both sexes. Adrenarche occurs only in primates and is not associated with puberty in all primate species.

Precocious puberty is defined as the onset of sexual traits before 8 and 9 years of age in girls and boys, respectively, whereas puberty is considered as delayed in girls if thelarche is not displayed by 13 years and at 14 years of age in boys when testicular volume of less than 4 mL (Becker and Epperson, 2006; Biro *et al.*, 2006; Den Hond and Schoeters, 2006; Himes, 2006; Muir, 2006; Ojeda *et al.*, 2006; Papathanasiou and Hadjiathanasiou, 2006; Tuvemo, 2006). Delays in boys can occur as a result of either primary hypothalamic–pituitary or gonadal failure, from head trauma or from infection. While the majority of these delays are transient, some cases are associated with gene mutations resulting in either hypogonadotropic hypogonadism or primary gonadal failure.

Of greatest concern current is the observation that in the United States and several other countries, the age of onset of puberty over the past 40 years has decreased from 0.5 and 1.0 years in girls and the age at menarche has declined by about 0.2 years (Kaplowitz, 2006). Northern European countries have not reported such a trend. Similar trends in male puberty have not been observed and similar trends have not been seen in boys.

Some scientists have attributed the trends in pubertal maturation of girls to obesity rates in children. Rapid early weight gain, obesity, and early development have been associated with the development of insulin resistance and an exaggerated adrenarche (Buck *et al.*, 2007). These endocrine alterations, together with elevated leptin levels and enhancement of hormonal activity by conversion of steroids to estrogens by fat cells, could affect the onset and progression of puberty in young obese girls. In addition, the role of environmental factors including endocrine disrupting chemicals (EDCs) in the etiology of this trend is also being investigated. Alterations of puberty in boys and girls can also be of genetic origin. Precocious puberty may result from early onset of HPG function or via gonadotropin-independent alterations.

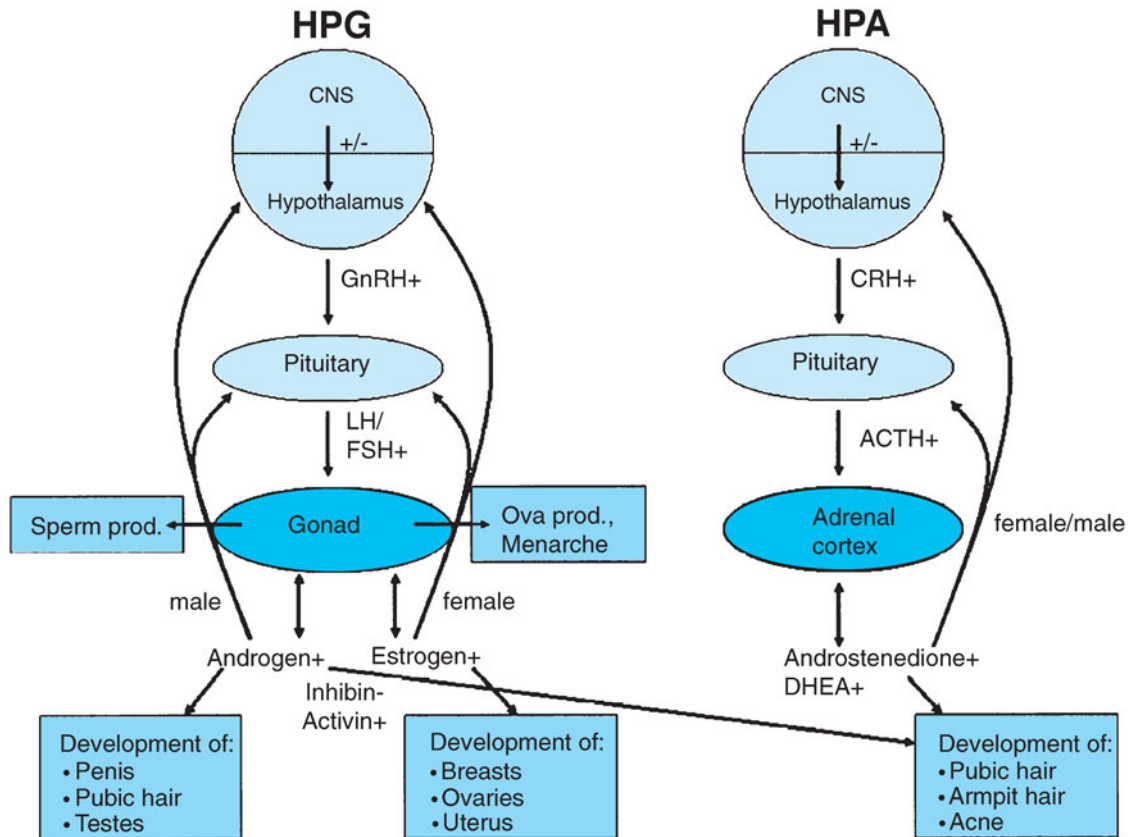
Premature thelarche and premature adrenarche are often referred to as pseudoprecocious puberty when the full spectrum of pubertal changes do not occur. Premature thelarche in girls and gynecomastia in boys is known to result from direct exposure estrogen-containing personal care and "natural" products (Henley *et al.*, 2007; Hertz, 1958; Massart *et al.*, 2006). Although these conditions are usually resolved after termination of exposure, untoward


Figure 20-5. Endocrine control of puberty in males and females.

consequences of these conditions may occur with prolonged exposure including shortened stature due to effects of estrogens on the growth plates of the long bones and sexual–social behavior that is inappropriate for chronological age of the child (Wacharasindhu *et al.*, 2006). Concerns have also been expressed that premature thelarche may enhance the likelihood of developing diseases like breast cancer and endometriosis.

Numerous human studies have examined the relationships between environmental factors and human puberty. Many studies have shown a positive relation between body fat and onset of the growth spurt, breast development, or menarche (Battaglia *et al.*, 2005; Biro *et al.*, 2006; Dunger *et al.*, 2005; Himes, 2006; McCartney *et al.*, 2007). Environmental exposure to persistent halogenated organic chemicals such as polychlorinated biphenyls (PCBs) (Den Hond and Schoeters, 2006), DDT/DDE (Charlier, 2006; Gladen *et al.*, 2004; Krstevska-Konstantinova *et al.*, 2001; Ouyang *et al.*, 2005), brominated flame retardants (Blanck *et al.*, 2000), dioxin (Eskenazi *et al.*, 2000; Hauser *et al.*, 2005; Warner *et al.*, 2004; Wolff *et al.*, 2005), hexachlorobenzene (HCB) (Charlier, 2005, 2006), endosulfan (Saiyed *et al.*, 2003), and heavy metals also have been studied for associated with pubertal alterations but a consensus about the causative role of these chemicals in altering puberty has not been achieved.

Rodent Models of Puberty

Rodents provide important animal models in the study of the genetic and environmental factors that regulate puberty. In the rat, GnRH secretion is at low levels during juvenile development until GnRH release is activated by neuronal networks during puberty. During the onset of puberty there is an increase in the excitatory amino acids and the peptide kisspeptin peptide (Tena-Sempere, 2006) along with decreases in inhibitory neurotransmitters gamma amino butyric acid (GABA), and opioid peptides. In addition, several growth factors like epidermal growth factor (EGF)-like ligands and members of the EGF receptor family contribute to glia-to-neuron communication (Ojeda *et al.*, 2006; Ojeda *et al.*, 2003). While the complete pathway triggering the onset of puberty in rodents has not yet been described, several early components have been identified including the kisspeptin-GPR-54 regulatory system. Mutations of the GPR54 receptor result in absence of puberty in humans and mice (Semple *et al.*, 2005). In addition, leptin (Vogel, 1996) and insulin-like growth factor 1 (IGF-1) Jaruratanasirikul *et al.*, 1999) appear to be in sustaining pubertal events once the process has been initiated.

In the laboratory rat the standard landmarks of puberty in the male are the age of male preputial separation (PPS), an androgen-mediated event, and the ages of vaginal opening (VO), an estrogen-mediated event, and first estrus, with VO normally coinciding with the first estrus and the onset of estrous cycles (Goldman *et al.*, 2000). In the laboratory mouse, VO is not a useful indicator of puberty because it is not associated with the ages at first estrus and the onset of estrous cyclicity.

The ages of VO in females and PPS in male rats were included as required endpoints in the 1998 USEPA multigenerational test guidelines (http://www.epa.gov/opptsfrs/publications/OPPTS_Harmonized/870_Health_Effects_Test_Guidelines/Series/870-3800.pdf). Furthermore, it is generally agreed among risk assessors that statistically significant alterations in pubertal maturation in the rat are adverse effects and these data have been used

as a critical effect to establish reference doses in some cases (see the USEPA Vinclozolin risk assessment, 2002). Because EDCs share mechanisms of action in common with many of the drugs used to treat altered human pubertal development, it is biologically plausible that these EDCs would also alter pubertal onset in boys and girls, if children were exposed to sufficient levels of these chemicals during this critical stage of life.

Toxicants can alter puberty as a consequence of in utero, lactational, or pubertal exposures. In a multigenerational study, discerning the stage of life when exposure induced the alteration may be challenging, if possible at all, because dosing is not initiated in the parent (F_0) generation, the only generation with in utero and lactational exposure, until well after puberty. Some alternate reproductive test protocols (Gray *et al.*, 1988a) can detect pubertal alterations in the F_0 generation since they initiate exposure right after weaning. In addition, short-term studies using the pubertal male and female rat assays (EDSTAC Final report, 1998) (Gray *et al.*, 2004a) can help resolve this uncertainty since exposures are initiated directly to the weanling rat and continued for 20–30 days for females and males, respectively. Comprehensive reviews describing the toxicology of puberty in rodents are found elsewhere (Goldman *et al.*, 2000; Stoker *et al.*, 2000; Gray *et al.*, 2004).

Studies using rats demonstrate that body weight at weaning is an important determinant of the age of VO in the female and PPS in the male. However, treatments that reduce growth by 10% or less have little effect on the attainment of the male and female pubertal landmarks. The onset of puberty can be altered in the male and female rat by disrupting the endocrine system at a variety of levels including the entire HPG axis. In addition to effects on the HPG axis, the landmarks of female rat puberty can be altered by the direct action of either estrogens or antiestrogens on VO and other components of the reproductive tract, whereas, androgens and antiandrogens can alter male rat pubertal landmarks by acting at the level of the male reproductive tract.

Because estrogen exposure in the peripubertal female rat can accelerate the onset of VO and at the age of the first estrus smear without accelerating the onset of regular estrous cycles it is useful to monitor all three landmarks of puberty in the female in order to discriminate pseudoprecocious puberty (accelerated age at VO but not the onset of estrous cyclicity) from true precocious puberty (both the ages at VO and the onset of estrous cyclicity are accelerated).

Selected Examples of Chemicals That Alter the Onset of Pubertal Landmarks in Rats After Acute in Utero and/or Lactational Exposures   In utero exposure to 2, 3, 7, 8-tetrachlorodibenzo-*p*-dioxin (TCDD) (a single dose of 0.001 mg/kg on gestational day (GD) 15) delays the onset of pubertal landmarks in male and female rats (Gray *et al.*, 1995; Gray and Ostby, 1995; Gray *et al.*, 1997b; Gray *et al.*, 1997c). The mode of action for these effects is not known but it likely involves permanent organizational effects of TCDD of the reproductive tract during sexual differentiation mediated via arylhydrocarbon receptor, AhR. In addition, the treated females display a persistent vaginal thread after puberty.

In utero exposure to the potent alkalating drug busulfan at (5 and 10 mg/kg sc on GD 15) destroys fetal germ cells resulting in gonadal atrophy and delayed puberty in both male and female rats (Gray and Ostby, 1998). Some females never displayed VO, or any other pubertal landmark likely due to a total absence of primary follicles in the ovary.

Prenatal androgen administration can induce agenesis of the lower vaginal canal in females, an effect that could be missed entirely of misconstrued as just a delay in VO unless the females are retained after weaning and thoroughly examined after the normal age at puberty (Hotchkiss *et al.*, 2007). Conversely, prenatal antiandrogen-treatments can result in the formation of a lower vaginal "pouch" in treated male rats (Gray *et al.*, 1994).

Administration of estrogens like ethinyl estradiol (EE) or methoxychlor (MXC) to the dam during gestation and lactation can accelerate VO in female rat offspring. In the higher dosage groups VO can be detected as early as 10–15 days of age, albeit a "pin-hole" like opening (Gray *et al.*, 1989).

Peripubertal administration of EDCs can alter the onset of pubertal landmarks in male (Gray *et al.*, 2004b; Monosson *et al.*, 1999) and female rats (Goldman *et al.*, 2000). Androgens play a key role in pubertal maturation in young males and antiandrogens like vinclozolin (Monosson *et al.*, 1999), linuron (Gray *et al.*, 1999), *o,p′* DDE (Kelce *et al.*, 1995), prochloraz (Blystone *et al.*, 2007), and the phthalates (Gray *et al.*, 1999) produce measurable delays in this process. For example, vinclozolin treatment delayed pubertal maturation and retarded sex accessory gland and epididymal growth (at 30 and 100 mg/kg/d) (Monosson *et al.*, 1999). Serum LH (significant at all dosage levels), testosterone and 5α-androstane, 3α,17β-diol (at 100 mg/kg/d) levels were increased. Testis size and sperm production, however, were unaffected. In contrast, reproductive toxicants like carbendazim that indirectly alter FSH levels without affecting serum testosterone fail to delay PPS even at dosage levels that cause profound alterations of testicular and hypothalamic-pituitary (FSH secretion) function (Gray *et al.*, 1990).

The ease with which a delay in PPS, a landmark of puberty in the rat, can be measured enables us to use this endpoint to evaluate chemicals for this form of endocrine activity. A "pubertal male assay" including an assessment of PPS is being considered by the USEPA and others (Gray, 1998; Gray *et al.*, 1997a; Stoker *et al.*, 2000) for screening chemicals for endocrine activity, as mandated by 1996 U.S. legislation (the Food Quality Protection Act and Safe Drinking Water Act).

Selected Examples of Chemicals That Alter the Onset of Pubertal Landmarks in Rats After Peripubertal Exposures   The "pubertal female rat assay" assay has been included in the proposed EDSTAC Tier 1 Screening (T1S) battery. In this assay, weanling female rats are dosed daily by gavage for 21 days and the age at VO (puberty) is monitored and the females are necropsied at about 42 days of age (reviewed by Goldman *et al.*, 2000). Vaginal estrous cycles are also determined by daily observation by light microscopy of the cell types present in a vaginal lavage, taken from VO until necropsy. Necropsy measurements include serum thyroid hormones, and uterine and ovarian weight and histology. This assay detects alterations in thyroid hormone status, HPG function, and inhibition of steroidogenesis, estrogens and antiestrogens. Recently, in studies from different laboratories the pubertal female assay was found to be highly reproducible and very sensitive to certain endocrine activities including estrogenicity, inhibition of steroidogenesis, and antithyroid activity (Gray *et al.*, 2004b) (see Table 20-4).

The "pubertal male assay rat" (Gray *et al.*, 2004; Stoker *et al.*, 2000; Monosson *et al.*, 1999) detects alterations of thyroid function, HPG maturation, steroidogenesis, and altered steroid hormone function (androgen). Intact weanling males are exposed to the test substance for about 30 days, the age at puberty is determined and

Table 20-4

Chemicals evaluated by the U.S. Environmental Protection Agency (EPA) using the standardized pubertal female rat assay in two contract laboratories or key studies performed in other laboratories

STUDIES PERFORMED IN LABORATORY 1 FOR THE EPA
Ethinyl estradiol: Positive estrogenic control
Tamoxifen: Mixed estrogen agonist–antagonist; successfully identified mixed action
Ketoconazole: Inhibits steroidogenesis; caused ovarian histological changes
Methoxychlor: Estrogenic pesticide; successfully detected by accelerated puberty
Phenobarbital: Alters liver, hypothalamic, pituitary, and ovarian function; delays puberty
Studies performed in Laboratory 2 for the EPA
Methoxychlor: Estrogenic pesticide; successfully detected by accelerated puberty
Ketoconazole: Inhibits steroidogenesis; caused ovarian histological changes
Bisphenol A: Weakly estrogenic plastic monomer; negative for endocrine effects
Propylthiouracil: Antithyroid agent; lowered T4, increased thyroid-stimulating hormone, and caused thyroid histological changes at low doses that slightly delayed rat puberty
Fenarimol: Fungicide that weakly inhibits aromatase; slight delay in puberty, but lowered T4 and retarded growth
Atrazine: Herbicide that alters hypothalamic-pituitary function; delays puberty and growth
Key published studies performed in other laboratories
Methoxychlor: Estrogenic pesticide; accelerates puberty (Gray *et al.*, 1989)*b*
Polybrominated diphenyl ether: DE71; antithyroid toxicant; affected thyroid endpoints and delayed puberty (Stoker *et al.*, 2004b)*b*
Fadrazole: Potent aromatase inhibitor; delayed puberty (Marty *et al.*, 1999)*b*
Antarelix: Gonadotropin-releasing hormone antagonist; delayed puberty (Ashby *et al.*, 2002b)*b*
Octylphenol: Estrogenic surfactant; accelerates female rat puberty (Gray and Ostby, 1998)*b*
DES: Estrogenic pharmaceutical; accelerated puberty (Kim *et al.*, 2002)*b*
Tamoxifen: A mixed agonist/antagonistic drug; accelerated puberty (Kim *et al.*, 2002)*b*
ICI 182,780: Estrogen receptor (ER) antagonist; delayed puberty (Ashby *et al.*, 2002a)*b*
ZM 189,154: ER antagonist; delayed puberty (Ashby *et al.*, 2002a)*b*

Pubertal female assay data from contract laboratories (Summary available at http://www.epa.gov/scipoly/oscpendo/assayvalidation/meetings.htm.

reproductive tissues are evaluated and serum taken for optional hormonal analyses. This assay produced reproducible responses among different labs and was sensitive to androgens, antiandrogens, inhibitors of steroidogenesis and antithyroid activity. The chemicals studied to date in this assay are listed in Table 20-5.

When antiandrogenic chemicals are administered to juvenile male rats these chemicals do not induce malformations of the reproductive tract but pubertal development is delayed. Throughout puberty and into adulthood, the sex accessory glands and other androgen-dependent tissues (i.e., muscles, nervous system) continue to be dependent upon testosterone (T) and 5α-dihydrotestosterone (DHT) for maturation and maintenance of function (7). Several androgen dependent events occur during puberty, most notably the separation of the prepuce from the penis (PPS), followed 10 days to 2 weeks later by the appearance of mature sperm in the epididymis (Monosson *et al.*, 1999). During pubertal maturation, there are gradual changes in serum concentrations of testosterone (T) and of its metabolite 5α-androstanediol. In very young rats, 5α-androstanediol is present in greater quantities than T. T concentrations begin to increase, however, as 5α-reductase activity decreases in the Leydig cells, resulting in higher serum T concentrations than androstanediol in older rats. Peak T concentrations generally occur around 50–60 days of age.

In addition to delaying PPS, some antiandrogens also alter serum LH and T, while others do not. In particular, peripubertal exposure to flutamide (from 23 to 38 days of age) or vinclozolin (from 23 to 55 days of age) causes reductions in prostate, seminal vesicle, and epididymis in rats whereas serum LH and testosterone are increased (Monosson *et al.*, 1999).

SEXUAL MATURITY

Hypothalamo-Pituitary-Gonadal Axis

FSH and LH are glycoproteins synthesized and released from a subpopulation of the basophilic gonadotropic cells of the pituitary gland. Hypothalamic neuroendocrine neurons secrete specific releasing or release-inhibiting factors into the hypophyseal portal system, which carries them to the adenohypophysis, where they act to stimulate or inhibit the release of anterior pituitary hormones. GnRH acts on gonadotropic cells, thereby stimulating the release of FSH and LH. Native and synthetic forms of GnRH stimulate the release of both gonadotrophic hormones.

The neuroendocrine neurons have nerve terminals containing monoamines (norepinephrine, dopamine, serotonin) that impinge on them. Reserpine, chlorpromazine, and monoamine oxidase (MAO) inhibitors modify the content or actions of brain monoamines that affect gonadotrophin production.

In the female (see Fig. 20-6 for structure of the female reproductive tract of the rat and Fig. 20-7 for basic endocrine control), LH acts on thecal cells of the ovary to induce steroidogenesis, particularly the production of progesterone and androgens which are transferred to the granulosa cells which can be stimulated by FSH to produce estradiol. These steroids then feedback on the hypothalamus and

Table 20-5

Chemicals evaluated by the U.S. Environmental Protection Agency (EPA) using the standardized pubertal male rat assay in two contract laboratories or key studies performed in other laboratories

STUDIES PERFORMED IN LABORATORY 1 FOR THE EPA

Flutamide: Potent antiandrogenic drug; delayed puberty, among other effects
Ketoconazole: Inhibits steroidogenesis
Methyltestosterone: Androgenic drug; accelerated puberty
Phenobarbital: Alters liver, hypothalamic, pituitary, and testis function; delayed puberty, among other effects
Vinclozolin: Antiandrogenic fungicide; delayed puberty puberty, among other effects
Dibutyl Phthalate: Plasticizer that inhibits Leydig cell testosterone function; delayed puberty, among other effects

Studies performed in Laboratory 2 for the EPA
Vinclozolin: Antiandrogenic fungicide; delayed puberty puberty, among other effects
Linuron: Antiandrogenic herbicide; delayed puberty, among other effects
p,p′-DDE: Antiandrogenic pesticide metabolite; delayed puberty, among other effects
Phenobarbital: Alters liver, hypothalamic, pituitary, and testis function; delayed puberty, among other effects
Methoxychlor: Estrogenic and antiandrogenic pesticide; reduced androgen-dependent tissues weights
Ketoconazole: Inhibits steroidogenesis
Atrazine: Herbicide, alters hypothalamic pituitary function; delays puberty and growth

Key published studies performed in other laboratories
Vinclozolin: Androgen receptor antagonistic fungicide; delayed puberty, increase serum T and luteinizing hormone (Monosson *et al.*, 1999)
Cyproterone acetate: Antiandrogenic drug; delayed puberty, among other effects
Polybrominated diphenyl ether, DE71; antithyroid toxicant; affected thyroid endpoints and delayed puberty (Stoker *et al.*, 2004a,b)
Finasteride: Potent inhibitor of enzyme 5 alpha reductase required for dihydrotesterone synthesis; reduced sex gland weight (Marty *et al.*, 2001)

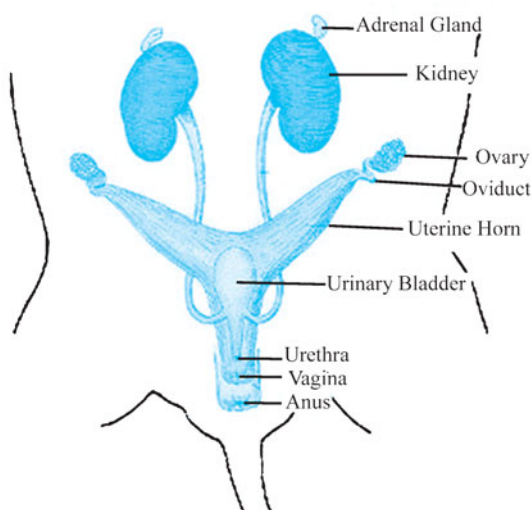
Pubertal female and pubertal male assay data from contract laboratories (summary available at http://www.epa.gov/scipoly/oscpendo/assayvalidation/meetings.htm.)


Figure 20-6. Rat Female reproductive system.

pituitary to regulate gonadotrophin production (see later sections on ovarian function).

Similarly in the male (see Fig. 20-8 for the basic structure of the male reproductive system and Fig. 20-9 for basic endocrine control), FSH acts primarily on the Sertoli cells, but it also appears to stimulate the mitotic activity of spermatogonia. LH stimulates steroidogenesis in the interstitial Leydig cells. A defect in the function of the testis (in the production of spermatozoa or testosterone)

will tend to be reflected in increased levels of FSH and LH in serum because of the lack of the "negative feedback" effect of testicular hormones.

The HPG feedback system is a very delicately modulated hormonal process. Several sites in the endocrine process can be perturbed by different chemicals.

Ovarian Function

Oogenesis Ovarian germ cells with their follicles have a dual origin; the theca or stromal cells arise from fetal connective tissues of the ovarian medulla, the granulosa cells from the cortical mesenchyme (Fig. 20-4). In women, about 400,000 follicles are present at birth in each human ovary. After birth, many undergo atresia, and those that survive are continuously reduced in number. Any chemical that damages the oocytes will accelerate the depletion of the pool and can lead to reduced fertility in females. About one-half of the numbers of oocytes present at birth remain at puberty; the number is reduced to about 25,000 by 30 years of age. About 400 primary follicles will yield mature ova during a woman's reproductive life span. During the approximately three decades of fecundity, follicles in various stages of growth can always be found. After menopause, follicles are no longer present in the ovary (Knobil and Neill, 1994).

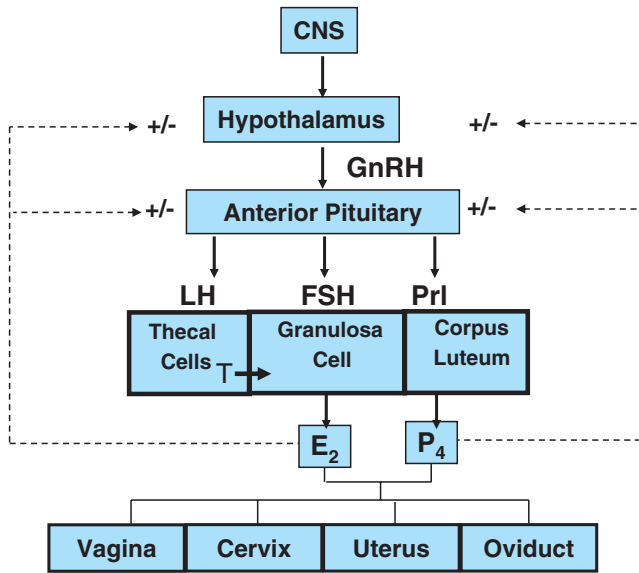
Follicles remain in a primary follicle stage following birth until puberty, when a number of follicles start to grow during each ovarian cycle. However, most fail to achieve maturity. For the follicles that continue to grow, the first event is an increase in size of the primary oocytes. During this stage, fluid-filled spaces appear among the cells


Figure 20-7. Endocrine Control of the Female Reproductive cycle.

CNS – Central Nervous system; GnRH – gonadotrophin releasing hormone; LH – luteinizing hormone; FSH – follicle stimulating hormone; Prl – Prolactin; T – testosterone; E_2 – estradiol; P_4 – progesterone.

of the follicle, which unite to form a cavity or antrum, otherwise known as the Graafian follicle.

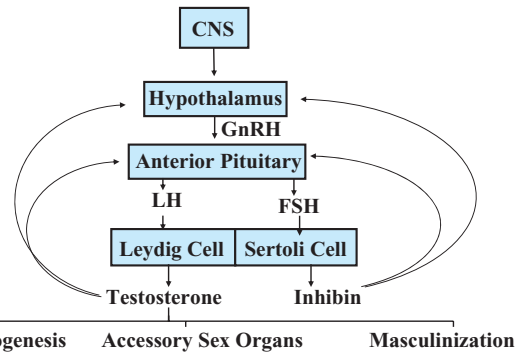
Primary oocytes undergo two specialized nuclear divisions, which result in the formation of four cells containing one-half the number of chromosomes (Fig. 20-4). The first meiotic division occurs within the ovary just before ovulation, and the second occurs just after the sperm fuses with the egg. In the first stage of meiosis, the primary oocyte is actively synthesizing DNA and protein in preparation for entering prophase. The DNA content doubles as each of the prophase chromosomes produces its mirror image. Each doubled chromosome is attracted to its homologous mate to form


Figure 20-9. Endocrine control of male reproduction.

tetrads. The members of the tetrads synapse or come to lie side by side. Before separation, the homologous pairs of chromosomes exchange genetic material by a process known as crossing over. Thus, qualitative differences occur between the resulting gametes. Subsequent meiotic stages distribute the members of the tetrads to the daughter cells in such a way that each cell receives the haploid number of chromosomes. At telophase, one secondary oocyte and a polar body have been formed, which are no longer genetically identical.

The secondary oocyte enters the next cycle of division very rapidly; each chromosome splits longitudinally; the ovum and the three polar bodies now contain the haploid number of chromosomes and half the amount of genetic material. Although the nuclei of all four eggs are equivalent, the cytoplasm is divided unequally. The end products are one large ovum and three rudimentary ova (polar bodies), which subsequently degenerate. The ovum is released from the ovary at the secondary oocyte stage; the second stage of meiotic division is triggered in the oviduct by the entry of the sperm.

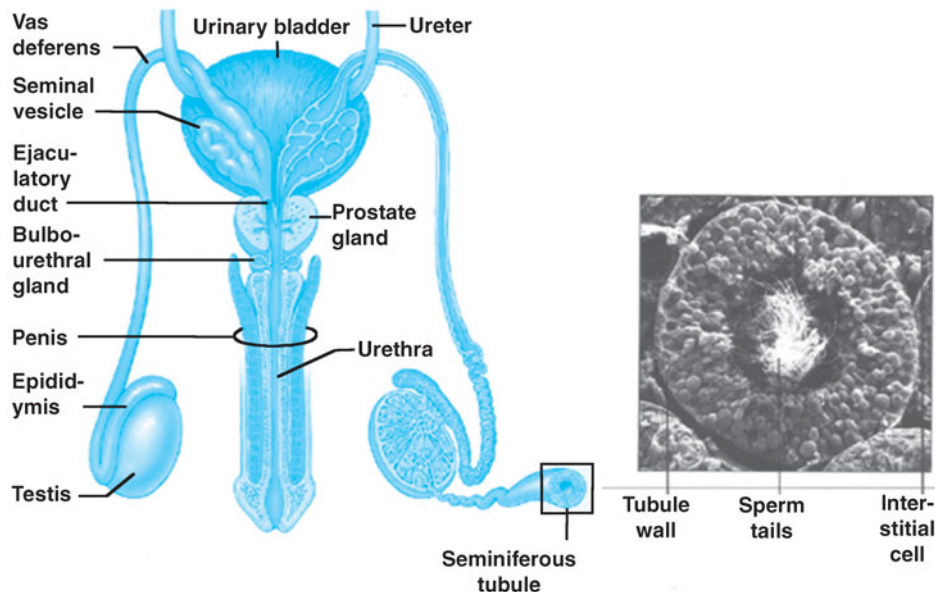
Although ovarian weight, unlike uterine weight, in the rat does not fluctuate during the estrous cycle, ovarian weight and histology can provide very useful information about the effects of toxicants on the female reproductive system. Ovarian weight can be reduced


Figure 20-8. Male reproductive system.

by either depletion of oocytes or disruption of the HPG axis. Toxicants affect ovarian histology inducing a variety of lesions, including polyovular follicles, oocyte depletion, interstitial cell hyperplasia, corpora albanicans, and absence of corpora lutea, for example. In addition, ovarian tissue can be cultured ex vivo after in vivo treatment or in vitro at different stages of the estrous cycle or during pregnancy to assess their steroidogenic capacity (Berman and Laskey, 1993; Calafat *et al.*, 2006; Gray *et al.*, 1997a).

Case Study—*Busulphan* The drug busulfan is an alkylating agent used to treat several diseases in humans including chronic myelogenous leukemia, certain myeloproliferative disorders such as severe thrombocytosis and polycythemia vera and busulfan is also used in combination with other drugs to treat myelofibrosis. Busulfan has been used in very high doses and in combination with other drugs to destroy the bone marrow in preparation for a bone marrow transplant. Busulfan may interfere with the normal menstrual cycles in women and block sperm production in men. In addition, busulfan causes ovarian failure and prevents or delays the onset of puberty in girls (http://www.nlm.nih.gov/medlineplus/ drug-info/medmaster/a682248.html).

In the rat, busulfan produces a similar profile of reproductive effects, the most dramatic occuring in utero. In rodents, endocrine function during adulthood can be altered by prenatal exposure to fetal germ cell toxicants. The ovary of the treated female offspring, lacking oocytes, developing follicles (the source of most serum estradiol) or corpora lutea (the major source of progesterone) fails to produce sex hormones. Administration of busulfan (10 mg/kg ip 5–7 d before birth) specifically inhibits germ cell development (Hemsworth and Jackson, 1963) in rats. Offspring of rats dose with 2.5 and 5 mg busulfan/kg on gestational day 14 display permanent reproductive and CNS alterations (Gray and Ostby, 1998). The most severely affected females do not display estrous cycles or spontaneous sexual behavior as a consequence of this effect. Puberty was markedly delayed in females treated with 10 mg of busulfan. In male progeny, testicular (at 2.5 mg), epididymal (2.5 mg), and ejaculated sperm (5.0 mg) counts, fertility and fecundity (10 mg), measured under continuous breeding conditions, were reduced. In female progeny, fertility and fecundity (2.5 mg) and ovarian weight (5 mg) were reduced and the incidence of constant vaginal estrus was increased (10 mg). In addition to these reproductive effects, brain weight was reduced in both sexes all dosage groups, even though body and other nonreproductive organ weights were only affected in the high-dose group (10 mg). Even though the gonads of both sexes were affected at similar dosage levels, fertility and gonadal hormone production were much more easily disrupted in female than male offspring, because the steroid producing cells in the ovary fail to differentiate in the absence of the oocyte. In the male, Leydig cell numbers and steroidogenesis are not so dependent upon normal gametogenesis. Hence, the lack of oocytes in the female progeny results in a lack of estrous cyclicity and the spontaneous display of female mating behavior at proestrus. Technically, busulphan is not considered to be an EDC because the cells that it eliminates, the oocytes, do not display endocrine activity. However, this classification is of little import because in their absence, ovarian thecal and granulosa cell endocrine functions are severely impaired.

In addition to busulfan, several environmental chemicals have been shown to disrupt ovarian development and oocyte numbers in the rat or mouse. Oral administration of some of the benzidine-based dyes on days 8–12 of pregnancy in the mouse or rat produces reproductive effects in the female offspring similar to those seen with the lower dose levels of busulfan, albeit at much higher dose levels (1 g/kg/d) (Gray and Kelce, 1996).

4-Vinylcyclohexene (VCH) is a chemical intermediate used in the production of flame retardants, flavors and fragrances, in the manufacture of polyolefins, and as a solvent and in the manufacture of its diepoxide. Low levels of occupational exposure have been measured during the production and use of 1,3-butadiene. In the mouse, 4-VCH destroys the small preantral follicles in the ovaries (Hoyer and Sipes, 2007) and the monoepoxide metabolites, 1,2-VCH epoxide, 7,8-VCH epoxide, and the diepoxide, VCD, cause preantral follicle loss in rats as well as mice. Mice are more susceptible to VCH than rats because they are capable of its metabolic bioactivation. Follicle destruction by VCD is selective for primordial and primary follicles and results from upregulating the rate of atresia (apoptosis) through activation of proapoptotic signaling events selectively in the small preantral follicles.

MXC is an organochlorine pesticide and reproductive toxicant that also produces antral follicle atresia, in part by altering apoptotic regulators (Bcl-2 and Bax). MXC directly inhibits follicle growth partly by Bcl-2 and Bax pathways, and increases atresia partly through Bcl-2 pathways (Miller *et a,.,* 2005) by inducing oxidative stress (Gupta *et al.*, 2006a, 2006b). A diagrammatic representation of the sites of actions of female reproductive toxicants is presented in Fig. 20-10.

Ovarian Cycle

The cyclic release of pituitary gonadotropins involving the secretion of ovarian progesterone and estrogen is depicted in Fig. 20-11. These female sex steroids determine ovulation and prepare the female accessory sex organs to receive the male sperm. Sperm, ejaculated into the vagina, must make their way through the cervix into the uterus, where they are capacitated. Sperm then migrate into the oviducts, where fertilization takes place. The conceptus then returns from the oviducts to the uterus and implants into the endometrium. This axis can be disrupted, resulting in infertility at any level of the endocrine system. For example, chemicals that block the LH surge transiently can prevent or delay ovulation resulting in infertility or lower fecundity due to delayed fertilization of ova (Cooper *et al.*, 1994, 2000; Goldman *et al.*, 1997, 1994, 1993; Stoker *et al.*, 1996, 1993, 2001, 2003, 2005).

Postovarian Processes

Female accessory sex organs function to bring together the ovulated ovum and the ejaculated sperm. The chemical composition and viscosity of reproductive tract fluids, as well as the epithelial morphology of these organs, are controlled by ovarian (and trophoblastic) hormones (see Fig. 20-6).

Oviducts The oviducts provide the taxis of the fimbria, which is under muscular control. The involvement of the autonomic nervous system in this process, as well as in oviductal transport of both the male and female gametes, raises the possibility that drugs known to alter the autonomic nervous system may alter function and therefore fertility. The progression of the fertilized eggs through the oviduct and uterus is under hormonal regulation and chemicals like the estrogens can stimulate oviductal transport and interfere with uterine endometrial function, precluding implantation (Cummings and Perreault, 1990).

Uterus Uterine endometrium reflects the cyclicity of the ovary as it is prepared to receive the conceptus. The myometrium's major role is contractile. In primates, at the end of menstruation, all but the deep layers of the endometrium are sloughed. Under the influence of estrogens from the developing follicle, the endometrium increases rapidly in thickness. The uterine glands increase in length but do not secrete to any degree. These endometrial changes are called proliferative. After ovulation, the endometrium becomes slightly edematous, and the actively secreting glands become tightly coiled and folded under the influence of estrogen and progesterone from the corpus luteum. These are secretory (progestational) changes (Fig. 20-11). When fertilization fails to occur, the endometrium is shed and a new cycle begins. Only primates menstruate (Knobil and Neill, 1994).

Other mammals have estrous cycles rather than menstrual cycles, see Figs. 20-12 and 20-13 for a diagrammatic comparison of the human menstrual and rat estrous cycles with regard to timing and endocrine control. In the young adult rat, the female has a 4–5 day estrous cycle which lacks a functional luteal phase (Knobil and Neill, 1994; Cooper *et al.*, 1984). During the estrous cycle the uterus and vagina display remarkable changes in morphology over the brief cycle. Uterine weight and fluid content increase many folds during proestrus under the influence of estrogen. The vaginal cytology also changes daily throughout the estrous cycle and this can be monitored by examining the cytology of the cells sloughed from the vaginal epithelium into the lumen with daily vaginal lavages.

Uterine weight is a very useful index of estrogenicity in the immature or adult ovariectomized female rat. Since uterine weight and histology fluctuate greatly during the estrous cycle, studies which necropsy females at different stages of the cycle will often be too variable to detect anything but the most profound effects on these endpoints, but nonetheless it can still be a useful endpoint and should be measured. A single vaginal lavage, taken at necropsy could be used as a covariate to analyze for treatment effects. It is noteworthy that both uterine weight and ovarian histology provided useful information in a surprising number of cases in the assessment of chemicals in the Pubertal Female Rat Assay being validated by the USEPA, OSCP, EDSP (reports available at http://www.epa.gov/scipoly/oscpendo/).

TESTICULAR STRUCTURE AND FUNCTION

Targets for Toxicity

For the adult male, the overall objective of the reproductive process is the production of gametes capable of fertilization and the production of viable offspring. In considering these processes there are numerous potential targets for the action of chemicals upon the system (see Fig. 20-13). These would range from the action of dopamine analogues on the hypothalamus interrupting the normal secretion of GnRH, the action of estrogens on the pituitary (and hypothalamus) to interfere with gonadotropin (LH and FSH—see Fig. 20-7) production through direct effects on spermatogenesis—where the vast majority of toxicants have their site of action. However, there are specific examples of chemicals that may impair spermatogenesis via an indirect mechanism not specifically related to the HPG axis. So for example, there are a number of examples of nutritional deficits (and overexposures) of critical vitamins and minerals (e.g., vitamin A and zinc) that are essential for normal reproduction. Perturbing the homeostasis of these nutrients can lead to direct effects on spermatogenesis and subsequent issues with fertility. Similarly,

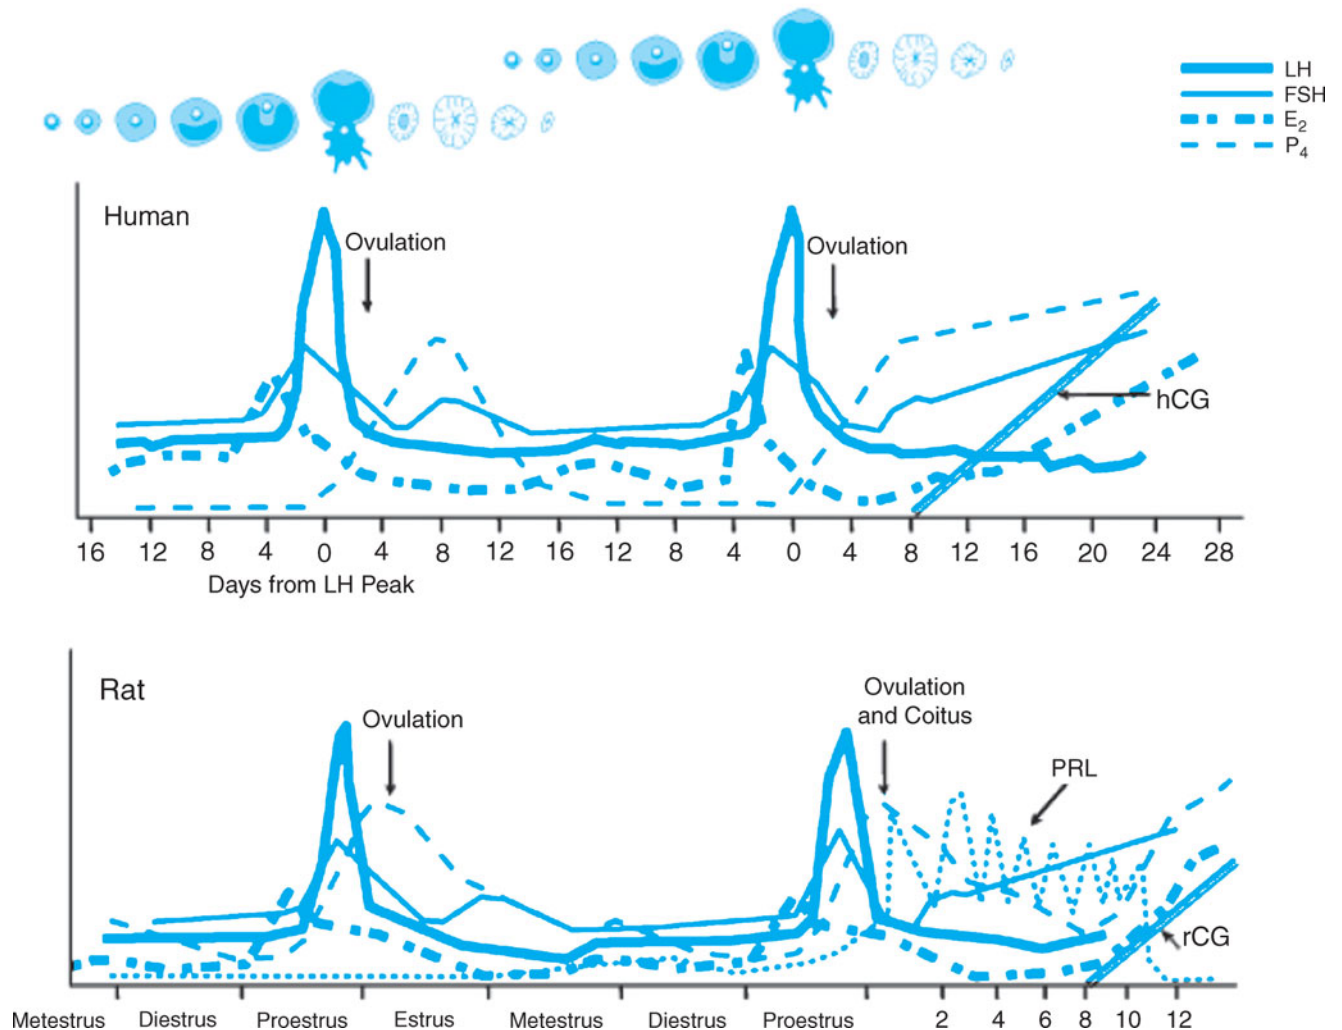
Comparative Endocrinology of Menstrual and Estrous Cycles and Early Pregnancy


Figure 20-12. Comparison of the timing of the human and rat cycles.

chemicals that have direct effects on the liver (e.g., CCl_4) can disturb the normal metabolism of sex steroids leading to changes in clearance (predominantly of glucuronide and sulfate conjugates of hydroxytestosterones in the male), indirectly affecting the HPG axis and exerting effects on male reproduction.

While most experimental rodents normally employed in reproductive toxicity studies do not show marked seasonality in breeding performance, there are dramatic exceptions (for example, the hamster, where during the breeding season (or under lab conditions of 14-hours light and 10-hours dark) up to 10% of an adult male's body weight may be testicular tissue). In the hamster markedly changing the light dark cycle to reduce the hours of daylight can influence melatonin levels and through a cascade of signaling responses cause regression of the testes and concurrent decreases in testicular steroids and mating behavior. This is a normal circumstance in the wild, but care should be taken in laboratory situations to ensure appropriate housing for the conduct of reproduction studies with this species.

The testis also has a finely tuned circulatory system in mammals, termed the pampininform plexus, design to shunt the arterial venous blood supply and aid in scrotal cooling. Some chemicals can actually target this structure and the testis circulatory system to induce ischemic shock to the testis resulting in injury and reduced fertility, with cadmium being an example of a chemical that can induce testicular damage via this "indirect" mechanism (Setchell and Waites, 1970).

Testicular Structure and Spermatogenesis

The experimenter should be cognizant of these indirect mechanisms affecting male reproductive biology, however the overwhelming number of chemicals known to affect the male reproductive system appears to do so by a direct effect on the testis and an interference with the process of spermatogenesis. In rodents, there is a highly efficient process for the production of sperm in large numbers. A simple cross section of the testis from a rat (see Fig. 20-14), the

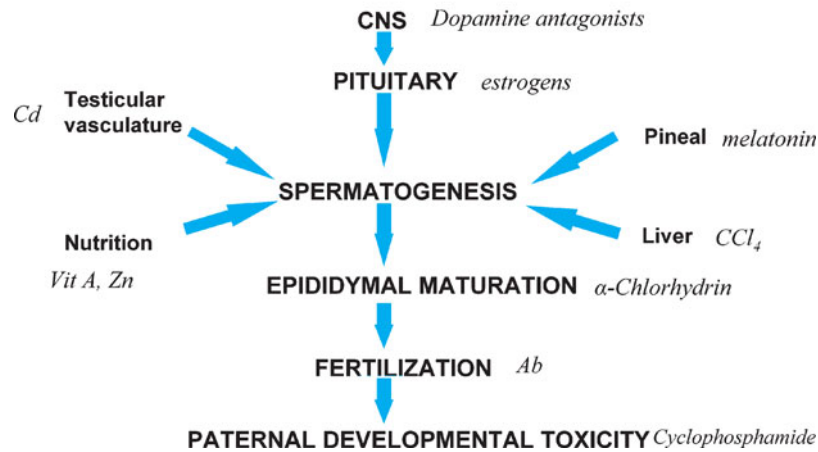
POTENTIAL TARGET SITES


Figure 20-13.   Potential target sites for male reproductive toxicants.

Examples of agents shown in italics.

most common species employed in reproductive toxicity studies, indicates that not all of the seminiferous tubules have an identical morphology. The generalized structure of the rat seminiferous tubule (see Figs 20-15 and 20-16) shows the organization of a number of different cell types comprising germ cells at different stages of differentiation supported by a somatic cell, the Sertoli cell, that provides structure to the epithelium and numerous support functions (e.g., hormonal signaling, nutrition, fluid provision, etc.) and serves to maintain the haploid germ cells in a protected environment (the so-called blood- tubule barrier) because these would be recognized as foreign by the host immune system. Thus, the seminiferous tubules can be divided into a number of physiological compartments (as indicated in Fig. 20-15) that facilitate the process of spermatogenesis. The boundary of the seminiferous tubule is surrounded by myoepithelial cells that aid in a peristaltic process in moving released spermatozoa present in the lumina of the tubules (at this time these sperm are both nonmotile and nonfertile) along the tubules through the rete testis (into which the seminiferous tubules open—these tubules have both ends attached to the rete) for further progression through the efferent ducts to the epididymis. It is here that a concentration of sperm and changes in their fluid environment occur as the sperm are ushered through the epididymis and acquire motility and fertilizing ability.

Spermatogenesis is an extremely ordered process in the rat (see Fig. 20-17). The spermatogonia have populations that act as the stem cells for the seminiferous tubules and a proportion of these cells then undergo a series of mitotic divisions to increase numbers, move into meiotic prophase and are then committed to becoming spermatozoa. These germ cells proceed through the various stages of prophase, preleptotene, leptotene, zygotene, and pachytene with increasingly larger cells that undertake DNA replication in preparation for the cells to enter meiosis. The germ cells enter diplotene and then diakinesis with two meiotic divisions, which eventually results in the production of the haploid spermatid population. These initially round cells then undergo an incredible metamorphosis to produce the elongated spermatozoa that mature and are then released into the seminiferous tubule lumen.

The spermatogonial stem cells undergo another round of mitotic division every approximately 13 days in the rat to produce
Figure 20-14. Control testis indicating different cellular associations noted in different seminiferous tubule cross-sections.

See also Fig. 20-19.

another wave of division and differentiation (see Fig. 20-18). For the rat, the time taken for a spermatogonial stem cell to become a mature spermatozoan takes approximately 8 weeks (and 10 weeks for humans) with an additional 10 days to 2 weeks for the released sperm to mature in the epididymis and be capable for ejaculation and fertilization of the ovum. One of the consequences of these successive longitudinal waves of differentiation is the highly ordered sequence of events reflected in seminiferous tubular morphology. The most primitive germ cells, the spermatogonia, reside at the periphery of the tubule and as they mature, they move toward the tubule lumen for eventual release (in a process termed spermiation). As can be seen from the Fig. 20-18, at any one time the tubule can contain cellular members from four and a half successive spermatogenic cycles, with the most primitive spermatogonia from the current cycle and the most mature, the late spermatids (about to become spermatozoa on release), generated up to 4.5 cycles earlier. Thus when we take a cross section through a seminiferous tubule, this is essentially taking a "snapshot" in time of the various spermatogenic cycles. This also explains why different tubular cross sections
***Figure 20-15. Diagrammatic representation of a portion of a seminiferous tubule showing the cellular
arragements and testicular compartments.***

Key: L – Leydig cell; M – myoepithelial peritubular cell; SC – Sertoli cell; Sd spermatid; Sg – spermato-
gonium and Sp – spermatocyte. (From Foster, 1988).

have different morphologies, depending on when this "snapshot" is
taken because of different cellular associations resulting from dif-
ferent cycles. It is possible for the various species to construct a
morphological diagram of the nature of these cellular associations
(Fig. 20-19 illustrates this for the rat). The most common system
employed for the rat was based on that published by Leblond and
Clermont and describes 14 different patterns of cellular association
(or stages—usually depicted by a roman numeral). We know that
different biochemical events can go on during the different stages
and indeed this can provide clues as to potential mode of action
of chemicals that produce stage specific lesions. Such occurrences
do occur regularly (e.g., certain phthalate esters, glycol ethers, an-
tiandrogenic agents etc.). In the case of a phthalate ester given to
an adult rat there is a marked stage specificity in response which
coincides with those stages that have the highest concentrations of

FSH receptors (in the Sertoli cells of the tubule) (Creasy *et al.*,
1987). Other Sertoli cell in vitro data indicate that the phthalate es-
ter metabolites responsible for in vivo damage could down regulate
Sertoli cell responsiveness to FSH with regard to cAMP production
(Lloyd and Foster, 1988) lending support to the establishment of a
potential mode of action for this class of chemicals in adult rats.

   At spermiation, when the step 19 spermatids are released into
the seminiferous tubule lumen, the excess cytoplasm and cellular
debris form a residual body that is then phagocytosed by the Ser-
toli cell. These bodies originate at the luminal surface of the tubule
and then as they are resorbed, can be seen to move through the
Sertoli cell toward the base of the tubule and eventually disappear.
Delays in spermiation—that is step 19 late spermatids being re-
tained beyond Stage VIII of the cycle are one of the more subtle yet
commonly noted testicular lesions (e.g., boric acid, Chapin and Ku,
Figure 20-16. Section of a rat seminiferous tubules showing the orientation of different germ cells and Sertoli cells (SC).

Compare with Figs. 20-15 and 20-18.

1994; Gray *et al*., 1990); dibromoacetic acid (Linder *et al.*, 1997; Melnick *et al.*, 2006); and hormonal withdrawal (Saito *et al.*, 2000) and are sometimes accompanied by abnormal residual body formation. Having this "extra" layer of germ cells is a lesion frequently missed by pathologists without a good knowledge and appreciation of the stages of the spermatogenic cycle.

Once sperm are released into the seminiferous tubule lumen and proceed to the epididymis, they can also be the target of toxi-

cant action. Chlorosugars and epichlohydrin have both been shown to inhibit energy metabolism in sperm that prevents them from functioning normally. The specificity of the response was noted, at least in part, from the specific isoform of lactate dehydrogenase found in testicular germs cells (LDH-X or C4) essential for energy production. We are now learning more about the molecular events that drive fertilization and it seems likely that here may be a potential target for the action of chemicals to disturb the process. We certainly know of the requirement for the expression of critical cell surface markers by the sperm that facilitate the normal binding of the sperm to the egg surface membrane. Lastly, there is the potential for effects in the male to induce paternally mediated developmental toxicity in the embryo/fetus. Whereas this is not a common occurrence it has been documented with one or two specific agents (e.g., cyclophosphamide, Trasler *et al*., 1985).

The number of known environmental chemicals that produce adverse responses in human males is not large. All of these have been shown to induce effects in rodents and especially the rat, although there may be differences in sensitivity based on dose. Interestingly, a number of the classic human testicular toxicants (e.g., DBCP, gossypol) do not seem to produce infertility or testicular toxicity in the mouse, and so the rat is more commonly employed as a model for male reproductive toxicity studies. However, this does not imply that all chemicals known to produce injury in the rat would indeed show toxicity in man. The human does not employ a longitudinal wave for the production of sperm in the testis noted above for the rat, rather cellular associations are organized in a helical fashion that
Figure 20-17. Diagrammatic depiction of spermatogenesis in the rat.

(From Foster, 1988).
Figure 20-18. *The cyclicity of the seminiferous epithelium of the rat.*

The process whereby successive spermatogenic "waves" (see Fig. 20-18) are interrelated. A transverse section of a tubule covering one cycle of the epithelium will contain cellar representatives at different stages of maturity from successive waves. (From Foster, 1988).
Figure 20-19. *Diagram of the 14 stages of spermatogenesis of the rat testis*

(After Leblond and Clermont, 1952). Each stage (Roman Numeral) contains different cellular associations of spermatogonia (A, IN or B), spermatocytes (R-resting/pre-leptotene; L – leptotene; Z – zygotene; P – pachytene; Di – diplotene, II – secondary), and spermatids (Arabic numerals 1-19). (From Foster, 1988).

is intrinsically less efficient for sperm production (when estimated on a sperm produced per gram of tissue basis) and thus humans are usually deemed more sensitive, from the risk assessment standpoint, because there are a greater range of values for semen parameters for the human population than the rat and a lesser decrement in sperm number or function is more likely to push larger numbers of men in the population into the infertile range.

Posttesticular Processes

Following the release of mature spermatids from the seminiferous epithelium, the extraneous cytoplasm and organelles form the residual body that is phagocytosed by the Sertoli cell and moves from the periphery of the tubule to its base. These nonmotile sperms are moved along the tubules by a peristaltic-like action of the myoepithelial cells of the tubule and eventually empty into the rete testis.

In rodents, but not humans, a large blood plexus forms over the rete (which is close to the surface and near the pole of the testis) where fluid exchange can take place. Sperm are then moved into the efferent ducts that exit in the testis. These ducts are rich in ER receptors (Oliveira *et al.*, 2004) and the fluid from the seminiferous tubules contains steroid hormones, but is low in overall total protein.

The efferent ducts then empty into the caput (head) of the epididymis, which is a single highly coiled tube derived from the Wolffian duct in utero. The epididymis can be divided into three anatomical portions, the caput, corpus (body), and cauda (tail), which has a changing chemical environment and fluid composition from the efferent ducts through to the cauda. The sperm undergo maturation in the caput and corpus and begin to acquire motility, whereas the cauda is principally used for sperm storage, although expression of some critical surface markers does occur that are involved in the process of fertilization. In humans, the passage of sperm takes approximately 6 days and is longer in rats (∼10 days). During the movement along the epididymal tubule, fluid is removed by active transport and this stage of the process is one that can be interfered with by toxicants resulting in an inappropriate environment for normal sperm development.

Most mammals possess seminal vesicles and a prostate (in experimental animals the exception is that dogs do not have seminal vesicles) and the accessory sex organs are depicted in Fig. 20-20. The physiology and anatomy of these organs varies widely among mammalian species with the rodent having a clear lobular pattern to the prostate that is not seen in humans. These organs are predominantly glandular/secretory in nature and produce much of the seminal plasma for the ejaculation of sperm to survive within the female reproductive tract. Other contributors to the seminal plasma are the epididymis and bulbourethral (Cowper's) glands. The seminal plasma contains many nutrients for sperm motion as well as distinct proteins and ion content. Any disturbance in these components may have an effect on subsequent fertility. For example, a diminution in energy substrates can affect sperm motion characteristics. These "accessory sex organs" are androgen dependent for their function and/or development and are frequently recorded in toxicity studies as indicators of androgen action. Indeed the Hershberger assay, used as part of the EPA's screening battery for endocrine disruptors (see section on Testing for Reproductive Toxicity), use changes in the weights of these organs as indicators of androgen or antiandrogen action in this pharmacological screen.

Semen volume varies considerably among species ranging from relatively small (1–10 mL: like humans) to much larger (∼500 mL in boars).

Erection and Ejaculation

These physiologic processes are controlled by the CNS but are modulated by the autonomic nervous system. Parasympathetic nerve stimulation results in dilatation of the arterioles of the penis, which initiates an erection. Erectile tissue of the penis engorges with blood, veins are compressed to block outflow, and the turgor of the organ increases. In the human, afferent impulses from the genitalia and descending tracts, which mediate erections in response to erotic psychic stimuli, reach the integrating centers in the lumbar segments of the spinal cord. The efferent fibers are located in the pelvic splanchnic nerves (Andersson and Wagner, 1995).

Ejaculation is a two-stage spinal reflex involving emission and ejaculation. Emission is the movement of the semen into the urethra; ejaculation is the propulsion of the semen out of the urethra at the time of orgasm. Afferent pathways involve fibers from receptors in the glans penis that reach the spinal cord through the internal pudendal nerves. Emission is a sympathetic response affected by contraction of the smooth muscle of the vas deferens and seminal vesicles. Semen is ejaculated out of the urethra by contraction of the bulbocavernosus muscle. The spinal reflex centers for this portion of the reflex are in the upper sacral and lowest lumbar segments of the spinal cord; the motor pathways traverse the first to third sacral roots of the internal pudendal nerves.

Little is known concerning the effects of chemicals on erection or ejaculation (Woods, 1984). Pesticides, particularly the organophosphates, are known to affect neuroendocrine processes involved in erection and ejaculation. Many drugs act on the autonomic nervous system and affect potency (Table 20-5) (see also (Buchanan and Davis, 1984; Keene and Davies, 1999; Stevenson and Umstead, 1984). Impotence, the failure to obtain or sustain

an erection, is rarely of endocrine origin; more often, the cause is psychological. The occurrence of nocturnal or early-morning erections implies that the neurologic and circulatory pathways involved in attaining an erection are intact and suggests the possibility of a psychological cause.

Normal penile erection depends upon the relaxation of smooth muscles in the corpora cavernosa. In response to sexual stimuli, cavernous nerves and endothelial cells release nitric oxide, which stimulates the formation of cyclic guanosine monophosphate (GMP) by guanylate cyclase. The drug sildenafil (Viagra) is used to treat erectile dysfunction; its mechanism of action resides in its ability to selectively inhibit cGMP-specific phosphodiesterase type 5. By selectively inhibiting cGMP catabolism in cavernosal smooth muscle cells, sildenafil restores the natural erectile response (Goldstein *et al.*, 1998; Uckert *et al.*, 2006). In the rat, prenatal exposure to the antiandrogenic fungicide vinclozolin induces a significant reduction of erections at all dose levels during the ex copula penile reflex tests in male offspring (Colbert *et al.*, 2005).

Case Studies for Effects on the Male

m-Dinitrobenzene   *m*-Dinitrobenzene (*m*-DNB) has been extensively studied for its ability to produce a rapid deleterious effects on the rat testis since the mid-1980s. The earliest studies using a 10-week dosing regime (5 d/wk by gavage in corn oil) reported effects at 6 mg/kg/d (Linder *et al.*, 1986), while others have reported testicular injury after a single gavage oral dose of 25–50 mg/kg (Blackburn *et al.*, 1988). This paper also showed that the other isomers of DNB (*o*- and *p*-) were without testicular effects when given using the same dosing regime. Gray *et al*. (1988a) showed that the activity was via a direct mechanism and not secondary to changes in the HPG axis. Foster (1989) showed that 5-day dosing with 5 mg/kg/d produced a minimal to moderate testicular lesion within 2 weeks and 10 mg/kg/d a moderate to severe lesion. Testicular weight remained reduced for many weeks after the treatment period with significant dose-related effects on fertility (measured by pregnancy rate and implantation success). Similar studies have shown abnormal sperm function and failure of fertilization in rat in vitro fertilization (IVF) studies (Holloway *et al.*, 1990). Detailed electron microscopic evaluation has shown initial lesions to be present in the Sertoli cells of the testis, which results rapidly in germ cell apoptosis and death. The primary testicular effects on Sertoli cells (see Fig. 20-21) are consistent with the period of infertility noted in the breeding study (see Fig. 20-22) and could also be modeled in Sertoli-germ cell cultures where the *o*- and *p*-isomers were also without effect. A futile redox cycle has been proposed to explain the difference in isomer toxicity in which only *m*-DNB is metabolized to its nitroso metabolite and further to the hydroxylamine which is recycled back to the nitroso intermediate to reduce cellular reducing equivalents, such as reduced glutathione (GSH) (Cave and Foster, 1990; Ellis and Foster, 1992; Foster *et al.*, 1987; Reeve *et al.*, 2002).

Ethylene Glycol Monomethyl Ether (EGME)   Since first published in 1979 (Nagano *et al.*, 1979) that EGME can elicit testicular toxicity in the mouse there has been significant effort expended on trying to understand the mode of action for the induction of these effects . Thus far, EGME has been shown to produce testicular toxicity in a wide variety of species, including nonmammals, the major toxicologically used species (rat, mouse, rabbit, dog) with reasonable evidence that it is likely to have effects in humans should exposure be high enough. A number of studies have described the pathogen-

esis of the EGME lesion (predominantly in the rat) which seems to be common for the species thus far examined. The earliest features of these studies after a single dose (250 or 500 mg/kg/d) were that there are Sertoli cell vacuoles and swollen germ cell mitochondria, followed by (or concurrent with) a breakdown of the membrane between the Sertoli cell and the pachytene spermatocyte in a spermatogenic stage-specific manner. This is followed quickly (within hours) by the death of (probably those) pachytene spermatocytes (Creasy *et al.*, 1986; Creasy and Foster, 1984; Foster *et al.*, 1983). See Fig. 20-23.

EGME is metabolized to active intermediates; these are methoxyacetaldehyde and methoxyacetic acid (MAA). MAA has a longer half-life and is generally considered the more important of the two. Treating animals with MAA produces identical testicular lesions as that of the parent compound.

The spermatogenic stage specific effects are on the pachytene spermatocytes immediately before and during meiotic division (so, in Stages XII–XIV of the cycle in the rat (see Fig. 20-24), and also the early pachytene spermatocytes, at stages I–IV of the cycle). Dead germ cells can be seen as soon as 12 hours after an effective dose. Continued treatment at a low effective dose seems to affect just the vulnerable cell types so that a window of missing cells appears downstream from the stage of damage as time progresses (see
Figure 20-23. *Effect of Ethylene glycol monomethyl ether (or its metabolite mehtoxyacetic acid) 24 hours after a single oral dose (100 mg/kg/d).*

Note the damaged spermatocytes (arrows) in lower tubule compared to the upper normal tubule.

Fig. 20-24). As with other testis toxicants, higher dose levels produce a more widespread lesion involving other cell types (Foster *et al.*, 1987), producing immediate (<24 hours) and widespread damage and destruction within the tubules. The Sertoli cell vacuolization regresses after about 12 hours and is not a prominent feature of this lesion as it is with other agents like hexanedione, or some of the phthalate esters. Some weak evidence of involvement of this cell type also comes from some in vitro data with isolated seminiferous tubules. In this system molecules that inhibit transcellular calcium movement block the germ cell death from occurring, supporting a change in Sertoli cell communication to germ cells resulting in the rapid cell death after MAA treatment. Leydig cells do not seem to be pivotally involved in the pathogenesis. The lesion is not characteristic of a low-androgen testicular lesion, and reduced accessory sex organ weights are not a prominent feature associated with the early testicular pathology.

Decrements in fertility in the rat after acute treatment with EGME, are entirely consistent with the primary effect on pachytene spermatocyte germ cells, the prominent period of infertility being approximately 5–6 weeks after dosing when the pachytene spermatocytes should have matured to become mature sperm capable of fertilization based on the known kinetics of the process (Chapin *et al.*, 1985).

MATING BEHAVIOR IN THE RAT

Female rats are only sexually receptive on the day of proestrus, which is characterized by round nucleated and cornified epithelial cells in the vaginal lavage (Knobil and Neill, 1994) (Chap. 35). The period of receptivity begins at the onset of the dark phase of their light cycle, terminating later in the evening before the next stage of the cycle, defined as estrus which is typically characterized by the display of a vaginal lavage of mostly cornified epithelial cells. Serum estradiol rises during proestrus and this is followed by initiation of an LH surge shortly after onset of the dark phase of the light cycle which in turn induces ovulation and a brief increase in progesterone. This is normally the only time during which the female is receptive to the male and the display of this behavior can be induced in ovariectomized female rats by a sequence of injections of estradiol for a couple of days prior to mating followed by progesterone administration a few hours before the mating trial is conducted, which must occur during the evening of the rat's diurnal cycle. Male and female rat mating behavior is sufficiently stereotyped that it can be easily quantified to assess the effects of toxicants on these behaviors (Gray and Ostby 1998; Gray *et al.*, 1988b).

During mating, the female rat displays proceptive behaviors like ear wiggling and darting to induce the male to mount, and when mounted the female is "receptive" displaying a lordosis posture characterized by a raised head and tail and fully arched back. The female maintains this posture for several seconds. In experienced male rats, the latency to the first mount is usually on a few seconds, but inexperienced males may take much longer. When the male rat mounts the lordosing female he will display a single pelvic thrust which may or may not result in intromission of the penis into the vagina. In rats, there is a rapid dismount after this single pelvic thrust. Within a few seconds, the male mounts again and this series continues until the male ejaculates. Ejaculation is usually identifiable by a slow dismount, after which the male retires for several minutes; a period termed the postejaculatory interval (PIE). During this period the male produces a 22 KHz vocalization, during which the female does not display proceptive behaviors (Porter *et al.*, 2005). Following the PIE, the series repeats itself several times throughout the evening. At the beginning of the second series, the male dislodges the copulatory plug, formed from the seminal secretions. The copulatory plug normally fits close to the cervix and it is necessary to facilitate sperm entry into the uterus. It is not unusual to find seven to eight copulatory plugs in the breeding cage the day after mating (Gray *et al.*, 1989). If mating does not occur, then the brief rise in serum progesterone declines by the next day.

In spontaneously ovulating species (e.g., rodents), the endocrine events are comparable with those in the menstrual cycle. In the rabbit, the LH surge and ovulation is a neural reflex produced by copulation (Knobil and Neill, 1994).

Cervix

The mucosa of the uterine cervix does not undergo cyclic desquamation, but there are regular changes in the cervical mucus. Estrogen, which makes the mucus thinner and more alkaline, promotes the survival and transport of sperm. Progesterone makes the mucus thick, tenacious, and cellular. The mucus is thinnest at the time of ovulation and dries in an arborizing, fernlike pattern on a slide. After ovulation and during pregnancy, it becomes thick and fails to form the fern pattern. Disruptions of the cervix may be expressed as disorders of differentiation (including neoplasia), disturbed secretion, and incompetence. Exfoliative cytologic (Papanicolaou's stain) and histologic techniques are currently used to assess disorders of differentiation. Various synthetic steroids (e.g., oral contraceptives) can affect the extent and pattern of cervical mucus.

Vagina

Estrogen produces a growth and proliferation of vaginal epithelium. The layers of cells become cornified and can be readily identified in vaginal smears. Vaginal cornification has been used as an index for estrogens. Progesterone stimulation produces a thick mucus and the epithelium proliferates, becoming infiltrated with leukocytes. The cyclic changes in the vaginal smear in rats are easily recognized. The changes in humans and other species are similar but less apparent. Analysis of vaginal fluid or cytologic studies of desquamated vaginal cells (quantitative cytochemistry) normally reflects ovarian function. However, administration of estrogenic toxicants can

Intensity of shading indicates magnitude of effect on spermatocytes. (After Foster *et al.,* 1987).

induce persistent vaginal cornification in both immature and adult ovariectomized females by acting directly on the cellular dynamics and cell cycling of the vaginal epithelium (Gray *et al.*, 1988b, 1989). Vaginal sampling of cells and fluid might offer a reliable and easily available external monitor of internal function and dysfunction.

FERTILIZATION

Fertilization is the process whereby the genome from one generation is passed to the next to begin the development of a new organism. In mammals the oocyte is surrounded by two layers—an outer layer of cumulus cells and an inner layer of extracellular matrix termed the zona pellucida (see review by Hoodbhoy and Dean 2004). To reach the oocyte, the sperm must penetrate both layers that require high motility, the release of sperm enzymes and the presence of proteins that will facilitate binding of the sperm to the oocyte. Moreover, once fertilization has occurred, mechanisms must be in place to prevent the binding of further sperm to the fertilized oocyte (the zygote). To facilitate these activites, sperm must be capacitated (Hunter and Rodriguez-Martinez, 2004) and the secretion of enzymes (hyaluronidases) allows the sperm to penetrate through the cumulus cells to the zona pellucida. This special extracellular matrix is composed of three glycoproteins and cell surface factors then cause the sperm to release the secretory enzymes present in the acrosome via binding to the specific carbohydrates present in this matrix. The release of these enzymes enables the sperm to penetrate through the zona pellucida to then bind and fuse with the oocyte plasma membrane through specialized proteins to release

the genetic material into the oocyte as the male pronucleus which eventually combines with the genetic material from the female to form the zygote. Once sperm fusion has occurred, a "zona block" is initiated to prevent any further sperm entering through the zona pellucida and fusing with the oocyte membrane. The precise mechanisms of how this occurs have not been fully elucidated (Hoodbhoy and Dean, 2004).

IMPLANTATION

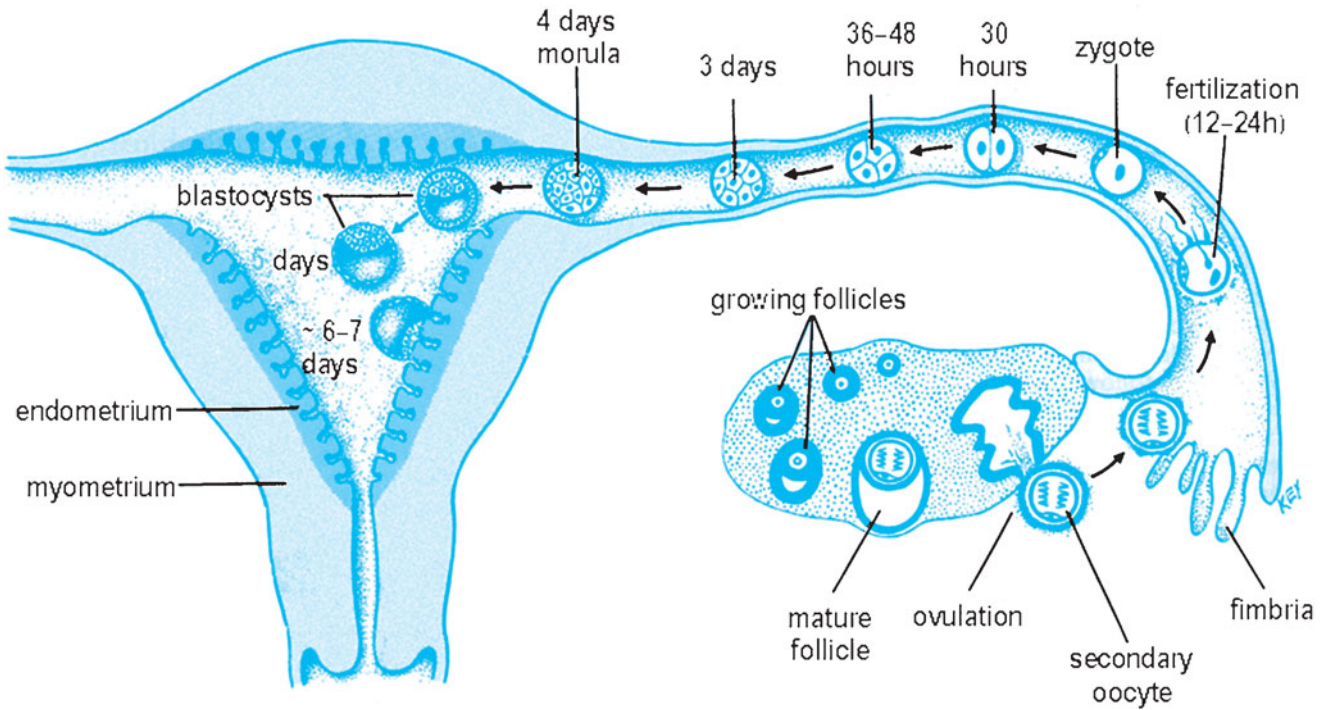
Implantation is an intricately timed event that allows mammals to nourish and protect their young during early development and results from an intimate relationship between the developing embryo and the differentiating uterus (see diagram in Fig. 20-25). Implantation can only occur when the embryo reaches the blastocyst stage and gains implantation competency, and the uterus, through steroid hormone dependent changes, attains a receptive state. This reciprocal interaction must occur between the blastocyst and uterus together with an increase in uterine vascular permeability at the site of blastocyst attachment. There are four stages that comprise early implantation in mammals: (1) apposition and adhesion of the blastocyst to the uterine lumen, (2) penetration of the epithelium, (3) decidualization of the stromal cells, and (4) trophoblastic invasion into the stromal vasculature. These four stages can vary in length and in precise order depending on the specific species studied and is further reviewed in (Aplin and Kimber, 2004; Lee and DeMayo, 2004; Schäfer-Somi, 2003; Tranguch *et al.*, 2005). The molecular understanding of these physiological events is far from complete,


Figure 20-25. Fertilization and implantation in the female reproductive tract.

with data being generated mainly from studies in the mouse that have indicated through gene abalation in the uterus, a number of critical factors and cytokines and involved in implantation, however a number of these critical gene products (e.g., VEGF, BMP-2, wnt-4) have also been shown to produce early embryonic lethality when knocked out. Another important aspect of the implantation process common to many species (and offering an experimental tool to study implantation) is the embryonic diapause (or delayed implantation) evolved as a strategy to ensure proper implantation timing, depending on environmental conditions (see review by .Lopes *et al.*, 2004). The regulation of this phenomenon varies widely between species ranging from photoperiod through to hormonal or nutritional influences.

PLACENTA

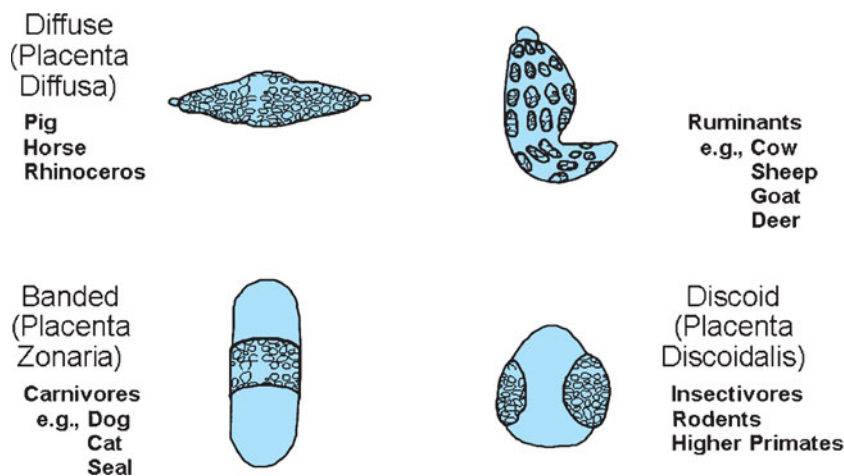
The placenta plays a key role in pregnancy, mediating exchanges between the mother and fetus and maternal tolerance of antigens produced by the fetus. There are a huge number of different placental types exhibited by eutherian mammals that exhibit differences in both structure and endocrinology including significant difference between the major experimental animal species and humans (see reviews by Enders and Carter, 2004; Malassine *et al.*, 2003 and Fig. 20-26). Humans and monkeys possess a hemochorial placenta. Pigs, horses, and donkeys have an epitheliochorial type of placenta, whereas sheep, goats, and cows have a syndesmochorial type of placenta. In laboratory animals (e.g., rat, rabbit, and guinea pig),


Figure 20-26. Types of placentae.

the placenta is termed a hemoendothelial type. Among the various species, the number of maternal and fetal cell layers ranges from six (e.g., pig, horse) to a single one (e.g., rat, rabbit). Primates, including humans, have three layers of cells in the placenta that a substance must pass across.

Early in implantation the blastocyst comes in contact with the endometrium and becomes surrounded by an outer layer or syncytiotrophoblast, a multinucleated mass of cells with no discernible boundaries, and an inner layer of individual cells, the cytotrophoblast. The syncytiotrophoblast erodes the endometrium, and the blastocyst implants. Placental circulation is then established and trophoblastic function continues. The blastocysts of most mammalian species implant about day 6 or 7 following fertilization. At this stage, the differentiation of the embryonic and extraembryonic (trophoblastic) tissues is apparent.

Trophoblastic tissue differentiates into cytotrophoblast and syncytiotrophoblast cells. The syncytiotrophoblast cells produce chorionic gonadotropin, chorionic growth hormones, placental lactogen, estrogen, and progesterone, which are needed to achieve independence from the ovary in maintaining the pregnancy. Rapid proliferation of the cytotrophoblast serves to anchor the growing placenta to the maternal tissue.

The developing placenta consists of proliferating trophoblasts, which expand rapidly and infiltrate the maternal vascular channels. Shortly after implantation, the syncytiotrophoblast is bathed by maternal venous blood, which supplies nutrients and permits an exchange of gases. Histotrophic nutrition involves yolk sac circulation; hemotrophic nutrition involves the placenta. Placental circulation is established quite early in women and primates and relatively much later in rodents and rabbits. One of the major differences in endocrine placental function between humans and rodents is in the production and regulation of progesterone necessary for the maintenance of pregnancy. In the rodent, the corpus luteum in the ovary has to produce progesterone throughout gestation and is regulated initially by pituitary prolactin secretion and then around midway through gestation by placental lactogens produced by the trophoblast. Thus, hypohysectomy (to remove pituitary influences) in a mouse does not terminate pregnancy after GD 11. In humans, the pituitary gland is not required for the initiation and maintenance of pregnancy, with maintenance of the corpus luteum to produce progesterone dependent on the secretion of human Chorionic Gonadotrophin (hCG) by the trophoblast. There is sufficient progesterone produced by the trophoblast after 8 weeks of gestation in humans to maintain pregnancy even in cases of ovariectomy.

Generally, the placenta is quite impermeable to chemicals/drugs with molecular weights of 1000 Da or more. Because most medications and xenobiotics have molecular weights of 500 Da or less, molecular size is rarely a factor in denying a drug's entrance across the placenta and into the embryo/fetus. Placental permeability to a chemical is affected by placental characteristics including thickness, surface area, carrier systems, and lipid-protein concentration of the membranes. The inherent characteristics of the chemical itself, such as its degree of ionization, lipid solubility, protein binding, and molecular size also affect its transport across the placenta.

PREGNANCY

In the female rat during mating, repeated cervical stimulation by the penis induces a surge of prolactin from the posterior pituitary within 20 minutes followed by the onset of twice-daily prolactin surges which persist for an 8- to 13-day period. During this pe-

riod, prolactin "rescues" the corpora lutea preventing regression. If sperm transport, fertilization or implantation are blocked, then the mated female is "pseudopregnant" for about 10–13 days (Swingle *et al.*, 1951). During days 6–10 of pregnancy, sustained ovarian luteal function also requires pituitary LH. Pregnancy loss, i.e., full-litter resorption, can be induced at this stage of pregnancy by inhibition of pituitary LH secretion which in turn causes a reduction in serum progesterone levels (Bielmeier *et al.*, 2004).

Midpregnancy of the rat is characterized by hypertrophic development of the corpus luteum which is dependent upon transition from the early LH and prolactin dependent phase of pregnancy to one that involves the secretion of hormones by the feto-placental unit (rCG and rPL) that induce rapid growth and differentiation of the corpora lutea, an increase in progesterone synthesis and a doubling in serum progesterone. Doody *et al* (1991) examined the levels of expression of mRNA species encoding cholesterol side-chain cleavage cytochrome P-450 (P-450scc), 17 α-hydroxylase cytochrome P-450 (P-450-17 α), aromatase cytochrome P-450 (P-450AROM) and 3 β-hydroxysteroid dehydrogenase (3 β-HSD) in rat ovaries during pregnancy. Expression of P-450scc mRNA is at low, but detectable, levels until day 14, thereafter expression increased to high levels (day 14–21 of gestation). Levels of P-450-17 α-mRNA on day 10 of gestation were low and decreased further on days 14 and 17. Expression of 3 β-HSD was decreased on day 10, but on days 14, 17, and 21 of gestation high mRNA levels were detectable. Ovarian expression of the three P-450AROM species is also dramatically increased between days 14 and 17 of pregnancy, but declines by day 21.

Because the transition from early to midpregnancy in the rat requires hormones from the feto-placental unit, if implantation or uterine decidualization are blocked by a chemical, then the female would resume her estrous cycles and the corpora lutea would regress (Knobil and Neill, 1994, Chap. 7). Chemicals that induce whole-litter loss at mid to late pregnancy may cause abortions in some of the females whereas others fail to deliver and appear pregnant for an unusually long period of time. Effects on female fertility due to disruption of hormones during pregnancy may be difficult to detect in standard testing studies if females are mated to similarly treated males if the chemical affects the reproductive system of both sexes. For example, with chronic di-*n*-butyl phthalate (DBP) administration at high dose levels induces whole litter loss at midpregnancy through reductions in ovarian progesterone production on GD 13. However, ovarian weight is not altered at GD 13 and the onset of female puberty, estrous cyclicity, and mating also were unaffected. This is in contrast to the robust reductions in testis size and histology, sex accessory gland size and sperm counts in pubertal males treated with DBP at 500 or 1000 mg/kg/d, treated F_0 females only display gross morphological reproductive alterations and reductions in uterine weights during midpregnancy. Hence, when female-mediated infertility is affected in this manner it may only be apparent when treated females are mated to untreated males. Chemicals that reduce serum progesterone production during pregnancy by inhibiting progesterone synthesis also may not alter the estrous cycles in the rat because the rat estrous cycle does not have a functional luteal phase, unlike humans.

Many abortificients induce pregnancy loss by reducing progesterone levels in the rat. Generally, reducing midpregnancy progesterone levels by half or more are sufficient to terminate pregnancy (Carnathan *et al.*, 1987). For example, treating pregnant rats with a prostaglandin F2alpha analogue ICI 81008, which reduces serum progesterone levels during pregnancy, induces full-litter loss in 40%

of 300 dams, while 25% had reduced litter sizes and 35% had normal litters (Warnock and Csapo, 1975). In comparison with the 107 control dams, all treated rats with full-litter loss had a drastic reduction in midpregnancy plasma progesterone levels. In contrast, those animals with only a partly resorbed litter only had a moderate reduction in progesterone until day 16. In contrast to progesterone, there was no correlation between plasma estradiol-17 beta levels and the consequences of treatment on pregnancy.

Corpora lutea function during pregnancy may also involve androgens and insulin-like 3 peptide hormone, in concert with lactogenic hormones. Whereas some of the androgenic actions are mediated by conversion of androgens to estrogens, pure androgenic effects also have been implicated (Goyeneche *et al.*, 2002). Goyeneche *et al.* (2002) reported that AR mRNA and protein were expressed throughout gestation in the rat corpus luteum. In addition, they found that androstenedione, the main circulating androgen in pregnant rats, opposed luteal regression, reduced the number of cells undergoing apoptosis, and enhanced the levels of circulating progesterone.

PARTURITION

Parturition is a complex process involving fetal, placental, and maternal signals and the precise molecular events controlling this physiological process are not clear. Parturition is thought best to be thought of as a release from the inhibitory effects of pregnancy on the myometrium of the uterus rather than an active process, although the timing and order of the precise events is an active process. For most mammals the uterus is held in a quiescent state by high levels of progesterone and it is the decrease of progesterone that provides the trigger for parturition. In humans, this does not seem to be the case (i.e., levels of progesterone do not drop). Some authors have postulated that progesterone receptor inactivity does appear to be related to onset of labor and that local metabolism of progesterone in the cervix and uterus produces a localized decrease in progesterone that initiates labor. The fetus also directly contributes to the onset of parturition by activation of its HPA axis producing increased levels of cortisol. This in turn directly upregulates steroidogenic enzymes (especially CYP 17) in the fetus and placenta which in turn leads to changes in prostaglandin (particularly PGF2α) and oxytocin production to induce uterine contractions together with the increased activity of cytokines (including NF-κB and IL-1β). In humans there is no CYP 17 in the placenta which maybe related to the lack of change of progesterone (see recent reviews by Challis *et al.*, 2005; Mendelson and Condon, 2005; Snegovskikh *et al.*, 2006).

LACTATION

The endocrine control of lactation is one of the most complex physiologic mechanisms of human parturition. Mammogenesis, lactogenesis, galactopoiesis, and galactokinesis are all essential to assure proper lactation. Prolactin is the key hormone of lactation and seems to be the single most important galactopoietic (milk synthesis) hormone. Oxytocin, serotonin, opioids, histamine, substance P, and arginine-leucine modulate prolactin release by means of an autocrine/paracrine mechanism, whereas estrogen and progesterone hormones can act at the hypothalamic and adenohypophysial levels. Human placental lactogen and growth factors play an essential role to assure successful lactation during pregnancy with oxytocin being the most powerful galactokinetic (milk ejection) hormone (Buhimschi, 2004).

SENESCENCE

Reproductive senescence is usually preceded by a dysregulation of the HPG axis. This dysregulation leads to alterations in serum HPG hormones, accompanied an upregulation in GnRH, LH, and activin activities and a decrease in steroids in the brain. Receptors for these hormones in the brain are intimately involved in cell proliferation and differentiation in growth and development. In females, reproductive senescence is associated with a transition from regular to irregular estrus (menstrual) cycles leading to acyclicity and ultimately a loss of fertility. GnRH neurons in the brain are affected morphologically and it is the changes in GnRH neurosecretion with changes in pulsatility and preovulatory release that are causal in producing acyclicity. Perinatal exposure to toxicants with estrogenic activity can defeminize the HPG axis such that the females are acyclic and infertile while less affected females display the "delayed anovulatory syndrome" and become anovulatory and acyclic at an early age (Gray *et al.*, 1989).

In males, a decrease in androgen is noted in around 20% of fit 60-year old men, but the value of androgen supplementation is not clear with regard to reproductive senescence. Dysregulation of the HPG axis is also found in aged male rats, with elevations in FSH and LH and decreased testosterone normally found. For reviews on reproductive senescence and possible associations with cognitive function see reviews by (Atwood *et al.*, 2005; Keefe *et al.*, 2006; Yin and Gore, 2006)

ENDOCRINE DISRUPTION (INCLUDING SCREENING AND PUBERTY)

Currently, the potential effects of "endocrine disrupting chemicals" (EDCs) on human health and the proven effects of EDCs on wildlife are a major focus among the scientific community. In 1996, the USEPA was given a mandate under the Food Quality Protection Act and Safe Drinking Water Act to develop test protocols to screen for endocrine effects. The initial impetus for these actions arose from a Work Session in 1991 on "Chemically Induced Alterations in Sexual Development: The Wildlife /Human Connection" (Colborn, 1994). Recent findings have contributed to these concerns; for example, it has been suggested that in utero exposure to environmental estrogens, antiandrogens or chemicals like phthalates or 2,3,7,8-TCDD could be responsible for the reported 50% decline in sperm counts in some areas and the apparent increase in cryptorchid testes (Toppari *et al.*, 2001), testicular cancer (Skakkebaek, 2002), and hypospadias (Aho *et al.*, 2000; Canning, 1999; Nassar *et al.*, 2007; Paulozzi *et al.*, 1997; Pierik *et al.*, 2002; Porter *et al.*, 2005; Toppari *et al.*, 2001). The differences in sperm counts between regions are so large that they cannot be explained by methodological biases and "environmental effects are entirely plausible" (Giwercman *et al.*, 2006; Jorgensen *et al.*, 2001, 2002). Indeed, it has been proposed (Skakkebaek, 2002) that the secular deficits in these human reproductive end points could be plausibly linked and have an origin in fetal life as the testes are developing. These authors proposed the term Testicular Dysgenesis Syndrome (see Fig. 20-27) to explain the interrelationship of these findings.

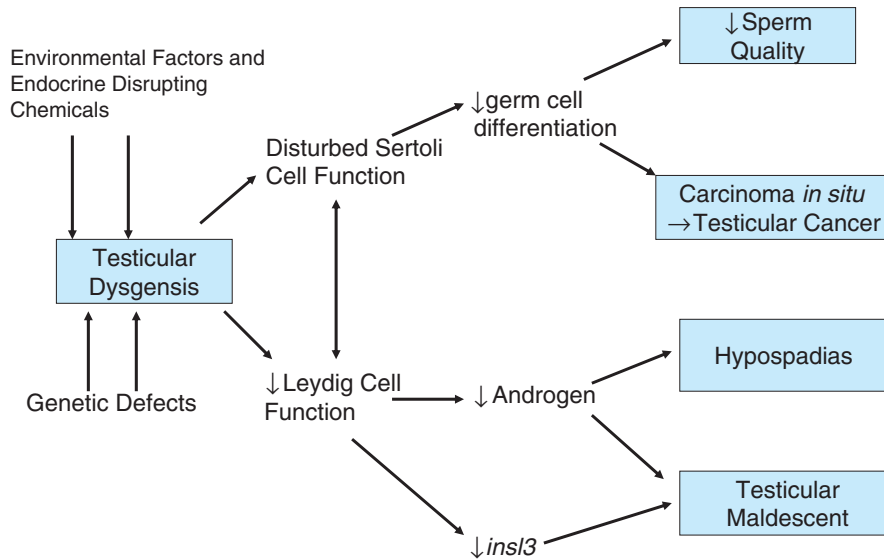
Phthalate exposures have been associated with reduced AGD in boys and lower testosterone levels in men. In females, exposure to EDCs during development could contribute to earlier age at puberty and to increased incidences of endometriosis and breast cancer, for example. The original focus for the discussion of "endocrine disrupters" was research on toxicants reported to possess estrogenic


Figure 20-27. Testicular Dysgenesis Syndrome. The hypothesis (See Skakkebaek et al., 2002).

That events occurring during the development of the testis in fetal life can be related to the secular increases in a number of human reproductive disorders.

activity, with little consideration given to other mechanisms of endocrine toxicity; mechanisms that, in fact, may be of equal or greater concern. In addition, there has been a great deal of misinformation communicated on issues concerning endocrine disrupters; for example, nonestrogenic chemicals (i.e., phthalates and p,p'-DDE) are repeatedly reported to be estrogenic. There is a lack of appreciation for the fact that many endocrine disrupters (i.e., TCDD, EE) are very potent reproductive toxicants. In addition, there has been a tendency to dismiss the wildlife data as correlative, ignoring examples of clear, cause and effect relationships between chemical exposure and reproductive alterations (e.g., DDT metabolite effects in birds, PCB effects in fish, and environmental estrogen effects in domestic animals). There is a lack of recognition that subtle, low-dose reproductive effects seen in laboratory studies with endocrine disrupters will be difficult, if not impossible, to detect in typical epidemiological studies because of high variability normally seen in human reproductive function (e.g., time to fertility, fecundity, and sperm measures), the delayed appearance of the reproductive lesions and a lack of high quality exposure data. There is also a lack of appreciation for the complexity of the multiple mechanisms by which a single chemical can alter the endocrine milieu, to say nothing of the complex endocrine alterations induced by mixtures of chemicals.

We are now not only concerned about pesticides and other toxic substances in the environment, but the issue has broadened considerably due to the growing awareness that the list of EDCs present in the environment from human activities includes potent pharmaceutical products and phytosterols. Among these drugs are estrogens, antibiotics, beta-blockers, antiepileptics, and lipid regulating agents. One study reported that the pharmaceuticals found as contaminants of aquatic systems included 36 of 55 pharmaceuticals and five of nine metabolites measured including antiepileptic drugs (Kolpin *et al.*, 1998, 2002, 2004).

In the area of wildlife toxicology and ecosystem health, it is apparent that clear cut cause and effect relationships exist between exposure to EDCs and adverse effects in several vertebrate classes from fish to mammals. One challenge in interspecies extrapolation is

to link laboratory mechanistic studies with EDCs to both individual and population effects in the field.

Reports of U-shaped (nonmontonic), ultra-low-dose effects and nonthreshold effects for EDCs are challenging some of the basic assumptions of risk assessment for noncancer endpoints. While the focus of this debate has centered on the low-dose effects of bisphenol A (Ashby *et al.*, 1999; Nagel *et al.*, 1997; Owens and Chaney, 2005; vom Saal *et al.*, 1998, 2005; Welshons *et al.*, 2006), well documented U-shaped dose-response curves are known from many other in vitro and some in vivo studies. For example, administration of testosterone produces a well characterized and reproducible U-shaped dose response for spermatogenesis (Ewing *et al.*, 1977, 1979, 1981; Robaire *et al.*,1979) in the intact adult male rat. In vitro studies show that such responses do not always involve multiple mechanisms of action. Several AR ligands, antagonists at low to moderate concentrations, became AR agonists at high concentrations. Furthermore, the basic tenet of toxicology from Paracelceus (1564) that "dose alone determines the poison" is too limited for some EDCs because the timing of exposure dictates not only the effect but also whether the effects are adverse or beneficial. Even when administered during adult life, drugs with EDC-activity can simultaneously have a beneficial effect on one tissue and an adverse effect on another.

Known Effects of EDCs in Humans and Animals

The list of chemicals that are known to affect humans, domestic animals, and/or wildlife via functional developmental toxicity or endocrine mechanisms includes 2,3,7,8-TCDD, PCBs and polychlorinated dibenzofurans (PCDFs), methylmercury, EE, alkylphenols, plant sterols, fungal estrogens, androgens, chlordecone, DBCP, o,p'-DDD (Mitotane), o,p' DDT, and p,p'-DDE (Gray *et al.*, 2001) (Gray 2002). In addition to these xenobiotics, over 30 different drugs taken during pregnancy have been found to alter human development as a consequence of endocrine disruption. These drugs are not limited to estrogens, like diethylstilbestrol (DES). EDCs are known to alter human development via several mechanisms besides the

estrogen receptor (ER): this includes binding to the AR, or retinoic acid (RAR, RXR) receptors, and by inhibition of steroidogenic enzymes or the synthesis of thyroid hormones. Findings on the effects of background levels of PCBs on the neurobehavioral development of the child have contributed to the concerns about the effects of EDCs on human health via alteration of hormone function including the thyroid (Brouwer *et al.*, 1999; Tan and Zoeller, 2007). In summary, there are several hundred epidemiology studies showing associations among EDCs and adverse human health effects, however, none of these has been sufficiently studied to claim that "cause and effect" exists.

Known Effects of Drugs on Human Sexual Differentiation   In humans (Bardin and Catterall, 1981; Carmichael *et al.*, 2005; Herbst, 1973; Ohyama, 2004) and laboratory rodents (Fisher, 2004; Foster *et al.*, 2001; Gray *et al.*, 2006), exposure to hormonally active chemicals during sex differentiation can produce pseudohermaphroditism. Androgenic drugs like Danazol and methyltestosterone can masculinize human females (i.e., "female pseudohermaphroditism") (Schardein, 2000; Kingsbury, 1985; Rosa, 1984). Laboratory studies demonstrate that these chemicals alter sex differentiation in rodents as well (Duck and Katayama, 1981). The drug aminoglutethimide, which alters steroid hormone synthesis in a manner identical to many fungicides, also masculinizes human females following in utero exposure (LeMaire *et al.*, 1972; Schardein, 2000).

DES provides an unfortunate example of how in utero exposure to a potent endocrine disrupter with estrogenic activity can alter reproductive development in humans (Herbst, 1987; Shaffer, 2000; Veurink *et al.*, 2005). Although a few cases of masculinized females were noted in the late 1950s, most of the effects of DES were not apparent until after the children attained puberty. Transplacental exposure of the developing fetus to DES causes clear cell adenocarcinoma of the vagina, as well as gross structural abnormalities of the cervix, uterus, and fallopian tube. These women are more likely to have an adverse pregnancy outcome, including spontaneous abortions, ectopic pregnancies, and premature delivery (DeCherney *et al.*, 1981). Some of the pathological effects that develop in males following fetal DES exposure appear to result from an inhibition of androgen action or synthesis (underdevelopment or absence of the vas deferens, epididymis, and seminal vesicles) and anti- Mullerian duct factor (persistence of the Mullerian ducts) (Niculescu, 1985). DES may also have caused epididymal cysts, hypotrophic testes, and infertility in males.

Known Effects of Plant and Fungal Products in Animals and Humans   The phytoestrogens and fungal mycotoxins are naturally occurring and widespread in nature. Farnsworth *et al.* (1975) listed over 400 species of plants that contain potentially estrogenic isoflavonoids or coumestans or were suspected of being estrogenic based on biological grounds (Farnsworth, 1990). Plants contain many other compounds in addition to estrogens that can affect reproductive performance, such as the purported antiandrogenic activity in the oil from saw palmetto (Gordon and Shaughnessy, 2003).

Although most naturally occurring environmental estrogens are relatively inactive, when compared to steroidal estrogens or DES, the phytoestrogen miroestrol is almost as potent as estradiol in vitro and even more potent than estradiol when administered orally (Cain, 1960; Matsumura *et al.*, 2005) . In addition, many plant estrogens occur in such high concentrations that they induce reproductive alterations in domestic animals (Adams 1990; Adams

and Sanders, 1988). "Clover disease," which is characterized by dystocia, prolapse of the uterus, and infertility, is observed in sheep grazed on highly estrogenic clover pastures. Permanent infertility (defeminization) can be produced in ewes by much lower amounts of estrogen over a longer time period than are needed to produce "clover disease." In domestic animals, feeds contaminated with the zearalenone-producing fungus (*Fusarium sp.*) induce adverse reproductive effects in a wide variety of domestic animals, including impaired fertility in cows and hyperestrogenism in swine and turkeys (Kuiper-Goodman *et al.*, 1987).

Known Effects of Organochlorine Compounds in Humans   In addition to drugs and plant substances, several pesticides and toxic substances have been shown to alter human reproductive function (listed above). An accidental high dose in utero exposure to PCBs and PCDFs have been associated with reproductive alterations in boys, increased stillbirths, low birth weight, malformations, and IQ and behavioral deficits (58). In addition to the effects associated with this inadvertent exposure, relatively subtle adverse effects were seen in infants and children exposed to relatively low levels of PCBs and PCDFs (36). The authors reported that the lowest observed adverse effect levels (LOAELs) for developmental neurobehavioral and reproductive endpoints are currently within the range of current human body burdens based on Toxicity Equivalency Factors.

One metabolite of DDT was found to alter adrenal function with sufficient potency to be used as a drug to reduce adrenal androgen production (Knappe *et al.*, 1997). o,p'-DDD (mitotane) is used to treat adrenal steroid hypersecretion associated with adrenal tumors. In addition to this usage, lower doses of mitotane restored menstruation in women with spanomenorrhea associated with hypertrichosis.

Occupational Exposures   Occupational exposure to pesticides and other toxic substances (i.e., chlordecone and DBCP) in the workplace have been associated with reduced fertility, lowered sperm counts, and/or endocrine alterations in male workers. Workers in Hopewell VA, exposed to high levels of chlordecone, an estrogenic (Hammond *et al.*, 1979) and neurotoxic (Landrigan *et al.*, 1980) organochlorine pesticide, displayed obvious signs of intoxication which included severe neurotoxicity and abnormal testicular function (Epstein, 1978; Reich and Spong, 1983). As this cohort was not followed, it is not known if the effects of chlordecone were completely reversible.

It is surprising to learn that occupational exposures to potential EDCs at effective concentrations apparently have not been entirely eliminated from the workplace. A series of publications from about 1990 to 1996 presented documentation of sexual impotence in chemical factory workers exposed to a DES-like stilbene derivative. National Institute of Occupation Safety and Health conducted two studies in response to complaints of impotence and decreased libido among male workers involved in the manufacture of 4,4′-diaminostilbene-2,2′ disulfonic acid (DAS), a key ingredient in the synthesis of dyes and fluorescent whitening agents (Grajewski *et al.*, 1996; Hammond *et al.*, 1987; Quinn *et al.*, 1990; Smith and Quinn, 1992; Whelan *et al.*, 1996). Both current and former workers had lower serum testosterone levels (Grajewski *et al.*, 1996) and reduced libido (Whelan *et al.*, 1996) as compared to control workers. In addition, duration of employment was negatively correlated with testosterone levels. These studies replicated the observations reported by Quinn *et al*. (1990) who reported low levels of serum testosterone

and problems with impotence in male workers. In a uterotropic assay, while DAS was only weakly to negligibly estrogenic (Smith and Quinn, 1992), a single sc 30 mg/kg dose of 4-nitrotoluene, a precursor of DAS, increased uterine weights without producing overt toxicity. Samples of DAS from the workplace displayed estrogenic activity.

Environmental Androgens

Androgenic activity has been detected in several complex environmental mixtures. Pulp and paper mill effluents (PME) from Florida, the Baltic Sea, the Great Lakes, and New Zealand (Ellis *et al.*, 2003; Larsson and Forlin, 2002; Parks *et al.*, 2001). PME effluents from sites on the Fenholloway River in Florida include a chemical mixture that binds AR and induces androgen-dependent gene expression in vitro. This mode of action is consistent with the masculinized female mosquitofish (*Gambusia holbrooki*) collected from contaminated sites on the river. Male-biased sex ratios of fish embryos have been reported near a pulp mill in broods of eelpout *(Zoarces viviparus)* in the vicinity of a large kraft pulp mill on the Swedish Baltic coast, suggesting that masculinizing compounds in the effluent were affecting gonadal differentiation and promoting skewed sex ratios. Efforts to date have not conclusively identified chemicals in PME responsible for androgenic activity (Durhan *et al.*, 2002).

Effluents from beef-cattle concentrated animal feeding operations (CAFO) from Nebraska and Ohio have been shown to display androgenicity. Orlando *et al.* (2004) found that CAFO discharge at a site in Nebraska exhibited androgenic activity and found that fish (fathead minnow; *Pimephales promelas*) collected at the site displayed small gonads as compared to fish from a reference site. Durhan *et al.*, (2005) detected the synthetic androgens 17α- and 17β-trenbolone in several water samples from a beef CAFO in Ohio where trenbolone acetate implants were used to stimulate weight gain and the samples collected from a direct discharge from the feedlot displayed significant androgenic activity in vitro. Complementary laboratory studies revealed both trenbolone isomers were androgenic in fathead minnows (Ankley *et al.*, 2003) and the rats (Wilson *et al.*, 2002). When administered in utero, 17β-trenbolone (TB) masculinized female rat offspring, increased AGD, nipple, and caused vaginal agenesis and induced male sex accessory tissues in females (Wolf *et al.*, 2002). TB binds to ARs with high affinity and induces androgen-dependent gene expression in vitro at concentrations similar to those for DHT (Wilson *et al.*, 2004).

In vivo androgenicity testing using the Hershberger assay shows that TB is as potent as testosterone propionate (TP) in inducing growth of the androgen-dependent levator ani-bulbocavernosus muscles (Wilson *et al.*, 2002), being about 70 times more potent when administered sc versus orally.

Environmental Antiandrogens

Fungicides   Vinclozolin and procymidone are two members of the dicarboximide fungicide class that act as AR antagonists (Kelce *et al.*, 1994; Ostby *et al.*, 1999). These pesticides, or their metabolites, competitively inhibit the binding of androgens to AR that leads to an inhibition of androgen-dependent gene expression in vitro and in vivo (Kelce *et al.*, 1997). Peripubertal administration of antiandrogens can alter the onset of pubertal landmarks in the male rat (Monosson *et al.*, 1999). Vinclozolin delays pubertal maturation and reduces sex accessory gland and epididymal growth and increases

serum LH, and testosterone and 5-androstane, 3,17-diol levels. In a Hershberger assay using castrated immature testosterone-treated male rats, vinclozolin and procymidone alone or in combination inhibited testosterone induced growth of androgen-dependent tissues (ventral prostate, seminal vesicles, and levator ani-bulbocavernosus muscles) in a dose-additive fashion (Gray *et al.*, 2001).

Administration of vinclozolin during sexual differentiation demasculinizes and feminizes the male rat offspring such that treated males display female-like AGD at birth, retained nipples, hypospadias, suprainguinal ectopic testes, a blind vaginal pouch, and small to absent sex accessory glands (Gray *et al.*, 1994). In contrast to the phthalates and linuron (see below), even at high dosages (200 mg/kg/d), epididymal hypoplasia was rare and no cases of gubernacular agenesis were noted. At low doses, vinclozolin reduces neonatal AGD and increases the incidence of retained nipples/areolae in infant male rats. In adult life, ventral prostate weight is permanently reduced and male offspring display permanent female-like nipples (Gray *et al.*, 1999a). Treatment at 50 and 100 mg/kg/d induces hypospadias and other reproductive tract malformations. The most sensitive period of development to the disruptive effects of vinclozolin is GD 16–17 with less severe effects seen in males exposed to vinclozolin on GD 14–15 and GD 18–19. In addition, Hotchkiss *et al.* (2003) demonstrated that neonatal injection of vinclozolin at 200 mg/kg/d demasculinized aggressive play behavior in male rats at 35 days of age, indicating that CNS sexual differentiation was altered an anti-androgenic manner.

When procymidone is administered from day 14 of pregnancy to day 3 after birth, AGD is shortened in male pups, and the males display retained nipples, hypospadias, cryptorchidism, cleft phallus, a vaginal pouch, and reduced sex accessory gland size (Ostby *et al.*, 1999). Procymidone also induces fibrosis, cellular infiltration, and epithelial hyperplasia in the dorsolateral and ventral prostatic and seminal vesicular tissues in the offspring when examined as adults.

Prochloraz is a fungicide that disrupts reproductive development and function by several modes of action (Noriega *et al.*, 2005; Vinggaard *et al.*, 2000, 2002). Prochloraz inhibits the steroidogenic enzymes 17, 20 lyase and aromatase and it is an AR antagonist. Wilson *et al*. (2004) found that prenatal prochloraz reduces fetal testis testosterone and increases progesterone production 10-fold on GD 18 without affecting Leydig cell insl3 mRNA levels. Prenatal prochloraz treatment delayed parturition and altered reproductive development in the male offspring in a dose-related manner (Noriega *et al.*, 2005). Treated males displayed reduced AGD and female-like areolas and high-dose males displayed hypospadias but the epididymides and gubernacular ligaments were relatively unaffected.

Linuron (Herbicide)   The herbicide linuron is a AR antagonist. It binds rat and human AR and inhibits DHT-hAR induced gene expression in vitro (Lambright *et al.*, 2000; McIntyre *et al.*, 2002a, 2002b). In vivo treatment with linuron elicits a positive response in the Hershberger assay for antiandrogens (Lambright *et al.*, 2000). In utero linuron exposure produces dramatic effects in male rat offspring. More than half of the males exposed to 100 mg linuron/kg/d (GD14-18) display epididymal and testicular abnormalities (Gray *et al.*, 1999b) with effects seen at dosage as low as 12.5 mg/kg/d (exposed from GD 10–22) (McIntyre *et al.*, 2000). In contrast to the effects of vinclozolin and procymidone, malformed external genitalia and undescended testes were rarely displayed by linuron-exposed males. Interestingly, the syndrome of effects for linuron

are atypical of an AR antagonist and more closely resembles those seen with in utero to phthalates which inhibit fetal Leydig cell insl3 hormone levels. Wilson *et al.* (2004) found that fetal testosterone production is significantly reduced in linuron treated fetal males, demonstrating that linuron is antiandrogenic via dual mechanisms of action.

p,p'-DDE (Pesticide Metabolite) Kelce *et al.* (1995; 1997) found that p,p'-DDE displayed AR antagonism both in vivo and in vitro. In vitro, p,p'-DDE binds to the AR and inhibits androgen-dependent gene expression. In vivo, p,p'-DDE delays pubertal development in male rats by about 5 days at 100 mg/kg/d and inhibits androgen-stimulated tissue growth in the Hershberger assay which uses castrated immature androgen-treated male rats (Table 20-1). p,p'-DDE administered to Long Evans Hooded and Sprague-Dawley male rats in utero reducesAGD, induces nipples, and permanently reduces androgen-dependent organ weights (Gray *et al.*, 1999a).

Phthalates (Plasticizers) The phthalates represent a class of high production volume chemicals that alter reproductive development. While a few in vitro studies suggested that some of the phthalates are estrogenic, DBP injections do not induce a uterotropic response or estrogen-dependent sex behavior (lordosis) in the ovariectomized adult female rats (Gray, 1998). Likewise, oral DBP or diethylhexyl phthalate (DEHP) treatments fail to accelerate VO or induce constant estrus in the intact female rats. In addition, neither the phthalate diesters nor their monoester metabolites appear to compete significantly with androgens for binding to the AR at environmentally relevant concentrations (Foster *et al.*, 2001; Parks *et al.*, 2000; Stroheker *et al.*, 2005). In utero, some phthalate esters alter the development of the male rat reproductive tract at relatively low dosages. Prenatal exposure to DBP, benzyl-butyl phthalate (BBP), di-isononyl phthalate (DINP) and DEHP treatment cause a syndrome of effects, including underdevelopment and agenesis of the epididymis and other androgen-dependent tissues and testicular abnormalities (Foster *et al.*, 2001; Gray *et al.*, 2000). Among the antiandrogenic EDCs, the phthalates are unique in their ability to induce agenesis of the gubernacular cords, a tissue whose development is dependent upon the peptide hormone insulin-like peptide-3. Wilson *et al.* (2004) found that the phthalates reduced both insl3 mRNA and testosterone levels during sexual differentiation of the male rat.

When pregnant SD rats are dosed by gavage with DEHP from GD 8 to day 17 of lactation with 0, 11, 33, 100, or 300 mg/kg/d, in utero exposure induces a low incidence of abnormalities consistent with the aphthalate syndrome in the 11, 33, and 100 mg/kg/d dose groups along with subtle reductions in reproductive organ weights. In the high-dose group, more than 25% of the males display testicular and/or epididymal abnormalities. Pubertal DEHP treatment alone is sufficient to delay puberty in Long Evans (LE) and SD rats due to lowered testosterone levels.

Prenatal exposure to DBP from day 10 to 22 of gestation produces effects nearly identical to those seen with DEHP, with effects occurring at dosage levels of 50–100 mg/kg/d (Mylchreest *et al.*, 1999, 2000). When administered in 4-day periods of gestation (GD 8–11, 12–15 or 16–19), DBP at 500 mg/kg/d was most effective in altering sexual differentiation at GD 16–19 (Gray *et al.*, 1999b). When Carruthers and Foster (2005) exposed SD rats to DBP at 500 mg/kg/day for 2-day periods (GD 14 and 15, 15 and 16, 16 and

17, 17 and 18, 18, and 19, or 19 and 20) they also found that the critical window for abnormal development is GD 16–18.

DBP also disrupts reproductive function in the rabbit. In rabbits exposed to 400 mg DBP/kg/day in utero (GD 15–29), male offspring exhibit reduced numbers of ejaculated sperm, testis weight and accessory sex gland weight (Higuchi *et al.*, 2003). Additionally, DBP caused a slight increase in histological alterations of the testis, a doubling of abnormal sperm and hypospadias, hypoplastic prostate, and cryptorchid testes with carcinoma in situ-like cells were present in 1/17 DBP-treated male rabbits.

Environmental Estrogens

Methoxychlor is an estrogenic pesticide that produces variety of estrogen-like effects in the male and female rat. This pesticide requires metabolic activation in order to display full endocrine activity in vitro. The active metabolites of M bind ER and activate estrogen dependent gene expression in vitro (Wilson *et al.*, 2005) and in vivo in the female rat; M stimulates a uterotropic response, accelerates VO and induces constant estrus, reduces ovarian weight lacking corpora lutea and infertility in the female rat (Gray *et al.*, 1989; Chapin, 1997). Ovarian function is also altered by M exposure. In the ovariectomized female rat, M also induces estrogen-dependent reproductive and nonreproductive behaviors (Gray *et al.*, 1988) including female sex behaviors, running wheel activity, and food consumption. Unlike estradiol, M is as effective, or is more effective, when administered orally than when it is injected.

When given to the dam during pregnancy and lactation both male and female offspring are affected, with females being the more sensitive gender with effects ranging from VO at 5 mg/kg/d and above and infertility at 100 mg/kg/d and above. At 50 mg/kg/d F_1 females display irregular estrous cycles and reduced fecundity. F_1 male fertility is unaffected at doses up to 200 mg/kg/d, even though they display permanent reductions in testis and other reproductive organ weights at 50 mg/kg/d and above.

EE is a synthetic derivative of estradiol that is very bioactive orally. This estrogen is in almost all modern formulations of combined oral contraceptive pills. Over time, formulations have decreased the EE dose from as high as 100 µg/d to as low as 20 µg/d. EE is found in many aquatic systems contaminated by sewage effluents, originating principally from human excretion. Along with natural steroidal estrogens, EE plays a major role in causing widespread endocrine disruption in wild populations of fish species and other lower vertebrate species (Jobling and Tyler, 2006).

In the immature SD and Wistar female rat, 0.3 µg/kg/d of EE is effective in inducing uterine weight when given sc, whereas orally 1.0 µg EE/kg/d stimulates uterine weight (Kanno *et al.*, 2001).

Administration of 0.5 mg EE/kg/d accelerates VO by 5–7 days and induces vaginal cornification in LE and SD weanling rats. When administered to the dam during gestation and lactation over a broad dose response (0.05–50 µg/kg/d) range, F_1 female LE rats display a variety of reproductive tract lesions including cleft phallus, accelerated VO, and infertility at 5 and 50 µg/kg/d, whereas F_1 males are less severely affected. F_1 males did not display any reproductive tract malformations and seminal vesicle, ventral prostate and other androgen-dependent organ weights were not affected at any dose whereas testis and epididymal weights were reduced at 50 µg EE/kg/d. In a similar study with the SD rat, EE only affected F_1 females at 50 µg/kg/d and it was reported that they were not infertile and no effects were noted in the male offspring (Sawaki *et al.*, 2003).

EDC Screening Programs

In response to the 1996 legislative mandate for an endocrine screening and testing program, the EPA formed the Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC), which proposed a tiered screening and testing strategy for EDCs in its final report in 1998 (http://www.epa.gov/scipoly/oscpendo/history/finalrpt.htm). The EDSTAC proposal included the following: (1) a process to prioritize chemicals for evaluation and recommendations, for (2) screening (Tier 1), and for (3) testing (Tier 2) batteries. The recommended screening battery was designed to detect alterations of HPG function; estrogen, androgen, and thyroid hormone synthesis; and androgen receptor (AR) and ER-mediated effects in mammals and other taxa. Based on a "weight-of-evidence" analysis, chemicals positive in Tier 1 would be considered as potential EDCs and subjected to testing (Tier 2). Equivocal effects in Tier 1 could be replicated or evaluated further in additional short-term assays before more extensive Tier 2 testing was initiated. Tier 1 should include assays sensitive enough to detect EDCs, whereas issues of "dose-response, relevance of the route of exposure, sensitive life stages and adversity" would be resolved in the Tier 2 testing phase.

In Vivo Mammalian Assays EDSTAC recommended the laboratory rat as the species of choice for the endocrine screening and testing assays. In vitro assays can produce false–positive responses at high concentrations due to a lack of specificity as assay conditions deteriorate. Although such false–positives can be eliminated by experimental measurement of Ki values, few in vitro screening strategies include Ki determinations to insure that the effects seen in binding and gene expression assays are the result of competitive inhibition of ER or AR. As a result, a high percentage of screened chemicals that are determined to be "positives" in vitro may not be true receptor ligands. Finally, because in vitro screening assays are unable to integrate the endocrine responses seen in the whole organism, the relationships between endocrine toxicity and other systemic effects cannot be simulated in vitro. To avoid the limitations described above, the EDSTAC proposed three short-term in vivo mammalian assays for the Tier 1 Screening Battery: the uterotropic, Hershberger, and pubertal female rat assays (Gray 1998; Gray *et al.*, 1997a; Gray *et al.*, 2002). Table 20-6 indicates the range of EDCs tested in validating these assays for use in the screening program.

Uterotropic Assay Estrogen agonists and antagonists are detected in a 3-day uterotropic assay using subcutaneous administration of the test compound. Based on the evaluation of four variations of the uterotropic assay protocol in the OECD interlaboratory studies, all of the protocols have produced acceptable responses without regard to rat strain, diet, or housing conditions (Kanno *et al.*, 2001; 2003a,b; Owens and Ashby, 2002; Owens *et al.*, 2003, 2006; Owens and Koeter, 2003). The selected uterotropic assays for estrogens and antiestrogens use either the intact juvenile or the castrated ovariectomized adult/juvenile female rat.

Hershberger Assay The second in vivo assay in T1S, the Hershberger assay, detects antiandrogenic activity simply by weighing androgen-dependent tissues in the castrated male rat (Gray, 1998; Gray *et al.*, 1997a, 2002; Hershberger *et al.*, 1953). In this assay, weights of the ventral prostate, Cowper's glands, seminal vesicle (with coagulating glands and fluids), glans penis, and levator ani/bulbocavernosus muscles are measured in castrated, testosterone-treated (or untreated) male rats after 10 days of oral treatment with the test compound. This assay is very sensitive for detection of androgens and antiandrogens. Other useful end-points that help reveal the mechanism of action and specificity of the response include weights of the adrenal, liver, and kidney, and measurements of serum (collected by cardiac puncture) levels of testosterone and LH. The Hershberger assay shows high sensitivity and specificity to chemicals with AR-mediated activity. Weakly antiandrogenic pesticides like p,p'-DDE and linuron are easily detected in the Hershberger assay (Lambright *et al.*, 2000; .Yamasaki *et al.*, 2003). Chemicals like finasteride, which inhibit 5-alpha reductase activity, are also active in this assay. They dramatically reduce male accessory sex gland weight with less effect on the levator ani/bulbocavernosus muscle, which has low levels of this enzyme. Chemicals that are positive in the Hershberger assay often produce adverse effects during puberty and after in utero exposure.

Pubertal Female Rat Assay The third in vivo mammalian/rat assay included in the screening battery is the pubertal female rat assay has been in use for nearly two decades (Gray *et al.*, 1988a, 1989). In this assay, weanling female rats are dosed daily by gavage for 21 days while the age at VO (puberty) is monitored. The females are necropsied at about 42 days of age (reviewed by (Goldman *et al.*, 2000). Measurements include serum thyroid hormones, uterine and ovarian weight, and histology. This assay detects alterations in thyroid hormone status, HPG function, inhibition of steroidogenesis, estrogens, and antiestrogens, and has been found to be highly reproducible and very sensitive to certain endocrine activities including estrogenicity, inhibition of steroidogenesis, and antithyroid activity.

Alternative Screening Assays Alternative in vivo assays were also discussed by EDSTAC and are being evaluated by the EPA. If they are of sufficient sensitivity, specificity, and relevance, they might replace or augment current T1S assays. However, whether they meet such criteria remains to be determined.

Pubertal Male Rat Assay One promising alternative assay is the pubertal male rat assay (Stoker *et al.*, 2000), which detects alterations of thyroid function, HPG maturation, steroidogenesis, and altered steroid hormone function (androgen). Intact weanling males are exposed to the test substance for approximately 30 days. The age at puberty is determined by measuring the age at PPS, and reproductive tissues are evaluated and serum taken for optional hormonal analyses. The studies conducted on contract for EPA using the pubertal male assay are also presented on the EPA EDSP web site. This assay produced reproducible responses among different laboratories and was sensitive to androgens and antiandrogens.

In Utero-Lactational Assay The EDSTAC recommended that the EPA develop and evaluate an in utero-lactational assay due to the unique sensitivity of the fetal reproductive system to disruption by some toxicants. For example, 2,3,7,8-TCDD (dioxin) alters sexual differentiation of male and female rats and hamsters at dosage levels approximately two orders of magnitude below those required to produce adverse effects in pubertal or adult rats (Gray *et al.*, 1997b, 1997c; Stoker *et al.*, 2000). One version of the proposed in utero-lactational assay now being evaluated by the EPA takes about 80 days and uses approximately 10 litters per group (120–150 pups). In this protocol, androgens and antiandrogens can be detected in approximately 2–3 weeks, and EDCs with antithyroid activity can be detected in infant or weanling offspring after 4–5 weeks of maternal treatment.

It is important to retain flexibility in the selection of new assays and endpoints for the screening and testing program so that new methods can be used as replacements or to augment the assays if they offer distinct advantages over the current battery of assays.

Table 20-6

Chemicals examined in protocols of the Organisation for Economic Cooperation and Development (OECD) and the U.S. Environmental Protection Agency (EPA), using standardized assays with oral or subcutaneous dosing

OECD UTEROTROPIC ASSAY (FOUR PROTOCOLS—ALL SUCCESSFULLY IDENTIFIED EACH CHEMICAL)

Ethinyl estradiol: Positive estrogenic control
Genistein: Phytoestrogen
Methoychlor: Estrogenic and antiandrogenic pesticide
Nonylphenol: Estrogenic "inert" ingredient and surfactant
o,p′-**DDT**: Estrogenic pesticide
Bisphenol A: Estrogenic plastic monomer
ZM 189,154: Antiestrogenic pharmaceutical
Dibutyl phthalate: Negative control; plasticizer that inhibits testis Leydig cells

OECD Hershberger assay (each chemical successfully identified)
Testosterone propionate: Androgenic positive control
Trenbolone: Androgenic veterinary pharmaceutical
Methyltestosterone: Potent androgenic pharmaceutical
Linuron: Antiandrogenic herbicide
p,p′-**DDE**: Antiandrogenic pesticide metabolite
Flutamide: Potent antiandrogenic pharmaceutical
Finasteride: Potent inhibitor of enzyme 5 alpha reductase required for DHT synthesis and full androgen-dependent growth of some sex accessory tissues
Vinclozolin: Antiandrogenic fungicide
Procymidone: Antiandrogenic fungicide

EPA in utero-lactational protocol (partially successful in identifying estrogenicity)
Methoxychlor: Estrogenic and antiandrogenic pesticide

EPA execution of adult intact male assay (did not successfully identify endocrine activity of either chemical)
Linuron: Antiandrogenic herbicide
Methoxychlor: Estrogenic and antiandrogenic pesticide

[a] Kanno *et al.*, 2001, 2002, 2003a,b; Owens and Koeter, 2003; Owens *et al.*, 2003 (see text).
[b] Yamasaki *et al.*, 2003 (see text).

Enhancements to current life cycle and multigenerational tests are also being considered in an effort to improve the quality of the data on EDCs that will be used for risk assessments. Scientists are attempting to minimize animal use by using as few animals as possible in the most precise and sensitive assays, by incorporating sensitive in vitro assays in T1S, and by using quantitative structure activity relationships (QSAR) models or high throughput prescreening assays in the prioritization of chemicals for use in vivo. It is also possible to avoid unwarranted animal use because chemicals negative in T1S are not subject to T2T. In addition, testing statistical "false positives" can be almost entirely eliminated by ensuring that T1S assay results are replicated in T1.5 before moving to T2T. Attempts to enhance T2T by adding more sensitive endpoints and a more thorough assessment of the animals already on study may also lead to additional reductions in animal use.

TESTING FOR REPRODUCTIVE TOXICITY

Screens and Multigeneration Studies

The testing of materials for reproductive toxicity has been refined over many decades to provide more comprehensive assessments of a test material's ability to affect the reproductive cycle in laboratory animal models and provide appropriate information to estimate potential risk of exposure to humans. The history and evolution of reproductive toxicity guidelines for pharmaceuticals has recently been reviewed (Collins, 2006). The types of protocols and guidelines employed depend on the type of chemical being tested and its intended use(s). For example, this would involve extensive and comprehensive testing of a food use pesticide, where all the population may be exposed, while much more limited information would be required for a specific drug (e.g., used to treat women for menopausal symptoms). In the specific drug case, the experimentation required would be directed at the "target" lifestage(s).

It should also be noted that comprehensive testing for reproductive toxicity normally involves the simultaneous exposures of both males and females. Only with specific protocol amendments will the affected sex(es) be determined (e.g., exposure of one sex, or a crossover mating study design in which treated males and females are mated with corresponding control animals). The details below apply to the rat, the most common species employed in reproductive toxicity studies. Suitable amendments can be made for other species (the mouse is sometimes used) and nonhuman primates occasionally employed—particularly for testing drugs.

A significant amount of attention has also been focused on the development of "screens" for reproductive toxicity as opposed to the more definitive protocols usually found in testing guidelines. Such a need has arisen primarily for the evaluation of the 80,000 chemicals used in commerce which have no reproductive toxicity testing information. Thus, the screens currently employed (and particularly the

OECD 421 and 422 guidelines) have been developed to prioritize chemicals for more comprehensive testing. Whereas such screening approaches can identify chemicals that have adverse effects on reproductive function, the dosing regimes, end points employed, number of dose levels used etc. serve only to provide a signal, albeit that the basic information is of a quality to set dose levels, or highlight potential areas of issue in more detailed studies. More problematic is what to do with negative data from these screens as these *do not* imply that the chemical tested is without reproductive toxicity, and may still present a risk to humans. Thus, the outcomes from such screens can be summarized as: "*a positive response is a positive, but a negative response is a maybe*." More detailed information on the proposed screening battery for EDCs is provided in section "Endocrine Disruption" including "Screening and Puberty".

The most comprehensive assessment of reproductive toxicity would be provided by a protocol that exposes the animal model throughout the reproductive cycle (see Fig. 20-1) and involves the assessment of multiple end points at different lifestages during this continuous exposure. The protocol and guideline coming closest to this ideal is the multigeneration reproduction study used for the assessment of chemicals, pesticides, and some food additives (OECD 416, EPA OPPTS 870.3800, FDA "redbook" and the NTP Reproductive Assessment by Continuous Breeding [RACB]). These all represent variations on the general theme noted in Fig. 20-28 and Fig. 20-29 and the reader is pointed to the specific guidelines for more detailed explanation of the differences. In general, parental (F_0) animals are exposed for approximately 10 weeks prior to mating (based the duration of the spermatogenic wave of 8 weeks and the passage of sperm through the epididymis and the availability of mature sperm for fertilization) (see Fig. 20-16). Exposure continues through mating (and after the mating pairs are separated), continues through gestation, birth, and lactation. Litters maybe "standardized" to ensure equal lactational demand on the dams and normalize the growth of pups (litters are usually reduced to four males and four females per litter on PND 4). At weaning, F_1 litters are usually culled to one male and one female that are raised and exposed until adulthood and the exposure continues through the same processes in the second breeding generation which usually halts at weaning of the F_2 pups. These studies normally have at least 3 dose levels (with the highest dose level designed to induce some toxicity) and at least 20 litters produced per dose group. The RACB study is unusual in that two to three litters are produced in each generation and in its latest form, four males and females are retained from the last F_1 and F_2 litters to adulthood. These multigeneration studies normally encompass detailed measurements of reproductive performance (number of pregnant females from number of pairs mated, number of females producing a litter, litter size, number of live pups with their birth weights and sex). Measurement of growth and analysis of the reproductive organs in the F_0 parental generation is conducted (including specific evaluations of ovarian follicles, estrous cyclicity, and sperm parameters). Similar measurements to those undertaken for the F_0 are made on the F_1 parents, but in addition offspring are normally carefully examined at birth (and sexually dimorphic end points may be collected such asAGD), at weaning, and at puberty (particularly the assessment of VO and time of first estrus in females and belanopreputial separation in males) in addition to the adult measurements of reproductive performance, organ weights, histology etc. In the EPA multigeneration study design, only 10 adult animals per sex, per group, per generation are required to have their tissues evaluated histologically. For the OECD 416 design, this number will increase to 20 per sex per group (i.e., each male and female selected for breeding in the F_1 generation).

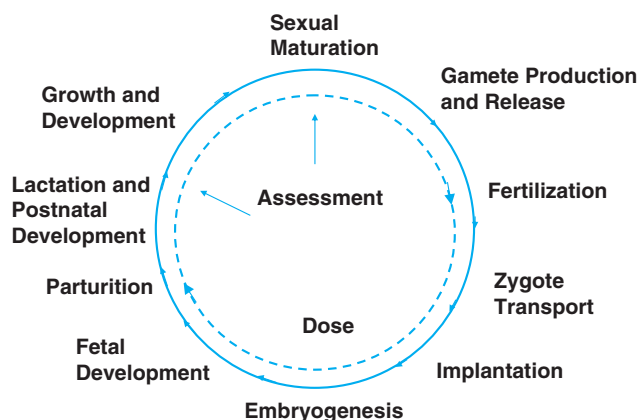
Multigeneration Reproduction Study


Figure 20-28. Multigeneration study.

Generally, only one mating is performed per generation, but in the presence of equivocal data, or clear indications that effects are becoming more adverse in succeeding generations, then extra litters or generations may be added to the standard designs to clarify potential reproductive toxicity.

Testing for Endocrine Disrupting Chemicals

In a tiered screening and testing approach, only chemicals that display positive reproducible responses in Tier 1 screening (T1S–see section "Endocrine Disruption" including "Screening and Puberty") or T1.5 would be evaluated further in full-life cycle or multigenerational tests. In Tier 2 testing (T2T), not T1S, issues of dose-response, relevance of the route of exposure, sensitive life stages, and adversity are resolved. For some endocrine activities, the number of sensitive endpoints and F_1 offspring examined in these assays should be expanded on a case-by-case basis.

AGD at birth and nipple/areola retention in infant female and male rats should be included in testing of androgens and antiandrogens, respectively, because they are sensitive, potentially permanent effects that are highly correlated with malformations and reproductive organ weight changes later in life (McIntyre *et al*., 2001). These early alterations constitute part of the antiandrogen-induced developmental syndromes. The syndrome induced by the AR antagonists differs to some degree from that induced by the phthalates, which inhibit the synthesis of fetal testosterone and insulin-like 3 peptide (insl-31) hormones.

Developmental Syndromes and Tailored Testing A careful evaluation of the male rat offspring allows one to distinguish the "phthalate syndrome," in which effects on reproductive development involve a decrease in fetal testicular testosterone and insl-3 peptide hormone biosynthesis (Gray *et al*., 2002; Mylchreest and Foster, 2000; Mylchreest *et al*., 1999; Parks *et al*., 2001; Wilson *et al*., 2004) from the "AR antagonist syndrome," induced by vinclozolin (Gray *et al*., 1994, 1999b; Lim *et al*., 2001) or flutamide (McIntyre *et al*., 2001). The main distinction between the two syndromes is that the phthalate syndrome includes agenesis of the testis, epididymis, and gubernacular cord. These lesions are rarely seen in the AR antagonist syndrome, even when all of the males display hypospadias. In addition, of all chemicals that interfere with the

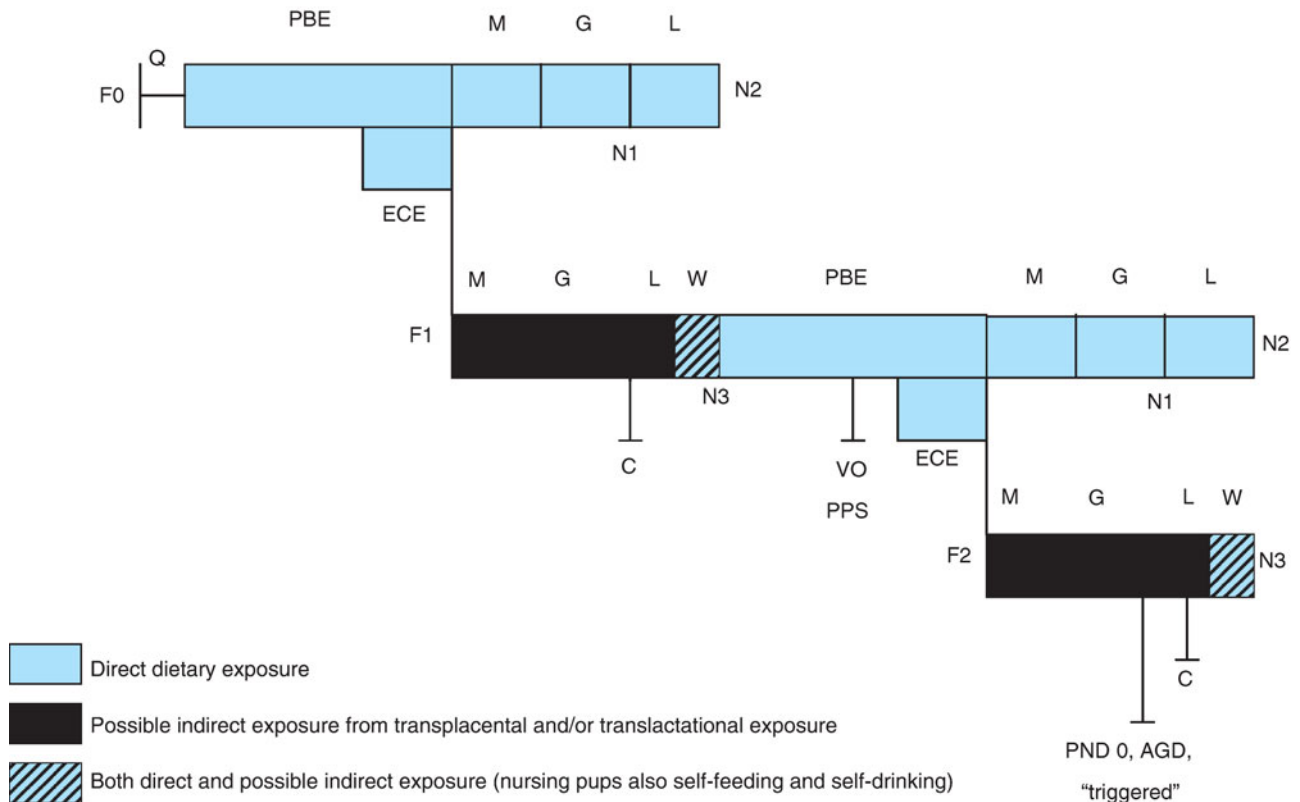
U.S. EPA OPPTS Study Design (1998)


Figure 20-29. Multigeneration reproduction study as recommended by EPA.

Key for the rat: Q – Quarantine (one week); PBE – Prebreed exposure (10 weeks); M – Mating (two weeks); G – Gestation (three weeks); L – Lactation (three weeks); VO – Vaginal opening (evaluated in F1 females on postnatal day 22 to acquisition); PPS – Preputial separation (evaluated in F1 males on postnatal day 35 to acquisition); W – Weaning (postnatal day 21); N1 – Necropsy of all paternal animals (organ weights, histology, andrological assessments); N2 – Necropsy of all maternal animals (organ weights, histology, ovarian follicle assessments); N3 – Necropsy of selected weanlings, three/sex/litter, if possible (organ weights); ECE – Estrous cyclicity evaluation (three weeks); C – Cull litters to ten pups (with equal sex ratio) on postnatal day 4; AGD – Anogenital distance measured in F2 pups on postnatal day 0 if triggered by effects on F1 reproductive development; N – Necropsy. Single generation reproduction study (e.g., OECD 415).

androgen signaling pathway in the fetal male rat, only the phthalates affect Leydig cell insl-3 hormone synthesis and cause undescended testes due to gubernacular agenesis (Wine *et al.*, 1997).

In contrast to the antiandrogens, which primarily affect the male offspring (see Table 20-7), in utero exposure to androgenic chemicals has more severe consequences for the female offspring (see Table 20-8). It is important to consider this information when tailoring T2T based on T1S results. For example, when the female rat fetus is exposed to testosterone (Hotchkiss *et al.*, 2007) or the veterinary pharmaceutical trenbolone, agenesis of the vagina and nipples is seen at a low rate in the lower dosage groups. In fact, most of the low-dose effects of androgens in the female offspring (retained prostatic and vesicular tissues, and nipple agenesis (Hotchkiss *et al.*, 2007; Wolf *et al.*, 2002) are effects that are likely to be missed in a standard necropsy.

When conducting a multigenerational study, it is important to summarize the data in a manner that clearly delineates the proportion of animals that are affected, indicating that they display any lesion (histological or gross pathology) consistent with the syndrome. In teratology studies, data are typically presented and analyzed in this manner, indicating the number of malformed/number observed on an individual and litter basis, whereas multigenerational studies are frequently presented and analyzed differently, even when clear teratogenic and other developmental responses are noted after birth. Multigenerational protocols are used in T2T because only these protocols expose the animals during all critical stages of development and examine reproductive function of offspring after they mature.

Although the new EPA multigenerational test provides for a comprehensive evaluation of the F_0 or parental generation, too few F_1 animals (offspring with developmental exposure) are examined after maturity to detect anything but the most profound reproductive teratogens (Gray and Foster, 2004). F_0 animals within a dose group typically respond in a similar fashion to the chemical exposure; however, the response to toxicants in utero can vary greatly even within a litter with only a few animals displaying severe reproductive malformations in the lower dosage groups. For example, dose-related adverse reproductive effects are seen in less than 10% of the F_1 offspring treated in utero with the phthalate DINP (male reproductive malformations, Gray *et al.*, 2000); 2,3,7,8-TCDD (permanent vaginal threads and ovarian atrophy, Gray *et al.*, 1997c); in utero busulfan (ovarian atrophy and delayed puberty, Gray and Ostby, 1998); DEHP (epididymal and testicular lesions, and linuron, McIntyre *et al.*, 2000); epididymal and testicular hypoplasia, and androgens (vaginal and nipple agenesis, Wolf *et al.*, 2002).

Table 20-7

Detecting developmental reproductive syndromes in male rat offspring. Multitude of effects of antiandrogens in male rat offspring that should be evaluated in Tier 2 testing studies displaying this activity in Tier 1 screening or other assays

Neonatal-infantile data

1   Anogenital distance at birth (1–3 days of age)
2   Areola/nipple retention in infant male rats at 13–14 days of age

External necropsy endpoints on all male rat offspring at maturity

1   Body weight any unusual malformations or anomalies, euthanize
2   Shave ventral surface from inguinal region to neck and count nipples and areolas (observer blind to treatment), record
        position of areolas and nipples.
3   Check animals for hypospadias, epispadias, cleft phallus, and measure AGD
4   Note if testes obviously undescended
5   Note if inguinal region soiled with urine
6   Note if prepuce partially or entirely detached from glans penis, especially if a persistent thread of tissue is present along
        frenulum.

Internal endpoints on all male rat offspring at maturity

1   Location of each testis (scrotal, abdominal, gubernaclum attached to abdominal wall)
2   Gubernacular cords, present or absent, and length in mm if abnormal
3   Note if present, cranial suspensory ligaments
4   Note if testes are small, absent, fluid filled, enlarged, appear infected or other
5   Note if epididymides are small, absent, or infected (record region of effects)
6   Note if ventral prostate is small, absent, or infected
7   Note if dorsolateral prostate is small, absent, or infected
8   Note if seminal vesicles are small, absent, infected, or one side larger than the other
9   Note if coagulating glands are small absent, infected, one side larger than the other or detached from seminal vesicles.
10   Note if kidneys display hydronephrosis, calcium deposits
11   Note presence of hydroureter
12   Note presence of bladder stones or bloody in bladder

Weigh the following organs on all male rat offspring at maturity

1   Each testis individually (examine histology of each testis)
2   Each corpus plus caput epididymis (examine histology of each segment)
3   Each cauda epididymis (examine histology of each segment)
4   Entire seminal vesicle, plus coagulating glands with fluid as a unit, if possible
5   Entire ventral prostate, if possible
6   Each kidney
7   Paired adrenals
8   Liver
9   Levator ani plus bulbocavernosus
10   Cowper's glands as a pair, if possible
11   Glans penis
12   Pituitary
13   Brain

Histology on all male F_1 offspring at maturity

1   Both testes
2   Both epididymides
3   Prostate glands
4   Any grossly abnormal reproductive tissues

Thus, a standard multigenerational protocol that examines only one F_1 animal per sex, per litter after maturity from 20 litters per dosage group, can detect statistically significant alterations only when they are displayed by 25% or more of the offspring. Histopathological alterations must be displayed by 50% or more of the offspring because a histological examination of the reproductive tract is required only in 10 F_1 animals per sex, per dose—far too few to detect anything but the most profound effects on reproductive development. Such

an approach would also create uncertainty associated with lowest observed adverse effect levels (LOAELs) and no observed adverse effect levels (NOAELs) identified in multigenerational studies for chemicals that do not include either a complete assessment of all of the endpoints that constitute the syndrome, or those included in the EPA new Multigenerational Test Guidelines.

In "transgenerational" protocols (Gray, 1998a; Gray and Ostby, 1995; Gray *et al.*, 1994, 1997c, 1999b,c, 2002; McIntyre *et al.*, 1998,

3	Vagina
4	Any suspected male reproductive tissues
5	Any grossly abnormal reproductive tissues

2000, 2001), we typically use fewer litters (7–10 per dose group) but examine all of the animals in each litter. These protocols actually use fewer animals but provide enhanced statistical power to detect reproductive effects in the F_1 generation. Additional factors, besides detection of adverse effects at necropsy or during data analysis and interpretation, limit interpretation of data from the standard multigenerational reproduction test. The life-long exposure of both males and females in the F_1 generation, which allows one to detect effects induced in utero, during lactation, or from direct exposure after puberty, can confound the identification of when the effect was induced (i.e., during adulthood vs. development) or even the affected sex. In studies, where the dosing period normally is terminated near birth or at weaning, precludes misinterpretation of the developmental origin of reproductive effects. Nevertheless, it is clear that transgenerational protocols would not be appropriate

for EDCs that induce low-dose alterations in the pubertal or adult animal in the F_0 generation.

Test Design and Numbers of F_1 Animals It is important to reiterate that the endpoints described above, which are sensitive to antiandrogens or androgens in utero (listed in detail in Gray and Foster, 2004), are not sensitive to xenoestrogens or some other EDCs. Thus, not all EDCs should be tested similarly to the androgens or antiandrogens. Testing should be tailored based on the pharmacological activity demonstrated in T1S. In addition, the developing fetus is not always the most sensitive life stage. Some EDCs disrupt pregnancy by altering maternal ovarian hormone production in F_0 dams at dosage levels that appear to be without direct effect on the offspring (Gray *et al.*, 1999b). In such cases, the standard EPA multigenerational protocol with minor enhancements would be

In Utero Lactational study Protocol

Dosing is from implantation until the litters are weaned.

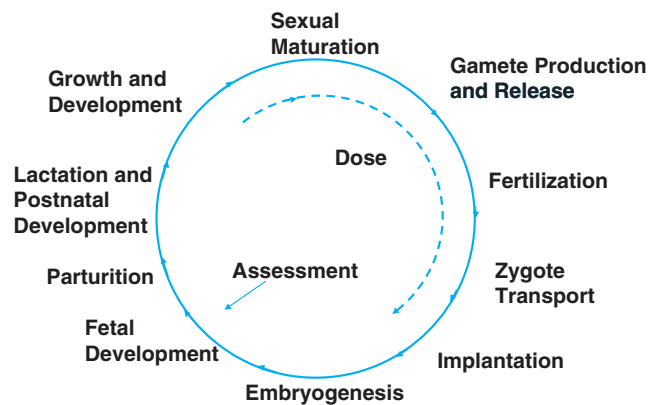
recommended, or a transgenerational protocol with exposure continued after weaning. The transgenerational or in utero-lactational protocols (see Fig. 20-30) fill a gap in the testing program for EDCs that should be used only on a case-by-case basis, as indicated by the results of T1S and any Tier 1 repeat study.

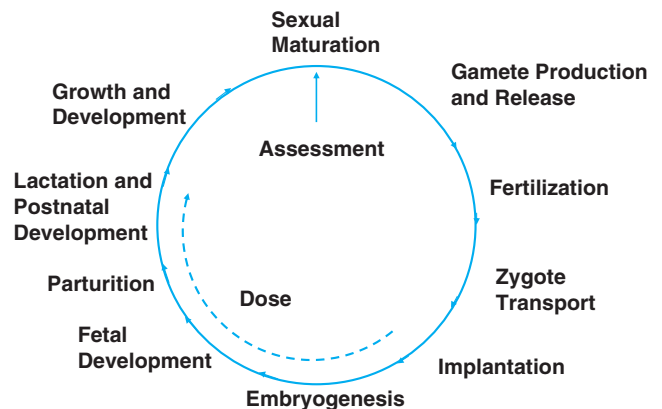
Testing Pharmaceuticals

In the case of pharmaceuticals, it is rare for multigeneration studies to be conducted, because it is not common for all the population to use a specific drug and that exposure to the drug is not necessarily chronic and over many different lifestages. Typically three specific studies are undertaken based on the recommendations of the International Conference on Harmonization of Guidelines S5A: Detection of toxicity to reproduction for medicinal products (see Collins 2006 for specific study descriptions) although any permutation or specific design is open to the investigator to explore specific toxicity based on the pharmacology of the drug tested. The three "most likely" studies are as follows.

1. **A study of fertility and early embryonic development** (see Fig. 20-31). Parental adults are exposed to the test chemical for 2 weeks (females) or 4 weeks (males) prior to breeding and then during breeding. Females then continue their exposure through to implantation. Males can be necropsied for the end points noted above for the multigeneration studies after pregnancy has been confirmed, and for the pregnant females, necropsy takes place any time after midgestation. As with the multigeneration study, reproductive and target organs are weighed and examined histologically, sperm parameters are assessed in males and in females, the uterine implantation sites and ovarian *corpora lutea* are counted, as well as live and dead embryos.

In this study design, the selection of the dosing regimen for males has been based on pragmatism in attempting to shorten the study, rather than the biology of spermatogenesis in the test species (as employed in the multigeneration study). It is thought that the majority of chemicals that might affect the male should be detectable (by histology) after 4 weeks exposure, however, there are a number of exceptions to this notion. One of the significant advantages of the pharmaceutical guideline approach is that the investigator is encouraged to tailor their testing proto-

cols to reflect the best science and available knowledge. One potential disadvantage is that the basic approach does represent a theoretical "gap" as some chemicals may not manifest a testis histological lesion in 4 weeks and also there is a potential disassociation of structure (testis histology and sperm parameters) from function (male breeding performance).




2. **A study of effects on pre- and postnatal development including maternal function** (see Fig. 20-32). In this study, pregnant females are exposed from implantation until weaning of their offspring (usually PND 21 in the rat). After cessation of exposure, selected offspring (one male and one female per litter) are raised to adulthood and then mated to assess reproductive competence. These animals are observed for maturation and growth (but are not exposed). Puberty indices, as employed in the multigeneration study, are measured. In addition, sensory function, reflexes, motor activity, learning and memory are also evaluated.

3. **A study of embryo–fetal development** (see Fig. 20-33). This study tests for enhanced toxicity relative to that noted in pregnant females and unlike the previous two studies, is normally

Embryo–Fetal Development Study

Figure 20-33. Embryo–fetal developmental toxicity study as used by FDA guidelines.

Dosing starts at implantations and continues to closure of the hard palate with an assessment of fetuses just prior to parturition.

EPA Prenatal Developmental Toxicity Study

Figure 20-34. Prenatal developmental toxicity study as used by EPA and OECD.

Note the extended dose period compared with that used in Figure 20-33.

conducted in two species (typically the rat and rabbit). Exposure occurs between implantation and closure of the hard palate and females are killed just prior to parturition. At necropsy, dams are observed for any affected organs and *corpora lutea* are counted. Live and dead fetuses counted and examined for external, visceral, and skeletal abnormalities. In the evaluation of prenatal developmental toxicity for a chemical or pesticide (e.g., OPPTS 870.3700, OECD 414), exposure of the pregnant dams is usually longer and can be continuous throughout pregnancy or, more normally, from implantation until just prior to birth (see Fig. 20-34). Other end points measured in the dam and fetuses are identical between the pharmaceutical embryo-fetal toxicity study and that employed for evaluation of an industrial chemical or pesticide.

The FDA Center for Drug Evaluation and Research produced a draft guidance document in 2001 that explored how data should

Single Generation Reproduction Study

Figure 20-35. Single generation reproduction study.

be passed through an integrative process to assess a drug for reproductive toxicity. The tool is used in a tiered manner consisting of three sections (1) methods applicable to all datasets, (2) approaches applicable only to datasets without evidence of reproductive and developmental toxicity, and (3) approaches applicable to datasets with positive indications of reproductive and/or developmental toxicity. This integration would provide one of three summary risk conclusions that would be applied to the drug label namely (1) not anticipated to produce reproductive and/or developmental effects above the background incidence for humans when used in accordance with the dosing information on the product label; (2) the drug may increase the incidence of adverse reproductive and/or developmental events, or (3) that the drug is expected to increase the incidence of adverse reproductive and/or developmental effects in humans when used according to the product label.

An examination of the reproductive cycle in a comparison of these three most likely options for FDA studies indicates an obvious gap in the exposure regime for the complete reproductive cycle, namely exposure of weanlings through puberty to adulthood. This exposure period has become of increasing interest to many companies developing drugs for specific administration to infants and juveniles and as such "bridging type" protocols to be used in addition to the three "most likely" have been developed to specifically address toxicity that may occur after exposure during this specific lifestage (Hurtt *et al.*, 2004).

The single generation reproduction study (OECD 415) is used more frequently in Europe where specific testing guidelines for reproductive toxicity may be triggered by the tonnage production of a specific chemical. This design (see Fig. 20-35) has a common F_0 parental exposure period to that used in the multigeneration guideline (OECD multigeneration study—416). Estimates are made of the standard litter parameters and reproductive performance of the F_0 parents, but in this design the study halts at the weaning of the F_1 offspring and no estimate is made of effects on adult F_1 offspring, nor on the ability of this generation to reproduce. This study design provides critical information on parental reproductive effects but has very limited information on the offspring aside from pup number, growth and survival to weaning, and thus has limited utility in the estimation of transgenerational effects, or postnatal reproductive consequences.

Newer Guidelines and Approaches

The International Life Sciences Institute sponsored a new endeavor looking at how Agricultural Chemicals might be assessed for toxicity, including reproductive toxicity in a proposed lifestage approach (Cooper *et al.*, 2006) using an extended one-generation study (see Fig. 20-36) in the rat. This approach incorporated many of the changes made more recently to testing guidelines (including extra endocrine related end points) and attempted to streamline the testing of chemicals for toxicity. The lifestages protocol was one of a tiered set of proposed studies, such that all data available could be incorporated into the study design and interpretation of the data. The approach was very laudable in that it proposed (unfortunately only as an option) incorporation of toxicokinetic data generated during pregnancy and lactation into the study design, as has long been required in drug testing, to aid study design and data interpretation. In addition, end points evaluating (at least to some degree) developmental neurotoxicity and developmental immunotoxicity would be measured as a standard, rather than as a triggered option. Its major aim was to reduce the number of animals required and increase the information available on young animals. However, these compromises were not without some flaws compared to the current multigeneration study used for pesticides by EPA or OECD. The study would seek to be a substitute for the current multigeneration study in most instances. The proposal does offer the opportunity to undertake a classical multigeneration study in a second tier but only if adverse events were not found in the Tier 1 study. Thus, a negative in the extended one-generation study could mean a halt to testing for reproductive toxicity. In particular, the paper recommends the use of the shortened exposure period before breeding the parental animals, similar to that implied in the international conference on harmonization of guidelines (ICH) guideline for fertility and early embryonic development, but it is much harder to justify that pesticides and other agricultural chemicals, unlike drugs, will not have human exposure at least subchronically and moreover the divorce of reproductive structure (e.g., histopathology of the reproductive organs) from function (e.g., litter parameters) could have serious implications for classification and labeling in some parts of the world.

As noted above, the new NTP RACB study attempts to overcome some of the shortcomings noted in standard multigeneration studies and the ILSI/ACSA designs by maintaining at least four males and four females of each litter until PND 90 for a full examination of the animals at sexual maturity and the increased power associated with keeping extra animals to detect low incidence phenomena. A standard multigeneration study keeping only one male and female from each of 20 litters could only detect a 25% incidence of a reproductive tract malformation if the background incidence is typically 0—precisely the types of adverse responses noted in studies with endocrine disruptors. The RACB study also takes multiple litters per generation to ensure the detection of latent effects that might not be observable only on the first breeding.

EVALUATION OF TOXICITY TO REPRODUCTION

Concordance of End Points

As noted in the testing section R, our standard testing protocols do not allow for discrimination between male and female effects except by some method modification. However, there is built-in redundancy in the number and type of end points evaluated in these studies that could indicate male, female, or effects on both sexes during testing. The following examples give an outline of the types of end points evaluated typically in rat multigeneration studies (the species most commonly used for reproductive toxicity evaluations).

There are a number of general points that the investigator should note in any estimation of potential reproductive toxicity:

- Adequacy of experimental design and conduct. Was there sufficient statistical power in the evaluation(s)?
- Occurrence of common versus rare reproductive deficits. Biological versus statistical significance.
- Use of historical control data to place concurrent control data into perspective and to estimate population background incidence of various reproductive parameters and deficits.
- Known structure-activity relationships for inducing reproductive toxicity.
- Concordance of reproductive end points (e.g., did a decrease in litter size relate to ovarian histology and changes in vaginal cytology?).
- Did the reproductive deficits become more severe with increases in dose—for example, did histological changes at one dose level become decrements in litter size and then reductions in fertility at higher dose levels in any generation?
- Did the reproductive deficits increase in prevalence (more individuals and/or more litters) with dose level in any generation?
- Special care should be taken for decrements in reproductive parameters noted in the F_1 generation (and potentially later generations) that were not seen in the F_0 generation, which may suggest developmental, as well as reproductive, toxicity. Likewise, findings in an F_1 generation animal may (or may not) be reproduced in F_2 offspring. For example, effects in the F_1 generation on reproductive parameters may have resulted in the selection out of sensitive animals in the population, thus not producing F_2 offspring for subsequent evaluation.

The first primary indication of a decrement in reproduction is obtained from the inspection of litter parameters from a breeding and determination of any functional effects. Thus, it is normal to inspect for various treatment groups versus the control, the number of fertile pairings, the mean litter size, pup weight at birth (small litters tend to have higher pup weights), and the sex ratio (to determine if there is a selective effect on any one sex).

In the parental females there should also be an evaluation of potential maternal toxicity that may or may not impact on the reproductive performance of these animals; these measures are crude and usually restricted to body weight, food consumption, and clinical signs. Gestation length is normally recorded (and this maybe shortened or lengthened) together with any signs of dystocia. Chemicals with progestin-like activity may also produce midgestational bleeding observable on the fur/or in the cage. At weaning of the litter (usually PND 21 in the rat), the parental females are usually necropsied (if no further pairings are required) and the uteri examined for implantation sites (which can be compared to the number of offspring produced) and the ovaries examined for corpora lutea and corpora albicans. These data are not as definitive for pre- versus postimplantation loss as in the developmental toxicity study, because the female will begin to cycle around postnatal day 15 and have representative corpora lutea from both the pregnancy and the new ovarian cycle(s).

In immature females after weaning, measurements can be made of the onset of puberty (which may be accelerated or delayed)

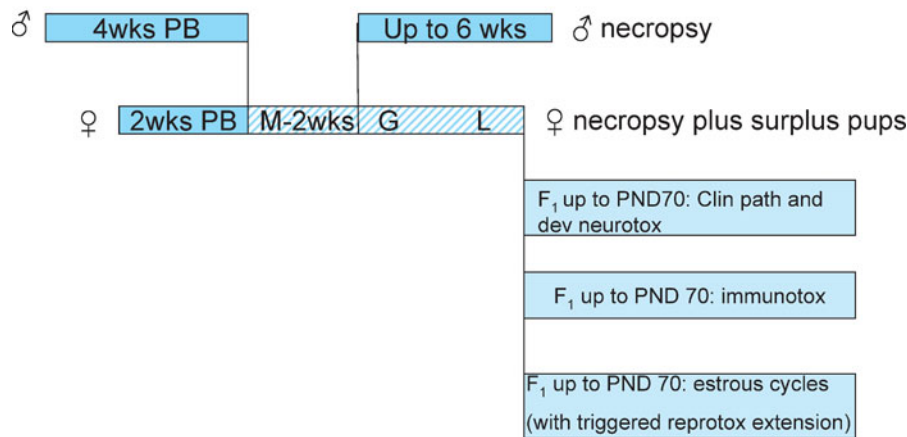
ILSI/ ACSA F₁- extended one generation rat reproduction study


Figure 20-36. The ILSI/ACSA lifestages study for the evaluation of reproduction with developmental immunotoxicity and neurotoxicity.

through estimates of the date of VO and first estrus from vaginal smears. Some care needs to be used in the impact of other toxicity on these pubertal parameters and it is usual to normalize based on bodyweight. However, timing of puberty should not be normalized by body weight at acquisition of puberty (since a delay will invariably mean that the females are larger compared to controls and vice versa for acceleration). Instead, it is more likely that the investigator would employ weight at weaning as a covariate in the analysis of these pubertal end points.

As the female matures, estimates will be made of estrous cyclicity particularly if they are normal or abnormal (a rat normally has a 4–5 day cycle) and the duration of the cycles (for example, was persistent estrus or diestrus noted). Vaginal smears are also noted during mating and the presence of a sperm positive smear would indicate a successful mating that provides at least some surrogate of normal reproductive behavior from the breeding pair.

At necropsy of the adult F_1 female, weights and histopathology would be undertaken on critical organs (e.g., ovaries, uterus, pituitary and perhaps adrenal [as another steroidogenic organ]). Histopathology of the ovary is not straightforward and some guidelines require the evaluation of primordial follicle counts in step sections of the ovary. However, such an examination provides only limited information on one type of follicle and it is essential that the pathologists make their evaluation with regard to the normal expected patterns of the different follicular types (from primordial to antral), and when necessary undertake quantitative analysis to confirm an effect on ovarian follicular development.

In the parental males, similar types of evaluation are available to the investigator with regard to potential parental toxicity. Decreases in fertile pairings and litter size may be equally applicable for the detection of a male effect. The presence of a sperm positive smear in the female is indicative that the male has successfully mounted and mated with the female (note the presence of a copulatory plug is not the same because these may be formed from accessory sex organ fluids in the absence of sperm).

Males going through puberty can be estimated using the date of belanopreputial separation of the penis as an index. This androgen dependent end point in the male is also corrected for growth, but the same caveats used in the female would apply to this male measurement. Decrements of ∼10% body weight are normally without significant effect on male or female puberty indicies (Carney *et al.*, 2004). As the male matures and is bred with a female, observations of the precoital interval (the time between pairing and evidence of mating) can indicate treatment related effects on mating performance or behavior. However, it should be noted that if the female is at a random stage of estrus when introduced to the male, she may not allow mating until estrus is attained. Thus delays of more than 4–5 days in precoital interval should be carefully examined.

Once a pregnancy has been achieved and there is no requirement for further matings, the parental male is necropised and organ weights and histological examination conducted usually of the testis, epididymis, prostate, seminal vesicles, and pituitary (and perhaps adrenal as for the female as another steroidogenic organ). Some studies also include other androgen-dependent organ weights such as the Levator ani-bulbocavernosus muscle, Cowper's gland, and penis. As with the ovary, histopathological examination of the testis requires some experience and the pathologist must be familiar with the different stages of the spermatogenic cycle. Although quantitative analysis of stage frequency is rarely required (and not useful in longer term studies) the noting of specific stages that may show a predilection for injury is most helpful, as is an appreciation of the different cellular associations affected within the seminiferous tubule. Such an analysis is essential in the detection of more subtle testicular effects.

At necropsy, a number of quantitative estimates can be made of sperm production and function. These can include testicular spermatid counts following homogenization (this end point entails destruction of one testis and has to be balanced with the information obtained from histopathology). A sperm sample is also taken from the vas or cauda epididymis for examination of sperm concentration, motility and morphology, which can be examined using manual methods. More often, computer assisted sperm analysis is used to evaluate these sperm end points and in addition further parameters can be collected, such as forward progressive motility, which is believed more closely related to fertility. Frequently, whole cauda epididymal sperm counts are also evaluated and normalized by weight.

Evaluation of male and female offspring follows the schema outline above for adults and for animals going through puberty. In addition, other useful end points may be included before weaning such as AGD, the presence of nipples and areolae (usually at postnatal day 13 before the pup fur has started to grow excessively to prevent examination), and the presence of certain reproductive tract malformations (see Tables 20-7 and 20-8). AGD and nipple retention are sexually dimorphic in the rat and under androgen control. Thus, normally AGD is twice the distance in males than females (this also seems to hold true for humans) and is dependent on levels of circulating DHT. In the normal male rat fetus, the presence of androgen around gestation day 17 causes the anlagen for the nipples to undergo apoptosis and thus males are born without nipples whereas females have the full complement of 12. The presence of an antiandrogen in males or an androgen in females would upset this balance to produce nipple retention in the males and a reduced number in the females reflective of the androgen status of these animals at critical periods of development. Some assessment must also be made of general growth of the offspring (usually bodyweight).

Consistency Across Generations

The F_0 reproductive parameters can differ markedly from those noted in the F_1 and similarly from the F_2 generation in a multigeneration study. Because exposure in a multigeneration study typically starts with the F_0 generation as young adults, critical periods of reproductive development have already taken place. The phthalates (e.g., DBP; Wine *et al.*, 1997) represent a classic example of weak effects noted in the F_0 generation (all the pairs were fertile but there was a small but significant effect on litter size and pup growth). In the F_1 generation where exposure is from conception to adulthood when these animals were bred at the same dose only 19/20 pairings resulted in a litter and thus the effects on reproduction were significantly enhanced in the F_1 generation and illustrate the importance of breeding the F_1 animals to detect functional effects on the offspring due to in utero exposure.

Differences between F_1 and F_2 generations can also arise. Here the exposure duration and critical windows of development are the same. However, because one normally only takes one male and female from each litter to generate the F_1 and F_2 parents it is distinctly possible that a selection bias can exist (e.g., if sensitive animals did not produce a litter, or the sensitive pups within a litter did not survive, then a pup from this pairing cannot be selected for further generations) and therefore potential effects may decrease in incidence or severity across generations. Other specific effects may increase severity in the F_2 versus the F_1. For example, a selective effect during in utero exposure of F_1 on the mammary gland would show the F_1 population as being normal with regard to reproduction, but when the F_1 animal becomes a parent, it cannot raise the F_2 adequately because of a mammary effect. In this instance there would be a more profound influence on the F_2 than the F_1 litters.

Graded Effects

In a similar fashion to developmental toxicity it is important to keep in mind the ability of changes in dose to alter the outcome of reproductive toxicity studies such that it is not just an increase in severity of a reproductive deficit that may be noted with increased dose but potentially an increased prevalence of a specific effect (on either an individual or litter basis). There may also be an increase in the severity of the type of lesion with the full constellation of the effects only noted at the highest dose level. Thus, for example, a single compound may produce a subtle effect on testis histology at low-dose levels. As the dose increases, this lesion may become more severe, with pathology noted in the epididymis, this in turn may affect semen parameters that result in a decrease in litter size and as the dose increases further, to a reduction in the number of fertile pairs—thus there is a continuum of effects that may be shown by a chemical producing reproductive toxicity that are interrelated and become important in selecting appropriate effect dose levels and therefore those exposures that maybe without effect.

TOXIC RESPONSES OF THE ENDOCRINE SYSTEM

Charles C. Capen

INTRODUCTION

Endocrine glands are collections of specialized cells that synthesize, store, and release their secretions directly into the bloodstream. They are sensing and signaling devices located in the extracellular fluid compartment and are capable of responding to changes in the internal and external environments to coordinate a multiplicity of activities that maintain homeostasis.

Endocrine cells that produce polypeptide hormones have a well-developed rough endoplasmic reticulum that assembles hormone and a prominent Golgi apparatus for packaging hormone into granules for intracellular storage and transport. Secretory granules are unique to polypeptide hormone- and catecholamine-secreting endocrine cells and provide a mechanism for intracellular storage of substantial amounts of preformed active hormone. When the cell receives a signal for hormone secretion, secretory granules are directed to the periphery of the endocrine cell, probably by the contraction of microfilaments.

Steroid hormone-secreting cells are characterized by prominent cytoplasmic lipid bodies that contain cholesterol and other precursor molecules. The lipid bodies are in close proximity to an extensive tubular network of smooth endoplasmic reticulum and large mitochondria which contain hydroxylase and dehydrogenase enzyme systems. These enzyme systems function to attach various side chains to the basic steroid nucleus. Steroid hormone-producing cells lack secretory granules and do not store significant amounts of preformed hormone. They are dependent on continued biosynthesis to maintain the normal secretory rate for a particular hormone.

Many diseases of the endocrine system are characterized by dramatic functional disturbances and characteristic clinicopathological alterations affecting one or several body systems. The affected animal or human patient may have clinical signs that primarily involve the skin (hair loss caused by hypothyroidism), nervous system (seizures caused by hyperinsulinism), urinary system (polyuria caused by diabetes mellitus, diabetes insipidus, and hyperadrenocorticism), or skeletal system (fractures induced by hyperparathyroidism) (Capen, 2006b).

The literature suggests that chemically induced lesions of the endocrine organs are most commonly encountered in the adrenal glands, followed in descending order by the thyroid, pancreas, pituitary, and parathyroid glands. In the adrenal glands, chemically induced lesions are most frequently found in the zona fasciculata/zona reticularis and to a lesser extent in either the zona glomerulosa or medulla. In a survey, conducted by the Pharmaceutical Manufacturers Association, of tumor types developing in carcinogenicity studies, endocrine tumors developed frequently in rats, with the thyroid gland third in frequency (behind the liver and mammary gland), followed by the pituitary gland (fourth), and adrenal gland (fifth). Selected examples of commonly encountered toxic endpoints involving endocrine organs in laboratory animals are discussed in this chapter. Mechanistic data is included whenever possible to aid in the interpretation of findings in animal toxicology studies and to determine their significance in risk assessment (Alison *et al.*, 1994).

PITUITARY GLAND

Normal Structure and Function

The pituitary gland (hypophysis) is divided into two major compartments: (1) the adenohypophysis (anterior lobe) of the human pituitary composed of the pars distalis, pars tuberalis, and pars intermedia; and (2) the neurohypophyseal system which includes the pars nervosa (posterior lobe), infundibular stalk, and nuclei (supraoptic and paraventricular) in hypothalamus that contain the neurosecretory neurons that synthesize and package into secretory granules the neurohypophyseal hormones. The pars intermedia forms the thin cellular zone between the adenohypophysis and neurohypophysis. The pituitary gland lies within the sella turcica of the sphenoid bone. The gland receives its blood supply via the posterior and anterior hypophyseal arteries which originate from the internal carotid arteries. Arteriolar branches penetrate the pituitary stalk near the median eminence, lose their muscular coat, and form a capillary plexus. These vessels drain into the hypophyseal portal veins which supply the adenohypophysis. The hypothalamic–hypophyseal portal system functionally is important as it transports the hypothalamic releasing- and release-inhibiting hormones directly to the adenohypophysis where they interact with their specific populations of trophic hormone-producing cells.

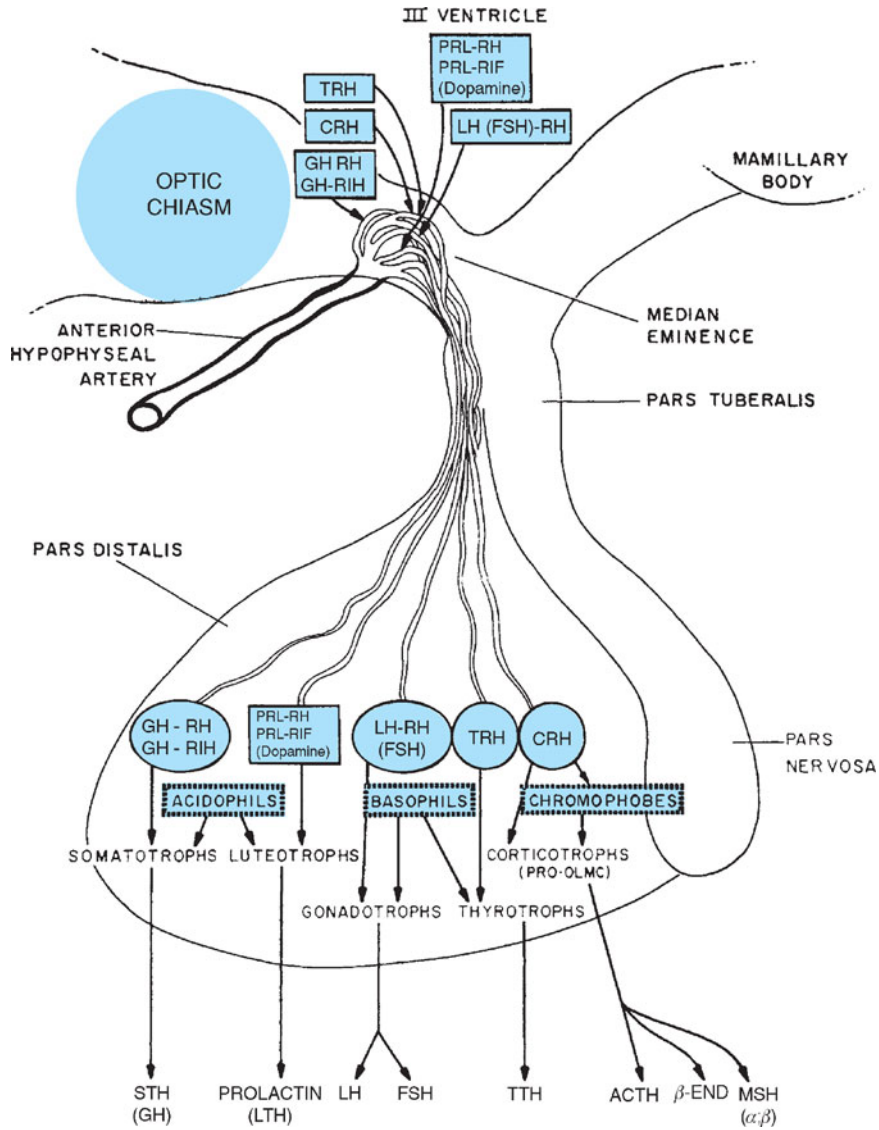
The adenohypophysis in many animal species completely surrounds the pars nervosa of the neurohypophyseal system in contrast to human beings where it is situated on the anterior surface. The pars distalis is the largest portion and is composed of the multiple populations of endocrine cells that secrete the pituitary trophic hormones. The secretory cells are surrounded by abundant capillaries derived from the hypothalamic–hypophyseal portal system (Capen, 1996a). The pars tuberalis consists of dorsal projections of supportive cells along the infundibular stalk. It functions primarily as a scaffold for


Figure 21-1. Control of trophic hormone secretion from the adenohypophysis by hypothalamic releasing hormones (RH) and release-inhibiting hormones (RIH).

The releasing and release-inhibiting hormones are synthesized by neurons in the hypothalamus, transported by axonal processes, and released into capillary plexus in the median eminence. They are transported to the adenohypophysis by the hypothalamic–hypophyseal portal system where they interact with specific populations of trophic hormone-secreting cells to govern the rate of release of preformed hormones, such as somatotropin (GH, STH), prolactin (LTH), prolactin (LTH), lutenizing hormone (LH), follicle-stimulating hormone (FSH), thyrotropic hormone (TTH), adrenocorticotropic hormone (ACTH), and melanocyte-stimulating hormone (MSH). There are RIH for those trophic hormones (e.g., prolactin and growth hormone) that do not directly influence the activity of target cells and result in production of a final endocrine product (hormone) that could exert negative feedback control.

the capillary network of the hypophyseal portal system during its course from the median eminence to the pars distalis. The pars intermedia is located between the pars distalis and pars nervosa and lines the residual lumen of Rathke's pouch. It contains two populations of endocrine cells in certain species. One of these cell types (B-cell) in the dog synthesizes and secretes adrenocorticotropic hormone (ACTH).

A specific population of endocrine cells is present in the pars distalis (and in the pars intermedia of dogs for ACTH) that synthesizes, processes, and secretes each of the pituitary trophic hor-

mones. Secretory cells in the adenohypophysis formerly were classified either as acidophils, basophils, or chromophobes based on the reactions of their secretory granules with pH-dependent histochemical stains. Based upon contemporary specific immunocytochemical procedures, acidophils can be further subclassified functionally into somatotrophs that secrete growth hormone (GH; somatotrophin) and luteotrophs that secrete luteotropic hormone (LTH; prolactin). Their granules contain simple protein hormones. Basophils include both gonadotrophs that secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH), and thyrotrophs that secrete thyrotropic

hormone (thyroid-stimulating hormone [TSH]). Chromophobes are pituitary cells that by light microscopy do not have stainable cytoplasmic secretory granules. They include the pituitary cells involved with the synthesis of ACTH and melanocyte-stimulating hormone (MSH) in some species, nonsecretory follicular (stellate) cells, degranulated chromophils (acidophils and basophils) in the actively synthesizing phase of the secretory cycle, and undifferentiated stem cells of the adenohypophysis.

Each type of endocrine cell in the adenohypophysis is under the control of a specific releasing hormone from the hypothalamus (Fig. 21-1). These releasing hormones are small peptides synthesized and secreted by neurons of the hypothalamus. They are transported by short axonal processes to the median eminence where they are released into capillaries and are conveyed by the hypophyseal portal system to specific trophic hormone-secreting cells in the adenohypophysis. Each hormone stimulates the rapid release of preformed secretory granules containing a specific trophic hormone. Specific releasing hormones have been identified for TSH, FSH and LH, ACTH, and GH. Prolactin (PRL) secretion is stimulated by a number of factors, the most important of which appears to be thyrotropin-releasing hormone (TRH). Dopamine serves as the major prolactin-inhibitory factor and suppresses prolactin secretion and also inhibits cell division and DNA synthesis of luteotrophs (Parkening *et al.*, 1980). Dopamine also suppresses ACTH production by corticotrophs in the pars intermedia of some species. Another hypothalamic release-inhibiting hormone is somatostatin (somatotropin-release inhibiting hormone, SRIH). This tetradecapeptide inhibits the secretion of both growth hormone and TSH. Control of pituitary trophic hormone secretion also is affected by negative feedback by the circulating concentration of target organ (thyroid, adrenal cortex, and gonad) hormones.

The neurohypophysis is subdivided into three anatomic parts. The pars nervosa (posterior lobe of the human pituitary) represents the distal component of the neurohypophyseal system. The infundibular stalk joins the pars nervosa to the overlying hypothalamus and is composed of long axonal processes from neurosecretory neurons in the hypothalamus. It is composed of numerous capillaries, supported by modified glial cells (pituicytes), which are termination sites for the nonmyelinated axonal processes of neurosecretory neurons. The neurohypophyseal hormones (i.e., oxytocin and antidiuretic hormone) are synthesized in the cell body of hypothalamic neurons, packaged into secretory granules, transported by long axonal processes, and released into the bloodstream in the pars nervosa.

Antidiuretic hormone (ADH or vasopressin) and oxytocin are nonapeptides synthesized by neurons situated either in the supraoptic (primarily ADH) or paraventricular (primarily oxytocin) nuclei of the hypothalamus. ADH and its corresponding neurophysin are synthesized as part of a common larger biosynthetic precursor molecule, termed propressophysin. The hormones are packaged with a corresponding binding protein (i.e., neurophysin) into membrane-limited neurosecretory granules and transported by axons to the pars nervosa for release into the circulation. As the biosynthetic precursor molecules travel along the axons in secretion granules from the neurosecretory neurons, the precursors are cleaved into the active hormones and their respective neurophysins. These secretory products can be detected immunocytochemically. In Brattleboro rats with hereditary hypothalamic diabetes insipidus, nerve cells in the hypothalamus that normally produce ADH and neurophysin-I are negative immunocytochemically for both proteins whereas neurosecretory stain positive for cells that produce vasopressin and neurophysin-II are positive.

In addition to the specific trophic hormone-secreting cells, a population of supporting cells is also present in the adenohypophysis. These cells are referred to as stellate (follicular) cells and can be stained selectively with antibodies to S-100 protein. The stellate cells typically have elongate processes and prominent cytoplasmic filaments. These cells appear to provide a phagocytic or supportive function in addition to producing a colloid-like material that accumulates in follicles.

Mechanisms of Pituitary Toxicity

Pituitary tumors can be induced readily by sustained uncompensated hormonal derangements leading to increased synthesis and secretion of pituitary hormones. The absence of negative feedback inhibition of pituitary cells leads to unrestrained proliferation (hyperplasia initially, neoplasia later). This effect can be potentiated by the concurrent administration of ionizing radiation or chemical carcinogens.

In the pituitary–thyroid axis, thyroxine (T_4) and triiodothyronine (T_3) normally regulate the pituitary secretion of TSH by a classical negative feedback control system. Surgical removal or radiation-induced ablation of the thyroid or interference with the production of thyroid hormones by the use of specific chemical inhibitors of thyroid hormone synthesis leads to a stimulation of TSH synthesis and secretion with elevated blood levels. The thyrotrophic cells in the adenohypophysis undergo prominent hypertrophy. Subsequently, hyperplasia of the thyrotrophs occurs concurrently with hypertrophy as a consequence of the lack of normal negative feedback control. In rodents foci of hyperplasia may progress to the formation of adenomas in the pituitary gland. The role of gonadectomy in pituitary tumor induction has been studied most intensively in mice. The pituitary tumors induced by gonadectomy in mice are markedly strain-dependent and may contain FSH, LH, or both.

The administration of estrogens is a reproducible method for inducing pituitary tumors in certain experimental animals. The effect of exogenous estrogen on the rat pituitary includes stimulation of prolactin secretion and the induction of prolactin-secreting tumors (Hart, 1990). The administration of estrogens in susceptible strains results in elevated serum prolactin levels, increased numbers of prolactin cells within the pituitary, enhanced incorporation of tritiated thymidine within the gland, and increased mitotic activity (Osamura *et al.*, 1982). The pituitary of the ovariectomized F344 female rat is more responsive to the tumorigenic effect of diethylstilbestrol than the intact female; however, there is considerable variation in the induction of pituitary tumors by estrogens in different rat strains. For example, F344 and Holtzman rats respond to an initial estrogen stimulus by increasing the rate of DNA synthesis in the pituitary within 2–4 days. The rate of DNA synthesis declines after 7–10 days of treatment to unstimulated levels in the Holtzman strain but remains elevated in F344 rats.

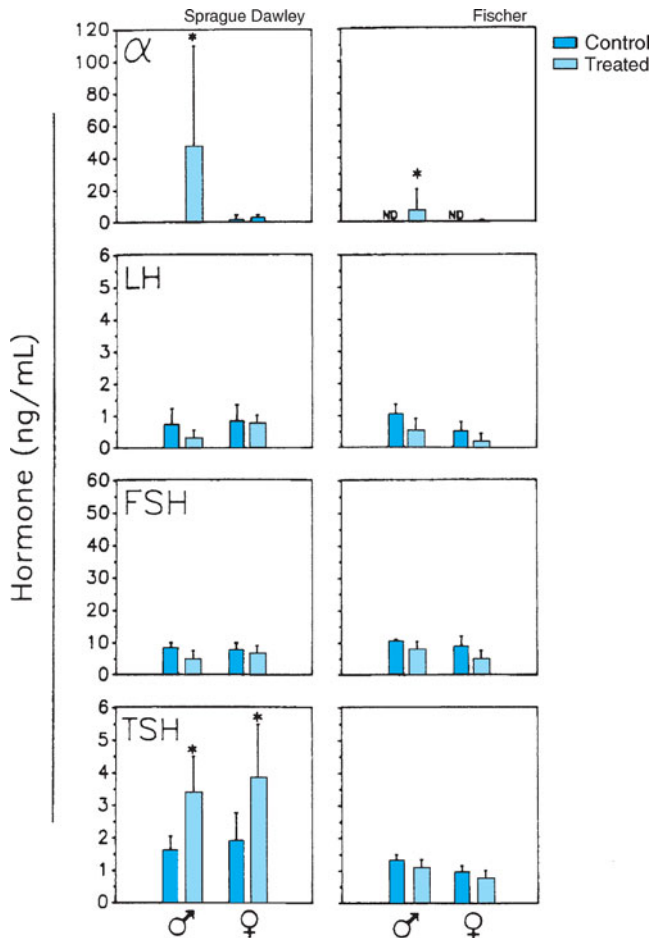
Sarkar *et al.* (1982) have reported that estrogen-induced pituitary adenomas derived from prolactin-secreting cells are associated with loss of hypothalamic dopaminergic neurons, which normally inhibit the function of prolactin-secreting cells. Prolactin-producing tumors when transplanted subcutaneously were also associated with degenerative changes in hypothalamic dopaminergic neurons. The tumorigenic action of estrogen may not be due exclusively to its effect on the hypothalamus because estrogen can produce prolactinomas in pituitaries grafted beneath the renal capsule. The effects of estrogens on prolactin cells have been studied in hypophysectomized rats bearing transplanted pituitaries beneath the kidney capsule. The studies of El Etreby *et al.* (1988) using this model have shown


Figure 21-2. Serum glycoprotein hormone levels in rats treated chronically with salmon calcitonin.

Sprague–Dawley (left panels) or Fischer rats (right panels) were treated for 52 weeks with vehicle (open bars) or calcitonin (80 IU/kg/d) (black bars). Results are the mean ± SD; *$P < 0.05$. (From Jameson *et al.*, 1992).

that dopamine agonists, including lisuride and bromocriptine, antagonize the direct stimulatory effects of estrogens on the prolactin cells. These dopamine agonists may act directly on dopaminergic receptors within the transplanted pituitaries.

Other chemicals, including caffeine, have been implicated in the development of pituitary adenomas in rats (Yamagami *et al.*, 1983). The administration of *N*-methylnitrosourea also is associated with the development of pituitary adenomas in Wistar rats. The neuroleptic agent sulpiride has been reported to cause the release of prolactin from the anterior pituitary in the rat and to stimulate DNA replication. The administration of clomiphene prevents the stimulation of DNA synthesis produced by sulpiride, but does not affect prolactin release from the gland. These findings suggest that the intracellular prolactin content of the pituitary plays a role in the regulation of DNA synthesis through a mechanism mediated by estrogens (Gunnison *et al.*, 1997).

Morphologic Alterations and Proliferative Lesions of Pituitary Cells

Jameson *et al.* (1992) reported that the administration of salmon calcitonin for one year to Sprague–Dawley and Fisher 344 rats

was associated with an increased incidence of focal hyperplasia and adenomas in the pituitary. The association of calcitonin treatment and pituitary tumors was dose-dependent and was more pronounced with salmon calcitonin than with porcine calcitonin (Brown *et al.*, 1993). Using both immunohistochemical analysis and measurements of serum hormone levels, they provided evidence that prolonged administration of calcitonin resulted in pituitary tumors that produced the common α-subunit of the glycoprotein hormones (leutinizing hormone [LH], follicle-stimulating hormone [FSH] and thyroid-stimulating hormones [TSH]), a type of tumor that has been reported to comprise a significant fraction of pituitary tumors in humans. Immunohistochemistry and in situ hybridization demonstrated that most pituitary tumors associated with the chronic administration of high doses of calcitonin expressed a glycoprotein hormone α-subunit, whereas expression of the α-subunit was identified infrequently in hyperplastic lesions of control rats.

Serum levels of each of the major pituitary hormones were measured in both sexes of Sprague–Dawley and Fisher rats administered calcitonin. There were no significant alterations in the circulating levels of growth hormone, prolactin, or ACTH and the tumors were negative by immunohistochemical and in situ hybridization assessment for these hormones. Serum LH and FSH levels were unaffected by the treatment with calcitonin; however, TSH levels were elevated 2.1-fold after calcitonin treatment in Sprague–Dawley but not Fischer rats of both sexes (Fig. 21-2). Interestingly, thyroid weights were decreased by 43% in calcitonin-treated male rats and there was atrophy of thyroid follicular cells in some treated rats, suggesting that the immunoreactivity detected by the TSH assay was not biologically active. After treatment with calcitonin, serum α-subunit levels were increased at least 20-fold in Sprague–Dawley males and fourfold in male Fischer rats (Figs. 21-3 and 21-4). There was a good correlation between histopathologic evidence of α-subunit-producing pituitary tumors and elevated serum levels. In each of the calcitonin-treated rats that had adenomas, the tumors were positive
Figure 21-4. Time course for the increase in serum α-subunit levels in male Sprague–Dawley rats.

for α-subunit by immunohistochemistry and in situ hybridization for expression of α-subunit mRNA.

Serum levels of α-subunit were elevated in male Sprague–Dawley rats after 2, 5, 8, 16, 24, 40, and 52 weeks to determine the time course for hormone elevation. Elevated levels of α-subunit were detected as early as 24 weeks in rats treated with calcitonin and the majority of animals had increased α-subunit levels by 40 weeks of treatment (Fig. 21-4), suggesting that pituitary tumors developed only after several months of exposure to calcitonin. Levels of α-subunit in vehicle-treated rats were below the detection limits of the assay at each time point.

The studies reported by Jameson *et al.* (1992) did not determine whether the effects of calcitonin on the pituitary were direct or indirect. Calcitonin is known to be produced in large amounts in the posterior hypothalamus and median eminence where it may normally exert an effect on the hypothalamus–pituitary axis. Calcitonin receptors have been identified in the hypothalamus and lower numbers of receptors are found in the pituitary gland. A striking feature of the calcitonin-induced pituitary tumors and elevated serum α-subunit levels was the predilection for male compared with female rats. The basis for the sex- and species-specific effects of calcitonin was not determined. The relevance of the effects of calcitonin in the rat pituitary gland to human pathophysiology is uncertain at present. However, neither the treatment of patients with calcitonin nor patients with the multiple endocrine neoplasia syndrome II with medullary thyroid cancer and elevated serum calcitonin levels have resulted in the development of pituitary tumors. The doses of calcitonin used in rats were from 25- to 50-fold greater on a per-weight basis than doses administered to patients. In addition, several strains of rats are known to be highly predisposed to develop pituitary tumors compared to humans.

The high frequency of spontaneous pituitary adenomas in laboratory rats is a well-recognized phenomenon which must be considered in any long-term toxicological study (Attia, 1985). The incidence of pituitary tumors is determined by many factors including strain, age, sex, reproductive status, and diet (Berry, 1986). Studies from the National Toxicology Program (NTP) historical database of 2-year-old F344 rats have shown that the incidence of pituitary adenomas was 21.7% and 44% for males and females, respectively. Corresponding figures for carcinomas arising in the adenohypophysis

were 2.4% and 3.5% for males and females, respectively. Numerous hypotheses have been invoked to explain the high incidence of pituitary adenomas in certain inbred rat strains. Both hereditary factors and the levels of circulating sex steroids have been suggested as important etiological mechanisms. The hypothalamus has also been incriminated in the development of these tumors (Azad *et al.*, 1989). Age-related hypothalamic changes may result in diminished activity of dopamine, the major prolactin-inhibitory factor.

Numerous studies have demonstrated the striking degree of strain variation in the incidence of pituitary tumors in rats, which has been reported to range from 10% to more than 90% (van Putten *et al.*, 1988; van Putten and van Zwieten, 1988; Sher *et al.*, 1982; Haseman *et al.*, 1998; Pickering and Pickering, 1984). Particularly high incidences of pituitary adenomas have been reported in Wistar, WAG/Rij, Osborne–Mendel, Long–Evans, Amsterdam, and Columbia-Sherman rats. In the BN/Bi strain, pituitary adenomas have been found in 26% of females and 14% of males. Adenomas were identified in 95% of females and 96% of males in the WAG/Rij strain whereas (WAG/Rij 3 BN) F_1 rats had incidences of 83% for females and 64% for males. Rapid body growth rates and high levels of conversion of feed to body mass in early life or high protein intake in early adult life predispose any strain of rat to the development of pituitary adenomas (Keenan *et al.*, 1994, 1995). In rats fed a low protein diet (less than 12.7% crude protein), the overall tumor incidence, the numbers of multifocal tumors, and the degree of cellular atypia within tumors are significantly lower than in rats fed a standard diet.

Cystoid Degeneration   Cystoid degeneration has been used to describe foci of parenchymal cell loss in the adenohypophysis. Foci of cystoid degeneration (50–150 mm in diameter) have margins composed of normal secretory cells of the pars distalis. Cystoid degeneration also may occur in hyperplastic foci and in neoplasms of the pituitary. The frequency of cystoid degeneration is increased by feeding diets containing diethylstilbestrol to female C3H HeN (MTV+) mice.

Pituitary Hyperplasia and Neoplasia   The separation between focal hyperplasia, adenoma, and carcinoma utilizing histopathological techniques is difficult in the pituitary gland. However, criteria for their separation have been established and should be applied in a consistent manner in the evaluation of proliferative lesions of the pituitary gland (Barsoum *et al.*, 1985; Berkvens *et al.*, 1980). For the specific trophic hormone-secreting cells of the adenohypophysis there appears to be a continuous spectrum of proliferative lesions between diffuse or focal hyperplasia and adenomas derived from a specific population of secretory cells. It appears to be a common feature of endocrine glands that prolonged stimulation of a population of secretory cells predisposes to the subsequent development of a higher than expected incidence of focal hyperplasia and tumors. Long-continued stimulation may lead to the development of clones of cells within the hyperplastic foci that grow more rapidly than the rest and are more susceptible to neoplastic transformation when exposed to the right combination of promoting carcinogens.

Focal ("nodular") hyperplasia in the adenohypophysis appears as multiple small areas that are well demarcated but not encapsulated from adjacent normal cells. Cells in areas of focal hyperplasia closely resemble the cells of origin; however, the cytoplasmic area may be slightly enlarged and the nucleus more hyperchromatic than in the normal cells. Adenomas usually are solitary nodules that are larger than the often multiple areas of focal hyperplasia. They are

sharply demarcated from the adjacent normal pituitary glandular parenchyma and there often is a thin, partial to complete, fibrous capsule. The adjacent parenchyma is compressed to varying degrees depending on the size of the adenoma. Cells composing an adenoma closely resemble the cells of origin morphologically and in their architectural pattern of arrangement.

Carcinomas usually are larger than adenomas in the pituitary and usually result in a macroscopically detectable enlargement. Histopathological features that are suggestive of malignancy include extensive intraglandular invasion, invasion into adjacent structures (e.g., dura mater, sphenoid bone), formation of tumor cell thrombi within vessels, and particularly the establishment of metastases at distant sites. The growth of neoplastic cells subendothelially in highly vascular benign tumors of the pituitary should not be mistaken for vascular invasion. Malignant cells often are more pleomorphic than normal, but nuclear and cellular pleomorphism are not a consistent criterion to distinguish adenoma from carcinoma in the adenohypophysis of rodents.

The vast majority of pituitary adenomas in humans and rodents have been described as chromophobic in type by light microscopy; however, many of these tumors have been found to stain for prolactin by immunohistochemistry. Of the prolactin-producing tumors, most are sparsely granulated with low levels of prolactin immunoreactivity by immunohistochemistry and having small numbers of secretory granules by electron microscopy (McComb *et al.*, 1984,1985; Sandusky *et al.*, 1988). Diffuse hyperplasia of the prolactin cells has been observed adjacent to some adenomas. The development of tumors and hyperplasia of prolactin-secreting cells often is accompanied by increasing serum levels of prolactin. Occasionally, prolactin cells within adenomas may be admixed with FSH/LH-, TSH-, or ACTH-positive cells in the rat pituitary.

ADRENAL CORTEX

Normal Structure and Function

The adrenal cortex is composed of three distinct zones. The outer zone is the zona glomerulosa and is composed of a thin region of columnar cells arranged in an arched or arcuate pattern. This zone is also called the zona multiformis in animals because of its different patterns of arrangement of secretory cells. The zona glomerulosa produces the steroid hormone, aldosterone, which is responsible for increasing sodium reabsorption and stimulating potassium excretion by the kidneys and thereby indirectly regulating extracellular fluid volume. Loss of this zone or the inability to secrete aldosterone may result in death due to retention of high levels of potassium with excess loss of sodium, chloride, and water. The zona fasciculata is the thickest zone (>70% of the cortex) and is composed of columns of secretory cells separated by prominent capillaries. The cells are polyhedral and have many intracellular lipid droplets. This zone produces glucocorticoids. The zona reticularis is also composed of polyhedral cells, whose arrangement is less linear and more as round nests or clumps of cells. The zona reticular produces glucocorticoids and in some species small amounts of sex steroids, namely, androgens, estrogens, and progestins. This zone is more distinct in rats compared to mice.

These are unique anatomical features of the adrenal gland blood supply that are important for its function and development of lesions. The gland is supplied by arterioles that penetrate the capsule, lose their muscular wall, and form a capillary bed that supplies the adrenal cortex. The arterioles that penetrate the capsule have a rapid reduction in lumen diameter and are a common site of embolization of bacteria or tumor cells. The capillaries of the cortex supply blood to the medulla via the cortical–medullary portal blood system. This results in a high concentration of glucocorticoids in the blood supplied to the medulla. Some of the arterioles directly supply the medulla with blood, so the medulla has two sources of blood, namely, cortical capillaries and primary arterioles. Blood leaves the adrenal gland via medullary veins.

Ultrastructural features of the cortical cells can be very useful for their identification. All three zones have prominent mitochondria that can be distinguished by the shape of their cristae. Cells of the zona glomerulosa are characterized by prominent mitochondria and Golgi apparatus, whereas cells of the zona fasciculata have many cytoplasmic lipid droplets, mitochondria with vesicular cristae, and abundant smooth endoplasmic reticulum. The zona reticularis is distinguished by the presence of prominent lysosomes in the cytoplasm.

The adrenal cortex of animals is prone to develop degenerative and proliferative lesions, the etiology of which may be either spontaneous in nature or experimentally induced (Ribelin, 1984). Therefore, testing of xenobiotic chemicals using various laboratory animal species is a valid means of assessing the toxic potential for humans exposed to various xenobiotic chemicals. The choice of test animal species also is critical as a number of studies have demonstrated that there often is a variable species susceptibility to chemical toxicity. This suggests that interspecies differences in metabolism play a role in the development of adrenal cortical toxicity and in the inhibition of steroidogenesis. The age of the test animal, to a lesser degree, can be a factor in the development of chemically induced adrenal cortical lesions.

The adrenal (suprarenal) glands in mammals are flattened bilobed organs located in close proximity to the kidneys. The adrenal glands receive arterial blood from branches of the aorta or from the phrenic, renal, and lumbar arteries resulting in a subcapsular sinusoidal vascular plexus that drains through the cortex into the medulla. The ratio of cortex:medulla is approximately 2:1 in healthy laboratory-reared animals.

The cortex is histologically characterized by defined regions or zones. The cortical zones consist of the zona glomerulosa (multiformis), zona fasciculata, and zona reticularis. The zones are not always clearly delineated, as in the normal rat adrenal cortex. The mineralocorticoid-producing zona glomerulosa (multiformis) (approximately 15% of the cortex) contains cells aligned in a sigmoid pattern in relationship to the capsule. Degeneration of this zone or an interference in the ability to produce mineralocorticoids (namely, aldosterone) results in a life-threatening retention of potassium and hypovolemic shock associated with the excessive urinary loss of sodium, chloride, and water. The largest part of the cortex is the zona fasciculata comprising >70% of the cortical width. Cells in this zone are arranged in long anastomosing columns separated by vascular sinusoids and are responsible for the secretion of glucocorticoid hormones (e.g., corticosterone or cortisol). The innermost portion of the cortex is the zona reticularis (>15% of the cortex), which secretes minute quantities of adrenal sex hormones.

The adrenal cortical cells contain large cytoplasmic lipid droplets which consist of cholesterol and other steroid hormone precursors. The lipid droplets are in close proximity to the smooth endoplasmic reticulum and large mitochondria which contain the specific hydroxylase and dehydrogenase enzyme systems required to synthesize the different steroid hormones. Unlike polypeptide-hormone-secreting cells, there are no secretory granules in the cytoplasm because there is direct secretion without significant storage of preformed steroid hormones.

Steroid-hormone-producing cells of the adrenal cortex synthesize a major parent steroid with one to four additional carbon atoms added to the basic 17-carbon steroid nucleus. Because steroid hormones are not stored in any significant amount, a continued rate of synthesis is required to maintain a normal secretory rate. Once in the circulation, cortisol or corticosterone are bound reversibly to plasma proteins (such as transcortin, albumin). Under normal conditions 10% of the glucocorticoids are in a free unbound state.

Adrenal steroids are synthesized from cholesterol by specific enzyme-catalyzed reactions and involve a complex shuttling of steroid intermediates between mitochondria and endoplasmic reticulum. The specificity of mitochondrial hydroxylation reactions in terms of precursor acted upon and the position of the substrate which is hydroxylated is confined to a specific cytochrome P-450. The common biosynthetic pathway from cholesterol is the formation of pregnenolone, the basic precursor for the three major classes of adrenal steroids. Pregnenolone is formed after two hydroxylation reactions at the carbon 20 and 22 positions of cholesterol and a subsequent cleavage between these two carbon atoms. In the zona fasciculata, pregnenolone is first converted to progesterone by two microsomal enzymes. Three subsequent hydroxylation reactions occur involving, in order, carbon atoms at the 17, 21, and 11 positions. The resulting steroid is cortisol, which is the major glucocorticoid in teleosts, hamsters, dogs, nonhuman primates, and humans. Corticosterone is the major glucocorticoid produced in amphibians, reptiles, birds, rats, mice, and rabbits. It is produced in a manner similar to the production of cortisol, except that progesterone does not undergo 17α-hydroxylation and proceeds directly to 21-hydroxylation and 11β-hydroxylation.

In the zona glomerulosa, pregnenolone is converted to aldosterone by a series of enzyme-catalyzed reactions similar to those involved in cortisol formation; however, the cells of this zone lack the 17α-hydroxylase and thus cannot produce 17α-hydroxyprogesterone which is required to produce cortisol. Therefore, the initial hydroxylation product is corticosterone. Some of the corticosterone is acted on by 18-hydroxylase to form 18-hydroxycorticosterone, which in turn interacts with 18-hydroxysteroid dehydrogenase to form aldosterone. Since 18-hydroxysteroid dehydrogenase is found only in the zona glomerulosa, it is not surprising that only this zone has the capacity to produce aldosterone. In addition to the aforementioned steroid hormones, cells in the zona reticularis also produce small amounts of sex steroids including progesterone, estrogens, and androgens.

The mineralocorticoids (e.g., aldosterone) are the major steroids secreted from the zona glomerulosa under the control of the rennin-angiotensin II system. The mineralocorticoids have their effects on ion transport by epithelial cells, particularly renal cells, resulting in conservation of sodium (chloride and water) and loss of potassium. In the distal convoluted tubule of the mammalian nephron, a cation exchange exists which promotes the resorption of sodium from the glomerular filtrate and the secretion of potassium into the lumen.

Under conditions of decreased blood flow or volume, the enzyme renin is released into the circulation at an increased rate by cells of the juxtaglomerular apparatus of the kidney. Renin release has also been associated with potassium loading or sodium depletion. Renin in the peripheral circulation acts to cleave a plasma globulin precursor (angiotensinogen produced by the liver) to angiotensin-I. An angiotensin-converting enzyme (ACE) subsequently hydrolyzes angiotensin-I to angiotensin-II, which acts as a trophic hormone to stimulate the synthesis and secretion of aldosterone. Under normal conditions negative feedback control to inhibit further renin release is exerted by the elevated levels of angiotensin (principally angiotensin-II) as well as the expanded extracellular fluid volume resulting from the increased electrolyte (sodium and chloride) and water reabsorption by the kidney.

The principal control for the production of glucocorticoids by the zona fasciculata and zona reticularis is exerted by adrenocorticotropin (ACTH), a polypeptide hormone produced by corticotrophs in the adenohypophysis of the pituitary gland. ACTH release is largely controlled by the hypothalamus through the secretion of corticotropin-releasing hormone (CRH). An increase in ACTH production results in an increase in circulating levels of glucocorticoids and under certain conditions also can result in weak stimulation of aldosterone secretion. Negative feedback control normally occurs when the elevated blood levels of cortisol act either on the hypothalamus, anterior pituitary, or both to cause a suppression of ACTH secretion (Rothuizen *et al*., 1991).

Fetal Adrenal Cortex   A specialized fetal adrenal cortex exists in primates during late gestation (Mesiano and Jaffe, 1997). The cortex is composed of large polyhedral cells that produce abundant cortisol and estrogen precursors. The hormones secreted by the cortex are important for normal development of the fetus, and the steroid precursor dihydroepiandrosterone is converted to estrogen by the placenta. The cells of the fetal cortex are produced in the outer cortex and migrate medially, where they undergo hypertrophy and eventually apoptosis. After birth, there is a rapid regression, apoptosis, and lysis of the fetal cortex with dilatation of cortical capillaries and replacement by the typical three cortical zones. It is important not to misinterpret this as a lesion in neonatal primates since it represents physiological replacement of the fetal cortex with the definitive postnatal adrenal cortex.

X-Zone of Adrenal Gland   The X-zone in the mouse adrenal cortex is a similar unique physiologic phenomenon as the fetal cortex in primates. In contrast to the fetal cortex of primates, the X-zone develops postnatally in the inner cortex of mice and is fully formed at weaning. Its function is unknown, but it may be similar to the fetal zone in primates. After weaning, the X-zone degenerates at variable rates, depending on the sex of the mouse. In male mice, the X-zone undergoes degeneration at puberty with accumulation of intracellular fat globules. In unbred females, the zone undergoes slow regression and degeneration during the first pregnancy. As with the fetal zone in primates, it is important not to misinterpret the degeneration associated with regression of the X-zone in mice as a lesion.

Mechanisms of Adrenal Cortical Toxicity

The reason the adrenal cortex is predisposed to the toxic effects of xenobiotic chemicals appears to be related to at least two factors. First, adrenal cortical cells of most animal species contain large stores of lipids used primarily as substrate for steroidogenesis. Many adrenal cortical toxic compounds are lipophilic and therefore can accumulate in these lipid-rich cells. Second, adrenal cortical cells have enzymes capable of metabolizing xenobiotic chemicals, including enzymes of the cytochrome P450 family. Many of these enzymes function in the biosynthesis of endogenous steroids and are localized in membranes of the endoplasmic reticulum or mitochondria. A number of toxic xenobiotic chemicals serve as
Figure 21-5. *Cholesterol metabolism and steroid biosynthesis in adrenocortical and ovarian interstitial cells.*

Cholesterol is the substrate for steroid biosynthesis. Conversion of cholesterol to pregnenolone occurs in the mitochondria and oxidative reactions catalyzed by P450 enzymes occur in the smooth endoplasmic reticulum and mitochondria. Sources of cholesterol include lipoprotein uptake from serum (LDL and HDL), de novo synthesis from acetate via the acetyl coenzyme A pathway, and hydrolysis of cholesteryl ester (CE) by neutral CE hydrolase (nCEH). The storage pool in the form of lipid droplets is derived principally from the conversion of free cholesterol to CE catalyzed by acyl coenzyme A:cholesterol acyltransferase (ACAT). Direct uptake of CE from serum to the storage pool is minimal in the rat. (From Latendresse *et al.*, 1993).

pseudosubstrates for these enzymes and can be metabolized to reactive toxic compounds. These reactive compounds result in direct toxic effects by covalent interactions with cellular macromolecules or through oxygen activation with the generation of free radicals (Colby, 1988; Hinson and Raven, 2006).

Impaired Steroidogenesis Impaired steroidogenesis is an important mechanism of toxicity in the adrenal cortex. It can occur by inhibition of cholesterol biosynthesis or metabolism and by disruption of cytochrome P-450 enzymes. Both these mechanisms will lead to the accumulation of increased cytoplasmic lipid in the form of discrete droplets.

Toxin Activation by CYP-450 Enzymes Toxins may be activated by many of the cytochrome P-450 enzymes in the cortical cells. Activation of toxins can result in the generation of reactive oxygen metabolites, membrane damage, and produce phospholipidosis in the cells.

Exogenous Steroids Exogenous steroids can disrupt normal function and structure of the adrenal cortex. Exogenous agonists will induce negative feedback inhibition of ACTH secretion by the pituitary and will result in atrophy of the zona fasciculata and reticularis. Some steroids, such as the sex steroids, can induce proliferative lesions in the adrenal cortex. Exogenous steroid antagonists will block steroid hormone action, lead to increased ACTH secretion, and diffuse hyperplasia of the cortex.

There is considerable species variation in the response of the adrenal cortex to exogenous chemicals. This is due to both inherent differences in the sensitivity to certain drugs and differences in the metabolic pathways of steroidogenesis. An interesting example is *o,p'*-DDD (Mitotane) which was originally developed to treat metastatic adrenal cortical cancer in humans; however, humans are relatively insensitive to the effects of *o,p'*-DDD, and the drug was not useful in the treatment of adrenal cancer. In contrast, dogs are more sensitive to the effects of *o,p'*-DDD, and it has been used ef-

fectively to treat pituitary-dependent hyperadrenocorticism due to autonomous secretion of ACTH by pituitary (corticotroph) tumors in a dose-dependent manner. *o,p'*-DDD is a selective toxin for the zona fasciculata and reticularis, thereby sparing the important functions of the zona glomerulosa (Vilar and Tullner, 1959).

The zonae reticularis and fasciculata appear to be the principal targets of xenobiotic chemicals in the adrenal cortex. Classes of chemicals known to be toxic for the adrenal cortex include short chain (3 or 4 carbon) aliphatic compounds, lipidosis-inducers, and amphiphilic compounds (Yarrington *et al.*, 1981, 1983, 1985). A variety of other compounds also may affect the medulla. The most potent aliphatic compounds are of 3-carbon length with electronegative groups at both ends. These compounds frequently produce necrosis, particularly in the zonae fasciculata and reticularis. Examples include acrylonitrile, 3-aminopropionitrile, 3-bromopropionitrile, 1-butanethiol, and 1,4-butanedithiol (Szabo *et al.*, 1980). By comparison, lipidosis inducers can cause the accumulations, often coalescing, of neutral fats which may be of sufficient quantity to cause a reduction or loss of organellar function and eventual cell destruction.

Lipidosis-Producing Compounds Cholesterol is the precursor substrate required to synthesize steroid hormones. Steroidogenic cells obtain cholesterol exogenously from serum lipoproteins and endogenously from *de novo* synthesis via the acetyl coenzyme A pathway (Fig. 21-5). The adrenal cortical cells and OI cells in the rat preferentially utilize serum high-density lipoproteins (HDLs) for their primary source of cholesterol and resort to *de novo* synthesis if HDL does not meet the demand of steroidogenesis. This is in contrast to Leydig cells of the testis, which preferentially utilizes *de novo* synthesis of cholesterol and uses an exogenous source only when intracellular synthesis does not meet the demand and the cholesterol pool has been depleted (Payne *et al.*, 1985). Examples of the compounds causing lipidosis include aminoglutethimide, amphenone, and anilines.

Tricresyl phosphate (TCP) and other triaryl phosphates cause a defect in cholesterol metabolism by blocking both the uptake from
Figure 21-6. Pathogenesis of cholesteryl lipidosis in adrenocortical cells and ovarian inter-stitial cells.

The defect in cholesterol metabolism occurs in the uptake from serum and storage pathways. An inhibition of neutral cholesteryl ester hydrolase (nCEH) by a xenobiotic chemical results in the accumulation of CE in the form of lipid droplets in the cytoplasm. Acyl coenzyme A:cholesterol acyltransferase (ACAT) (catalyzes the formation of CE from cholesterol) activity remains near normal levels. (From Latendresse *et al*., 1993).

serum and storage pathways. An inhibition of cytosolic neutral cholesteryl ester hydroxylase (nCEH) by triaryl phosphate (97% inhibition compared to controls) results in the progressive accumulation of cholesteryl ester in the form of lipid droplets in the cytoplasm of adrenal cortical and ovarian interstitial (OI) cells (Fig. 21-6) but not in testicular Leydig cells of rats (Latendresse *et al*., 1993). Acyl coenzyme A: cholesterol acyl transferase (ACAT), an enzyme that esterifies cholesterol to make cholesteryl ester, was depressed only 27% (compared to controls) resulting in elevated intracellular storage of cholesterol in the form of lipid droplets (Fig. 21-7) (Latendresse *et al*., 1994a,b, 1995).

Disruption of Membrane Organellar Membrane Turnover Biologically active cationic amphiphilic compounds produce a generalized phospholipidosis that involves primarily the zonae reticularis and fasciculata and produce microscopic phospholipid-rich inclusions. These compounds affect the functional integrity of lyso-

somes, which appear ultrastructurally to be enlarged and filled with membranous lamellae or myelin figures. Examples of compounds known to induce phospholipidosis include chloroquine, triparanol, and chlorphentermine.

Selective Destruction of Mitochondria and Smooth Endoplasmic Reticulum In addition, there is a miscellaneous group of chemicals that affect hydroxylation and other functions of mitochondrial and microsomal fractions (e.g., smooth endoplasmic reticulum) in the adrenal cortex. Examples of these compounds include *o,p'*-DDD and α-(1,4-dioxido-3-methylquinoxalin-2-yl)-*N*-methylnitrone (DMNM). Other compounds in this miscellaneous category cause their effects by means of cytochrome P-450 metabolism and the production of toxic metabolites. A classic example is the activation of carbon tetrachloride, resulting in lipid peroxidation and covalent binding to cellular macromolecules of the adrenal cortex.
Figure 21-7. The effects of tricresyl phosphate (TCP) and butylated triphenyl phosphate (BTH) on the concentration of cholesteryl ester (CE) and cholesterol in adrenal gland and ovary of rats.

Mean $\pm$ SEM ($n = 8$–9) mg/g wet weight of adrenal gland and ovary. ***Different ($p \leq 0.01$, $p \leq$ 0.05, respectively) from control. (From Latendresse *et al*., 1993).

Studies with o,p'-DDD have shown a dose-dependent mitochondrial degeneration with vacuolization in the zonae fasciculata and reticularis (cortisol- and sex hormone-producing zone) with sparing of the aldosterone-producing zona glomerulosa (multiformis) (Hart *et al.*, 1971). The canine adrenal cortex is unusually sensitive to the cytotoxic effects of o,p'-DDD, which has led to the development of an effective drug (Lysodren or Mitotane) for the medical management of pituitary-dependent hypercortisolism (Cushing's disease). Cessation of weekly maintenance treatment with o,p'-DDD after regression of clinical signs often results in a recrudescence of functional disturbances of cortisol-excess due to chronic ACTH over-stimulation of the adrenal cortex leading to hypertrophy and hyperplasia of the cortisol-producing zones. The canine adrenal cortex is considerably more sensitive to the effects of o,p'-DDD than the adrenal cortices of humans.

Selective Inhibition of Angiotensin Converting Enzyme (ACE)
Drugs such as Captopril, used in the medical management of hypertension, selectively inhibit ACE and result in atrophy of the outer zona glomerulosa (multiformis) in the adrenal cortex. Inhibition of ACE decreases the synthesis of angiotensin II from angiotensin I leading to trophic atrophy of the zona glomerulosa. The decreased production of aldosterone results in decreased renal tubular reabsorption of sodium and chloride, increased serum potassium due to decreased tubular excretion, and decreased tubular reabsorption of water resulting in lower blood volume and pressure.

Selective Inhibition of ACYL-CoenzymeA: Cholesterol ACYL Transferase (ACAT) Compounds that inhibit ACAT often result in degeneration of the zonae fasciculata and reticularis in the adrenal cortex. There is a distinct species sensitivity with dogs > guinea pigs > rabbits > monkeys > rats. It is uncertain whether the mechanism of toxicity is due to a direct cytotoxic effect of the compound or the result of the selective ACAT inhibition (Dominick *et al.*, 1993a,b; Reindel *et al.*; 1994; Junquero *et al.*, 2001; Robertson *et al.*, 2001).

Many of the chemicals that cause morphological changes in the adrenal glands also affect cortical function. Chemically induced changes in adrenal function result either from blockage of the action of adrenocorticoids at peripheral sites or by inhibition of synthesis and/or secretion of hormone. In the first mechanism, many antisteroidal compounds (antagonists) act by competing with or binding to steroid hormone-receptor sites; thereby, either reducing the number of available receptor sites or by altering their binding affinity. Cortexolone (11α-deoxycortisol) an antiglucocorticoid and spironolactone, an antimineralocorticoid, are two examples of peripherally acting adrenal cortical hormone antagonists.

Xenobiotic chemicals affecting adrenal function often do so by altering steroidogenesis and result in histologic and ultrastructural changes in adrenal cortical cells. For example, chemicals causing increased lipid droplets often inhibit the utilization of steroid precursors, including the conversion of cholesterol to pregnenolone. Chemicals that affect the fine structure of mitochondria and smooth endoplasmic reticulum often impair the activity of 11α-, 17α-, and 21α-hydroxylases, respectively, and are associated with lesions primarily in the zonae reticularis and fasciculata. Atrophy of the zona glomerulosa may reflect specific inhibition of aldosterone synthesis or secretion, either directly (e.g., inhibition of 18α- hydroxylation) or indirectly (e.g., suppression of the rennin-angiotensin system II) by chemicals such as spironolactone and captopril.

It is well documented that synthetic and naturally occurring corticosteroids are potent teratogens in laboratory animals. The principal induced defect is cleft lip or palate; however, there is a paucity of information on the direct effect of xenobiotic chemicals on the development of the adrenal cortex. For example, adrenal aplasia occurred in 7.6 of 9.8% of white Danish rabbits when thalidomide was given to their dams.

Pathologic Alterations and Proliferative Lesions in Cortical Cells

Macroscopic lesions of chemically affected adrenal glands are characterized either by enlargement or reduction in size that often is bilateral. Cortical hypertrophy due to impaired steroidogenesis or hyperplasia due to long-term stimulation often is present when the adrenal cortex is increased in size. Small adrenal glands often are indicative of degenerative changes or trophic atrophy of the adrenal cortex. Midsagittal longitudinal sections of adrenal glands under the above conditions will reveal either a disproportionately wider cortex relative to the medulla or vice versa, resulting in an abnormal cortical:medullary ratio. Nodular lesions that distort and enlarge one or both adrenal glands suggest that a neoplasm is present. A single well-demarcated nodular lesion suggests a cortical adenoma whereas widespread incorporation of the entire adrenal gland by a proliferative mass is suggestive of cortical carcinoma, especially if there is evidence of local invasion into periadrenal connective tissues or into adjacent blood vessels and the kidney.

Non-neoplastic lesions of the adrenal cortex induced by xenobiotic chemicals are characterized by changes ranging from acute progressive degeneration to reparative processes such as multifocal hyperplasia. Early degenerative lesions characterized by enlarged cortical cells filled with cytoplasmic vacuoles (often lipid) may result in a diffuse hypertrophy of the cortex. A lesion of this type has been observed in rats treated with an antibacterial compound α-(1,4-dioxido-3-methylquinoxalin-2-yl)-N-methylnitrone (DMNM). This type of vacuolar degeneration is a reflection of impaired steroidogenesis resulting in an accumulation of steroid precursors. More destructive lesions such as hemorrhage and/or necrosis are associated with an inflammatory response in the cortex. If the zona glomerulosa remains functional there will be no life-threatening electrolyte disturbances and no signs of hypoadrenocorticism (Addison's disease). While many chemical agents that affect the adrenal cortex initially involve the zona reticularis and inner zona fasciculata, certain chemicals such as DMNM can cause a progressive degeneration of the entire adrenal cortex. Occasionally, a chemical's effect is limited to a specific zone of the adrenal cortex and may be species specific (Yarrington and Johnston, 1994).

Ultrastructural alterations of adrenal cortical cells associated with chemical injury are quite diverse in nature. The zonae reticularis and fasciculata typically are most severely affected, although eventually the lesions involve the zona glomerulosa. These lesions may be classified as follows: endothelial damage (e.g., acrylonitrile), mitochondrial damage (e.g., DMNM, o, p'-DDD, amphenone), endoplasmic reticulum disruption (e.g., triparanol), lipid aggregation (e.g., aniline), lysosomal phospholipid aggregation (e.g., chlorophentermine), and secondary effects due to embolization by medullary cells (e.g., acrylonitrile). Mitochondrial damage with vacuolization and accompanying changes in the endoplasmic reticulum and autophagocytic responses appear to be among the most common ultrastructural changes observed following chemical injury in the adrenal cortex. Because mitochondria and smooth endoplasmic

reticulum form an intimate subcellular organellar network in cortical cells with important hydroxylases and dehydrogenase enzymes, it is not surprising that many chemical agents altering the ultrastructural morphology of cortical cells inhibit steroidogenesis.

Chemically induced proliferative lesions of the adrenal cortex are less frequently reported and include hyperplasia, adenoma, and carcinoma. Unlike the diffuse cortical hyperplasia/hypertrophy associated with excess ACTH stimulation, chemically induced hyperplasia usually is nodular in type, often multiple in distribution, and composed of increased numbers of normal or vacuolated cortical cells.

A variety of different chemicals are associated with an increased incidence of adrenal cortical neoplasia. Most of the reported tumors tend to be benign (adenomas) although an occasional tumor may be malignant (carcinomas). The zonae reticularis and fasciculata are more prone to develop tumors following chemical injury whereas the zona glomerulosa is spared unless invaded by an expanding tumor in the adjacent zones of the cortex. The tumorigenic agents of the adrenal cortex have a diverse chemical nature and use.

Spontaneous proliferative lesions may be found in all zones of the adrenal cortex but in adult rats are found most frequently in the zona fasciculata. Spontaneous nodular hyperplasia of the adrenal cortex is common in the rabbit, golden hamster, rat, mouse, dog, cat, horse, and baboon. Naturally occurring adrenal cortical tumors are found infrequently in domestic animals, except adult dogs and castrated male goats. However, cortical adenomas and (to a lesser extent) cortical carcinomas have been reported in moderately high incidence in certain strains of laboratory hamsters (e.g., BIO 4.24 and BIO 45.5 strains) and rat (e.g., Osborne–Mendel, WAG/Rij, BUF, and BN/Bi strains). The incidence often increases markedly in rats over 18 months of age. Adrenal cortical neoplasms in mice are uncommon but the incidence may be increased by gonadectomy.

Assessment of Function of the Adrenal Cortex

It may be useful to measure the function of the adrenal cortex. This can be accomplished by measuring glucocorticoid hormone concentrations in the blood or urine (expressed as a ratio to creatinine). It is important to remember the diurnal variations in secretion. Provocative testing is a useful tool to evaluate the functional capacity of the zonae fasciculata and reticularis by measuring the increase in secretion of glucocorticoids in response to exogenous ACTH. Light and electron microscopy and histomorphometry (cortico:medullary ratio and width of different cortical zones) are useful to characterize lesions that may disrupt the function of the cortical cells.

ADRENAL MEDULLA

Normal Structure and Function

The medulla constitutes approximately 10% of the volume of the adrenal gland. In the normal rodent adrenal gland and in most other laboratory animal species the medulla is sharply demarcated from the surrounding cortex. The bulk of the medulla is composed of chromaffin cells, which are the sites of synthesis and storage of the catecholamine hormones (Tischler *et al.*, 1988a). In the rat and mouse, norepinephrine and epinephrine are stored in separate cell types that can be distinguished ultrastructurally after fixation in glutaraldehyde and postfixation in osmium tetroxide. The norepinephrine-containing core of the secretory granules appears electron-dense and is surrounded by a wide submembranous space

whereas epinephrine-containing granules are less dense, have a finely granular core, and a narrow space beneath the limiting membrane. Granules of varying densities may be found in the same cell types in the adrenal medulla of immature rats (Tischler and DeLellis, 1988a). Human adrenal medullary cells may contain both norepinephrine and epinephrine within a single chromaffin cell.

The adrenal medulla contains variable numbers of ganglion cells in addition to chromaffin cells (Reznik *et al.*, 1980). A third cell type has been described in the medulla and designated the small granule-containing (SGC) cell or small intensely fluorescent (SIF) cell. These cells morphologically appear intermediate between chromaffin cells and ganglion cells, and may function as inter-neurons. The adrenal medullary cells also contain serotonin and histamine, but it has not been determined if these products are synthesized in situ or taken up from the circulation. A number of neuropeptides also are present in rat chromaffin cells including enkephalins, neurotensin, and neuropeptide Y.

In the catecholamine biosynthetic pathway, tyrosine is acted on by tyrosine hydroxylase to produce dopa, which is converted to dopamine by dopa decarboxylase. Dopamine in turn, is acted on by dopamine beta-hydroxylase to form norepinephrine, which is converted to epinephrine by phenylethanolamine-*N*-methyltransferase (PNMT). Tyrosine hydroxylase and PNMT are the principal rate limiting steps in catecholamine synthesis. The conversion of tyrosine into dopa and dopamine occurs within the cytosol of chromaffin cells. Dopamine then enters the chromaffin granule where it is converted to norepinephrine. Norepinephrine leaves the granule and is converted into epinephrine in the cytosol and epinephrine re-enters and is stored in the chromaffin granule. In contrast to the synthesis of catecholamines, which occurs in the cytosol, neuropeptides and chromogranin-A proteins are synthesized in the granular endoplasmic reticulum and are packaged into granules in the Golgi apparatus.

Innervation plays an important role in regulating the functions of chromaffin cells. During adult life, stresses such as insulin-induced hypoglycemia or reserpine-induced depletion of catecholamines produces a reflex increase in splanchnic nerve discharge, resulting both in catecholamine secretion and transsynaptic induction of catecholamine biosynthetic enzymes, including tyrosine hydroxylase. These effects become apparent during the first week of life, following an increase in the number of nerve terminals in the adrenal medulla. Other environmental influences including growth factors, extracellular matrix, and a variety of hormonal signals that generate cyclic AMP, may also regulate the function of chromaffin cells.

Mechanisms of Adrenal Medullary Toxicity

Proliferative lesions of the medulla, particularly in the rat, have been reported to develop as a result of a variety of different mechanisms (Rosol *et al.*, 2001; Tischler *et al.*, 1985, 1988b, 1991). Warren *et al.* (1966) studied over 700 pairs of rats with parabiosis and found that more than 50% of male irradiated rats developed adrenal medullary tumors. A relationship exists between adenohypophyseal (anterior pituitary) hormones and the development of adrenal medullary proliferative lesions (Manger *et al.*, 1982). For example, the long-term administration of growth hormone is associated with an increased incidence of pheochromocytomas as well as the development of tumors at other sites. Prolactin-secreting pituitary tumors, which occur commonly in many rat strains, also play a role in the development of proliferative medullary lesions. In addition,
Figure 21-8. Effects of vitamin D₃ on percent of chromaffin cells labeled with BrdU during weeks 4, 8, 12, and 26 of dietary supplementation.

Asterisks indicate statistically significant increases over corn oil controls. Numbers in parenthesis indicate numbers of rats scored for each point. Premature deaths or euthanasia caused loss of three animals from the 20,000 IU/kg/day group, two from the 10,000 IU/kg/day group and one control. Histological examination of these animals' adrenal glands showed no detectable abnormalities. One extra animal at the start of the experiment was assigned to the control group at week 1. At least 2500 chromaffin cells were scored for each rat. (From Tischler *et al.*, 1999).

several neuroleptic compounds that increase prolactin secretion by inhibiting dopamine production have been associated with an increased incidence of proliferative lesions of medullary cells in chronic toxicity studies in rats.

Both nicotine and reserpine have been implicated in the development of adrenal medullary proliferative lesions in rats. Both chemicals act by a shared mechanism since nicotine directly stimulates nicotinic acetylcholine receptors whereas reserpine causes a reflex increase in the activity of cholinergic nerve endings in the adrenal (Tischler *et al.*, 1995). A short dosing regimen of reserpine administration in vivo stimulates proliferation of chromaffin cells in the adult rat and the mechanism may involve a reflex increase in neurogenic stimulation via the splanchnic nerve. Several other drugs have been reported to increase the incidence of adrenal medullary proliferative lesions. These include zomepirac sodium (a nonsteroidal inflammatory drug) (Mosher and Kircher, 1988), isoretinoin (a retinoid), and nafarelin (LHRH analog), atenolol (β-adrenergic blocker), terazosin (α-adrenergic blocker), ribavirin (antiviral), and pamidronate (bisphosphonate) (Davies and Monro, 1995).

Lynch *et al.* (1996) have reported that nutritional factors have an important modulating effect on the spontaneous incidence of adrenal medullary proliferative lesions in rats. Several sugars and sugar alcohols have produced adrenal medullary tumors at high dosages (concentrations of 10–20% in the diet), including xylitol, sorbitol, lacitol, and lactose (Baer, 1988). Although the exact mechanism involved is not completely understood, an important role for calcium has been suggested. High doses of slowly absorbed sugars and starches increase the intestinal absorption and urinary excretion of calcium. Hypercalcemia is known to increase catecholamine synthesis in response to stress, and low-calcium diets will reduce the incidence of adrenal medullary tumors in xylitol-treated rats. Other

compounds that may act by a similar mechanism of altered calcium homeostasis include the retinoids (which produce hypercalcemia) and conditions such as progressive nephrocalcinosis in aging male rats treated with nonsteroidal anti-inflammatory agents.

Roe and Bar (1985) have suggested that environmental and dietary factors may be more important than genetic factors as determinants of the incidence of adrenal medullary proliferative lesions in rats. The incidence of adrenal medullary lesions can be reduced by lowering the carbohydrate content of the diet. Several of the chemicals that increase the incidence of adrenal medullary lesions, including sugar alcohols, increase absorption of calcium from the gut. Calcium ions as well as cyclic nucleotides and prostaglandins may act as mediators capable of stimulating both hormonal secretion and cellular proliferation.

Tischler *et al.* (1996, 1999) presented data that vitamin D is the most potent in vivo stimulus yet identified for chromaffin cell proliferation in the adrenal medulla. Vitamin D₃ (5000, 10,000, or 20,000 IU/kg/day in corn oil) resulted in a four- to fivefold increase in bromodeoxyuridine (BrdU) labeling at week 4 that diminished to a twofold increase by week 26 (Fig. 21-8). An initial preponderance of epinephrine-labeled (PNMT-positive) cells subsequently gave way to norepinephrine-labeled cells. By week 26, 89% of rats receiving the two highest doses of vitamin D₃ had focal medullary proliferative lesions (BrdU-labeled focal hyperplasia, "hot spots") and pheochromocytomas in contrast to absence of proliferative lesions in controls. This increase in medullary cell proliferation was associated with a significant increase in circulating levels of both calcium and phosphorus after vitamin D administration (Fig. 21-9). The nuclei of hyperplastic chromaffin cells were labeled by BrdU but were phenylethanolamine-*N*-methyl transferase-negative indicating that they most likely were norepinephrine-producing cells

Figure 21-9. Effects of vitamin D$_3$ on serum calcium and phosphorus levels at weeks 4, 8, 12, and 26. Sustained perturbation of both Ca^{++} and PO$_4$ concentrations persisted throughout the time course. (From Tischler et al., 1999).

Figure 21-10. Photomicrographs of adrenal medullary sections stained for BrdU (dark nuclei) and PNMT (dark cytoplasm) to compare BrdU labeling of epinephrine (E) and norepinephrine (NE) cells.

Vitamin D$_3$ (20,000 IU/kg/day) caused a dramatic increase in BrdU labeling of predominantly E-cells at week 4. The response was greatly reduced at week 26 and there was no longer an E-cell predominance. A representative hyperplasic nodule in the vitamin D$_3$-stimulated adrenal medulla at week 26 (top left) is densely labeled with BrdU and is PNMT-negative (bar = 100 μm). (From Tischler et al., 1999).

Pathologic Alterations and Proliferative Lesions of Adrenal Medullary Cells

Adrenal Medullary Hyperplasia and Neoplasia   The adrenal medulla undergoes a series of proliferative changes ranging from diffuse hyperplasia to benign and malignant neoplasia. The latter neoplasms have the capacity to invade locally and to metastasize to distant sites. Diffuse hyperplasia is characterized by symmetrical expansion of the medulla with maintenance of the usual sharp demarcation between the cortex and the medulla. The medullary cell cords often are widened, but the ratio of norepinephrine to epinephrine cells is similar to that of normal glands. Focal hyperplastic lesions are often juxtacortical but may occur within any area of the medulla. The small nodules of hyperplasia in general are not associated with compression of the adjacent medulla; however, the larger foci may be associated with limited medullary compression. The foci of adrenal medullary hyperplasia are typically composed of small cells with round to ovoid nuclei and scanty cytoplasm. At the ultrastructural level, the cells composing these focal areas of hyperplasia contain small numbers of dense core secretory granules resembling the granules of SIF or SGC cells (Tischler and DeLellis, 1988b).

Larger benign adrenal medullary proliferative lesions are designated as pheochromocytomas. These lesions may be composed of relatively small cells similar to those found in smaller hyperplastic foci or larger chromaffin cells or a mixture of small and large cells. According to some authors, the lack of a positive chromaffin reaction in these focal proliferative lesions precludes the diagnosis of pheochromocytoma; however, the chromaffin reaction is quite insensitive and catecholamines (particularly norepinephrine) can be demonstrated in these proliferative lesions by biochemical extraction studies and by the formaldehyde- or glyoxylic-acid-induced fluorescence methods. Even in some of the larger medullary lesions, the chromaffin reaction is equivocal but catecholamines can be demonstrated both biochemically and histochemically.

of the rat medulla (Fig. 21-10). The proliferative lesions usually were multicentric, bilateral, peripheral in location in the medulla, nearly all were PNMT negative, and appeared to represent morphologic continuum rather than separate entities. Earlier studies reported by the same research group had demonstrated that the vitamin D$_3$ (20,000, 40,000 IU/kg/day) increase in chromaffin cell proliferation was observed as early as 1 week and had declined by 4 weeks. These findings support the hypothesis that altered calcium homeostasis is involved in the pathogenesis of pheochromocytomas in rodents, most likely through effects on increasing chromaffin cell proliferation (Fig. 21-11). Vitamin D$_3$, calcitrol (active metabolite of D$_3$), lactose, and xylitol all failed to stimulate directly the proliferation of rat chromaffin cells in vitro.

In summary, three dietary factors have been suggested to lead to an increased incidence of adrenal medullary proliferative lesions in chronic toxicity studies in rats (Roe and Bar, 1985). These are (1) excessive intake of food associated with feeding ad libitum; (2) excessive intake of calcium and phosphorus, since commercial diets contain 2–3 times more calcium and phosphorus than needed by young rats; and (3) excessive intake of other food components (e.g., vitamin D and poorly absorbable carbohydrates) which increase calcium absorption.

Figure 21-11. Pathogenesis of adrenal medullary proliferative lesions associated with ingestion of polyols resulting in elevation of the blood calcium concentration. (Modified from Lynch et al., 1996).

Malignant pheochromocytomas invade the adrenal capsule and often grow in the periadrenal connective tissues with or without distant metastases.

Proliferative lesions occur with high frequency in many strains of laboratory rats. The incidence of these lesions varies with strain, age, sex, diet, and exposure to drugs, and a variety of environmental agents (Nyska *et al*., 1999; Roe *et al*., 1995). Studies from the NTP historical database of two-year-old F344 rats have reported that the incidence of pheochromocytomas was 17.0% and 3.1% for males and females, respectively. Malignant pheochromocytomas were detected in 1% of males and 0.5% of females. In addition to F344 rats, other strains with a high incidence of pheochromocytomas include Wistar, NEDH (New England Deaconess Hospital), Long–Evans, and Sprague–Dawley. Pheochromocytomas are considerably less common in Osborne–Mendel, Charles River, Holtzman, and WAG/Rij rats. Most studies have revealed a higher incidence in males than in females (Figs. 21-12 and 21-13). Crossbreeding of animals with high and low frequencies of adrenal medullary proliferative lesions results in F_1 animals with an intermediate tumor frequency. Pheochromocytomas are less common in mice than in most strains of rats.

There is a conspicuous relationship between increasing age and the frequency, size, and bilateral occurrence of adrenal medullary proliferative lesions in the rat. In the Long–Evans strain, medullary nodules have been found in less than 1% of animals under 12 months of age. The frequency increases to almost 20% in 2-year-old animals and to 40% in animals between 2 and 3 years of age. The mean tumor size increases progressively with age as does the frequency of bilateral and multicentric occurrence.

A variety of techniques may be used for the demonstration of catecholamines in tissue sections. The chromaffin reaction is the oxidation of catecholamines by potassium dichromate solutions and results in the formation of a brown-to-yellow pigment in medullary tissue. The chromaffin reaction as traditionally performed possesses a low level of sensitivity and should not be used for the definitive demonstration of the presence of catecholamines in tissues. Similarly, both the argentaffin and argyrophil reactions, which have been used extensively in the past for the demonstration of chromaffin cells, also possess low sensitivity and specificity. Fluorescence techniques using formaldehyde or glyoxylic acid represent the methods of choice for the demonstration of catecholamines at the cellular level. These aldehydesform highly fluorescent derivatives

with catecholamines, which can be visualized by ultraviolet microscopy. Immunohistochemistry provides an alternative approach for the localization of catecholamines in chromaffin cells and other cell types. Antibodies are available that permit epinephrine- and norepinephrine-containing cells to be distinguished in routinely fixed and embedded tissue samples. Several of the important enzymes involved in the biosynthesis of catecholamine hormones also may be demonstrated by immunohistochemical procedures. Antibodies to chromogranin-A can be used for the demonstration of this unique protein in chromaffin cells (Puchacz *et al.*, 1996; Tischer *et al.*, 1990, 1994).

Pheochromocytomas in rats and human beings are both composed of chromaffin cells with variable numbers of hormone-containing secretory granules (Fig. 21-14). The incidence is high in many strains of rats by comparison to human patients where pheochromocytomas are uncommon except in patients with inherited clinical syndromes of multiple endocrine neoplasia (MEN). These tumors in rats usually do not secrete excess amounts of catecholamines whereas human pheochromocytomas episodically secrete increased amounts of catecholamines leading to hypertension

and other clinical disturbances. There appears to be a striking species difference in the response of medullary chromaffin cells to mitogenic stimuli with rats being very sensitive compared to humans (Fig. 21-14).

Tischler and Riseberg (1993) reported that adult rat chromaffin cells had a marked (10–40%) increase in bromodeoxyuridine (BrdU) labeled nuclei in vitro following the addition of the following mitogens: nerve growth factor (NGF), fibroblast growth factor (FGF), forskolin, and phorbol myristate (PMA) whereas human chromaffin cells had a minimal ($<0.1\%$) response to the same mitogens (Fig. 21-15). This striking difference in sensitivity to mitogenic stimuli may explain the lower frequency of adrenal medullary proliferative lesions in humans compared to many rat strains (Tischler and Riseberg, 1993). The mouse adrenal medulla, which like humans has a low spontaneous incidence of proliferative lesions of chromaffin cells, also failed to respond to a variety of mitogenic stimuli (Fig. 21-15). These findings and others suggest that chromaffin cells of the rat represent an inappropriate model to assess the potential effects of xenobiotic chemicals on chromaffin cells of the human adrenal medulla (Lynch *et al.*, 1996).

Chemically Induced Medullary Toxicity

Medullary chromaffin cells in rats are susceptible to acute necrosis and cytolysis by salinomycin, which occurs in less than 10 hours (Chen-Pan *et al.*, 1999). However, the adrenal medulla is capable of replenishing the chromaffin cells in as little as 24 hours by an unknown mechanism. It appears that the adrenal medulla recruits undifferentiated chromaffin cells to repopulate the medulla by a rapid and orderly process of differentiation. Repopulation is not dependent on mitosis. Therefore, chemically induced acute necrosis of the adrenal medulla may be easily overlooked if short experimental time points (<24 hours) were not examined.

Chen-Pan *et al.* (2002), in a subsequent study with salinonycin, found the rapid recovery to be based on differentiation of pre-existing primitive undifferentiated chromaffin cells, rather than by mitosis, due to a lack of 5-bromo-2-deoxyuridine incorporation in the differentiating and/or differentiated chromaffin cells. Schwann cells actively functioned as phagocytes and appeared to indirectly stimulate the differentiation of undifferentiated chromaffin cells. Inflammatory cells were rare with only a few lymphocytes evident inside the clusters of necrotic medullary cells.

THYROID GLAND (FOLLICULAR CELLS)

Normal Structure and Function

The thyroid gland is the largest of the endocrine organs that functions exclusively as an endocrine gland (Capen 2000). The basic histologic structure of the thyroid is unique for endocrine glands, consisting of follicles of varying size (20–250 μm) that contain colloid produced by the follicular cells (thyrocytes). The follicular cells are cuboidal to low columnar (under conditions of normal iodine intake) and their secretory polarity is directed toward the lumen of the follicles. An extensive network of interfollicular capillaries provides the follicular cells with an abundant blood supply. Follicular cells have extensive profiles of rough endoplasmic reticulum and a large Golgi apparatus in their cytoplasm for synthesis and packaging substantial amounts of protein (e.g., thyroglobulin) that are then transported into the follicular lumen. The interface between the luminal side of follicular cells and the colloid is modified by numerous microvillous projections.

The synthesis of thyroid hormones is unique among endocrine glands because the final assembly of hormone occurs extracellularly within the follicular lumen. Essential raw materials, such as iodide ion (I^-), are trapped by follicular cells from plasma, transported rapidly against a concentration gradient to the lumen of the follicle, and oxidized by a peroxidase enzyme in the microvillar membranes to iodine (I_2).

Biosynthesis of Thyroid Hormones   The assembly of thyroid hormones within the follicular lumen is made possible by a unique protein, thyroglobulin, synthesized by follicular cells (Fig. 21-16). Thyroglobulin is a high molecular-weight glycoprotein synthesized in successive subunits on the ribosomes of the endoplasmic reticulum in follicular cells. The constituent amino acids (tyrosine and others) and carbohydrates (mannose, fructose, galactose) are derived from the circulation. Recently synthesized thyroglobulin leaving the Golgi apparatus is packaged into apical vesicles which are extruded into the follicular lumen. The amino acid tyrosine, an essential component of thyroid hormones, is incorporated within the molecular structure of thyroglobulin. Iodine is bound to the tyrosyl residues in thyroglobulin at the apical surface of follicular cells to form successively monoiodotyrosine (MIT) and diiodotyrosine (DIT). These biologically inactive iodothyronines subsequently are coupled together under the influence of the thyroperoxidase to form the two biologically active iodothyronines (thyroxine-T4, triiodothyronine-T3) secreted by the thyroid gland.

The functionally important thyroperoxidase enzyme in the thyroid hormone synthetic pathway is present in the apical plasma membrane and microvilli as well as in other membranous structures of the follicular cells (Tice and Wollman, 1972, 1974). Thyroperoxidase is a membrane-bound, heme-containing glycoprotein composed of 933 amino acids with a transmembrane domain. This important enzyme oxidizes (in the presence of hydrogen peroxidase) iodide ion (I^-) taken up by follicular cells through the function of the sodium-iodide symporter into reactive iodine (I_2), which binds to the tyrosine residues in the thyroglobulin. Iodine is incorporated not
Figure 21-16. Normal thyroid follicular cells illustrating two-way traffic of materials from capillaries into the follicular lumen and from lumen back into interfollicular capillaries.

Raw materials, such as iodine, are concentrated by follicular cells and rapidly transported into the lumen (left). Amino acids (tyrosine and others) and sugars are assembled by follicular cells into thyroglobulin (thg), packaged into apical vesicles (AV), and released into the lumen. The iodination of tyrosyl residues occurs within the thyroglobulin molecule to form thyroid hormones in the follicular lumen. Elongation of microvilli and endocytosis of colloid by follicular cells occurs in response to thyroid-stimulating hormone (TSH) stimulation (right). The intracellular colloid droplets (Co) fuse with lysosomal bodies (Ly), active thyroid hormone is enzymatically cleaved from thyroglobulin, and free tetraiodothyronine (T4) and triiodothyronine (T3) are released into circulation. M, mitochondria; N, nucleus; CHO, carbohydrates; GA, Golgi apparatus; R, receptor; TgB, thyroid-binding globulin; PL, phagolysosome; TTR, transthyretin; ECF, extra cellular fluids; Mf, microfilaments; and Mt, microtubules. (From Capen, 2004).

only into newly synthesized thyroglobulin recently delivered to the follicular lumen but also into molecules already stored in the lumen. Thyroperoxidase also functions as a coupling enzyme to combine MIT and DIT to form triiodothyronine (T$_3$) or two DITs to form thyroxine (T$_4$).

The mechanism of active transport of iodide has been shown to be associated with a sodium-iodide (Na$^+$-I$^-$) symporter (NIS) present in the basolateral membrane of thyroid follicular cells (Fig. 21-17) (LaPerle and Jhiang, 2003). Transport of iodide ion across the thyroid cell membrane is linked to the transport of Na$^+$.
Figure 21-17. The sodium-iodide (NA+-I$^-$) symporter (NIS) and thyroid hormone biosynthesis.

The NIS located in the basolateral membrane of thyroid follicular cells is responsible for the rapid uptake and concentration of iodide ion (I$^-$) from the circulation. The enzyme thyroperoxidase (TPO) in microvilli on the lumenal surface oxidizes I$^-$ in the presence of hydrogen peroxide (H$_2$O$_2$) to reactivate iodine (I$_2$) that subsequently binds to tyrosyl residues in the thyroglobulin (TG) molecule of the colloid. Pendrin is a CI$^-$/I$^-$ transport protein on the apical surface of thyrocytes. AC, adenylate cyclase; CD, colloid droplet; CI-, chlorine ion; G, G protein; I$^-$, iodide ion; R, receptor; T3, triiodothyronine; T4, tetraiodothyronine (thyroxine); and TSH, thyroid-stimulating hormone. (From La Perle *et al.*, 2003.)

The ion gradient generated by the Na$^+$–K$^+$ ATPase appears to be the driving force for the active co-transport of iodide. The transporter protein is present in the basolateral membrane of thyroid follicular cells and is a large protein containing 643 amino acids with 13 transmembrane domains.

Other tissues such as the salivary gland, gastric mucosa, choroid plexus, ciliary body of the eye, and lactating mammary gland also have the capacity to actively transport iodide, albeit at a much lower level than the thyroid (Lacroix *et al.*, 2001). In the salivary glands the NIS protein has been detected in ductal cells but not in acinar cells. Only the thyroid follicular cells accumulate iodide in a TSH-dependent manner.

The NIS gene is complex (15 exons, 14 introns) and its expression in the thyroid is upregulated by TSH. The functionally active iodine transport system in the thyroid gland has important pathophysiologic applications in the evaluation, diagnosis, and treatment of several thyroid disorders, including cancer. The NIS and active transport of iodide can be selectively inhibited by competitive anion inhibitors (e.g., perchlorate, thiocyanate); thereby, effectively blocking the ability of the gland to iodinate tyrosine residues in thyroglobulin and synthesize thyroid hormones.

The ability of NIS to concentrate iodide holds clinical relevance, in addition to its physiological importance, by providing the basis for using radioactive iodine in the treatment and management of various thyroid diseases. Radioactive iodine is commonly used to destroy hyperactive thyrocytes in patients with thyrotoxicosis, to ablate normal and malignant thyroid tissues in patients who have undergone total thyroidectomy for thyroid carcinoma, and to perform whole-body scans for the detection of recurrent and metastatic thyroid cancer.

Iodide ion once within the thyrocyte is passively transported via pendrin into the follicular lumen (Royaux *et al.* 2000; Kohn *et al.* 2001). Pendrin is a ~86 kDa chloride/iodide transport protein, is located at the apical membrane of thyrocytes, and is responsible for the transport of iodide ion into the follicular lumen (Fig. 21-17) (Scott *et al.*, 1999). It is the product of the gene responsible for Pendred syndrome, a genetic disorder in human patients characterized clinically by sensorineural hearing loss and goiter (Everett *et al.*, 1999, 2001; Kopp, 1999; Bidart *et al.*, 2000). Pendrin is characterized by 11 or 12 putative-transmembrane domains and is closely related to a family of sulfate transport proteins; however, pendrin does not transport sulfate and unlike NIS does not require sodium for its transport of iodide.
Figure 21-18. Hypothalamic–pituitary–thyroid axis.

Thyroid-stimulating hormone (TSH) from the pituitary stimulates the secretion of both the tetraiodothyronine (T_4) and triiodothyronine (T_3). These act at the pituitary (PIT) level to control secretion of TSH by a negative-feedback mechanism. In addition, T_4 is converted to T_3 within the pituitary by a monodeiodinase. TSH secretion is stimulated by thryotropin-releasing hormone (TRH) from the hypothalamus and inhibited by somatostatin and, to a lesser extent, by dopamine. Thyroid hormones act at the hypothalamus to stimulate the secretion of somatostatin. T_4 also is deiodinated to T_3 within the hypothalamus, and this conversion may play a role in feedback regulation. (From Reichlin, 1998.)

Thyroid Hormone Secretion   The secretion of thyroid hormones from stores within luminal colloid is initiated by elongation of microvilli on follicular cells and formation of pseudopodia. These elongated cytoplasmic projections are increased by pituitary TSH, extend into the follicular lumen, and indiscriminatingly phagocytize a portion of adjacent colloid (Fig. 21-16). Colloid droplets within follicular cells subsequently fuse with numerous lysosomal bodies that contain proteolytic enzymes (Wollman *et al.*, 1964; Sagartz *et al.*, 1995; Ozaki *et al.*, 1995; Nilsson *et al.*, 1986). Triiodothyronine (T_3) and thyroxine (T_4) are released from the thyroglobulin molecule and because of their hydrophobic nature diffuse out of follicular cells into the adjacent capillaries. The biologically inactive iodotyrosines (MIT, DIT) simultaneously released from the colloid droplets are deiodinated enzymatically and the iodide generated is either recycled to the follicular lumen to iodinate new tyrosyl residues or released into the circulation under normal conditions. Thyroxine is rapidly bound in plasma to albumin and several globulin fractions (especially high-affinity thyroxine-binding globulin [TBG]) produced by the liver, and triiodothyronine is bound to albumin (transthyretin) and one globulin fraction in dogs.

Negative feedback control of thyroid hormone secretion is accomplished by the coordinated response of the adenohypophysis and specific hypothalamic nuclei to circulating levels of thyroid hormones (especially T_3). A decrease in thyroid hormone concentration in plasma is sensed by groups of neurosecretory neurones in the hypothalamus that synthesize and secrete a small peptide (3 amino acids), thyrotropin-releasing hormone (TRH), into the hypophyseal portal circulation. Thyroid-stimulating hormone (TSH) or thyrotropin (TTH) is conveyed to thyroid follicular cells where it binds to the basilar aspect of the cell, activates adenyl cyclase, and increases the rate of biochemical reactions concerned with the synthesis and secretion of thyroid hormones (Wynford-Thomas *et al.*, 1987) (Fig. 21-18).

Biologic Effects of Thyroid Hormones   Thyroxine (T_4) and triiodothyronine (T_3) once released into the circulation act on many different target cells in the body. The overall functions of the hormones are similar though much of the biologic activity is the result of monodeiodination by 5′-deiodinase to 3,5,3′-triiodothyronine (active T_3) prior to interacting with target cells. Under certain conditions (protein starvation, neonatal animals, liver and kidney disease, febrile illness, etc.) or exposure to xenobiotic chemicals, thyroxine is preferentially monodeiodinated by 5′-deiodinase to 3,3′,5′-triiodothyronine ("reverse T3"). Because this form of T_3 is biologically inactive, monodeiodination to form reverse T3 provides a mechanism to attenuate the metabolic effects of thyroid hormones in peripheral tissues.

The overall physiologic effects of thyroid hormones are to: increase the basal metabolic rate; make more glucose available to meet the elevated metabolic demands by increasing glycolysis, gluconeogenesis, and glucose absorption from the intestine; stimulate new protein synthesis; increase lipid metabolism and conversion of cholesterol into bile acids and other substances; activate lipoprotein lipase and increase sensitivity of adipose tissue to lipolysis by other hormones; stimulate the heart rate, cardiac output, and blood flow; increase neural transmission, cerebration, and neuronal development in young animals (Lima *et al.*, 2001).

The subcellular mechanism of action of thyroid hormones resembles that for steroid hormones in that free hormone enters target cells and binds loosely to cytosol-binding proteins (Fig. 21-19). Free triiodothyronine initially binds to receptors on the inner mitochondrial membrane to activate mitochondrial energy metabolism, and subsequently binds to high-affinity nuclear receptors and increases transcription of the genetic message (mRNA) to facilitate new protein synthesis (e.g., structural, enzymatic, and binding proteins).

Thyroid hormone functions in target cells are mediated by three nuclear receptors: T_3R alpha$_1$, T_3R beta$_1$, and T_3R beta$_2$ that are encoded by two genes, namely T_3R alpha and T_3R beta. Thyroid hormones are essential for numerous postnatal developmental processes including growth and neurogenesis. The T_3R alpha gene is widely expressed from early development whereas the T_3R beta gene is highly restricted and expressed later in development (Fraichard *et al.*, 1997). Mice with targeted disruption of the T_3R alpha gene have markedly reduced production of both T_4 and T_3 associated with growth arrest and delayed development of bones and small intestine.

Species Differences in Thyroid Hormone Economy

Long-term perturbations of the pituitary–thyroid axis by various xenobiotics or physiological alterations (e.g., iodine deficiency, partial thyroidectomy, and natural goitrogens in food) are more likely to predispose the laboratory rat to a higher incidence of proliferative lesions (e.g., hyperplasia and benign tumors [adenomas] of follicular
Figure 21-19. Subcellular mechanism of action of thyroid hormones in target cells.

Free triiodothyronine (T_3) primarily enters target cells because most of the tetraiodothyronine (T_4) undergoes monodeiodination in the liver or elsewhere in the periphery to form T_3. In the cell T_3 binds either to cytosolic-binding proteins (CBPs) or to high-affinity receptors on the inner mitochondrial (MT) membrane and activates oxidative phosphorylation in target cells. Binding to nuclear receptors by T_3 increases transcription of messenger RNA, which returns to the cytoplasm to direct the synthesis of new proteins. The increased synthesis of new proteins (structural or enzyme) carries out the multiple biological effects of the thyroid hormones.

cells) in response to chronic TSH stimulation than in the human thyroid (Capen and Martin, 1989; Curran and DeGroot, 1991; Capen, 1997; Zbinden *et al.*, 1988). This is particularly true in the male rat which has higher circulating levels of TSH than in females. The greater sensitivity of the rodent thyroid to derangement by drugs, chemicals, and physiological perturbations also is related to the shorter plasma half-life of thyroxine T_4 in rats than in humans due to the considerable differences in the transport proteins for thyroid hormones between these species (Döhler *et al.*, 1979).

The plasma T_4 half-life in rats is considerably shorter (12–24 hours) than in humans (5–9 days). In human beings and monkeys circulating T_4 is bound primarily to thyroxine-binding globulin (TBG), but this high-affinity binding protein is not present in rodents, birds, amphibians, or fish (Table 21-1).

The binding affinity of TBG for T_4 is approximately one thousand times higher than for prealbumin. The percent of unbound active T_4 is lower in species with high levels of TBG than in animals in which T_4 binding is limited to albumin and prealbumin. Therefore, a rat without a functional thyroid requires about 10 times more T_4 (20 μg/kg body weight) for full substitution than an adult human (2.2 μg/kg body weight). Triiodothyronine (T_3) is transported bound to TBG and albumin in human beings, monkey, and dog but only to albumin in mouse, rat, and chicken (Table 21-2). In general, T_3 is bound less avidly to transport proteins than T_4, resulting in a faster turnover and shorter plasma half-life in most species. These differences in plasma half-life of thyroid hormones and binding to

transport proteins between rats and human beings may be one factor in the greater sensitivity of the rat thyroid to developing hyperplastic and/or neoplastic nodules in response to chronic TSH stimulation.

Thyroid-stimulating hormone levels are higher in male than female rats and castration decreases both the baseline serum TSH and response to thyrotropin-releasing hormone (TRH) injection. Follicular cell height often is higher in male than in female rats in response to the greater circulating TSH levels. The administration of exogenous testosterone to castrated male rats restores the TSH level to that of intact rats. Malignant thyroid tumors (carcinomas or "cancer") develop at a higher incidence following irradiation in males than females (2:1) and castration of irradiated male rats decreases the incidence to that of intact irradiated female rats. Testosterone replacement to castrated male rats restores the incidence of irradiation-induced thyroid carcinomas in proportion to the dose of testosterone and, similarly, serum TSH levels increase proportionally to the dose of replacement hormone. Likewise, higher incidence of follicular cell hyperplasia and neoplasia has been reported in males compared to female rats following the administration of a wide variety of drugs and chemicals in chronic toxicity/carcinogenicity testing.

There are also marked species differences in the sensitivity of the functionally important peroxidase enzyme to inhibition by xenobiotics. Thioamides (e.g., sulfonamides) and other chemicals can selectively inhibit the thyroperoxidase and significantly interfere with the iodination of tyrosyl residues incorporated in the thyroglobulin molecule, thereby, disrupting the orderly synthesis of T_4 and T_3. A number of studies have shown that the long-term administration of sulfonamides results in the development of thyroid nodules frequently in the sensitive species (such as the rat, dog, and mouse)

but not in species resistant (e.g., monkey, guinea pig, chicken, and human beings) to the inhibition of peroxidase in follicular cells.

Mechanisms of Thyroid Follicular Cell Toxicity

Numerous studies have reported that chronic treatment of rodents with goitrogenic compounds results in the development of follicular cell adenomas (Capen, 1996b, 1998, 1999, 2006a; Hard, 1988). Thiouracil and its derivatives have this effect in rats (Napalkov, 1976) and mice (Morris, 1955). This phenomenon has also been observed in rats that consumed brassica seeds (Kennedy and Purves, 1941), erythrosine (FD&C Red No. 3) (Borzelleca *et al.*, 1987; Capen and Martin, 1989), sulfonamides (Swarm *et al.*, 1973), and many other compounds (Paynter *et al.*, 1988; Hill *et al.*, 1989). The pathogenetic mechanism of this phenomenon has been understood for some time (Furth, 1954) and is widely accepted by the scientific community. These goitrogenic agents either directly interfere with thyroid hormone synthesis or secretion in the thyroid gland, increase thyroid hormone catabolism and subsequent excretion into the bile, or disrupt the peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3). The ensuing decrease in circulating thyroid hormone levels results in a compensatory increased secretion of pituitary thyroid-stimulating hormone (TSH) (Hotz *et al.*, 1997). The receptor-mediated TSH stimulation of the thyroid gland leads to proliferative changes of follicular cells that include hypertrophy, hyperplasia, and ultimately, neoplasia in rodents (Hill *et al.*, 1998, 1999; Hurley *et al.*, 1998).

Excessive secretion of TSH alone (i.e., in the absence of any chemical exposure) has also been reported to produce a high incidence of thyroid tumors in rodents (Ohshima and Ward, 1984, 1986). This has been observed in rats fed an iodine-deficient diet (Axelrod and Leblond, 1955) and in mice that received TSH-secreting pituitary tumor transplants (Furth, 1954). The pathogenetic mechanism of thyroid follicular cell tumor development in rodents involves a sustained excessive stimulation of the thyroid gland by TSH. In addition, iodine deficiency is a potent promoter of the development of thyroid tumors in rodents induced by intravenous injection of *N*-methyl-*N*-nitrosourea (Fig. 21-20) (Ohshima and Ward, 1984). The subsequent parts of thyroid section discuss specific mechanisms by which xenobiotic chemicals disrupt thyroid hormone synthesis and secretion, induce hepatic microsomal enzymes that enhance thyroid hormone catabolism or inhibit enzymes involved in monodeiodination in peripheral tissues that result in perturbations of thyroid hormone economy, which in rodents predisposes to the development of follicular cell tumors in chronic studies.

Xenobiotic Chemicals that Directly Inhibit Thyroid Hormone Synthesis

Blockage of Iodine Uptake   The biosynthesis of thyroid hormones is unique among endocrine glands because the final assembly of the hormones occurs extracellularly within the follicular lumen. Essential raw materials, such as iodide, are trapped efficiently at the basilar aspect of follicular cells from interfollicular capillaries, transported rapidly against a concentration gradient to the lumen, and oxidized by a thyroid peroxidase in microvillar membranes to reactive iodine (I_2) (Fig. 21-21). The mechanism of active transport of iodide has been shown to be associated with a sodium-iodide (Na^+-I^-) symporter (NIS) present in the basolateral membrane of thyroid follicular cells. Transport of iodide ion across the thyroid cell membrane is linked to the transport of Na^+. The ion gradient generated by the Na^+-K^+ ATPase appears to be the driving force for the active co-transport of iodide. The transporter protein is present in the basolateral membrane of thyroid follicular cells (thyrocytes) and is a large protein containing 643 amino acids with 13 transmembrane domains.

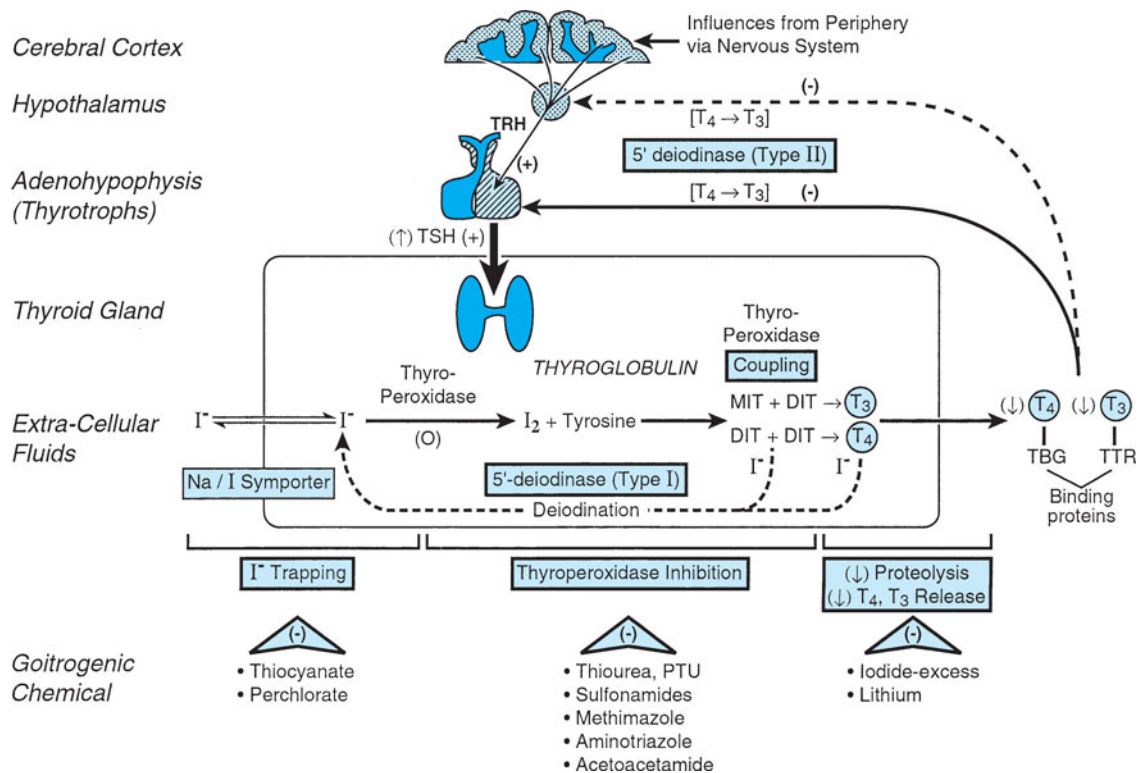
Immunohistochemical staining using a polyclonal antibody against the human NIS fusion protein (hNIS) revealed that expression of the protein is heterogenous in the normal human thyroid and detected only in occasional thyrocytes of a follicle (Jhiang *et al.*, 1998b). The hNIS-positive thyrocytes usually were detected in small


Figure 21-21. Mechanism of action of giotrogenic chemicals on thyroid hormone synthesis and secretion.

Chemicals can interfere with thyroid function either by (a) blocking iodide ion trapping, (b) inhibiting organic binding–coupling, or (c) disrupting proteolysis and release of T_4 and T_3 from colloid. DIT, diiodotyrosine; I_2, reactive iodine; MIT, monoiodotyrosine; PTU, propylthiouracil; T_3, triiodothyronine; T_4, tetraiodothyronine; TBG, thyroxine-binding globulin; TRH, thyrotropin-releasing hormone; and TSH, thyroid-stimulating hormone. (From Capen, 2004a).

follicles composed of cuboidal to columnar cells but rarely were detected in large follicles composed of flattened thyrocytes. The heterogeneity of hNIS expression among thyroid follicles is consistent with the finding that iodide concentrating ability also varies between follicles in the thyroid gland (Spitzweg *et al.*, 2000).

Other tissues such as the salivary gland, gastric mucosa, choroid plexus, ciliary body of the eye, and lactating mammary gland also have the capacity to actively transport iodide, albeit at a much lower level than the thyroid. In the salivary glands the hNIS protein was detected in ductal cells but not in acinar cells. Only the thyroid follicular cells accumulate iodide in a TSH-dependent manner. The NIS gene is complex (15 exons, 14 introns) and its expression in the thyroid is upregulated by TSH. The functionally active iodine transport system in the thyroid gland has important clinical applications in the evaluation, diagnosis, and treatment of several thyroid disorders, including cancer. The NIS and active transport of iodide can be selectively inhibited by competitive anion inhibitors; thereby, effectively blocking the ability of the gland to iodinate tyrosine residues in thyroglobulin and synthesize thyroid hormones.

The initial step in the biosynthesis of thyroid hormones is the uptake of iodide from the circulation and transport against a gradient across follicular cells to the lumen of the follicle. A number of anions act as competitive inhibitors of iodide transport in the thyroid, including perchlorate (ClO_4^-), thiocyanate (SCN^-), and pertechnetate (Fig. 21-21) (Atterwill *et al.*, 1987). Thiocyanate is a potent inhibitor of iodide transport and is a competitive substrate for the thyroid peroxidase but it does not appear to be concentrated in the thyroid. Blockage of the iodide trapping mechanism has a disruptive effect on the thyroid–pituitary axis, similar to iodine deficiency. The blood levels of T_4 and T_3 decrease, resulting in a compensatory increase in the secretion of TSH by the pituitary gland. The hypertrophy and hyperplasia of follicular cells following sustained exposure results in increased thyroid weights and the development of goiter.

Perchlorate from combustion of solid-propelled rocket engines and missiles, and other environmental sources (e.g., explosives, fireworks, road flares, commercial fertilizers, and airbag inflation systems) has contaminated water sources nationwide and more than 11 million people have perchlorate in their public drinking water at concentrations of 4 ppb (4 μg/L). Perchlorate is an ion that can affect thyroid function because it competitively inhibits the transport of iodine into thyroid follicular cells by inhibiting the action of the sodium-iodide symporter (Soldin *et al.*, 2001; Clewell *et al.*, 2004). Exposure to perchlorate in drinking water is a concern due to potential disruption of thyroid function with the development of hypothyroidism at various stages of life and subsequent effects on neurointellectual development (Li *et al.*, 2000; Lamm *et al.*, 1999; Lamm and Doemland, 1999). A normal secretion of thyroid hormones are required for the development and growth of neurones and supporting glial cells, the formation of synapses between neurones, the formation of myelin sheaths surrounding neuronal processes, and the development of neurotransmitters (National Research Council, 2005).

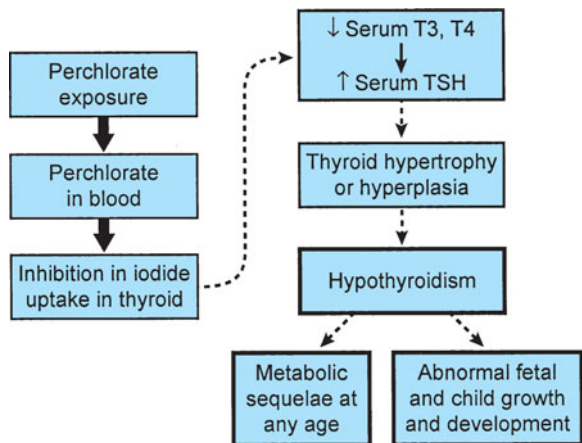
Review of the extensive scientific literature following perchlorate exposure or administration to humans and animals by a National Academy of Sciences committee concluded that the most


Figure 21-22. Suggested mode-of-action model for perchlorate toxicity in humans.

Solid arrows represent outcomes observed in humans during perchlorate exposure. Dashed arrows represent outcomes not clearly demonstrated in humans exposed to perchlorate but biologically plausible in absence of adequate compensation. The thyroid response to increased serum TSH concentrations and the independent increase in thyroid iodide uptake would act to raise T_3 and T_4 production to normal and thus prevent later steps of the model from occurring. (From Health Implications of Perchlorate Ingestion. National Research Council, The National Academic Press, Washington, DC, 2005).

reasonable mode of action pathway of events after perchlorate exposure would be changes in thyroid hormones and TSH secretion followed by thyroid follicular cell hypertrophy and hyperplasia. Hypothyroidism would develop only in people unable to compensate with an increased thyroid iodide uptake (National Research Council, 2005) (Fig. 21-22). Mechanisms exist that permit the body to compensate for decreases in T_4 and T_3 production. The compensatory increase in TSH secretion and thyroidal iodide uptake returns T_4 and T_3 production to normal without causing adverse affects (National Research Council, 2005). Any effects that follow and result from hypothyroidism (e.g., metabolic sequelae at any age such as decreased basal metabolic rate and slowing of function of many organ systems or abnormal growth and development of fetuses and children) clearly would be adverse. The Committee that investigated the health implications of perchlorate ingestion concluded that transient changes in serum thyroid hormones or TSH concentrations are not adverse effects but simply biochemical changes that might precede adverse effects. Based upon clinical studies, occupational and environmental epidemiologic studies, and investigations following the long-term administration of perchlorate to patients with hyperthyroidism, the committee recommended that a perchlorate reference dose (RfD) of 0.0007 μg/kg/day should protect the health of even the most sensitive populations (National Research Council, 2005). This is equivalent to 24.5 ppb concentration of perchlorate in drinking water assuming a body weight of 70 kg, daily water consumption of 2 L and drinking water as the only dietary source of perchlorate (DeGroef *et al.*, 2006). Recent studies in healthy volunteers have reported that 6 months of exposure to perchlorate at doses up to 3 mg/day had no effect on thyroid function including thyroidal iodide uptake as well as serum levels of thyroid hormones, TSH, and thyroglobulin (Braverman *et al.*, 2006).

Sodium chlorate (NaClO$_3$) is another xenobiotic chemical that results in perturbations of thyroid hormone economy, most likely by an inhibition of sodium-iodide symporter, and in chronic stud-
Figure 21-23. Chemicals disrupting thyroid function (decreased synthesis of thyroid hormones) by inhibiting thyroperoxidase.

ies increased the incidence of thyroid follicular cell tumors when administered in drinking water to rats (Hooth *et al.*, 2001). The dose-dependent decrease in serum T4 was greater after 4 than 21 days but on day 90 T4 levels were similar to controls. The significant compensatory increases in serum TSH were greater after 4 and 21 days than at 90 days when only the high dose rats had a very modest increase in circulating levels. This increase in TSH is associated with the administration of NaClO$_3$ resulted in a 13% incidence of thyroid follicular cell adenoma plus carcinoma in males and a 9% incidence in females compared to 2% in controls of both sexes (Hooth *et al.*, 2001).

Inhibition of Thyroid Peroxidase Resulting in an Organification Defect A wide variety of chemicals, drugs, and other xenobiotics affect the second step in thyroid hormone biosynthesis (Fig. 21-21). The stepwise binding of iodide to the tyrosyl residues in thyroglobulin requires oxidation of inorganic iodide (I^2) to molecular (reactive) iodine (I_2) by the thyroid peroxidase present in the luminal aspect (microvillar membranes) of follicular cells and adjacent colloid. Classes of chemicals that inhibit the organification of thyroglobulin include (1) the thionamides (such as thiourea, thiouracil, propylthiouracil, methimazole, carbimazole, and goitrin); (2) aniline derivatives and related compounds (e.g., sulfonamides, paraaminobenzoic acid, paraaminosalicylic acid, and amphenone); (3) substituted phenols (such as resorcinol, phloroglucinol, and 2,4-dihydroxybenzoic acid); and (4) miscellaneous inhibitors (e.g., aminotriazole, tricyanoaminopropene, antipyrine, and its iodinated derivative [iodopyrine]) (Fig. 21-23).

Many of these chemicals exert their action by inhibiting the thyroid peroxidase which results in a disruption both of the iodination of tyrosyl residues in thyroglobulin and also the coupling reaction of iodotyrosines [(e.g., monoiodothyronine (MIT) and diiodothyronine (DIT)] to form iodothyronines (T_3 and T_4) (Fig. 21-24). Propylthiouracil (PTU) has been shown to affect each step in thyroid hormone synthesis beyond iodide transport in rats. The order of susceptibility to the inhibition by PTU is the coupling reaction (most susceptible), iodination of MIT to form DIT, and iodination of tyrosyl residues to form MIT (least susceptible). Thiourea differs from PTU and other thioamides in that it neither inhibits guaiacol oxidation (the standard assay for peroxidase) nor inactivates the thyroid peroxidase in the absence of iodine. Its ability to inhibit organic iodinations is due primarily to the reversible reduction of active I_2 to $2I^-$.

The goitrogenic effects of sulfonamides have been known for more than 50 years, since the reports of the action of sulfaguanidine on the rat thyroid. Sulfamethoxazole and trimethroprim exert a potent goitrogenic effect in rats, resulting in marked decreases in circulating T_3 and T_4, a substantial compensatory increase in TSH,
Figure 21-24. Mechanisms by which xenobiotic chemicals decrease thyroid hormone synthesis by inhibiting thyroperoxidase in follicular cells.

Figure 21-25. Variable species sensitivity of thyroperoxidase inhibition by sulfonamides. (From Takayama et al., 1986).

and increased thyroid weights due to follicular cell hyperplasia. The dog also is a species sensitive to the effects of sulfonamides, resulting in markedly decreased serum T_4 and T_3 levels, hyperplasia of thyrotrophic basophils in the pituitary gland, and increased thyroid weights.

By comparison, the thyroids of monkeys and human beings are resistant to the development of changes that sulfonamides produce in rodents (rats and mice) and the dog. Rhesus monkeys treated for 52 weeks with sulfamethoxazole (doses up to 300 mg/kg/day) with and without trimethroprim had no changes in thyroid weights and the thyroid histology was normal. Takayama *et al*. (1986) compared the effects of PTU and a goitrogenic sulfonamide (sulfamonomethoxine) on the activity of thyroid peroxidase in the rat and monkey using the guaiacol peroxidation assay. The concentration required for a 50% inhibition of the peroxidase enzyme was designated as the inhibition constant$_{50}$ (IC_{50}). When the IC_{50} for PTU was set at 1 for rats it took 50 times the concentration of PTU to produce a comparable inhibition in the monkey. Sulfamonomethoxine was almost as potent as PTU in inhibiting the peroxidase in rats. However, it required about 500 times the concentration of sulfonamide to inhibit the peroxidase in the monkey compared to the rat. Studies such as these with sulfonamides demonstrate distinct species differences between rodents and primates in the response of the thyroid to chemical inhibition of hormone synthesis. It is not surprising that the sensitive species (e.g., rats, mice, and dogs) are much more likely to develop follicular cell hyperplasia and thyroid nodules after long-term exposure to sulfonamides than the resistant species (e.g., subhuman primates, human beings, guinea pigs, and chickens) (Fig. 21-25).

Recent evidence suggests that propylthiouracil (PTU) or feeding a low iodine diet markedly increase thyroid follicular cell proliferation in rats by disrupting the movement of small molecular weight ions and molecules through gap junctions (Kolaja *et al*., 2000). Inhibition of gap-junction intercellular communication (GJIC) prior to induction of cell proliferation has been reported with several tumor promoters and in proliferative diseases. After 14 days of either PTU or a low iodine diet (plus 1% $KClO_4$ in water) serum T_3 and T_4 were decreased to undetectable levels, serum TSH was increased significantly and thyroid follicular cell proliferation was increased nearly threefold. This was accompanied by a 30–35% decrease in GJIC (determined by an ex vivo method with Lucifer-yellow—a small molecular weight [457] fluorescent dye) and a twofold increase in apoptosis in both treated groups. Therefore, inhibition of GJIC by PTU or a low iodine diet may result in increased thyroid follicular cell proliferation, similar to other tissues, possibly by disrupting the passage of regulatory substance(s) through these highly permeable intercellular channels.

A contemporary example of a chemical acting as a thyroperoxidase inhibitor is sulfamethazine (Poirier *et al*., 1999). This is a widely used antibacterial compound in food-producing animals with a current permissible tissue residue level of 100 ppb. Carcinogenicity studies at NCTR reported a significant increase of thyroid tumors in male Fischer 344 rats administered the high dose (2400 ppm) of sulfamethazine (McClain, 1995). The incidence of thyroid tumors was increased in both male and female $B_6C_3F_1$ mice after two years in the high-dose (4800 ppm) group but not in the lower dose groups. Quantitative risk assessment based upon these carcinogenicity findings, using low-dose linear extrapolation, yielded a 1×10^6 lifetime risk of 90 ppb in female rats and 40 ppb in male rats. A consideration of the ratio of intact drug to metabolites further reduced the tissue residue level to 0.4 ppb, which would be unachievable in practice (McClain, 1995).

A number of mechanistic studies have been performed in collaboration with Dr. McClain and others with the objective of developing a database that would support the hypothesis that the thyroid tumors observed in rats and mice from chronic studies were secondary to hormonal imbalances following the administration of high doses of sulfamethazine. In a 4-week mechanistic study, the effects of 10 dose levels (0–12,000 ppm) of sulfamethazine, spanning the range that induced thyroid tumors in rodents, were evaluated on thyroid hormone economy in Sprague–Dawley rats. There was a characteristic log–dose response relationship in all parameters of thyroid function evaluated. There were no significant changes at the six lower doses (20–800 ppm) of sulfamethazine, followed by sharp relatively linear changes at the four higher dose levels (1600–12,000 ppm) in percent decrease of serum T_3 and T_4, increase in serum TSH, and increase in thyroid weight. A similar, nonlinear dose response was present in the morphologic changes of thyroid follicular cells following the feeding of varying levels of sulfamethazine. Follicular cell hypertrophy was observed at lower doses of sulfamethazine than hyperplasia, which was increased only at dose levels of 3300 ppm and above (Fig. 21-26).

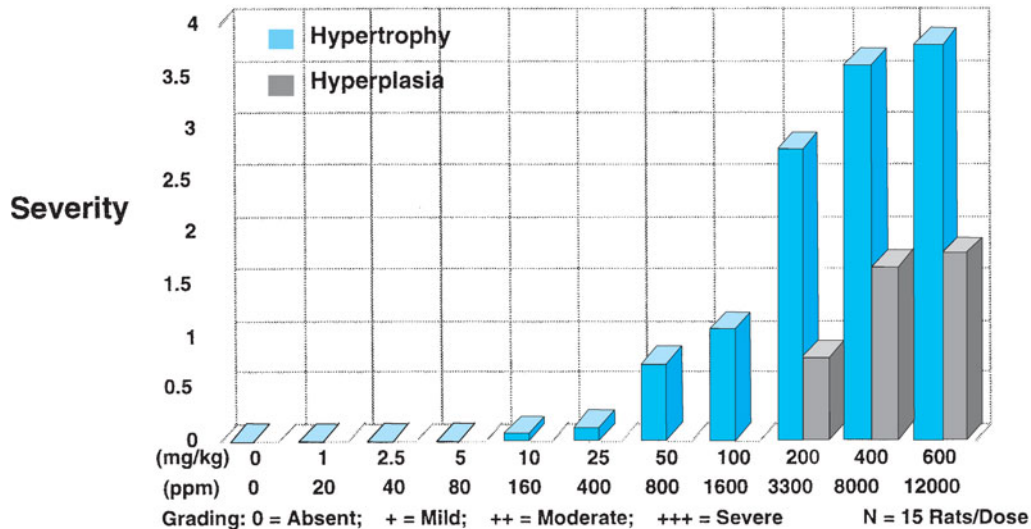
Other mode-of-action studies have demonstrated sulfamethazine to be a potent inhibitor of thyroperoxidase in rodents with an IC_{50} of 1.2×10^{-6} M. The morphologic effects on the thyroid were reversible after withdrawal of compound, and supplemental T_4 in the diet inhibited the development of the functional and morphologic changes in thyroid follicular cells (McClain, 1995). Hypophysectomized rats (with no TSH) administered sulfamethazine did not develop morphologic changes in the thyroid. Sulfamethazine


Figure 21-26. Nonlinear dose–response in morphologic changes in thyroid follicular cells in response to 10 dose levels of sulfamethazine administered in the feed to male Sprague–Dawley rats. (From Capen, 1997).

did not increase thyroid cell proliferation in vitro in the absence of TSH and there was no effect on thyroid structure/function in cynomologous monkeys administered sulfamethazine. Nonhuman primates and human beings are known to be more resistant than rodents to the inhibition of thyroperoxidase.

Xenobiotic Chemicals that Disrupt Thyroid Hormone Secretion

Blockage of Thyroid Hormone Secretion   Relatively few chemicals selectively inhibit the secretion of thyroid hormone from the thyroid gland (Fig. 21-21). An excess of iodine has been known for years to inhibit secretion of thyroid hormone and occasionally can result in goiter and subnormal function (hypothyroidism) in animals and human patients. High doses of iodide have been used therapeutically in the treatment of patients with Grave's disease and hyperthyroidism to lower circulating levels of thyroid hormones. Several mechanisms have been suggested for this effect of high iodide levels on thyroid hormone secretion, including a decrease in lysosomal protease activity (in human glands), inhibition of colloid droplet formation (in mice and rats), and inhibition of TSH-mediated increase in cAMP (in dog thyroid slices). Rats fed an iodide-excessive diet had a hypertrophy of the cytoplasmic area of follicular cells with an accumulation of numerous colloid droplets and lysosomal bodies (Collins and Capen, 1980a; Kanno *et al.*, 1994; Many *et al.*, 1985). However, there was limited evidence ultrastructurally of the fusion of the membranes of these organelles and of the degradation of the colloid necessary for the release of active thyroid hormones (T_4 and T_3) from the thyroglobulin. Circulating levels of T_4, T_3, and rT_3 all would be decreased by an iodide-excess in rats.

Lithium has also been reported to have a striking inhibitory effect on thyroid hormone release (Fig. 21-21). The widespread use of lithium carbonate in the treatment of manic states occasionally results in the development of goiter with either euthyroidism or occasionally hypothyroidism in human patients. Lithium inhibits colloid droplet formation stimulated by cAMP in vitro and inhibits the release of thyroid hormones.

Xenobiotic-Induced Thyroid Pigmentation or Alterations in Colloid

The antibiotic minocycline produces a striking black discoloration of the thyroid lobes in laboratory animals and humans with the formation of brown pigment granules within follicular cells (Ambrogio *et al.*, 1999; Eisen and Hakim, 1998; Tajima *et al.*, 1985). The pigment granules stain similarly to melanin and are best visualized on thyroid sections stained with the Fontana–Masson procedure. Electron-dense material first accumulates in lysosome-like granules and in the rough endoplasmic reticulum. The pigment appears to be a metabolic derivative of minocycline and the administration of the antibiotic at high dose to rats for extended periods may result in a disruption of thyroid function and the development of goiter. The release of T_4 from perfused thyroids of minocycline-treated rats was significantly decreased but the follicular cells retained the ability to phagocytose colloid in response to TSH and had numerous colloid droplets in their cytoplasm.

Other xenobiotics [or metabolite(s)] selectively localize in the thyroid colloid of rodents resulting in abnormal clumping and increased basophilia to the colloid. Brown to black pigment granules may be present in follicular cells, colloid, and macrophages in the interthyroidal tissues resulting in a macroscopic darkening of both thyroid lobes. The physiochemically altered colloid in the lumen of thyroid follicles appears to be less able than normal colloid either of reacting with organic iodine in a step-wise manner to result in the orderly synthesis of iodothyronines or being phagocytized by follicular cells and enzymatically processed to release active thyroid hormones into the circulation. Serum T_4 and T_3 are decreased, serum TSH levels are increased by an expanded population of pituitary thyrotrophs, and thyroid follicular cells undergo hypertrophy and hyperplasia. As would be expected, the incidence of thyroid follicular cell tumors in 2-year carcinogenicity studies is increased at the higher dose levels usually with a greater effect in males than females. Autoradiographic studies often demonstrate tritiated material to be preferentially localized in the colloid and not within follicular cells. Tissue distribution studies with ^{14}C-labelled compound may reveal preferential uptake and persistence in the thyroid gland compared to other tissues. However, thyroperoxidase activity is normal
Figure 21-27. Hepatic microsomal enzyme induction by the chronic administration of xenobiotic chemicals leading to thyroid follicular cell hyperplasia and neoplasia.

and the thyroid's ability to take up radioactive iodine often is increased compared to controls in response to the greater circulating levels of TSH. Similar thyroid changes and/or functional alterations usually do not occur in dogs, monkeys, or humans.

Hepatic Microsomal Enzyme Induction

Hepatic microsomal enzymes play an important role in thyroid hormone economy because glucuronidation is the rate-limiting step in the biliary excretion of T_4 and sulfation primarily by phenol sulfotransferase for the excretion of T_3 (Vansell and Klaassen, 2001, 2002a; Shelby *et al*., 2003; Dunn and Klaassen, 2000). Long-term exposure of rats to a wide variety of different chemicals may induce these enzyme pathways and result in chronic stimulation of the thyroid by disrupting the hypothalamic–pituitary–thyroid axis (Curran and DeGroot, 1991; Vansell and Klaassen, 2002b). The resulting chronic stimulation of the thyroid by increased circulating levels of TSH often results in a greater risk of developing tumors derived from follicular cells in 2-year or lifetime chronic toxicity/carcinogenicity studies with these compounds in rats (Fig. 21-27). Recent studies have suggested that glucuronidation and enhanced biliary excretion of T_3 may be the reason why serum TSH is increased in short-term (7 days) studies with some microsomal enzyme-inducing chemicals (e.g., phenobarbital, pregnenolone-16α-carbonitrile) but is less affected with others (3-methylcholanthrene, PCB). However, microsomal enzyme inducers are more effective in reducing serum T_4 than serum T_3 (Hood and Klaassen, 2000a). Outer-ring deiodinase (ORD) activity, an enzyme involved in the peripheral conversion of T_4 (major secretory product of the thyroid) to T_3, was reduced (not increased as would be expected if this was the mechanism) following the administration of four well-characterized enzyme inducers in rats. Type I ORD was measured in thyroid, kidney, and liver whereas type II ODR was quantified in brown adipose tissue, pituitary gland, and brain (Hood and Klaassen, 2000b).

Xenobiotics that induce liver microsomal enzymes and disrupt thyroid function in rats include CNS-acting drugs (e.g., phenobarbital, benzodiazepines); calcium channel blockers (e.g., nicardipine, bepridil); steroids (spironolactone); retinoids; chlorinated hydrocarbons (e.g., chlordane, DDT, TCDD), polyhalogenated biphenyls (PCB, PBB), among others (Waritz *et al*., 1996). Most of the hepatic microsomal enzyme inducers have no apparent intrinsic carcinogenic activity and produce little or no mutagenicity or DNA damage. Their promoting effect on thyroid tumors usually is greater in rats than in mice, with males more often developing a higher incidence of tumors than females. In certain strains of mice these compounds alter liver cell turnover and promote the development of hepatic tumors from spontaneously initiated hepatocytes.

Phenobarbital has been studied extensively as the prototype for hepatic microsomal inducers that increase a spectrum of cytochrome P-450 isoenzymes (McClain *et al*., 1988). McClain *et al*. (1989) reported that the activity of uridine diphosphate glucuronyltransferase (UDP-GT), the rate-limiting enzyme in T_4 metabolism, is increased in purified hepatic microsomes of male rats when expressed as picomoles/min/mg microsomal protein (1.3-fold) or as total hepatic activity (3-fold). This resulted in a significantly higher cumulative (4-hours) biliary excretion of ^{125}I-T_4 and bile flow than in controls.

Phenobarbital-treated rats develop a characteristic pattern of changes in circulating thyroid hormone levels (McClain *et al*., 1988, 1989). Plasma T_3 and T_4 are markedly decreased after 1 week and remain decreased for 4 weeks. By 8 weeks T_3 levels return to near normal due to compensation by the hypothalamic–pituitary–thyroid axis. Serum TSH values are elevated significantly throughout the first month but often decline after a new steady state is attained. Thyroid weights increase significantly after 2–4 weeks of phenobarbital, reach a maximum increase of 40–50% by 8 weeks, and remain elevated throughout the period of treatment.

McClain *et al*. (1988) in a series of experiments have shown that supplemental administration of thyroxine (at doses that returned the plasma level of TSH to the normal range) blocked the thyroid tumor-promoting effects of phenobarbital and that the promoting effects were directly proportional to the level of plasma TSH in rats. The sustained increase in circulating TSH levels results initially in hypertrophy of follicular cells, followed by hyperplasia, and ultimately places the rat thyroid at greater risk to develop an increased incidence of benign tumors.

Phenobarbital has been reported to be a thyroid gland tumor promoter in a rat initiation–promotion model. Treatment with a nitrosamine followed by phenobarbital has been shown to increase serum TSH concentrations, thyroid gland weights, and the incidence of follicular cell tumors in the thyroid gland (McClain *et al*., 1988, 1989). These effects could be decreased in a dose-related manner by simultaneous treatment with increasing doses of exogenous thyroxine. McClain *et al*. (1989) have demonstrated that rats treated with phenobarbital have a significantly higher cumulative biliary excretion of ^{125}I-thyroxine than controls (Fig. 21-28). Most of the increase in biliary excretion was accounted for by an increase in T_4-glucuronide due to an increased metabolism of thyroxine in phenobarbital-treated rats. This is consistent with enzymatic activity measurements which result in increased hepatic T_4-UDP-glucuronyl transferase activity in phenobarbital-treated rats (Fig. 21-29). Results from these experiments are consistent with the hypothesis that the promotion of thyroid tumors in rats was not a direct effect of phenobarbital on the thyroid gland but rather an indirect effect mediated by TSH secretion from the pituitary secondary to the hepatic microsomal enzyme-induced increase of T_4 excretion in the bile.

The activation of the thyroid gland during the treatment of rodents with substances that stimulate thyroxine catabolism is a well-known phenomenon and has been investigated extensively with phenobarbital and many other compounds (Curran and DeGroot, 1991). It occurs particularly with rodents, first because UDP-glucuronyl transferase can easily be induced in rodent species, and second
Figure 21-28. Cumulative biliary excretion of [125] I-thyroxine (percentage of administered dose) in control and phenobarbital treated rats (100 mg/kg/day in the diet for 4–6 weeks).

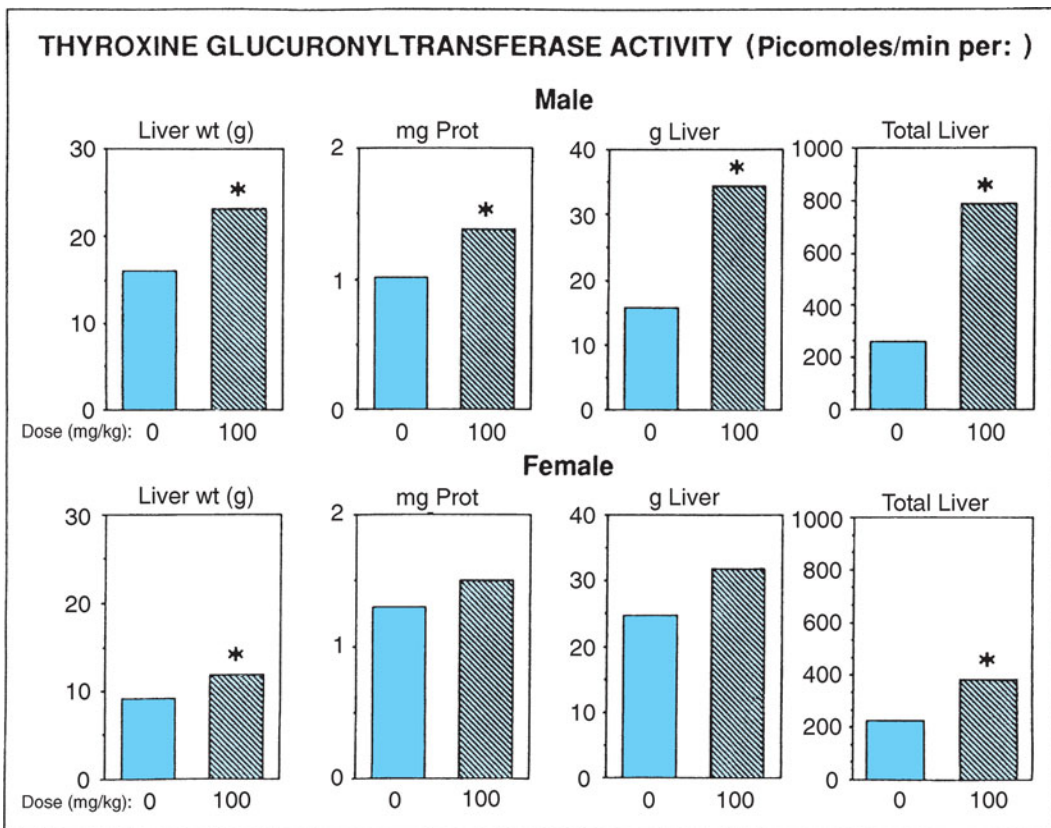
Phenobarbital treatment resulted in an increase in the cumulative excretion of thyroxine over a 4-hour period. Thin layer chromatography of bile samples indicated that most of the increase in biliary excretion was accounted for by an increase in the fraction corresponding to thyroxine-glucuronide. (From McClain, 1998).


Figure 21-29. Hepatic thyroxine glucuronyltransferase activity in control and phenobarbital-treated rats (100 mg/kg/day in the diet for 4 weeks).

Glucuronyltransferase activity was measured in hepatic microsomes using thyroxine as a substrate. Phenobarbital treatment induced thyroxine-glucuronyltransferase in male and female rats; however, the effect in male rats was quantitatively larger. (From McClain, 1998).

because thyroxine metabolism takes place very rapidly in rats in the absence of thyroxine-binding globulin. In humans a lowering of the circulating T_4 level but no change in TSH and T_3 concentrations has been observed only with high doses of very powerful enzyme-inducing compounds, such as rifampicin with and without antipyrine.

Although phenobarbital is the only UDP-glucuronyl transferase (UDP-GT) inducer that has been investigated in detail to act as a thyroid tumor promoter, the effects of other well-known UDP-GT inducers on the disruption of serum T_4 TSH and thyroid gland have been investigated. For example, pregnenolone-16α-carbonitrile (PCN), 3-methylcholanthrene (3MC), and aroclor 1254 (PCB) induce hepatic microsomal UDP-GT activity toward T_4 (Barter and Klaassen, 1992a). These UDP-GT inducers reduce serum T_4 levels in both control as well as in thyroidectomized rats that are infused with T_4, indicating that reductions in serum T_4 levels are not due to a direct effect of the inducers on the thyroid gland (Barter and Klaassen, 1992b, 1994). However, serum TSH levels and the thyroid response to reductions in serum T_4 levels by UDP-GT inducers are not always predictable. While PCN increased serum TSH and resulted in thyroid follicular cell hyperplasia, similar to that observed with phenobarbital, 3MC and PCB in these short-duration experiments and at the dose levels used did not increase serum TSH levels or produce thyroid follicular cell hyperplasia (Hood et al., 1995; Liu et al., 1995). These findings support the overall hypothesis that UDP-GT inducers can adversely affect the thyroid gland by a secondary mechanism, but this applies only to those UDP-GT inducers that increase serum TSH in addition to reducing serum T_4 (Kolaja and Klaassen, 1998).

Additional investigations by this research group demonstrated that hepatic microsomal enzyme-inducing xenobiotic chemicals [e.g., phenobarbital and pregnenolone-16α-carbonitrile (PCN)] increased serum TSH (0–75%) much less than the thyroperoxidase inhibitor propylthiouracil (PTU) (830%) (Hood et al., 1999a,b). Phenobarbital and PCN administration increased thyroid weight approximately 80% compared to a 500% increase in PTU-treated rats. Thyroid follicular cell proliferation (determined by BrdU labeling) was increased 260, 330, and 850% in rats treated with phenobarbital, PCN, and PTU, respectively, for 7 days but the labeling index had returned to control levels by the 45th day of treatment. These findings demonstrate that certain hepatic microsomal enzyme-inducing chemicals that result in mild to modest elevations in serum TSH lead to dramatic increases in thyroid follicular cell proliferation which peaked after 7 days of treatment and then rapidly returned to control values (Klaassen and Hood, 2001). These findings are similar to those of Wynford-Thomas et al. (1982), who reported a maximal proliferative response (evaluated by mitotic index) after 7 days of treatment with aminotriazole (a thyroperoxidase inhibitor). The decline in thyroid follicular cell proliferation was suggested to be due to desensitization of the cells to the mitogenic actions of TSH (Wynford-Thomas et al., 1982a).

Hood et al. (1999) reported that moderate increases in serum TSH of between 10 and 20 ng/mL increased the number of proliferating thyroid follicular cells but had no effect on thyroid weight, emphasizing that small increases in serum TSH can be sufficient to stimulate proliferation. These important findings suggest that quantitation of follicular cell proliferation may be more useful than thyroid weights for assessing alterations in thyroid growth in rats administered xenobiotic chemicals that produce only small to moderate increases in serum TSH.

Another classic example of a chemical that induces hepatic microsomal enzymes and disrupts thyroid function are the polychlorinated biphenyls (Vansell et al., 2004). Polychlorinated biphenyls are commonly used industrial compounds that have been released into the environment and have caused widespread contamination. The disease-producing capability of these compounds includes alterations in reproduction, growth, and development. PCBs cause a significant reduction in serum levels of thyroid hormones due to alterations in thyroid structure, in addition to the well-known induction of hepatic UDP-glucuronyl transferase and increased secretion of thyroxine-glucuronide in the bile (Collins and Capen, 1980b).

Feeding of PCB produced a dose-dependent significant reduction in serum T_4 levels in rats. Following withdrawal of PCB from the diet, blood T_4 levels return to the normal range at 35 weeks but not at 12 weeks. These changes in circulating levels of T_4 were accompanied by a striking hypertrophy and hyperplasia of thyroid follicular cells compared with controls. The most consistent lesions in follicular cells following the feeding of PCB were the accumulation of numerous large colloid droplets and irregularly shaped lysosomal bodies in the expanded cytoplasmic area. Microvilli on the lumenal surface were shortened with abnormal branchings. The chronic administration (12-week) of PCB resulted in a striking distention of many follicular cells with large lysosomal bodies that were strongly acid phosphatase positive and with colloid droplets, blunt and abnormally branched microvilli, and mitochondrial vacuolation. The principal lesion produced by PCB in follicular cells that contributed to the altered thyroid function appeared to be an interference in the interaction between the numerous colloid droplets and lysosomal bodies that is necessary for the enzymatic release of thyroid hormones.

Another recently-investigated example of an inducer of hepatic microsomal enzymes that increase the incidence of thyroid follicular cell tumors in rats is pyrethrins. Pyrethrins comprise a mixture of natural products isolated from Pyrethrum flowers, which have been used for many years as an insecticide for household and other applications. Pyrethrins exhibit a low order of oral toxicity in mammals and are rapidly metabolized. Short-term tests for genotoxic potential have demonstrated that pyrethrins are not genotoxic agents. Pyrethrins were not carcinogenic to male and female CD-1 mice in an 18-month study when administered at dietary levels of 0, 100, 2500, and 5000 ppm (Schoenig, 1995). The treatment of male and female Sprague–Dawley (CD) rats for 2 years with 100 ppm pyrethrins had no effect on tumor incidence. However, higher doses of pyrethrins produced effects in the liver of female rats and in the thyroid glands of both sexes. A small increase in the incidence of hepatocellular adenoma was observed in female rats given 3000 ppm pyrethrins. Although treatment with 1000 ppm pyrethrins had no significant effect on the incidence of thyroid gland follicular cell tumors in female rats, the combined incidence of follicular cell adenomas and/or carcinomas was significantly increased in male rats given 1000 and 3000 ppm pyrethrins and in female rats fed 3000 ppm pyrethrins.

In a subsequent mechanistic study, male Sprague–Dawley (CD) rats were fed diets containing 0 and 8000 ppm pyrethrins and female rats diets containing 0, 100, 3000, and 8000 ppm pyrethrins for periods of 7, 14, and 42 days followed by 42 days reversal (Finch et al., 2006). Rats also were fed diets containing 1200–1558 ppm sodium phenobarbital (NaPb) for 7 and 14 days as a positive control. Treatment of male rats with 8000 ppm pyrethrins, female rats with 3000 and 8000 ppm pyrethrins, and both sexes with NaPb resulted in increased thyroid gland weights
Figure 21-30. Effect of pyrethrins and NaPB on thyroid weights of Sprague–Dawley rats. (From Finch et al., 2006).

Figure 21-31. Effect of pyrethrins and NaPB on thyroid follicular cell labelling index of Sprague–Dawley rats. (From Finch et al., 2006).

(Fig. 21-30) associated with follicular cell hypertrophy. Thyroid follicular cell replicative DNA synthesis was increased by treatment of both males and females with pyrethrins and NaPb for 14 days (Fig. 21-31). Treatment with pyrethrins and NaPb increased serum TSH (Fig. 21-32) and reduced serum levels of T_4 (Fig. 21-33) (Finch et al., 2006).

The treatment of male and female rats with 8000 ppm pyrethrins for 7, 14, and 42 days and 1200–1558 ppm NaPb for 7 and 14 days produced increases in hepatic microsomal cytochrome P450 (CYP) content and a marked induction of CYP2B-dependent 7-pentoxyresorufin O-depentylase and testosterone 16β-hydroxylase activities (Price et al., 2007). Significant increases also were observed in CYP3A-dependent testosterone β-hydroxylase and thyroxine UDP-glucuronosyltransferase activities (Fig. 21-34). Relative potency calculations indicated that NaPb was 8.8 and 3.8X more potent than pyrethrins in inducing CYP2B and CYP3A enzymes in male and female rats, respectively. Hepatic effects of pyrethrins were dose-dependent in female rats (100 ppm being a no effect level) and after the cessation of treatment were reversible in both sexes. The mode of action of pyrethrins-induced rat liver and thyroid tumors appears to be similar to that of other nongenotoxic inducers of hepatic xenobiotic metabolism (Price et al., 2007).

In addition to disturbances in thyroid hormone economy associated with induction of hepatic microsomal enzymes and increased biliary excretion of conjugated thyroid hormones, recent studies have reported xenobiotic chemical-induced rapid hepatobiliary clearance of unconjugated T_4 (Wong et al., 2005). Serum T_4 levels were significantly lowered after 12 hours and were undetectable after
72 hours of administration of a selective corticotrophin-releasing factor (CRF) receptor-1 antagonist to male Sprague–Dawley rats. By comparison propylthiouracil (PTU) (used as a positive control) did not lower serum T4 levels until 72 hours. A significant compensatory increase in serum TSH also was detected after 12 hours with the CRF-1 receptor-1 antagonist compared to after 48 hours with PTU. A decreased mean ^{125}I–T_4 plasma concentration was detected after 1 hour when the first sample was collected and continued to rapidly decrease over a 24-hours period. Phenobarbital (used as a positive control) resulted only in a slight decrease of ^{125}I–T_4 in plasma compared to controls over a similar 24-hours experimental period (Wong et al., 2005). A single oral dose of the compound resulted in a rapid (at 3 hours) significant increase in mRNA for hepatic organic anion transporting protein (Oatp2) that persisted over the 24 hours of the experiment. Other studies have reported that microsomal enzyme inducers can increase the expression of these transporter proteins that mediate the uptake of xenobiotics from blood into the liver (Klaassen and Slitt, 2005). In addition, the CRF receptor-1 antagonist also induced the mRNA's of the multidrug resistance protein-2, a canalicular transporter, that mediates the efflux of compounds from liver into bile (Johnson and Klaassen, 2002a,b; Klaassen, 2002; Wong et al., 2005; Chen and Klaassen, 2004; Chen et al., 2003, 2005; Cheng et al., 2005; Cherrington et al., 2002, 2003; Guo et al., 2002; Maher et al., 2005; Slitt et al., 2006).

Xenobiotic chemical-induced perturbations in thyroid hormone economy are encountered more frequently in rats than in mice. Viollon-Badie et al. (1999) administered four classic hepatic microsomal enzyme-inducing chemicals (e.g., clofibrate [300 mg/kg],
Figure 21-32. *Effect of pyrethins and NaPB on serum TSH in Sprague–Dawley rats. (From Finch et al., 2006).*
Figure 21-33. *Effect of pyrethrins and NaPB on serum thyroxine (T_4) in Sprague–Dawley rats. (From Finch et al., 2006).*

phenobarbital (PB) [80 mg/kg], pregnenolone-16α carbonitrile [PCN] [100 mg/kg], and β-naphthoflavone [80 mg/kg]) to rats and mice and compared the effects on hepatic T_4-UDP-glucuronyl transferase. Rats had a consistent and significant increase in enzyme activity whereas the modest increase in mice was not significant compared to controls. However, Hood *et al*. (2003) clearly demonstrated that B6C3F male mice respond to classic hepatic enzyme inducers (e.g., PB, PCB, PCN, and 3-methylcholanthrene (3-MC)) by increasing liver weight, increased hepatic T4-UDP-glucuronyl transferase activity, decreased serum T_4 (only with PB and PCB), and increased serum TSH (markedly by PCN and 3-MC, only slight by PB and PCB). All four microsomal enzyme inducers dramatically increased thyroid follicular cell proliferation in mice as quantitated by the BrdU-labeling index.

There is no convincing evidence that humans treated with drugs or exposed to chemicals that induce hepatic microsomal enzymes are at increased risk for the development of thyroid cancer (Curran and DeGroot, 1991). In a study on the effects of microsomal enzyme-inducing compounds on thyroid hormone metabolism in normal healthy adults, phenobarbital (100 mg daily for 14 days) did not affect the serum T_4, T_3, or TSH levels (Ohnhaus *et al*., 1981). A decrease in serum T_4 levels was observed after treatment with either a combination of phenobarbital plus rifampicin or a combination of phenobarbital plus antipyrine; however, these treatments had no effect on serum T_3 or TSH levels (Ohnhaus and Studer, 1983). Epidemiological studies of patients treated with therapeutic doses

of phenobarbital have reported no increase in risk for the development of thyroid neoplasia (Clemmesen *et al*., 1974; Clemmesen and Hjalgrim-Jensen, 1977, 1978, 1981; White *et al*., 1979; Friedman, 1981; Shirts *et al*., 1986; Olsen *et al*., 1989). Highly sensitive assays for thyroid and pituitary hormones are readily available in a clinical setting to monitor circulating hormone levels in patients exposed to chemicals potentially disruptive of pituitary–thyroid axis homeostasis.

Likewise, there is no substantive evidence that humans treated with drugs or exposed to chemicals that induce hepatic microsomal enzymes are at increased risk for the development of liver cancer. This is best exemplified by the extensive epidemiological information on the clinical use of phenobarbital. Phenobarbital has been used clinically as an anticonvulsant for more than 80 years. Relatively high microsomal enzyme-inducing doses have been used chronically, sometimes for lifetime exposures, to control seizure activity in human beings. A study of over 8000 patients admitted to a Danish epilepsy center from 1933 to 1962 revealed no evidence for an increased incidence of hepatic tumors in phenobarbital-treated humans when patients receiving thorotrast, a known human liver carcinogen, were excluded (Clemmesen and Hjalgrim-Jensen, 1978). A follow-up report on this patient population confirmed and extended this observation (Clemmesen and Hjalgrim-Jensen, 1981; Olsen *et al*., 1989). The results of two other smaller studies (2099 epileptics and 959 epileptics) also revealed no hepatic tumors in patients treated with phenobarbital (White *et al*., 1979).

Chemical Inhibition of 5′-Monodeiodinase

FD&C Red No. 3 (erythrosine) is an example of a well-characterized xenobiotic that results in perturbations of thyroid function in rodents and in long-term studies is associated with an increased incidence of benign thyroid tumors. Red No. 3 is a widely used color additive in foods, cosmetics, and pharmaceuticals. A chronic toxicity/carcinogenicity study revealed that male Sprague–Dawley rats

fed a 4% dietary concentration of Red No. 3 beginning in utero and extending over their lifetime (30 months) developed a 22% incidence of thyroid adenomas derived from follicular cells compared to 1.5% in control rats and a historical incidence of 1.8% for this strain (Borzelleca *et al.*, 1987; Capen, 1989) (Fig. 21-35). There was no significant increase in follicular cell adenomas in the lower dose groups of male rats or an increase in malignant thyroid follicular cell tumors. Female rats fed similar amounts of the color did not develop a significant increase in either benign or malignant thyroid tumors. Feeding of the color at the high dose (4%) level provided male rats with 2464 mg/kg of Red No. 3 daily; by comparison human consumption in the United States is estimated to be 0.023 mg/kg/day.

The results of mechanistic studies with FD&C Red No. 3 have suggested that a primary (direct) action on the thyroid is unlikely to result from: (1) failure of the color (^{14}C-labeled) to accumulate in the gland, (2) negative genotoxicity and mutagenicity assays, (3) lack of an oncogenic response in mice and gerbils, (4) a failure to promote thyroid tumor development at dietary concentrations of 1.0% or less in male and female rats (Capen, 1989), and (5) no increased tumor development in other organs. Investigations with radiolabeled compound have demonstrated that the color does not accumulate in the thyroid glands of rats following the feeding of either 0.5% or 4.0% FD&C Red No. 3 for 1 week prior to the oral dose of ^{14}C-labeled material.

Mechanistic investigations with FD&C Red No. 3 included, among others, a 60-day study of male Sprague–Dawley rats fed either 4% (high dose) or 0.25% (low dose) Red No. 3 compared to controls, whose food was without the color, in order to determine the effects of the color on thyroid hormone economy. The experimental design of the study was to sacrifice groups of rats ($n = 20$ rats/interval and dose) fed Red No. 3 and their control groups after 0, 3, 7, 10, 14, 21, 30, and 60 days.

A consistent effect of Red No. 3 on thyroid hormone economy was the striking increase in serum reverse T_3 (Fig. 21-36). In the rats fed high doses, reverse T_3 was increased at all intervals compared to controls and this also held for rats killed at 10, 14, and 21 days in the low-dose group. The mechanisms responsible for the increased serum reverse T_3 appear to be, first, substrate (T_4) accumulation due to 5′-monodeiodinase inhibition with subsequent conversion to reverse T_3 rather than active T_3; and, second, reverse T_3 accumulation due to 5′-monodeiodinase inhibition resulting in an inability to degrade reverse T_3 further to diiodothyronine (T_2).

Serum triiodothyronine (T$_3$) was decreased significantly at all intervals in rats of the high-dose group compared to interval controls (Fig. 21-37). The mechanism responsible for the reduced serum T$_3$ following feeding of Red No. 3 was decreased monodeiodination of T$_4$ due to an inhibition of the 5′-monodeiodinase by the color.

Serum TSH was increased significantly at all intervals in rats of the high-dose (4%) group compared to controls. Rats fed 0.25% Red No. 3 had increased serum TSH only at days 21, 30, and 60 (Fig. 21-38). The mechanism responsible for the increased serum TSH following ingestion of Red No. 3 was a compensatory response by the pituitary gland to the low circulating levels of T$_3$ that resulted from an inhibition of the 5′-monodeiodinase. Serum T$_4$ also was increased at all intervals in rats fed 4% Red No. 3 compared to controls (Fig. 21-39). The mechanism responsible for the increased serum T$_4$

was, first, accumulation due to an inability to monodeiodinate T$_4$ to T$_3$ in the liver and kidney from the inhibition of 5′-monodeiodinase by the color; and, second, TSH stimulation of increased T$_4$ production by the thyroid gland.

[125]I-labeled T$_4$ metabolism was altered in liver homogenates prepared from rats fed 4% FD&C Red No. 3. Degradation of labeled T$_4$ was decreased to approximately 40% of the values in control homogenates (Fig. 21-40). This was associated with a 75% decrease in percent generation of ^{125}I and an approximately 80% decrease in percent generation of ^{125}I-labeled T$_3$ from radiolabeled T$_4$ substrate. These mechanistic investigations suggested that the color results in a perturbation of thyroid hormone economy in rodents by inhibiting the 5′-monodeiodinase in the liver, resulting in long-term stimulation of follicular cells by TSH, which over their lifetime predisposed to an increased incidence of thyroid tumors (Borzelleca *et al.*, 1987; Capen and Martin, 1989). The color tested negative in

standard genotoxic and mutagenic assays, and it did not increase the incidence of tumors in other organs.

Morphometric evaluation was performed on thyroid glands from all rats at each interval during the 60-day study. Four levels of exposure of rat thyroid to Red No. 3 were evaluated, with 25 measurements from each rat. The direct measurements included the diameter of thyroid follicles, area of follicular colloid, and height of follicular cells. Thyroid follicular diameter was decreased significantly in both low- and high-dose groups at 3, 7, 10, and 14 days compared to interval controls. The area of follicular colloid generally reflected the decrease in thyroid follicular diameter and was decreased significantly at days 3 and 10 in high-dose rats and days 7 and 10 in the low-dose group compared to interval controls. These reductions in thyroid follicular diameter and colloid area were consistent with morphological changes expected in response to an increased serum TSH concentration.

Thyroid follicular height was increased significantly only after feeding FD&C Red No. 3 for 60 days in both the high- and low-dose groups compared to interval controls. The absence of morphometric evidence of follicular cell hypertrophy at the shorter intervals was consistent with the modest increase (15.8%) in thyroid gland:body weight ratio after this relatively short exposure to the color. The lack of follicular cell hypertrophy at the shorter intervals of feeding Red No. 3 in rats with severalfold elevations in serum TSH levels may be related, in part, to the high iodine content (58% of molecular weight) interfering with the receptor-mediated response of thyroid follicular cells to TSH. The thyroid responsiveness to TSH is known to vary inversely with iodine content (Ingbar, 1972; Lamas and Ingbar, 1978). Thyroid glands of rats fed FD&C Red No. 3 would be exposed to an increased iodine concentration primarily from sodium iodide contamination of the color and, to a lesser extent, from metabolism of the compound and release of iodide.

Secondary Mechanisms of Thyroid Tumorigenesis and Risk Assessment

Understanding the mechanism of action of xenobiotics on the thyroid gland provides a rational basis for extrapolation findings from long-term rodent studies to the assessment of a particular compound's safety for humans (McClain, 1994). Many chemicals and drugs disrupt one or more steps in the synthesis and secretion of thyroid hormones, resulting in subnormal levels of T_4 and T_3, associated with a compensatory increased secretion of pituitary TSH (Fig. 21-41). When tested in highly sensitive species, such as rats and mice, early on these compounds resulted in follicular cell hypertrophy/hyperplasia and increased thyroid weights, and in long-term studies they produced an increased incidence of thyroid tumors by a secondary (indirect) mechanism associated with hormonal inbalances.

Review of the U.S. *Physicians' Desk Reference* (PDR) reveals a number of marketed drugs that result in a thyroid tumorigenic response when tested at high concentrations in rodents, primarily in rats. A broad spectrum of product classes are represented including antibiotics, calcium-channel blockers, antidepressants, hypolipidemic agents, amongst others (Fig. 21-42). Amiodarone (an antiarrhythmic drug) and iodinated glycerol (an expectorant) are highly iodinated molecules that disrupt thyroid hormone economy by mechanisms similar to the food color, FD&C Red No. 3 (Fig. 21-43).

In the secondary mechanism of thyroid oncogenesis in rodents, the specific xenobiotic chemical or physiological perturbation evokes another stimulus (e.g., chronic hypersecretion of TSH) that promotes the development of nodular proliferative lesions (initially hypertrophy, followed by hyperplasia, subsequently adenomas, infrequently carcinomas) derived from follicular cells (Hiasa *et al.*, 1987). Thresholds for "no effect" on the thyroid gland can be established by determining the dose of xenobiotic that fails to elicit an elevation in the circulating level of TSH. Compounds acting by this indirect (secondary) mechanism with hormonal imbalances usually show little or no evidence for mutagenicity or for producing DNA damage.

In human patients who have marked changes in thyroid function and elevated TSH levels, as is common in areas with a high incidence of endemic goiter due to iodine deficiency, there is little if any increase in the incidence of thyroid cancer (Doniach, 1970; Curran and DeGroot, 1991). The relative resistance to the development of thyroid cancer in humans with elevated plasma TSH levels is in marked contrast to the response of the thyroid gland to chronic TSH stimulation in rats and mice. The human thyroid is much less sensitive to this pathogenetic phenomenon than rodents (McClain *et al.*, 1989).

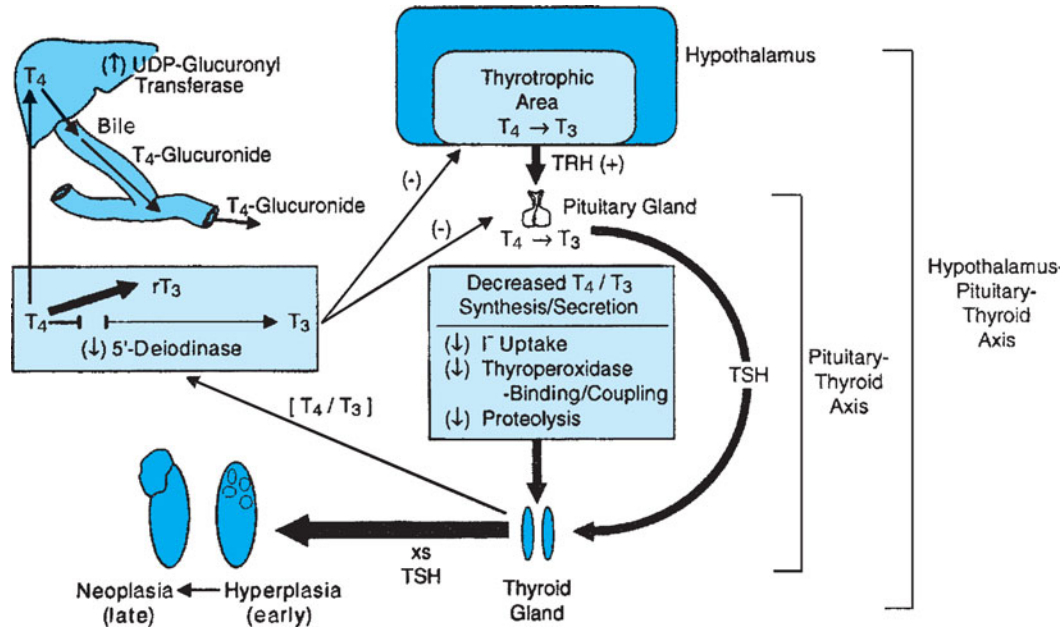
Human patients with congenital defects in thyroid hormone synthesis (dyshormonogenetic goiter) and markedly increased circulating TSH levels have been reported to have an increased incidence of thyroid carcinomas (McGirr *et al.*, 1959; Cooper *et al.*, 1981). Likewise, thyrotoxic patients with Grave's disease, in which follicular cells are autonomously stimulated by an immunoglobulin (long-acting thyroid stimulator, or LATS) also appear to be at greater risk of developing thyroid tumors (Clements, 1954; Pendergrast *et al.*, 1961). Therefore, the literature suggests that prolonged stimulation of the human thyroid by TSH will induce neoplasia only in exceptional circumstances, possibly by acting together with some other metabolic or immunologic abnormality (Curran and DeGroot, 1991).


Figure 21-41. *Multiple sites of disruption of the hypothalamic–pituitary–thyroid axis by xenobiotic chemicals.*

Chemicals can exert direct effects by disrupting thyroid hormone synthesis or secretion and indirectly influence the thyroid through an inhibition of 5′-deiodinase or by inducing hepatic microsomal enzymes (e.g., T_4-UDP glucuronyltransferase). All of these mechanisms can lower circulating levels of thyroid hormones (T_4 and/or T_3), resulting in a release from negative-feedback inhibition and increased secretion of thyroid-stimulating hormone (TSH) by the pituitary gland. The chronic hypersecretion of TSH predisposes the sensitive rodent thyroid gland to develop an increased incidence of focal hyperplastic and neoplastic lesions (adenomas) by a secondary (epigenetic) mechanism.

Initiating Chemicals in Thyroid Carcinogenesis

In contrast to the previous categories of indirect-acting thyrotoxic compounds, certain chemicals and irradiation appear to have a direct effect on the thyroid gland resulting in genetic damage that leads to cell transformation and tumor formation in animals (Doniach, 1963; Lee *et al*., 1982; Capen *et al*., 1999). Examples of thyroid initiators include 2-acetylaminofluorine (2-AAF), *N*-methyl-*N*-nitrosourea [MNU], *N*-bis(2-hydroxypropyl) nitrosamine [DHPN], methylcholanthrene, dichlorobenzidine, and polycyclic hydrocarbons. Chemicals in this group often increase the incidence of both benign and malignant thyroid tumors. Iodine deficiency is a strong promoter of MNU-initiated thyroid tumors in rats.

Thyroid Tumors in Humans

Thyroid carcinomas are the most common endocrine neoplasms in humans, affecting approximately 1% of the population (Sherman, 2003). Roughly 95% of all thyroid tumors are of thyroid follicular epithelial cell origin, including papillary, follicular, and anaplastic thyroid carcinomas. The remaining 5% are medullary thyroid carcinomas of C-cell origin (Cho *et al*., 1999; Sherman, 2003). The subclassification of thyroid cancers into these four categories is clinically significant. Papillary thyroid carcinomas metastasize via lymphatics to local lymph nodes in an estimated 50% of cases but have the most favorable prognosis, with a 98% 10-year survival rate. Follicular carcinomas are associated with poorer prognoses. Follicular thyroid carcinomas are more prevalent in areas of dietary iodine deficiency, metastasize hematogenously, and are less likely than papillary thyroid carcinomas to take up radioactive iodide for imaging and therapeutic ablation. However, the 10-year survival rate for follicular thyroid carcinomas is still high at 92%. Anaplastic thyroid carcinomas are almost invariably fatal due to rapid invasion of critical structures in the neck, distant metastases, and a failure to take up radioactive iodide.

Medullary thyroid carcinomas, also commonly known as C-cell carcinomas, arise from calcitonin-secreting C-cells and are associated with inherited syndromes, such as multiple endocrine neoplasia (MEN), in approximately 20–25% of cases (Cho *et al*., 1999; Sherman, 2003). Medullary carcinomas frequently metastasize via the bloodstream, in addition to lymphatic spread, and are treated with surgical resection and/or external beam radiation. In contrast to follicular origin thyroid tumors, C-cells and tumors arising from them do not have the ability to take up radioactive iodide. The five-year survival rate for medullary thyroid carcinomas is approximately 50%.

Genetic Events in Thyroid Tumors of Follicular Cell Origin
Thyroid follicular cells are responsible for iodide uptake and thyroid hormone synthesis and can undergo neoplastic transformation to carcinomas of three histotypes: papillary, follicular, and anaplastic. It is well known that papillary thyroid carcinomas can occur secondary to ionizing radiation exposure, particularly in children (Sherman, 2003; Boice, 2005). After the Chernobyl nuclear reactor accident in 1986, the incidence of thyroid carcinomas in children in affected areas of Belarus increased from less than one per million to more than 90 per million (Cardis *et al*., 2005). The primary known molecular mechanism of radiation-induced papillary carcinoma development is through the Ret/PTC group of oncogenes. *Ret* proto-oncogene is a receptor tyrosine kinase normally involved in the glial-derived neurotropic factor signaling pathway in neuroendocrine and neural cells. In thyroid follicular cells, the alignment of chromosomes during interphase places the *ret* proto-oncogene in close proximity to several other constitutively expressed genes with which it can recombine during repair of ionizing radiation-induced double-stranded DNA breaks (Nikiforov, 2002, 2000). These Ret/PTC rearrangements allow for unregulated expression of chimeric oncoproteins with constitutive tyrosine kinase activity. Ret/PTC expression is found in roughly one-third of all papillary carcinomas, but in the majority of all radiation-induced papillary carcinomas (Klugbauer *et al*., 1995). Whereas Ret/PTC1-expressing papillary carcinomas are often well differentiated, Ret/PTC3 expression is associated with a solid phenotype and a more aggressive clinical course (Nikiforov, 2002; Williams *et al*., 2004).

Sporadic papillary thyroid carcinomas unrelated to radiation exposure make up more than two-thirds of all cases, and several genetic events have been identified as important in their tumorigenesis (Nikiforov, 2004). A form of the B-type Raf kinase, or BRAF, with a point mutation resulting in V600E has been identified in approximately 45% of sporadic papillary carcinomas, particularly the tall-cell variant (Xing, 2005). BRAF expression has been associated with dedifferentiation and disease progression. NTRK1 is a receptor tyrosine kinase normally involved in nerve growth factor signaling (Tallini, 2002). Like Ret/PTC rearrangements, NTRK1 can recombine with the 5' end of other heterologous genes and form a constitutively active oncogene, such as TRK-T1, leading to papillary carcinomas. However, NTRK1 rearrangements are less frequent than Ret/PTC rearrangements and are not associated with radiation exposure.

Genetically Engineered Mouse Models of Thyroid Cancer

Genetically engineered mouse models of thyroid cancer facilitate analysis of the roles of specific genetic mutations in thyroid tumorigenesis (Jhiang *et al*., 1996, 1998b; Sagartz *et al*., 1997; Capen and Sagartz, 1998). Because thyroid cancer truly encompasses several diseases with different etiologies and relevant genetic mutations, no single transgenic mouse model of thyroid cancer can fully recapitulate the full spectrum of disease. However, several models have successfully reproduced various aspects and have offered insight into genetic mutations underlying thyroid tumorigenesis. These mouse models of thyroid cancer offer examples of positive genotype–phenotype correlation (Knostman *et al*., 2007) (Table 21-3).

Over the past decade, several genetically engineered mouse models of thyroid cancer have been utilized to replicate variants of the human disease (Table 21-3). In most cases, transgenic mice have been produced using the highly active bovine thyroglobulin (Tg) promoter to specifically target transgene expression to thyroid follicular cells or using the human or rat calcitonin/calcitonin gene-related peptide (CGRP) promoter to target transgene expression to C-cells. In some cases, tumor suppressor gene knockout mice have been created and cross-bred with transgenic mice expressing thyroid-specific oncogenes, resulting in increased tumorigenesis and/or an aggressive phenotype. Transgenic mice expressing Ret/PTC1, Ret/PTC3 Trk-T1, BRAF or ras offer a reasonable approximation of the features of papillary thyroid carcinomas in humans. However, even with a p53 knock-out, no model has been able to demonstrate significant tumor dedifferentiation or metastasis (LaPerle *et al*., 2000). One limitation has been the fact that p53 knockout mice develop extrathyroidal neoplasms at a high rate,

Table 21-3

Comparison of Human Thyroid Tumors and Genetically Engineered Mouse Models of Thyroid Cancer with Similar Genetic Mutations

GENETIC ALTERATION	TUMOR MORPHOLOGY		BIOLOGIC BEHAVIOR		HORMONAL DERANGEMENT	
	HUMAN	MOUSE	HUMAN	MOUSE	HUMAN	MOUSE
Ret/PTC1	Typical PTC	Typical PTC	Frequent local invasion, regional lymph node and less common distant metastases	Local invasion without any metastasis	None typical	Hypothyroidism
Ret/PTC3	Typical to solid PTC	Typical to solid PTC	Frequent local invasion, regional lymph node and less common distant metastases	Local invasion with rare lymph node metastases	None typical	NR
BRAF^{V600E}	Tall-cell variant or typical PTC with necrosis and anaplasia	Tall-cell variant or typical PTC with foci of anaplasia	Very frequent local invasion and anaplasia; loss of differentiation markers	Local invasion and anaplasia; maintenance of thyroglobulin expression	None typical	High TSH euthyroid
TRK	Typical PTC	PTC with absence of characteristic nuclear abnormalities	Local invasion, regional lymph node and less common distant metastases	Invasion not reported; absence of metastases	None typical	None
ras	FTC or follicular variant PTC	Typical PTC	Local invasion, regional lymph node, and/or hematogenous metastases	Local invasion with rare lung metastases	None typical	None
p53 inactivation/loss	ATC	Increased anaplasia, invasion and metastases in Ret/PTC models of PTC (p53 not examined alone)	Rapid local invasion and metastases with loss of differentiation markers	Local invasion with rare metastases and early death	None typical	Hypothyroidism (in combination with Ret/PTC transgene expression)

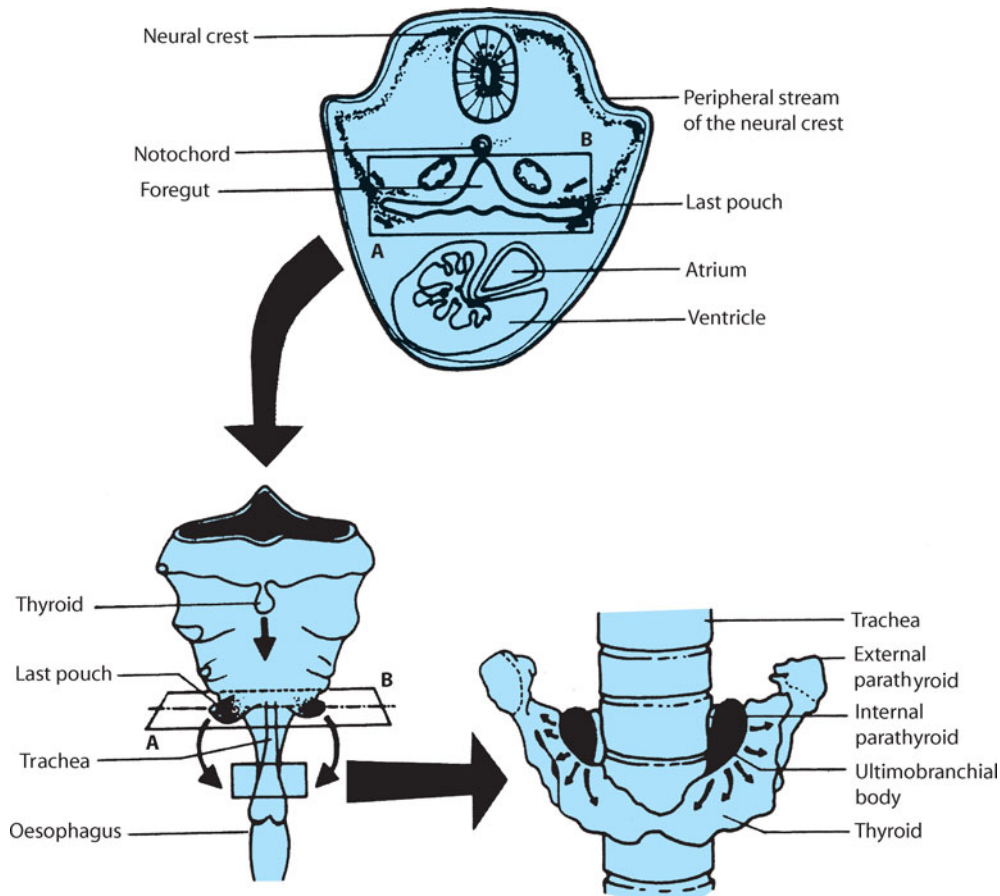

Figure 21-44. Schematic representation of neural crest origin of calcitonin-secreting C-cells.

Primordial cells arising from neural crest migrate ventrally during embryonic life to become incorporated in the last (ultimobranchial) pharyngeal pouch. The ultimobranchial body fuses with primordia of the thyroid and distributes C-cells to varying degrees throughout the mammalian thyroid gland. (From Foster *et al.*, 1972).

resulting in a shortened life span. A tissue-specific p53 knockout would help to eliminate this problem and allow the mice to live long enough to potentially develop more advanced thyroid cancer (Knostman *et al.*, 2007).

Follicular thyroid carcinoma has been primarily investigated using a single mouse model, $TR\beta^{PV/PV}$. The limitation of this model is the presence of hyperthyroidism and thyroid hormone resistance, which is not typical of the human disease. Because follicular thyroid carcinomas are more common in areas of dietary iodide deficiency, it is interesting that chronic TSH stimulation in the $TR\beta^{PV/PV}$ mice resulted in this type of neoplasm. However, rodents are notoriously susceptible to thyroid neoplasia due to perturbations of the pituitary–thyroid axis (Capen, 1997, 2001).

Many of the mouse models of thyroid follicular cell neoplasia fail to reproduce the normal hormonal milieu present in humans with thyroid cancer. For example, derangement of thyroid function in mouse models remains a problem. Rapid onset of dysplasia or neoplasia replacing the majority of the normal thyroid tissue, especially in neonatal and juvenile mice, often results in significant hypothyroidism unless thyroid hormone supplementation is instituted. In addition, human thyroid neoplasms are more than twofold more common in women than in men, suggesting that estrogen plays a role in tumorigenesis, while no sex predilection has been achieved in the current mouse models.

THYROID C-CELLS

Normal Structure and Function

Calcitonin (CT) has been shown to be secreted by a second population of endocrine cells in the mammalian thyroid gland that are much less numerous than follicular cells. C-cells (parafollicular or light cells) are distinct from follicular cells in the thyroid that secrete T_4 and T_3 (Nonidez, 1931–32; Kalina and Pearse, 1971). They are situated either within the follicular wall immediately beneath the basement membrane or between follicular cells and as small groups of cells between thyroid follicles. C-cells do not border the follicular colloid directly, and their secretory polarity is oriented toward the interfollicular capillaries. The distinctive feature of C-cells, compared to thyroid follicular cells, is the presence of numerous small membrane-limited secretory granules in the cytoplasm. Immunocytochemical techniques have localized the calcitonin activity of C-cells to these secretory granules (DeGrandi *et al.*, 1971).

Calcitonin-secreting thyroid C-cells have been shown to be derived embryologically from cells of the neural crest. Primordial cells from the neural crest migrate ventrally and become incorporated within the last (ultimobranchial) pharyngeal pouch (Foster *et al.*, 1972) (Fig. 21-44). They move caudally with the ultimobranchial body to the point of fusion with the midline thyroglossal duct
Thyroid C-Cell

Figure 21-45. *Biosynthesis of calcitonin in C-cells of the thyroid gland.*

Preprocalcitonin (prePRO-CT) and procalcitonin (PRO-CT) are biosynthetic precursors that undergo posttranslational processing to form biologically active calcitonin (CT). Some of these precursor molecules and biologically active calcitonin may undergo enzymatic degradation to the constituent amino acids (AAs) prior to secretion from the C cell. Under certain disease conditions (e.g., neoplasms), C-cells may secrete other neuroendocrine products, including serotonin, bradykinin, and adrenocorticotropic hormone (ACTH). ER, endoplasmic reticulum; GA, Golgi apparatus; mRNA, messenger ribonucleic acid; and SG, secretory granule.

primordia that gives rise to the thyroid gland. The ultimobranchial body fuses with and is incorporated into the thyroid near the hilus in mammals and C-cells subsequently are distributed throughout the gland. Although C-cells are present throughout the thyroid gland of humans and most other mammals in postnatal life, they often remain more numerous near the hilus and point of fusion with the ultimobranchial body. Under certain conditions colloid-containing follicles lined by follicular cells also can differentiate from cells of ultimobranchial origin (Leblanc *et al.*, 1990; Teitelbaum *et al.*, 1970).

In contrast to the iodothyronines (T_4 and T_3) produced by follicular cells, calcitonin is a polypeptide hormone composed of 32 amino acid residues arranged in a straight chain (Copp, 1970). Calcitonin is synthesized as part of a larger biosynthetic precursor molecule (Wolfe, 1982) called pre-procalcitonin (Fig. 21-45). It is transported to the Golgi apparatus where it is converted to procalcitonin and then to calcitonin prior to packaging in membrane-limited secretory granules. Depending upon the need for calcitonin, a proportion of the precursors and active hormone undergo degradation prior to release from C-cells. The concentration of calcium ion in plasma and extracellular fluids is the principal physiological stimulus for the secretion of CT by C-cells. CT is secreted continuously under conditions of normocalcemia but the rate of secretion of CT is increased greatly in response to elevations in blood calcium. C-cells

store substantial amounts of CT in their cytoplasm in the form of membrane-limited secretory granules. In response to hypercalcemia there is a rapid discharge of stored hormone from C-cells into interfollicular capillaries. The hypercalcemic stimulus, if sustained, is followed by hypertrophy of C-cells and an increased development of cytoplasmic organelles concerned with the synthesis and secretion of CT. Hyperplasia of C-cells occurs in response to long-term hypercalcemia. When the blood calcium is lowered, the stimulus for CT secretion is diminished and numerous secretory granules accumulate in the cytoplasm of C-cells.

Calcitonin exerts its function by interacting with target cells, primarily in bone and kidney. The action of calcitonin is antagonistic to that of parathyroid hormone on mobilizing calcium from bone, but synergistic on decreasing the renal tubular reabsorption of phosphorus. The storage of large amounts of preformed hormone in C-cells and rapid release in response to moderate elevations of blood calcium are a reflection of the physiologic role of calcitonin as an "emergency" hormone to protect against the development of hypercalcemia. Calcitonin and parathyroid hormone, acting in concert, provide a dual negative feedback control mechanism to maintain the life-sustaining concentration of calcium ion in extracellular fluids within narrow limits. Calcitonin secretion is increased in response to a high-calcium meal often before a significant rise in plasma calcium can be detected. Gastrin, pancreozymin,
Figure 21-46. The gastrointestinal hormone-thyroid C-cell axis.

This axis provides a mechanism for rapid release of calcitonin from the thyroid in response to a high-calcium diet before a significant elevation in blood calcium occurs. (From Rosol and Capen, 1997).

and intestinal glucagon are examples of gastrointestinal hormones whose secretion is stimulated by an oral calcium load which, in turn, act as secretagogues for calcitonin release from the thyroid gland (Fig. 21-46).

The calcitonin gene is expressed differently in thyroid (C-cells) than in neural tissues (Steenbergh *et al*., 1984; Jacobs, 1985). In C-cells of the mammalian thyroid, the mRNA encodes primarily for pre-procalcitonin with a molecular weight of 17,400 Da, whereas in neural tissues there is alternative RNA processing and encoding for pre-procalcitonin gene-related peptide (CGRP). This CGRP is a neuropeptide composed of 37 amino acids with a molecular weight of 15,900 Da and participates in nociception, ingestive behavior, and modulation of the nervous and endocrine systems.

The structure of calcitonin differs considerably between species. The molecular structure of calcitonin for five selected species share only 9 of the 32 amino acid residues. However, the amino terminal portion of the calcitonin molecule is similar in all species. It consists of a seven-member ring enclosed by an intra-chain (1–7) disulfide bridge. The complete sequence of 32 amino acids and the disulfide bond are essential for full biologic activity. It is surprising that on a weight basis, salmon calcitonin is more potent in lowering blood calcium than any of the other calcitonins when administered to mammals, including humans. The reason for the greater biologic potency of salmon calcitonin in mammals is uncertain but probably is related to an increased resistance to metabolic degradation and longer half-life or to a greater affinity for receptor sites in bone and other target tissues.

Serum levels of calcitonin are best measured by radioimmunoassay (RIA). Because of the low degree of homology of calcitonin between species there is poor cross reactivity of RIAs for calcitonin. There is comparatively limited need to measure calcitonin in clinical veterinary medicine due to the low incidence of calcitonin-secreting neoplasms and metabolic disorders resulting from abnormal levels of calcitonin. Since the sequencing of canine calcitonin, a canine-specific RIA has been developed to measure serum calcitonin in dogs (Hazewinkel, 1991).

Mechanisms of Thyroid C-cell Toxicity

Nodular and/or diffuse hyperplasia of C-cells occurs with advancing age in many strains of laboratory rats and in response to long-term hypercalcemia in certain animal species and human beings. Focal aggregation of C-cells near the thyroid hilus are a normal anatomical finding in the thyroids of dogs and should not be over-interpreted as areas of C-cell hyperplasia. There is suggestive evidence that focal or diffuse hyperplasia precedes the development of C-cell neoplasms (DeLellis *et al*., 1977, 1979, 1986) (Fig. 21-47). Other studies (Triggs and Williams, 1977) have demonstrated elevated circulating levels of immunoreactive calcitonin in rats with C-cell neoplasms compared to either young or old rats without C-cell tumors. Neither consistent changes in total blood calcium and phosphorus nor bone lesions have been reported in rats with calcitonin-secreting C-cell neoplasms.

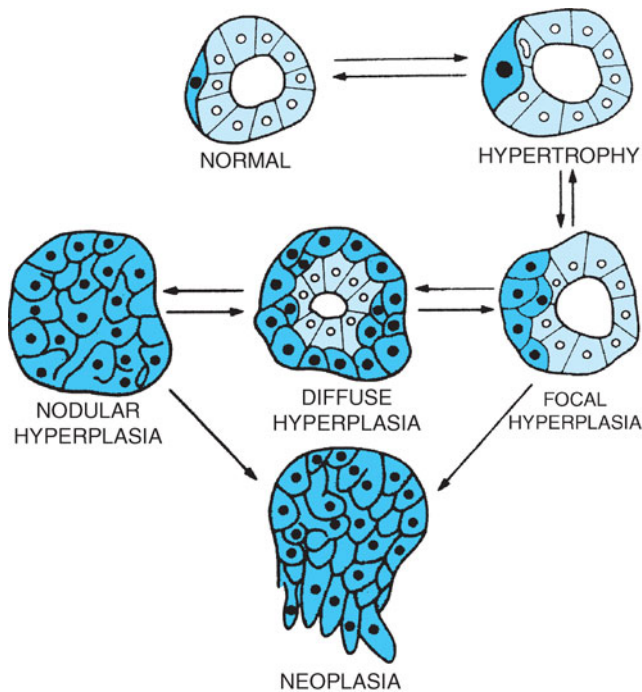
Triggs and Williams (1977) reported that radiation (5 or 10 μCi ^{131}I) increased the incidence of C-cell (as well as follicular cell) thyroid tumors in Wistar rats but that high dietary calcium intake (2000 mg/100 g) did not further increase the incidence of C-cell tumors in irradiated rats. Further studies by Thurston and Williams (1982) found that irradiated rats receiving diets high in vitamin D that developed hypercalcemia had a higher incidence of C-cell tumors than rats fed diets adequate or deficient in vitamin D. Stoll *et al*. (1978) reported that the antithyroid drug, thiamazole, can result in proliferative lesions (hyperplasia and adenoma) in thyroid C-cells as well as in follicular cells in rats.


Figure 21-47. Focal and nodular hyperplasia of C-cells in the thyroid often precedes the development of C-cell neoplasms. (From DeLellis et al., 1977).

Thyroid C-cells are known to have receptors for certain gastrointestinal hormones that permit the release of calcitonin from the thyroid gland following a high-calcium meal prior to significant elevations in the blood calcium concentration. The link between the gastrointestinal tract and thyroid C-cells has been demonstrated following pharmacologically induced elevations of the gastrointestinal hormone, gastrin, during treatment with the gastric acid secretion inhibitor, omeprazole (Yeomans, 1994).

Another of the gastrointestinal hormones that can influence thyroid C-cell function glucagon-like peptide-1 (GLP-1), which is being developed for the treatment of diabetes mellitus either as monotherapy or with other glucose-lowering drugs. Glucagon-like peptide-1 is an incretin hormone secreted by L-cells in the lower intestine (Kieffer and Habener, 1999) and is a potent stimulus of insulin biosynthesis and release from beta cells of the pancreas (Drucker *et al.*, 1987; Holz *et al.*, 1993; Bulotta *et al.*, 2002, 2003). Circulating levels of calcitonin can serve as a specific and sensitive biomarker for drugs or chemicals that stimulate thyroid C-cells by a receptor-mediated mechanism. Preclinical studies for pharmacologic agents that altered homeostasis, such as recombinant human PTH 1-34 (Teriparatide, Forteo®), have reported stimulation of thyroid C-cells and an increased incidence of C-cell tumors in rats (FDA, 2005). Not surprisingly, an increased incidence of C-cell tumors was reported in a 2-year rat study with a GLP-1 receptor agonist (Exenatide), the first approved drug in this class for the treatment of type 2 diabetes mellitus (FDA, 2005a). However, C-cells in the thyroids of monkeys and humans have a much lower expression of GLP-1 receptors that would result in a much lower level of C-cell stimulation and calcitonin release in response to a GLP-1 agonist. The C-cell proliferative lesions observed in rats following chronic GLP-1 agonist administration are unlikely to be of relevance to humans.

Morphologic Alterations and Proliferative Lesions of Thyroid C-cells

C-cell proliferative lesions occur commonly in many rat strains but are uncommon in the mouse. Rat strains with high incidences of these lesions include WAG/Rij, Sprague–Dawley, Fisher, Wistar, Buffalo, and Osborne–Mendel. The incidence varies from 19% to 33% with no obvious sex differences. Burek (1978) reported that crossbreeding of high (WAG/Rij) and low (BN/Bi) incidence strains results in F_1 animals with intermediate tumor incidences. As with proliferative lesions of other endocrine organs there is a correlation between the age of the animal and the presence of the entire spectrum of C-cell proliferative lesions. For example, Long–Evans rats under 1 year of age rarely have C-cell neoplasms in the thyroid. Rats which were between 12 and 24 months of age had a 10% incidence whereas approximately 20% of 2- to 3-year-old rats had C-cell tumors. Similarly, the frequency of focal and diffuse C-cell hyperplasia increased progressively with age in this strain of rat. According to the NTP historical database of 2-year-old F344 rats, the incidence of C-cell neoplasms was 8.9% in males and 8.5% in females.

There are two types of C-cell hyperplasia, namely diffuse and focal (nodular) hyperplasia (Fig. 21-47). In diffuse hyperplasia, the numbers of C-cells are increased throughout the thyroid lobe to a point where they may be more numerous than follicular cells. In contrast to the predominantly central distribution of C-cells in thyroids from young rats, C-cells in the more severe forms of hyperplasia extend to the extreme upper and lower poles as well as the peripheral regions of the lobes. Focal (nodular) hyperplasia of C-cells often occurs concurrently with diffuse hyperplasia in the thyroid glands of rats. Follicular cells adjacent to the proliferating C-cells often are compressed and atrophic with prominent supranuclear accumulations of lipofuscin. In the later stages, follicles with intense C-cell hyperplasia often assume irregular, twisted, and elongate configurations. Occasional colloid-filled thyroid follicles are entrapped among the proliferating C-cells.

The histological distinction between focal hyperplasia and adenoma of C-cells is indistinct and somewhat arbitrary. The diagnosis of C-cell hyperplasia refers to a focal or diffuse increase of C-cells between thyroid follicles and/or within the follicular basement membrane. The C-cells appear normal with an abundant, lightly eosinophilic, granular cytoplasm and a round-to-oval nucleus with finely stippled chromatin. In focal C-cell hyperplasia the accumulations of proliferating C-cells are of a lesser diameter than five average colloid-containing thyroid follicles with minimal evidence of compression of adjacent follicles. Hyperplastic C-cells within the follicular basement membrane may compress individual thyroid follicles.

The ultimobranchial body (last, usually fifth, pharyngeal pouch) that delivers the neural crest-derived C-cells to the postnatal thyroid gland fuses with each thyroid lobe at the hilus during embryonic development and distributes C-cells throughout each lobe to varying degrees in different species (Fig. 21-44). In the dog, nodular aggregations of C-cells frequently persist along the course of the major vessels to the thyroid; therefore, C-cell hyperplasia in dogs should be diagnosed only when there is a definite increase in C-cells throughout each thyroid lobe compared to age-matched controls. Both thyroid lobes should be sectioned longitudinally in a consistent manner for microscopic evaluation. This will minimize the prominent regional differences of C-cells in the thyroid glands of normal dogs that can result in the over interpretation of these

focal aggregations of C-cells as a significant lesion. There are occasional ultimobranchial-derived, colloid-containing follicles within the focal accumulations of microscopically normal C-cells along the course of vessels within the thyroid lobe or in the connective tissues of the thyroid hilus in dogs.

By comparison C-cell adenomas are discrete, expansive masses of C-cells larger than five average colloid-containing thyroid follicles. Adenomas either are well circumscribed or partially encapsulated from adjacent thyroid follicles that often are compressed to varying degrees. C-cells comprising an adenoma may be subdivided by fine connective tissue septae and capillaries into small neuroendocrine packets. Some C-cell adenomas are composed of larger pleomorphic cells with amphophilic cytoplasm, large nuclei with coarsely clumped chromatin, prominent nucleoli, and bear a histological resemblance to ganglion cells. Occasional amyloid deposits may be found both in nodular hyperplasia and in adenomas.

C-cell carcinomas often result in macroscopic enlargement of one or both thyroid lobes due to the extensive proliferation and infiltration of C-cells. There is evidence of intrathyroidal and/or capsular invasion by the malignant C-cells, often with areas of hemorrhage and necrosis within the neoplasm. The malignant C-cells are more pleomorphic than those comprising benign proliferative lesions. Immunoperoxidase reactions for calcitonin generally are more intense in diffuse or nodular hyperplasia; whereas, in adenomas and carcinomas calcitonin immunoreactivity is much more variable between tumors and in different regions of a tumor. Hyperplastic C-cells adjacent to adenomas and carcinomas usually are intensely positive for calcitonin. In addition to calcitonin, some of the tumor cells and adjacent hyperplastic C-cells have positive staining for somatostatin or bombesin.

Medullary thyroid carcinomas in humans, also commonly known as C-cell carcinomas, arise from calcitonin-secreting C-cells and are associated with inherited syndromes, such as multiple endocrine neoplasia (MEN), in approximately 20–25% of cases (Cho *et al*., 1999; Sherman, 2003). Medullary carcinomas frequently metastasize via the bloodstream, in addition to lymphatic spread, and are treated with surgical resection and/or external beam radiation. In contrast to follicular origin thyroid tumors, C-cells and tumors arising from them do not have the ability to take up radioactive iodide. The five-year survival rate for medullary thyroid carcinomas is approximately 50%.

Genetic Events in Tumors of Thyroid C-cells

Medullary thyroid carcinomas, or C-cell carcinomas, arise from the calcitonin-secreting parafollicular C-cells of the thyroid gland. These tumors can occur as part of an inherited syndrome, such as multiple endocrine neoplasia (MEN) type 2A or type 2B, or familial medullary thyroid carcinoma (FMTC), which together account for 20–25% of all medullary thyroid carcinomas (Cho *et al*., 1999; Sherman, 2003; Quayle and Moley, 2005). The *ret* proto-oncogene, which can undergo rearrangements in papillary carcinoma as previously described, is also important in initiating medullary carcinoma. In medullary carcinoma, the full-length *ret* proto-oncogene has gain-of-function point mutations involving one of several possible codons (Michiels *et al*., 1997; Cranston and Ponder, 2003; Quayle and Moley, 2005). As a result, Ret is constitutively active in the neuroendocrine tissues normally expressing this protein, such as thyroid C-cells and neuroendocrine cells of the adrenal medulla. All of the known hereditary forms of medullary carcinoma are autosomal dominant and involve *ret* mutations. While sporadic medullary

carcinomas comprise more than 75% of cases, little is known about specific genetic mutations initiating this form of thyroid cancer. However, somatic *ret* point mutations have been identified in up to 50% of sporadic cases (Gimm and Dralle, 1999; Knostman *et al*., 2007).

Reproduction of the MEN 2A syndrome using CGRP-Ret[C634R] has been quite successful. However, in this model, as well as the Rb[+/−] models, there appears to be a significant contribution of background strain to the development of medullary thyroid carcinomas. In addition, these models develop several extrathyroidal neoplasms common to the MEN 2A syndrome, whereas only the CGRP-v-Ha-ras model mimics the presence of medullary thyroid carcinoma alone, which is the most common form of the disease in humans.

PARATHYROID GLAND

Calcium Metabolism

Calcium plays a key role as an essential structural component of the skeleton and also in many fundamental biological processes. These processes include neuromuscular excitability, membrane permeability, muscle contraction, enzyme activity, hormone release, and blood coagulation, among others. The precise control of calcium in extracellular fluids is vital to health. To maintain a constant concentration of calcium, despite marked variations in intake and excretion, endocrine control mechanisms have evolved that primarily consist of the interactions of three major hormones—parathyroid hormone (PTH), calcitonin (CT), and cholecalciferol (vitamin D) (Fig. 21-48).

Disruption of the normal regulation of calcium balance in animals results in hypercalcemia or hypocalcemia and can lead to metabolic disease and death. Pathological effects associated with abnormal levels of calcium in the body include mineralization of vital organs and other soft tissues, rickets, osteoporosis, and metabolic disorders (Siesjo, 1989).

Approximately 99% of the calcium of the body is present in the inorganic matrix of bone as hydroxyapatite. Most of the remaining calcium is sequestered in the plasma membrane and endoplasmic reticulum of cells. Extracellular fluid contains 0.1% of the body's calcium mass with a total calcium concentration of about 2.5 mmol/L. Extracellular and serum calcium exists in three forms: (1) ionized, (2) complexed to anions such as citrate, bicarbonate, phosphate, or lactate (5% of total calcium), and (3) protein bound (Fig. 21-49). The protein-bound fraction of Ca^{2+} is dependent on the pH of the serum and is principally bound to negatively charged sites on albumin with smaller amounts bound to globulins. As the pH of serum becomes more acidic, the $[Ca^{2+}]$ will increase due to the competition of hydrogen ions $[H^+]$ for binding to the negatively charged sites on serum proteins. Approximately 50% of the extracellular calcium (1.2 mmol/L) is in the ionized form (Ca^{2+}), which is the biologically active form of calcium (Fig. 21-49). The ionized and complexed Ca^{2+} compose the ultrafilterable fraction of Ca^{2+} and represent the fraction that is present in the glomerular filtrate. Neonatal animals have slightly greater concentrations of extracellular calcium compared to adult animals. There is very little calcium in the cytosol, approximately 100 nM, which is predominantly in the ionized form.

Calcium serves two primary functions in the body: (1) structural integrity of bones and teeth, and (2) as a messenger or regulatory ion. There is a 10,000-fold concentration gradient of Ca^{2+} between the extracellular fluid (1.2 mmol/L) and the cytoplasm
Figure 21-48. Interrelationship of parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxycholecalciferol (1,25(OH)$_2$VD$_3$) in the hormonal regulation of calcium (Ca) and phosphorus in extracellular fluids.

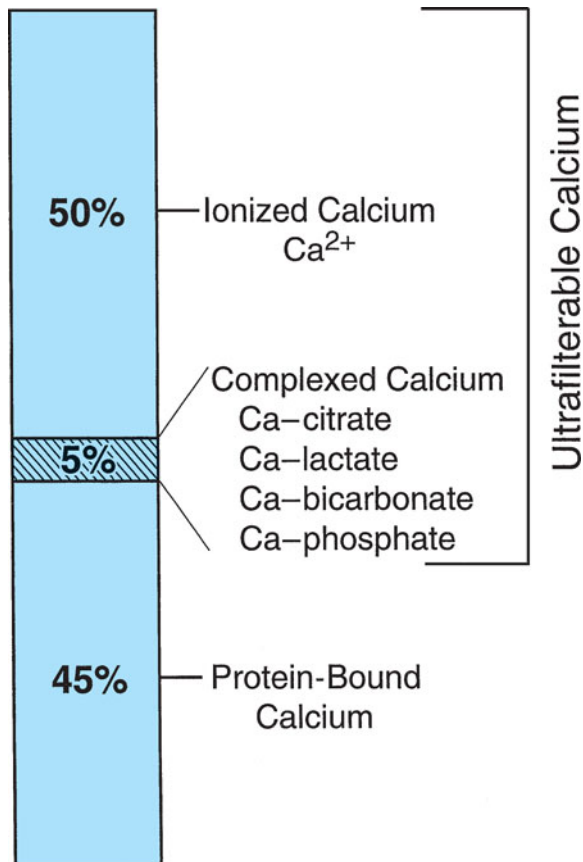
Receptors for PTH are on osteoblasts and for CT on osteoclasts in bone. PTH and CT are antagonistic in their action on bone but synergistic in stimulating the renal excretion of phosphorus. Vitamin D exerts its action primarily on the intestine to enhance the absorption of both calcium and phosphorus.


Figure 21-49. Fractions of extracellular calcium (Ca). (From Rosol et al., 1995.)

(100 nM). This gradient permits Ca^{2+} to function as a signaling ion to activate intracellular processes. The lipid bilayer of the cell membrane has a low permeability to Ca^{2+}; therefore, influx of Ca^{2+} into the cytoplasm is controlled by a heterogeneous group of calcium channels regulated by membrane potential, cell membrane receptors, or intracellular secondary messengers. Influx of Ca^{2+} into cells can: (1) regulate cellular function by interactions with intracellular calcium-binding proteins (e.g., calmodulin) and calcium-sensitive protein kinases, and (2) stimulate biologic responses such as neurotransmitter release, contraction, and secretion. Ionized calcium also plays an important role in cell adhesion and blood coagulation. In addition, Ca^{2+} may regulate cellular function by binding to a G-protein-linked Ca^{2+}-sensing receptor in the cell membrane, such as in parathyroid chief cells or renal epithelial cells (Brown *et al.*, 1995).

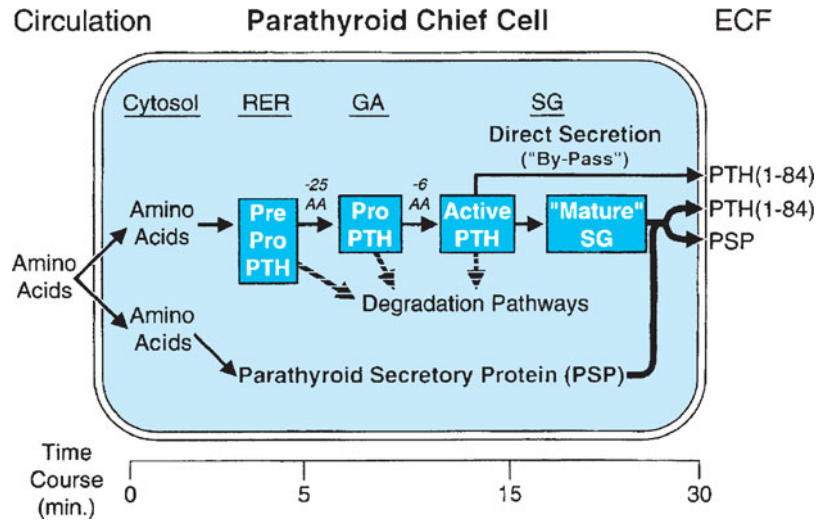
The kidney normally reabsorbs 98% or more of the filtered calcium. This high degree of reabsorption is an important mechanism to maintain the balance of calcium in the body. If necessary, the kidneys excrete large amounts of calcium in the urine. Ionized and complexed calcium enters the glomerular filtrate by convection and is reabsorbed by the renal tubules. The kidneys reabsorb approximately 40-fold more calcium than is absorbed by the intestinal tract due to the high degree of blood flow and ultrafiltration in the glomerulus. Reduction of glomerular filtration impairs the ability of the kidneys to excrete calcium. About 70% of filtered calcium is reabsorbed in the proximal convoluted tubules by diffusion and convection with water uptake between the epithelial cells. The thick ascending loop of Henle also absorbs about 20% of the filtered calcium, but the precise mechanism is unclear. Much of the calcium reabsorption appears to be passive, but an active component (Rouse and Suki, 1990) may also be present in the distal convoluted tubule, which reabsorbs approximately 10% of the


***Figure 21-50.** Biosynthesis of parathyroid hormone (PTH) and parathyroid secretory protein (PSP) by parathyroid chief cells.*

Active PTH is synthesized as a larger biosynthetic precursor molecule (preproPTH) that undergoes rapid posttranslational processing to proPTH prior to secretion from chief cells as active PTH (amino acids 1–84).

filtered calcium. The principal stimulator of calcium reabsorption in the distal convoluted tubule is parathyroid hormone. Reabsorption of calcium in the distal convoluted tubule is an active transcellular process requiring the presence of calcium channels in the luminal cell membrane, intracellular calcium-binding proteins, such as calbindins, a Ca^{2+}-ATPase, and Na^+/Ca^{2+} exchanger in the basolateral cell membranes. Renal epithelial cells express the Ca^{2+}-sensing receptor on their cell membranes and the distribution of the receptor overlaps with the localization of PTH receptors, so the kidneys may partially autoregulate the renal reabsorption of calcium based on concentration of Ca^{2+} in the blood.

Normal Structure and Function of Chief Cells

Biosynthesis of Parathyroid Hormone   Parathyroid glands are present in all air-breathing vertebrates. Phylogenetically, the parathyroids first appeared in amphibians, coincidentally with the transition of life from an aquatic to a terrestrial environment. It has been suggested that the appearance and development of parathyroid glands may have arisen from the need to protect against the development of hypocalcemia and the necessity to maintain skeletal integrity in terrestrial animals, which often are in a relatively low-calcium, high-phosphorus environment (Capen *et al*., 1996).

The parathyroid glands in most animal species consist of two pairs of glands, the internal and the external parathyroids, usually situated in the anterior cervical region in close proximity to the thyroid gland. The laboratory rat is an exception to this general rule as they have a single pair of parathyroids closely associated with the thyroid lobes. Embryologically, both parathyroid glands are of entodermal origin. The external parathyroid is derived from the third (III) and the internal parathyroid is derived from the fourth (IV) pharyngeal pouches, in close association with the primordia of the thymus (Capen, 1996c).

Parathyroid chief cells in humans and many animal species store relatively small amounts of preformed hormone but they respond quickly to variations in the need for hormone by changing the rate of hormone synthesis. Parathyroid hormone, like many peptide hormones, is first synthesized as a larger biosynthetic precursor molecule that undergoes posttranslational processing in chief cells. Preproparathyroid hormone (preproPTH) is the initial translation product synthesized on ribosomes of the rough endoplasmic reticulum in chief cells. It is composed of 115 amino acids and contains a hydrophobic signal or leader sequence of 25 amino acid residues that facilitates the penetration and subsequent vectorial discharge of the nascent peptide into the cisternal space of the rough endoplasmic reticulum (Kronenberg *et al*., 1986) (Fig. 21-50). PreproPTH is rapidly converted within 1 min or less of its synthesis to proparathyroid hormone (ProPTH) by the proteolytic cleavage of 25 amino acids from the NH_2-terminal end of the molecule (Habener, 1981). The intermediate precursor, proPTH, is composed of 90 amino acids and moves within membranous channels of the rough endoplasmic reticulum to the Golgi apparatus (Fig. 21-50). Enzymes within membranes of the Golgi apparatus cleave a hexapeptide from the NH_2-terminal (biologically active) end of the molecule forming active PTH. Active PTH is packaged into membrane-limited, macromolecular aggregates in the Golgi apparatus for subsequent storage in chief cells. Under certain conditions of increased demand (e.g., a low calcium ion concentration in the extracellular fluid compartment), PTH may be released directly from chief cells without being packaged into secretion granules by a process termed *bypass secretion*.

Although the principal form of active PTH secreted from chief cells is a straight chain peptide of 84 amino acids (molecular weight 9500), the molecule is rapidly cleaved into amino- and carboxy-terminal fragments in the peripheral circulation and especially in the liver. The purpose of this fragmentation is uncertain because the biologically active amino-terminal fragment is no more active than the entire PTH molecule (amino acids 1–84). The plasma half-life of the N-terminal fragment is considerably shorter than that of the biologically inactive carboxy-terminal fragment of parathyroid hormone. The C-terminal and other portions of the PTH molecule are degraded primarily in the kidney and tend to accumulate with chronic renal disease (Goltzman *et al*., 1986).
Figure 21-51. Autocrine/paracrine action of chromogranin A (CgA)-derived peptides. PTH and CgA are co-released from chief cells in response to a low calcium ion signal.

Pancreastatin (PST) is a 49 amino acid peptide derived from CgA that exerts local negative feedback on chief cells and decreases PTH secretion from chief cells. (Modified from Cohn *et al,*. 1993).

Control of Parathyroid Hormone Secretion   Although secretory cells in the parathyroid gland store small amounts of preformed hormone, they are capable of responding to minor fluctuations in calcium concentration by rapidly altering the rate of hormonal secretion and more slowly by altering the rate of hormonal synthesis. In contrast to most endocrine organs that are under complex controls involving both long and short feedback loops, the parathyroids have a unique feedback controlled by the concentration of calcium (and to a lesser extent magnesium) ion in serum. The concentration of blood phosphorus has no direct regulatory influence on the synthesis and secretion of PTH; however, several disease conditions with hyperphosphatemia in both animals and humans are associated clinically with secondary hyperparathyroidism. An elevated blood phosphorus level may lead indirectly to parathyroid stimulation by virtue of its ability to lower blood calcium, primarily by suppressing the 1α-hydroxylase in the kidney and decreasing the production of the active form of vitamin D [1,25-$(OH)_2$-cholecalciferol], thereby diminishing the rate of intestinal calcium absorption. Magnesium ion has an effect on parathyroid secretion rate similar to that of calcium, but its effect is not equipotent to that of calcium.

The concentration of ionized calcium in serum and extracellular fluid can regulate cellular function by interacting with a recently identified Ca^{2+}-sensing receptor in the plasma membrane of various cells (Brown and Hebert, 1996; Chattopadhyay *et al.*, 1996). The cell membrane Ca^{2+} receptor is coupled to G-protein and the 7-transmembrane domain of this receptor is unique because the ligand for the receptor is an ion. The Ca^{2+} receptor plays an important role in the regulation of extracellular Ca^{2+} homeostasis and is present on parathyroid chief cells, thyroid C-cells, renal epithelial cells, brain, and placenta amongst other tissues. The Ca^{2+} receptor is responsible for sensing serum Ca^{2+} concentration and modifying parathyroid hormone secretion, calcitonin secretion, and calcium transport by renal epithelial cells. Mutations in one or both of the Ca^{2+}-sensing receptor genes in humans results in familial hypocalciuric hypercalcemia or neonatal severe hypercalcemia, respectively, due to an inadequate ability to sense the extracellular Ca^{2+} concentration and coordinate the appropriate cellular response.

The serum [Ca^{2+}] that results in half maximal PTH secretion is defined as the serum calcium "set-point" and is stable for an individual animal. The sigmoidal relationship between serum [Ca^{2+}] and PTH secretion permits the chief cells to respond rapidly to a reduction in serum Ca^{2+}. The major inhibitors of PTH synthesis and secretion are increased serum [Ca^{2+}] and 1,25-dihydroxyvitamin D. Inhibition of PTH synthesis by 1,25-dihydroxyvitamin D completes an important endocrine feedback loop between the parathyroid chief cells and the renal epithelial cells because PTH stimulates renal production of 1,25-dihydroxyvitamin D.

Chief cells synthesize and secrete another major protein termed "parathyroid secretory protein (I)" or chromogranin A (CG-A). It is a higher molecular weight molecule (70 kD) composed of 430–448 amino acids that is co-stored and secreted with PTH. A similar molecule has been found in secretory granules of a wide variety of peptide hormone-secreting cells and in neurotransmitter secretory vesicles (Doss *et al.*, 1998). An internal region of the parathyroid secretory protein or chromogranin A molecule is identical in sequence to pancreastatin, a C-terminal amidated peptide, that inhibits glucose-stimulated insulin secretion. This 49 amino acid proteolytic cleavage product (amino acids number 240–280) of parathyroid secretory protein has been reported to inhibit low calcium-stimulated secretion of parathyroid hormone and chromogranin A from parathyroid cells. These findings suggest that chromogranin A-derived peptides may act locally in an autocrine manner to inhibit the secretion of active hormone by endocrine cells, such as chief cells of the parathyroid gland (Fasciotto *et al.*, 1990; Barbosa *et al.*, 1991; Cohn *et al.*, 1993) (Fig. 21-51).

Although the functions of CGA are still under investigation, several roles have been postulated. Chromogranin A is suspected to play an important role in the maturation of secretory granules. Inside the Golgi apparatus, CGA is involved in the packaging of the contents of newly formed vesicles. Chromogranin A precipitates as it diffuses into the trans-Golgi network and secretory products such as parathyroid hormone become entrapped in the growing CGA conglomerate and are subsequently packaged into secretory granules. Chromogranin A has a large calcium-binding capacity which may enhance the stability of secretory vesicles. As granules mature, they accumulate up to 40 mM of calcium, which also may serve as a route of Ca^{2+} secretion. Chromogranin A-calcium complexes are important in maintaining the integrity of the secretory granules.

Cellular Control of Bone Resorption
Figure 21-52. Cellular control of bone resorption.

Specific receptors for parathyroid hormone (PTH and PTH-rP) are present on osteoblasts but not on osteoclasts. RANK L is a membrane-bound protein on osteoblasts that stimulates differentiation of cells of the osteoclast lineage. Expression of RANK L in osteoblasts is upregulated by osteotrophic factors such as PTH, calcitriol, and interleukin 11. M-CSF, macrophage colony-stimulating factor; PTH-rP, parathyroid hormone-related peptide; R, receptor for PTH or PTH-rP; R, receptor; and RANK L, receptor activator NF-κB ligand. (From Capen, 2004).

The absence of calcium causes dissociation of protein complexes and results in osmotic lysis of the vesicle.

The intragranular functions of CGA include hormone packaging, stabilization of the granule against osmotic gradients, and the excretion of intracellular calcium. During the process of secretion, the contents of secretory granules are extruded into the pericapillary space. The pH and calcium concentration of the extracellular fluid promote the dissociation of CGA complexes and solubilization of bound calcium and other contents of the granule. Once solubilized, extracellular peptidases cleave CGA into biologically active peptides, which act as paracrine or autocrine regulators of endocrine secretion (Deftos, 1991).

Biologic Effects of Parathyroid Hormone Parathyroid hormone is the principal hormone involved in the minute-to-minute, fine regulation of blood calcium in mammals. It exerts its biologic actions by directly influencing the function of target cells, primarily in the bone and kidney, and secondarily in the intestine to maintain plasma calcium at a level sufficient to ensure the optimal functioning of a wide variety of body cells. In general, the most important biologic effects of PTH are to: (1) elevate the blood concentration of calcium, (2) decrease the blood concentration of phosphorus, (3) increase the urinary excretion of phosphorus by a decreased rate of tubular reabsorption, (4) increase the renal tubular reabsorption of calcium, (5) increase the rate of skeletal remodeling and the net rate of bone resorption, (6) increase the numbers of osteoclasts on bone surfaces and the rate of osteolysis, (7) increase the urinary excretion of hydroxyproline, (8) activate adenylate cyclase in target cells, and (9) accelerate the formation of the principal active vitamin D metabolite (1,25-dihydroxycholecalciferol; 1,25-dihydroxy vitamin D) through a trophic effect of PTH on the 1α-hydroxylase in mitochondria on the epithelial cells lining the proximal convoluted tubules of the kidney.

Parathyroid hormone mobilizes calcium from skeletal reserves into the extracellular fluids. The response of bone to parathyroid hormone is biphasic. The immediate effects are the result of increasing the activity of existing osteocytes and osteoclasts. This rapid effect of PTH depends upon the continuous presence of hormone and results in an increased flow of calcium to the bone surface through the coordinated action of osteocytes and activation of endosteal lining cells (inactive osteoblasts). The later effects of parathyroid hormone on bone are of a greater magnitude of response and are not dependent upon the continuous presence of PTH. Osteoclasts are primarily responsible for the long-term actions of PTH on increasing bone resorption and overall bone remodeling. This is particularly interesting, in light of studies which have demonstrated the presence of receptors for PTH on osteoblasts but not on osteoclasts (Fig. 21-48).

Recombinant human PTH (1–34), the 34 amino acid N-terminal portion of the natural hormone, has been developed as a new

treatment for osteoporosis. Teriparatide (Forteo®) administered by once-daily subcutaneous injection stimulated new bone formation by activating quiescent bone-lining cells, by stimulating osteoblast differentiation from precursor cells, and by inhibiting osteoblast apoptosis (Hock, 2001). This anabolic effect of PTH was distinct from its well-known catabolic effects on the skeleton through the activation of osteoclasts and increased bone resorption associated with chronic elevations of hormone in humans and animals from renal disease or nutritional imbalances. Teriparatide stimulates mineral apposition into trabecular, endocortical, and periosteal bone surfaces in rats, monkeys, and humans resulting in substantial increases in bone mass, improved architecture, and enhanced biomechanical strength (Sato *et al.*, 1997; Jerome *et al.*, 1999; Jiang *et al.*, 2003; Zanchetta *et al.*, 2003).

A 2-year rat carcinogenicity study reported that once-daily subcutaneous administration of Teriparatide resulted in large, dose-dependent increases in bone mass, as well as bone proliferative lesions, including osteosarcoma at all dose levels tested (Sato *et al.*, 2002; Vhale *et al.*, 2002). This study had several design features that differ from the intended short-term use of Teriparatide, making relevance of the rat findings difficult to assess in terms of safety for humans (Tashjian and Chabner, 2002). Rats were treated once daily for 24 months starting at approximately 2 months of age at initiation of treatment. The rats were treated for nearly their entire lifespan (70–80% of lifetime) and during the rapid phase of longitudinal skeletal growth (Vhale *et al.*, 2002). The intended clinical use of Teriparatide is up to 2 years of therapy in older patients with a mature skeleton, which corresponds to approximately 2–3% of the human lifespan.

A long-term study subsequently was conducted in female F344 rats to determine the relative importance of dose, treatment duration, and age at initiation of treatment on the incidence of bone proliferative lesions induced by Teriparatide (Vhale *et al.*, 2004). Treatment groups consisted of different combinations of dose (0, 5, or 30 μg/kg/day), treatment duration (6, 20, or 24 months) and age at initiation of treatment (2 or 6 months of age). Significant increases in the incidence of bone tumors (osteoma, osteoblastoma, and osteosarcoma) appeared in rats treated with 30 μg/kg for 20 or 24 months. No neoplasms were found when rats were administered 5 μg/kg at 6 months of age and continued for either 6 or 20 months (up to 70% of lifespan). These results demonstrated that treatment duration and administered dose are important factors in the induction of bone tumors in rats by Teriparatide (Vhale *et al.*, 2004; Sato *et al.*, 2002).

Bone resorption is a complex, multistep process that involves the activation of multiple genes and the action of multiple hormones (Teitelbaum, 2000). Most hormones and cytokines that are involved in the regulation of bone resorption (e.g., parathyroid hormone, calcitriol, interleukin-1 beta, tumor necrosis factor [TNF], interleukin-6, and prostaglandin E_2) act via receptors on osteoblasts. Three new family members of the TNF ligand and receptor signaling system have been identified and cloned recently that play a critical role in the regulation of bone resorption (Hofbauer, 1999; American Society for Bone and Mineral Research [ASBMR] Special Committee on Nomenclature, 2000; Hofbauer *et al.*, 2000). In the presence of permissive concentrations of macrophage colony-stimulating factor (M-CSF), the new TNF superfamily molecules constitute the common pathway for regulation of osteoclast formation and function by cells of the osteoblast lineage, thereby, mediating the biologic effects of many upstream hormones and cytokines (Suda *et al.*, 1999).

Figure 21-53. *Control of osteoclast functions by products of osteoblast cell lineage.*

Note that all steps of osteoclast formation and function are regulated by the OPG-L/OPG ratio, including initiation of differentiation, fusion of preosteoclasts to form active mature osteoclasts, regulation of osteoclast function, and osteoclast apoptosis. M-CSF is required only for the initiation of differentiation by uncommitted osteoclast precursors in bone marrow. M-CSF, macrophage colony-stimulating factor; OCIF, osteoclastogenesis inhibitory factor; ODF, osteoclast differentiation factor; OPG, osteoprotegerin; OPG L, osteoprotegerin ligand; and RANK L, receptor activator NF-κB ligand. (Modified and redrawn from Hofbauer *et al.*, 2000.)

RANK, RANK Ligand and Osteoprotegerin   The receptor ligand (RANK ligand or RANK L) is a membrane-bound protein on osteoblasts that serves as a common mediator for osteoclastic bone resorption (Takahashi *et al.*, 1999; Martin and Gillespie, 2001). This ligand (initially termed osteoclast differentiation factor [ODF]) and osteoprotegrin ligand [OPG L] is produced by osteoblast lineage cells and stimulates differentiation of cells of the osteoclast lineage, enhances the functional activity of mature osteoclasts, and prolongs osteoclast life by inhibiting apoptosis (ASBMR Special Committee on Nomenclature 2000; Hock *et al.*, 2001) (Figs. 21-52 and 21-53). Targeted deletion of the receptor ligand in mice leads to osteopetrosis, shortened bones, impaired tooth eruption, and immunologic abnormalities. Expression of RANK L in osteoblasts/stromal cells

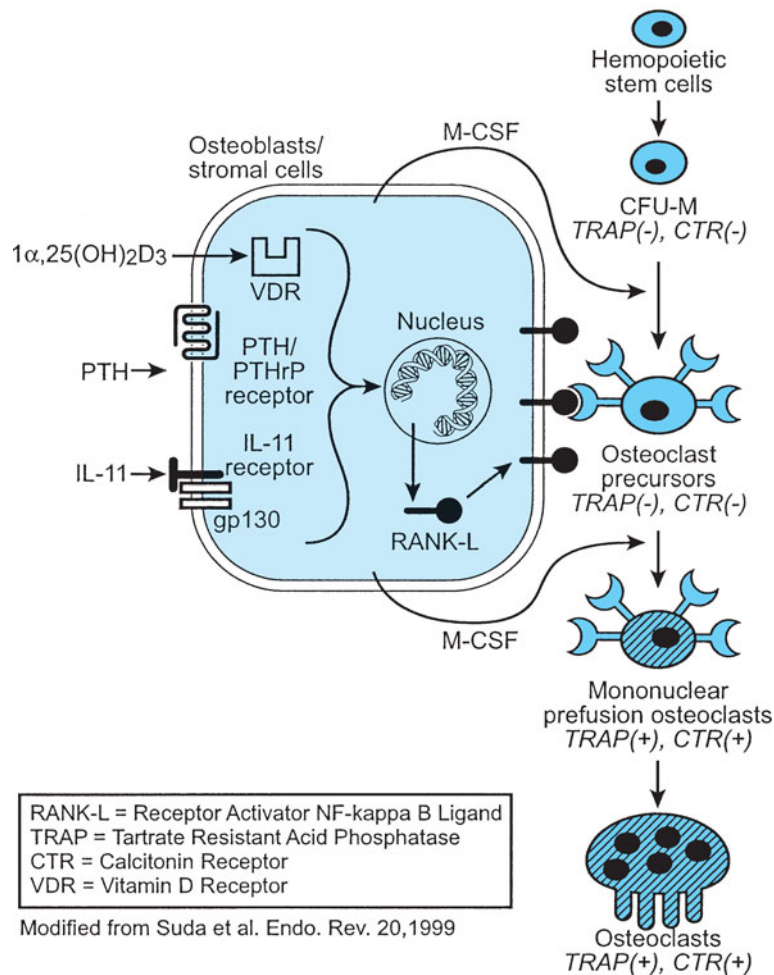
Control of Osteoclast Differentiation


Figure 21-54. *Concept of osteoclast differentiation.*

Osteotropic factors such as $1\alpha,25(OH)_2D_3$ (dihydroxycholecalciferol), parathyroid hormone (PTH), and interleukin-11 (IL-11) stimulate osteoclast formation in co-cultures of osteoblasts/stromal cells and hemopoietic cells. Target cells for these factors are osteoblasts/stromal cells. Three different signaling pathways mediated by the vitamin D receptor (VDR), PTH/PTH-rP receptor, and gp130 similarly induce osteoclast differentiation factor (ODF) or stromal osteoclast-forming activity (SOFA) as a membrane-associated factor in osteoblasts/stromal cells. Osteoclast progenitors of the monocyte–macrophage lineage recognize ODF/SOFA in osteoblasts/stromal cells through cell-to-cell interaction and then differentiate into osteoclasts. Macrophage colony-stimulating factor (M-CSF) produced by osteoblasts/stromal cells is a prerequisite for both proliferation and differentiation of osteoclast progenitors. CFU-M, colony-forming unit-megakaryocyte; CTR, calcitonin receptor; PTH-rP, parathyroid hormone-related peptide; RANK L, receptor activator NF-κB ligand; and TRAP, tartrate-resistant acid phosphatase. (Modified and redrawn from Suda *et al.*, 1999.)

is upregulated by osteotrophic factors such as calcitriol, PTH, and interleukin-11 (Suda *et al.*, 1999). This molecule is identical to TNF-related activation-induced cytokine (TRANCE) or receptor activator of NF-kappa B ligand (RANK L) reported to stimulate T-cell growth and dendritic cell function in the immunology literature (ASBMR Special Committee on Nomenclature, 2000).

The membrane receptor (RANK) for the ligand (RANK L) on cells of the osteoclast lineage is identical with a receptor of similar name identified previously on immune cells (Suda *et al.*, 1999; ASBMR Special Committee on Nomenclature, 2000) (Fig. 21-51).

The receptor also has been referred to in the literature as osteoclast differentiation and activation receptor [ODAR]. Binding of the ligand to this receptor activates signaling pathways in osteoclasts that lead to increased functional activity. Osteoclast precursors express RANK, recognize RANK L through cell-to-cell interaction with osteoblasts/stromal cells, and differentiate into prefusion osteoclasts in the presence of M-CSF. Mice made deficient in RANK by targeted deletion of the gene develop severe osteopetrosis due to decreased osteoclast function and fail to develop peripheral lymph nodes (ASBMR Special Committee on Nomenclature, 2000).
Figure 21-55. Regulation of osteoclast functions by cytokines.

The convergence hypothesis proposes two levels of regulation of osteoclast funtions. A variety of upstream cytokines and hormones alter the pool size of active osteoclasts by converging at the level of OPG L/ODF and OPG/OCIF. These two downstream factors serve as the final effectors for osteoclastogenesis and also affect osteoclast activation and osteoclast apoptosis. At steady state, there is a balance of levels of OPG L/ODF and OPG/OCIF that maintain a pool size of active osteoclasts that supports normal levels of bone resorption. When a change in one or more upstream factors tilts the balance toward a functional excess of OPG L/ODF, the pool size decreases. 17β-E2, 17β-estradiol; PGE$_2$, prostaglandin E$_2$; PTH, parathyroid hormone; RANK-L, receptor activator of NF-κB ligand; and TGF-β, transforming growth factor β. (Modified and redrawn from Hofbauer *et al*., 2000.)

Osteoprotegerin (OPG) ("decoy receptor") is a novel member of the TNF receptor superfamily produced by cells of the osteoblast lineage/stromal cells and a negative regulator of bone resorption (Hofbauer, 1999; Hofbauer *et al*., 2000) (Figs. 21-52 and 21-53). When this soluble decoy receptor binds to the ligand (RANK L) it prevents the ligand from binding to its biological membrane receptor (RANK) thereby resulting in its inactivation. Overexpression of this decoy receptor in transgenic mice leads to osteopetrosis associated with decreased osteoclast formation and function. In contrast, targeted gene ablation in mice results in severe osteoporosis and arterial mineralization (ASBMR Special Committee on Nomenclature, 2000).

These recent findings clearly indicate that microenvironment in bone marrow provided by osteoblast lineage/stromal cells regulate osteoclast differentiation and function. Osteoclast formation appears to be determined by the ratio of RANK L:OPG, and alterations in this ratio may be a major cause of bone loss in certain metabolic disorders such as estrogen-deficiency and glucocorticoid-excess (Hofbauer *et al*., 2000; Rodan and Martin, 2000) (Figs. 21-54 and 21-55). A long-term increase in the secretion of PTH also may result in the formation of greater numbers of osteoblasts and an increase in bone formation and resorption. However, because bone resorption by osteoclasts usually is greater than bone formation by osteoblasts, there is a net negative balance in skeletal mass.

The initial binding of PTH to osteoblasts lining bone surfaces causes the cells to contract, thereby exposing the underlying mineral to osteoclasts (Fig. 21-48). If the increase in PTH is sustained, the size of the active osteoclast pool in bone is increased by the activation of progenitor cells of the osteoclastic lineage. The plasma membrane of osteoclasts in intimate contact with the resorbing bone surface is modified to form a series of membranous projections referred to as the brush "ruffled" border. This area of active bone resorption is isolated from the extracellular fluids by adjacent transitional "sealing" zones, thereby localizing the lysosomal enzymes and acidic environment to the immediate area undergoing dissolution. The mineral and organic components such as hydroxyproline released from bone are phagocytized by osteoclasts and transported across the cell in transport vesicles to be released into the extracellular fluid compartment.

Parathyroid hormone also has a direct and rapid effect on renal tubular function. About 5–10 minutes after PTH administration, the reabsorption of phosphate is decreased, causing phosphaturia. The site of action of PTH on the tubular reabsorption of phosphate has been localized by micropuncture methods to the proximal convoluted tubule of the nephron. In addition, PTH leads to the increased urinary excretion of potassium, sodium bicarbonate, cyclic adenosine monophosphate, and amino acids. Although the effect of PTH on the tubular reabsorption of phosphate has been considered to be of importance, the capability of PTH to enhance the renal reabsorption of calcium is of more importance in the maintenance of calcium homeostasis. This effect of PTH upon tubular reabsorption of calcium appears to be due to a direct action on cells of the distal convoluted tubule of the kidney nephron. The other important effect of PTH on the kidney is the regulation of the conversion of 25-hydroxycholecalciferol to 1,25-dihydroxycholecalciferol and other metabolites of vitamin D.

Assay of Parathyroid Hormone

Under normal conditions, PTH is secreted continuously from chief cells. Biologically active parathyroid hormone is a linear peptide chain of 84 amino acids which is cleaved in the liver and possibly elsewhere, an amino-terminal fragment comprising approximately one-third of the PTH molecule, and a larger carboxy-terminal fragment which is biologically inactive. Parathyroid hormone is secreted in two forms by chief cells: *first*, an intact PTH peptide comprising amino acids 1 through 84 (PTH 1-84) and *second*, a C-terminal peptide (PTH 35–84). Intact PTH (1–84) is the principal circulating biologically active form of PTH, has a half-life of less than 5 minutes, and is rapidly removed from the circulation by endopeptidases in hepatic Kupffer cell membranes or by glomerular filtration (Arnaud and Pun, 1992). Some C-terminal peptide is released into the circulation by Kupffer cells and is then cleared by the kidney. The kidney is a major organ for the degradation of PTH. As a result the C-terminal PTH fragment has a biological half-life that is longer than that of intact PTH (1–84) and is present in the serum in higher concentrations (50–90% of total PTH), especially in cases of hyperparathyroidism associated with chronic renal disease.

The multiple forms of PTH and PTH fragments in the circulation made the development of specific and sensitive radioimmunoassays (RIAs) for this hormone difficult. Early assays for PTH were single-site radioimmunoassays for C-terminal peptides. These assays were suboptimal because both the biologically active and inactive forms of PTH were quantified; nevertheless, the assay was clinically useful to diagnose and monitor hyperparathyroidism in

patients with normal renal function. Mid-region and C-terminal RIAs measure both intact PTH (active) and C-terminal PTH (inactive) which renders them less clinically relevant. In addition, conditions that reduce the glomerular filtration rate, such as renal failure, result in a large increase in the serum concentration of C-terminal PTH. Concentrations of intact PTH in the serum of animals are best measured by a two-site immunoradiometric assay (IRMA).

Xenobiotic Chemical-Induced Toxic Injury of Parathyroids

Ozone Inhalation of a single dose of ozone (0.75 ppm) for 4–8 hours has been reported to produce light and electron microscopic changes in parathyroid glands (Atwal and Wilson, 1974). Subsequent studies have utilized longer (48-hours) exposure to ozone in order to define the pathogenesis of the parathyroid lesions (Atwal *et al.*, 1975; Atwal, 1979). Initially (1–5 days post-ozone exposure), many chief cells undergo compensatory hypertrophy and hyperplasia with areas of capillary endothelial cell proliferation, interstitial edema, degeneration of vascular endothelium, formation of platelet thrombi, leukocyte infiltration of the walls of larger vessels in the gland, and disruption of basement membranes. Chief cells had prominent Golgi complexes and endoplasmic reticulum, aggregations of free ribosomes, and swelling of mitochondria (Atwal and Pemsingh, 1981).

Inactive chief cells with few secretory granules predominate in the parathyroids in the later stages of exposure to ozone. There was evidence of parathyroid atrophy from 12 to 20 days post-ozone exposure with mononuclear cell infiltration and necrosis of chief cells. The reduced cytoplasmic area contained vacuolated endoplasmic reticulum, a small Golgi apparatus, and numerous lysosomal bodies. Plasma membranes of adjacent chief cells were disrupted resulting in coalescence of the cytoplasmic area. Fibroblasts with associated collagen bundles were prominent in the interstitium and the basal lamina of the numerous capillaries often was duplicated.

The parathyroid lesions in ozone-exposed animals are similar to isoimmune parathyroiditis in other species (Lupulescu *et al.*, 1968). Antibody against parathyroid tissue was localized near the periphery of chief cells by indirect immunofluorescence, especially 14 days following ozone injury (Atwal *et al.*, 1975).

Aluminum Evidence for a direct effect of aluminum on the parathyroid was suggested from studies of patients with chronic renal failure treated by hemodialysis with aluminum-containing fluids or orally administered drugs containing aluminum. These patients often had normal or minimal elevations of immunoreactive parathyroid hormone (iPTH), little histological evidence of osteitis fibrosa in bone, and a depressed response by the parathyroid gland to acute hypocalcemia (Bourdeau *et al.*, 1987). Studies by Morrissey *et al.* (1983) have reported that an increase in aluminum concentration in vitro over a range of 0.5–2.0 mM in a low calcium medium (0.5 mM) progressively inhibited the secretion of PTH. At 2.0 mM aluminum, PTH secretion was inhibited by 68% while high calcium-containing medium (2.0 mM) without aluminum maximally inhibited PTH secretion only 39%. The inhibition of PTH secretion by aluminum does not appear to be related to an irreversible toxic effect because normal secretion was restored when parathyroid cells were returned to 0.5 mM calcium medium without aluminum. The incorporation of [^{3}H] leucine into total cell protein, parathyroid secretory protein, proparathyroid hormone, or PTH was not affected

by aluminum; however, the secretion of radiolabeled protein by dispersed parathyroid cells was inhibited by aluminum (Morrissey *et al.*, 1983).

The molecular mechanism by which aluminum inhibits PTH secretion, reducing diglyceride levels in chief cells (Morrissey and Slatopolsky, 1986), appears to be similar to that of the calcium ion. Aluminum appears to decrease diglyceride synthesis, which is reflected in a corresponding decrease in synthesis of phosphatidylcholine and possible triglyceride; however, phosphatidylinositol synthesis was not affected by aluminum.

Calcium regulates PTH gene expression by a post-transcriptional mechanism plus parathyroid gland growth through activation of the calcium-sensory receptor. Aluminum impairs parathyroid function through a calcium-like mechanism due to a lack of specificity of the calcium-sensing receptor. In addition, aluminum decreases parathyroid calcium-sensing receptor mRNA levels and the regulatory mechanism was post-transcriptional (González-Suárez *et al.*, 2005).

L-**Asparaginase** Tettenborn *et al.* (1970) and Chisari *et al.* (1972) reported that rabbits administered L-asparaginase develop severe hypocalcemia and tetany characterized by muscle tremors, opisthotonos, carpopedal spasms, paralysis, and coma. This drug was of interest in cancer chemotherapy because of the beneficial effects of guinea pig serum against lymphosarcoma in mice.

Parathyroid chief cells appeared to be selectively destroyed by L-asparaginase (Young *et al.*, 1973). Chief cells were predominately inactive and degranulated, with large autophagic vacuoles present in the cytoplasm of degenerating cells. Cytoplasmic organelles concerned with synthesis and packaging of secretory products were poorly developed in chief cells. Rabbits developed hyperphosphatemia, hypomagnesemia, hyperkalemia, and azotemia in addition to acute hypocalcemia. Rabbits with clinical hypocalcemic tetany did not recover spontaneously; however, administration of parathyroid extract prior to or during treatment with L-asparaginase decreased the incidence of hypocalcemic tetany.

The development of hypocalcemia and tetany have not been observed in other experimental animals administered L-asparaginase (Oettgen *et al.*, 1970). However, this response may not be limited to the rabbit because some human patients receiving the drug also have developed hypocalcemia (Jaffe *et al.*, 1972). The L-asparaginase-induced hypoparathyroidism in rabbits is a valuable model for investigating drug-endocrine cell interactions, somewhat analogous to the selective destruction of pancreatic beta cells by alloxan with production of experimental diabetes mellitus.

Proliferative Lesions of Parathyroid Chief Cells

Chief Cell Tumors Parathyroid adenomas in adult-aged rats vary in size from microscopic to unilateral nodules several millimeters in diameter, located in the cervical region by the thyroids or infrequently in the thoracic cavity near the base of the heart. Parathyroid neoplasms in the precardiac mediastinum are derived from ectopic parathyroid tissue displaced into the thorax with the expanding thymus during embryonic development. Tumors of parathyroid chief cells do not appear to be a sequela of long-standing secondary hyperparathyroidism of either renal or nutritional origin (Capen, 1997b). The unaffected parathyroid glands may be atrophic if the adenoma is functional, normal if the adenoma is nonfunctional, or enlarged if there is concomitant hyperplasia. In functional adenomas the normal mechanism by which PTH secretion is regulated, changes in the

concentration of blood calcium ion, is lost and hormone secretion is excessive in spite of an increased level of blood calcium.

Adenomas are solitary nodules that are sharply demarcated from adjacent parathyroid parenchyma. Because the adenoma compresses the rim of surrounding parathyroid to varying degrees depending upon its size, there may be a partial fibrous capsule, resulting either from compression of existing stroma or from proliferation of fibrous connective tissue.

Adenomas are usually nonfunctional (endocrinologically inactive) in adult-aged rats from chronic toxicity/carcinogenicity studies (Capen, 1997b; Arnold *et al.*, 2003). Chief cells in nonfunctional adenomas are cuboidal or polyhedral and arranged either in a diffuse sheet, lobules, or acini with or without lumens. Chief cells from functional adenomas often are closely packed into small groups by fine connective tissue septae. The cytoplasmic area varies from normal size to an expanded area. There is a much lower density of cells in functional parathyroid adenoma compared to the adjacent rim with atrophic chief cells.

Larger parathyroid adenomas, such as those that are detected macroscopically, often nearly incorporate the entire affected gland. A narrow rim of compressed parenchyma may be detected at one side of the gland or the affected parathyroid may be completely incorporated by the adenoma. Chief cells in this rim often are compressed and atrophic due to pressure and the persistent hypercalcemia. Peripherally situated follicles in the adjacent thyroid lobe may be compressed to a limited extent by larger parathyroid adenomas. The parathyroid glands that do not contain a functional adenoma also undergo trophic atrophy in response to the hypercalcemia and become smaller.

Influence of Age on Development of Parathyroid Tumors   There are relatively few chemicals or experimental manipulations reported in the literature that increase the incidence of parathyroid tumors. Long-standing renal failure with intense diffuse hyperplasia does not appear to increase the development of chief cell tumors in rats. The historical incidence of parathyroid adenomas in untreated control male F344 rats in studies conducted by the NTP was 4/1315 (0.3%), and for female F344 rats it was 2/1330 (0.15%). However, parathyroid adenomas are an example of a neoplasm in F344 rats whose incidence increases dramatically when life span data are compared to 2-year studies. Solleveld *et al.* (1984) reported that the incidence of parathyroid adenomas increased in males from 0.1% at 2 years to 3.1% in lifetime studies. Corresponding data for female F344 rats was 0.1% at 2 years and 0.6% in lifetime studies.

Influence of Gonadectomy   Oslapas *et al.* (1982) reported an increased incidence of parathyroid adenomas in female (34%) and male (27%) rats of the Long–Evans strain administered 40 μCi sodium ^{131}I and saline at 8 weeks of age. There were no significant changes in serum calcium, phosphorus, and parathyroid hormone compared to controls. Gonadectomy performed at 7 weeks of age decreased the incidence of parathyroid adenomas in irradiated rats (7.4% in gonadectomy vs. 27% in intact controls) but there was little change in the incidence of parathyroid adenomas in irradiated females. X-irradiation of the thyroid–parathyroid region also increased the incidence of parathyroid adenomas. When female Sprague–Dawley rats received a single absorbed dose of X-rays at 4 weeks of age, they subsequently developed a 24% incidence of parathyroid adenomas after 14 months (Oslapas *et al.*, 1981).

Influence of Xenobiotic Chemicals   Parathyroid adenomas have been encountered infrequently following the administration of a variety of chemicals in 2-year bioassay studies (Capen, 1997a,b). In a study with the pesticide Rotenone in F344 rats, there appeared to be an increased incidence of parathyroid adenomas in high-dose (75 ppm) males (4 of 44 rats) compared to either low-dose (38 ppm) males, control males (1 of 44 rats), or NTP historical controls (0.3%) (Abdo *et al.*, 1988). It was uncertain whether the increased incidence of this uncommon tumor was a direct effect of Rotenone feeding or the increased survival in high-dose males. Chief cell hyperplasia was not present in parathyroids that developed adenomas.

Influence of Irradiation and Hypercalcemia Induced by Vitamin D   Wynford-Thomas *et al.* (1982) reported that irradiation significantly increases the incidence of parathyroid adenomas in inbred Wistar albino rats and that the incidence could be modified by feeding diets with variable amounts of vitamin D. Neonatal Wistar rats were given either 5 or 10 μCi radioiodine (^{131}I) within 24 h of birth. In rats 12 months of age and older, parathyroid adenomas were found in 33% of rats administered 5 μCi ^{131}I and in 37% of rats given 10 μCi ^{131}I compared to 0% in unirradiated controls. The incidence of parathyroid adenomas was highest (55%) in normocalcemic rats fed a low vitamin D diet and lowest (20%) in irradiated rats fed a high vitamin D diet (40,000 IU/kg) that had a significant elevation in plasma calcium.

Age-Related Changes in Parathyroid Function

Serum immunoreactive parathyroid hormone (iPTH) (as well as calcitonin [iCT]) have been reported to be different in young compared to aged Fischer 344 (F344) rats; however, the serum calcium concentration does not change with age (Wongsurawat and Armbrecht, 1987). This suggests that the regulation of iPTH (and iCT) secretion may be affected by the process of aging. The decreased responsiveness of chief cells to calcium may be due to age-related changes in the regulation of the secretory pathway. This could include age-related changes in the effect of calcium on release of stored PTH, intracellular degradation of PTH, or modification of adenylate cyclase activity as observed in other tissues that utilize calcium as an intermediary signal (Brown, 1982). Therefore, the sensitivity of parathyroid chief cells to circulating calcium ion concentration appears not to be fixed but may change during development, aging, and in response to certain disease processes.

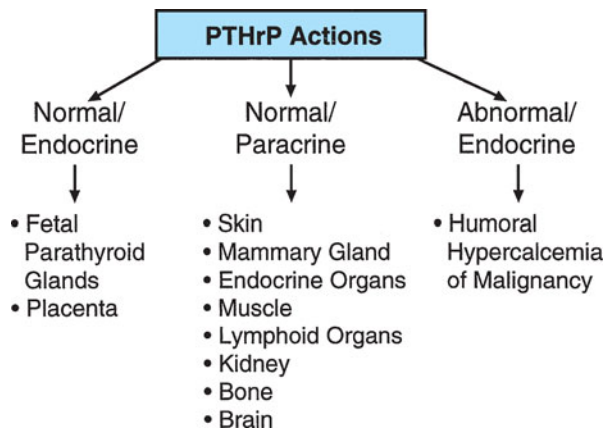
The increased secretion of iPTH with advancing age in rats could be due to several factors (Capen, 1994): *first*, an increased number of parathyroid secretory cells with age or *second*, an altered regulation of chief cells in response to calcium ion associated with the process of aging. For example, a decreased sensitivity of chief cells to negative feedback by calcium ion could result in the higher blood levels of iPTH in aged F344 rats. Wada *et al.* (1992) reported that the early age-related rise in plasma PTH in F344 rats was neither a consequence of low plasma calcium nor of renal insufficiency. Age-related changes in the responsiveness of chief cells to circulating levels of other factors which modulate iPTH secretion, particularly 1,25-dihydroxycholecalciferol and alpha and beta adrenergic catecholamines, also could contribute to the variations in blood levels of iPTH in rats of different ages. In addition, target cell responsiveness to PTH also decreases with advancing age in rats. PTH does not increase the renal production of 1,25-dihydroxyvitamin D in adult (13-month-old) male F344 rats compared to young (2-month-old) rats where its production


Figure 21-56. Actions of parathyroid hormone-related protein (PTHrP) under normal and abnormal conditions. (From Rosol and Capen, 1997.)

was increased 61% (Armbrecht *et al.*, 1982). Older rats have a decreased calcemic response and decreased renal production of 1,25-dihydroxycholecalciferol compared to young rats (Armbrecht *et al.*, 1982; Kalu *et al.*, 1982).

Parathyroid Hormone-Related Protein (PTHrP)

Relationship to Parathyroid Hormone　Parathyroid hormone-related protein (PTHrP) was first identified in 1982 as an important PTH-like factor that plays a central role in the pathogenesis of cancer-associated hypercalcemia (humoral hypercalcemia of malignancy). PTHrP is a 139, 141, or 173 amino acid peptide, originally isolated from human and animal tumors associated with humoral hypercalcemia of malignancy (Gröne *et al.*, 1997). Humoral hypercalcemia of malignancy (HHM) (pseudohyperparathyroidism) is a syndrome associated with diverse malignant neoplasms in animal and human patients (Rosol and Capen, 1992, 1997, 2000). Characteristic clinical findings in patients with HHM include hypercalcemia, hypophosphatemia, hypercalciuria (often with decreased fractional calcium excretion), increased fractional excretion of phosphorus, increased nephrogenous cAMP, and increased osteoclastic bone resorption. Hypercalcemia is induced by humoral effects on bone, kidney, and possibly the intestine. The PTHrP peptide shares 70% sequence homology with the first 13 amino acids of intact PTH. The N-terminal region of PTHrP (amino acids 1–34) binds to and activates PTH receptors in bone and kidney cells with equal affinity as PTH. However, PTHrP is not strictly a calcium-regulating hormone and it has been determined that PTHrP is widely produced in the body and acts as a paracrine factor in the tissues in which it is produced (Fig. 21-56).

Role in the Fetus　The fetus maintains higher concentrations of serum calcium compared to the dam (Care, 1991). Because the fetal parathyroid glands produce low levels of PTH, the mechanism of maintaining increased serum concentrations of calcium was unknown until the finding that PTHrP maintains calcium balance in the fetus (Care, 1991) and is the major hormone secreted by the chief cells of the fetal parathyroid glands. The PTHrP produced by the placenta also stimulates the uptake of calcium by the fetus. Parathyroid hormone-related peptide plays a role in the differentiation of many tissues during gestation and is especially important in the growth and development of bone. Growth of cartilage at the

epiphyseal plate is regulated by the actions or PTHrP which stimulates chondrocyte proliferation, inhibits apoptosis, and inhibits the maturation of chondrocytes from the proliferative zone to the hypertrophic zone (Vortkamp *et al.*, 1996), responses which are dependent on the translocation of PTHrP to the nucleus and nucleolus (Henderson *et al.*, 1995).

Role in Adults　Many tissues in adult animals including endocrine glands, smooth, skeletal, and cardiac muscles, brain, lymphocytes, lactating mammary gland, kidney, prostate gland, lung, skin, and bone produce PTHrP. The function of PTHrP in most of these tissues is incompletely understood, but likely is an autocrine or paracrine regulatory factor. Circulating concentrations of PTHrP in normal animals and humans are low (<1 pM) (Burtis, 1992; Rosol *et al.*, 1995) and the PTH/PTHrP receptor is often expressed on the same or adjacent cells in tissues that synthesize PTHrP.

Epidermal keratinocytes produce PTHrP which plays a role in their proliferation or differentiation. However, keratinocytes do not contain the classic PTH/PTHrP receptor, which suggests that keratinocytes have an alternate PTHrP receptor (Orloff *et al.*, 1992). The greatest concentration of PTHrP is found in milk (10–100 nmol/L) and is 10,000 to 100,000-fold greater than in the serum (Ratcliffe, 1992; Riond *et al.*, 1995). The function of PTHrP in the mammary gland and in milk is poorly understood at present. However, over-expression of PTHrP in the mammary gland during glandular development prior to lactation results in glandular hypoplasia due to a reduction in the morphogenesis and branching of the mammary ducts.

Biologically active PTHrP produced by alveolar epithelial cells during lactation results in the high concentration of PTHrP in milk and this PTHrP may play a role in stimulating the transport of calcium by alveolar epithelial cells from serum to milk (Parfitt, 1987; Barlet *et al.*, 1992). Synthesis of PTHrP by the mammary gland abruptly ceases when suckling stops and the gland undergoes involution. The PTHrP peptide is enzymatically cleaved in milk, but the N-terminal PTHrP fragment retains biologic activity. Although circulating concentrations of PTHrP may be minimally increased in lactating dams, no significant relationship has been demonstrated between PTHrP and the pathogenesis of parturient hypocalcemia and paresis in lactating dairy cattle (Riond *et al.*, 1996). Hence PTHrP from the mammary gland likely plays a minor role in the systemic calcium balance of lactating animals but may have physiological functions in suckling neonates, such as regulation of growth or differentiation of the gastrointestinal tract.

TESTIS

Structure and Endocrinologic Regulation of Leydig (Interstitial) Cells

Leydig (interstitial) cell tumors are one of the more frequently occurring endocrine tumors in rodents in chronic toxicity/carcinogenicity studies, and a great deal of research has been published in the literature investigating their pathogenesis and implications for safety assessment. Rodent testicular tumors are classified into five general categories including tumors derived from cells of the gonadal stroma, neoplasms of germ cell origin, tumors derived from adnexal structures or serous membranes, and, lastly, a group of tumors derived from the supporting connective tissues and vessels of the testis.

Neoplasms of the gonadal stroma include benign and malignant tumors derived from Leydig (interstitial) cells, Sertoli cells

Figure 21-57. Spontaneous incidence of Leydig cell tumors of the testis in Sprague–Dawley, Wistar, and Fischer rats. (From Bär, 1992).

carcinogenicity studies, including the Fischer 344 and Wistar strains. The spontaneous incidence of Leydig cell tumors in three different strains of rats is illustrated in Fig. 21-57 (Bär, 1992). The actual incidence of Leydig cell tumors in old rats is lowest in Sprague–Dawley, highly variable in Wistar rats, and highest in Fischer rats (in which the incidence at 2 years of age often approaches 100%). The specific numerical incidence of benign Leydig cell tumors in rats also will vary considerably depending upon the histological criteria used by the pathologist in the separation of focal hyperplasia from adenomas.

In comparison to rodents, the incidence of Leydig cell tumors in human patients is extremely rare, something to the order of one in five million with age peaks at approximately 30 and 60 years. Ninety or more percent of Leydig cell tumors in humans are benign and some appear to be endocrinologically active and associated clinically with gynecomastia. The most common and clinically important testicular neoplasms in men are of germ cell origin (e.g., seminona). By comparison, germ cell tumors are rare in rodents either as a spontaneous lesion or following exposure to large doses of xenobiotic chemicals.

Although the numbers of Leydig cells vary somewhat among different animal species and humans, the basic structural arrangement is similar. In the rat, there are small groups of Leydig cells clustered around blood vessels in the interstitium, between seminiferous tubules with an incomplete layer of endothelial cells around the groups of Leydig cells. In humans, the Leydig cells are present as small groups in the interstitium near blood vessels or in loose connective tissue but without the surrounding layer of endothelial cells. Leydig cells are much more numerous in some animal species, such as the domestic pig. Microscopic evaluation of the normal rat testis reveals the inconspicuous clusters of Leydig cells in the interstitium between the much larger seminiferous tubules composed of spermatogonia and Sertoli cells. The close anatomic association of Leydig cells and interstitial blood vessels permits the rapid exchange of materials between this endocrine cell population and the systemic circulation.

The endocrinological regulation of Leydig cells involves the coordinated activity of the hypothalamus and adenohypophysis (anterior pituitary) with negative feedback control exerted by the blood concentration of gonadal steroids (Fig. 21-58). Hypothalamic

of the seminiferous tubules, as well as a rare mixed tumor with an admixture of both cell types. The Leydig cell tumor is the most common tumor developing in the rodent testis and frequently presents a problem in separating between focal hyperplasia and early neoplastic growth (i.e., adenoma formation).

The incidence of Leydig cell tumors in old rats varies considerably depending upon the strain. In general, Sprague–Dawley, Osborne–Mendel, and Brown–Norway strains have a much lower incidence than other strains frequently used in chronic toxicity/

Figure 21-58. Hypothalamus–anterior pituitary gland–gonad axis in the endocrine control of Leydig and Sertoli cells by luteinizing hormone (LH) and follicle-stimulating hormone (FSH). (From Hedge et al., 1987).
Figure 21-59. Hormonal control of testicular function.

Luteinizing hormone (LH) stimulates testosterone (T) release by binding to its receptor (R) and increasing the conversion of cholesterol (chol) to pregnenolone (preg) via a cAMP-protein kinase (PK) cascade. Spermatogenesis (bold arrows) is controlled by both FSH and testosterone acting via Sertoli cells. (From Hedge *et al.*, 1987.)

gonadotrophin-releasing hormone (GnRH) stimulates the pulsatile release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from gonadotrophs in the adenohypophysis. Luteinizing hormone is the major trophic factor controlling the activity of Leydig cells and the synthesis of testosterone. The blood levels of testosterone exert negative feedback on the hypothalamus and, to a lesser extent, on the adenohypophysis. Follicle-stimulating hormone binds to receptors on Sertoli cells in the seminiferous tubules and, along with the local concentration of testosterone, plays a critical role in spermatogenesis. Testosterone, by controlling GnRH release, is one important regulator of FSH secretion by the pituitary gland. The seminiferous tubules also produce a glycopeptide, designated as inhibin, that exerts negative feedback on the release of FSH by the gonadotrophs.

Leydig cells have a similar ultrastructural appearance as other endocrine cells that synthesize and release steroid hormones. The abundant cytoplasmic area contains numerous mitochondria, abundant profiles of smooth endoplasmic reticulum, prominent Golgi apparatuses associated with lysosomal bodies, and occasional lipofucsin inclusions. However, they lack the hormone-containing secretory granules that are found characteristically in peptide-hormone-secreting endocrine cells.

The hormonal control of testicular function is largely the result of the coordinated activities of LH and FSH from the pituitary gland. LH binds to high-affinity, low-capacity receptors on the surface of Leydig cells and activates adenylate cyclase in the plasma membrane resulting in the generation of an intracellular messenger, cyclic AMP (Fig. 21-59). The cyclic AMP binds to a protein kinase, resulting in the phosphorylation of a specific set of proteins in the cytosol, which increases the conversion of cholesterol to pregnenolone by making more substrate available and increasing the activity of an

enzyme that cleaves the side chain of cholesterol. The pregnenolone in Leydig cells is rapidly converted to testosterone, which is released into interstitial blood vessels or taken up by adjacent Sertoli cells. Testosterone in Sertoli's cells binds to nuclear receptors where it increases genomic expression and transcription of mRNAs that direct the synthesis of proteins (e.g., androgen-binding protein and others) involved in spermatogenesis. In the rat, the mitotic phase of gametogenesis can occur without hormonal stimulation but testosterone is necessary for meiosis of spermatocytes to spermatids. FSH is required for the later stages for spermatid maturation to spermatazoa (Fig. 21-59). Once FSH and testosterone initiate spermatogenesis at puberty in the rat, testosterone alone is sufficient to maintain sperm production.

Pathology of Leydig (Interstitial) Cell Tumors

Before discussing the pathology of focal proliferative lesions of Leydig cells, a few points should be made about the importance of standardized sectioning methods for the complete evaluation of the rodent testis. It is not unusual to have less than optimal sections to evaluate, due either to a lack of a consistent plane of section or to inadequate fixation. The goal should be to include the largest testicular area containing all anatomic features on a mid-sagittal section along the long axis of the testis to include spermatic vessels, attachment sites of the epididymis, tubulus rectus, and intratesticular rete testis. It is also important to emphasize the need to cut the thick outer covering (tunica albuginea) of the testis at several points prior to immersion in the fixative, in order to permit more rapid penetration of the formalin or other fixing solution.

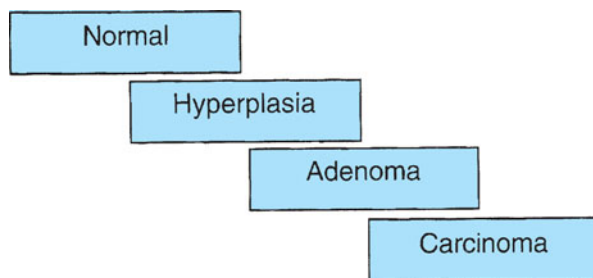
The major issue in the interpretation of focal proliferative lesions of Leydig cells in the rodent testis is the accurate and
Figure 21-60. Multistage model of carcinogenesis of proliferative lesions in endocrine tissues of rodents.


Figure 21-61. Morphological continuum of proliferative lesions in endocrine tissues of rodents.

consistent separation of focal hyperplasia from benign tumors (adenomas) that possess autonomous growth. The separation of focal hyperplasia from adenomas derived from Leydig cells is arbitrary based upon current methods of evaluation and often is based primarily on the size of the focal lesion, since cytologic features usually are similar between focal hyperplastic and benign neoplastic lesions derived from Leydig cells.

In the multistage model of carcinogenesis, proliferative lesions are designated as beginning with hyperplasia, often progressing to benign tumors (adenomas), and infrequently a few assume malignant potential and form carcinomas ("cancer") (Fig. 21-60). Although this terminology often is applied to focal proliferative lesions in rodent endocrine tissues for convenience and standardization, it is essential to understand that the separation, especially between focal hyperplasia and adenoma, is based primarily on size and morphologic changes in the proliferating Leydig cells. It is important to emphasize that focal proliferative lesions in rodent endocrine tissues also including Leydig cells, adrenal medullary cells, thyroid follicular and C-cells, among others, represent a morphologic continuum that begins with hyperplasia and progresses often but not always to the formation of adenomas that grow autonomously and only occasionally undergo a malignant transformation to form carcinomas ("cancer") (Fig. 21-61).

The National Toxicology Program (NTP), in an attempt to standardize the classification of focal proliferative lesions of Leydig cells between studies with different xenobiotic chemicals and different testing laboratories, established the following diagnostic criteria (Boorman *et al.*, 1987): (1) hyperplasia was defined as a focal collection of Leydig cells with little atypia and a diameter of less than one seminiferous tubule. (2) An adenoma was defined as a mass of Leydig cells larger in diameter than one seminiferous tubule with some cellular atypia and compression of adjacent tubules. (3) It was emphasized that the separation was arbitrary since at that time little was known about the biological behavior of these lesions in rodents.

A more contemporary set of diagnostic criteria for focal proliferative lesions of Leydig cells has been published recently by the Society of Toxicologic Pathologists (STP) (McConnell *et al.*, 1992). Recognizing that many small focal proliferative lesions of Leydig cells (i.e., between 1 and 3 tubule diameters) will regress following removal of the inciting stimulus, they recommend the diagnosis of Leydig cell adenoma be used for a mass of interstitial cells equal to or greater than the diameter of three adjacent seminiferous tubules plus one or more of the following criteria: symmetrical peripheral compression of adjacent tubules, evidence of cellular pleomorphism, or an increase in the nuclear:cytoplasmic ratio, an endocrine sinusoidal vascular network, increased mitotic activity, or coalescence of adjacent cell masses.

Leydig cell neoplasms in laboratory rats rarely undergo malignant transformation with progression to the development of carcinomas ("cancer"). Histological features of malignancy include invasion into the epididymus, spermatic cord, or tunica albuginea. The most definitive criteria of malignancy is the demonstration of metastases in extratesticular sites. Leydig cell carinomas are large and often distort the overall contour of the affected testis with extensive areas of both hemorrhage and necrosis. The cytology of Leydig cell carcinomas usually is more pleomorphic than with adenomas consisting of an admixture of poorly differentiated cells with an increased nuclear:cytoplasmic ratio and larger, more differentiated cells with an abundant vacuolated eosinophilic cytoplasmic area. The frequency of mitotic figures may be increased either in focal areas or throughout the Leydig cell carcinomas. The most convincing evidence of malignancy in carcinomas is the establishment of foci of growth outside of the testis, such as multiple foci of tumor cell emboli growing within and distending vessels of the lung.

Mechanisms of Leydig (Interstitial) Cell Tumor Development

Leydig (interstitial) cells of the testis frequently undergo proliferative changes with advancing age and following chronic exposure to large doses of xenobiotic chemicals. In addition, it should be emphasized that the "sensitivity" of rodent endocrine tissues, such as Leydig cells of the testis and other populations of endocrine cells, appears to be increasing over time particularly if one compares data generated in the 1970s to that gathered in the 1990s for the same compound (Table 21-4). This appears to be the result of several factors, including: (1) animal husbandry practices, such as specific pathogen-free conditions, that result in a greater survival for 2 years,

Table 21-4

high body weight related to over feeding, and immobility; and (2) the genetic selection process for high productivity and rapid growth.

Pathogenic mechanisms reported in the literature to be important in the development of proliferative lesions of Leydig cells include irradiation, the species and strain differences mentioned previously, and exposure to certain chemicals such as cadmium salts (Waalkes *et al*., 1997) and 2-acetoaminofluorene (Prentice and Meikle, 1995) (Table 21-5). Other pathogenic mechanisms include physiological perturbations such as cryptorchidism, a compromised blood supply to the testis, or heterotransplantation into the spleen. Data from several studies in the recent literature emphasize the importance of several of these pathogenetic factors in the frequent development of Leydig cell tumors in rats. Thurman *et al*. (1994) reported the effects of food restriction on the development of Leydig cell adenomas in the high incidence strain of Fischer 344 rats (Table 21-6). Beginning at 13 weeks of age, rats were either continued on an ad libitum feeding or they were food-restricted 40% (NIH-31 diet with 1.673 fat soluble and B vitamins) over their lifetime until they died or became moribund due to spontaneous disease. The incidence of Leydig cell adenomas was decreased to 19% in food-restricted rats compared to 49% in the ad-libitum-fed group (Table 21-6). In another group from the food restriction study reported by Thurman *et al*. (1994), rats were periodically removed for serial sacrifice at 6-month intervals. Food restriction resulted in a similar marked reduction in Leydig cell adenomas (23% compared to 60% in ad-libitum-fed rats) (Table 21-7). Examination of the serially sacrificed F344 rats in this study also demonstrated that feed restriction delayed the onset of development, as well as decreasing the incidence of Leydig cell adenomas compared to the ad-libitum-fed group (Table 21-8). For example, at the 30-month sacrifice, only 17% of feed-restricted F344 rats had developed Leydig cell adenomas compared to 100% in the ad libitum group.

Disturbances of the Hypothalamic–Hypophyseal–Gonadal Axis
Hormonal imbalances also are important factors in the development of focal proliferative lesions of Leydig cells, including increased estrogenic steroids in mice and hamsters and elevated pituitary gonadotrophins resulting from the chronic administration of androgen receptor antagonists, 5α-reductase inhibitors, testosterone biosynthesis inhibitors, GnRH agonists, and aromatase inhibitors

(Fig. 21-62) (Clegg *et al*., 1997; Cook *et al*., 1992, 1999). Many xenobiotic chemicals when administered chronically to rats disrupt the hypothalamic–pituitary–testis axis at one of several possible sites interfering with negative feedback control, resulting in an over production of luteinizing hormone (LH) that causes the proliferative

changes (hyperplasia, adenoma) in Leydig cells (Fig. 21-63). For example, chronic exposure to chemicals with antiandrogenic activity, such as procymidone due to binding to the androgen receptor, increases circulating levels of LH and results in stimulation of Leydig cells leading to an increased incidence of hyperplasia and adenomas in rats (Murakami *et al.*, 1995).

Investigations reported by Chatani *et al.* (1990) documented the importance of hormonal imbalances on the incidence of Leydig cell adenomas and hyperplasia in Fischer rats (Table 21-9). The incidence of adenomas was 70% and of hyperplasia 100% in control rats killed at 70 weeks of age. In rats administered testosterone for 28 weeks (by silastic tubes implanted subcutaneously at 42 weeks of age), the incidence of Leydig cell adenomas and hyperplasias was decreased to 0% for both at 70 weeks of age. This dramatic reduction in the incidence of focal proliferative lesions of Leydig cells was associated with a significant lowering in circulating levels of LH, through negative feedback exerted by testosterone on the pituitary gland.

The important studies reported by Chatani *et al.* (1990) also demonstrated that hormones other than testosterone could markedly decrease the development of Leydig cell adenomas in F344 rats (Table 21-9). The administration of estradiol-17β for 28 weeks (by silastic tubes implanted subcutaneously) decreased the incidence of Leydig cell adenomas to 0% (compared to 100% in controls) and significantly reduced serum LH, due to negative feedback control on the pituitary gland. An LH-releasing hormone agonist administered continuously for 28 weeks (injection of microcapsules every 4 weeks at a dose of 5 mg/2 mL/kg) also decreased the incidence of Leydig cell adenomas to 0% and significantly decreased circulating LH levels, most likely a result of the known downregulation of LH–RH receptors on pituitary gonadotrophs (Table 21-10).

The studies of Bartke *et al.* (1985) demonstrated that hyperprolactinemia also markedly decreased the incidence of Leydig cell adenomas in Fischer rats (Table 21-11). Pituitaries transplanted beneath the renal capsule (four per rat) resulted in a chronic elevation of circulating prolactin levels, owing, most likely, to the lack of dopamine inhibition of prolactin secretion, which occurs when the pituitary gland is in its normal anatomic location in close proximity to the hypothalamus. In this interesting experiment, 83% of sham-operated rats developed Leydig cell adenomas at 21–24 months of

age, whereas 0% of rats developed tumors in animals with ectopic pituitaries and elevated serum prolactin levels.

The administration of a calcium-channel blocker (SVZ 200-110) at high doses (62.5 mg/kg/day for 2 years) significantly increased the incidence of Leydig cell adenomas in Sprague–Dawley rats. Endocrinological studies demonstrated that increased serum levels of LH and FSH were present only after 52 and 66 weeks, respectively, and persisted to week 104 for LH. This compound is unusual in that most xenobiotic chemicals that cause hormonal imbalances result in earlier significant changes in circulating hormone levels.

Inhibition of Testosterone Synthesis Another important mechanism by which xenobiotic chemicals increase the incidence of Leydig cell tumors in rats is by inhibition of testosterone synthesis by cells in the testis. For example, lansoprazole is a substituted benzimidazole which inhibits the hydrogen-potassuim ATPase (proton pump) responsible for acid secretion by the parietal cells in the fundic mucosa of the stomach (Fort et al., 1995). The presence of the imidazole moiety in lansoprazole was suggestive of an effect on testosterone synthesis because several imidazole compounds (e.g., ketoconazole and miconazole) are known to inhibit testosterone synthesis. Lansoprazole resulted in decreased circulating levels of testosterone, increased levels of LH, and an increased incidence of

Leydig cell hyperplasia and benign neoplasia (adenomas) in chronic studies in rats (Fort et al., 1995). The most sensitive site for inhibition of testosterone synthesis by lansoprazole was the transport of cholesterol to the cholesterol side chain cleavage enzyme.

Leydig Cell Tumorigenesis in Rodents and Relevance for Human Risk Assessment Although several hormonal imbalances result in an increased incidence of Leydig cell tumors in rodents, in human patients several disease conditions associated with chronic elevations in serum LH (including Klinefelter's syndrome and gonadotroph adenomas of the pituitary gland) have not been associated with an increased development of this type of rare testicular tumor.

There are a number of reports in the literature of xenobiotic chemicals (many of which are marketed drugs) that increase the incidence of proliferative lesions of Leydig cells in chronic toxicology/carcinogenicity in rats. These include indomethacin, lactitol, muselergine, cimetidine, gemfibrozil, and flutamide, among many others (Table 21-12).

Flutamide is a potent nonsteroidal, antiandrogen compound that displaces testosterone from specific receptors in target cells and decreases negative feedback on the hypothalamus–pituitary gland, resulting in elevated circulating levels of LH and FSH. The chronic administration of flutamide is known to result in a striking increase in the incidence of Leydig cell adenomas in rats. The Schering-Plough Research Institute's Department of Drug Safety and Metabolism completed an important reversibility study in which Sprague–Dawley rats were administered flutamide daily either for 1 year, 1 year followed by a 1-year recovery period, or continuously for 2 years (Table 21-13). This important study emphasizes the lack of autonomy of many focal proliferative lesions of Leydig cells in rats and their continued dependence upon compound administration for stimulation of growth. There was a reduction in the incidence of Leydig cell adenomas (using the conservative NTP criteria of greater than 1 tubule diameter) in rats administered 3 dose levels of flutamide daily for 1 year followed by a 1-year recovery prior to termination, compared to rats given flutamide for 1 year and immediately evaluated (Table 21-13). Conversely, in rats administered flutamide for 2 years the numbers of adenomas continued to increase until 95% of animals in the mid- and high-dose groups (30 and 50 μg/kg, respectively) had developed Leydig cell tumors. There also was a marked reduction in the incidence of focal hyperplasia (focus less than 1 tubule diameter) after 1 year of

recovery, compared to rats terminated immediately following 1 year of flutamide administration, a finding that emphasizes the frequent reversibility of these small proliferative lesions of Leydig cells.

Although a number of xenobiotic chemicals have been reported to increase the incidence of Leydig cell adenomas in chronic studies in rats, similar compounds such as cimetidine, ketoconazole, and certain calcium channel-blocking drugs have not resulted in an increased incidence of Leydig cell neoplasia in man. In summary, Leydig cell tumors are a frequently occurring tumor in rats, often associated mechanistically with hormonal imbalances; however, they are not an appropriate model for assessing the potential risk to human males of developing this rare testicular tumor.

OVARY

Ovarian Tumors in Rodents

Ovarian tumors in rodents can be subdivided into five broad categories including epithelial tumors, sex cord-stromal tumors, germ cell tumors, tumors derived from nonspecialized soft tissues of the ovary, and tumors metastatic to the ovary from distant sites. The epithelial tumors of the ovary include cystadenomas and cystadenocarcinomas, tubulostromal adenomas, and mesothelioma. The tubular (or tubulostromal) adenomas are the most important of the ovarian tumors in mice, and they are the tumors whose incidence often is increased by various endocrine perturbations associated with exposure to xenobiotics, senescence, or inherited genic deletion (Murphy and Beamer, 1973). Tubular adenomas are a unique lesion that develops frequently in the mouse ovary, accounting for approximately 25% of naturally occurring ovarian tumors in this species (Rehm *et al*., 1984; Alison and Morgan, 1987). They are uncommon in rats, rare in other animal species, and not recognized in the ovaries of women. In some ovarian tumors of this type in mice, there is an intense proliferation of stromal (interstitial) cells of sex cord origin. These tumors often are designated tubulostromal adenomas or carcinomas to reflect the bimorphic appearance.

The tubulostromal adenomas in mice are composed of numerous tubular profiles derived from the surface epithelium, plus abundant large luteinized stromal cells from the ovarian interstitium (Capen, 2004; Capen *et al*., 1995). The differences in histological appearance of this type of unique ovarian tumor in mice are interpreted to represent a morphological spectrum with variable contributions from the surface epithelium and sex cord-derived ovarian interstitium rather than being two distinct types of ovarian tumors. The histogenic origin of this unique ovarian tumor in mice has been a controversial topic in the literature but most investigators currently agree that it is derived from the ovarian surface epithelium, with varying contributions from stromal cells of the ovarian interstitium. However, some early reports suggested an origin from the rete ovarii or thecal/granulosal cells of the ovary.

Another important group of ovarian tumors are those derived from the sex cords and/or ovarian stroma. These include the granulosal cell tumors, luteoma, thecoma, Sertoli cell tumor, tubular adenoma (with contributions from ovarian stroma), and undifferentiated sex cord-stromal tumors. The granulosal cell tumor is the most common of this group which, according to Alison and Morgan (1987), accounts for 27% of naturally occurring ovarian tumors in mice. Granulosal cell tumors may develop within certain tubular or tubulostromal adenomas following a long-term perturbation of endocrine function associated with genic deletion, irradiation, oocytotoxic chemicals, and neonatal thymectomy (Li and Gardner, 1949; Hummel, 1954; Frith *et al*., 1981; Davis and Maronpot, 1996).

Mechanisms of Ovarian Tumorigenesis

Five model systems of ovarian tumorigenesis in mice have been reported in the literature. The first model system identified was the production of ovarian neoplasms by radiation (Furth and Boon, 1947; Gardner, 1950). After acute radiation exposure, the initial change was a rapid loss of oocytes and a destruction of graafian follicles. There was proliferation and down-growth of the ovarian epithelium into the stroma within 10 weeks after radiation exposure. The first ovarian tumors developed approximately 1 year after exposure. The tubular adenomas that develop following radiation often were bilateral, endocrinologically inactive, and not lethal unless they reached a very large size. Some irradiated mice also developed endocrinologically active granulosal cell tumors, which transplantation experiments have shown to be different from the tubular adenomas. Granulosal cell tumors were transplantable into the spleen and often grew rapidly, whereas tubular adenomas grew slowly after transplantation, most successfully in castrated animals.

The second model of ovarian tumorigenesis arose out of the work published by Biskind and Biskind (1944). They transplanted ovaries into the spleen of castrated rats to prevent negative feedback by circulating sex hormones on the hypothalamus and pituitary gland because estrogen is degraded as it circulates through the liver. Transplantation resulted in a rapid loss of ovarian follicles as well as an interference with estrogen feedback on the hypothalamus. Following the loss of graafian follicles, the epithelial covering of the ovary began to proliferate and invaginate into the ovary, with an accompanying increase in stromal tissue that ultimately resulted in the formation of tubular adenomas and, occasionally, granulosal cell tumors (Guthrie, 1957). The presence of a single functioning gonad prevented the development of the proliferative lesions in the ovary, suggesting that the lack of negative feedback from estrogen was necessary for the changes to develop. Administration of exogenous estrogen or testosterone after transplantation completely suppressed development of the proliferative changes in the ovarian cortex.

The third model of ovarian tumorigenesis was described by Marchant (1957, 1960), who reported that ovarian tumors developed in mice exposed to dimethylbenzanthracene. This chemical is a reproductive toxicant that is cytotoxic to oocytes, resulting in the loss of graafian follicles from the ovary. This was followed by a proliferation of the interstitial (stromal) tissue, invaginations of the surface epithelium, and subsequent development of tubular adenomas and occasionally granulosal cell tumors of the ovary (Taguchi *et al*., 1988). Support for an endocrinological mechanism of hormonal imbalance included the observation that the xenobiotic chemical first must cause sterility, because the presence of a single normal gonad prevented the development of the hyperplastic lesions and tumors of

the ovary. The administration of estrogen prevented tumor formation even in sterile mice, and hypophysectomy also prevented the development of ovarian tumors.

The fourth model of ovarian tumorigenesis was described by Nishizuki *et al*. (1979). They reported that removal of the thymus from neonatal mice resulted in ovarian dysgenesis and the development of ovarian tumors. Thymectomy prior to 7 days of age resulted in an immune-mediated destruction of follicles in the ovary. Because estrogen was not produced by the follicles, these mice also developed hormone-mediated proliferative lesions and ovarian tumors identical to those in the previously described models. After the immune-mediated destruction of follicles, there was a proliferation of the interstitial (stromal) and surface epithelial cells of the ovary, resulting in the formation of tubular adenomas. If the mice survived for longer periods, some animals developed granulosal cell tumors and luteomas in the ovary. Because this model also did not involve exposure to any carcinogen, it is another indication that the prerequisite for ovarian tumor response in mice is the production of sterility, which results in hormonal imbalances that lead to stimulation of the sensitive populations of target cells (Michael *et al*., 1981). The fifth model system of ovarian tumorigenesis in rodents is associated with administration of xenobiotic chemicals.

Ovarian Tumors Associated Xenobiotic Chemicals

Nitrofurantoin   Nitrofurantoin is an example of a chemical that, when fed at high doses to mice for 2 years in an NTP study, increased the incidence of ovarian tumors of the tubular or tubulostromal type (Table 21-14). Nitrofurantoin fed at both low (1300 ppm) and high (2500 ppm) doses to B6C3F1 mice caused sterility due to the destruction of ovarian follicles, leading to hormonal imbalances, which resulted in the development of an increased incidence of this unique type of ovarian tumor.

Mice administered nitrofurantoin had a consistent change in the ovarian cortex, termed *ovarian atrophy*. This lesion was characterized by an absence of graafian follicles, developing ova, and corpora lutea; by focal or diffuse hyperplasia with localized or diffuse downgrowth of surface epithelium into the ovary; and by varying numbers of polygonal, often vacuolated, sex-cord-derived stromal (interstitial) cells between the tubular profiles. The ovaries were small, had irregular surfaces due to the tubular down-growths into the cortex, and had scattered eosinophilic stromal cells between tubular profiles. In addition, there was a lack of graafian follicles and corpora lutea throughout the ovarian cortex.

The benign ovarian tumors in this study were classified either as tubular adenomas (5 of 50 mice) or as tubulostromal tumors (4 of 50 mice) (Table 21-14). In tubulostromal adenomas, the proliferating stromal (interstitial) cells between the tubules were considered to represent a significant component of the lesion. However, the separation between these two types of proliferating ovarian lesions in mice was not distinct and both appeared to be part of a continuous morphological spectrum. Because all treated mice in the NTP nitrofurantoin feeding study were sterile due to ovarian atrophy, an indirect mechanism secondary to a disruption of endocrine function leading to hormonal imbalances was suggested to explain the development of the ovarian tubular adenomas.

The results of an investigative study demonstrated that nitrofurantoin had an effect on graafian follicles in the ovary of B6C3F1 mice. Female mice of the same strain were fed 350 or 500 mg/kg/day of nitrofurantoin beginning at 7 weeks of age. These levels approximate the low (1300 ppm) and high (2500 ppm) doses used in the

Figure 21-64. Morphometric evaluation of ovaries of mice following the administration of 350 and 500 mg/kg/day of nitrofurantoin.

The numbers of small, medium, and large ovarian follicles were numerically decreased after 17 weeks and significantly decreased after 43 and 64 weeks due to a direct action of the nitrofurantoin.

NTP study with nitrofurantoin. Ten female mice per group were sacrificed at 4, 8, 13, 17, 43, and 64 weeks of feeding nitrofurantoin. The numbers of follicles were quantified from nitrofurantoin-treated and control mice on serial sections of the ovary. The morphometric data revealed that the numbers of small, medium, and large follicles in nitrofurantoin-treated mice were numerically decreased at 17 weeks compared with controls and were significantly decreased in rats fed 350 and 500 mg/kg/day nitrofurantoin after 43 and 64 weeks (Fig. 21-64). All mice in the treated groups were sterile by 43 weeks of feeding nitrofurantoin.

Selective Estrogen Receptor Modulators   Selective estrogen receptor modulators (SERMs) are compounds that have estrogen ago-nist effects on some tissues and estrogen antagonist actions on other tissues (Cohen *et al*., 2000). The triphenylethylene SERMs tamoxifen and toremifene have estrogen antagonist effects in the breast and currently are used in the medical management of breast cancer. The benzothiophene SERM raloxifene has estrogen agonist effects on bone and serum lipids but estrogen antagonist actions on the uterus and breast (Delmas *et al*., 1997). This is in contrast to tamoxifen that has an estrogen agonist effect on bone and also may stimulate the uterine endometrium. These SERMs (e.g., tamoxifen, toremifene, and raloxifene) all have been reported to increase the incidence of ovarian tumors when administered chronically to mice. For example, CD_1, mice administered raloxifene (9, 50, 225 mg/kg) per day for 21 months developed an increased incidence of granulosa/theca cell tumors (benign and malignant) and tubular/papillary adenomas of the ovary. However, there is no evidence of an increased risk for ovarian cancer in women administered SERMs since tamoxifen has been used clinically since 1978 (Fisher *et al*., 1994; Cook *et al*., 1995).

Raloxifene binds to the estrogen receptor (Yang *et al*., 1996) and appears to block the negative feedback of circulating levels of estrogen on the hypothalamus, resulting in a sustained increase in circulating levels of LH. Mice (CD_1) administered raloxifene (233 or 236 mg/kg) daily for 2 and 4 weeks had a dose-dependent significant elevation of serum LH levels (4- to 7-fold and 4.4-fold compared to controls, respectively) (Cohen *et al*., 2000). Raloxifene-treated mice had sustained elevations in serum LH over a 24-hour period and did not have the preovulatory LH surge present in many control mice. Histomorphologic changes in the ovary were indicative of arrested follicular maturation including anovulatory hemorrhagic follicles, some developing follicles, and few corpora lutea. Following a recovery period of 3 weeks during which no raloxifene was administered, serum LH concentrations were indistinguishable from controls and follicular maturation and corpora lutea distribution were normal. Raloxifene binding to the estrogen receptor resulted in an elevation of serum LH and ovarian tumor development similar to those in estrogen receptor-α knock-out mice with genetic deletion of the estrogen receptor (Korach, 1994), suggesting that the tumors in both instances develop secondary to the hormonal imbalances.

Ovarian Tumors in Mutant Strains of Mice

W^x/W^v Strain with Genetic Deletion of Germ Cells in Ovarian Cortex   In an attempt to arrive at further mechanistic

explanations for the development of tubular adenomas in B6C3F1 mice fed high doses of nitrofurantoin, ovaries were evaluated from several mutant mouse strains not exposed to any xenobiotic chemicals but that are known to develop ovarian tumors (Blaakaer *et al*., 1995). In this mutant mouse strain, referred to as W^x/W^v, few germ cells migrate into the ovary during development. Murphy (1972) reported that less than 1% of the normal complement of oocytes were present in the ovary at 1 day of age and the numbers of graafian follicles decrease progressively until none were present at 13 weeks of age. In this mutant mouse strain (W^x/W^v), a mutant allele at the C-kit locus encodes for a defective protein kinase receptor, resulting in an inability to respond to stem cell growth factor encoded by the Steel locus (Majumder *et al*., 1988; Witte, 1990). A failure of proliferation of primordial germ cells during gonadogenesis leads to the marked reduction of graafian follicles in the ovarian cortex.

Ovaries from mutant mice at age 13 weeks were small, had an irregular surface, were devoid of graafian follicles, and had numerous hyperplastic tubules growing into the cortex. These tubules were lined by a hyperplastic cuboidal epithelium similar to that on the surface of the ovary. Interspersed between the tubular profiles were luteinized stromal cells of the ovarian interstitium with a lightly eosinophilic, often vacuolated, cytoplasm. The proliferative changes observed in the ovary of these mutant (W^x/W^v) mice at 13 weeks of age were similar morphologically to the ovarian atrophy lesions in the NTP nitrofurantoin study.

The ovaries of heterozygous controls (1/1) of this strain were larger than in the mutant mice and had a histological appearance similar to normal mouse ovaries. The ovarian cortex in control mice had plentiful graafian follicles with developing ova. The surface epithelium covering the ovary consisted of a single layer of cuboidal cells without the down-growth of tubules into the underlying cortex.

The ovaries of mutant (W^x/W^v) mice at 22 weeks of age had a more intense proliferation of surface epithelium either with extensive down-growths of hyperplastic tubules into the cortex or the formation of small tubular adenomas. The tubular adenomas in the mutant (W^x/W^v) mice with genetic deletion of graafian follicles but without any exposure to xenobiotic chemicals were composed of proliferating tubules of surface epithelium that replaced much of the ovary. They were similar microscopically to the smaller tubular adenomas in the B6C3F1 mice fed the high dose (2500 ppm) of nitrofurantoin in the 2-year NTP feeding study. Interspersed between the hyperplastic profiles of surface epithelium in the tubular adenomas were scattered luteinized stromal cells with varying degrees of vacuolation of the eosinophilic cytoplasm. In mutant (W^x/W^v) mice, age 22 weeks, whose ovaries had been under long-term intense gonadotrophin stimulation, there appeared to be a morphological continuum between ovarian atrophy and tubular adenomas.

At age 20 months, ovaries of the mutant (W^x/W^v) mice without any exposure to xenobiotic chemicals consistently had large tubular adenomas that incorporated all of the ovarian parenchyma and greatly enlarged the ovary. These neoplasms were similar histologically to the larger tubular adenomas in the high-dose (2500 ppm) mice of the NTP study. Several of the larger ovarian neoplasms of the 20-month-old mutant mice had evidence of malignancy with invasion of tumor cells through the ovarian capsule into the periovarian tissues, often accompanied by a localized desmoplastic response. Histopathologic evidence of malignancy was not observed in the ovarian tubular adenomas from the high-dose (2500 ppm) female mice in the NTP study. An occasional mutant mouse at 20 months of age also had developed focal areas of hyperplasia of granulosal cells or small granulosal cell tumors.

- TUMORS DEVELOP ONLY IN STERILE MICE
- REQUIRES AN INTACT HYPOTHALAMUS-PITUITARY-OVARIAN AXIS
- EXOGENOUS ESTROGEN PREVENTS OVARIAN TUMOR DEVELOPMENT

Figure 21-65. Secondary mechanisms of ovarian oncogenesis in mice.

Hypogonadal (hpg/hpg) Mice Unable to Synthesize Hypothalamic Gonadotrophin-Releasing Hormone (GnRH)   Mutant hypogonadal mice, designated hpg/hpg, are unable to synthesize normal amounts of hypothalamic GnRH (Tennent and Beamer, 1986). They have low circulating levels of pituitary gonadotrophins, and boast FSH and LH; however, these hypogonadal mice have a normal complement of ovarian follicles (Cattanach *et al*., 1977).

In the studies of Tennent and Beamer (1986), both genetically normal littermates and hypogonadal (hpg/hpg) mice were irradiated at age 30 days to destroy the oocytes. The irradiated control mice of this strain produced normal amounts of pituitary gonadotrophic hormones and developed ovarian tubular adenomas at age 10–15 months. The tumors that developed in the absence of any exposure to xenobiotic chemicals had similar histological characteristics as tubular adenomas in the high-dose (2500 ppm) females of the nitrofurantoin study. They either were small nodules involving only a portion of the ovary or large masses that completely incorporated the affected gonad. They were composed predominantly of tubular profiles, some of which were dilated, with interspersed stromal cells.

The irradiated hypogonadal (hpg/hpg) mice failed to develop tubular adenomas or to have intense hyperplasia of the ovarian surface epithelium and interstitial (stromal) cells, in the absence of GnRH and with low circulating levels of pituitary gonadotrophins. The ovaries of irradiated hypogonadal mice were small and had single- or multiple-layered follicles, without oocytes, scattered throughout the ovary. There also was an absence of stromal cell hypertrophy and hyperplasia, a change frequently observed in ovaries of the irradiated normal littermates.

The experiments reported by Tennent and Beamer (1986) demonstrated that a normal secretion of hypothalamic GnRH and pituitary gonadotrophins was necessary for the intense proliferation of ovarian surface epithelium and stromal cells, leading to the formation of tubular adenomas in mice, which develop subsequent to irradiation-induced loss of ovarian follicles and decreased ability to produce gonadal steroids (especially estradiol-17β).

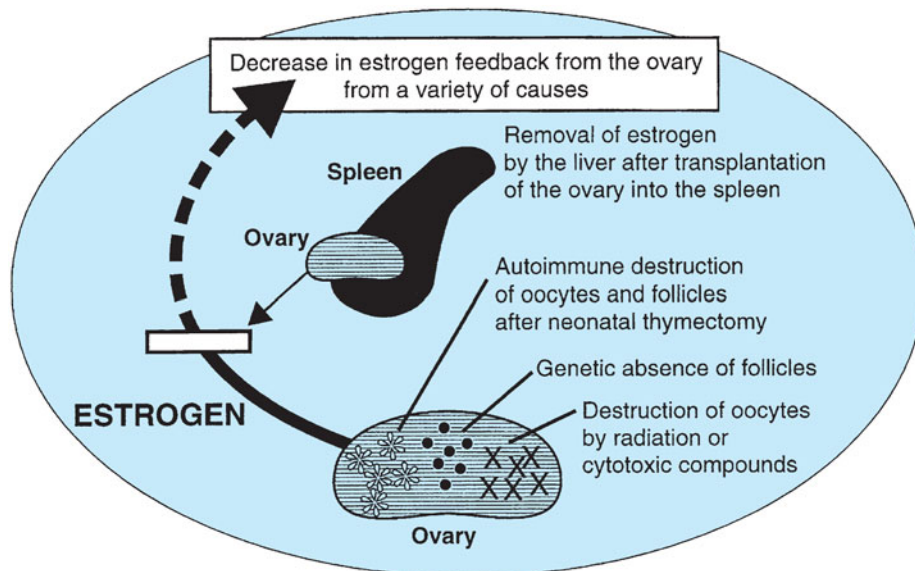
Genetically Engineered Mouse Models of Ovarian Tumors
Transgenic mice expressing a chimeric lutenizing hormone (LH) β submit (LHβ) in pituitary gonadotrophs have increased pituitary expression of LH mRNA and elevated circulating levels of LH (as well as estradiol and testosterone) but are infertile (Risma *et al*., 1995, 1997). They ovulate infrequently, maintain a prolonged luteal phase, and develop a variety of ovarian lesions including cyst (blood and fluid filled) formation and ovarian tumors. A subset of LHβ transgenic mice developed ovarian granulosa and theca-interstitial cell tumors by 4–8 months of age as a result of the chronic stimulation


Figure 21-66. Multiple pathogenic mechanisms in ovarian tumorigenesis of mice resulting in decreased negative feedback by diminished levels of gonadal steroids, particularly estrogen.
Figure 21-67. Decreased circulating estrogens release the hypothalamus–pituitary gland from negative feedback inhibition.

The increased gonadotrophin levels (LH and FSH) result in the mouse ovary being at greater risk of developing tubular adenomas in chronic studies.

by the elevated gonadotropin (LH) levels. The findings of granulosa and stromal cell tumors in transgenic mice whose only genetic alteration is the addition of a gene encoding a chimeric gonadotropin suggest that abnormal gonadotropin stimulation is tumorigenic to the ovary in mice. In addition, genetically altered mice deficient in inhibin (hormone which suppresses the secretion of follicle stimulating hormone [FSH]) have elevated blood concentrations of FSH (two- to threefold) and develop granulosa cell tumors and mixed or incompletely differentiated gonadal stromal tumors of the ovary (Matzuk *et al*., 1992; Amsterdam and Selvaraj, 1997).

Another example of hormonal dysregulation leading to the induction of ovarian tumors are the estrogen receptor knockout (ERKO) mice that lack the alpha estrogen receptors and are unable to regulate gonadotropin secretion due to a lack of negative feedback control by the blood estrogen level (Lubahn *et al*., 1993; Korach,

1994). Female mice are infertile with hypoplastic uteri and hyperemic ovaries with no detectable corpora lutea. There was no uterine stimulation (uterotropic response) when treated with tamoxifen (an estrogen agonist in mice). ERKO mice also develop ovarian granulosal cell tumors in response to the chronic elevations in circulating gonadotropin levels.

Secondary Mechanisms of Ovarian Tumoringenesis in Rodents

A review of studies on mutant mice and the NTP study of nitrofurantoin support an interpretation that the unique intense hyperplasia of ovarian surface epithelium and stromal cells, leading eventually to an increased incidence of tubular adenomas and occasionally granulosa cell tumors, develops secondary to chronic pituitary

gonadotrophic hormone stimulation (Willemsen *et al.*, 1993). Factors that destroy or greatly diminish the numbers of ovarian follicles, such as senescence, genetic deletion of follicles, X-irradiation, drugs and chemicals such as nitrofurantoin, and early thymectomy with the development of autoantibodies to oocytes, are known to diminish sex steroid hormone secretion by the ovary. This results in elevated circulating levels of gonadotrophins, especially LH, due to decreased negative feedback on the hypothalamic-pituitary axis by estrogens and possibly other humoral factors produced by the graafian follicles (Carson *et al.*, 1989). The long-term stimulation of stromal (interstitial) cells, which have receptors for LH (Beamer and Tennent, 1986), and, indirectly, the ovarian surface epithelium appears to place the mouse ovary at increased risk for developing the unique tubular or tubulostromal adenomas.

The finding of similar tubular adenomas in the ovaries of the xenobiotic-treated and genetically sterile mice not exposed to exogenous chemicals supports the concept of a secondary (hormonally mediated) mechanism of ovarian oncogenesis associated with hormonal imbalances (Fig. 21-65). The ovarian tumors developed only in sterile mice in which the pituitary–hypothalamic axis was intact; administration of exogenous estrogen early in the course will prevent ovarian tumor development. The intense proliferation of ovarian surface epithelium and stromal (interstitial) cells with the development of unique tubular adenomas in response to sterility does not appear to have a counterpart in the ovaries of human adult females.

Experimental ovarian carcinogenesis has been investigated in inbred and hybrid strains of mice and induced by a diversity of mechanisms, including X-irradiation, oocytotoxic xenobiotic chemicals, ovarian grafting to ectopic or orthotopic sites, neonatal thymectomy, mutant genes reducing germ cell populations, and aging (Fig. 21-66). Disruptions in the function of graafian follicles by a variety of mechanisms results in a spectrum of ovarian proliferative lesions, including tumors (Hsu and Hsueh, 1997; Rao, 1981). The findings in mutant mice support the concept of a secondary (hormonally mediated) mechanism of ovarian carcinogenesis in mice, associated with sterility. Multiple pathogenetic factors that either destroy or diminish the numbers of graafian follicles in the ovary result in decreased sex hormone secretion (especially estradiol-17β), leading to a compensatory overproduction of pituitary gonadotrophins (particularly LH) (Fig. 21-66), which places the mouse ovary at an increased risk for developing tumors (Fig. 21-67). The intense proliferation of ovarian surface epithelium and stromal (interstitial) cells with the development of unique tubular adenomas in response to sterility does not appear to have a counterpart in the ovaries of human adult females.

TOXIC AGENTS

This page intentionally left blank

CHAPTER 22

TOXIC EFFECTS OF PESTICIDES

Lucio G. Costa

INTRODUCTION

Pesticides can be defined as any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating pests. Pests can be insects, rodents, weeds, and a host of other unwanted organisms (Ecobichon, 2001a). Thus, pesticides occupy a rather unique position among the many chemicals that we encounter daily, in that they are deliberately added to the environment for the purpose of killing or injuring some form of life. Ideally, their injurious action would be highly specific for undesirable targets; in fact, however, most pesticides are not highly selective, but are generally toxic to many nontarget species, including humans. Thus, the use

of pesticides must minimize the possibility of exposure of nontarget organisms to injurious quantities of these chemicals (Murphy, 1986).

It is not uncommon for people to refer to pesticides as a single unitary class of chemicals, while in fact the term pesticide should be equated to that of pharmaceutical drugs. As there are dozens of drugs with different therapeutical indications and different mechanisms of action, several different classes of pesticides exist, with different uses, mechanisms and, hence, toxic effects in nontarget organisms. The most common classification of pesticides relies on the target species they act on. The four major classes (and their target pests) are those of insecticides (insects), herbicides (weeds),

fungicides (fungi, molds), and rodenticides (rodents), but there are also acaricides (mites), molluscides (snails, other mollusks), miticides (mites), larvicides (larvae), and pediculocides (lice). In addition, for regulatory purposes, plant growth regulators, repellants, and attractants (pheromones) often also fall in this broad classification of chemicals. Furthermore, within each class, several subclasses exist, with substantially different chemical and toxicological characteristics. For example, among insecticides, one can find organophosphorus compounds, carbamates, organochlorines, pyrethroids, and many other chemicals. Even within each of these subclasses, significant differences can exist, as is the case, for example, of organochlorine compounds such as DDT, aldrin, or chlordecone. Thus, detailed knowledge of the toxicological characteristics of each chemical is needed to properly evaluate their potential risks for nontarget species.

The literature pertaining to the chemistry, development, nomenclature, biotransformation and degradation, environmental effects, toxicity in target and nontarget species, and mode of action of pesticides over the past 60 years is very extensive, and the reader is referred to the monographs of O'Brien (1967), Ecobichon and Joy (1982), Hayes (1982), Wagner (1983), Matsumura (1985), Costa *et al.* (1987), Baker and Wilkinson (1990), Dikshith (1991), Hayes and Laws (1991), Chambers and Levi (1992), and Krieger (2001), for more indepth discussions.

HISTORICAL DEVELOPMENTS

Pesticides have been used to a limited degree since ancient times. The Ebers Papyrus, written about 1500 B.C., lists preparations to expel fleas from the house. The oldest available record is Homer's mention (about 1000 B.C.) that Odysseus burned sulfur ". . . to purge the hall and the house and the court" (Odyssey XXII, 493–494). Pliny the Elder (A.D. 23–79) collected in his Natural History many anecdotes on the use of pesticides in the previous three to four centuries (Shepard, 1939). Dioscorides, a Greek physician (A.D. 40–90), knew of toxic properties of sulfur and arsenic. There are records showing that by A.D. 900 the Chinese were using arsenic sulfides to control garden insects. *Veratrum album* and *Veratrum nigrum,* two species of false hellebore, were used by the Romans as rodenticides (Shepard, 1939). In 1669, the earliest known record of arsenic as an insecticide in the Western world mentioned its use with honey as an ant bait. Use of tobacco as contact insecticide for plant lice was mentioned later in the same century. Copper compounds were known since the early 1800s to have fungicidal value, and the Bordeaux mixture (hydrated lime and copper sulfate) was first used in France in 1883. Hydrocyanic acid, known to the Egyptians and the Romans as a poison, was used as a fumigant in 1877 to kill museum pests in insect collections, and carbon disulfide has been used as a fumigant since 1854 (Costa, 1987). Even in this century, until the 1930s, pesticides were mainly of natural origins or inorganic compounds. Arsenicals have played a major role in pest control, first as insecticides, then as herbicides. Sulfur has been widely used as a fumigant since the early 1800s, and remains one of the most widely used fungicides as of today. Nicotine has been widely used as an insecticide all over the world, as has been rotenone, used as a fish poison in South America since 1725 (Costa, 1987). Mercuric chloride was used as a fungicide since 1891, slowly replaced by phenylmercury and alkylmercury. Outbreaks of poisoning with the latter compounds (Bakir *et al.*, 1973) have led to a ban on these chemicals.

The period between 1935 and 1950 was characterized by the development of major classes of pesticides, particularly insecticides. In 1939 Paul Müller found that DDT (dichlorodiphenyltrichloroethane), which had been first synthesized in 1874, acted as a poison on flies, mosquitoes, and other insects. DDT was commercialized in 1942 and was used extensively and successfully for the control of typhus epidemics and particularly of malaria. Together with DDT, other chlorinated hydrocarbon insecticides were developed. In the early 1940s, scientists in England and France recognized the gamma isomer of hexachlorocyclohexane, commonly known as lindane, which had been first synthesized in 1825 by Faraday, as a highly potent insecticide (Ecobichon, 1992). Starting in the mid-1940s several other chlorinated insecticides were commercialized, including chlordane, heptachlor, aldrin, and dieldrin. The organophosphorus insecticides were first synthesized in Germany in the late 1930s. Gerhard Schrader, a chemist at the I. G. FarbenIndustrie in Germany, is considered the "father" of organophosphorus insecticides. The first one, tetraethylpyrophosphate (TEPP), was brought to the market in 1944, but had little success because of its instability in aqueous solution. Several thousand molecules were synthesized by Schrader, and one (code name E605) was eventually introduced into the agricultural market under the trade name parathion, to become one of the most widely employed insecticides in this class. During those years, compounds of much greater toxicity than parathion, such as sarin, soman, and tabun, were also synthesized as potential chemical warfare agents. The mechanisms of action of organophosphates, i.e., inhibition of acetylcholinesterase, was soon discovered, primarily by knowledge of the effects and mechanism of action of physostigmine. This alkaloid had been isolated in 1864 from Calabar beans, the seeds of *Physostigma venenosum,* a perennial plant in tropical West Africa, and its mode of action as a cholinesterase inhibitor was identified in 1926 (Casida, 1964). Despite the early studies on physostigmine, the carbamates were introduced as insecticides only in the early 1950s. Though pyrethrum flower and extracts had been used for several centuries, pyrethrins were characterized only between 1910 and 1924 (Casida, 1980). This led then to the development of synthetic pyrethroids, the first of which, allethrin, was followed by several others in the early 1970s, particularly because of the work of Michael Elliott in England and of scientists at Sumitomo Chemical Company in Japan. Several other classes of insecticides (e.g., avermectins, neonicotinoids, N-phenylpyrazoles) have also been developed in the past few decades.

The past 60 years have also seen the development of hundreds of other chemicals used as herbicides, fungicides, and rodenticides. The development of thioureas, such as ANTU, and of anticoagulants such as warfarin, as rodenticides, dates back to the mid to late 1940s. A few years later, two important fumigants were introduced, 1,2-dichloropropene and methyl bromide. In the 1950s, phenylureas and chlorophenoxy compounds were developed as herbicides, together with the fungicides captan and folpet. Triazines, chloroacetanilides and paraquat, all widely used herbicides, came to the market in the 1960s, and so did the important class of dithiocarbamate fungicides, while the herbicide glyphosate was introduced in the mid-1970s.

ECONOMICS AND PUBLIC HEALTH

As with all chemicals, including therapeutic drugs, the use of pesticides must take into consideration the balance of the benefits that may be expected versus the possible risks of injury to human health

or degradation of environmental quality. Pesticides play a major role in the control of vector-borne diseases, which represent a major threat to the health of large human populations. Pesticides of various types are used in the control of insects, rodents, and other pests that are involved in the life cycle of vector-borne diseases such as malaria, filariasis, yellow fever, viral encephalitis, typhus, and many others (Novak and Lampman, 2001). The case of DDT exemplifies the difficulty in striking a balance between benefits of its use and risks, in this case mainly to the environment. When introduced in 1942, DDT appeared to hold immense promise of benefit to agricultural economics and protection of public health against vector-borne diseases. For example, in the Italian province of Latina there were 175 new cases of malaria in 1944, but after a DDT spray control program was initiated, no new cases of malaria appeared by 1949 (Murphy, 1986). Indeed, at the time, the public health benefits of DDT were viewed so great that Mueller was awarded the Nobel prize in Medicine in 1948. However, because of its bioaccumulation in the environment and its effects on bird reproduction, DDT was eventually banned in most countries by the mid-1970s. In South Africa, DDT was only banned in 1996, and at the time <10,000 cases of malaria were registered in that country. By the year 2000, cases of malaria had increased to 62,000, but with the reintroduction of DDT at the end of that year, cases were down to 12,500 (Maharaj *et al.*, 2005). There are still hundreds of millions of people in the world who are at risk from schistosomiasis, filariasis, and intestinal worm infestations, particularly in Africa and some Asian countries, and these major health problems require a continuous judicious use of pesticides (Novak and Lampman, 2001).

In many parts of the world, excessive loss of food crops to insects or other pests may contribute to possible starvation, and use of pesticides seems to have a favorable cost-benefit relationship (Murphy, 1986). In developed countries, pesticides allow production of abundant, inexpensive, and attractive fruits and vegetables, as well as grains. In this case, cost-benefit considerations are based on economic considerations, particularly with regard to labor costs. Along with insecticides, herbicides and fungicides play a major role in this endeavor. Loss of harvested crops by postharvest infestation by insects, fungi, and rodents is also a major problem (Ecobichon, 2001a,b), that is dealt with by the use of fumigants and other pesticides. Pesticides, particularly herbicides, also find useful application in forestry, during reforestation, as well as the clearing of roadways, train tracks and utilities' rights of way. In the urban setting, pesticides find multiple uses in the home and garden area, to control insects, weeds and other pests (Rust, 2001; Marsh, 2001). It is estimated that 75% of households in the United States utilize some form of pesticides (Table 22-1). These could include, for example, chemicals to control termite, cockroach or rodent infestations, herbicides to control weeds in the garden, or insect repellents.

Use of Pesticides

It is commonly believed that there is a continuous increase in the use of pesticides. While this is certainly true for the period 1950–1980, in the past twenty years or so, use of pesticides (as amount of active ingredient) has actually reached a plateau (Table 22-2). This is due in part to the utilization of more efficacious compounds, that require less active ingredients to be applied to obtain the same degree of pest control, and in part to the introduction of integrated pest management approaches and organic farming, at least in the developed countries. Expenditures on pesticides, however, have increased (Table 22-2), as new chemicals are more expensive than older ones.

Table 22-1

Number of U.S. Households Using Pesticides (2000)

PESTICIDE TYPE	US HOUSEHOLDS (MILLIONS)	% OF TOTAL HOUSEHOLDS[1]
Insecticides	59	56
Herbicides	41	39
Fungicides	14	13
Repellents	53	50
Disinfectants	59	56
Any pesticide	78	74

[1]Based on 105.5 million households and a population of 281.4 million (U.S. Census Bureau, 2000).

TOTAL	1,203	100	5,046	100

[1]Includes herbicides and plant growth regulators.
[2]Other = rodenticides, fumigants, nematocides, molluscicides, and other chemicals. a.i. = active ingredient.
SOURCE: Kiely *et al.*, 2004.

In the United Stastes, almost half of the pesticides used are herbicides, while in other countries, particularly Africa, Asia, and Central America, there is also a substantial use of insecticides (Table 22-3). Because the latter compounds are generally more acutely toxic, they contribute to the still large number of yearly pesticide poisonings (see below). Tables 22-4 and 22-5 show the main pesticides used in the agricultural, and home and garden sectors in the United States

Pesticides are often, if not always, used as multiagent formulations, in which the active ingredient is present together with other ingredients to allow mixing, dilution, application, and stability. These other ingredients are lumped under the term "inert" or "other" (Tominack, 2000). Though they do not have pesticidal action, such inert ingredients may not always be devoid of toxicity; thus, an ongoing task of manufacturers and regulatory agencies is

Table 22-4

Most Commonly Used Conventional Pesticide Active Ingredients in the United States in the Agricultural Market Sector: 2001[1]

ACTIVE INGREDIENT	TYPE	MILLIONS OF POUNDS
Glyphosate	H	85–90
Atrazine	H	74–80
Metam sodium	Fum	57–62
Acetochlor	H	30–35
2,4-D	H	28–33
Malathion	I	20–25
Methyl bromide	Fum	20–25
Dichloropropene	Fum	20–25
Metolachlor-s	H	20–24
Metolachlor	H	15–22
Pendimethalin	H	15–19
Trifluralin	H	12–16
Chlorothalonil	F	8–11
Copper salts	F	8–10
Chlorpyrifos	I	8–10

[1]Does not include sulfur (172 mil. lb) and petroleum oil (60 mil. lb). H = herbicide; I = insecticide; F = fungicide; Fum = fumigant.

to assure that inert ingredients do not pose any unreasonable risk of adverse health effects (Tominack, 2000).

Exposure

Exposure to pesticides can occur via the oral or dermal routes or by inhalation. From a quantitative perspective, oral exposure lies on the extremes of a hypothetical dose–response curve. High oral doses, leading to severe poisoning and death, are achieved as a result of pesticide ingestion for suicidal intents, or of accidental ingestion, commonly due to storage of pesticides in improper containers. Chronic low doses on the other hand, are consumed by the general population as pesticide residues in food, or as contaminants in drinking

water. Regulations exist to ensure that pesticide residues are maintained at levels below those that would cause any adverse effects (see below). Workers involved in the production, transport, mixing and loading, and application of pesticides, as well as in harvesting of pesticide-sprayed crops, are at highest risk for pesticide exposure. The dermal route is thought in this case to offer the greatest potential for exposure, with a minor contribution of the respiratory route when aerosols or aerial spraying are used. In these latter cases, bystanders or individuals living in proximity of the spraying may also be exposed because of off-target drifts. In the occupational setting, dermal exposure during normal handling or application of pesticides, or in case of accidental spillings, occurs in body areas not covered by protective clothing, such as the face or the hands. Furthermore, deposition of pesticides on clothing may lead to slow penetration through the tissue and/or to potential exposure of others, if clothes are not changed and washed upon termination of exposure. Several methodologies exist to assess exposure by passive dosimetry, such as the use of absorbent cloth or paper patches, of biosensors, or of tracers followed by video imaging (USEPA 1999; Fenske *et al.*, 1986). Biological monitoring is also used, to measure the absorbed dose of pesticides. Analysis of body fluids and excreta, usually urine, for parent compound or metabolites, can provide both a quantitative and a qualitative measurement of absorbed dose. The advantage of such approach over passive dosimetry is that it evaluates actual, rather than potential absorption, and integrates absorption from all routes of exposure. In some cases, modifications of biochemical parameters or a consequence of exposure can be measured as an indication of both exposure and of a biological effect. This is the case, for example, of measurements of plasma or erythrocyte cholinesterases upon exposure to organophosphorus insecticides (Storm *et al.*, 2000).

Human Poisoning

Pesticides are not always selective for their intended target species, and adverse health effects can occur in nontarget species, including humans. In the general population and in occupationally exposed workers, a primary concern relates to a possible association between pesticide exposure and increased risk of cancer (Alavanja *et al.*, 2004; Pearce and McLean, 2005; Jaga and Dharmani, 2005). More recently, the acknowledgment that pesticide standards are based on healthy adults, and thus may not be sufficiently protective of susceptible populations, such as children, has led to new concerns, research, and regulations (NRC, 1993; Colborn, 2006). Evidence that some pesticides may act as endocrine disruptors, possibly contributing to various adverse effects in humans, including cancer and reproductive and developmental toxicity, has also prompted additional concerns and initiatives (Porterfield, 2000; Safe, 2005). Yet, from a global perspective, the major problem with pesticides remains that of acute human poisoning. The World Health Organization (WHO) estimated that there are around three million hospital admissions for pesticide poisoning each year, that result in around 220,000 deaths (WHO, 1990). Most occur in developing countries, particularly in Southeast Asia, and a large percentage is due to intentional ingestion for suicide purposes (Gunnell and Eddleston, 2003). The WHO has recommended a classification of pesticides by hazard, where acute oral or dermal toxicities in rats were considered (Table 22-6; IPCS, 2005). An analysis of commercially available pesticides indicates that, as a class, insecticides are the most acutely toxic. Indeed, among the 74 active ingredients listed in Class 1A (Extremely hazardous) and Class 1B (Highly hazardous), 48 (65%) are insecticides, in particular organophosphates

Table 22-6
WHO-Recommended Classification of Pesticides by Hazard

		LD$_{50}$ IN RAT (mg/kg body weight)			
		ORAL		DERMAL	
CLASS		SOLIDS	LIQUIDS	SOLIDS	LIQUIDS
Ia	Extremely hazardous	5 or less	20 or less	10 or less	40 or less
Ib	Highly hazardous	5–50	20–200	10–100	40–400
II	Moderately hazardous	50–500	200–2000	100–1000	400–4000
III	Slightly hazardous	Over 500	Over 2000	Over 1000	Over 4000
IV+	Unlikely to present hazard in normal use	Over 2000	Over 3000	Over 4000	Over 6000

SOURCE: IPCS, 2005.

(IPCS, 2005). Rodenticides are also highly toxic to rats, but do not present the same hazard to humans. Indeed, warfarin, one of the most widely used rodenticides, is the same chemical used as an effective "blood thinner" (anticoagulant) for prevention of stroke and other blood clot related conditions. Herbicides, again as a class, have generally moderate to low acute toxicity, one exception being paraquat (which has a low dermal toxicity but causes fatal effects when ingested). Fungicides vary in their acute toxicity, but this is usually low.

Reports of human poisonings worldwide confirm this analysis. In Costa Rica between 1980 and 1986, 3330 individuals were hospitalized for pesticide poisoning, and 429 died. Cholinesterase inhibitors (organophosphates and carbamates) caused 63% of hospitalizations and 36% of deaths, while paraquat accounted for 24% of hospitalizations and 60% of deaths. Cholinesterase inhibitors also caused more than 70% of occupational accidents (Wesseling *et al.*, 1993). Of 335 poisoning deaths in Manipal, India, in the 1990s, 70% were due to cholinesterase inhibitors (Mohanty *et al.*, 2004). In Sri Lanka between 1986 and 2000, hospital admissions for pesticide poisoning were 12–20 thousand/year, with approximately a 10% fatality rate (Roberts *et al.*, 2003). Organophosphates and the organochlorine insecticide endosulfan (which was banned in 1998), were the compounds most commonly involved. The same pattern of poisoning can also be seen in developed countries. For example, in Greece, the number of poisonings ranged between 1200 and 1700/year during the periods 1988–1999. Of these, 40% were due to occupational exposure and 45% to accidental exposure. Organophosphates, carbamates and paraquat were again involved in the majority of cases (Bertsias *et al.*, 2004). In a four year period in Japan, 346 cases of pesticide poisoning were reported; in this case 70% were due to suicide attempts. Again, cholinesterase inhibitors and paraquat were involved in more than 60% of poisonings. Death rate from poisoning with paraquat was over 70%, whereas it was <10% with the herbicides glyphosate or glufosinate (Nagami *et al.*, 2005).

Regulatory Mandate

The awareness that the misuse of pesticides may pose potential health hazards has led to a realm of regulatory measures to ensure their safe use and the protection of the population. In the United States, the primary authority for pesticide regulation resides with the U.S. Environmental Protection Agency (EPA), under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) and the Federal Food, Drug and Cosmetic Act (FFDCA). Under FIFRA,

EPA registers pesticides for use, whereas under FFDCA, EPA establishes maximum allowable levels of pesticide residues (tolerances) in foods and animal feeds, which are enforced by other federal agencies (Fenner-Crisp, 2001).

The first legislation passed in the United States was the Federal Insecticide Act of 1910, which only prohibited the manufacture of any insecticide or fungicide that was adulterated or misbranded. FIFRA was originally passed by Congress in 1947, adding the requirement of registration by the Secretary of Agriculture before sale of insecticides, rodenticides, fungicides, and herbicides. Amendments in subsequent years added other pesticides to FIFRA jurisdiction, and provided the U.S. Department of Agriculture (USDA) with the authority to deny, suspend or cancel registrations of products. In 1954, Congress amended the FFDCA to require the Food and Drug Administration (FDA) to establish tolerances for pesticides in raw agricultural commodities. This was extended four years later to processed foods. In 1970, the primary federal authority for the regulation of pesticides was transferred from USDA and FDA to the newly formed EPA. Between 1970 and 1990, FIFRA was amended several times, to address various issues related to pesticide safety and registration processes.

In 1996, the Food Quality and Protection Act (FQPA) brought important changes to pesticide regulations in the United States, that affected both FIFRA and FFDCA. For example, FQPA provided the statutory mandate, under FIFRA, for continuing the expedited consideration of applications for pesticides that may provide reduced risks for human health, nontarget species, and the environment (Fenner-Crisp, 2001). Perhaps more significant were the changes to the FFDCA mandate. In 1958, an amendment of the FFDCA, the Delaney clause (Section 409), stated that "...no additive shall be deemed safe if it is found to induce cancer when ingested by man or animal or if it is found, after tests which are appropriate for the evaluation of the safety of food additives, to induce cancer in man or animal..." Pesticides were included in this "additive" legislation. Under FQPA, however, pesticide residues are excluded from the definition of food additive, and the Delaney clause no longer applies to residues in food. Thus, tolerances can be set also for carcinogens. FQPA also directs EPA to consider aggregate exposure in the risk assessment process, i.e., exposure which occurs from all food uses for a pesticide, as well as from exposures that occur from nonoccupational sources (e.g., drinking water, indoor residential or school use, etc.). Additionally, EPA must consider whether certain pesticides, as well as other substances, may have the same mechanism of toxicity, and if so, carry out a cumulative risk assessment.

Table 22-7

Basic Toxicology Testing Requirements for Pesticide Registration

TEST	ANIMAL SPECIES*
Acute lethality (oral, dermal, inhalation)	Rat, mouse, guinea pig, rabbit
Dermal irritation	Rabbit, rat, guinea pig
Dermal sensitization	Guinea pig
Eye irritation	Rabbit
Acute delayed neurotoxicity	Hen
Genotoxicity studies (in vitro, in vivo)	Bacteria, mammalian cells, mouse, rat, drosophila
Teratogenicity	Rabbit, rodent (mouse, rat, hamster)
Two–four week toxicity study (oral, dermal, inhalation)	Rat, mouse
90-Day toxicity study (oral)	Rat
Chronic toxicity study (oral; 6 months–2 years)	Rat, dog
Oncogenicity study	Rat, mouse
Reproductive/fertility study	Rat
Developmental neurotoxicity study	Rat

*Substantial efforts are being devoted to develop alternative nonanimal test systems. As of 2006, only one in vitro test (for primary irritation) has been validated and accepted by EU regulatory bodies (OECD).

Another change introduced by FQPA gives EPA the mandate to assess special risks of pesticides to infants and children. The Agency must assess aggregate risks based on dietary consumption patterns of children, possible susceptibility of infants and children to pesticides, and cumulative effects of compounds that share the same mechanism of toxicity. In the absence of adequate data, an additional default 10-fold safety factor should be applied to ensure children's safety. Finally, provisions are included for EPA to determine whether certain substances may have endocrine disrupting effects in humans. Additional regulations concerning pesticides are present in other laws, such as the Safe Drinking Water Act or the Clean Air Act.

Under FIFRA, all pesticides sold or distributed in the United States must be registered by the EPA. Older products, registered before 1984, must undergo a re-registration process. To register a pesticide or a formulated product, a large number of studies (over 140) are required, a process that takes several years and anywhere between $50 and $100 million. The data base should include information on product and residue chemistry, environmental fate, toxicology, biotransformation/degradation, occupational exposure and reentry protection, spray drift, environmental impact on non-target species (birds, mammals, aquatic organisms, plants, soil), environmental persistence and bioaccumulation, as well as product performance and efficacy. Table 22-7 lists the basic requirements regarding toxicology data needed for new pesticide registration (see also Chap. 2). New tiered approaches to toxicity testing for agricultural chemicals, that would reduce the use of animals and improve the risk assessment process, have been recently proposed (Doe *et al.*, 2006; Cooper *et al.*, 2006).

Other nations, such as Canada, Japan, and most European countries have promulgated legislation similar to that of the United States for registration of pesticides. In 1991, the European Union (EU) passed a directive that created a harmonized Union-wide framework for pesticide regulation. Applications for registration can be directed to the EU, or at the level of individual member states. Some developing nations, with a shortage of trained technical, scientific, and legal professionals to develop their own legislation, have adopted the regulatory framework of one or another industrialized nation. The World Health Organization provides guidance, particularly with the setting of acceptabe daily intake (ADI) values for pesticides, through its Joint FAO/WHO Meeting on Pesticide Residues

(JMPR). In a few countries, still no legislation has been introduced to curb adverse effects of pesticides on the environment and human health.

INSECTICIDES

Insecticides play a most relevant role in the control of insect pests, particularly in developing countries. All of the chemical insecticides in use today are neurotoxicants, and act by poisoning the nervous systems of the target organisms (Table 22-8). The central nervous system of insects is highly developed and not unlike that of mammals, and the peripheral nervous system, though less complex, also presents striking similarities (Ecobichon, 2001a). Thus, insecticides are mostly not species-selective with regard to targets of toxicity, and mammals, including humans, are highly sensitive to their toxicity. When selectivity exists, this is often due to differences in detoxication pathways between insects and mammals, or to differential interactions with their target. As a class, insecticides have higher acute toxicity toward nontarget species compared to other pesticides. Some of them, most notably the organophosphates, are involved in a great number of human poisonings and deaths each year. The literature pertaining to the chemistry, development, biotransformation, environmental effects, and toxicity in target and nontarget species of insecticides is extensive, and the reader should refer to the monographs of O'Brien (1967), Hayes (1982), Ecobichon and Roy (1982), Matsumura (1985), Ford *et al.* (1986), Clark and Matsumura (1986), Costa *et al.* (1987), Hayes and Laws (1991), Chambers and Levi (1992), Krieger (2001), and Gupta (2006).

Organophosphorus Compounds

Although a number of organic phosphorus (OP) compounds were synthesized in the 1800s, their development as insecticides only occurred in the late 1930s and early 1940s (Gallo and Lawryk, 1991; Costa, 1988). The German chemist Gerhard Schrader is credited for the discovery of the general chemical structure of anticholinesterase OP compounds, and for the synthesis of the first commercialized OP insecticide [Bladan, containing TEPP (tetraethyl pyrophosphate) as the active ingredient], and for one of the most known, parathion, in

Table 22-8
Molecular Targets of the Major Classes of Insecticides

TARGET	INSECTICIDE	EFFECT
Acetylcholinesterase	Organophosphates	Inhibition
	Carbamates	Inhibition
Sodium channels	Pyrethroids (Type I and II)	Activation
	DDT	Activation
	Dihydropyrazoles	Inhibition
Nicotinic acetylcholine receptors	Nicotine	Activation
	Neonicotinoids	Activation
GABA receptors-gated chloride channels	Cyclodienes	Inhibition
	Phenylpyrazoles	Inhibition
	Pyrethroids (Type II)	Inhibition
Glutamate-gated chloride channels[1]	Avermectins	Activation
Octopamine receptors[2]	Formamidines	Activation
Mitochondrial complex I	Rotenoids	Inhibition

[1] Found only in insects. In mammals avermectins activate $GABA_A$ receptors.
[2] In mammals, formamidines activate $alpha_2$-adrenoceptors.

1944. Since then, hundreds of OP compounds have been made and commercialized worldwide in a variety of formulations. More than half of the insecticides used are OPs, and some OPs are among the most extensively used pesticides.

The chemistry of OPs has been thoroughly investigated (Chambers *et al.*, 2001). The general structure of OP insecticides can be represented by
Where X is the so-called "leaving group," that is displaced when the OP phosphorylates acetylcholinesterase (AChE), and is the most sensitive to hydrolysis; R_1 and R_2 are most commonly alkoxy groups (i.e., OCH_3 or OC_2H_5), though other chemical substitutes are also possible; either an oxygen or a sulfur (in this case the compound should be defined as a phosphorothioate) are also attached to the phosphorus with a double bond. Based on chemical differences, OPs can be divided into several subclasses, which include phosphates, phosphorothioates, phosphoramidates, phosphonates, and others (Chambers *et al.*, 2001). Figure 22-1 shows the chemical structures of some commonly used OPs. Most are phosphorothioates, and need to be bioactivated in vivo to their oxygen analogs to exert their toxic action, but some (e.g., dichlorvos or the nerve agent sarin) have P=O bonds. Most OPs used as insecticides have two methoxy or ethoxy side chains (Fig. 22-1).

Biotransformation   The complex array of reactions involved in the biotransformation of OPs in target and nontarget species has been the subject of extensive investigations (Tang *et al.*, 2006). For all compounds that contain a sulfur bound to the phosphorus, a metabolic bioactivation is necessary for their biological activity to be manifest, as only compounds with a P=O moiety are effective inhibitors of AChE. This bioactivation consists in an oxidative desulfuration mediated, mostly but not exclusively in the liver, by cytochrome

P450 enzymes (CYPs), and leading to the formation of an "oxon," or oxygen analog of the parent insecticide (Fig. 22-2). Though this reaction has been known for several decades, the exact CYP isoforms involved have only been recently investigated, and available data suggest that the overall picture is quite complex. Multiple CYPs have been shown to activate organophosphorothioates to their oxons, with different substrate specificities. For example, diazinon is activated by human hepatic CYP2C19, whereas parathion is activated primarily by CYP3A4/5 and CYP2C8, and chlorpyrifos by CYP2B6 (Kappers *et al.*, 2001; Tang *et al.,* 2001; Mutch *et al.*, 2003). In addition to oxidative desulfuration, other reactions can activate OPs (Costa, 1988). Of relevance to insecticidal OPs is thioether oxidation (formation of a sulfoxide, S=O, followed by the formation of a sulfone, O=S=O) which occurs in the leaving group moiety, and is also catalyzed by CYPs. For example, in case of the OP disulfoton, the sulfoxide and the sulfone are more potent inhibitors of AChE than the parent compound. Many other biochemical reactions are detoxication reactions, as they lead to metabolites of lesser or no toxicity (Fig. 22-2). Some, e.g., oxidative dearylation or *O*-dealkylation, are mediated by CYPs, and differences between CYPs exist also in the detoxication process. For example, dearylation of chlorpyrifos is catalyzed primarily by CYP2C19, whereas that of parathion by CYP2B6 (Tang *et al.*, 2001; Hodgson, 2003). Catalytic hydrolysis by phosphotriesterases, known as A-exterases (which are not inhibited by OPs), also plays an important role in the detoxication of certain OPs. One example is the enzyme paraoxonase (PON1) which hydrolyzes the oxons of chlorpyrifos and diazinon, and at least in vitro, also of parathion (Costa *et al.*, 2002; Li *et al.*, 2000). Noncatalytic hydrolysis of OPs also occurs when these compounds phosphorylate serine esterases classified as B-esterases, that are inhibited by OPs but cannot catalytically hydrolyze them. Examples are the carboxylesterases (CarE) and butyrylcholinesterase (BuChE), in addition to the OP target, AChE. CarE also performs a catalytic hydrolysis of the carboxylic esters of malathion, and is believed to be a major determinant of its low toxicity in mammals. Indeed, insects have low CarE activity, and inhibition of CarE by other OPs greatly potentiates the toxicity of malathion in mammals (Murphy, 1986). Glutathione *S*-transferases may also contribute to the detoxication of OPs, particularly the methoxy compounds (Abel *et al.*, 2004).
Figure 22-1. Structures of some organophosphorus insecticides and of the nerve agent sarin.

Note that most commonly used compounds are organophosphorothioates (i.e., have a P=S bond) but some, including sarin, have a P=O bond and do not require metabolic activation.

Signs and Symptoms of Toxicity and Mechanism of Action OP insecticides have high acute toxicity, with oral LD_{50} values in rat often below 50 mg/kg, though for some widely used compounds (e.g., chlorpyrifos, diazinon) toxicity is somewhat lower, due to effective detoxication. One exception is malathion, which has an oral LD_{50} in rat of >1 g/kg, due, as said, to rapid detoxication by CarE. For several OPs acute dermal toxicity is also high, with some exceptions being azinphosmethyl and malathion (Murphy, 1986). The primary target for OPs is AChE, a B-esterase whose physiological role is that of hydrolyzing acetylcholine, a major neurotransmitter in the central and peripheral (autonomic and motor-somatic) nervous systems. Acetylcholine released from cholinergic nerve terminals is disposed of solely through hydrolysis by AChE. In fact, in contrast to other neurotransmitters (e.g., norepinephrine), it is choline, the product of acetylcholine hydrolysis by AChE, that is taken up by the presynaptic terminal. Hence, inhibition of AChE by OPs causes accumulation of acetylcholine at cholinergic synapses, with overstimulation of cholinergic receptors of the muscarinic and nicotinic type. As these receptors are localized in most organs of the body, a "cholinergic syndrome" ensues, which includes increased sweating and salivation, profound bronchial secretion, bronchoconstriction, miosis, increased gastrointestinal motility, diarrhea, tremors, muscular twitching, and various central nervous system effects (Table 22-9). When death occurs, this is believed to be due to respiratory failure due to inhibition of respiratory centers in the brain stem, bronchoconstriction and increased bronchial secretion, and flaccid paralysis of respiratory muscles (Gallo and Lawryk, 1991; Lotti, 2000, 2001). The time interval between exposure and onset of symptoms varies with the route and degree of exposure, and the chemical nature of the OP. The first signs to appear are usually muscarinic,
Figure 22-2. General scheme of biotransformation of dialkyl, aryl phosphorothioate insecticides.

Reaction 1 is the bioactivation, by oxidative desulfuration, of the parent compound to the active metabolite, the oxon. The other reactions are enzymatic detoxication reactions that yield products that do not inhibit acetylcholinesterase. Reaction 2 and 4 are dealkylation reactions, while reaction 3 is a dearylation. All are mediated by various cytochromes P450. Reaction 5 is a hydrolytic reaction, catalyzed by paraoxonase (PON1). Note that not all reactions occur with every organophosphorus insecticide.

which may or may not be in combination with nicotinic signs. While respiratory failure is a hallmark of severe OP poisoning, mild poisoning and/or early stages of an otherwise severe poisoning may display no clear-cut signs and symptoms (Lotti, 2001). Therefore, diagnosis is made through symptom recognition; miosis is observed most often, followed by gastrointestinal symptoms (nausea, vomiting, abdominal pain) and hypersalivation.

The interaction of OPs with AChE has been studied in much detail. OPs with a P=O moiety phosphorylate an hydroxyl group on serine in the active (esteratic) site of the enzyme, thus impeding its action on the physiological substrate (Fig. 22-3). The first reaction leads to the formation of a Michaelis complex, while a subsequent reaction leads to phosphorylated AChE (Table 22-10). Rates of these two reactions, that are usually very rapid, indicate the affinity of the enzyme for a given OP. The bond between the phosphorus atom and the esteratic site of the enzyme is much more stable than the bond between the carbonyl carbon of acetate (in acetylcholine) at the same enzyme site. While breaking of the carbon–enzyme bond is complete in a few microseconds, breaking of the phosphorus-enzyme bond can take from a few hours to several days, depending on the chemical structure of the OP. Phosphorylated AChE is hydrolyzed by water at a very slow rate (Fig. 22-3; Table 22-10), and the rate of "spontaneous reactivation" depends on the chemical nature of the R substituents. Reactivation decreases in the order demethoxy > diethoxy ≫ diisopropoxy (Gallo and Lawryk, 1991). Whereas water is a weak nucleophilic agent, certain hydroxylamine derivatives, known as oximes, can facilitate dephosphorylation of AChE, and are utilized in the therapy of OP poisoning (see below). Reactivation of phosphorylated AChE does not occur once the enzyme-inhibitor complex has "aged" (Fig. 22-3). Aging consists of the loss

(by nonenzymatic hydrolysis) of one of the two alkyl (R) groups, and the rate of aging depends on the nature of the alkyl group. When phosphorylated AChE has aged, the enzyme can be considered to be irreversibly inhibited, and the only means of replacing its activity is through synthesis of new enzyme, a process that may take days.

Treatment of Poisoning   Upon OP poisoning, prompt treatment is essential. Procedures aimed at decontamination and/or at minimizing absorption depend on the route of exposure. In case of dermal exposure, contaminated clothing should be removed, and the skin washed with alkaline soap (Lotti, 2001). Special attention should be exercised by medical personnel, because passive contamination may occur. In case of ingestion, procedures to reduce absorption from the gastrointestinal tract do not appear to be very effective (Lotti, 2001). Atropine represents the cornerstone of the treatment for OP poisoning; it is a muscarinic receptor antagonist, and thus prevents the action of accumulating acetylcholine on these receptors. Atropine is preferably given intravenously, though the intramuscular route is also effective. The best clinical approach is to administer doses of atropine large enough to achieve evidence of atropinization, i.e., flushing, dry mouth, changes in pupil size, bronchodilation, and increased heart rate; atropinization should be maintained for at least 48 hours (Lotti, 2001). Indicative doses of atropine are 1 mg or 2–5 mg in case of mild or moderate poisoning, respectively. Higher doses by continuous infusion may be required in severe cases. Overdosage with atropine is rarely serious in OP poisoned patients (Lotti, 2001).

Oximes, such as pralidoxime (2-PAM) are also used in the therapy of OP poisoning. 2-PAM contains a positively charged atom capable of attaching to the anionic site of AChE, and facilitate

Table 22-9
Signs and Symptoms of Acute Poisoning with Anticholinesterase Compounds

SITE AND RECEPTOR AFFECTED	MANIFESTATIONS
Exocrine glands (M)	Increased salivation, lacrimation, perspiration
Eyes (M)	Miosis, blurred vision
Gastrointestinal tract (M)	Abdominal cramps, vomiting, diarrhea
Respiratory tract (M)	Increased bronchial secretion, bronchoconstriction
Bladder (M)	Urinary frequency, incontinence
Cardiovascular system (M)	Bradycardia, hypotension
Cardiovascular system (N)	Tachycardia, transient hypertension
Skeletal muscles (N)	Muscle fasciculations, twitching, cramps, generalized weakness, flaccid paralysis
Central nervous system (M,N)	Dizziness, lethargy, fatigue, headache, mental confusion, depression of respiratory centers, convulsions, coma

M = muscarinic receptors; N = nicotinic receptors.

dephosphorylation of the enzyme (Fig. 22-4), thus restoring the catalytic site of AChE to its function. However, this chemical reaction occurs only when the phosphorylated AChE has not undergone aging. Dosing regimens for various oximes depend on the specific compound and the severity of OP poisoning. For example, for pralidoxime chloride, an initial 1 g dose given intravenously is recommended, followed after 15–30 minutes by another 1 g if no improvement is seen. If still no improvement is seen, an infusion of 0.5 g/h can be started (Lotti, 2001). The recommended dosage schedule is aimed at achieving a plasma oxime concentration of 4 mg/L, which was shown to be effective for pralidoxime methanesulfonate in cats poisoned with a quaternary analogue of sarin (Sundwall, 1961). While animal data consistently show a marked positive effect of oximes, several authors reported limited or no efficacy of oximes in the treatment of OP poisoning (Bismuth *et al.*, 1992; Singh *et al.*, 1995; Buckley *et al.*, 2005). A recent meta-analysis of several studies of OP-poisoned patients concluded that use of oximes was associated "with either a null effect or possible harm" (Peter *et al.*, 2006). On the other hand, inadequate dosing has been held as a major factor for lack of response to oxime therapy (Johnson *et al.*, 2000; Eddleston *et al.,* 2002). Furthermore, poisoning by OPs bearing two methoxy groups (malathion, methylparathion, dimethoate) is considered to be rather resistant to oxime therapy (Worek *et al.*, 1999a). Additionally, time of oxime administration following OP poisoning is crucial, as their therapeutic window is determined by the rate of aging. For example, 1 day after intoxication with a dimethyl phosphoryl compound, virtually all phosphorylated AChE would be expected to be in the aged form, so that oxime therapy will be useless by that time (Johnson *et al.*, 2000). Oximes also have the potential to form stable phosphoryl oximes that have themselves anticholinesterases activity; for this reason, and because of rapid reactivation of carbamylated AChE, oximes are not indicated in case of poisoning with carbamate insecticides.

In addition to oximes, diazepam (10–20 mg) is also used in the treatment of acute OP poisoning to relieve anxiety in mild cases, and to reduce muscle fasciculations and antagonize convulsions in the more severe cases (Lotti, 2001).

Biochemical Measurements   In addition to synapses, AChE is also present in red blood cells (RBC). Additionally, BuChE, also known as pseudo-cholinesterase, is found in plasma. The physiological functions of these enzymes are yet to be discovered. Never-

theless, because activity of both enzymes is usually inhibited upon exposure to OPs, their measurement is widely used as an indication of exposure, and/or biological effect of OPs. The specificity and usefulness of measurements of RBC AChE and of plasma BuChE in case of OP exposure have been debated for some time (Lotti, 1995). The main issues can be summarized as follows (Costa *et al.*, 2005): (1) Different OPs may inhibit AChE or BuChE to a different degree. For example, the oxygen analogs of malathion, diazinon and chlorpyrifos, and dichlorvos, are stronger inhibitors of plasma BuChE than of RBC AChE. (2) There is a high degree of variability of enzyme activity (particularly of BuChE) among individuals, in part due to genetic differences (see below). This requires establishment of a baseline value for each individual, or in case this is not available, of repeated postexposure measurements to determine possible changes back toward baseline values. (3) RBC AChE activity is better correlated with target tissue (e.g., brain, diaphragm) AChE, than is plasma BuChE activity, as indicated by animal studies (Padilla *et al.*, 1994). There is also a good correlation between the severity of signs and symptoms of poisoning and the degree of inhibition of RBC AChE (Lotti, 2001). (4) Neither measurement is specific for a certain OP, and indeed, other insecticides, such as carbamates, also inhibit AChE and BuChE. (5) A 30% or greater decrease of plasma BuChE from pre-exposure baseline raises a red flag, and requires health and workplace surveillance, and removal of the worker from the exposure; however, the toxicological significance of such decrease is still much debated (Carlock *et al.*, 1999; USEPA, 2000). Despite these caveats, measurements of plasma BuChE, and particularly of RBC AChE, remain a very valid way to determine exposure to OPs, and early biological effects of OP exposure, to be used as confirmation of diagnosis of OP poisoning, or to monitor occupationally exposed workers. Several methods exist to measure activity of these two enzymes (Reiner and Simeon-Rudolf, 2006). Whole blood AChE may also be measured, considering that only about 10% of the activity is due to the plasma enzyme (Worek *et al.*, 1999b).

Several analytical methods are available to measure OPs and their metabolites in body fluids; the parent compound is measured in blood, whereas metabolites are measured in urine (Lotti, 2001). These measurements are rarely carried out in the clinical setting, but are extensively utilized in epidemiological studies; indeed, determination of metabolite levels in urine is the most practical method to estimate exposure to OPs (Maroni *et al.*, 2000). Such metabolites

include alkylphosphate derivatives, as well as chemical residues (the "leaving group") specific for each compound. The alkylphosphates or alkyl-(di)-thiophosphates are the result of metabolism of parent compounds or their oxygen analogs by CYPs or esterases. They are not specific for a certain OP, but are useful to assess exposure to (or internal dose of) several OPs. Some alkylphosphate metabolites of commonly used OPs are shown in Table 22-11. Other metabolites are specific for certain OP compounds; for example, p-nitrophenol in urine is an indicator of exposure to parathion or methyl parathion, whereas 3,5,6–trichloropyridinol is useful to assess exposure to chlorpyrifos or methyl chlorpyrifos. While measurements of urinary metabolites of OPs have been widely used to assess exposure to OP from occupational, environmental, and dietary sources, caution should be exercised when interpreting results, as dialkylphosphates, and also leaving groups, can be found in the environment, including food and drinks, as a result of OP degradation. This would lead to an overestimate of OP exposure (Lu *et al.*, 2005).

The Intermediate Syndrome   A second distinct manifestation of exposure to OPs is the so-called intermediate syndrome, which was first conceptualized by clinicians in Sri Lanka involved in the treatment of suicide attempts (Senanayake and Karalliedde, 1987). The intermediate syndrome is seen in 20–50% of acute OP poisoning cases, and has been observed following exposure to a large variety of OPs. The syndrome develops one to several days after the poisoning, during recovery from cholinergic manifestations, or in some cases, when patients are completely recovered from the initial cholinergic crisis. Prominent features of the intermediate syndrome

are a marked weakness of respiratory, neck, and proximal limb muscles. Mortality due to respiratory paralysis and complications ranges from 15–40%, and recovery in surviving patients usually takes up to 15 days. The intermediate syndrome is not a direct effect of AChE inhibition, and its precise underlying mechanisms are unknown. One hypothesis is that muscle weakness may result from nicotinic receptor desensitization due to prolonged cholinergic stimulation (Lotti, 2001). There is no specific treatment for the intermediate syndrome and intervention is exclusively supportive.

Organophosphate-Induced Delayed Polyneuropathy   A few OPs may also cause another type of toxicity, known as organophosphate-induced delayed polyneuropathy (OPIDP). Signs and symptoms include tingling of the hands and feet, followed by sensory loss, progressive muscle weakness and flaccidity of the distal skeletal muscles of the lower and upper extremities, and ataxia (Lotti, 1992; Ehrich and Jortner, 2001; Lotti and Moretto, 2005). These may occur 2–3 weeks after a single exposure, when signs of both the acute cholinergic and the intermediate syndromes have subsided. OPIDP can be classified as a distal sensorimotor axonopathy. Neuropathological studies in experimental OPIDP have evidenced that the primary lesion is a bilateral degenerative change in distal levels of axons and their terminals, primarily affecting larger/longer myelinated central and peripheral nerve fibers, leading to breakdown of neuritic segments and the myelin sheats (Ehrich and Jortner, 2001). OPIDP is not related to AChE inhibition. Indeed, one of the compounds involved in several epidemics of this neuropathy, including the so-called Ginger-Jake paralysis in the 1930s in the United States, is TOCP (tri-ortho-cresyl phosphate), which is a very poor AChE inhibitor. Extensive studies carried out in the past 30 years (Johnson, 1982; Johnson and Glynn, 2001; Lotti, 1992) have identified the target for OPIDP as an esterase, present in nerve tissues as well as other tissues (e.g., lymphocytes), named neuropathy target esterase (NTE). Several OPs, depending on their chemical structure, can inhibit NTE, as do some non-OPs, such as certain carbamates and sulfonyl fluorides. Phosphorylation of NTE by OPs is similar to that observed for AChE. However, only OPs whose chemical structure leads to aging of phosphorylated NTE (by a process analogous to that described for AChE) can cause OPIDP. Other compounds that inhibit NTE but cannot undergo the aging reaction, are not neuropathic, indicating that inhibition of NTE catalytic activity is not the mechanism of axonal degeneration. For OPIDP to be initiated, phosphorylation and subsequent aging of at least 70% of NTE is necessary, and this two-step process occurs within hours of
Figure 22-5. A summary of initiation, protection and promotion of OPIDP, showing the relationships among dosing, NTE inhibition and clinical response, when DFP (diisopropylfluorophosphate) and PMSF (phenylmethanesulfonyl fluoride) are given alone or in combination.

poisoning. When the first clinical signs of OPIDP are evident some weeks later, NTE activity has recovered. Hypotheses to explain the consequences of OP-NTE interactions include a loss of nonesterase functions of NTE, that would be essential for the axon, or a gain of toxic function of phosphorylated/aged NTE (Lotti and Moretto, 2005). Though reductions in axonal transport have been found to precede overt clinical signs, the exact chain of events occurring between phosphorylation and aging of NTE and axonal degeneration remain obscure. The physiological functions(s) of NTE are also unknown. Recent studies have shown that NTE has a 41% identity with the Swiss Cheese Protein (SWS) in neurons of *Drosophila*. Studies in genetically modified mice have indicated that NTE is required for normal blood vessel and placental development, and that absence of brain NTE results in neuronal degeneration and loss of endoplasmic reticulum in various brain areas (Moser *et al.*, 2004; Akossoglou *et al.*, 2004). Interestingly, in *Drosophila* SWS mutants, extensive vacuolation is seen in the brain (Kretzschmar *et al.*, 1997). NTE also appears to play a role in membrane lipid metabolism, and may be involved in intra-neuronal membrane trafficking and lipid homeostasis (Zaccheo *et al.*, 2004; Glynn, 2006). However, the most crucial issues in the mechanisms of OPIDP development and progression remain obscure.

Though several epidemics of OPIDP have occurred in the past, its occurrence in humans is now rare. Before commercialization, OPs must undergo specific neurotoxicity testing in the hen (one of the most sensitive species) to determine whether OPIDP is produced (Moretto, 1999). High doses of OPs are used, and animals are protected from acute cholinergic toxicity with atropine, and clinical, morphological, and biochemical measurements are carried out. In vitro tests can provide the ratio of relative inhibitory potency toward AChE and NTE, but these have not been accepted by regulatory agencies (Ehrich *et al.*, 1997). Despite these tests, a few commercialized OPs (metamidophos, trichlorfon, chlorpyrifos) have caused

OPIDP in humans, mostly as a result of extremely high exposures in suicide attempts (Lotti and Moretto, 2005). Though it was once thought that some animal species (e.g., rodents) were insensitive to OPIDP, only mice appear to be somewhat resistant (Veronesi *et al.*, 1991). On the other hand, age is an important determinant of susceptibility, with young animals displaying more resistance; in young chicks the threshold for NTE inhibition and aging is >90% vs. 70% in adult hens (Peraica *et al.*, 1993). Children are also more resistant to OPIDP.

As noted earlier, compounds that inhibit NTE but do not age, do not cause OPIDP. When given to experimental animals *before* a neuropathic OP, these compounds exert a protective role, by occupying the NTE active site. However, when given *after* a neuropathic OP, these compounds have been shown to promote OPIDP (Fig. 22-5; Lotti *et al.*, 1991; Lotti, 2002a,b). By borrowing a terminology used for carcinogenic compounds, agents that phosphorylate NTE and age have been named initiators, whereas NTE inhibitors that do not initiate NTE but can promote it, have been named promoters (Lotti, 2002a,b). It is easy to understand why these latter compounds would be protective when given before an OP initiator; however, how they are able to promote OPIDP is still unknown. Promoters can also potentiate axonal degeneration caused by means other than OPs, such as traumatic nerve lesion, or 2,5-hexanedione (Moretto, 2000). Furthermore, promotion has also been shown to occur, in some cases, even when the promoter is given at doses that do not inhibit NTE, suggesting that another protein, rather than NTE, may be the target for the promoting effect. Because promotion is less efficient in chicks, where the compensation/repair mechanisms are thought to be more efficient, an hypothesis is that promotion may directly affect compensation/repair mechanism(s) of the nervous system (Lotti, 2002a,b). The issue of promotion may have a bearing on risk assessment of potential insecticide mixtures. Indeed, exposure to an initiator at a dose lower than that required to elicit OPIDP,

would nevertheless result in OPIDP if followed by exposure to a promoter.

Genetic Susceptibility   Genetically determined variations in biotransformation enzymes or target molecules can modify the response to OPs (Costa, 2001). As discussed earlier, CYPs are important for the activation and detoxication of OPs. Variant forms of several CYPs have been identified, and these polymorphisms confer differences in catalytic activity or levels of expression which may result in varying rates of oxidation of OPs. Limited in vitro studies have indeed shown that polymorphic forms of some CYPs (e.g., CYP2C19 or CYP3A4) cause differential desulfuration and dearylation of chlorpyrifos (Hodgson, 2003), but their overall influence on OP toxicity in vivo has not been investigated. The liver and plasma A-esterase paraoxonase (PON1), which detoxifies chlorpyrifos oxon and diazoxon, also presents several polymorphisms in the coding and promoter regions, that affect the catalytic efficiency of the enzyme toward different substrates (the Q192R polymorphism), and its level of expression (e.g., the C-108T polymorphism) (Costa *et al.*, 2002, 2003). Studies in transgenic animal models have clearly indicated that PON1 "status," encompassing both the Q192R polymorphism and the level of PON1 activity, plays a most relevant role in modulating the acute toxicity of some OPs (Fig. 22-6; Li *et al.*, 2000; Cole *et al.*, 2005).

High levels of BuChE are present in plasma, and OPs can inhibit its activity. Though its physiological function is unclear, BuChE, by scavenging OPs, can guard against their toxicity, as the OP would be unavailable for reaction with its primary target AChE (Costa, 2001). At least 39 genetic variants of BuChE have been identified, with nucleotide alterations in the coding region. Several of these variants are silent, but they are rare; most common variants have a reduced activity and are far less efficient scavengers of cholinesterase inhibitors (Lockridge and Masson, 2000; Goodal, 2006). Individuals with such BuChE variants would be predicted to be more susceptible to OP toxicity, as suggested by a study in Brazilian farmers (Fontoura-da-Silva and Chautard-Friere-Maira, 1996). To date, only a few genetic variants of human AChE have been described (Goodal, 2006). One resulted in an amino acid change but had no effect on the catalytic properties of the enzyme (Masson *et al.*, 1994), whereas a polymorphism in the distal promoter region was associated with an enhanced response to pyridostigmine (Shapira *et al.*, 2000). A third study identified several polymorphisms in the coding region, that also did not appear to alter the catalytic action of AChE (Hasin *et al.*, 2004). Transgenic mice carrying one deficient AChE allele (AChE $^{+/-}$) are healthy, and display supersensitivity to OPs (Lockridge *et al.*, 2005). Genetic polymorphisms of AChE in humans that would cause partial AChE deficiency have been hypothesized, but not yet demonstrated; such individuals would be expected to display increased susceptibility to OP toxicity.

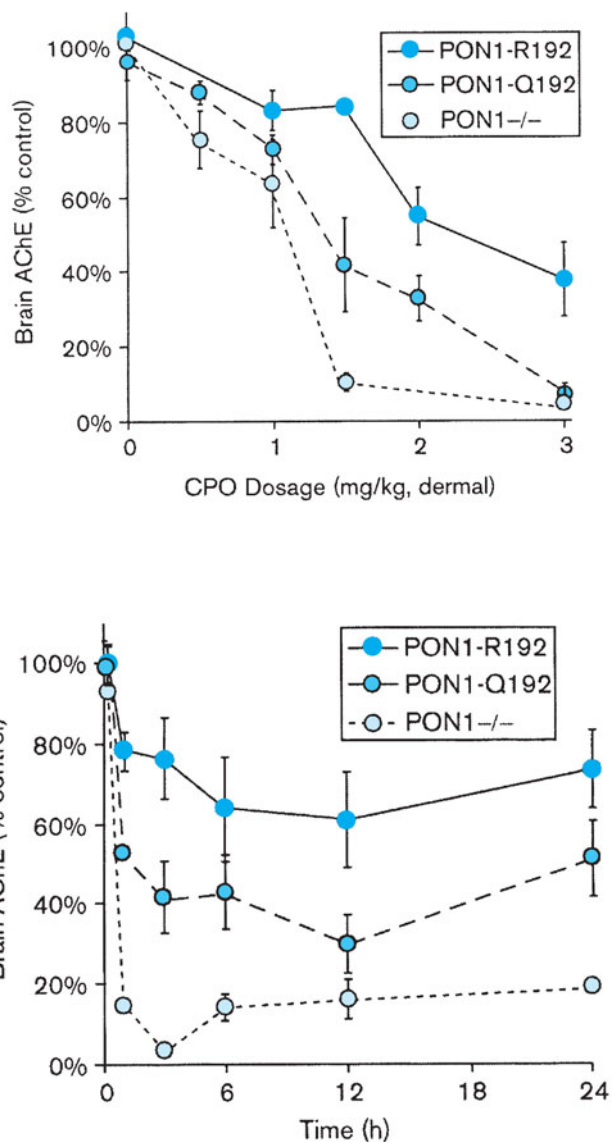
Long-Term Toxicity   Whereas the effects of acute exposure to OPs have been clearly identified and characterized by thousands of animal studies and cases of human poisonings, there is still controversy on possible long-term effects of OPs. That acute exposure to high doses of OPs may result, in some cases, in long-lasting adverse health effects (particularly in the CNS) has been shown in animals, as well as humans (Sanchez-Santed *et al.*, 2004; Rosenstock *et al.*, 1991). More controversial is the possibility that low exposure to OPs, at doses that produce no cholinergic signs, may lead to long-term adverse health effects, particularly in the central and peripheral


Figure 22-6. Dose–response (top panel) and time-course (bottom panel) of brain acetylcholinesterase (AChE) inhibition by chlorpyrifos oxon (CPO) in PON1 knockout mice (PON1 -/-) or in mice expressing either of the two human PON1$_{R192}$ or PON1$_{Q192}$ transgenes in place of endogenous mouse PON1.

Note that mice lacking PON1 are most sensitive to CPO toxicity, while those expressing human PON1$_{R192}$ are most resistant. Mice expressing human PON1$_{Q192}$ show intermediate sensitivity, despite expressing similar levels of PON1. The experiments indicate the role of PON1 "status" in modulating the toxicity of CPO. Modified with permission from Cole TB, Walter BJ, Shih DM *et al.*: Toxicity of chlorpyrifos and chlorpyrifos oxon in a transgenic mouse model of the human paraoxonase (PON1) Q192R polymorphism. *Pharmacogenet Genomics* 15:589–598, 2005.

nervous systems. Chronic exposure of animals to OPs, at doses that significantly inhibit AChE, but may not be associated with clinical signs, results in the development of tolerance to their cholinergic effects (which is mediated, at least in part, by down-regulation of cholinergic receptors), and has been associated with neurobehavioral abnormalities, particularly at the cognitive level (Costa *et al.*, 1982; Prendergast *et al.*, 1998). Evidence describing long-term
		LD$_{50}$ in rats (mg/kg)		Water solubility (g/L)

neuropsychological or neuropsychiatric alterations in humans upon low chronic exposure is contradictory (Daniell *et al.*, 1992; Jamal and Julu, 2002), and most recent expert reviews tend to conclude that the balance of evidence does not support the existence of clinically significant neuropsychological effects, neuropsychiatric abnormalities, or peripheral nerve dysfunction in humans chronically exposed to low levels of OPs (Ray, 1998; Lotti 2002a,b; Colosio *et al.*, 2003; IOM, 2000). Yet, research in this area, and the ensuing debate, will undoubtedly continue.

OPs as a class are not considered to be mutagenic, and there is little evidence that they may be carcinogenic. Immunotoxicity of OPs has been suggested from in vitro or high dose animal studies, but evidence in humans is lacking. Some OPs have also endocrine disrupting activities in vitro (Tamura *et al.*, 2003), but in vivo studies, even at dose levels that inhibit brain AChE activity, have not substantiated these findings (Okahashi *et al.*, 2005).

Developmental Toxicity and Neurotoxicity   In the past decade, a report from the National Academy of Sciences has highlighted the potential higher exposure of children to pesticides (NRC, 1993), and FQPA indicates that in the risk assessment process, an additional safety factor should be included to ensure protection of children who are presumed to be more sensitive to the effects of toxicants (FQPA, 1996). Experimental data indicate that young animals are more sensitive to the acute toxicity of OPs (Costa, 2006). This increased sensitivity does not appear to be due to intrinsic differences in AChE, but rather to lower detoxication abilities of young animals.

For example, low detoxication by CYPs or PON1 accounts for the age-dependent susceptibility of parathion and chlorpyrifos, respectively (Benke and Murphy, 1975; Mortensen *et al.*, 1996). In contrast, as discussed earlier, the young appear to be more resistant to OPIDP. In recent years, accumulating evidence suggests perinatal exposure to OPs may cause developmental neurotoxicity. Studies in rodents indicate that OPs can affect various cellular processes (e.g., DNA replication, neuronal survival, neurite outgrowth), noncholinergic pathways (e.g., serotoninergic synaptic functions, the adenylate cylase system), and cause various behavioral abnormalities (Song *et al.,* 1997; Dam *et al.*, 1998; Jett *et al.*, 2001; Aldridge *et al.*, 2003; Ricceri *et al.*, 2003; Garcia *et al.*, 2005). Such effects were often seen at dose levels that produced no cholinergic signs of toxicity. These findings, together with results of biomonitoring studies that indicate exposure of children, particularly in inner cities and farming communities, to OPs, have led to regulatory restrictions on the use of certain OPs, and to heightened concern for their potential neurotoxic effects in children (Eskenazi *et al.*, 1999; Weiss *et al.*, 2004). Furthermore, specific guidelines for developmental neurotoxicity have been implemented (Tilson, 2000).

Carbamates

Carbamate insecticides have a variety of chemical structures (Fig. 22-7), but all derive from carbamic acid, the majority being *N*-methylcarbamates. They present different degrees of acute oral toxicity, ranging from moderate to low toxicity such as carbaryl, to
Figure 22-8. Time-course of acetylcholinesterase (AChE) inhibition in different tissues of mice following administration of a single dose of the carbamate insecticide propoxur (10 mg/kg, i.p.).

Note the near complete recovery of AChE activity two hours after propoxur administration. With permission from Costa LG, Hand H, Schwab BW *et al.*: Tolerance to the carbamate insecticide propoxur. *Toxicology* 21:267–278, 1981.

extremely high toxicity, such as aldicarb (Fig. 22-7). Dermal toxicity is lower, but skin penetration is increased by organic solvents and emulsifiers present in most formulations (Ecobichon, 2001b). Carbamates are susceptible to a variety of enzyme-catalyzed biotransformation reactions, and the principal pathways involve oxidation and hydrolysis (Fukuto, 1972; Tang *et al.*, 2006). For the most part, the metabolites are devoid of biological activity, but this is not always the case. For example, two metabolites of aldicarb, the sulfoxide and the sulfone, are more potent anticholinesterases than the parent compound (Risher *et al.*, 1987). The mechanism of toxicity of carbamates is analogous to that of OPs, in that they inhibit AChE. However, inhibition is transient and rapidly reversible, because there is rapid reactivation of the carbamylated enzyme in the presence of water (Table 22-10). Additionally, carbamylated AChE does not undergo the aging reaction. The sign and symptoms of carbamate poisoning are the same as observed following intoxication with OPs, and include miosis, urination, diarrhea, salivation, muscle fasciculation, and CNS effects (Table 22-9). However, differently from OPs, acute intoxication by carbamates is generally resolved within a few hours. Figure 22-8 shows experimental data on AChE inhibition by propoxur in mice; maximal inhibition is achieved very rapidly, as carbamates are direct AChE inhibitors and do not require metabolic bioactivation, and enzyme activity returns to control levels within two hours. Carbamates also inhibit BuChE; the degree of such inhibition varies depending on the specific compound, but is generally modest after moderate exposure (when, however, inhibition of red blood cells and nervous tissue AChE can be substantial), and equivalent to that of AChE after severe exposure (Ecobichon, 2001b).

The transient nature of AChE inhibition following carbamate exposure poses several problems in measurements of its activity. First, measurements should be made shortly (a few hours at most) following exposure; otherwise, even if severe inhibition and symptoms of toxicity were present, the latter would be resolved, and

no enzyme inhibition would be detected. Secondly, particular care should be taken even if blood samples are drawn shortly after exposure, as temperature and time elapsed before the assay would cause reversal of inhibition. The treatment of carbamate intoxication relies on the use of the muscarinic antagonist atropine. Use of oximes is generally not recommended, as 2-PAM has been shown to aggravate the toxicity of carbaryl (Murphy, 1986). Yet, oximes may have beneficial effects in case of other carbamates such as aldicarb (Ecobichon, 2001b). There are several cases of human poisoning associated with exposure to various carbamates, in particular carbaryl (Cranmer, 1986) and propoxur (Hayes, 1982). Most cases, however, involved aldicarb. This compound, which has a very high acute toxicity, is also highly water soluble (Fig. 22-7). Though, because of this characteristic, it is not registered for use on any fruit or vegetable having a high water content, its illegal use in hydroponically grown cucumbers, and in watermelons have led to outbreaks of poisoning (Goes *et al.*, 1980; Goldman *et al.*, 1990). Contamination of drinking water has also been reported (Zaki *et al.*, 1982). Carbamates can inhibit NTE, but because carbamylated NTE cannot age, they are thought to be unable to initiate OPIDP. Additionally, when given before a neuropathic organophosphate, carbamates offer protection against OPIDP (Johnson and Lawerys, 1969), but when given after, they can promote OPIDP (Lotti, 2002b). A few case reports indicate that exposure to very high dosages of methylcarbamates (e.g., carbaryl, carbofuran), may result in a peripheral polyneuropathy similar to OPIDP (Dickoff *et al.*, 1987; Yang *et al.*, 2000). This would imply that aging is not required for OPIDP to develop, or, alternatively, that in these cases, carbamates may have amplified a pre-existing subclinical neuropathy. Carefully conducted animal studies would be needed to substantiate this hypothesis.

Subchronic and chronic toxicity studies on carbamate insecticides have been carried out mostly for registration purposes, and their main findings (inhibition of cholinesterases, effects on organ weight and hematological parameters, histopathological changes) are described in detail by Baron (1991). Development of tolerance to some carbamates (propoxur, carbaryl) upon repeated exposure has been observed, and this appears to be due to an induction of microsomal enzymes (Costa *et al.*, 1981). As a class, methylcarbamates are not mutagenic, and there is also no evidence of carcinogenicity. Embryotoxicity or fetotoxicity are observed only at maternally toxic doses (Baron, 1991). Limited evidence suggests that carbamates (e.g., aldicarb) may be more acutely toxic to young animals than to adults (Moser, 1999), possibly because of lower detoxication, but this aspect has not been investigated in the same detail as for OPs.

Pyrethroids

Pyrethrins were first developed as insecticides from extracts of the flower heads of *Chrisanthenum cinerariaefolium*, whose insecticidal potential was appreciated in ancient China and Persia. However, because pyrethrins were decomposed rapidly by light, synthetic analogs, the pyrethroids, were developed. Because of their high insecticidal potency, relatively low mammalian toxicity, lack of environmental persistence, and low tendency to induce insect resistance, pyrethroids have encountered much success in the past thirty years, and now account for more than 25% of the global insecticide market (Soderlund *et al.*, 2002). Pyrethroids are used widely as insecticides both in the house and in agriculture, in medicine for the topical treatment of scabies and head lice, and in tropical countries in soaked bed nets to prevent mosquito bites. Pyrethroids are known to alter

the normal function of insect nerves by modifying the kinetics of voltage-sensitive sodium channels, which mediate the transient increase in the sodium permeability of the nerve membrane that underlies the nerve action potential (Soderlund *et al.*, 2002). All pyrethroid insecticides contain an acid moiety, a central ester bond, and an alcohol moiety (Fig. 22-9). The acid moiety contains two chiral carbons, thus pyrethroid typically exist as stereoisomeric compounds (*trans* and *cis*). Additionally, some pyrethroids also have a chiral carbon on the alcohol moiety, allowing for a total of eight different stereoenantiomers. These chemical considerations are relevant, as pyrethroids' effects on sodium channels, their insecticidal activity, and their mammalian toxicity, are stereospecific. The *cis* isomers are generally more toxic than the corresponding *trans* isomers (Casida *et al.*, 1983). The acute oral mammalian toxicity of pyrethroids is generally low. Values of LD_{50} range, for example, from 100 mg/kg (deltamethrin) to 10,000 mg/kg (phenothrin). To underline the relevance of stereospecificity, the LD_{50} for 1R, *trans*-resmethrin is 8,000 mg/kg, but that of 1R, *cis*-resmethrin is 100 mg/kg (Casida *et al.*, 1983). The low mammalian toxicity of pyrethroids is confirmed by the fact that despite their extensive worldwide use, there are relatively few reports of human poisonings, and only a dozen deaths (Bradberry *et al.*, 2005). Most deaths occurred following accidental or intentional exposure to pyrethroids. For example, a 45-year-old man died three hours after eating beans and cheese prepared using a 10% cypermethrin solution instead of oil (Poulos *et al.*, 1982). The dermal toxicity of pyrethroid is even lower, because of limited absorption through the skin.

Upon absorption, pyrethroids are very rapidly metabolized through two major biotransformation routes: hydrolysis of the ester linkage, which is catalyzed by hepatic and plasma carboxylesterases, and oxidation of the alcohol moiety by cytochromes P450 (Miyamoto, 1976; Soderlund and Casida, 1977). These initial reactions are followed by further oxidations, hydrolysis and coniugation with sulfate or glucuronide. The relative importance of the hydrolytic or oxidative biotransformation varies from compound to compound, and from isomer to isomer for each pyrethroid. For example, the *trans* isomer of permethrin is more susceptible to hydrolysis by carboxylesterase than the *cis* isomer (Soderlund and Casida, 1977; Ross *et al.*, 2006). Type II pyrethroids (see below) are less sensitive to hydrolysis. For instance, deltamethrin, a type II pyrethroid containing a cyano group (Fig. 22-9), and present solely as the *cis* isomer, is more extensively metabolized by hepatic cytochromes P450, particularly CYP1A2 and CYP1A1 (Vmax/Km = 34.9), than by liver carboxylesterase (Vmax/Km = 11.5) (Anand *et al.*, 2006a). Though it has been suggested that oxidative metabolism may lead in some cases, to bioactivation of certain pyrethroids (Dayal *et al.*, 2003; Ray and Fry, 2006), the current line of evidence would suggest that hydrolytic and oxidative metabolism achieve detoxication of the parent, active compound (Soderlund *et al.*, 2002). Inhibition of cytochromes P450 by piperonyl butoxide indeed increases pyrethroid toxicity, and so does inhibition of carboxylesterase (Casida *et al.*, 1983). Piperonyl butoxide is added to most pyrethroid formulations as a synergist. Inhibition of carboxylesterase may be of significance, if unauthorized pyrethroid/organophosphate mixtures are utilized (Ray and Forshaw, 2000). In fact, several organophosphates inhibit carboxylesterase activity, and may thus be expected to potentiate pyrethroid toxicity (Choi *et al.*, 2004).

Signs and Symptoms of Toxicity and Mechanism of Action
The acute mammalian toxicity of pyrethroids is well character-

Table 22-12

Classification of Pyrethroid Insecticides Based on Toxic Signs in Rats

SYNDROME	SIGNS AND SYMPTOMS	EXAMPLES
Type I (T syndrome)	Aggressive sparring Increased sensitivity to external stimuli Whole body tremors Prostration	Allethrin Bioallethrin Resmethrin Phenothrin
Type 2 (CS syndrome)	Pawing and burrowing Profuse salivation Coarse Tremor Choreoatetosis Clonic seizures	Deltamethrin Fenvalerate Cypermethrin Cyhalothrin

ized. Based on toxic signs in rats, pyrethroids have been divided into two types (Table 22-12; Verschoyle and Aldridge, 1980). Type I compounds produce a syndrome consisting in marked behavioral arousal, aggressive sparring, increased startle response, and fine body tremor progressing to whole-body tremor and prostration (Type I or T syndrome). Type II compounds produce profuse salivation, coarse tremor progressing to choreoatetosis and clonic seizures (Type II or CS syndrome) (Soderlund *et al.*, 2002; Ray and Fry, 2006). A key structural difference between type I and type II pyrethroids is the presence only in the latter of a cyano group at the α carbon of the alcohol moiety of the compound (Fig. 22-9). However, certain pyrethroids (e.g., cyphenothrin, flucythrinate) elude such classification, as they produce a combination of the two syndromes (Soderlund *et al.*, 2002; Ray and Fry, 2006).

The mode of action of pyrethroids in mammals is the same as in insects, disruption of the voltage-gated sodium channels (Narahashi, 1996). Pyrethroids bind to the α subunit of the sodium channel and slow the activation (opening), as well as the rate of inactivation (closing) of the sodium channel, leading to a stable hyperexcitable state. Sodium channels then open at more hyperpolarized potentials, and are held open longer, allowing more sodium ions to cross and depolarize the neuronal membrane (Shafer *et al.*, 2005). In general, type II compounds delay the inactivation of sodium channels substantially longer (>10 ms) than do type I compounds (<10 ms) (Ray and Fry, 2006). Type I compounds prolong channel opening only long enough to cause repetitive firing of action potential (repetitive discharge), analogously to DDT (Vijveberg *et al.*, 1982); type II compounds hold the channels open for such long periods that the membrane potential ultimately becomes depolarized to the point at which generation of action potential is not possible (depolarization-dependent block) (Fig. 22-10; Shafer *et al.*, 2005). These differences in the time of opening of sodium channels are believed to be at the basis of the differences observed between the T and CS syndromes (Ray and Fry, 2006). The higher sensitivity of insects to pyrethroid toxicity, compared to mammals, is believed to result from a combination of higher sensitivity of insect sodium channels, lower body temperature (as pyrethroids show a negative temperature coefficient of action), and slower biotransformation (Ray and Fry, 2006). Type II pyrethroids, but not type I compounds, also bind to, and inhibit $GABA_A$-gated chloride channels (Lawrence and Casida, 1983), albeit at higher concentrations than those sufficient to affect
Figure 22-9. *Structures of Type I (left) and Type II (right) pyrethroid insecticides. Note that all Type II pyrethroids display a cyano (CN) group.*

sodium channels (10^{-7}M vs 10^{-10}M). This effect is believed to contribute to the seizures that accompany severe type II pyrethroid poisoning. However, drugs that enhance GABAergic transmission (e.g., diazepam), have modest effects toward deltamethrin-induced choreoatetosis or seizures. Type II pyrethroids, such as deltamethrin, also inhibit at low concentration (10^{-10}M) voltage-dependent chloride channels (Forshaw *et al.*, 1993). Because chemicals that open these chloride channels, such as ivermectin and pentobarbital, antagonize pyrethroid-induced choreoatetosis and salivation, inhibition of maxi voltage-dependent chloride channels by pyrethroid may contribute to the type II poisoning syndrome (Forshaw *et al.*, 2000). Other reported targets for pyrethroids include calcium ATPase and voltage-gated calcium channels, which are however, affected at higher concentrations (10^{-5} M and 10^{-6}M, respectively). Of potential interest was the observation that several pyrethroids could stimulate protein kinase C-dependent protein phosphorylation at very low concentrations (10^{-13}M), (Enan and Matsumura, 1993), but whether this interaction is involved in the modulation of sodium and/or chloride channels remains to be determined.

Young animals are more sensitive to the acute toxicity of certain pyrethroids, such as deltramethrin and cypermethrin (Sheets, 2000), most likely because of a lesser capacity for metabolic detoxification (Anand *et al.*, 2006b); however, only minor age-related differences were found for other compounds (Sheets, 2000). Some studies have suggested that certain pyrethroids may cause devel-

opmental neurotoxicity, but current evidence has been judged inadequate (Shafer *et al.*, 2005). Furthermore, levels of background pyrethroid exposure (presumably through residues in the diet) in children has been found to be of orders of magnitude lower than the corresponding acceptable daily intake (Heudorf *et al.*, 2004). Also, the use of deltamethrin-impregnated bed nets does not appear to pose any health risk in children and neonates (Barlow *et al.*, 2001), while substantially reducing infant mortality from malaria (Alonso *et al.*, 1991).

Upon occupational exposure, the primary adverse effect resulting from dermal contact with pyrethroids is paresthesia (Flannigan *et al.*, 1985; He *et al.*, 1989). Symptoms include continuous tingling or pricking or, when more severe, burning. The condition reverses in about 24 hours, and topical application of vitamin E has been shown to be an effective treatment. Paresthesia is presumably due to abnormal pyrethroid-induced repetitive activity in skin nerve terminals (Ray and Fry, 2006).

Chronic studies with pyrethroids indicate that at high dose levels they cause slight liver enlargement often accompanied by some histopathological changes. There is little evidence of teratogenicity and mutagenicity (Miyamoto, 1976; Ray, 1991). An increased rate of lymphoma incidence in rodents has been reported for deltamethrin, but the effect was not dose-dependent (Cabral *et al.*, 1990). There is no compelling evidence that pyrethroids may act as endocrine disruptors (Kim *et al.*, 2004). Pyrethroids are particularly toxic to fish, but not to birds (Miyamoto, 1976).
Figure 22-10. Effect of pyrethroids on neuronal excitability.

Depolarization opens voltage sensitive sodium channels (VSSCs) allowing Na^+ to enter the cell. To limit Na^+ entry and depolarization length, VSSCs inactivate and return to a "resting" state before reopening (top left). Pyrethroids delay inactivation (double arrows between states) of the channel and allow continued Na+ flux (Open *) (top right). Under normal circumstances, depolarization leads to a rapidly inactivating current, and generates a single action potential (bottom left). Pyrethroid-modified VSSCs remain open when depolarization ends, resulting in a "tail" current. Type I compounds depolarize the cell membrane above the threshold for action potential generation, resulting in a series of action potential (repetitive firing). Type II compounds cause greater membrane depolarization, diminishing the Na^+ electrochemical gradient and subsequent action potential amplitude, eventually leading to depolarization-dependent block (bottom right). From Shafer *et al*. (2005) with permission.

Organochlorine Compounds

The organochlorine insecticides include the chlorinated ethane derivatives, such as DDT and its analogues; the cyclodienes, such as chlordane, aldrin, dieldrin, heptachlor, endrin, and toxaphene; the hexachlorocyclohexanes, such as lindane; and the caged structures mirex and chlordecone (Figs. 22-11 and 22-12). From the 1940s to the 1970s and 1980s, the organochlorine insecticides enjoyed wide use in agriculture, structure insect control, and malaria control programs. Their acute toxicity is moderate (less than that of organophosphates), but chronic exposure may be associated with adverse health effects particularly in the liver and the reproductive system. Primarily because of ecological considerations, these compounds have been banned in most countries in the past thirty years. Yet, because of their environmental persistence and high lipophilicity, exposure to these compounds continues, most notably through the diet. Furthermore, some, such as DDT, are being reintroduced in part of the world for malaria control; hence, a discussion of their toxicity has more than historical value.

DDT and Its Analogues   DDT [1,1,1-trichloro-2, 2-bis (4-chlorophenyl) ethane] was first synthesized by O. Zeidler in 1874, but its insecticidal activity was discovered only in 1939 by Paul Mueller in Switzerland. Early experiments showed that DDT was effective against a wide variety of agricultural pests, as well as against insects that transmit some of the world's most serious diseases, such as typhus, malaria, and yellow fever. In the United States, annual use of DDT rose until 1959 to about 36,000 tons, after which it declined gradually until its ban in 1972 (Rogan and Chen, 2005). However, as said, because of its high persistence, global redistribution, and its current use in many parts of the world, a discussion of the toxicology of DDT is still of relevance (Longnecker, 2005). While

DDT is the universally accepted common name of the insecticide, technical-trade DDT is a mixture of several isomers (Fig. 22-11), with p,p′-DDT being responsible for the insecticidal activity.

DDT has a moderate acute toxicity when given by the oral route, with an LD_{50} of about 250 mg/kg; p,p′-DDT is at least 10-fold more toxic than o, p′-DDT (Smith, 2001). Dermal absorption of DDT is very limited, resulting in dermal LD_{50} values of >1000 mg/kg. In humans, oral doses of 10–20 mg/kg produce illness, but doses as high as 285 mg/kg have been ingested accidentally without fatal results. Toxicity from dermal exposure in humans is also low, as evidenced by the lack of significant adverse health effects when thousands of people were liberally dusted with this compound. Upon absorption, DDT distributes in all tissues, and the highest concentrations are found in adipose tissue. DDT is also extensively but slowly metabolized, with DDE, DDD and DDA (in each case both the p,p′ and the o,p′ isomers) being the primary metabolites in humans (Smith, 2001). DDE is also stored in adipose tissue. Excretion is through the bile, urine, and the milk.

Acute exposure to high doses of DDT causes motor unrest, increased frequency of spontaneous movements, abnormal susceptibility to fear and hypersusceptibility to external stimuli (light, touch, sound). This is followed by the development of fine tremors, progressing to coarse tremors, and eventually tonic-clonic convulsions. Symptoms usually appear several hours after exposure, and death, usually due to respiratory failure, may follow after 24–72 hours (Ecobichon and Joy, 1982). Signs and symptoms of poisoning are similar in most animals species, with dogs displaying prominent convulsions. There is no evidence that young animals may be more sensitive than adults to the acute toxicity of DDT, and they may actually be less sensitive (Smith, 2001). In humans, the earliest symptom of poisoning by DDT is hyperesthesia of the mouth and lower part of the face, followed by paresthesia of the same area and of the tongue.
Figure 22-11. Structures of the organochlorine insecticide p,p'-DDT and its isomers.

The percentage of each isomer present in technical grade DDT is indicated in parenthesis. DDE and DDD also result from biotransformation of DDT.

Dizziness, tremor of the extremities, confusion and vomiting follow, while convulsions occur only in severe poisoning.

Signs and symptoms of acute poisoning clearly point at the nervous system as the primary target for DDT toxicity (Woolley, 1982). Both in insects and in mammals, DDT interferes with the sodium channels in the axonal membrane by a mechanism similar to that of Type I pyrethroids (Vijverberg et al., 1982). DDT has little or no effect on the resting potential or the rising phase and peak amplitude of the action potential. However, it greatly prolongs the depolarizing (negative) afterpotential of the action potential, and this produces a period of increased neuronal excitability immediately after the spike phase. This, in turn, enhances the probability of repetitive firing, and the insurgence of a "train" of action potentials (Fig. 22-13). Voltage clamp studies have shown that the principal effect of DDT is to slow down the closing of sodium channels once they have opened, while having little or no effect on closed gates. In addition to this effect on sodium channels, DDT also affects ATPases. Though DDT inhibits Na^+, K^+-ATPase, this action would not contribute to its neurotoxic effect (Matsumura and Patil, 1969). Rather, inhibition of a Ca^{2+}-ATPase (an ecto-ATPase, located on the outside of the cell membrane) may be involved in the effects of DDT. As the function of this Ca^{2+}-ATPase is believed to be that of maintaining high external calcium concentrations, its inhibition would lower external calcium and

contribute to membrane instability and repetitive firing (Matsumura and Ghiasuddin, 1979). Several neurochemical studies have also shown that DDT exposure alters the levels of some neurotransmitters such as acetylcholine, norepinephrine, and serotonin, as well as of cyclic GMP, but these effects appear to be the results, rather than the cause, of DDT-induced neurotoxicity (Woolley, 1982). Treatment for DDT poisoning focuses on the nervous system. In animals, phenytoin and calcium gluconate have been found to reduce DDT-induced tremors and mortality, respectively. In humans, in addition to decontamination and supportive treatment, diazepam or phenobarbital may be beneficial to control convulsions, if present.

While acute exposure to DDT is a rare event, chronic exposure has been, and still is, a primary concern. In this regard, an important target for DDT is the liver. DDT and DDE increase liver weight and cause hepatic cell hypertrophy and necrosis, and are potent inducers of cytochromes P450, particularly CYP2B and CYP3A (Smith, 1991, 2001). DDT has been shown to be hepatocarcinogenic in mice and rats, but results in other species are inconclusive. DDT also increased incidence of lung tumors and adenomas in mice. Both DDE and DDD were also shown to be carcinogenic, causing primarily an increase in liver tumors. DDT is not genotoxic in in vitro and in vivo tests. Based on animal data, DDT is classified as a possible human carcinogen by IARC; however, evidence of human carcinogenicity

is still inconclusive. Along with many negative studies, there is some, albeit contradictory, evidence of increased risks for pancreatic cancer, liver cancer, and multiple myeloma, associated with exposure to DDT (Turosov *et al.*, 2002; Beard, 2006). Given the endocrine disrupting actions of DDT and DDE (see below), particular attention has been devoted to possible associations between exposure to these compounds and hormonally sensitive cancers, such as those of the breast, the endometrium and the prostate, but the results have been inconclusive (Safe, 2005; Beard, 2006).

Methoxychlor [2,2-bis (p-methoxyphenyl) −1, 1, 1-trichloroethane) is the p,p′-dimethoxy analog of p,p′-DDT. Because of its low acute toxicity (LD$_{50}$ in rat = 5000 mg/kg) and short

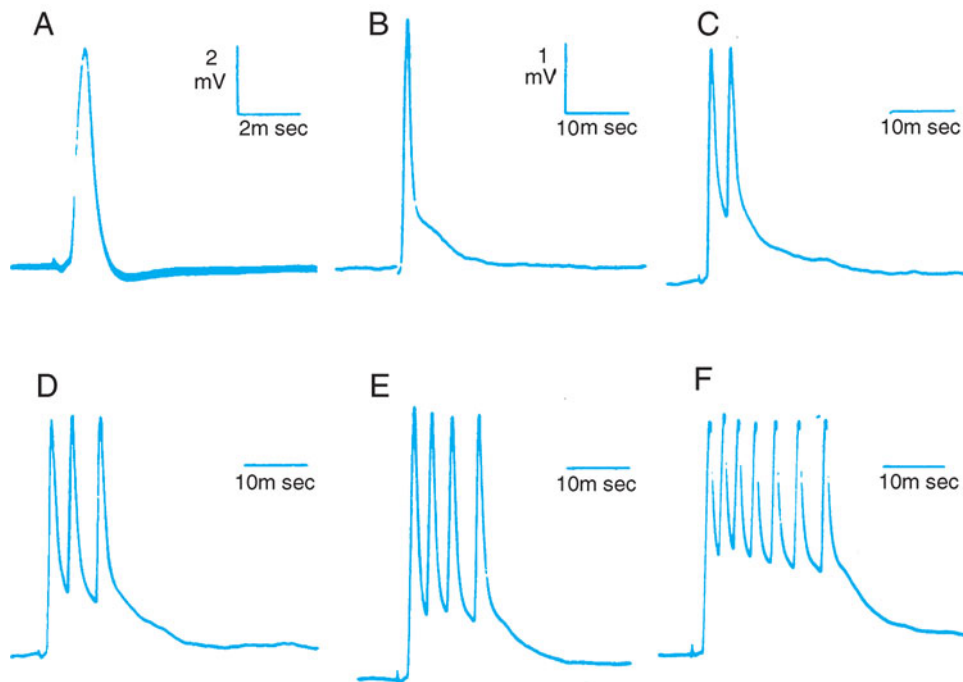
biological half-life, its use has greatly expanded following the ban of DDT. Furthermore, methoxychlor is rapidly metabolized, and does not accumulate in tissues. Though convulsions have been reported in dogs after high doses, in the rat depression of the central nervous system, mild tremors, diarrhea and anorexia were observed (Smith, 2001). Upon chronic exposure, methoxychlor has been found to be a modest inducer of liver microsomal enzymes, and to cause chronic nephritis, and hypertrophy of kidneys, mammary glands, and uterus. Testicular atrophy and decreased spermatogenesis were also observed. Evidences of mutagenicity and carcinogenicity are inconclusive. Methoxychlor is metabolized by CYP2C19 and CYP1A2 to demethylated compounds, which


Figure 22-13. *Action potential of a single nerve fiber from the sciatic nerve of the toad Xenopus laevis, before (A), and 65, 85, 90, 105, and 135 min (B–F) after in vitro exposure to 10^{-4} M DDT. Note the difference in time-scale between A and B. The first observable effect is the development of a negative after-potential (B). With time of exposure, repetitive spike discharge is initiated and increased in proportion to the amplitude of the negative after-potential (C-F).*

have estrogenic activity (Smith, 2001); these are likely responsible for the effects caused by methoxychlor on the reproductive system in both male and female animals.

Hexachlorocyclohexanes and Cyclodienes These two families of organochlorine insecticides comprise a large number of compounds that share a similar mechanism of neurotoxic action. Lindane is the γ isomer of benzene hexachloride (BHC; 1,2,3,4,5,6- hexachlorocyclohexane) (Fig. 22-12). BHC is composed of eight stereoisomers, and the γ isomer is the one with insecticidal activity (Smith, 1991). Cyclodiene compounds include chlordane, dieldrin, aldrin (which is rapidly metabolized to dieldrin), heptachlor, and endrin (Fig. 22-12). Toxaphene, a complex mixture of chlorinated bornanes and camphenes, is also classified as an organochlorine insecticide. All of these compounds were introduced in the late 1940s to early 1950s, and have experienced wide use before being banned in most countries due to their persistence and environmental and human health effects, one exception being lindane. Lindane has been used as an insecticide in agriculture and has found many uses as a scabicide and pediculocide in lotions and shampoos. The primary use of chlordane has been for termite control, while other compounds were primarily used in agriculture. Endrin was registered for use as a rodenticide to control voles in orchards, a testament to its rather high acute toxicity, compared to most other organochlorines (Fig. 22-12).

Lindane and cyclodienes have moderate to high acute oral toxicity (Fig. 22-12). However, in contrast to DDT, these compounds are readily absorbed through the skin. The primary target for their toxicity is the central nervous system. Unlike DDT, tremor is essen-

tially absent, but convulsions are a prominent aspect of poisoning. These are due to the ability of these compounds to interfere with γ-aminobutyric acid (GABA)–mediated neurotransmission. GABA is an important neurotransmitter in the mammalian and insect CNS and in the insect neuromuscular junction. GABA receptors are members of the superfamily of ligand-gated ion channels that contain a chloride ionophore; by binding to these receptors, endogenous GABA causes the opening of chloride channels resulting in hyperpolarization of the membrane. Lindane and cyclodienes bind to a specific site (the picrotoxin site) on the chloride channel, thereby blocking its opening and thus antagonizing the "inhibitory" action of GABA (Cole and Casida, 1986; Eldefrawi and Eldefrawi, 1987; Narahashi, 1996). Treatment of acute poisoning is symptomatic; phenobarbital and diazepam can be used as anticonvulsants. Additional reported neurochemical effects of organochlorine insecticides include inhibition of Na^+- K^+, Ca^{2+}, and Mg^{2+} -ATPases, and changes in neurotransmitter levels.

As with DDT, these compounds are slowly metabolized, and have a tendency to bioaccumulate in adipose tissue; they are also excreted in milk. Cyclodienes are inducers of microsomal biotransformation enzymes and cause liver enlargement upon chronic exposure (Smith, 1991). They are not genotoxic, but have been shown to act as tumor promoters and cause liver tumors in mice. As with DDT, they are extremely persistent in the environment, and some have endocrine disrupting properties.

Mirex and Chlordecone These two organochlorine insecticides have a cage-like structure and were introduced in the late 1950s for

Table 22-13

use against fire ants and leaf-eating insects, respectively. Chlordecone (Kepone) has been the most studied because of one episode which involved 148 workers in a chlordecone producing factory in Hopewell, Virginia, between 1973 and 1975 (Taylor *et al.*, 1978). The primary manifestation of chlordecone toxicity is the presence of tremors, which are observed in animals as well as in humans (Guzelian, 1982). The exact mechanism of chlordecone neurotoxicity has not been elucidated, but it is believed to involve inhibition of ATPases (both Na^+-K^+ and Mg^{++} ATPases), and ensuing inhibition of the uptake of catecholamines (Desaiah, 1982). In contrast to cyclodienes, chlordecone does not cause seizures.

Chlordecone induces hepatic drug metabolizing enzymes, and causes hepatosplenomegaly in rats and humans. It is not mutagenic, but can induce liver tumors in rodents (Smith, 1991). Chlordecone also causes reproductive toxicity in animals, likely by mimicking the effects of excessive estrogens. Low or absent sperm count was found in chlordecone-exposed workers (Taylor *et al.*, 1978; Guzelian, 1982). Cholestyramine, an anion-exchange resin, has been shown effective both in animals and humans as a means to increase fecal excretion of chlordecone, probably by sequestering the unmetabolized compound that is secreted into the intestinal lumen via biliary excretion; this interrupts enterohepatic circulation and shortens the biological half-life (Guzelian, 1982).

Environmental Ubiquity and Persistence The properties (low volatility, chemical stability, lipid solubility, slow rate of biotransformation, and degradation) that made organochlorine compounds such effective insecticides, also brought about their demise because of their persistence in the environment, bioconcentration and biomagnification in food chains, and the acquisition of biologically active body burdens at higher trophic levels (Ecobichon, 2001a). Sweden banned DDT in 1970, the United States in 1972, and the UK in 1986. Most other organochlorine insecticides were also banned in the United States during this period; for example, aldrin and dieldrin in 1975, toxaphene in 1982, and chlordane in 1988. These bans occurred largely on the basis of ecological considerations. Their extensive use and their environmental persistence made them widespread pollutants. Studies carried out in the Great Lakes region in the United States exemplify the nature and the extent of the problem. Table 22-13 shows the tendency of DDT to bioaccumulate in the food chain. Adverse effects on bird reproduction (e.g., eggshell thinning) were among the first ecological effects to be identified and denounced (Carson, 1962; Peakall, 1970), and played an important role in the decision to ban DDT (USEPA, 1975). Monitoring of organochlorine insecticides in fish in the Great Lakes shows extreme high levels in 1970 (e.g., 20,000 ng/g of total DDT, which also includes DDE and DDD), and a progressive decline after the use of these compounds was restricted or banned (Hickey *et al.*, 2006).

Because of their stability and high lipophilicity, organochlorines are present in adipose tissues of most individuals. For example, DDE, the breakdown product of DDT in the environment and the result of its biotransformation, is an extremely stable compound ($t_{1/2} = 7$–11 years), which accumulates in fat, and is usually found in human tissue at the highest concentration. Studies in populations from different countries in the 1960s showed that all adipose tissue samples contained DDT at concentrations ranging from 5–20 mg/kg (ppm), with DDE accounting for about 60% of total DDT (WHO, 1979). Though concentrations of DDT in humans show a decreasing trend, those of DDE, which is ingested with food, particularly meat and fish, remain more constant or decrease only slightly. Organochlorine insecticides are also excreted in the milk. Though levels have decreased in most countries in the last decades (Smith, 1999), elevated levels remain in several developing countries (Table 22-14; Chao *et al.*, 2006). Data presented in Table 22-14 also indicate a differential DDE/DDT ratio among milk samples from different populations; a higher ratio is an indication of high environmental persistence and continuous bioaccumulation, while a low DDE/DDT ratio indicates recent exposure to DDT, as the biological half-life of DDT is shorter than DDE (Jaga and Dharmani, 2003).

Endocrine Disruption An endocrine, or hormone, disruptor can be defined as an exogenous chemical that interferes with the synthesis, secretion, transport, binding, action or elimination of natural hormones in the body, that are responsible for the maintenance of homeostasis, reproduction, development and behavior (Crisp *et al.*,1998). Several pesticides may fall into this category, and among these, a large number are organochlorine insecticides. The o,p′-isomer of DDT, which comprise approximately 15% of the technical grade product (Fig. 22-11), has estrogenic properties, in that it can act as an agonist at estrogen receptors (ER) α and β (Table 22-15). A metabolite of DDT, p,p′-DDE, in contrast, inhibits androgen binding to androgen receptor (Table 22-15; Kelce *et al.*, 1995). Metabolites of the DDT analog, methoxychlor, are active as ERα agonists, ERβ antagonists and are antiandrogenic. Chlordecone also has estrogenic properties (Table 22-15; Guzelian, 1982). Other organochlorine compounds with weak estrogenic activity are dieldrin, endosulfan, toxaphene, lindane and the β isomer of hexachlorocyclohexane (βBHC). In all cases, the potency of the insecticides or their metabolites were several orders of magnitude less then those of the hormones. Experimental studies have shown that administration of these compounds to animals can cause hormonally-mediated adverse health effects. For example, p,p′-DDE had clear antiandrogenic effect when given to fetal, pubertal, and adult male rats (Kelce *et al.*, 1995). Several studies have shown that chlordecone and methoxychlor affect the male reproductive system (Guzelian, 1982; Kavlock, 2001). Of possible relevance is the recent finding that exposure to methoxychlor during gestation (E8–E15) induced transgenerational defects in spermatogenic capacity and sperm viability, i.e., these abnormalities were also observed in F2 generation animals (Anway *et al.*, 2005). All these findings, though provocative, were obtained at dosage levels that far exceed anticipated environmental exposure. It has been suggested that estrogen equivalents from phytoestrogens present in foods and beverages are several orders of magnitude higher than estrogen equivalents resulting from estrogenic organochlorine insecticide contaminants in food (Safe, 2000). More importantly, the association between exposure to organochlorine compounds and possible related diseases in humans (breast cancer, decreased sperm count, cryptorchidism, testicular cancer,

etc.) is weak at best, and inconclusive (Golden *et al.*, 1998; Safe, 2005). Nevertheless, the possibility that these chemicals, as well as several other endocrine disruptors, may contribute to hormonally mediated cancers, reproductive effects, and developmental abnormalities, should not be discounted, and additional research in this area is warranted.

DDT and Public Health: Risk-Benefit Considerations The Stockholm Convention on Persistent Organic Pollutants, ratified in 2004 by 50 states, outlawed the use of 12 industrial chemicals (the "Dirty Dozen"), including DDT. Yet, an exemption clause allows malaria-endemic nations to continue utilizing DDT for indoor residual wall spraying. The United Nations Environment Program estimates that about 25 countries would use DDT under this exemption from its ban. This situation is keeping the debate on the risks and benefits of DDT usage very much alive. On one hand, the environmental and human health effects of DDT are evident; on the other, one has to come to grips with the burden of mortality from malaria worldwide. Indeed, each year up to three million deaths due to malaria occur throughout the world, with 90% occurring in Africa (Breman *et al.*, 2004). Most such mortality occurs in the first five years of life (Rogan and Chen, 2005). Thus, use of DDT might reduce mortality from malaria and overall infant mortality, if spraying is carried out according to planned schedule, which is not always the case, and if malaria-transmitting mosquitoes do not become resistant to DDT, a problem that in the past has forced switching to other insecticides. The successful results obtained in South Africa in recent years (see earlier section "Economics and Public Health"), would support a continuous use of DDT. Indoor residual spraying might not cause the ecological effects that caused the ban of DDT, but could expose humans to amounts of DDT that may cause adverse health effects. In this regard, reproductive outcomes are of most concern. In particular, preterm births and early weaning (decreased duration of lactation), which can lead to increased infant mortality, have been associated with DDT exposure (Chen and Rogan, 2003; Rogan and Chen, 2005), though findings are controversial (Roberts *et al.*, 2004). DDT remains, however, a public health intervention that is cheap, long lasting, and effective. Its judicious use should be combined with that of insecticide-treated bed nets, to prevent mosquito biting, and with a better availability of therapeutic interventions in affected populations.

Other Old and New Insecticides

Rotenoids The roots of the East Asian Derris plants, particularly *Derris Elliptica,* and those of *Lonchocarpus utilis* and *Lonchocarpus urucu* in South America contain at least six rotenoid esters, among which the most abundant is rotenone. Rotenone is used as an agricultural insecticide/acaricide, particularly in organic farming (Isman, 2006). It is rather persistent in food crops after treatment, as indicated by half-life of 4 days in olives (Cabras *et al.*, 2002). Rotenone is very toxic to fish; root extracts were used to paralyze fish for capture and consumption, and rotenone is still used in fishery management. Toxicity of rotenone in target and nontarget species is due to its ability to inhibit, at nanomolar concentrations, the mitochondrial respiratory chain, by blocking electron transport at NADH-ubiquinone reductase, the energy conserving enzyme complex commonly known as Complex I. Insect and fish mitochondria are particularly sensitive to Complex I inhibition (Degli Esposti, 1998). Purified rotenone has a high acute toxicity in rodents and dogs, and is less toxic to rabbits and birds (Ujvary, 2001). Poisoning symptoms include initial increased respiratory and cardiac rates, clonic and tonic spasms, and muscular depression, followed by respiratory depression. Acute intoxication in humans is rare, and the lethal dose in adults has been estimated at >140 mg/kg. However, a case report describes a fatal case in a 3.5-year-old girl who ingested an estimated 40 mg/kg of rotenone. Of note is that the label

on the insecticide, which was manufactured in France and recommended for external use on animals, had stated "Natural Product – Non Toxic" (De Wilde *et al.*, 1986).

In recent years, rotenone has received much attention because of its potential role in the etiology of Parkinson's disease. An earlier study by Heikkila *et al.* (1985) showed that stereotaxic administration to rats of rotenone damaged the dopaminergic nigrostriatal pathway, same as what observed with MPP$^+$ (1-methyl-4-phenyl pyridinium, the active metabolite of 1-methyl-4-phenyl- 1,2,3,6-tetrahydropyridine, MPTP), a known parkinsonism-causing chemical, which is also a Complex I inhibitor (Degli Esposti, 1998). More recent studies have shown that administration of rotenone to rats (2–3 mg/kg/d for 1–5 weeks) caused selective nigrostriatal degeneration, though inhibition of Complex I was observed uniformly in brain (Betarbet *et al.*, 2000; Sherer *et al.*, 2003). The finding that rotenone also produced protein inclusions, similar to Lewy bodies, that stained positively for ubiquitin and alpha-synuclein, suggests that the rotenone model for Parkinson's disease would be even better than the MPTP model (Betarbet *et al.*, 2002). However, the severe systemic toxicity of rotenone, the high variability across and within strains, and reports on nonspecific CNS effects (LaPointe *et al.*, 2004), have also pointed out the limitations of the rotenone model (Li *et al.*, 2005). There is no evidence of Parkinson's disease-like clinical signs or neurodegenerative pathology in chronic dietary studies (Hollingworth, 2001). Thus, although rotenone may represent an useful experimental model, its primary role, if any, in the etiology of Parkinson's disease in the general population is still unproven (Hollingworth, 2001; Li *et al.*, 2005).

Nicotine   The tobacco plant (*Nicotiana tabacum, Nicotiana rustica*) was introduced in Europe in 1559 from the Americas where it had long been cultivated primarily for smoking. Tobacco extracts have been used to repel and kill insects since 1690, and tobacco smoke was also used for fumigation (Ujvary, 2001). Nicotine is an alkaloid extracted from the leaves of tobacco plants, and is used as a free base or as the sulfate salt. The most notorious commercial preparation, Black Leaf 40, has been discontinued. Very little nicotine is used currently in the United States, but nicotine is still used as a minor insecticide in some Asian countries. It is a systemic insecticide effective toward a wide range of insects, including aphids, thrips, and whiteflies (Ujvary, 1999). As the primary component of tobacco used for smoking or chewing, nicotine's pharmacology and toxicology have been thoroughly investigated (Benowitz, 1996; Taylor, 1996). Nicotine exerts its pharmacological and toxic effects in mammals and insects by activating nicotinic acetylcholine receptors (nAChRs). In vertebrates, nAChRs are expressed at neuromuscular junctions, in the PNS and in the CNS; in insects, nAChRs are confined to the nervous system (Eldefrawi and Eldefrawi, 1997). Interaction of nicotine with nAChRs produces initial stimulation followed by protracted depolarization, which results in receptor paralysis. The overall effect is the summation of stimulatory and inhibitory effects of nicotine at all sites expressing nAChRs. At high doses, parasympathetic stimulation and ganglionic and neuromuscular blockade predominate (Matyunas and Rodgers, 2001). Nicotine has a high acute toxicity in vertebrates, with LD$_{50}$s usually below 50 mg/kg (Ujvary, 2001). Signs and symptoms of poisoning include nausea, vomiting, muscle weakness, respiratory effects, headache, lethargy, and tachycardia. Most cases of poisoning with nicotine occur after exposure to tobacco products, or gum or patches.

Workers who cultivate, harvest, or handle tobacco may experience green tobacco sickness, caused by dermal absorption of nicotine.

Neonicotinoids   By various chemical modifications of nicotine and other nAChRs agonists, new classes of insecticides have been developed that contain a nitromethylene, nitroimine or cyanoimine group, and are referred to as neonicotinoids. One of the first compounds synthesized was nithiazine, a nitromethylenyl heterocyclic compound highly toxic toward insects but with low mammalian toxicity. Nithiazine was not developed commercially because of its photo-instability. Further structure-activity studies led to the development of imidacloprid, nitenpyram, acetamiprid, and other neonicotinoid compounds (Fig. 22-14; Matsuda *et al.*, 2001). The insecticidal activity of neonicotinoids is attributed to activation of nAChRs. They are used primarily for crop protection as systemic insecticides, but are also effective against fleas in cats and dogs (Schenker *et al.*, 2003). The mammalian toxicity of neonicotinoids is similar to that of nicotine, and correlates with agonist action and binding affinity at the nAChRs. Acute oral toxicity (LD50) in rats ranges from 180 to >2000 mg/kg (Fig. 22-14), while dermal toxicity is much lower (2000–5000 mg/kg), likely because of the low lipophilicity (Tomizawa and Casida, 2005). Signs and symptoms of toxicity are attributable to stimulation of nAChRs. Some neonicotinoids (imidocloprid, thiacloprid) are particularly toxic to birds, others (thiacloprid) to fish. Most neonicotinoids are not mutagenic or carcinogenic, nor teratogenic. Neonicotinoids undergo limited biotransformation in mammals, involving mostly cytochrome P450-mediated oxidative reactions (Sheets, 2001; Tomizawa and Casida, 2005). Neonicotinoids account for 10–15% of the total insecticide market, and their use is increasing faster than other insecticides (Matsuda *et al.*, 2001; Tomizawa and Casida, 2005). The main reason for their success lies in their selectivity profile, which is largely attributable to their specificity toward insect vs. mammalian nAChRs. The nAChR consists of diverse subtypes assembled in combination from ten α and four β, γ, δ, ε subunits. The most abundant subtypes in the vertebrate nervous system are $\alpha 4\beta 2$ and $\alpha 7$, which are insensitive and sensitive, respectively, to α-bungarotoxin. In insects, neonicotinoids have been shown to bind to at least three pharmacologically distinct nAChRs (Sheets, 2001; Matsuda *et al.*, 2001). Table 22-16 shows the in vitro effects of some neonicotinoids toward insect nAChRs and mammalian $\alpha 4\beta 2$ nAChRs, and compares them to nicotine. Structural features of neonicotinoids that contribute to their selective actions at insect nAChRs have been described (Nakayama and Sukekawa, 1998; Matsuda *et al.*, 2001; Tomizawa and Casida, 2005).

Formamidines   Formamidines, such as chlordimeform [(N′-(4-chloro-o-tolyl)-*N*, *N*-dimethylformamidine] or amitraz [*N*′-2,4-(dimethyl-phenyl)-*N*-*N* ((2,4-dimethylphenyl) imino) methyl-*N*-methanimidamide] are used in agriculture and in veterinary medicine as insecticides/acaricides (Hollingworth, 1976). Their structures are closely related to the neurotransmitter norepinephrine (Fig. 22-15). In invertebrates, these compounds exert their toxicity by activating an octopamine-dependent adenylate cyclase (Nathanson, 1985). In mammals, symptoms of formamidines poisoning are sympathomimetic in nature (Beeman and Matsumura, 1973). The similarity between insect octopamine receptors and mammalian α_2-adrenergic receptors had suggested the latter as a possible target for formamidines. In vivo and in vitro studies have indeed shown that formamidines act as rather selective
	Log P	Acute oral LD50 (mg/kg; rat)

agonists at α_2–adrenergic receptors (Hsu and Lu, 1984; Hsu and Kakuk, 1984; Costa *et al.*, 1988; Altobelli *et al.*, 2001). Chlordimeform's metabolism plays a most relevant role in its toxicity. The *N*-demethylated metabolite (desmethylchlordimeform) is more acutely toxic than chlordimeform, and displays a >400-fold higher potency toward α_2–adrenoceptors (Ghali and Hollingsworth, 1985; Costa and Murphy, 1987). Two other metabolites of chlordimeform, 4-chloro-toluidine and *N*-formyl-4-chloro-o-toluidine, are believed to be responsible for the observed haemangioendotheliomas in mice observed in carcinogenicity studies (IPCS, 1998). Chlordimeform was classified as a probable human carcinogen (Group 2A) by IARC

in 1990. Given the increasing evidence of an association between exposure to chlordimeform and 4-chloro-o-toluidine and bladder cancer (Popp *et al.*, 1992), chlordimeform was withdrawn form the market in 1992. Amitraz, in contrast, remains on the market and is still used worldwide for the control of ectoparasites in farm animals and crops. In recent years several cases of acute amitraz poisoning have been reported, particularly in Turkey, and most involved children (Yaramis *et al.*, 2000; Caksen *et al.*, 2003; Elinav *et al.*, 2005; Proudfoot, 2003). Signs and symptoms of poisoning mimicked those of α_2-adrenergic receptor agonists such as clonidine, and included nausea, hypotension, hyperglycemia, bradycardia, and

miosis. No deaths occurred. Though α_2-adrenoceptor antagonists such as yohimbine have proven useful as antidotes in animals (Andrade and Sakate, 2003), their usefulness in managing amitraz poisoning in humans has not been evaluated.

Avermectins   The avermectins are macrocyclic lactones, first isolated in 1975 from the fermentation broth of the actinomycete *Streptomyces avermitilis,* which originated from a Japanese soil sample (Campbell, 1989; Fisher and Mrozik, 1992). This fungus synthesizes eight individual avermectins, of which avermectin B_{1a} displays the highest antiparasitic activity. Currently, abamectin (a mixture of 80% avermectin B_{1a} and 20% avermectin B_{1b}) is used as an insecticide, whereas the semisynthetic derivatives of avermectin B_{1a}, emamectin benzoate, and ivermectin, are used as insecticides, and for parasite control in human and veterinary medicine, respectively (Stevens and Breckenridge, 2001). Abamectin is used primarily to control mites, whereas emamectin benzoate is effective at controlling lepidopterian species in various crops. Ivermectin is used as an antihelmintic and antiparasitic drug in veterinary medicine, and in humans it has proven to be an effective treatment for infection of intestinal threadworms, onchocerciasis (river blindness), and lymphatic filariasis (Stevens and Breckenridge, 2001). In insects and nematodes, avermectins exert their toxic effects by binding to, and activating, glutamate-dependent chloride channels (Arena *et al.*, 1995). Avermectins have a high acute toxicity, with oral LD_{50}s in rats of 11 (abamectin) to 80 (emamectin) mg/kg. Toxicity is higher in neonate animals, possibly because of a deficient blood-brain barrier (Stevens and Breckenridge, 2001). Signs and symptoms of intoxication include hyperexcitability, tremors, and incoordination, followed by ataxia and coma-like sedation. These effects are due to the ability of avermectins to activate $GABA_A$ receptor-gated chloride channels in the vertebrate CNS (Pong *et al.*, 1982; Fisher and Mrozik, 1992). Activity at $GABA_A$ receptors also mediates the anticonvulsant effects of avermectins, but because the same target seems to mediate both pharmacological and toxic effects, the potential of avermectins as anticonvulsants is limited (Dawson *et al.*, 2000). Avermectins are also strong inhibitors of P-glycoprotein, a plasma membrane protein whose main function is the ATPase-dependent transport of foreign substances from the cell (Didier and Loor, 1996). As such, avermectins are being investigated for their potential ability to inhibit multidrug resistance of tumor cells (Korystov *et al.*, 2004). In this respect, the complete sequencing of the *S. avermitilis* genome would allow the definition of the precise biosynthetic pathways and regulatory mechanisms for avermectins, which in turn may lead to engineering of this fungus to produce pharmacological compounds of interest (Yoon *et al.*, 2004). Given the wide use of avermectins, and particularly that of ivermectin in Africa, there is little evidence of adverse health effects in humans. The major effect following administration of active doses of ivermectin (0.1–0.2 mg/kg) is a severe inflammatory response (the Mazzotti reaction), characterized by pruritis, erithema, vesicle and papulae formation, and attributable to the killing of microfiliae which dislodge from their site of infestation and are transported in the blood and body fluids (Ackerman *et al.*, 1990).

Phenylpyrazoles   A relatively new class of insecticides is that of phenylpyrazole derivatives, of which fipronil, commercialized in the mid-1990s, was the first one brought to market. Fipronil is a broad-spectrum insecticide with moderate mammalian toxicity (LD_{50} in rat: oral, 97 mg/kg; dermal, >2000 mg/kg), and a high selectivity for target species. Fipronil acts as a blocker of the $GABA_A$-gated chloride channel, but binds to a site different from the picrotoxin binding site used by organochlorine insecticides. It also has a much higher specificity for insect receptors over mammalian receptors (Hainzl *et al.*, 1998). There is no evidence that fipronil is an eye or skin irritant, or has any mutagenic, carcinogenic, or teratogenic effects. A number of human poisonings with fipronil have been reported that resulted from accidental or intentional ingestion. Less than 20% of

the patients developed seizures, and all recovered (Mohamed *et al.*, 2004).

Bacillus Thuringiensis   The past decade has seen increasing research and development in the area of biopesticides, that is pesticides derived from natural materials such as plants, bacteria, and fungi. As of 2001, there were 195 registered biopesticide active ingredients in the United States, and 780 products. Biopesticides fall into three major classes: (1) Microbial pesticides, which consist of a microorganism (e.g., a bacterium, fungus or protozoan) as the active ingredient. The most widely used microbial pesticides are subspecies and strains of *B. thuringiensis* (Bt) which act as insecticides. Other microbial pesticides can control different kinds of pests; for example there are fungi that can control certain weeds, and others that can kill specific insects. (2) Plant-incorporated-protectants, which are pesticidal substances that plants produce from genetic material that has been added to the plant. For example, a plant can be genetically manipulated to produce the Bt pesticidal protein. (3) Biochemical pesticides, that are naturally occurring substances that control pests by nontoxic mechanisms. Examples are sex pheromones, that interfere with mating of insects, or various scented plant extracts that attract insect pests to traps (Sudakin, 2003). Biopesticides represent a little more than 1% of the world pesticide market, but Bt products represent 80% of all biopesticides sold (Whalon and Wingend, 2003). Bt is a soil microorganism that produces proteins that are selectively toxic to certain insects. Its name comes from the German region of Thuringia, where this strain was found in 1915. Bt-based microbial insecticides were commercialized in France in 1938 and in the United States in 1961. Over 150 insecticidal crystal proteins (Cry) have been identified in Bt and in the closely related *Bacillus cereus* (Schnepf *et al.*, 1998). After ingestion of Bt by an insect, the crystal proteins are solubilized, and proteolytically processed to active toxins (δ-endotoxin) in the insect's midgut. Here they bind to specific receptors in the epithelial cells and insert into the cellular membrane. Next, aggregation of inserted crystal protein occurs, resulting in the formation of pores, which lead to changes in K^+ fluxes across the epithelial cells, and to changes in pH. Ultimately, cells of the midgut epithelium are destroyed by the high pH and by osmotic lysis. Insects eventually die as a result of gut paralysis and feeding inhibition, and subsequent starvation and septicemia (Gringorten, 2001). Bt targets primarily leaf-feeding lepidoptera, breaks down rapidly in UV light, and exhibits low mammalian toxicity. The basis for the selective toxicity of Bt is attributed to the fact that crystalline Bt endotoxins require activation by alkalis and/or digestion, conditions absent in the mammalian stomach (Ujvary, 2001). A summary of the toxicology studies in mammals of Bt-based insecticides is provided by McClintock *et al.* (1995). Adverse health effects in humans are infrequent and include allergic reactions and infections (Ujvary, 2001). Bt genes are also expressed in a variety of crop plants, most notably cotton and corn. Thus, the plant, instead of the Bt bacterium, produces the substance that affects the insect upon feeding. Resistance can develop to Bt toxins that involves alterations in the processing of Cry toxin in the insect's gut or in its binding to receptors (Whalon and Wingerd, 2003).

INSECT REPELLENTS

Insect-transmitted diseases remain a major source of illness and death worldwide, as mosquitoes alone transmit disease to more than 700 million persons annually (Fradin and Day, 2002). Though insect-borne diseases represent a greater health problem in tropical and subtropical climates, no part of the world is immune to their risks. For example, in 1999, the West Nile virus, transmitted by mosquitoes, was detected for the first time in the western hemisphere. In the New York City area, 62 persons infected with the West Nile virus were hospitalized and seven died (Nash *et al.*, 2001). Other arthropod-borne viral diseases (e.g., equine encephalitis) and tick-borne diseases (e.g., Lyme disease) are also of concern; additionally, other insect bites can be associated with variable adverse health effects, from mild irritation and discomfort to possible allergic reactions. Insect repellents are thus widely used to provide protection toward insect bites. The best known and most widely used insect repellent is DEET. Botanical insect repellents based on citronella or oil of eucalyptus, and a biopesticide structurally similar to the aminoacid alanine are also commercialized in Europe and the United States (Fradin and Day, 2002). A new compound, picaridin, has been recently approved for use as an insect repellent; it is effective against biting flies, mosquitoes, ticks and fleas, and has a very favorable toxicological profile (USEPA, 2005).

DEET

DEET (*N*, *N*-diethyl-m-toluamide or *N*, *N*-diethyl-3-methyl-benzamide) was first developed by the USDA in 1946 for use in the military, and was registered as an insect repellent for the general public in 1957. The USEPA estimates that 30% of the U.S. population uses DEET every year. More than 200 formulations exist with varying concentrations of DEET (commonly 4.75–40%) which are applied directly to the skin or on clothing. DEET is very effective at repelling insects, flies, fleas, and ticks, and protection time increases with increasing concentrations (Fradin and Day, 2002). Percutaneous absorption of DEET varies from 7.9 to 59%, depending on the species tested and the conditions of the study (Osimitz and Murphy, 1997). DEET undergoes oxidative biotransformation catalyzed by various cytochromes P450, and is excreted mostly in the urine (Sudakin and Trevathan, 2003). DEET has low acute toxicity, with LD_{50} values in the rat of 1892 mg/kg (oral) and >5,000 mg/kg (dermal) (Schoenig and Osimitz, 2001). From 1961 to 2002, eight deaths were reported related to DEET: three resulted from deliberate ingestion, while two were reported following dermal exposure (Tenenbein, 1987; Bell *et al.*, 2002). The remaining three cases were children, age 17 months to 6 years (Zadikoff, 1979). Subchronic toxicity studies in various species did not reveal major toxic effects, with the exception of renal lesions in male rats; these were considered to be reflective of α_{2u}-globulin induced nephropathy, a condition unique to male rats and not occurring in humans (Schoenig and Osimitz, 2001). No significant effects of DEET were seen in mutagenicity, reproductive toxicity, and carcinogenicity studies. Acute and chronic neurotoxicity studies also provided negative results (Schoenig *et al.*, 1993). Yet, several case reports over the past 40 years have indicated neurological effects of DEET, and most of these were in children (Petrucci and Sardini, 2000; Osimitz and Murphy, 1997; Hampers *et al.*, 1999; Sudakin and Trevathan, 2003; Briassoulis *et al.*, 2001; MMWR, 1989; Gryboski *et al.*, 1961). The most common symptoms reported were seizures. Given that seizure disorders occur in 3–5% of children, and almost 30% of children in the United States are utilizing DEET, an association just by chance is certainly possible. Possible mechanism(s) responsible for neurotoxic effects of DEET are unknown, though it has been suggested that DEET's structure is similar to that of nikethamide, a convulsant (Briassoulis *et al.*, 2001). It has also been suggested that DEET may disrupt the permeability of the blood–brain barrier,

Table 22-17
Some Mechanisms of Action of Herbicides

MECHANISM	CHEMICAL CLASSES (EXAMPLE)
Inhibition of photosynthesis	Triazines (atrazine), Substitued ureas (diuron), Uracils (bromacil)
Inhibition of respiration	Dinitrophenols
Auxin growth regulators	Phenoxy acids (2,4-D), Benzoic Acids (dicamba), Pyridine acids (picloram)
Inhibition of protein synthesis	Dinitroanilines
Inhibition of lipid synthesis	Aryloxyphenoxyproprionates (diclofop)
Inhibition of specific enzymes	
• Glutamine synthetase	Glufosinate
• Enolpyruvylshikimate -3-phosphate synthetase	Glyphosate
• Acetalase synthase	Sulfonylureas
Cell membrane disruptors	Bipyridyl derivatives (Paraquat)

but results are inconclusive (Abdel-Rahman *et al.*, 2002). Overall, given its long-standing and widespread use, DEET appears to be relatively safe when used as recommended (Osimitz and Murphy, 1997; Koren *et al.*, 2003). A risk assessment by the Canadian Pest Management Regulatory agency has recommended, however, that toddlers and children, up to 12 years old, should only be exposed to products with up to 10% DEET (Sudakin and Trevathan, 2003). For all other individuals, products with up to 30% DEET can be used, as they appear safe and effective (Fradin and Day, 2002).

HERBICIDES

Herbicides are chemicals that are capable of either killing or severely injuring plants. They represent a very broad array of chemical classes and act at a large number of sites of metabolic functions and energy transfer in plant cells (Duke, 1990). Some of the various mechanisms by which herbicides exert their biological effects are shown in Table 22-17, together with examples for each class. Another method of classification pertains to how and when herbicides are applied. Thus, *preplanting* herbicides are applied to the soil before a crop is seeded; *preemergent* herbicides are applied to the soil before the time of appearance of unwanted vegetation; and *postemergent* herbicides are applied to the soil or foliage after the germination of the crop and/or weeds (Ecobichon, 2001a). Herbicides are also divided according to the manner they are applied to plants. *Contact* herbicides are those that affect the plant that was treated, while *translocated* herbicides are applied to the soil or to above-ground parts of the plant, and are absorbed and circulated to distant tissues. Nonselective herbicides will kill all vegetation, while selective compounds are those used to kill weeds without harming the crops. In the past decade, the development of herbicide-resistant crops through transgenic technology has allowed the use of nonselective compounds as selective herbicides (Duke, 2005). A final classification, of relevance to adverse health effects in nontarget species, relies, on the other hand, on chemical structures, as indicated below.

For the past several decades, herbicides have represented the most rapidly growing sector of the agrochemical market, and these compounds now represent almost half of the pesticides used in the United States, and more than one-third of those utilized worldwide (Table 22-3). This can be ascribed in part to movement to monocultural practices, where the risk of weed infestation has increased, and to mechanization of agricultural practices because of increased labor costs. In addition to agriculture and home and garden uses, herbicides are also widely utilized in forestry management and to clear roadsides, utilities' rights of way, and industrial areas.

In terms of general toxicity, herbicides, as a class, display relatively low acute toxicity, compared for example to most insecticides. There are exceptions, however, such as paraquat. A number of herbicides can cause dermal irritation and contact dermatitis, particularly in individuals prone to allergic reactions. Other compounds have generated much debate for their suspected carcinogenicity or neurotoxicity. The principal classes of herbicides associated with reported adverse health effects in humans are discussed below.

Chlorophenoxy Compounds

Chlorophenoxy herbicides are characterized by an aliphatic carboxylic acid moiety attached to a chlorine-or-methyl-substituted aromatic ring. The most commonly used compound of this class is 2,4-dichlorophenoxyacetic acid (2,4-D), while others are 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) and 4-chloro-2-methylphenoxyacetic acid (MCPA) (Fig. 22-16). Chlorophenoxy herbicides are chemical analogues of auxin, a plant growth hormone, and produce uncontrolled and lethal growth in target plants. Because the auxin hormone is critical to the growth of many broad-leaved plants, but is not used by grasses, chlorophenoxy compounds can suppress the growth of weeds (e.g., dandelions) without affecting the grass. Once absorbed, they selectively eliminate broad-leaved plants, due to their larger leaf area and greater absorption. 2,4-D is one of the most widely used herbicides throughout the world, and is primarily used in agriculture to control weeds in corn and grain, in forestry, and in lawn care practices. 2,4,5-T has been largely withdrawn from use because of concerns that arose from contamination of some formulations with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which can derive from the reaction of two molecules of 2,4,5-trichlorophenol (Fig. 22-17). A 50:50 mixture of the n-butyl esters of 2,4,-D and 2,3,5-T, known as Agent Orange (from the color of the barrels which contained it), was extensively used as a defoliant during the Vietnam War, and was found to be contaminated with TCDD to a maximum of 47 μg/g. Exposure of military personnel and Vietnamese population to Agent Orange has raised concerns on possible long-term health effects, particularly carcinogenicity and reproductive toxicity (IOM, 1996), which are ascribed to the presence of TCDD.

2,4-D is a compound of low to moderate acute toxicity, with oral LD_{50}s in rodents of 300–2000 mg/kg. The dog is more sensitive, possibly because of its lower ability to eliminate organic acids via the kidney. Upon oral exposure, 2,4-D is rapidly absorbed, and its salts and esters rapidly dissociate or hydrolyze in vivo, so that toxicity depends primarily on the acid form. It binds extensively to serum albumin, but does not accumulate in tissue, and is excreted almost exclusively through the urine. Ingestion of 2,4-D has caused several cases of acute poisoning in humans, usually at doses above 300 mg/kg, though lower doses have been reported to elicit symptoms. Vomiting, burning of the mouth, abdominal pain, hypotension, myotonia and CNS involvement including coma, are among the clinical signs observed (Bradberry *et al.*, 2000; 2004a). Management of 2,4-D poisoning appears to be aided by urine alkalinization, through intravenous administration of bicarbonate (Proudfoot *et al.*, 2004;

Effect of Urine Alkalinization on Renal Clearance and Plasma Half-Life of 2,4-D

URINE pH	RENAL CLEARANCE (mL/min)	HALF-LIFE (h)
5.10–6.5	0.28	219
6.55–7.5	1.14	42
7.55–8.8	9.60	4.7

SOURCE: Park *et al.*, (1977).

Bradberry *et al.*, 2004a). Ionization of an acid, such as 2,4-D, is increased in an alkaline environment. Though, at pH 5.0, practically all 2,4-D would already be ionized, further alkalinization of urine, to pH 7.5 or above, would reduce the non-ionized fraction from approximately 0.53 to 0.0017%. As a result, the fraction prone to reabsorption would be >300-times lower (Bradberry *et al.*, 2004a). This explains why alkalinization of the urine diminishes reabsorption and increases 2,4-D elimination. An example of the effect of urine alkalinization on 2,4-D renal clearance and plasma half-life is given in Table 22-18. Dermal exposure is by far the major route of unintentional exposure to 2,4-D in humans. Dermal absorption studies in rats, mice and rabbit, indicate an absorption of 12–36%; the absorption in humans, however, is lower (2–10%), and is usually less than 6% (Ross *et al.*, 2005). Acute poisoning by 2,4-D via the dermal route is thus uncommon; no reports of systemic toxicity following dermal exposure have been reported for over 20 years, and no fatalities have ever occurred (Bradberry *et al.*, 2004a).

The precise mechanisms of toxicity of chlorophenoxy herbicides have not been completely elucidated, but experimental studies indicate the possible involvement of three actions: (1) Cell membrane damage; (2) Interference with metabolic pathways involving acetyl-coenzyme A; (3) Uncoupling of oxidative phosphorylation (Bradberry *et al.*, 2000). The toxicity of chlorophenoxy herbicides has been summarized in several reviews (Sterling and Arundel, 1986; Munro *et al.*, 1992; Garebrant and Philbert, 2002). 2,4-D and its salts and esters are not teratogenic in mice, rats, or rabbits,

unless the ability of the dam to excrete the chemical is exceeded. There is also no convincing evidence that 2,4-D is associated with human reproductive toxicity (Garabrant and Philbert, 2002). Subchronic and chronic toxicity studies have not provided evidence of immunotoxicity, and there is very limited evidence that 2,4-D may affect the nervous system (Mattsson *et al.*, 1997). There are, however, several case reports suggesting an association between exposure to 2,4-D and neurologic effects like peripheral neuropathy, demyelination and ganglion degeneration in the CNS, reduced nerve conduction velocity, mytonia and behavioral alterations (Garabrant and Philbert, 2002).

Numerous in vitro and in vivo studies with 2,4-D indicate that it has very little genotoxic potential (Munro *et al.*, 1992). Long-term bioassays in rats, mice and dogs provided no evidence to suggest that 2,4-D is a carcinogen in any of these species. An earlier study in rat reported an increase in the incidence of brain astrocytomas in male animals, only at the highest dose tested (45 mg/kg/d) (Serota *et al.*, 1986). However, a review of this study concluded that the observed tumors were not treatment-related (Munro *et al.*, 1992), and more recent studies did not replicate the original finding (Charles *et al.*, 1996). Nevertheless, the chlorophenoxy herbicides have attracted much attention because of the association between exposure and non-Hodgkin's lymphoma or soft-tissue sarcoma, found in a small number of epidemiological studies (Hoar *et al.*, 1986; Hardell *et al.*, 1994). In a recent review that follows several previous ones discussing this topic (Woods *et al.*, 1987; Munro *et al.*, 1992; USEPA, 1994), Garabrant and Philbert (2002) evaluated all cohort and case-control studies available to date, and concluded that the evidence from epidemiological studies was not adequate

to conclude that exposure to 2,4-D is associated with soft-tissue sarcoma, non-Hodgkin's lymphoma or Hodgkin's disease. 2,4-D is classified as a Group D agent (not classifiable as to human carcinogenicity) (USEPA, 1997).

Bipyridil Compounds

This class of herbicides comprises paraquat and diquat (Fig. 22-18). Of these, paraquat (1,1′-dimethyl-4,4′-bipyridilium dichloride) is of most toxicological concern, and will be discussed in more detail. First described in 1882, paraquat's redox properties were discovered in 1933, when the compound was called methyl viologen. Paraquat, introduced as a herbicide in 1962, is formulated as an aqueous solution or as a granular formulation. Paraquat is a fast-acting, nonselective contact herbicide, used to control broad-leaved weeds and grasses in plantations and fruit orchards, and for general weed control (Lock and Wilks, 2001a).

Paraquat has one of the highest acute toxicity among herbicides; its oral LD_{50} in rat is approximately 100 mg/kg, while guinea pigs, rabbits, and monkeys are more sensitive. Paraquat is more toxic when given by the i.p. route (LD_{50} in rats = 10–20 mg/kg), suggesting that it is poorly absorbed from the gastrointestinal tract. Paraquat is also poorly absorbed through the skin. Upon absorption, independent of the route of exposure, paraquat accumulates in the lung and the kidney, and these two organs are the most susceptible to paraquat-induced injury. Paraquat is very poorly metabolized, and is excreted almost unchanged in the urine. Paraquat has minimal to no genotoxic activity, is not carcinogenic in rodents, has no effect on fertility, is not teratogenic, and only produces fetotoxicity at maternally toxic doses (Lock and Wilks, 2001a). Thus, the major toxicological concerns for paraquat are related to its acute systemic effects, particularly in the lung, and secondarily, the kidney. Rose *et al.* (1974) first described an energy-dependent accumulation of paraquat in lung tissue, particularly, but not exclusively, in type II alveolar epithelial cells. The loss of paraquat from lung tissue following in vivo administration is slow. Thus, the basis for the selective

toxicity of paraquat to the lung resides in its ability to concentrate in alveolar type II and I cells and Clara cells.

The mechanism(s) by which paraquat is toxic to living cells have been extensively investigated (Autor, 1974; Bus and Gibson, 1984; Smith, 1987). Paraquat can be reduced to form a free radical, which in the presence of oxygen, rapidly reoxidizes to the cation, with a concomitant production of superoxide anion ($O2^-$). Thus, once paraquat enters a cell, it undergoes alternate reduction followed by reoxidation, a process known as redox cycling (Adam *et al.*, 1990). Superoxide dismutases (SOD) are a family of metalloenzymes that can dismutate superoxide anions to hydrogen peroxide and oxygen. The finding that transgenic mice lacking copper/zinc SOD show marked increase in sensitivity to paraquat (Ho *et al.*, 1998), supports a role for superoxide anions in paraquat's cellular toxicity. Nevertheless, superoxide anion itself is unlikely to be the ultimate toxic species (Lock and Wilks, 2001a). Three hypotheses have been proposed to account for the ensuing cytotoxicity, which are not mutually exclusive. The generation of superoxide anion and subsequently of hydroxy radicals, would initiate lipid peroxidation, ultimately leading to cell death (Bus and Gibson, 1984). Intracellular redox cycling of paraquat would also result in the oxidation of NADPH, leading to its cellular depletion, which is augmented by the detoxification of hydrogen peroxide formed in the glutathione peroxidase/reductase enzyme system to regenerate GSH (Fig. 22-19). A third hypothesis is that paraquat toxicity is due to mitochondrial damage; however, paraquat does not affect complex I in isolated brain mitochondria (Richardson *et al.*, 2005).

Upon acute exposure to lethal doses of paraquat, mortality may occur 2–5 days after dosing, though death can also occur after longer periods (Clark *et al.*, 1966). Damage to alveolar epithelial cells is seen within 24 hours after exposure. Damage progresses in the following 2–4 days with large areas of the alveolar epithelium completely lost. This is followed by alveolar edema, extensive infiltration of inflammatory cells into the alveolar interstitium, and finally death due to severe anoxia (Smith and Heath, 1976). Survivors of this first phase, called the destructive phase, show extensive proliferation of fibroblasts in the lung. The second phase, called the proliferative phase, is characterized by attempts by the alveolar epithelium to regenerate and restore normal architecture, and presents itself as an intensive fibrosis (Smith and Heath, 1976). Some individuals who survive the first phase may still die from the progressive loss of lung function several weeks after exposure.

Attempts to develop treatments for paraquat poisoning have focused on prevention of absorption from the gastrointestinal tract, removal from the bloodstream, prevention of its accumulation in the lung, use of free radical scavengers, and prevention of lung fibrosis (Lock and Wilks, 2001a). Though some approaches have shown promises in vitro or in isolated lung tissue preparations, only the first one, removal of the ingested material by emesis or purgation of the gastrointestinal tract, has been shown to be effective in vivo in animals.

Since its introduction as a herbicide, there have been thousands of episodes of acute poisoning with paraquat in humans, a large percentage of which results in death (Malone *et al.*, 1971; Casey and Vale, 1994; Wesseling *et al.*, 2001). Most cases involved ingestion of a 20% paraquat concentrate solution for suicidal purposes, or as a result of accidental poisoning due to decanting in unlabeled drink bottles or containers. To avoid the latter, in the 1980s, the manufacturers added a blue pigment, a stenching compound, and an emetic substance to the formulation, to make severe unintentional poisoning due to oral intake virtually impossible (Sabapathy, 1995). As
Figure 22-19. Mechanism of toxicity of paraquat.

(1) Redox cycling of paraquat utilizing NADPH; (2) formation of hydroxy radicals leading to lipid peroxidation (3); (4) detoxication of H_2O_2 via glutathione reductase/peroxidase couple, utilizing NADPH. Modified from Smith (1987), with permission from Palgrave Macmillan.

said, absorption of paraquat across the human skin is very low (but is increased by damage to skin, and paraquat is a skin irritant), and inhalation exposure is even lower. Few cases of paraquat poisoning have been reported following dermal exposure. Signs and symptoms of paraquat poisoning in humans reflect those previously described. A dose of 20–30 mg/kg can cause mild poisoning, while 30–50 mg/kg can cause delayed development of pulmonary fibrosis, which can be lethal. Higher doses usually cause death within a few days due to pulmonary edema, and renal and hepatic failure (Smith and Heath, 1976). No single therapeutic intervention, among those outlined earlier, has proven efficacious in case of severe acute paraquat poisoning (Bismuth *et al.*, 1982). In rare instances, heart/lung transplant has been used to treat severely paraquat-poisoned patients.

Chronic exposure of experimental animals to paraquat affects the same target organs of acute toxicity, i.e., the lung and the kidney, and no-effect levels have been established. Under normal use conditions, exposure to paraquat is very low and can be monitored by measuring paraquat levels in urine, as the compound is excreted unchanged. In the late 1970s concern was raised about possible exposure of marijuana smokers to paraquat by inhalation. Paraquat was indeed used to destroy marijuana fields, and residues were still

present in the final products (Landrigan *et al.*, 1983). However, no clinical cases were identified.

Chronic paraquat exposure has also been suggested as a possible etiological factor in the development of Parkinson's disease, and the first suggestion came from a study in the Canadian province of Quebec (Barbeau *et al.*, 1986). The hypothesis arose by the structural similarity of paraquat to MPP^+ (1-methyl-4-phenylpyridinium ion), the toxic metabolite of MPTP (1-methyl-4-phenyl-1,2,3,5-tetrahydropyridine). MPP^+ itself was initially developed as a possible herbicide, but was never commercialized. It has been argued that paraquat, being positively charged, cannot easily pass the blood–brain barrier. Yet, animal studies have shown that paraquat can cause CNS effects, most notably a neurodegeneration of dopaminergic neurons (McCormack *et al.*, 2002). Paraquat may be transported into the brain by a neutral amino acid transporter, such as the system L carrier (LAT-1) (Shimizu *et al.*, 2001). The ability of paraquat to cause oxidative damage through a free radical mechanism may explain the selective vulnerability of dopaminergic neurons, which are per se more susceptible to oxidative damage (McCormack *et al.*, 2005). Paraquat neurotoxicity is, however, distinct from that of MPTP or rotenone (Richardson *et al.*, 2005). Whereas these animal studies are of interest, there is still no solid evidence that paraquat may be associated with Parkinson's disease in humans (Li *et al.*, 2005). Furthermore, a 5–10 years follow-up of individuals who survived paraquat poisoning did not provide any evidence of parkinsonism (Zilker *et al.*, 1988).

Despite the chemical similarity to paraquat (Fig. 22-18), the herbicide diquat presents a different toxicological profile. Acute toxicity is somewhat lower, with oral LD_{50} in rats of approximately 200 mg/kg (Lock and Wilks, 2001b). Diquat is not a skin sensitizer, has minimal or no genotoxic activity, is not carcinogenic in rodents, has no effect on fertility, and is not teratogenic. In contrast to paraquat, it does not accumulate in the lung, and no lung toxicity is seen upon acute or chronic exposure. Upon chronic exposure, target organs for toxicity are the gastrointestinal tract, the kidney, and particularly the eye. Diquat indeed causes a dose- and time-dependent appearance of cataracts in both rats and dogs (Lock and Wilks, 2001b). Like paraquat, diquat can be reduced to form a free radical and then reoxidized in the presence of oxygen, with the concomitant production of superoxide anion. This process of redox cycling occurs in the eye and is believed to be the likely mechanism of cataract formation (Lock and Wilks, 2001b). A limited number of cases of human poisoning with diquat have occurred. Clinical symptoms include nausea, vomiting, diarrhea, ulceration of mouth and esophagus, decline of renal functions and neurologic effects, but no pulmonary fibrosis. As for paraquat, therapy for intoxication is directed at preventing absorption and enhancing elimination (Vanholder *et al.*, 1981; Lock and Wilks, 2001b).

Chloroacetanilides

Representative compounds of this class of herbicides are alachlor, acetochlor, and metolachlor (Fig. 22-20), which are used to control herbal grasses and broad-leaved weeds in a number of crops (corn, soybeans, peanuts). Chloroacetanilides display moderate to low acute toxicity, with oral LD_{50} in rat ranging from about 600 mg/kg (propachlor) to 2800 mg/kg (metolachlor). Dermal LD_{50} values are higher, indicating poor absorption of these compounds across the skin (Heydens *et al.*, 2001). Subchronic and chronic toxicity studies, carried out in multiple species, have identified the liver and kidney as principal target organs, and no-adverse-effect

levels have been established. Alachlor was found to produce an ocular lesion, termed "progressive uveal degeneration syndrome," in rats (Heydens, 1998). However, an investigation of similar eye abnormalities in alachlor production workers considered to have the highest alachlor exposure, provided no evidence of ocular disease (Ireland *et al.*, 1994). None of the chloroacetanilides appears to be teratogenic or cause reproductive or developmental toxicity (Heydens *et al.*, 2001).

Chloroacetanilides have been extensively tested for genotoxicity in vitro and in vivo, and these studies indicate, on the basis of a weight-of-evidence approach, that these compounds are not genotoxic (Ashby *et al.*, 1996; Heydens *et al.*, 1999, 2001). Yet these compounds have been shown to induce tumors at various sites in rats. Tumors in mice (lung adenomas), found with alachlor and acetochlor, were considered not to be treatment-related (Ashby *et al.*, 1996; Heydens *et al.*, 1999). In rats, nasal epithelial (olfactory) tumors and thyroid follicular tumors were observed in carcinogenic-

ity studies with alachlor, acetochlor, and butachlor, while glandular stomach tumors were found with alachlor and butachlor. These findings led to the classification of alachlor, acetochlor, and butachlor as probable human carcinogens (Group B2). The discovery of alachlor in well water led to cancellation of its registration in some countries, and to its restriction in others. A series of mechanistic studies in the past decade has provided evidence that tumors observed in rats may be species-specific, show a threshold, and are not due to genotoxic mechanisms, and hence may not be relevant to humans (Ashby *et al.*, 1996; Heydens *et al.*, 1999, 2001). Alachlor and other chloroacetanilides are extensively metabolized in rats; more than 30 metabolites have been identified in this species, whereas in primates alachlor is metabolized to a limited number of glutathione and glucuronide metabolites. Furthermore, in rats, biliary excretion and enterohepatic recirculation of metabolites is observed, whereas in primates excretion is primarily via the kidneys. Thus, in rats, alachlor and butachlor are initially metabolized in the liver via the cytochrome P450 pathway and by glutathione conjugation, and the metabolites undergo enterohepatic circulation and further metabolism in liver and nasal tissue, to form the putative carcinogenic metabolite diethyl quinoneimine (DEIQ) (Feng *et al.*, 1990). In the case of acetochlor, the carcinogenic metabolite is EMIQ, an acetochlor quinoneimine compound analogous to DEIQ. Quinoneimines are electrophilic, deplete glutathione and exert cellular toxicity, which is followed by regenerative cell proliferation. Whole-body autoradiography studies have shown that alachlor-derived radioactivity specifically localizes in the nasal mucosa of rats, but not mice or monkeys. Furthermore, the ability of rat nasal tissue to form DEIQ is much higher than human nasal tissue (Wilson *et al.*, 1995). With regard to stomach and thyroid tumors, it is suggested that these result from tissue-specific toxicity, leading to compensatory cell proliferation in the fundic mucosa, and to alterations of thyroid stimulating hormone homeostasis. Both are believed to be threshold-sensitive phenomena. Epidemiological investigations in workers involved in the manufacturing of alachlor have not demonstrated any evidence of increased mortality or cancer incidence (Leet *et al.*, 1996).

Triazines

The family of triazine herbicides comprises several compounds (atrazine, simazine, propazine; Fig. 22-21), that are extensively used for the preemergent control of broad-leaved weeds (Stevens *et al.*, 2001). Triazines have low acute oral and dermal toxicity, and chronic toxicity studies indicate primarily decreased body weight gain. In dogs, cardiotoxicity is seen with atrazine, and was used to derive the NOEL for this compound (0.5 mg/kg/d) (Gammon *et al.*, 2005). There is no evidence that triazines are teratogenic, nor developmental or reproductive toxicants. Evidence from in vitro and in vivo studies indicate that atrazine is not genotoxic (Brusick, 1994), although a more recent study has suggested a possible clastogenic effect (Taets *et al.*, 1998). Oncogenicity studies found that triazines cause an increased incidence of mammary carcinomas in female Sprague–Dawley rats (Stevens *et al.*, 2001; Gammon *et al.*, 2005). Such tumors were not observed in male Sprague–Dawley rats, or in Fischer 344 rats or CD-1 mice of either sex (IARC, 1999; Stevens *et al.*, 2001). It is believed that such mammary tumors arise from an endocrine effect that might be expected to show a threshold. In contrast to most rodent species, female Sprague–Dawley rats have a high degree of spontaneous mammary tumors, due to their reproductive aging; they display prolonged or persistent estrus associated with high estrogen levels (Eldridge *et al.*, 1996). This is supported by the

Figure 22-21.   **Structures of triazine herbicides.**

Figure 22-22.   **Structures of the phosphomethyl amino acids glyphosate and glufosinate. Note that though having a P=O moiety like organophosphates, these compounds are not acetylcholinesterase inhibitors.**

et al., 2003). Both atrazine and simazine are classified as Group 3 carcinogens (not classifiable as to its carcinogenicity to humans) by IARC.

Though exposure to atrazine through residues in food commodities is very low, contamination of ground water and drinking water is common (Villanueva *et al.*, 2005). Several European countries have banned the use of atrazine in recent years, mainly because it was often detected at levels exceeding the 0.1 mg/L standard for drinking water. Recent publications have reported a possible feminization of frogs, measured in laboratory and field studies, by atrazine levels around 0.1 mg/L (Hayes *et al.*, 2002). However, other investigators failed to reproduce these findings (Carr *et al.*, 2003). The USEPA has concluded that the conflicting results do not allow any firm conclusion in this regard, and that further studies are needed (USEPA, 2003). Nevertheless, the known hormonal effects of triazines call for careful evaluation of endocrine disrupting effects of these herbicides.

Phosphonomethyl Amino Acids

The two compounds of this class are glyphosate (N-phosphonomethyl glycine) and glufosinate (N-phosphonomethyl homoalanine). Both are broad-spectrum nonselective systemic herbicides used for postemergent control of annual and perennial plants, and are marketed primarily as the isopropylamine salt (glyphosate) or ammonium salt (glufosinate). Though both compounds contain a P=O moiety (Fig. 22-22), they are not organophosphates, but rather organophosphonates, and do not inhibit AChE (Farmer, 2001).

Glyphosate   Glyphosate exerts its herbicidal action by inhibiting the enzyme 5-enolpyruvylshikimate-3-phosphate synthase, responsible for the synthesis of an intermediate in the biosynthesis of various amino acids. Although important in plant growth, this metabolic pathway is not present in mammals. The toxicity profile of technical grade glyphosate is unremarkable (Williams *et al.*, 2000; Farmer, 2001). Oral and dermal LD_{50} are >5000 mg/kg, and chronic toxicity studies show only nonspecific effects, such as failure to gain weight. It has no teratogenic, developmental or reproductive effects. Genotoxicity and carcinogenicity studies in animals were negative; on the basis of all available evidence glyphosate has been classified as a Group E compound (evidence of noncarcinogenicity in humans) by the USEPA (Farmer, 2001).

finding that ovariectomy eliminates mammary tumors in Sprague–Dawley rats that arise both spontaneously and as a result of atrazine administration (Stevens *et al.*, 1999). The possible mechanisms for the effect of atrazine involve an action on pituitary luteinizing hormone, regulated by hypothalamic gonadothropin-releasing hormone, in turn controlled by hypothalamic norepinephrine (Cooper *et al.*, 2000). Some regulatory agencies have thus concluded that mammary tumors in female Sprague–Dawley rats are formed via a secondary, hormone-mediated mechanism, of little or no toxicological relevance to humans. Epidemiological studies of triazine herbicides and cancer have provided inconclusive results (Sathiakumar and Delzell, 1997). More recent studies have suggested an increased risk of prostate cancer associated with triazine herbicides (Mills and Yang, 2003), but this has not been substantiated by others (Alavanja

Glyphosate is one of the most widely used herbicides in the United States and worldwide (Table 22-4), and the development of transgenic crops that can tolerate glyphosate treatment have expanded its utilization. Given its widespread use, including the home and garden market, accidental or intentional exposure to glyphosate is inevitable. For example, in the period 2001–2003, there were over 13,000 reports to the American Association of Poisons Control Centers' Toxic Exposure Surveillance System relating to glyphosate exposure (Bradberry *et al.*, 2004b). There was a major adverse outcome in 18 patients, and five died. Several other cases of glyphosate ingestions have been published, with a 10–15% mortality rate (Sawada *et al.*, 1988; Talbot *et al.*, 1991; Lee *et al.*, 2000; Stella and Ryan, 2004; Bradberry *et al.*, 2004b). Given the low acute toxicity of glyphosate itself, the attention has been focused on its formulation, which contains surfactants to aid its penetration. The most widely used glyphosate product is Roundup® which is formulated as a concentrate containing water, 41% glyphosate (as isopropylamine salt) and 15% polyoxyethyleneamine (POEA). Animal studies suggest that the acute toxicity of this glyphosate formulation is due to the surfactant POEA, which has an oral LD in rat of 1200 mg/kg (Bradberry *et al.*, 2004b). Mild intoxication results mainly in transient gastrointestinal symptoms, while moderate or severe poisoning presents with gastrointestinal bleeding, hypotension, pulmonary dysfunction and renal damage (Talbot *et al.*, 1991).

Glufosinate Glufosinate is a nonselective contact herbicide that acts by irreversibly inhibiting glutamine synthetase (Ebert *et al.*, 1990). Plants die as a consequence of the increased levels of ammonia. Mammals have other metabolizing systems that can cope with the effects on glutamine synthetase activity to a certain limit. In brain, however, inhibition of >10% of this enzyme activity is considered an adverse effect (EFSA, 2005). Glufosinate has relatively low acute toxicity, and chronic toxicity studies provided a NOAEL of 4.5 mg/kg/d, based on decreased glutamine synthetase activity. There is no evidence of genotoxicity or carcinogenicity, or direct effects on reproductive performance and fertility. Developmental toxic effects were found in rabbits (premature deliveries, abortions, dead fetuses). The most commonly used form of glufosinate is as ammonium salt, which is formulated with an anionic surfactant. Several cases of acute human poisoning from glufosinate ammonium-containing products have been reported, particularly in Japan, due to suicidal intent or accidental misuse. Symptoms include gastrointestinal effects, impaired respiration, neurological disturbance, and cardiovascular effects (Koyama *et al.*, 1994; Watanabe and Sano, 1998; Ujvary, 2001). Though glufosinate does not inhibit cholinesterase, a reduction of red blood cell and plasma cholinesterase was found in poisoned patients. As is the case for glyphosate, a role for the surfactant in the acute toxicity has been proposed, particularly with regard to the cardiovascular effects (Ujvary, 2001).

FUNGICIDES

Fungal diseases are virtually impossible to control without chemical application. Fungicidal chemicals are derived from a variety of structures, from simple inorganic compounds, such as copper sulfate, to complex organic compounds. The majority of fungicides are surface or plant protectants, and are applied prior to potential infection by fungal spores, either to plants or to postharvest crops. Other fungicides can be used therapeutically, to cure plants when

an infestation has already begun. Still others are used as systemic fungicides, that are absorbed and distributed throughout the plant.

With few exceptions, fungicides have low acute toxicity in mammals. However, several produce positive results in genotoxicity tests and some have carcinogenic potentials. The effects are often associated with the mechanisms by which these compounds act on their targets, the fungi. A 1987 evaluation by the National Research Council concluded that fungicides, though accounting for only 7% of all pesticide sales, and less than 10% of all pounds of pesticides applied, accounted for about 60% of estimated dietary oncogenic risk (NRC, 1987). Some fungicides have been associated with severe epidemics of poisoning, and have thus been banned. Methylmercury was associated with poisoning in Iraq, when treated grains were consumed (Bakir *et al.*, 1973). Hexachlorobenzene (HCB), used in the 1940–1950s to treat seed grains, was associated with an epidemic of poisoning in Turkey from 1955 to 1959 (Cam and Nigogosyan, 1963). HCB has a high cumulative toxicity and caused a syndrome called black sore, characterized by blistering and epidermolysis of the skin, pigmentation and scarring. HCB also causes porphyria as well as hepatomegaly and immunosuppression (Ecobichon, 2001a). The main classes of fungicides currently in use are discussed below; additional discussions of fungicide use and toxicity can be found in Hayes (1982) and in Edwards *et al.* (1991).

Captan and Folpet

Captan and folpet are broad-spectrum protectant fungicides; together with captafol, which was taken off the market in 1988, they are called chloroalkylthio fungicides, due to the presence of side chains containing chlorine, carbon, and sulfur (Fig. 22-23). Captan was first registered in the United States in 1949, and folpet followed a few years later. As for most fungicides, captan and folpet have low acute oral and dermal toxicity ($LD_{50} = \sim 5$g/kg). They are potent eye irritants, but only mild skin irritants. Dermal absorption is low. Both are extensively and rapidly metabolized in mammals, through hydrolysis and thiol interactions, with thiophosgene being a common metabolite (Gordon, 2001). Captan and folpet, as well as thiophosgene, are mutagenic in in vitro tests; however, in vivo mutagenicity tests are mostly negative, possibly because of the rapid degradation of these compounds. Both fungicides induce the development of duodenal tumors in mice, and on this basis, they are classified by the USEPA as probable human carcinogens. The mode of action for these tumors is thought to be dependent on irritation and cell loss in the intestinal villi, followed by a compensatory increase in proliferation in the crypt compartment (Gordon, 2001). Captan and folpet share a common mechanism of toxicity with regard to the development of duodenal tumors in mice, as well as other toxicity end points, and are considered for cumulative risk assessment under the FQPA (Bernard and Gordon, 2000). Tumors observed in rats (renal adenomas and uterine sarcomas) are suggested not to be treatment-related (Gordon, 2001), but are considered in the carcinogenicity classification of these fungicides. Because of their structural similarity to the potent teratogen thalidomide (Fig. 22-23), chloroalkylthio fungicides have been extensively tested in reproductive/developmental studies in multiple species, but no evidence of teratogenicity has been found (McLaughlin *et al.*, 1969).

Dithiocarbamates

Dithiocarbamates are a group of fungicides that have been widely used since the 1940s to control about 400 fungal pathogens in a

variety of crops. The nomenclature of many of these compounds arises from the metal cations with which they are associated; thus, there are for example Maneb (Mn), Ziram and Zineb (Zn), and Mancozeb (Mn and Zn) (Fig. 22-24). Thiram is an example of dithiocarbamate without a metal moiety (Fig. 22-24). The dithiocarbamates have low acute toxicity by the oral, dermal, and respiratory route (Hurt *et al.*, 2001). However, chronic exposure is associated with adverse effects that may be due to the dithiocarbamate acid or the metal moiety. These compounds are metabolized to a common metabolite, ethylenethiourea (ETU), which is responsible for the effects of dithiocarbamates on the thyroid. ETU produced thyroid tumors in rats and mice, that result from the inhibition of the synthesis of the thyroid hormones thyroxine (T4) and triiodothyronine (T3). This leads to elevated serum levels of thyroid stimulating hormone (TSH), via feedback stimulation of the hypothalamus and the pituitary, and subsequent hypertrophy and hyperplasia of thyroid follicular cells, that progresses to adenomas and carcinomas (Chhabra *et al.*, 1992). Similarly, dithiocarbamates alter thyroid hormone levels, and cause thyroid hypertrophy. The hormonal mechanism of thyroid tumors would imply a threshold model for hazard assessment. ETU also causes liver tumors in mice, by yet unknown mechanisms, although levels of ETU resulting from fungicide metabolism at maximum tolerated doses are believed to be insufficient to produce hepatic tumors (Hurt *et al.*, 2001). Neither dithiocarbamates nor ETU are genotoxic in in vitro and in vivo tests.

Developmental toxicity and teratogenicity is observed with dithiocarbamates and ETU at maternally toxic doses. These effects are ascribed to an effect of ETU on the thyroid. A key concern with chemicals affecting thyroid functions, is their potential developmental neurotoxicity, given the essential role of thyroid hormones in brain development (Chan and Kilby, 2000), and this deserves further investigation. There is also some evidence that dithiocarbamates may cause neurotoxicity by mechanisms not involving ETU.
High doses of several of these compounds cause hind limb paralysis, which is possibly related to the release of the carbon disulfide moiety (Johnson *et al.*, 1998). Chronic exposure to Maneb has been associated with parkinsonism, which is likely ascribed to exposure to the manganese moiety, rather than the dithiocarbamate (Ferraz *et al.*, 1988; Meco *et al.*, 1994). Maneb has also been shown to produce nigrostriatal degeneration when given in combination with paraquat (Thiruchelvam *et al.*, 2000), and to potentiate the neurotoxicity of MPTP (McGrew *et al.*, 2000). It has been shown that Maneb affects dopaminergic neurons by inhibiting mitochondrial functions (Zhang *et al.*, 2003).

The structure of dithiocarbamate fungicides resembles that of disulfiram, a compound used therapeutically to produce intolerance to alcohol, by virtue of its ability to inhibit aldehyde dehydrogenase. Interactions of dithiocarbamates with alcohol, leading to elevation in acetaldehyde levels, have been reported (Edwards *et al.*, 1991).

Chlorothalonil

Chlorothalonil (Bravo®) is a halogenated benzonitrile fungicide (Fig. 22-25), widely used to treat vegetable, ornamental, and orchard diseases (Table 22-4). Whereas oral and dermal toxicities are low ($LD_{50}s$ = 5–10 g/kg), it is highly toxic by the intraperitoneal and inhalation routes. It also causes severe irreversible eye lesions in the rabbit, because of its irritant properties. Dermal absorption is low, but following oral administration, chlorothalonil is rapidly
Figure 22-25. Structures of the fungicides choroathalonil and benomyl.

absorbed and metabolized through glutathione conjugation. Chlorathalonil is not mutagenic in in vitro and in vivo tests (Parsons, 2001). Tumors in the forestomach and the kidney have been found in chronic toxicity studies in both rats and mice, but not in dogs. Tumors are believed to be due to regenerative hyperplasia, and it is assumed that a threshold can be established for carcinogenicity (Parsons, 2001). Chlorothalonil is not a reproductive or developmental toxicant. Known adverse effects in humans are limited to its irritant effects on the eye and the skin.

Benzimidazoles

Benomyl is the main representative of this class of fungicides (Fig. 22-25). It inhibits fungal growth by binding to tubulin, and this mechanism also accounts for its toxic effects in mammals. Acute toxicity is low, whereas chronic studies have found effects in the liver, testes, bone marrow and gastrointestinal tract (Mull and Hershberger, 2001). Because of its ability to disrupt microtubule assembly during cell division, Benonyl causes chromosomal aberrations (aneuploidy) both in vitro and in vivo, but does not interact directly with DNA. Liver tumors have been observed in chronic oncogenicity studies in mice. The action on dividing cells has also raised concern for Benomyl's potential teratogenicity and developmental toxicity. Teratogenic effects were observed following administration of high doses of Benomyl and Carbendazim (a metabolite of Benomyl, which is commercialized as a fungicide but not in the United States) to rats (Mull and Hershberger, 2001). However, such effects were not seen in feeding studies in rats or rabbits. Anecdotal evidence suggests that maternal exposure to Benomyl may result in anophthalmia in humans, but epidemiological studies did not demonstrate any convincing association (Spagnolo *et al.*, 1994).

Inorganic and Organometal Fungicides

Several inorganic and organic metal compounds are, or have been, used as fungicides (Clarkson, 2001). The fungicidal activity of

soluble copper salts was discovered as early as 1807, and by 1890 copper sulfate found extensive use, particularly in the formulation known as Bordeaux mixture (copper sulfate and calcium hydroxide). Copper sulfate has overall low toxicity and remains one of the most widely used fungicides (Table 22-4). Among organotin compounds, triphenyltin acetate is used as a fungicide, while tributyltin is utilized as an antifouling agent. Triphenyltin has moderate to high acute toxicity, but may cause reproductive toxicity and endocrine disruption (Golub and Doherty, 2004). Organic mercury compounds, such as methylmercury, were used extensively as fungicides in the past for the prevention of seed-borne diseases in grains and cereals. Given their high toxicity, particularly neurotoxicity, and large episodes of human poisoning (Bakir *et al.*, 1973), their use has since been banned. A discussion of organometal compounds is found in Chap. 23.

RODENTICIDES

Rats and mice can cause health and economic damages to humans. Rodents are vectors for several human diseases, including plague, endemic rickettsiosis, spirochetosis, and several others; they can occasionally bite people; they can consume large quantities of postharvest stored foods, and can contaminate foodstuff with urine, feces, and hair, that may cause diseases. Hence, there is a need to control rodent population. Limiting their access to feed and harborage, and trapping, are two approaches; however, rodenticides still play and will likely continue to play an important role in rodent control. To be effective, yet safe, rodenticides must satisfy several criteria: (1) the poison must be very effective in the target species once incorporated into bait in small quantity; (2) baits containing the poison must not excite bait shyness, so that the animal will continue to eat it; (3) the manner of death must be such that survivors do not become suspicious of its cause; and (4) it should be species-specific, with considerable lower toxicity to other animals (Murphy, 1986; Ecobichon, 2001a).

The compounds used as rodenticides comprise a diverse range of chemical structures having a variety of mechanisms of action. The ultimate goal is to obtain the highest species selectivity; in some cases (e.g., norbormide) advantage has been taken of the physiology and biochemistry unique to rodents. With other rodenticides, the sites of action are common to most mammals, but advantage is taken of the habits of the pest animal and/or the usage, thereby minimizing toxicity for nontarget species. Because rodenticides are used in baits which are often placed in inaccessible places, widespread exposures or contaminations are unlikely. However, toxicologic problems can arise from acute accidental ingestions or from suicidal/homicidal attempts. In particular, poison centers receive thousands of calls every year related to accidental ingestions of rodenticide baits by children, most of which are resolved without serious consequences.

Fluoroacetic Acid and Its Derivatives

Sodium fluoroacetate (Compound 1080) and fluoroacetamide are the main representatives of this class of rodenticides. They are white in color and odorless, and due to their high mammalian toxicity, their use is restricted to trained personnel. Both compounds have indeed high acute toxicity (oral LD_{50}s in the rat = 2 and 13 mg/kg, respectively). The main targets of toxicity are the central nervous system and the heart. Fluoroacetate is incorporated into fluoracetyl-coenzyme A, which condenses with oxolacetate to form fluorocitrate, which inhibits mitochondrial aconitase. This results in

inhibition of the Krebs cycle, leading to lowered energy production, reduced oxygen consumption, and reduced cellular concentration of ATP. Blockage of energy metabolism is believed to account for most signs of toxicity, though some may be due to accumulation of citrate, which is a potent chelator of calcium ions (Pelfrene, 2001). Since 1946, when sodium fluoroacetate was introduced in the United States, several cases of human poisoning have been reported. Initial gastrointestinal symptoms are followed by severe cardiovascular effects (ventricular tachycardia, fibrillation, hypotension), as well as CNS effects (agitation, convulsions, coma). The estimated lethal dose in humans ranges from 2–10 mg/kg. There is no specific antidote for sodium fluoroacetate. Monacetin (60% glycerol monoacetate) has proved beneficial in the treatment of poisoned primates. Use of procainamide (for cardiac arrhythmia) and barbiturates (to control seizures) are also indicated. Use of Compound 1080 in the United States is severely restricted primarily because of toxicity to nontarget animals, such as dogs.

Thioureas

The discovery of α-naphtyl thiourea (ANTU) occurred fortuitously in the mid-1940s in the Psychobiological Laboratory of Curt Richter in Baltimore. While studying thioureas, favored by geneticists for taste tests, because they are so bitter to some people and tasteless to others, he discovered that ANTU was lethal yet tasteless to rodents, while being of low toxicity to humans (Keiner, 2005). A wide range of acute oral LD_{50} values has been reported for different species, the rat being the most sensitive at 6 mg/kg, and the monkey the least susceptible at 4 g/kg. The main target of toxicity is the lung, where ANTU causes marked edema of the subepithelial spaces of the alveolar walls. ANTU is believed to be biotransformed to a reactive intermediate which binds to lung macromolecules; however, the exact mechanism of its toxicity is unknown. Young rats are resistant to the chemical, whereas older rats become tolerant to it; both situations have been ascribed to developmentally low, or to ANTU-induced inhibition of, microsomal enzymes involved in its bioactivation (Boyd and Neal, 1976). There are no reports of human poisonings with ANTU. However, several cases involving a combination of chloralose and ANTU were reported in France; symptoms included motor agitation and coma, both characteristic of chloralose poisonings, and pulmonary effects, due to ANTU, but all patients recovered (Pelfrene, 2001). Suggestions that the presence of an impurity in ANTU, β-naphthylamine, may increase risk of bladder cancer, remain unsubstantiated (Case, 1966; Pelfrene, 2001).

Anticoagulants

Following the report of an hemorrhagic disorder in cattle that resulted from the ingestion of spoiled sweet clover silage, the hemorrhagic agent was identified in 1939 as bishydroxycoumarin (dicoumarol). In 1948, a more potent synthetic congener was introduced as an extremely effective rodenticide; the compound was named warfarin, as an acronym derived from the name of the patent holder, Wisconsin Alumni Research Foundation (Majerus and Tollefsen, 2006). In addition to their use as rodenticides, coumarin derivatives, including warfarin itself, are used as anticoagulant drugs and have become a mainstay for prevention of thromboembolic disease (Majerus and Tollefsen, 2006). Coumarins antagonizes the action of vitamin K in the synthesis of clotting factors (factors II, VII, IX, and X). Their specific mechanism involves inhibition of the enzyme vitamin K epoxide reductase, which

regenerates reduced vitamin K necessary for sustained carboxylation and synthesis of relevant clotting factors (Fig. 22-26). The acute oral toxicity of warfarin in rats is approx. 50–100 mg/kg, whereas the 90-day dose LD_{50} has been reported as 0.077 mg/kg, indicating that multiple doses are required before toxicity develops.

Human poisonings by these rodenticides are rare because they are dispersed in grain-based baits. However, there is a significant number of suicide or homicide attempts or of accidental consumption of warfarin. One often reported case involved a Korean family that consumed a diet of corn containing warfarin over a two-week period. Symptoms (massive bruises, hematomata, gum and nasal hemorrhage) appeared about 10 days after the beginning of the warfarin consumption. Consumption of warfarin in this episode was estimated to be in the order of 1–2 mg/kg/d (Lange and Terveer, 1954). Monitoring of anticoagulant therapy is done by measuring prothrombin time (PT) in comparison to normal pooled plasma. Values of INR (International Normatized Ratio) are then derived, with a target value of 2–3. In case of poisoning, PT is significantly longer, and leads to severe internal bleeding. When INR is above 5, vitamin K can be given as an antidote.

The appearance of rats resistant to warfarin and to other early anticoagulant rodenticides, led to the development of "second generation" anticoagulants. Some are coumarins, such as the "superwarfarins" brodifacoum or difenacoum, whereas others are indan-1,3 -dione derivatives (diphacinone, chlorophacinone). These compounds essentially act like warfarin, but have prolonged half-lives (e.g., brodifacoum 156 hours vs. warfarin 37 hours), and cause very long-lasting inhibition of coagulation. Some are extremely toxic to most mammalian species; for example the oral LD_{50} of brodifacoum is about 0.3 mg/kg in rat, rabbit, and dog (Pelfrene, 2001).

Other Compounds

Norbormide   This compound shows a remarkable selectivity in both toxicity and pharmacological effects. Oral LD_{50} in rat is about 5–10 mg/kg, whereas in dog and monkey 1000 mg/kg produces no effect. Such species difference in toxicity seems to be accounted for by differences in response of the peripheral blood vessels to norbormide-induced vasoconstriction. The exact mechanisms of this effect are not known.

Zinc Phosphide   The toxicity of this chemical can be accounted for by the phosphine gas (PH_3) formed on ingestion following a hydrolytic reaction with water in the stomach. Phosphine causes widespread cellular toxicity with necrosis of the gastrointestinal tract and injury to liver and kidney. Cases of human poisoning have been reported (Ecobichon, 2001a). Additional inorganic compounds that have been used as rodenticides include aluminum phosphide, thallium sulfate, and arsenic salts. Thallium sulfate has the unusual feature of causing extensive alopecia (hair loss); because of its high acute toxicity in nontarget species, it was banned in the United States in 1972 (Clarkson, 2001).

Other   Some rodenticides used in the past that have become obsolete include strychnine, an extremely poisonous alkaloid derived from the seeds of *Strychnos nux-vomica,* which is a potent convulsant; red squill (sea onion) and its bioactive principle, scilliroside, which affect the cardiovascular and central nervous systems and cause emesis; the inability of rodents to vomit explains the rather selective action in these species; and pyriminyl, a substituted urea
Figure 22-26. Site of action of the anticoagulant rodenticide warfarin.

Reduced vitamin K (hydroquinone) serves as cofactor for the conversion of glutamic acid to γ-carboxyglutamic acid in the peptide chains of coagulation factors II, VII, IX, and X. During this reaction, vitamin K is oxidized to an epoxide that is then reduced to quinone and hydroquinone by vitamin K reductase, which is inhibited by warfarin.

introduced in 1975 but withdrawn in the United States a few years later. This compound targets complex I in the mitochondria, and there are many reports of human poisoning in the short period of its use (Pelfrene, 2001). As many other ureas, it has diabetogenic properties.

FUMIGANTS

A large number of compounds are used for soil fumigation or for fumigating postharvest commodities. They are active toward insects, mites, nematodes, weed seeds, fungi or rodents, and have in common the property of being in the gaseous form at the time they exert their pesticidal action. They can be liquids that readily vaporize (e.g., ethylene dibromide), solids that can release a toxic gas on reaction with water (e.g., phosphine released by aluminum phosphide), or gases (e.g., methyl bromide). For soil fumigation, the compound is injected directly into the soil, which is then covered with plastic sheeting, which is sealed. By eliminating unwanted pests, this treatment enhances the quality of the crops and increases yield. Fumigation of postharvest commodities, such as wheat, cereals, and fruits to eradicate pest infestations, typically occurs where the commodities are stored (e.g., warehouses, grain elevators, ship holds). Compounds used as fumigants are usually nonselective, highly reactive, and cytotoxic. They provide a potential hazard from the standpoint of inhalation exposure, and to a minor degree for dermal exposure or ingestion, in case of solids or liquids. Several fumigants used in the past are no longer marketed

because of toxicological concerns. These include, for example, carbon disulfide, which is neurotoxic; carbon tetrachloride, a potent hepatotoxicant; 1,2-dibromo-3-chloropropane, a male reproductive toxicant; and ethylene dibromide, a carcinogen. Their toxicity is discussed in other sections of the book. Some of the most commonly used fumigants are discussed below.

Methyl Bromide

Methyl bromide is a broad-spectrum pesticide, used for soil fumigation, commodity treatment, and structural fumigation. It has been used as a fumigant for over 50 years, and its use is strictly controlled and restricted to certified applicators. Since the mid-1990s, use of methyl bromide has substantially decreased, because of environmental and toxicological concerns (Ruzo, 2006). Methyl bromide is thought to contribute to ozone depletion in the stratosphere. In 1987, with the signing of the Montreal Protocol on Substances that Deplete the Ozone Layer, the international community initiated a series of steps to reduce emissions of ozone-depleting products, including methyl bromide. Concerns on certain toxicological aspects of methyl bromide, have also contributed to its decreasing use, and to the search of viable alternatives (Ruzo, 2006; Schneider *et al.*, 2003). Yet, while several countries are substantially curtailing the use of methyl bromide, this compound still remains one of the most extensively used pesticides in the United States (Table 22-4; Ruzo, 2006), likely for convenience and economic reasons (Norman, 2005; McCook, 2006).

The acute toxicity of methyl bromide relates to both its concentration and the duration of exposure. For example, LC_{50} values in rats were 2833 ppm for a 30 minute exposure, and 302 ppm for an 8 hour exposure (Piccirillo, 2001). Between 1953 and 1981, 301 cases of systemic poisoning and 60 fatalities resulted from use of methyl bromide as a fumigant (Alexeef and Kilgore, 1983). Additional cases of human intoxication have since been reported (Herzstein and Cullen, 1990). Acute exposure results in respiratory, gastrointestinal and neurologic symptoms; the latter include lethargy, headache, seizures, paresthesias, peripheral neuropathy, and ataxia, and are considered to be more relevant than other toxic effects for human risk assessment (Alexeef and Kilgore, 1983; Lifshitz and Gavrilov, 2000; Piccirillo, 2001). Acute and chronic neurotoxicity studies in rats have demonstrated behavioral effects and morphological lesions, which were concentration- and time-dependent (Piccirillo, 2001). Long-lasting behavioral and neuropsychiatric effects are also seen in humans (De Haro *et al.*, 1997; Lifshitz and Gavrilov, 2000). The mechanism(s) underlying methyl bromide neurotoxicity are not known. Depletion of GSH in brain areas was observed following exposure of rats to methyl bromide (140 ppm for 6 h/d, for 5 days) (Davenport *et al.*, 1992). This may be due to conjugation of methyl bromide with GSH. The role of GSH and the possible ensuing increase in oxidative stress in methyl bromide neurotoxicity remains, however, uncertain. In various subchronic toxicity studies, the NOEL for neurotoxicity ranges between 18 and 200 ppm (Piccirillo, 2001).

Methyl bromide is positive in several genotoxicity tests in vitro and in vivo. Carcinogenicity studies produced carcinomas in the forestomach of rats following oral ingestion, and increased incidence of adenomas of the pituitary gland in male rats in an inhalation study. Other studies in rats and mice, however, provided no evidence of carcinogenicity. Methyl bromide is classified by IARC in Group 3 (not classifiable as to its carcinogenicity to humans), given the limited evidence in animals and the inadequate evidence in humans. As methyl bromide is an odorless and colorless gas, another fumigant, chloropicrin, which has a pungent odor and causes irritation of the eyes, is often used in conjunction with methyl bromide and other fumigant mixtures, to warn against potentially harmful exposures.

1,3–Dichloropropene

1,3–Dichloropropene, first introduced over fifty years ago, is a soil fumigant, extensively utilized (see Table 22-4) for its ability to control soil nematodes. It has a moderate to high acute toxicity in animals (oral LD_{50} in rats: 130–713 mg/kg; dermal LD_{50}: >1200 mg/kg; inhalation LD_{50}: ~ 1000 ppm). Human fatalities following oral exposure have been reported (Hernandez *et al.*, 1994). 1,3–Dichloropropene is an irritant, and can cause redness and necrosis of the skin. It is extensively metabolized, with the mercapturic acid conjugate being the major urinary metabolite. Data on genotoxicity are contradictory, and carcinogenicity studies in rodents have found an increase in benign liver tumors in rats but not in mice, after oral administration (Stebbins *et al.*, 2000), and of benign lung adenomas in mice following inhalation exposure (Lomax *et al.*, 1989). The toxicology of 1,3 - dichloropropene has been recently reviewed (Stott *et al.*, 2001).

Metam Sodium

Metam sodium ($C_2H_4NNaS_2$) is a widely used soil fumigant (Table 22-4), whose toxic action toward soil nematodes, fungi, and weed seeds is due to its hydrolysis product, methyl isothiocyanate (MITC). In mammals, metam sodium is metabolized in vivo to carbon disulfide and MITC (Pruett *et al.*, 2001). In humans, metam sodium can act as a contact sensitizer, inducing allergic dermatitis, possibly due to MITC. Immunotoxicity is observed in rodents. In 1991, because of the derailment of a train car, approximately 19,000 gallons of metam sodium was spilled into the Sacramento River in California, causing a large kill of aquatic organisms. Symptoms reported by exposed individuals included headache, eye irritation, nausea, shortness of breath and dermatitis (Pruett *et al.*, 2001). Metam sodium is increasingly being used as an alternative to methyl bromide (Ruzo, 2006).

Sulfur

Elemental sulfur is considered the oldest of all pesticides, and its pesticidal properties were known to the ancient Greeks as early as 1000 B.C. (Tweedy, 1981). It is very effective as a fumigant for the control of many plant diseases, particularly fungal diseases, and still represents the most heavily used crop protection chemical in the United States (Table 22-4). Sulfur finds its major uses in grapes and tomatoes, and can be used in organic farming (Gammon *et al.*, 2001). Though it is generally considered an environmentally and toxicologically safe compound, elemental sulfur used as a fungicide can make the soil too acidic for the continuous optimal growth of a particular crop (Gammon *et al.*, 2001). The primary health effect in humans associated with the agricultural use of elemental sulfur is dermatitis (Gammon *et al.*, 2001). In ruminants, excessive sulfur ingestion can cause cerebrocortical necrosis (polioencephalomalacia), possibly due to its conversion by microorganisms in the rumen to hydrogen sulfide (Gammon *et al.*, 2001).

TOXIC EFFECTS OF METALS

Jie Liu, Robert A. Goyer, and Michael P. Waalkes

INTRODUCTION

What is a Metal?

The definition of a metal is not inherently obvious and the differences between metallic and nonmetallic elements can be subtle (Vouk, 1986a). Metals are typically defined by physical properties of the element in the solid state, but they vary widely with the metallic element. General metal properties include high reflectivity (luster); high electrical conductivity; high thermal conductivity; and mechanical ductility and strength. A toxicologically important characteristic of metals is that they may react in biological systems by losing one or more electrons to form cations (Vouk, 1986a). In the periodic table, within a group there is often a gradual transition from nonmetallic to metallic properties going from lighter to heavier atoms (e.g., Group IVa transitions from carbon to lead). Many metals exhibit variable oxidation states. Various names are applied to subsets of metallic elements including alkali metals (e.g., lithium and sodium), the alkaline earth metals (e.g., beryllium and magnesium), the transition (or heavy) metals (e.g., cadmium and zinc), and the metalloids (e.g., arsenic and antimony), which have characteristics between metal and nonmetals.

In the periodic table, over 75% of the elements are regarded as metals and eight are considered metalloids. This chapter discusses metals that have been reported to produce significant toxicity in humans. This discussion will include major toxic metals (e.g., lead, cadmium), essential metals (e.g., zinc, copper), medicinal metals (e.g., platinum, bismuth), and minor toxic metals including metals in emerging technology (e.g., indium, uranium). *Metal Toxicology* will also discuss toxic metalloids (e.g., arsenic, antimony) and certain nonmetallic elemental toxicants (e.g., selenium, fluoride). An overview of *Metal Toxicology* is shown in Fig. 23-1.

Metals as Toxicants

The use of metals has been critical to the progress and success of human civilization. It would be difficult to image an advanced society without extensive utilization of metallic compounds. Metals are unique among pollutant toxicants in that they are all naturally occurring and, in many cases, are ubiquitous within the human environment. Thus, regardless of how safely metals are used in industrial processes or consumer products, some level of human exposure is inevitable. In addition, all life has evolved in the presence of metals and organisms have been forced to deal with these potentially toxic, yet omnipresent, elements. In fact, many metals have become essential to various biological processes. Essentiality goes hand-in-hand with intentional accumulation and safe transport, storage, and usage mechanisms. Nonetheless, even essential metals will become toxic with increasing exposure. It is often the case that the nonessential toxicant metals mimic essential metals and thereby gain access to, and potentially disrupt, key cellular functions. This can also account for bioaccumulation of toxic metals.

Metals differ from other toxic substances because, as elements, they are neither created nor destroyed by human endeavors. What human industry has accomplished is to concentrate metals in the biosphere. The anthropogenic contribution to the levels of metals in air, water, soil, and food is well recognized (Beijer and Jernelov, 1986). Human use of metals can also alter the chemical form or speciation of an element and thereby impact toxic potential. With a few notable exceptions, most metals are only sparingly recycled once used. These factors combine to make metals very persistent in the human environment.

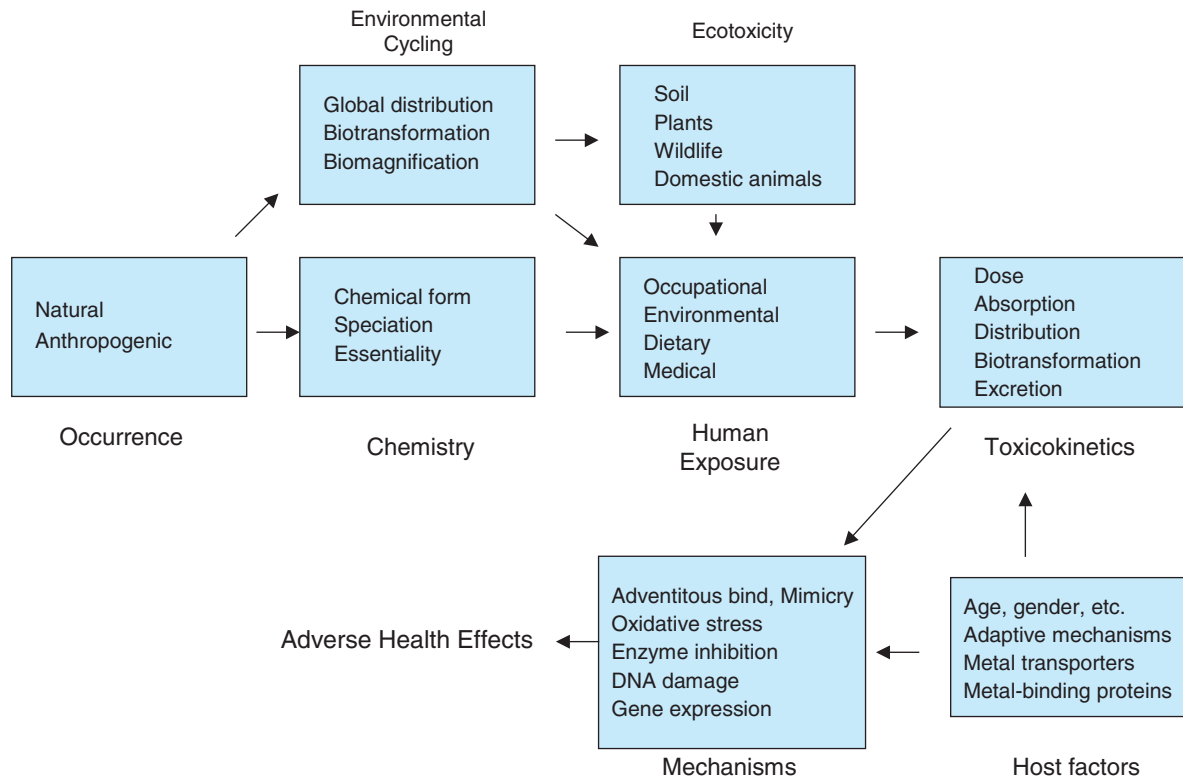
Metals are certainly one of the oldest toxicants known to humans due to their very early use. For instance, human use of lead


Figure 23-1. Overview of Metal Toxicology.

probably started prior to 2000 BC, when abundant supplies were obtained from ores as a byproduct of smelting silver. The first description of abdominal colic in a man who extracted metals is credited to Hippocrates in 370 BC. Arsenic and mercury are discussed by Theophrastus of Erebus (370–287 BC), and Pliny and Elder (AD 23–79). Arsenic was used early on for decoration in Egyptian tombs and as a "secret poison," whereas mercury assumed almost a mystical stature in early science and was a large focus of alchemy. However, most of the use of the metals has occurred since the onset of the industrial revolution. In this regard, many of the metals of toxicological concern today were only relatively recently discovered. For instance, cadmium was first recognized in the early 1800s, and it was much later before the metal was widely used. The toxicological importance of some of the rarer or lesser used metals might well increase with new applications, such as chemotherapy and microelectronics, or other emerging technologies.

Historically, metal toxicology largely concerned acute or overt, high-dose effects, such as abdominal colic from lead or the bloody diarrhea and uropenia after mercury ingestion. Because of advances in our understanding of potential toxicity of metals, and consequent improvements in industrial hygiene and stricter environmental standards, such acute high-dose effects are now uncommon. Focus has shifted to subtle, chronic, low-dose effects, in which cause-and-effect relationships may not be immediately clear. These might include a level of effect that causes a change in an important, but highly complex index of affected individual's performance, such as lower than expected IQs due to childhood lead exposure. Other important chronic toxic effects include carcinogenesis, and several metals have emerged as human carcinogens. Assigning responsibility for such toxicological effects can often be difficult, particularly when the endpoint in question lacks specificity, in that it may be a

complex disease caused by a number of different chemicals or even combinations of chemicals. In addition, humans are never exposed to only a single metal, but rather to complex mixtures. The metals as a class of toxicants clearly present many challenges in toxicological research.

The elemental nature of metals impacts their biotransformation and toxicity, as detoxification by destructive metabolism to subcomponents of lesser toxicity cannot occur with these atomic species. In essence, as elemental species metals are non-biodegradable. This indestructibility combined with bioaccumulation contributes to the high concern for metals as toxicants. Most elemental metals tend to form ionic bonds. However, biological conjugation to form organometallic compounds can occur for various metals (Dopp *et al.*, 2004), particularly with metalloids, like arsenic, that show mixed carbonaceous and metallic qualities. The redox capacity of a given metal or metallic compound should also be considered as part of its metabolism. The metabolism of metals is intricate and subtle but can directly impact toxic potential.

Movement of Metals in the Environment

Metals are redistributed naturally in the environment by both geologic and biologic cycles. Rainwater dissolves rocks and ores and transports materials, including metals, to rivers and underground water (e.g., arsenic), depositing and stripping materials from adjacent soil and eventually transporting these substances to the ocean to be precipitated as sediment or taken up into forming rainwater to be relocated elsewhere. Biological cycles moving metals include biomagnification by plants and animals resulting in incorporation into food cycles. In comparison, human activity often intentionally shortens the residence time of metals in ore deposits, and can result in

the formation of new, non-naturally occurring metallic compounds. For instance, cadmium distribution mainly comes from human activities. Human industry greatly enhances metal distribution in the global environment by discharge to soil, water, and air, as exemplified by the 200-fold increase in lead content of Greenland ice since the onset of the industrial revolution. Mercury undergoes global cycling with elevated levels being found far from points of discharge, as, for example, with mercury in the Arctic Ocean. Mercury also undergoes biomethylation and biomagnification by aquatic organisms (see Fig. 23-6).

Increased distribution of metals and metal compounds in the environment, especially through anthropogenic activities, raises increasing concern for ecotoxicological effects. Reports of metal intoxication are common in plants, aquatic organisms, invertebrates, fish, sea mammals, birds, and domestic animals. The ecotoxicity of various metals is discussed under each individual section. Mercury poisoning from consumption of fish containing high levels of methylmercury and cadmium poisoning from consumption of rice grown in soils contaminated with cadmium from industrial discharges are examples of human consequences from environmental pollution.

Not all human toxicity occurs from metals deposited in the biosphere by human activity. For example, chronic arsenic poisoning from high levels of naturally occurring inorganic arsenic in drinking water is a major health issue in many parts of the world. Endemic intoxication from excess fluoride, selenium, or thallium can all occur from natural high environmental levels.

Chemical Mechanisms of Metal Toxicology

The precise chemical basis of metal toxicology is inadequately understood but a uniform mechanism for all toxic metals is implausible because of the great variation in chemical properties and toxic endpoints. Chemically, metals in their ionic form can be very reactive and can interact with biological systems in a large variety of ways. In this regard, a cell presents numerous potential metal-binding ligands. For instance, metals like cadmium and mercury readily attach to sulfur in proteins as a preferred bio-ligand. Such adventitious binding is an important chemical mechanism by which exogenous metals exert toxic effects that can result in steric re-arrangement that impairs the function of biomolecules (Kasprzak, 2002). An example would be the inhibition of enzyme activity by metal interaction at sites other than the active center, such as the inhibition of heme synthesis enzymes by lead. The inhibition of biologically critical enzymes is an important molecular mechanism of metal toxicology.

The metals can show more specific forms of chemical attack through mimicry. In this regard the toxic metals may act as mimics of essential metals, binding to physiological sites that normally are reserved for an essential element. Owing to their rich chemistry, essential metals control, or are involved in, a variety of key metabolic and signaling functions (Kasprzak, 2002; Cousins et al., 2006). Through mimicry, the toxic metals may gain access to, and potentially disrupt a variety of important or even critical metal-mediated cellular functions. For example, mimicry for, and replacement of zinc, is a mechanism of toxicity for cadmium, copper, and nickel. Thallium mimics potassium and manganese mimics iron as a critical factor in their toxicity. Mimicry of arsenate and vanadate for phosphate allows for cellular transport of these toxic elements whereas selenate, molybdate, and chromate mimic sulfate and can compete for sulfate carriers and in chemical sulfation reactions (Bridges and Zalpus, 2005). Organometallic compounds can also act as mimics of

biological chemicals, as, for example, with methylmercury, which is transported by amino acid or organic anion transporters (Bridges and Zalpus, 2005). Indeed, molecular or ionic mimicry at the level of transport is often a key event in metal toxicity.

Another key chemical reaction in metal toxicology is metal-mediated oxidative damage. Many metals can directly act as catalytic centers for redox reactions with molecular oxygen or other endogenous oxidants, producing oxidative modification of biomolecules such as proteins or DNA. This may be a key step in the carcinogenicity of certain metals (Kasprzak, 2002). Besides oxygen-based radicals, carbon- and sulfur-based radicals may also occur. Nickel and chromium are two examples of metals that act, at least in part, by generation of reactive oxygen species or other reactive intermediates (Kasprazak, 2002). Alternatively, metals may displace redox active essential elements from their normal cellular ligands, which, in turn, may result in oxidative cellular damage. For instance, cadmium, which is not redox active, may well cause oxidative stress through the release of endogenous iron, an element with high redox activity (Valko et al., 2006).

Metals in their ionic form can be very reactive and form DNA and protein adducts in biological systems. For example, once hexavalent chromium enters the cell it is reduced by various intracellular reductants to give reactive trivalent chromium species that form DNA adducts or DNA-protein cross-links, events likely to be important in chromium genotoxicity (Zhitkovich, 2005). Metals can also induce an array of aberrant gene expression, which, in turn, produces adverse effects. For example, nickel can induce the expression of Cap43/NDRG1, under the control of the hypoxia-inducible transcription factor (HIF-1), which is thought to play a key role in nickel carcinogenesis (Costa et al., 2005). An array of aberrant hepatic gene expressions occurs in adult mice after in utero arsenic exposure, which could be an important molecular event in arsenic hepatocarcinogenesis (Liu et al., 2006).

Factors Impacting Metal Toxicity

The standard factors that impact the toxic potential of all chemicals apply to the metals as well. Exposure-related factors include dose, route of exposure, duration, and frequency of exposure. Because metals can be quite reactive, and the portal of entry is often initially the organ most affected, as with the lung after inhalation.

Host-based factors that can impact metal toxicity include age at exposure, gender, and capacity for biotransformation. For instance, it is quite clear that younger subjects are often more sensitive to metal intoxication, as, for example, with the neurotoxicity of lead in children. The major pathway of exposure to many toxic metals in children is food, and children consume more calories per pound of body weight than adults. Moreover, children have higher gastrointestinal absorption of metals, particularly lead. The rapid growth and proliferation in the perinate represent opportunities for toxic effects, including potentially carcinogenesis, of metallic agents, and several metals (e.g., arsenic, nickel, lead, and chromium) are transplacental carcinogens in rodents. Fetal-stage toxicity of metals is well documented, as with methylmercury, and many metals are teratogenic. For many inorganics there is no impediment to transplacental transport, as with lead or arsenic, and human fetal blood lead levels are similar to maternal levels. Elderly persons are also believed to be generally more susceptible to metal toxicity than younger adults. Recognition of factors that influence toxicity of a metal is important in determining risk, particularly in susceptible subpopulations.

Chemical-related factors directly impact the toxic potential of metals. This would include the precise metal compound and its valence state or speciation. For instance, methylmercury is a potent neurotoxin, whereas the inorganic mercurials primarily attack the kidney. Similarly, the oxidation state of chromium can differentiate the essential (naturally occurring trivalent chromium) from toxic species (hexavalent chromium).

Lifestyle factors such as smoking or alcohol ingestion may have direct or indirect impacts on the level of metal intoxication. For instance, cigarette smoke by itself contains many toxic metals, such as cadmium, and it is thought that smoking will double the life-time burden of cadmium in nonoccupationally exposed individuals. Other components of cigarette smoke may also influence pulmonary effects, as, for instance, with metals that are lung carcinogens. Alcohol ingestion may influence toxicity by altering diet, reducing essential mineral intake, and altering hepatic iron deposition. The composition of the diet can significantly alter gastrointestinal absorption of various dietary metals.

The essentiality of metals has direct bearing on the toxic potential of a metal. Any "free" ionic metal would be potentially toxic due to reactive potential. The need to accumulate essential metals dictates the evolution of systems for the safe transport, storage, and utilization as well as, within limits, elimination of excess. For example, metallothionein is a metal-binding protein that may function in the homeostatic control of zinc (Cousins *et al.*, 2006), and may represent a storage or transport form of this metal. Such factors imply that a threshold would exist for toxicity due to essential metal exposure. In this regard, the essential metallic elements would be expected to show a "U"-shaped dose–response curve in that, at very low exposure levels, toxic adverse effects would occur from deficiency, but at high exposure levels toxicity also occurs. The nonessential toxic metals can mimic essential elements and disrupt homeostasis, as with cadmium which will potentially displace zinc to bind to zinc-dependent transcription factors and enzymes (Waalkes, 2003).

Adaptive mechanisms can be critical to the toxic effects of metals, and organisms have a variety of ways in which they can adapt to otherwise toxic metal insults. Typically, adaptation is acquired after the first few exposures and can be long lasting or transient after exposure ceases. Adaptation can be at the level of uptake or excretion, or with some metals, through long-term storage in a toxicological inert form. For instance, it appears enhanced arsenic efflux is involved in acquired tolerance to the metalloid on the cellular level (Liu *et al.*, 2001). Conversely, intentional sequestration of toxic metals is another adaptive tactic and examples of such long-term storage include lead-inclusion bodies, which form in various organs and contain protein-immobilized lead in a distinct cellular aggresome. These bodies are thought to be protective by limiting the level of free, and therefore toxic, lead within the cell, and the inability to form such bodies clearly increases the chronic toxic effects of lead, including carcinogenesis (Waalkes *et al.*, 2004c). Similarly, cadmium exposure causes the overexpression of metallothionein which will sequester cadmium and reduce its toxicity as an adaptive mechanism (Klaassen and Liu, 1998). Metal exposure can also induce a cascade of molecular/genetic responses that may, in turn, reduce toxicity, such as with metal-induced oxidative stress responses (Valko *et al.*, 2006). It is clear that acquired metal adaptation, although allowing immediate cellular survival, may in fact be a potential contributing factor in long-term toxicity (Waalkes *et al.*, 2000). For instance, acquired self-tolerance to cadmium- or arsenic-induced apoptosis may actually contribute to eventual carcinogenesis by allowing survival of damaged cells that would otherwise have been eliminated (Hart *et al.*, 2001; Pi *et al.*, 2005).

Biomarkers of Metal Exposure

Biomarkers of exposure, toxicity, and susceptibility are important in assessing the level of concern with metal intoxication. Exposure biomarkers, such as concentrations in blood or urine, have long been used with metals. Techniques in molecular toxicology have greatly expanded the possibilities for biomarkers. Thus, in the case of chromium, DNA–protein complexes may serve as a biomarker of both exposure and carcinogenic potential. The capacity for expression of genes that potentially play protective roles against metal toxicity, as, for example, with metallothionein and heme oxygenase, show promise as markers of both effect and susceptibility. The use of such biomarkers may well allow identification of particularly sensitive subpopulations.

Estimates of the relationship of exposure level to toxic effects for a particular metal are in many ways a measure of the dose–response relationships discussed in great detail earlier in this book. The dose of a metal is a multidimensional concept and is a function of time as well as concentration. The most toxicologically relevant definition of dose is the amount of active metal within cells of target organs. The active form is often presumed to be the free metal, but it is technically difficult or impossible to precisely determine.

A critical indicator of retention of a metal is its biological half-life, or the time it takes for the body or organ to excrete half of an accumulated amount. The biological half-life varies according to the metal as well as the organ or tissue. For example, the biological half-lives of cadmium in kidney and lead in bone are 20–30 years, whereas for some metals, such as arsenic or lithium, they are only a few hours to days. For many metals, more than one half-life is needed to fully describe the retention. The half-life of lead in blood is only a few weeks, as compared to the much longer half-life in bone. After inhalation of mercury vapor, at least two half-lives describe the retention in brain, one on the order of a few weeks and the other measured in years. Continued metal exposure clearly complicates retention kinetics.

Blood, urine, and hair are the most accessible tissues for quantifying metal exposure. Results from single measurements may reflect recent exposure or long-term or past exposure, depending on retention time in the particular tissue. Blood and urine concentrations usually, but not always, are reflective of more recent exposures and correlate with acute adverse effects. An exception is urinary cadmium, which may reflect kidney damage related to a renal cadmium accumulation over several decades. Hair can be useful in assessing variations in exposure to metals over the period of its growth. Analyses can be performed on segments of the hair, so that metal content of the newest growth can be compared with past exposures. Hair levels of mercury have been found to be a reliable measure of exposure to methylmercury. For most other metals, however, hair is not a reliable tissue for measuring exposure because of metal deposits from external contamination that may complicate analysis.

Metal-binding Proteins and Metal Transporters

Protein binding of metals is a critical aspect of essential and toxic metal metabolism (Zalpus and Koropatnick, 2000). Many different types of proteins play roles in the disposition of metals in the body. Nonspecific binding to proteins, like serum albumin or hemoglobin, act in metal transport and tissue distribution. Metals vary in their

preferred site of proteinaceous binding, and can attack a variety of amino acid residues. For instance, cysteine sulfurs are preferred by cadmium and mercury, and these residues are commonly involved with overall protein structure. In addition, proteins with specific metal-binding properties play special roles in the trafficking of specific essential metals, and toxic metals may interact with these proteins through mimicry. Metal-binding proteins are an important, emerging issue in the physiology and toxicology of metals and only a few examples are highlighted here.

The *metallothioneins* are a very important class of metal-binding proteins that function in essential metal homeostasis and metal detoxification (Klaassen *et al*., 1999). They are small (6000 Da), soluble, and rich in internally oriented thiol ligands. These thiol ligands provide the basis for high-affinity binding of several essential and toxic metals including zinc, cadmium, copper, and mercury. The metallothioneins are highly inducible by a variety of metals or other stimulants. Metallothioneins clearly play an important role in metal toxicity, as illustrated in the discussion of cadmium below.

Transferrin is a glycoprotein that binds most of the ferric iron in plasma and helps transport iron across cell membranes. The protein also transports aluminum and manganese. *Ferritin* is primarily a storage protein for iron. It has been suggested that ferrin may serve as a general metal detoxicant protein, because it binds a variety of toxic metals including cadmium, zinc, beryllium, and aluminum.

Ceruloplasmin is a copper-containing glycoprotein oxidase in plasma that converts ferrous iron to ferric iron, which then binds to transferrin. This protein also stimulates iron uptake by a transferrin-independent mechanism.

In all cells there are mechanisms for metal ion homeostasis that frequently involve a balance between uptake and efflux systems. A rapidly increasing number of metal transport proteins are being discovered that transport metals across cell membranes and organelles inside the cells. Metal transporters are important for cellular resistance to metals or metalloids (Rosen, 2002). For instance, enhanced efflux via multidrug resistance protein pumps is involved in acquired tolerance to arsenic (Liu *et al*., 2001), wheraes decreased influx via reduced calcium G-type channels is involved in acquired tolerance to cadmium (Leslie *et al*., 2006). Over ten zinc transporters and four Zip family proteins are involved in cellular zinc transport, trafficking, and signaling (Cousins *et al*., 2006). The importance of metal transporters in human diseases is well illustrated by Menkes disease and Wilson disease, which are caused by genetic mutations in the copper-transport protein gene *ATP7A*, resulting in copper deficiency (Menkes disease), or *ATP7B*, resulting in copper overload (Wilson disease) (see Fig. 23-7).

Pharmacology of Metals

Metal and metal compounds have a long history of pharmacological use. Metallic agents, largely because of their potential toxicity, have been often used in chemotherapeutic settings. For instance, mercury was used in the treatment of syphilis as early as the 16th century. Similarly, Ehrlich's *magic bullet* (arsphenamine) was an organoarsenical. Today, many metallic chemicals remain valuable pharmacological tools in the treatment of human disease, as exemplified by the highly effective use of platinum compounds in cancer chemotherapy. In addition, gallium and titanium complexes are promising metal compounds in cancer chemotherapy. Other medicinal metals used today include aluminum (antacids and buffered analgesics), bismuth (peptic ulcer and *Helicobacter pylori* asso-

ciated gastritis), lithium (mania and bipolar disorders), and gold (arthritis).

Treatment of metal poisoning is sometimes used to prevent, or even attempt to reverse, toxicity. The typical strategy is to give metal chelators that will complex the metal and enhance its excretion (Klaassen, 2001). Most chelators are not specific and will interact with a number of metals, eliminating more than the metal of concern. In addition, the vast array of biological metal ligands is a formidable barrier to chelator efficacy (Klaassen, 2001). Metal chelation therapy should be considered a secondary alternative to reduction or prevention of toxic metal exposures. Such therapy can be used for many different metals including lead, mercury, iron, and arsenic. For detailed discussion on the pharmacology of chelation therapy, see Klaassen (2001).

MAJOR TOXIC METALS

Arsenic

Arsenic (As) is a toxic and carcinogenic metalloid. The word *arsenic* is from the Persian word *Zarnikh*, as translated to the Greek *arsenikon*, meaning "yellow orpiment." Arsenic has been known and used since ancient times as the *Poison of Kings and the King of Poisons*. The element was first isolated in about 1250. Arsenicals have been used since ancient times as drugs and even today are very effective against acute promyelocytic leukemia (Soignet *et al*., 2001). Arsenic exists in the trivalent and pentavalent forms and is widely distributed in nature. The most common inorganic trivalent arsenic compounds are arsenic trioxide and sodium arsenite, while common pentavalent inorganic compounds are sodium arsenate, arsenic pentoxide, and arsenic acid. Important organo-arsenicals include arsenilic acid, arsenosugars, and several methylated forms produced as a consequence of inorganic arsenic biotransformation in various organisms, including humans. Arsine (AsH_3) is an important gaseous arsenical.

Occupational exposure to arsenic occurs in the manufacture of pesticides, herbicides, and other agricultural products. High exposure to arsenic fumes and dusts may occur in smelting industries (ATSDR, 2005a). Environmental arsenic exposure mainly occurs from arsenic-contaminated drinking water. Arsenic in drinking water is often from natural sources. Although most U.S. drinking water contains arsenic at levels lower than 5 μg/L (ppb), it has been estimated that about 25 million people in Bangladesh alone drink water with arsenic levels above 50 ppb (IARC, 2004). Environmental exposure to arsenic also occurs from burning of coal containing naturally high levels of arsenic (Liu *et al*., 2002), and perhaps from wood treated with arsenical preservatives (Khan *et al*., 2006). It is not known, however, to what extent arsenic-treated wood products contribute to human exposure. Food, especially seafood, may contribute significantly to daily arsenic intake. Arsenic in seafood is largely in an organic form called arsenobetaine that is much less toxic than the inorganic forms (ATSDR, 2005a).

Toxicokinetics   Inorganic arsenic is well absorbed (80–90%) from the gastrointestinal tract, distributed throughout the body, often metabolized by methylation, and then excreted primarily in urine (NRC, 2001). Arsenic compounds of low solubility (e.g., arsenic trioxide, arsenic selenide, lead arsenide, and gallium arsenide) are absorbed less efficiently after oral exposure. Skin is a potential route of exposure to arsenic, and systemic toxicity has been reported in persons having dermal contact with solutions of inorganic arsenic
Figure 23-2. Arsenic Metabolism.

GSH, reduced glutathione; GSTO1, glutathione S-transferase omega-1; SAM, *S*-adenosylmethionine; SAH, *S*-adenosyl-homocysteine; AS3MT, arsenic methyltransferase (Cyt19); MMA^{5+}, monomethylarsonic acid; MMA^{3+}, monomethylarson-ous acid; DMA^{5+}, dimethylarsinic acid; DMA^{3+}, dimethylarsinous acid; TMAO, trimethylarsenic oxide.

(Hostynek *et al.*, 1993). Airborne arsenic is largely trivalent arsenic oxide. Deposition in airways and absorption of arsenicals from lungs is dependent on particle size and chemical form. Excretion of absorbed arsenic is mainly via the urine. The whole-body biological half-life of ingested arsenic is about 10 hours, and 50–80% is excreted over 3 days. The biological half-life of methylated arsenicals is in the range of 30 hours. Arsenic has a predilection for skin and is excreted by desquamation of skin and in sweat, particularly during periods of profuse sweating. It also concentrates in forming fingernails and hair. Arsenic exposure produces characteristic transverse white bands across fingernails (Mees' line), which appear about 6 weeks after the onset of symptoms of arsenic toxicity. Arsenic in the fingernails and hair has been used as a biomarker for exposure, including both current and past exposures, while urinary arsenic is a good indicator for current exposure.

Methylation of inorganic arsenic species is no longer considered as a detoxication process, as recent work has identified the highly toxic trivalent methylated arsenicals. Some animal species even lack arsenic methylation capacity, perhaps as an adaptation mechanism. Figure 23-2 illustrates the biotransformation of arsenic. Arsenate (As^{5+}) is rapidly reduced to arsenite (As^{3+}) by arsenate reductase (presumably purine nucleoside phosphorylase). Arsenite is then sequentially methylated to form methylarsonate (MMA^{5+}) and dimethylarsinic acid (DMA^{5+}) by arsenic methyltransferase (AS3MT or Cyt19) or arsenite methyltransferase using *S*-adenosylmethionine (SAM) as a methyl group donor. The intermediate metabolites, methylarsonous acid (MMA^{3+}) and dimethylarsinous acid (DMA^{3+}), are generated during this process, and these trivalent methylated arsenicals are now thought to be more toxic than even the inorganic arsenic species (Aposhian and Aposhian, 2006; Thomas *et al.*, 2007). In humans, urinary arsenicals are composed of 10–30% inorganic arsenicals, 10–20% MMA, and 55–76% DMA (NRC, 2001). However, large variations in arsenic methylation occur due to factors such as age and sex, and it is suspected that ge-

netic polymorphisms may exist. Arsenic metabolism also changes through the course of pregnancy, reflected in higher urinary excretion of DMA and lower urinary levels of inorganic arsenic and MMA, which may have toxicologic impact on the developing fetus (Hopenhayn *et al.*, 2003).

Toxicity

Acute Poisoning   Ingestion of large doses (70–180 mg) of inorganic arsenic can be fatal. Symptoms of acute intoxication include fever, anorexia, hepatomegaly, melanosis, cardiac arrhythmia and, in fatal cases, eventual cardiac failure. Acute arsenic ingestion can damage mucous membranes of the gastrointestinal tract, causing irritation, vesicle formation, and even sloughing. Sensory loss in the peripheral nervous system is the most common neurologic effect, appearing at 1–2 weeks after large doses and consisting of Wallerian degeneration of axons, a condition that is reversible if exposure is stopped. Anemia and leucopenia, particularly granulocytopenia, occur a few days following high-dose arsenic exposure and are reversible. Intravenous arsenic infusion at clinical doses in the treatment of acute promyelocytic leukemia may be significantly or even fatally toxic in susceptible patients, and at least three sudden deaths have been reported (Westervelt *et al.*, 2001). Acute exposure to a single high dose can produce encephalopathy, with signs and symptoms of headache, lethargy, mental confusion, hallucination, seizures, and even coma (ATSDR, 2005a).

Arsine gas, generated by electrolytic or metallic reduction of arsenic in nonferrous metal production, is a potent hemolytic agent, producing acute symptoms of nausea, vomiting, shortness of breath, and headache accompanying the hemolytic reaction. Exposure toarsine is fatal in up to 25% of the reported human cases and may be accompanied by hemoglobinuria, renal failure, jaundice, and anemia in nonfatal cases when exposure persists (ATSDR, 2005a).

Chronic Toxicity The skin is a major target organ in chronic inorganic arsenic exposure. In humans, chronic exposure to arsenic induces a series of characteristic changes in skin epithelium. Diffuse or spotted hyperpigmentation and, alternatively, hypopigmentation can first appear between 6 months to 3 years with chronic exposure to inorganic arsenic. Palmar-plantar hyperkeratosis usually follows the initial appearance of arsenic-induced pigmentation changes within a period of years (NRC, 2001). Skin cancer is common with protracted high-level arsenical exposure (see below).

Liver injury, characteristic of long-term or chronic arsenic exposure, manifests itself initially as jaundice, abdominal pain, and hepatomegaly (NRC, 2001; Mazumder, 2005). Liver injury may progress to cirrhosis and ascites, even to hepatocellular carcinoma (Centeno *et al*., 2002; Liu *et al*., 2002).

Repeated exposure to low levels of inorganic arsenic can produce peripheral neuropathy. This neuropathy usually begins with sensory changes, such as numbness in the hands and feet but later may develop into a painful "pins and needles" sensation. Both sensory and motor nerves can be affected, and muscle tenderness often develops, followed by weakness, progressing from proximal to distal muscle groups. Histological examination reveals a dying-back axonopathy with demyelination, and effects are dose-related (ATSDR, 2005a).

An association between ingestion of inorganic arsenic in drinking water and cardiovascular disease has been shown (NRC, 2001; Chen *et al*., 2005; Navas-Acien *et al*., 2005). Peripheral vascular disease has been observed in persons with chronic exposure to inorganic arsenic in the drinking water in Taiwan. It is manifested by acrocyanosis and Raynaud's phenomenon and may progress to endarteritis and gangrene of the lower extremities (Blackfoot disease). Arsenic-induced vascular effects have been reported in Chile, Mexico, India, and China, but these effects do not compare in magnitude or severity to Blackfoot disease in Taiwanese populations, indicating other environmental or dietary factors may be involved (Yu *et al*., 2002).

Some studies have shown an association between high arsenic exposure in Taiwan and Bangladesh and an increased risk of diabetes mellitus, but the data for occupational exposure is inconsistent (Navas-Acien *et al*., 2006). Additional research is required to verify a link between inorganic arsenic exposure and diabetes.

Immunotoxic effects of arsenic have been suggested (ATSDR, 2005a). The hematologic consequences of chronic exposure to arsenic may include interference with heme synthesis, with an increase in urinary porphyrin excretion, which has been proposed as a biomarker for arsenic exposure (Ng *et al*., 2005).

Mechanisms of Toxicity The trivalent compounds of arsenic are thiol-reactive, and thereby inhibit enzymes or alter proteins by reacting with proteinaceous thiol groups. Pentavalent arsenate is an uncoupler of mitochondrial oxidative phosphorylation, by a mechanism likely related to competitive substitution (mimicry) of arsenate for inorganic phosphate in the formation of adenosine triphosphate. Arsine gas is formed by the reaction of hydrogen with arsenic, and is a potent hemolytic agent (NRC, 2001).

In addition to these basic modes of action, several mechanisms have been proposed for arsenic toxicity and carcinogenicity. Arsenic and its metabolites have been shown to produce oxidants and oxidative DNA damage, alteration in DNA methylation status and genomic instability, impaired DNA damage repair, and enhanced cell proliferation (NRC, 2001; Rossman, 2003). Unlike many carcinogens, arsenic is not a mutagen in bacteria and acts weakly in mammalian cells, but can induce chromosomal abnormalities, aneuploidy, and micronuclei formation. Arsenic can also act as a co-mutagen and/or co-carcinogen (Rossman, 2003; Chen *et al*., 2005). These mechanisms are not mutually exclusive and multiple mechanisms likely account for arsenic toxicity and carcinogenesis. Some mechanisms, however, may be organ specific.

Carcinogenicity The carcinogenic potential of arsenic was recognized over 110 years ago by Hutchinson, who observed an unusual number of skin cancers occurring in patients treated for various diseases with medicinal arsenicals. IARC (2004) has classified arsenic as a known human carcinogen, associated with tumors of the skin, lung, and urinary bladder, and possibly kidney, liver, and prostate (NRC, 2001; IARC, 2004).

Arsenic-induced skin cancers include basal cell carcinomas and squamous cell carcinomas, both arising in areas of arsenic-induced hyperkeratosis. The basal cell cancers are usually only locally invasive, but squamous cell carcinomas may have distant metastases. In humans, the skin cancers often, but not exclusively, occur on areas of the body not exposed to sunlight (e.g., on palms of hands and soles of feet). They also often occur as multiple malignant lesions. Animal models have shown that arsenic acts as a rodent skin tumor copromoter with 12-*O*-teradecanoyl phorbol-13-acetate in v-Ha-*ras* mutant Tg.AC mice (Germolec *et al*., 1998) or as a co-carcinogen with UV irradiation in hairless mice (Rossman *et al*., 2001).

The association of internal tumors in humans with arsenic exposure is well recognized (NRC, 2001). This includes arsenic-induced tumors of the urinary bladder, and lung, and potentially the liver, kidney, and prostate. In rats, the methylated arsenic species, DMA^{5+}, is a urinary bladder tumor initiator and promoter (Wei *et al*., 2002) and produces urothelial cytotoxicity and proliferative regeneration with continuous exposure (Cohen *et al*., 2001). However, the relevance of this finding to inorganic arsenic carcinogenesis must be extrapolated cautiously, due to the high dose of DMA required to produce these changes in rats (NRC, 2001).

In contrast to most other human carcinogens, it has been difficult to confirm the carcinogenicity of inorganic arsenic in experimental animals. Recently, a transplacental arsenic carcinogenesis model has been established in mice. Short-term exposure of the pregnant rodents from gestation day 8 to day 18, a period of general sensitivity to chemical carcinogenesis, produces tumors in the liver, adrenal, ovary, and lung of offspring as adults (Waalkes *et al*., 2003, 2004a). The tumor spectrum after in utero arsenic exposure resembles estrogenic carcinogens and is associated with overexpression of estrogen-linked genes (Liu *et al*., 2006), and thus a hypothesis that arsenic may somehow act on estrogen signaling to produce hepatocarcinogenic effects has been proposed (Waalkes *et al*., 2004b). Indeed, when in utero arsenic exposure is combined with postnatal treatment with the synthetic estrogen diethylstilbestrol, synergistic increases in malignant urogenital system tumors, including urinary bladder tumors and liver tumors, are observed (Waalkes *et al*., 2006a,b). As a corollary in humans, increased mortality occurs from lung cancer in young adults following in utero exposure to arsenic (Smith *et al*., 2006). Thus, the developing fetus appears to be hypersensitive to arsenic carcinogenesis.

Treatment For acute arsenic poisoning, treatment is symptomatic, with particular attention to fluid volume replacement and support of blood pressure. The oral chelator penicillamine or succimer

(2,3-dimercaptosuccinic acid, DMSA) is effective in removing arsenic from the body. Dimercaptopropanesulfonic acid (DMPS) has also been used for acute arsenic poisoning with fewer side effects (Aposhian and Aposhain, 2006). However, for chronic poisoning, chelator therapy has not proven effective in relieving symptoms (Rahman *et al.*, 2001; Liu *et al.*, 2002) except for a limited preliminary trial with DMPS (Mazumder, 2005). The best strategy for preventing chronic arsenic poisoning is by reducing exposure.

Beryllium

Beryllium (Be), an alkaline earth metal, was discovered in 1798. The name beryllium comes from the Greek *beryllos*, a term used for the mineral beryl. Beryllium compounds are divalent. Beryllium alloys are used in automobiles, computers, sports equipment, and dental bridges. Pure beryllium metal is used in nuclear weapons, aircraft, X-ray machines, and mirrors. Human exposure to beryllium and its compounds occur primarily in beryllium manufacturing, fabricating, or reclaiming industries. Individuals may also be exposed to beryllium from implanted dental prostheses. The general population is exposed to trace amounts of beryllium through the air, food, and water, as well as from cigarette smoke (WHO, 1990; ATSDR, 2002).

Toxicokinetics   The primary route of exposure to beryllium compounds is through the lungs. After being deposited in the lung, beryllium is slowly absorbed into the blood. In patients accidentally exposed to beryllium dust, serum beryllium levels peak about 10 days after exposure with a biological half-life of 2–8 weeks (ATSDR, 2002). Gastrointestinal and dermal absorption of beryllium is low (<1%), but incidental oral exposure to soluble beryllium compounds or exposure through damaged skin may significantly contribute to total body burden (Deubner *et al.*, 2001). Most of the beryllium circulating in the blood is bound to serum proteins, such as prealbumins and globulins. A significant part of the inhaled beryllium is stored in the bone and lungs. More soluble beryllium compounds are distributed to the liver, lymph nodes, spleen, heart, muscle, skin, and kidney. Elimination of absorbed beryllium occurs mainly in the urine and only to a minor degree in the feces. Because of the long residence time of beryllium in the skeleton and lungs, its biological half-life is over one year (WHO, 1990; ATSDR, 2002).

Toxicity

Skin Effects   Effects in the skin are the most common beryllium-related toxicity. Exposure to soluble beryllium compounds may result in conjunctivitis and papulovesicular dermatitis of the skin, which is likely an inflammatory response to beryllium. Beryllium exposure may also cause a delayed-type hypersensitivity reaction in skin, which is a cell-mediated immune response. If insoluble beryllium-containing materials become embedded under the skin, a chronic granulomatous lesion develops, which may be necrotizing and ulcerative. Skin is a route of beryllium exposure and sensitization, and the beryllium sulfate skin test and the beryllium lymphocyte proliferation test have been used to identify beryllium-sensitive individuals (Fontenot *et al.*, 2002; Tinkle *et al.*, 2003). Beryllium fluoride patch test may in itself be sensitizing, which has been replaced by the use of 1% beryllium sulfate (ATSDR, 2002; Fontenot *et al.*, 2002).

Acute Chemical Pneumonitis   Inhalation of beryllium can cause a fulminating inflammatory reaction of the entire respiratory tract, involving the nasal passages, pharynx, tracheobronchial airways, and the alveoli. In the most severe cases, it produces acute fulminating pneumonitis. This occurs almost immediately following inhalation of aerosols of soluble beryllium compounds, particularly the fluoride, during the ore extraction process. Fatalities have occurred, although recovery is generally complete after a period of several weeks or even months.

Chronic Granulomatous Disease   Berylliosis, or chronic beryllium disease (CBD), was first described among fluorescent lamp workers exposed to insoluble beryllium compounds, particularly beryllium oxide. Granulomatous inflammation of the lung, along with dyspnea on exertion, cough, chest pain, weight loss, fatigue, and general weakness, are the most typical features. Impaired lung function and hypertrophy of the right heart are also common. Chest X-ray shows miliary mottling. Histologically, the alveoli contain small interstitial granulomas resembling those seen in sarcoidosis. In severe cases, CBD may be accompanied by cyanosis and hypertrophic osteoarthropathy (WHO, 1990; ATSDR, 2002). Beryllium sensitization following initial exposure can progress to CBD (Newman *et al.*, 2005). As the lesions progress, interstitial fibrosis increases, with loss of functioning alveoli, impairment of effective air-capillary gas exchange, and increasing respiratory dysfunction. CBD involves an antigen-stimulated, cell-mediated immune response. Human leukocyte antigen, T cells, and proinflammatory cytokines (TNF-α and IL-6) are believed to be involved in the pathogenesis of CBD (Fontenot *et al.*, 2002; Day *et al.*, 2006).

Carcinogenicity   A number of epidemiology studies in U.S. beryllium workers found that death due to lung cancer was increased, along with increased incidence of respiratory diseases. The increase in lung cancers are linked to high exposure levels which occurred prior to stricter exposure regulations introduced in the 1950s. The likelihood of lung cancer was greater in workers with acute beryllium disease than CBD (ATSDR, 2002; Gordon and Bowser, 2003). Beryllium has been classified as a human carcinogen (IARC, 1993).

Experimental studies confirmed carcinogenic potential of beryllium compounds by inhalation. For example, a single, short (<48 min) exposure to 410–980 mg/m^3 beryllium metal aerosol induced lung tumors in rats 14 months after exposure. Chronic beryllium sulfate inhalation (13 months, 0.034 mg Be/m^3) resulted in 100% lung tumor incidence in rats (Gordon and Bowser, 2003). Injection of beryllium compounds also induced osteosarcomas in rabbits (WHO, 1990). Beryllium compounds are negative in bacterial mutation assays. In mammalian cells, soluble beryllium compounds show weak mutagenic potential, but can induce malignant transformation. The ability of beryllium compounds to produce chromosomal aberrations is controversial, and appears to depend on the compound, dose, and experimental conditions (Gordon and Bowser, 2003). The carcinogenic mechanism of beryllium is not yet clear. Several molecular events can occur including oncogene activation (K-*ras*, c-*myc*, c-*fos*, c-*jun*, and c-*sis*), and tumor suppressor gene dysregulation (p53, p16), but mutations in *p*53 or K-*ras* are not evident. Beryllium-induced lung tumors show hypermethylation of p16 leading to loss of expression, and have decreased expression of genes associated with DNA repair (Gordon and Bowser, 2003).

Cadmium

Cadmium (Cd) is a toxic transition metal that was discovered in 1817 as an impurity of "calamine" (zinc carbonate) for which it is named (from the Latin *cadmia*). Until recently the industrial use of cadmium was quite limited, but now it has become an important metal with many uses. About 75% of cadmium produced is used in batteries, especially nickel–cadmium batteries. Because of its noncorrosive properties, cadmium has been used in electroplating or galvanizing alloys for corrosion resistance. It is also used as a color pigment for paints and plastics, in solders, as a barrier to control nuclear fission, as a plastic stabilizer and in some special application alloys. This metal is typically found in ores with other metals, and is commercially produced as a byproduct of zinc and lead smelting, which are sources of environmental cadmium. Cadmium ranks close to lead and mercury as one of the top toxic substances (Jarup *et al*., 1998; ATSDR, 1999).

Exposure Food is the major source of cadmium for the general population. Many plants readily accumulate cadmium from soil. Both natural and anthropogenic sources of cadmium contamination occur for soil, including fallout of industrial emissions, some fertilizers, soil amendments, and use of cadmium-containing water for irrigation, all resulting in a slow but steady increase in the cadmium content in vegetables over the years (Jarup *et al*., 1998). Shellfish accumulate relatively high levels of cadmium (1–2 mg/kg), and animal liver and kidney can have levels higher than 50 μg Cd/kg. Cereal grains such as rice and wheat, and tobacco concentrate cadmium to levels of 10–150 μg Cd/kg. With nearby industrial emission, air can be a significant source of direct exposure or environmental contamination. Total daily cadmium intake from all sources in North America and Europe ranges from 10 to 30 μg Cd/day. Of this about 10% or less is retained (Jarup *et al*., 1998). Cigarette smoking is a major nonoccupational source of cadmium exposure, because of cadmium in the tobacco. Smoking is thought to roughly double the life-time body burden of cadmium (Satarug and Moore, 2004).

Historically, levels of cadmium in the workplace have dramatically improved with the appreciation of its potential toxicity in humans, development of safety restrictions, and improved industrial hygiene. Inhalation is the dominant route of exposure in occupational settings. Airborne cadmium in the present-day workplace environment is generally 5 μg/m^3 or less and occupational standards range from 2 to 50 μg/m^3. Occupations potentially at risk from cadmium exposure include those involved with refining zinc and lead ores, iron production, cement manufacture, and industries involving fossil fuel combustion, all of which can release airborne cadmium. Other occupations include the manufacture of paint pigments, cadmium-nickel batteries, and electroplating (WHO, 1992; ATSDR, 1999).

Toxicokinetics Gastrointestinal absorption of cadmium is limited to 5–10% of a given dose. Cadmium absorption can be increased by dietary deficiencies of calcium or iron and by diets low in protein. In the general population, women have higher blood cadmium levels than men, possibly due to increased oral cadmium absorption because of relatively low iron stores in women of childbearing age. Indeed, women showing low serum ferritin levels have twice the normal rate of oral cadmium absorption (Berglund *et al*., 1994). It has recently been shown that rats on an iron-deficient diet have an increased absorption of cadmium, which correlated with the upreg-

ulation of the iron transporter, DMT, which transports both iron and cadmium (Ryu *et al*., 2004). Absorption of cadmium after inhalation is generally greater, ranging from 5 to 35%, depending on the specific compound, site of deposition, and particle size. For instance, 50% of cadmium fumes, as generated in cigarette smoke, may be absorbed. It is thought that as much as 100% of cadmium eventually reaching the alveoli can be transferred to blood (Satarug and Moore, 2004).

Once absorbed, cadmium is very poorly excreted and only about 0.001% of the body burden is excreted per day. Both urinary and fecal excretory routes are operative (ATSDR, 1999; Satarug and Moore, 2004). Cadmium transport into cells is mediated through calcium channels (Leslie *et al*., 2006) and through molecular mimicry (Zalpus and Ahmad, 2003). Gastrointestinal excretion occurs through the bile as a glutathione complex. Cadmium excretion in urine increases relative to body burden (Friberg *et al*., 1986; ATSDR, 1999). Cadmium is nephrotoxic, and when renal pathology is present the urinary excretion of cadmium is increased due to decreased renal absorption of filtered cadmium (Zalpus and Ahmad, 2003).

The relationship of cadmium metabolism and toxicity is shown in Fig. 23-3. Cadmium is transported in blood by binding to albumin and other larger molecular-weight proteins. It is rapidly taken up by tissues and is primarily deposited in the liver and to a lesser extent in the kidney. In the liver, kidney, and other tissues, cadmium induces the synthesis of metallothionein (MT), a low-molecular-weight, high affinity metal-binding protein (Klaassen *et al*., 1999). Cadmium is stored in the liver primarily as cadmium–MT. Cadmium–MT may be released from the liver and transported via blood to the kidney, where it is reabsorbed and degraded in the lysosomes of the renal tubules. This releases cadmium to induce more cadmium–MT complex or cause renal toxicity.

Blood cadmium levels in nonoccupationally exposed, nonsmokers are usually less than 1 μg/L. Cadmium does not readily cross the placenta. Breast milk is not a major source of early life exposure. About 50–75% of the retained cadmium is found in the liver and kidneys. The biological half-life of cadmium in humans is not known exactly, but is probably in the range of 10–30 years.

Toxicity Acute, high-dose cadmium toxicity in humans is now a rare event. Acute cadmium toxicity from the ingestion of high concentrations of cadmium in the form of heavily contaminated beverages or food causes severe irritation to the gastrointestinal epithelium. Symptoms include nausea, vomiting, and abdominal pain. Inhalation of cadmium fumes or other heated cadmium-containing materials may produce acute pneumonitis with pulmonary edema. Inhalation of large doses of cadmium can be lethal for humans (ATSDR, 1999). Acute cadmium toxicity depends on solubility of cadmium compounds (ATSDR, 1999). For instance, with acute inhalation exposures, the more soluble cadmium chloride, oxide fume, and carbonate are more toxic than the relatively less soluble sulfide (Klimisch, 1993). The major long-term toxic effects of low-level cadmium exposure are renal injury, obstructive pulmonary disease, osteoporosis, and cardiovascular disease. Cancer is primarily a concern in occupationally exposed groups. The chronic toxic effects of cadmium are clearly a much greater concern than the rare acute toxic exposures.

Nephrotoxicity Cadmium is toxic to tubular cells and glomeruli, markedly impairing renal function. Pathologically, these lesions
Figure 23-3. Cadmium Transport, Protein-Binding, and Toxicity.

GSH, glutathione; MT, metallothionein; aa, amino acids; Cd-Alb, Cd-albumin; Cd-LMWPr, Cd associated with low molecular weight proteins.

consist of initial tubular cell necrosis and degeneration, progressing to an interstitial inflammation and fibrosis. There appears to be a critical concentration of cadmium in the renal cortex that, once exceeded, is associated with tubular dysfunction. This concentration depends on the individual, and chronic cadmium nephropathy is seen in about 10% of the population at renal concentrations of $\sim$200 μg/g and in about 50% of the population at about 300 μg/g. Because of the potential for renal toxicity, there is considerable concern about the levels of dietary cadmium intake for the general population. In fact, it is thought that upwards of 7% of the general population may have significant cadmium-induced kidney alterations due to chronic exposure with kidney cadmium levels as low as 50 μg/g (Jarup *et al.*, 1998).

Cadmium-induced renal toxicity is reflected by proteinuria as a result of renal tubular dysfunction. The predominant proteins include β_2-microglobulin, N-acetyl-β-D-glucosaminidase (NAG), and MT, as well as retinol-binding protein, lysozyme, ribonuclease, α_1-microglobulin, and immunoglobulin light chains (Bernard, 2004; Chen *et al.*, 2006). The presence of larger proteins, like albumin and transferrin, in the urine after occupational cadmium exposure suggests a glomerular effect as well. The pathogenesis of the glomerular lesion in cadmium nephropathy is not well understood (Bernard, 2004). Urinary excretions of proteins and cadmium have been used as biomarkers for cadmium exposure.

The induction of MT by cadmium and the subsequent sequestration of cadmium as the cadmium–MT complex likely protect tissues from cadmium toxicity. However, if cadmium–MT complex is injected it is acutely nephrotoxic (Nordberg, 2004). This led to the hypothesis that the cadmium–MT complex was responsible for chronic cadmium nephropathy. In this scenario, cadmium–MT released from the liver would be filtered by the kidney and reabsorbed in proximal tubule cells, where it is degraded releasing locally high levels of "free" cadmium (Fig. 23-3). Nephrotoxicity in normal rats following liver transplantation from cadmium-exposed

rats supported this hypothesis (Chan *et al.*, 1993). However, MT-null mice, which are unable to produce the major forms of MT, are hypersensitive to chronic cadmium nephropathy (Liu *et al.*, 1998a), suggesting that cadmium nephropathy is not necessarily mediated through the cadmium–MT complex. Kidney pathology from a single injection of cadmium–MT also differs greatly from that induced by chronic oral inorganic cadmium exposure (Liu *et al.*, 1998b). Inorganic cadmium can be taken into the kidney from the basolateral membrane, and is more toxic than cadmium–MT to cultured renal cells (Prozialeck *et al.*, 1993; Liu *et al.*, 1994; Zalpus and Ahmad, 2003). It is likely that inorganic cadmium can bind to other low-molecular proteins or other complexes for renal uptake, and these complexes can contribute to chronic cadmium nephropathy (Zalpus and Ahmad, 2003).

Chronic Pulmonary Disease Cadmium inhalation is toxic to the respiratory system in a fashion related to the dose and duration of exposure. Cadmium-induced obstructive lung disease in humans can be slow in onset, and results from chronic bronchitis, progressive fibrosis of the lower airways, and accompanying alveolar damage leading to emphysema. Pulmonary function is reduced with dyspnea, reduced vital capacity, and increased residual volume. The pathogenesis of these lung lesions is not completely understood, but can be duplicated in rodents (WHO, 1992; ATSDR, 1999). The chronic effects of cadmium on the lung clearly increased the mortality of cadmium workers with high exposure.

Skeletal Effects Occupational cadmium exposure is a well recognized cause for renal tubular dysfunction associated with hypercalciuria, renal stone formation, osteomalacia, and osteoporosis (Kazantzis, 2004). The long-term consumption of cadmium-contaminated rice caused *Itai-Itai* disease, which occurred mostly in multiparous elderly women and was characterized by severe osteomalacia and osteoporosis, resulting in bone deformities

and concomitant renal dysfunction. Vitamin D deficiency and perhaps other nutritional deficiencies are thought to be cofactors in *Itai-Itai* disease. Issues with loss of bone density, height loss, and increased bone fractures have now been reported in populations exposed to far lower levels of environmental cadmium than *Itai-Itai* victims (Kazantzis, 2004). Cadmium affects calcium metabolism, at least partially through renal dysfunction, and excess excretion of calcium often occurs in the urine. The skeletal changes are probably related to calcium loss and interference with the actions of parathyroid hormone and vitamin D. Cadmium may also act directly on bone and animal studies have shown the metal stimulates osteoclast activity, resulting in the breakdown of bone matrix. Cadmium in bone interferes with calcification and bone remodeling (Wang and Bhattacharyya, 1993). In accord with human victims of *Itai-Itai*, multiparity in mice enhances the osteotoxicity of cadmium (Bhattacharyya *et al*., 1988).

Cardiovascular Effects Some epidemiologic evidence suggests cadmium may be an etiologic agent for cardiovascular disease including hypertension, although these associations are not observed in all studies (Jarup *et al*., 1998). The population-based U.S. NHANES II study and studies in Belgium (Staessen *et al*., 1996) have not supported a role for cadmium in the etiology of hypertension or cardiovascular disease in humans. Animal studies indicate that cadmium may be toxic to myocardium (Kopp *et al*., 1982), although the relevance of these results to humans is not clear.

Neurotoxicity There is only limited data from animals and humans that cadmium can be neurotoxic (Jarup *et al*., 1998; ATSDR, 1999). Studies in humans have suggested a relationship between abnormal behavior and/or decreased intelligence in children and adults exposed to cadmium, but are typically complicated by exposure to other toxic metals. Furthermore, the blood–brain barrier severely limits cadmium access to the central nervous system, and a direct toxic effect appears to occur only with cadmium exposure prior to blood–brain barrier formation (young children), or with blood–brain barrier dysfunction under certain pathological conditions. Additionally, the choroid plexus epithelium may accumulate high levels of cadmium reducing access to other areas (Zheng, 2001). Although a special form of MT (MT-3) occurs in the brain, the role of MT in cadmium neurotoxicity is incompletely defined (Klaassen *et al*., 1999).

Carcinogenicity Cadmium compounds are considered to be human carcinogens (IARC, 1993; NTP, 2004). In humans, occupational respiratory exposure to cadmium has been most clearly associated with lung cancer (IARC, 1993; NTP, 2004). Early human studies also indicated a possible link to cancer of the prostate, which has not been confirmed by more recent work (Sahmoun *et al*., 2005), despite evidence that the prostate can be a target of cadmium carcinogenesis in rats (Waalkes, 2003). Both the kidney and pancreas accumulate high concentrations of cadmium and exposure to cadmium may also be associated with human renal (Il'yasora and Schwartz, 2005) and pancreatic cancer (Schwartz and Reis, 2000; Kriegel *et al*., 2006).

Multiple rodent studies have confirmed that inhalation of various cadmium compounds will lead to lung cancer (IARC, 1993; Waalkes, 2003; NTP, 2004). Lung tumors can also be produced by systemic cadmium exposure in mice (Waalkes, 2003). Beyond the lung, in rodents cadmium can produce a variety of tumors, including malignant tumors at the site of repository injection (subcutaneous, etc.). Compounds such as cadmium chloride, oxide, sulfate, sulfide, and cadmium powder produce local sarcomas in rodents after subcutaneous or intramuscular injections. A single injection can be effective, but multiple injections of cadmium at the same site cause more aggressive sarcomas that show a higher rate of local invasion and distant metastasis. The relevance of injection site sarcoma production to human cancer is unclear. Cadmium also induces tumors of the testes, specifically benign Leydig cell tumors, but this is likely due to a high-dose mechanism involving acute testicular necrosis, degenerative testicular atrophy, and subsequent over-stimulation by luteinizing hormone, factors very likely of limited relevance in humans (Waalkes, 2003). Other studies have found that cadmium exposure can induce tumors of the pancreas, adrenals, liver, kidney, pituitary, and hematopoietic system in mice, rats, or hamsters. Cadmium can be carcinogenic in animals after inhalation or oral administration or by various injection routes (Waalkes, 2003). Various studies indicate zinc administration will generally block cadmium carcinogenesis, whereas dietary zinc deficiency can enhance the response (IARC, 1993; Waalkes, 2003; NTP, 2004). The mechanism of cadmium carcinogenesis is poorly understood (Waalkes, 2003).

Treatment At the present time, there is no effective clinical treatment for cadmium intoxication. In experimental systems some chelators can reduce acute cadmium-induced mortality (Klaassen *et al*., 1984), but chelation therapy for cadmium generally results in significant adverse effects.

Chromium

Chromium (Cr) was named from the Greek word "*chroma*" meaning color, because of the many colorful compounds made from it. Chromium is part of the mineral crocoite (lead chromate), and the element was first isolated in 1798. Hexavalent chromium (Cr^{6+}) is a by-product of various industrial processes. Hexavalent chromium is a human carcinogen and produces a variety of toxic effects (ATSDR, 2000). The major industrial source of chromium is from chromite ore. Chromates are produced by smelting, roasting, and extraction processes. Ferrochrome is used for the production of stainless steel and alloys. Sodium chromate and dichromate are the principal substances for the production of chromium chemicals. Chromium compounds are used for plating, leather tanning, and the manufacture of dyes and pigments, cooking utensils and as wood preservatives (ATSDR, 2000). Chromium in ambient air originates primarily from industrial sources, particularly ferrochrome production, ore refining, and chemical processing. Chromium fallout is deposited on land and water, and eventually, in sediments. Widespread industrial uses have increased chromium levels in the environment. The hexavalent chromium compounds are also toxic to the ecosystems, and microbial and plant variants occur that adapt to high chromium levels in the eco-environment (Cervantes *et al*., 2001). Up to 38% of drinking water supplies in California have detectable levels of hexavalent chromium, but little is known about the health effects from environmental exposures (Costa and Klein, 2006; Sedman *et al*., 2006). Cobalt-chromium alloy hip replacement can increase blood levels of chromium (Bhamra and Case, 2006).

Trivalent chromium (Cr^{3+}) is a naturally occurring essential trace nutrient important for glucose metabolism and will be discussed separately in the "Essential Metal" section.

Toxicokinetics Absorption of hexavalent chromium compounds is higher (2–10%) than that of trivalent chromium compounds (0.5–2%). Hexavalent chromium readily crosses cell membranes on carriers for sulfate and phosphate, whereas the less insoluble trivalent chromium compounds are absorbed via passive diffusion and phagocytosis. Absorption of inhaled chromium compounds takes place in the lung via transfer across alveolar cell membranes. Dermal absorption depends on the chemical form, the vehicle, and the integrity of the skin. Concentrated potassium chromate may cause chemical burns in the skin that facilitate absorption. Once in the blood, hexavalent chromium is taken up by erythrocytes, whereas trivalent chromium is only loosely associated with erythrocytes. Chromium compounds are distributed to all organs of the body, with high levels in liver, spleen, and kidney. Particles containing chromium can be retained in the lungs for years. Absorbed chromium is excreted primarily in urine. The half-life for excretion of potassium chromium is about 35–40 hours (ATSDR, 2000; Sedman *et al.*, 2006).

Once hexavalent chromium enters cells, it is reduced intracellularly by ascorbic acid, glutathione, and/or cysteine, ultimately to trivalent chromium. It is thought that the toxicity of hexavalent chromium compounds results from damage to cellular components during this process, including the generation of free radicals and the formation of DNA adducts (Zhitkovich, 2005).

Toxicity Toxic effects have been attributed primarily to airborne hexavalent chromium compounds in industrial settings. Hexavalent chromium is corrosive and may cause chronic ulceration and perforation of the nasal septum, as well as chronic ulceration of other skin surfaces (ATSDR, 2000). Hexavalent chromium elicits allergic contact dermatitis among previously sensitized individuals, which is a type-IV allergic reaction inducing skin erythema, pruritus, edema, papule, and scars. The prevalence of chromium sensitivity is less than 1% among the general population (Proctor *et al.*, 1998). Occupational exposure to chromium may be a cause of asthma (Bright *et al.*, 1997). Accidental ingestion of high doses of hexavalent chromium compounds may cause acute renal failure characterized by proteinuria, hematuria, and anuria, but kidney damage from lower-level chronic exposure is equivocal (ATSDR, 2000).

Carcinogenicity Occupational exposure to hexavalent chromium compounds, particularly in the chrome production and pigment industries, is associated with increased risk of lung caner, and hexavalent chromium-containing compounds are considered to be human carcinogens (IARC, 1990). Hexavalent chromium compounds are genotoxic. A review of more than 700 sets of short-term genotoxicity test results with 32 chromium compounds revealed 88% of hexavalent chromium compounds were positive, as a function of solubility and bioavailability to target cells (De Flora, 2000). Trivalent chromium compounds were generally nongenotoxic, probably because trivalent chromium is not readily taken up by cells (De Flora, 2000). Once hexavalent chromium enters the cell, it is reduced by various intracellular reductants to give reactive trivalent chromium species. During the reduction process, various genetic lesions can be generated, including chromium–DNA adducts, DNA protein cross-links, DNA–chromium intrastrand cross-links, DNA strand breaks, and oxidized DNA bases (O'Brien *et al.*, 2003; Zhitkovich, 2005). Hexavalent chromium compounds are mutagenic, causing base substitutions, deletions, and transversions in bacterial systems, and hypoxanthine guanine phosphoribosyl transferase, *supF* muta-

tions, etc., in mammalian mutagenesis systems (Cohen *et al.*, 1993; O'Brien *et al.*, 2003).

Hexavalent chromium compounds also react with other cellular constituents during the intracellular reduction process. They can cause the generation of reactive oxygen radicals, inhibit protein synthesis and arrest DNA replication. Hexavalent chromium can also cause disturbances of the p53 signaling pathway, cell cycle arrest, apoptosis, interference of DNA damage repair, and neoplastic transformation. All these effects could well play an integrated role in chromium carcinogenesis (O'Brien *et al.*, 2003; Costa and Klein, 2006).

Inhaled chromium compounds can penetrate to many tissues in the body, and thus have the potential to cause cancer at sites other than the lung. Accumulating evidence indicates an association between cancers of the bone, prostate, hematopoietic system, stomach, kidney, and urinary bladder and hexavalent chromium exposure (Costa, 1997). Furthermore, exposure of hexavalent chromium compounds through the drinking water enhances UV-induced skin cancer in the hairless mouse model (Costa and Klein, 2006). An association of hexavalent chromium in the drinking water with stomach cancer has also been reported (Sedman *et al.*, 2006).

Lead

Lead (Pb) has been used by humans for at least 7000 years, because it is widespread, easy to extract, and easy to work with. It is highly malleable and ductile as well as easy to smelt. In the early Bronze Age, lead was used with antimony and arsenic. Lead's elemental symbol Pb, is an abbreviation of its Latin name *plumbum*. Lead in lead compounds primarily exists in the divalent form. Metallic lead (Pb^0) is resistant to corrosion and can combine other metals to form various alloys. Organolead compounds are dominated by Pb^{4+}. Inorganic lead compounds are used as pigments in paints, dyes, and ceramic glazes. Organolead compounds were used as gasoline additives. Lead alloys are used in batteries, shields from radiation, water pipes, and ammunition. Environmental lead comes mainly from human activity and is listed as a top toxic substance (ATSDR, 2005c). The phasing out of leaded gasoline, the removal of lead from paint, solder, and water supply pipes have significantly lowered blood lead levels (BLL) in the general population. Lead exposure in children still remains a major health concern. Lead is not biodegradable and the concerns for ecotoxicity of lead are increasing. For instance, the leaded fish sinkers or pellets lost in the bottom of lakes and river banks can be mistaken for stone and ingested by birds causing adverse effects including death (De Francisco *et al.*, 2003).

Exposure Lead-containing paint is a primary source of lead exposure in children. Major environmental sources of lead for infants and toddlers up to 4 years of age is hand-to-mouth transfer of lead-containing paint chips or dust from floors of older housing (Manton *et al.*, 2000). Lead in household dust can also come from outside of the home and may be related to lead in neighborhood soil (von Lindren *et al.*, 2003). A major route of exposure for the general population is from food and water. Dietary intake of lead has decreased dramatically in recent years, and for infants, toddlers, and young children is <5 μg/day (Manton *et al.*, 2005). A review by the EPA in 2004 found lead levels in 71% of the water systems in the US showed <5 μg Pb/L (ppb). Only 3.6% exceeded the action level of 15 ppb. Lead in urban air is generally higher than rural air. Air lead in rural areas of eastern United States is typically 6–10 ng/m^3 (ATSDR, 2005c).

Other potential sources of lead exposure are recreational shooting, hand-loading ammunition, soldering, jewelry making, pottery making, gun smithing, glass polishing, painting, and stained glass crafting. Workplace exposure is gradually being reduced. Herbal medicines could be potential sources of lead exposure. Certain Ayurvedic herbal products were found to be contaminated with lead ranging up to 37 mg/g and over 55 cases of lead poisoning have been related to the ingestion of herbal medicines (Patrick, 2006).

Blood lead levels (BLL) are commonly used for monitoring human exposure to lead. The uses of other biomarkers for lead exposure have been critically reviewed (Barbosa *et al.*, 2005).

Toxicokinetics   Adults absorb 5–15% of ingested lead and usually retain less than 5% of what is absorbed. Children absorb 42% of ingested lead with 32% retention (Ziegler *et al.*, 1978). Lead absorption can be enhanced by low dietary iron and calcium, especially in children (Mahaffey, 1985). Airborne lead is a minor component of exposure. Lead absorption by the lungs depends on the form (vapor versus particle), particle size, and concentration. About 90% of lead particles in ambient air that are inhaled are small enough to be retained. Absorption of retained lead through alveoli is relatively efficient.

Lead in blood is primarily (99%) in erythrocytes bound to hemoglobin, only 1% of circulating lead in serum is available for tissue distribution (ATSDR, 2005c). Lead is initially distributed to soft tissues such as kidney and liver, and then redistributed to skeleton and hair. The half-life of lead in blood is about 30 days. The fraction of lead in bone increases with age from 70% of body burden in childhood to as much as 95% in adulthood, with a half-life of about 20 years. Lead in trabecular bone is more labile and has a shorter turnover time than cortical bone. Lead released from bones may contribute up to 50% of the lead in blood, and is a significant source of endogenous exposure. Bone lead release may be important in adults with accumulated occupational exposure and in women due to bone resorption during pregnancy, lactation, menopause, and from osteoporosis (Silbergeld *et al.*, 1988; Gulson, *et al.*, 2003). Lead crosses the placenta, so that cord blood generally correlates with maternal BLL but is often slightly lower. Lead accumulation in fetal tissues, including brain, is proportional to maternal BLL (Goyer, 1996).

The major route of excretion of absorbed lead is the kidney. Renal excretion of lead is usually through glomerular filtrate with some renal tubular resorption. Fecal excretion via biliary tract accounts for one-third of total excretion of absorbed lead (ATSDR, 2005c).

Physiological-based pharmacokinetic (PBPK) models have been developed for lead risk assessment. The O'Flaherty model is a model for children and adults; The integrated exposure uptake (IEUBK) model is developed by EPA for predicting BLL in children. The Leggett model allows simulation of lifetime exposures and can be used to predict blood lead in both children and adults (ATSDR, 2005c).

Toxicity   Lead can induce a wide range of adverse effects in humans depending on the dose and duration of exposure. The toxic effects range from inhibition of enzymes to the production of severe pathology or death (Goyer, 1990). Children are most sensitive to effects in the central nervous system, while in adults peripheral neuropathy, chronic nephropathy, and hypertension are concerns. Other target tissues include the gastrointestinal, immune, skeletal,

and reproductive systems. Effects on the heme biosynthesis provide a sensitive biochemical indicator even in the absence of other detectable effects.

Neurological, Neurobehavioral, and Developmental Effects in Children   Clinically overt lead encephalopathy may occur in children with high exposure to lead, probably at BLL of 70 μg/dL or higher. Symptoms of lead encephalopathy begin with lethargy, vomiting, irritability, loss of appetite, and dizziness, progressing to obvious ataxia, and a reduced level of consciousness, which may progress to coma and death. The pathological findings at autopsy are severe edema of the brain due to extravasations of fluid from capillaries in the brain. This is accompanied by the loss of neuronal cells and an increase in glial cells. Recovery is often accompanied by sequelae including epilepsy, mental retardation, and, in some cases, optic neuropathy and blindness (Goyer, 1990; Bellinger, 2004; ATSDR, 2005c; Laraque and Trasande, 2005).

The most sensitive indicators of adverse neurological outcomes are psychomotor tests or mental development indices, and broad measures of IQ. Most studies report a 2- to 4-point IQ deficit for each μg/dL increase in BLL within the range of 5–35 μg/dL. The Centers for Disease Control and Prevention set the goal of eliminating ≥ 10 μg/dL BLL in children by 2010 (CDC, 2005). However, effects of lead on IQ may occur below this level (Bellinger, 2004). Recent studies found that deficits in cognitive and academic skills could occur with BLL < 5.0 μg/dL (Lamphear *et al.*, 2000). A study of a cohort of children from pregnancy through 10 years of age found that lead exposure around 28 weeks of gestation is a critical period for later child intellectual development, and lead's effect on IQ occurs with first few μgs of BLL (Schnaas *et al.*, 2006).

Lead can affect the brain by multiple mechanisms (Goyer, 1996; ATSDR, 2005c). Lead may act as a surrogate for calcium and/or disrupt calcium homeostasis. The stimulation of protein kinase C may result in alteration of blood–brain barrier and inhibition of cholinergic modulation of glutamate-related synaptic transmissions. Lead affects virtually every neurotransmitter system in the brain, including glutamatergic, dopaminergic, and cholinergic systems. All these systems play a critical role in synaptic plasticity and cellular mechanisms for cognitive function, learning, and memory.

Neurotoxic Effects in Adults   Adults with occupational exposure may demonstrate abnormalities in a number of measures in neurobehavior with cumulative exposures resulting from BLL > 40 μg/dL (Lindgren *et al.*, 1996). Peripheral neuropathy is a classic manifestation of lead toxicity in adults. More than a half-century ago, footdrop and wristdrop characterized the house painter and other workers with excessive occupational exposure to lead but are rare today. Peripheral neuropathy is characterized by segmental demyelination and possibly axonal degeneration. Motor nerve dysfunction, assessed clinically by electrophysiological measurement of nerve conduction velocities, occurred with BLL as low as 40 μg/dL (Goyer, 1990).

Hematologic Effects   Lead has multiple hematologic effects, ranging from increased urinary porphyrins, coproporphyrins, δ-aminolevulinic acid (ALA), and zinc-protoporphyrin to anemia. The heme biosynthesis pathway and the sites of lead interference are shown in Fig. 23-4. The most sensitive effects of lead are the inhibition of δ-aminolevulinic acid dehydratase (ALAD) and ferrochelatase. ALAD catalyzes the condensation of two units of ALA to form phorphobilinogen (PBG). Inhibition of ALAD results in
Figure 23-4. Metallothionein Intensity and Localization in Lead-Induced Nuclear Inclusion Bodies from the Kidneys of Wild-type Mice.

Immunohistochemical assessment of a representative section including inclusion bodies showing intense surface staining for metallothionein (*dark brown*; x400) (From Waalkes *et al*., 2004c, with permission).

accumulation of ALA. Ferrochelatase catalyzes the insertion of iron into the protoporphyrin ring to form heme. Inhibition of ferrochelatase results in accumulation of protophorphyrin IX, which takes the place of heme in the hemoglobin molecule and, as the erythrocytes containing protoporphyrin IX circulate, zinc is chelated at the site usually occupied by iron. Erythrocytes containing zinc-protoporphyrin are intensely fluorescent and may be used to diagnose lead exposure. Feeding lead to experimental animals also raises

heme oxygenase activity, resulting in increases in bilirubin formation. Anemia only occurs in very marked cases of lead toxicity, and is microcytic and hypochromic, as in iron deficiency. The changes in ALAD in peripheral blood and excretion of ALA in urine correlate with BLL and serve as early biochemical indices of lead exposure (ATSDR, 2005c).

Genetic polymorphisms have been identified for alleles of the *ALAD* gene which may affect the toxicokinetics of lead. However, no firm evidence exists for an association between *ALAD* genotype and susceptibility to lead toxicity at background exposures, and thus, population testing for *ALAD* polymorphism is not justified (Kelada *et al*., 2001).

Renal Toxicity   Acute lead nephrotoxicity consists of proximal tubular dysfunction and can be reversed by treatment with chelating agents. Chronic lead nephrotoxicity consists of interstitial fibrosis and progressive nephron loss, azotaemia and renal failure (Goyer, 1989). A characteristic microscopic change is the presence of intranuclear inclusion bodies (Fig. 23-5). By light microscopy the inclusions are dense, homogeneous, and are eosinophilic with hematoxylin and eosin staining. The bodies are composed of a lead–protein complex. The protein is acidic and contains large amounts of aspartic and glutamic acids with little cystine. The inclusion bodies are a form of aggresome accumulating large amounts of lead in a relatively inert, nontoxic state. Metallothionein-null mice cannot form inclusion bodies following lead treatment and are hyper-sensitive to lead-induced nephropathy and carcinogenesis, suggesting that lead inclusion body formation requires metallothionein as a participant (Qu *et al*., 2002; Waalkes *et al*., 2004c). In fact, metallothionein is found on the outer surface of lead inclusion bodies, indicating
Figure 23-5. Lead Interruption of Heme Biosynthesis.

ALA, δ-aminolevulinate; Pb, sites for lead effects. The major lead inhibition sites are ALA dehydrogenase and ferrochelatase.

that it may transport the metal to the forming inclusion (Waalkes *et al.*, 2004c). Lead nephrotoxicity impairs the renal synthesis of heme-containing enzymes in the kidney, such as heme-containing hydroxylase involved in vitamin D metabolism causing bone effects (ATSDR, 2005c). Hyperuricemia with gout occur more frequently in the presence of lead nephropathy (Batuman, 1993). Lead nephropathy is also a cause of hypertension (Gonick and Behari, 2002).

Effects on Cardiovascular System   There is evidence of a causal relationship between lead exposure and hypertension (Gonick and Behari, 2002; ATSDR, 2005c). A study related bone lead with blood pressure in a cohort of 590 men that indicated an increase in hypertension for individuals with elevated bone lead (Hu *et al.*, 1996). Analysis of data from the National Health and Nutrition Examination Survey (NHANES II) for the U.S. population, including BLL and blood pressure measurements in a general population (5803 people aged 12–74), found a correlation between BLL at relatively low levels and blood pressure (Harlan, 1988). An epidemiology reappraisal using meta-analysis of 58,518 subjects from both the general population and occupationally exposed groups from 1980 to 2001 suggested a weak, but significant association between BLL and blood pressure (Nawrot *et al.*, 2002). Elevated blood pressure is more pronounced in middle age than at young age (ATSDR, 2005c).

A review of chronic lead exposure on blood pressure in experimental animals indicated that at lower doses, lead consistently produced hypertension effects, whereas at higher doses results are inconsistent (Victery, 1988). The pathogenesis of lead-induced hypertension is multifactorial including: (1) inactivation of endogenous nitric oxide and cGMP, possibly through lead-induced reactive oxygen species; (2) changes in the rennin–angiotensin–aldosterone system, and increases in sympathetic activity, important humoral components of hypertension; (3) alterations in calcium-activated functions of vascular smooth muscle cells including contractility by decreasing Na^+/K^+-ATPase activity and stimulation of the Na^+/Ca^{++} exchange pump; and (4) a possible rise in endothelin and thromboxane (Gonick and Behari, 2002; Vaziri and Sica, 2004).

Immunotoxicity   The developing immune system is sensitive to toxic effects of lead (Dietert *et al.*, 2004). A hallmark of lead-induced immunotoxicity is a pronounced shift in the balance in T helper cell function toward Th2 responses at the expense of Th1 functions, resulting in elevated IgE levels. Increased IgE levels and inflammatory cytokines were found in lead-exposed neonatal rodents, and there is an association between BLL and elevated IgE levels in children (Karmaus *et al.*, 2005; Luebke *et al.*, 2006). Thus, lead immunotoxicity might be a risk factor for childhood asthma (Dietert *et al.*, 2004). In experimental animals, lead has been shown to target macrophages and T cells, especially $CD4^+$ T cells. In occupational exposure, lead-associated changes include altered T-cell subpopulations, reduced immunoglobin levels, and reduced polymorphonuclear leukocyte chemotactic activity (Dietert *et al.*, 2004; Luebke *et al.*, 2006).

Bone Effects   Lead has an extremely long half-life in bone, accounting for over 90% of the body lead in adults. Lead can affect bone by interfering with metabolic and homeostatic mechanisms including parathyroid hormone, calcitonin, vitamin D, and other hormones that influence calcium metabolism. Lead substitutes for calcium in bone (Pounds *et al.*, 1991). Lead is known to affect osteoblasts, osteoclasts, and chrondrocytes and has been associated with osteoporosis and delays in fracture repair (Carmouche *et al.*,

2005). In children exposed to lead, a higher bone mineral density (BMD) was observed. This may be due to accelerated bone maturation through inhibition of parathyroid hormone-related peptide, may ultimately result in lower peak BMD in young adulthood, and might predispose subjects to osteoporosis later in life (Campbell *et al.*, 2004). A positive association between lead exposure and dental caries in children has been shown in a number of studies. Lead is deposited in teeth, inhibits mineralization of enamel and dentine, and affects metabolism of the cells in the dental pulp (ATSDR, 2005c).

Other Effects   Lead colic is a major gastrointestinal symptom of severe lead poisoning, and is characterized by abdominal pain, nausea, vomiting, constipation, and cramps (ATSDR, 2005c). It is rarely seen today.

Lead-induced gametotoxic effects have been demonstrated in both male and female animals (Goyer, 1990). There is also evidence that lead may disrupt the hypothalamic–pituitary–gonadal axis. An increase in the maternal BLL may also contribute to premature birth and reduced birth weight (ATSDR, 2005c).

Carcinogenicity   The association of lead exposure with increased human cancer risk was strengthened by recent studies (ATSDR, 2005c), and inorganic lead compounds were recently reclassified as probably carcinogenic to humans (IARC, 2004). A study of a cohort of 20,700 workers coexposed to lead and engine exhaust found a 1.4 fold increase in the overall cancer incidence and a 1.8 fold increase in lung cancer among those who ever had elevated BLLs (Anttila *et al.*, 1995). Another epidemiological study of 27,060 brain cancer cases and 108,240 controls that died of nonmalignant disease in US from 1984 to 1992 provides evidence for a potential link between occupational exposure to lead and brain cancer (Cocco *et al.*, 1998). A meta-analysis of published data on cancer incidence among workers in various industries with lead exposure indicates a significant excess of cancer deaths from stomach cancer, lung cancer, and bladder cancer (Fu and Boffetta, 1995). Analysis of eight principal studies with well-documented lead exposures suggests associations of lead exposure with increased lung and stomach cancers (Steenland and Boffetta, 2000). However, workers were not only exposed to lead alone, and exposures to other potential carcinogens such as arsenic, cadmium, and engine exhausts could confound these interpretations. Lead does not appear to be directly genotoxic in vivo or in vitro, and lead may interact with other toxicants to facilitate chemical carcinogenesis (Silbergeld, 2003).

Lead is a nephrocarcinogen in adult rodents (Waalkes *et al.*, 1995, 2004c; IARC, 2006). Lead-induced renal tumors also occur after perinatal exposure in the absence of the extensive chronic nephropathy (Waalkes *et al.*, 1995). Metallothionein-null mice, which do not form lead inclusion bodies, are hypersensitive to lead-induced proliferative lesions of the kidney (Waalkes *et al.*, 2004c).

Several mechanisms have been proposed for lead-induced carcinogenesis, including regenerative repair, inhibition of DNA synthesis or repair, generation of reactive oxygen species with oxidative damage to DNA, substitution of lead for zinc in transcriptional regulators, interaction with DNA-binding proteins, and aberrant gene expression (Silbergeld *et al.*, 2000; Qu *et al.*, 2002; Silbergeld, 2003).

Treatment   Chelation therapy is warranted in workmen with BLL > 60 μg/dL. For children, criteria have been established (Laraque and

Table 23-1
Blood Lead Levels (BLL) in Children as an Indicator for Risk Assessment

BLL (μG/DL)	RISK LEVEL	POTENTIAL EFFECT WITH BLL (μG/DL)
<10	I	
10–14	II, moderate	IQ Deficits (10–15), ALA-D inhibition (10)
15–19	II, moderate	Developmental effects (10–15)
20–44	III, high	Increased U-ALA (40), decrease nerve, conduction velocity, hearing, vitamin D metabolism
45–69	IV, urgent	Nephropathy, colic (40–60)
>70	V, emergency	Encephalopathy, anemia (80–100)

Trasande, 2005) that may serve as guidelines to assist in evaluating the individual case with potential health effects (Table 23-1). The oral chelating agent dimercaptosuccinic acid (DMSA, also called Succimer) has advantages over EDTA in that it can be given orally and is effective in temporarily reducing BLL. However, DMSA does not improve long-term BLL in children, nor reduce brain lead levels beyond the cessation of lead exposure alone (Cremin *et al.*, 1999; O'Connor and Rich, 1999). A recent study shows that DMAS lowered BLL in children, but had no detectable benefit on learning and behavior (Dietrich *et al.*, 2004).

Mercury

Mercury (Hg) was named after the Greco-Roman god known for swift flight. Also called quicksilver, metallic mercury is in liquid state at room temperature. The symbol Hg was derived from the Latinized Greek *hydrargyrum*, meaning "water" and "silver." Mercury was known in ancient times from ∼1500 BC. By 500 BC mercury was used to make amalgams with other metals. Mercury vapor (Hg^0) is much more hazardous than the liquid form. Mercury binds to other elements (such as chlorine, sulfur, or oxygen) to form inorganic mercurous (Hg^{1+}) or mercuric (Hg^{2+}) salts. This metal can form a number of stable organometallic compounds by attaching to one or two carbon atoms. Methylmercury (CH_3Hg^+, or MeHg) is the toxicologically most important organic form (ATSDR, 1999). Mercurial compounds have characteristic toxicokinetics and health effects that depend on oxidation state and associated organic species.

Global Cycling and Ecotoxicology   Mercury exemplifies movement of metals in the environment (Fig. 23-6). Atmospheric mercury, in the form of mercury vapor (Hg^0), is derived from natural degassing of the earth's crust and through volcanic eruptions as well as from evaporation from oceans and soils. Anthropogenic sources have become a significant contributor to atmospheric mercury. These include emissions from metal mining and smelting (mercury, gold, copper, and zinc), coal-combustion, municipal incinerators, and chloralkali industries. Mercury vapor is a chemically stable monatomic gas and its residence time in atmosphere is about one year. Thus, mercury is globally distributed even from point resources. Eventually, it is oxidized to a water-soluble inorganic form (Hg^{2+}) and returned to the earth's surface in rainwater. At this stage, the metal may be reduced back to mercury vapor and returned to the atmosphere, or it may be methylated by microorganisms present in sediments of bodies of fresh and ocean water. This natural biomethylation reaction produces methylmercury (MeHg). Methylmercury enters the aquatic food chain starting with plankton, then herbivorous fish, and finally ascending to carnivorous fish and sea mammals. On the top of the food chain, tissue mercury can rise to levels 1800 to 80,000 times higher than levels in the surrounding water. This biomethylation and bioconcentration result in human exposure to methylmercury through consumption of fish (Clarkson, 2002; Risher *et al.*, 2002). Organomercurial compounds are generally more toxic than inorganic mercury to aquatic organisms, aquatic invertebrates, fish, plants, and birds. Organisms in the larval stages are generally more sensitive to toxic effects of mercury (Boening, 2000).

Exposure

Dietary Exposure   Consumption of fish is the major route of exposure to methylmercury. Unlike the case of polychlorinated biphenyls, which are also deposited in fat, cooking the fish does not lower the methylmercury content. Inorganic mercury compounds are also found in food. The source of inorganic mercurial is unknown but the amounts ingested are far below known toxic levels. Mercury in the atmosphere and in drinking water is generally so low that they do not constitute an important source of exposure to the general population (ATSDR, 1999; Clarkson, 2002).

Occupational Exposure   Inhalation of mercury vapor can occur from the working environment, as in the chloralkali industry, where mercury is used as a cathode in the electrolysis of brine. Occupational exposure may also occur during manufacture of a variety of scientific instruments and electrical control devices, and in dentistry where mercury amalgams are used in tooth restoration. In the processing of and extraction of gold, especially in developing countries, large quantities of metallic mercury are used to form an amalgam with gold. The amalgam is then heated to drive off the mercury, resulting in a substantial atmospheric release (ATSDR, 1999; Eisler, 2003).

Medicinal Exposure   Mercury was an important constituent of drugs for centuries and was used as an ingredient in diuretics, antiseptics, skin ointments, and laxatives. These uses have largely been replaced by safer drugs. Thimerosal contains the ethylmercury radical attached to the sulfur group of thiosalicylate (49.6% mercury by weight as ethylmercury), and has been used as a preservative in many vaccines since 1930s. The use of mercury amalgam in dental restoration releases mercury vapor in the oral cavity and can result in increased mercury body burden. However, the amounts are low compared to occupational exposure (Clarkson *et al.*, 2003).

Accidental Exposure   Fatal mercury poisonings come mainly from accidental exposure. Elemental mercury spills can occur in many ways, such as from broken elemental mercury containers, medicinal devices, barometers, and from melting tooth amalgam fillings to recover silver. Inhalation of large amount of mercury vapor can be deadly (Baughman, 2006). Oral ingestion of large amounts of inorganic mercury chloride has also been lethal in suicide cases (ATSDR, 1999). A well-known organomercurial poisoning episode was from consumption of fish contaminated with methylmercury from industrial waste in Minamata, Japan. Consumption of grains and rice treated with methylmercury or ethylmercury as fungicides
Figure 23-6. The Movement of Mercury in the Environment.

In nature, mercury vapor (Hg^0), a stable monoatomic gas, evaporates from the earth's surface (both soil and water) and is emitted by volcanoes. Anthropogenic sources include emissions from coal-burning power stations and municipal incinerators. After $\sim$1 year, mercury vapor is converted to soluble form (Hg^{2+}) and returned to the earth by rainwater. It may be converted back to the vapor by microorganisms and reemitted into the atmosphere. Thus, mercury may recirculate for long periods. Mercury attached to aquatic sediments is subjected to microbial conversion to methylmercury, starting with plankton, then herbivorous fish, and finally ascending to carnivorous fish and sea mammals. This biomethylation and biomagnification result in human exposure to methylmercury through consumption of fish, and poses the health risk to humans, especially the developing fetus.

to prevent plant root diseases in Iraq and China also led to a significant number of poisonings (Clarkson, 2002; Risher *et al.*, 2002). Contact with even a small amount of dimethylmercury (CH_3CH_3Hg) can penetrate laboratory gloves resulting in rapid transdermal absorption, delayed cerebellar damage and death (Nierenberg *et al.*, 1998).

Toxicokinetics

Mercury Vapor   Mercury vapor is readily absorbed (about 80%) in the lungs, rapidly diffuses across alveolar membranes into the blood, and distributes to all tissues in the body due to its high lipid solubility. Once the vapor has entered the cell, it is oxidized to divalent inorganic mercury by tissue and erythrocyte catalase. A significant portion of mercury vapor crosses the blood–brain barrier and placenta before it is oxidized by erythrocytes, and thus shows more neurotoxicity and developmental toxicity compared to administration of inorganic mercury salts which cross membranes less rapidly. After mercury vapor undergoes oxidation, its deposition resembles inorganic mercury. Approximately 10% of mercury vapor is exhaled within a week of exposure, and that converted to inorganic mercury is excreted mainly in urine and feces, with a half-life of 1–2 months (ATSDR, 1999; Clarkson *et al.*, 2003). Liquid metallic mercury,

such as that swallowed from a broken thermometer, is only poorly absorbed by the gastrointestinal tract (0.01%), is not biologically reactive, and is generally thought to be of little or no toxicological consequence.

Inorganic Mercury   Inorganic mercury is poorly absorbed from the gastrointestinal tract. Absorption ranges 7% to 15% of ingested dose, depending on the inorganic compound. A small portion of absorbed inorganic mercury is formed by reduction in tissues and exhaled as mercury vapor. The highest concentration of inorganic mercury is found in kidney, a major target. Renal uptake of mercury salts occurs through two routes: from luminal membranes in renal proximal tubule in the form of the cysteine *S*-conjugates (Cys-*S*-Hg-*S*-Cys) or from the basolateral membrane through organic anion transporters (Bridges and Zalpus, 2005). Inorganic mercury salts do not readily pass blood–brain barrier or placenta and are mainly excreted in urine and feces, with a half-life of about 2 months.

Methylmercury   Methylmercury is well absorbed from the gastrointestinal tract. About 95% of methylmercury ingested from fish is absorbed. It is distributed to all tissues in about 30 hours. About 10% of absorbed methylmercury is distributed to the brain and 5% remains in blood. The concentration in erythrocytes is 20 times that in plasma. Methylmercury is bound to thiol-containing molecules

such as cysteine (CH$_3$Hg-S-Cys), which mimic methionine to cross the blood–brain barrier and placenta through the neutral amino acid carrier. Methylmercury avidly accumulates in hair, and although concentrations are proportional to that in blood, they are about 250-fold higher. Thus, hair mercury is often used as an indicator of exposure. Methylmercury undergoes extensive enterohepatic recycling, which can be interrupted to enhance fecal excretion. Methylmercury is slowly metabolized to inorganic mercury by microflora in intestine (about 1% of the body burden per day). In contrast to inorganic mercury, 90% of the methylmercury is eliminated from the body in the feces, and less than 10% is in the urine, with a half-life of 45–70 days (Clarkson, 2002; Risher *et al*., 2002; Bridges and Zalpus, 2005).

The disposition of ethylmercury is similar to methylmercury. The major differences include that the conversion to inorganic mercury in the body is much faster for ethylmercury, which can result in renal injury. The mercury concentrations in brain are lower for ethylmercury than methylmercury. The half-life for ethylmercury is only 15–20% of that for methylmercury (Clarkson *et al*., 2003).

Figure 23-7. A Dose–Response Simulation of Estimated Methylmercury Body Burden and the Onset and Frequency of Symptoms from Iraq Epidemic Poisoning in 1970s.

Toxicity

Mercury Vapor   Inhalation of mercury vapor at extremely high concentrations may produce an acute, corrosive bronchitis and interstitial pneumonitis and, if not fatal, may be associated with central nervous system effects such as tremor or increased excitability. With chronic exposure to mercury vapor, the major effects are on the central nervous system. Early signs are nonspecific, and this condition has been termed the *asthenic-vegetative syndrome* or *micromercurialism.* Identification of the syndrome requires neurasthenic symptoms and three or more of the following clinical findings: tremor, enlargement of the thyroid, increased uptake of radioiodine in the thyroid, labile pulse, tachycardia, dermographism, gingivitis, hematologic changes, or increased excretion of mercury in urine. The triad of tremors, gingivitis, and erethism (memory loss, increased excitability, insomnia, depression, and shyness) has been recognized historically as the major manifestation of mercury poisoning from inhalation of mercury vapor. Sporadic instances of proteinuria and even nephrotic syndrome may occur in persons with exposure to mercury vapor, particularly with chronic occupational exposure. The pathogenesis is probably immunologically similar to that occuring after exposure to inorganic mercury (ATSDR, 1999; Clarkson, 2002). Mercury vapor release from amalgam is in general too low to cause significant toxicity (Clarkson *et al*., 2003; Factor-Litvak *et al*., 2003; Horsted-Bindslev, 2004).

Inorganic Mercury   Kidney is the major target organ for inorganic mercury (ATSDR, 1999). Although a high dose of mercuric chloride is directly toxic to renal tubular cells, chronic low-dose exposure to mercury salts may induce an immunologic glomerular disease (Bigazzi, 1999). Exposed persons may develop proteinuria that is reversible after they are removed from exposure. Experimental studies have shown that the pathogenesis has two phases including an early phase characterized by an anti-basement membrane glomerulonephritis, followed by a superimposed immune-complex glomerulonephritis with transiently raised concentrations of circulating immune complexes (Henry *et al*., 1988). The pathogenesis of the nephropathy in humans appears similar, although antigens have not been characterized. In humans, the early glomerular nephritis may progress to interstitial immune-complex nephritis (Pelletier and Druet, 1995; Bigazzi, 1999).
Methylmercury   The major human health effect from exposure to methylmercury is neurotoxicity. Clinical manifestations of neurotoxicity include paresthesia (a numbness and tingling sensation around the mouth, lips) and ataxia, manifested as a clumsy, stumbling gait, and difficulty in swallowing and articulating words. Other signs include neurasthenia (a generalized sensation of weakness), vision and hearing loss, and spasticity and tremor. These may finally progress to coma and death. Neuropathological observations have shown that the cortex of the cerebrum and cerebellum are selectively involved with focal necrosis of neurons, lysis, and phagocytosis, and replacement by glial cells. These changes are most prominent in the deeper fissures (sulci), as in the visual cortex and insula. The overall acute effect is cerebral edema, but with prolonged destruction of gray matter and subsequent gliosis, cerebral atrophy results (Takeuchi, 1977). A study of the Iraq epidemic of methylmercury exposure (Bakir *et al*., 1973) has provided dose–response estimates of the body burden of mercury required for the onset and frequency of symptoms (Fig. 23-7).

Mechanism of Toxicity   High-affinity binding of divalent mercury to sulfhydryl groups of proteins in the cells is an important mechanism for producing nonspecific cell injury or even cell death. Other general mechanisms, such as the interruption of microtubule formation, inhibition of enzymes, oxidative stress, interruption of protein and DNA synthesis, and autoimmune responses, have also been proposed (ATSDR, 1999; Clarkson, 2002). Mercury causes overexpression of metallothionein and glutathione system-related genes in rat tissues (Brambila *et al*., 2002; Liu *et al*, 2003), probably as an adaptative mechanism.

Sensitive Sub-populations   Early life stages are particularly vulnerable to mercury intoxication (Counter and Buchanan, 2004). In Minamata, Japan, pregnant women who consumed fish contaminated with methylmercury, manifested mild or minimal symptoms, but gave birth to infants with severe developmental disabilities, raising initial concerns for mercury as a developmental toxicant.

Methylmercury crosses the placenta and reaches the fetus, and is concentrated to a level in fetal brain at least 5–7 times that of maternal blood (Clarkson, 2002). Prenatal methylmercury exposure at high levels can induce widespread damage to the fetal brain. However, the observed effects from low-level exposures are inconsistent (Counter and Buchanan, 2004; Davidson *et al.*, 2004). In the Seychelles Children Development Study, a group with significant methylmercury exposure from a diet predominantly of fish was studied for adverse developmental effects. These children were examined six times over 11 years using extensive batteries of age-appropriate developmental end-points, but no convincing associations were found except for delayed walking (Davidson *et al.*, 2006). The National Research Council reviewed the epidemiologic studies relating in utero methylmercury exposure and fetal neurological development. It concluded that the current EPA reference dose (RfD) for methylmercury of 0.1 μg/kg per day or 5.8 μg/L cord blood is scientifically justifiable for protection of human health (NRC, 2000). The RfD is equivalent to 12 ppm methylmercury in maternal hair.

The safety of thimerosal (ethylmercury) used in childhood vaccines has also received extensive attention. A recent review indicates that thimerosal is safe at the doses used in vaccines, except for a potential for local hypersensitivity (Clarkson *et al.*, 2003). However, some infants may be exposed to cumulative levels of mercury during the first six months of life that may exceed EPA recommendations (Ball *et al.*, 2001). Steps have been rapidly taken to remove thimerosal from vaccines in the US by switching to single-dose vials that do not require preservatives. Nonetheless, the World Health Organization concluded that it is safe to continue using thimerosal in vaccines, which is important for developing countries where it is essential to use multidose vials (Clarkson *et al.*, 2003).

Although the use of mercury amalgam in children can contribute to mercury exposure, the exposure is too low to cause significant toxicological effects (DeRouen *et al.*, 2006).

Acrodynia occurred in children chronically exposed to inorganic mercury compounds in teething powder and diaper disinfectants, as well as to organomercurials. Acrodynia is characterized by pink hands and feet (also called Pink Disease). These subjects are photophobic and suffer from joint pains (Clarkson, 2002).

Treatment Therapy for mercury poisoning should be directed toward lowering the concentration of mercury at the critical organ or site of injury. For the most severe cases, particularly with acute renal failure, hemodialysis may be the first measure, along with administration of chelating agents for mercury, such as cysteine, EDTA, BAL, or penicillamine. Caution should be taken to avoid inappropriate use of chelating agents in putative mercury poisoning patients (Risher and Amler, 2005).

Chelation therapy is not very helpful for alkyl mercury exposure. Biliary excretion and reabsorption by the intestine can be interrupted by oral administration of a nonabsorbable thiol resin, which can bind mercury and enhance fecal excretion (Clarkson, 2002).

Nickel

Nickel (Ni) has been in use since ancient times. However, because the ores of nickel were easily mistaken for ores of silver, a more complete understanding of this metal and its specific use dates to more contemporary times. In 1751, nickel was first isolated from the ore kupfernickel (niccolite) for which it is named. Metallic nickel is produced from sulfide and silicate-oxide ores. In the US ~200,000 metric tons of nickel are used each year. Nickel is used in various metal alloys, including stainless steels and in electroplating. Major properties of nickel alloys include strength, corrosion resistance, and good thermal and electrical conductivity. Occupational exposure to nickel occurs by inhalation of nickel-containing aerosols, dusts, or fumes, or dermal contact in workers engaged in nickel production (mining, milling, refinery, etc.) and nickel-using operations (melting, electroplating, welding, nickel–cadmium batteries, etc.) (ATSDR, 2005d). Nickel is ubiquitous in nature, and the general population is exposed to low levels of nickel in air, cigarette smoke, water, and food. These exposures are generally too low to be of toxicological concern (Kasprzak *et al.*, 2003). Nickel has various oxidation states but the 2+ oxidation state is the most prevalent form in biosystems. The major soluble nickel compounds are nickel acetate, nickel chloride, nickel sulfate, and nickel nitrate. The important water-insoluble nickel compounds include nickel sulfide, nickel subsulfide, nickel oxide, nickel carbonyl, and nickel carbonate (ATSDR, 2005d).

Toxicokinetics Inhaled nickel particles are deposited in the respiratory tract and, as with all inhaled particles, the site of deposition depends on the particle size. Large particles (5–30 μm) deposit in the nasopharyngeal area via impaction, smaller particles (1–5 μm) enter the trachea and bronchiolar region by sedimentation, and particles smaller than 1 μm enter the alveolar space. About 25–35% of the inhaled nickel that is retained in the lungs is absorbed into the blood. The insoluble nickel particles can be taken up into cells by phagocytosis. In the skin the rate of absorption depends on the rate of penetration into the epidermis, which differs for different chemical forms of nickel. In humans, about 27% of a single oral dose of nickel in drinking water is absorbed, whereas only about 1% is absorbed when nickel is given with food. Intestinal nickel absorption occurs through calcium or iron channels, or by the divalent metal transport protein-1 (ATSDR, 2005d).

The main transport proteins of nickel in blood are albumin, histidine, and α_2-microglobulin. Nickelplasmin and metallothionein also bind and transport nickel. Following inhalation exposure, nickel is distributed to the lungs, skin, kidneys, liver, pituitary, and adrenals. The half-life of nickel is 1–3 days for nickel sulfate, 5 days for nickel subsulfide, and more than 100 days for nickel oxide (ATSDR, 2005d). Absorbed nickel is excreted into urine. Urinary nickel correlates closely with exposure to airborne levels of insoluble nickel compounds. Thus, urinary nickel may serve as a suitable measure of current nickel exposure.

The marked differences in carcinogenic activities of various nickel compounds may be due to differences in delivery of nickel to specific cells and subcellular target molecules. For example, injection of animals with crystalline nickel subsulfide or crystalline nickel sulfide results in a high incidence of tumors at the site of injection sites, although tumors are not observed in animals similarly injected with soluble nickel sulfate. The crystalline nickel particles can be actively phagocytized and deliver larger quantities of nickel ions into the nucleus than water-soluble nickel compounds (Kasprzak *et al.*, 2003; Costa *et al.*, 2005).

Essentiality of nickel in higher organisms is questionable, although nickel may be nutritionally essential for some plants, bacteria, and invertebrates. Nickel deficiency syndromes have not been reported in humans and nickel-dependent enzymes or cofactors are unknown (Denkhaus and Kalnikow, 2002).

Toxicity

Contact Dermatitis   Nickel-induced contact dermatitis is the most common adverse health effect from nickel exposure and is found in 10–20% of the general population. It can result from exposure to airborne nickel, liquid nickel solutions, or prolonged skin contact with metal items containing nickel, such as coins and jewelry. Nickel sensitization usually arises from prolonged contact with nickel or exposure to a large dose of nickel. The resulting dermatitis is an inflammatory reaction mediated by type IV delayed hypersensitivity (ATSDR, 2005d).

Nickel Carbonyl Poisoning   Metallic nickel combines with carbon monoxide to form nickel carbonyl ($Ni[CO]_4$), which decomposes to nickel and carbon monoxide on heating to 200˚C (the Mond process). This reaction provides a convenient and efficient method for nickel refining. However, nickel carbonyl is extremely toxic, and many cases of acute toxicity have been reported. Intoxication begins with headache, nausea, vomiting, and epigastric or chest pain, followed by cough, hyperpnea, cyanosis, gastrointestinal symptoms, and weakness. The symptoms may be accompanied by fever and leukocytosis. The more severe cases can progress to pneumonia, respiratory failure, and eventually to cerebral edema and death.

Carcinogenicity   Nickel is a respiratory tract carcinogen in nickel-refining industry workers (IARC, 1990). Risks are highest for lung and nasal cancers among workers heavily exposed to nickel sulfide, nickel oxide, and metallic nickel. A cohort of 418 workers employed in a Finnish refinery reported a twofold increased incidence of lung cancer and a large increase in sinonasal cancers (Karjalainen *et al.*, 1992). A follow-up of this study, including a total of 1155 workers, confirmed an elevated risk of lung and nasal cancers among refinery workers, with a greater risk among workers with a longer latency (greater than 20 years) (Anttila *et al.*, 1998). Because the refining of nickel in the plants that were studied involved the Mond process, with the formation of nickel carbonyl, it was believed for some time that nickel carbonyl was the principal carcinogen. However, additional epidemiologic studies of workers in refineries that do not use the Mond process also showed an increased risk of respiratory cancer, suggesting that the source of the increased risk is the mixture of nickel sulfides present in molten ore. Studies with experimental animals have shown that the nickel subsulfite produces local tumors at injection sites and lung tumors by inhalation in rats. Differences in the carcinogenic activities of nickel compounds may be attributed to variations in their solubility and capacities to provide nickel ions at critical sites within target cells (Sunderman, 1989; Costa, 2005). However, nickel compounds lose their original chemical identity upon entering the blood, so that it is not possible to identify the original source of exposure (Grant and Mushak, 1989). Carcinogenesis studies of soluble nickel compounds have also yielded positive results in rodents (Kasprzak *et al.*, 2003). For instance, nickel acetate is a complete transplacental carcinogen for the rat pituitary and initiator of kidney tumors in the rat (Diwan *et al.*, 1992). However, many rodent studies using soluble nickel compounds or metallic nickel have yielded negative results (Oller, 2002; Sivulka, 2005).

Mechanism for Nickel Carcinogenesis   The carcinogenicity of nickel was thought to be due to the ionic nickel species, but on this basis alone it is difficult to explain the differences in carcinogenic potency between different nickel compounds. Some studies

suggest that water-insoluble crystalline nickel compounds were responsible for lung and nasal cancers (IARC, 1990). However, not all water-insoluble crystalline nickel compounds induce tumors, so factors other than solubility are probably involved.

Carcinogenic nickel particles that are phagocytized and deliver large quantities of nickel ions into the nucleus are generally not mutagenic but are clastogenic (Costa *et al.*, 2005). Crystalline nickel sulfide compounds produce specific chromosomal damage, notable in the heterochromatic long arm of the X chromosome which suffers regional decondensation, frequent deletions, and other aberrations (Costa *et al.*, 2005). Nickel compounds also produce chromosomal abnormalities such as sister chromatid exchange, especially in hetrochromatin, micronuclei formation in human lymphocytes, microsatellite mutations in human lung cancer cells, and mutations in renal cells (Kasprzak *et al.*, 2003).

Epigenetic Effects   A broad spectrum of epigenetic effects occurs with nickel and include alterations in gene expression resulting from DNA hypermethylation and histone hypoacetylation. A notable nickel-inducible gene is Cap43/NDRG1, under the control of the hypoxia-inducible transcription factor (HIF-1). During tumor development, HIF-1 facilitates angiogenesis and regulates numerous genes including glucose transport and glycolysis, which are essential for tumor growth. A correlation of overexpression of Cap43 with the neoplastic state of the cells was noted (Costa *et al.*, 2005). Another nickel-induced gene amplification is the Ect2 gene. The Ect2 protein is overexpressed in nickel-transformed cells, which can cause microtubule disassembly and cytokinesis, and may contribute to morphological changes in cells (Clemens *et al.*, 2005). Nickel produces rather low, but measurable reactive oxygen species in cells and depletes cellular glutathione. Oxidative DNA damage (including the formation of 8-hydroxyguanine and DNA strand breaks), oxidative protein damage and lipid peroxidation, as well as inhibition of DNA repair enzymes, can be observed following nickel exposure (Kasprzak *et al.*, 2003; Valko *et al.*, 2005).

Sunderman and Barber (1988) proposed that nickel interacts with DNA by replacement of zinc in zinc-binding sites of DNA-binding proteins. DNA-binding proteins with finger loop domains have been identified on some proto-oncogenes and are thought to be likely targets for metal toxicity. In addition, nickel may interfere with the metabolism of iron, calcium, magnesium, or manganese to produce its toxic or carcinogenic effects (Kasprzak *et al.*, 2003).

Treatment of Nickel Toxicity   Blood nickel levels immediately following exposure to nickel carbonyl provide a guideline as to the severity of exposure and are an indication for chelation therapy (Sunderman, 1979). Sodium diethylcarbodithioate (DDTC) is the preferred drug. Disulfiram, another nickel-chelating agent, has been used in nickel dermatitis and in nickel carbonyl poisoning. Other chelating agents, such as D-penicillamine and DMPS, provide some degree of protection from clinical effects (Blanusa *et al.*, 2005).

ESSENTIAL METALS WITH POTENTIAL FOR TOXICITY

Cobalt

Cobalt (Co) is a relatively rare, ferromagnetic transition metal first isolated in the 1730s. The name cobalt comes from the German word *kobalt*, which is derived from *kobold* meaning "goblin," a name applied by miners of the time to cobalt ore, which was thought

to be worthless and poisonous. Cobalt is usually not mined alone and tends to be produced primarily as a byproduct of copper and nickel mining. Cobalt is useful in various alloys, where it provides corrosion- and wear-resistance, and in cemented carbides ("hard" metals). It is used in permanent magnets, as a paint or varnish dryer, in catalysts, and in pigments production.

Toxicokinetics The toxicokinetics and possible adverse health effects of inorganic cobalt compounds have been reviewed (Elinder and Friberg, 1986; De Boeck *et al.*, 2003). Cobalt absorption depends on the compound. Less than 5% of an oral dose of cobalt oxide is absorbed whereas about 30% of an oral dose of cobalt chloride is absorbed in rodents (Elinder and Friberg, 1986). Oral absorption of cobalt varies widely in humans, and it is estimated to be between 5% and 45% (Elinder and Friberg, 1986). Increasing doses of cobalt results in a decreasing proportional absorption so increased cobalt levels tend not to cause significant accumulation. Absorption of inhaled cobalt compounds appears to be relatively effective in humans and animals (Elinder and Friberg, 1986). About 80% of absorbed cobalt is excreted in urine, and about 15% is excreted in feces. The liver, kidneys, adrenals, and thyroid have relatively high concentrations. The normal levels in human urine and blood are about 1.0 and 0.18 μg/L, respectively. Cobalt in blood is largely associated with red blood cells.

Essentiality Cobalt is an essential nutrient, in small amounts, to mammals, including humans. The essential form of cobalt is cobalamin, a cobalt-containing tetrapyrrolic ring and critical component of Vitamin B_{12}. Vitamin B_{12} is required for the production of red blood cells and in the prevention of pernicious anemia. Insufficient natural levels of cobalt in the diet of sheep and cattle result in cobalt deficiency disease, characterized by anemia and loss of weight or retarded growth. If other requirements for cobalt exist, they are not well defined (Herbert, 1996).

Toxicity Occupational inhalation of cobalt-containing dust in industrial settings may cause respiratory irritation at air concentrations between 0.002 to 0.01 mg/m^3. Higher concentrations may be a cause of "hard metal" pneumoconiosis, a progressive form of pulmonary interstitial fibrosis. Occupational dermal exposure is sometimes associated with an allergic dermatitis.

Although the data linking cobalt exposure to cancer in humans is considered inadequate (IARC, 1991; NTP, 2004), in rodents, inhalation of cobalt sulfate induces lung tumors, including carcinoma, in rats and mice (Bucher *et al.*, 1999). Repository injections or implantation of various cobalt compounds can produce local sarcomas in rodents (IARC, 1991). The mechanism by which cobalt produces cancer is not defined.

Cobalt can be erythropoietic when excessive amounts are ingested by most mammals, including humans (Elinder and Friberg, 1986). Chronic oral administration of high levels of cobalt for the treatment of anemia can cause goiter, and epidemiologic studies suggest that the incidence of goiter is higher in regions containing increased levels of cobalt in water and soil. The goitrogenic effect has been elicited by the oral administration of 3–4 mg/kg to children in the course of treatment of sickle cell anemia. Intravenous exposure to cobalt can cause increased blood pressure, slowed respiration, tinnitus, and deafness due to nerve damage. Cardiomyopathy with signs of congestive heart failure has been associated with excessive cobalt intake (>10 mg/day), particularly from drinking beer

to which cobalt was added as a foaming agent. Autopsy findings in such cases have found a tenfold increase in the cardiac levels of cobalt. In animals, myocardial degeneration can be produced by cobalt injection. In rats cobalt injection will produce hyperglycemia due to pancreatic β-cell damage (Seghizzi *et al.*, 1994).

Copper

Copper (Cu) has been used for many centuries. By 2000 BC, copper–tin alloys or 'bronze' were in wide use in Europe. In Roman times, copper became known as *cyprium* because so much of it was mined in Cyprus, and eventually Anglicized into *copper*. Copper is an essential element widely distributed in nature. Food, beverages, and drinking water are major sources of exposure in the general population. Daily intake of copper in adults varies between 0.9 and 2.2 mg, and in children between 0.6 to 0.8 mg (WHO, 1998). The Recommended Dietary Allowance (RDA) of copper varies according to age, pregnancy, and lactation, and for adults is 0.9 mg/day (IOM, 2001).

Copper exposure in industry is primarily from inhaled particulates in mining or metal fumes in smelting operations, welding, or related activities. Excess copper in the water represents a risk factor to the aquatic environment, producing endocrine disruption and other toxic effects in fish (Handy, 2003).

Toxicokinetics Approximately 55% to 75% of an oral dose of copper is absorbed from the gastrointestinal tract, primarily in the duodenum. Intestinal copper absorption can be reduced by zinc, iron, molybdate, and fructose (IOM, 2001). The cellular transport and metabolism of copper comprises a series of copper-binding proteins and small peptides, such as albumin, ceruloplasmin, glutathione, metallothionein, and cytosolic copper chaperons, which work in conjunction with copper-ATPases to maintain copper homeostasis (Harris, 2000; Mercer, 2001). Copper levels are maintained mainly through control of excretion, although copper binding to hepatic metallothionein may act as a form of copper storage. In mammals, little copper is excreted into the urine, and the bile is the major route of excretion. Bile secretion, enterohepatic recirculation, and intestinal absorption all help to control copper status.

Essentiality Copper is an essential component of several metalloenzymes, including type A oxidases and type B monoamine oxidases. Of the type B oxidases, cytochrome *c*-oxidase is probably the most important because it catalyzes a key reaction in energy metabolism, and inherited mutational defects can result in severe pathology in humans (Hamza and Gitlin, 2002). Of the type A oxidases, lysyl oxidase plays a major role in the formation and repair of extracellular matrix by oxidizing lysine residues in elastin and collagen, thereby initiating the covalent crosslinkage (Kagan and Li, 2003). Copper/zinc superoxide dismutase is present in most cells, particularly of the brain, thyroid, liver, lung, and blood, and helps protect from oxygen toxicity by reducing superoxide radicals to hydrogen peroxide (Valko *et al.*, 2005).

Copper deficiency is uncommon in humans. Copper deficiency can occur as a result of malnutrition, overdose of molybdenum, or excessive consumption of zinc (Maret and Standstead, 2006). Copper deficiency manifests clinically by hypochromic, microcytic anemia that is refractory to iron supplementation and predisposes to infection. This deficiency is sometimes accompanied by bone abnormalities. Less frequent manifestations are hypopigmentation

of the hair and hypotonia. Biomarkers of copper deficiency include serum and urine copper levels, ceruloplasmin concentration, and copper-dependent enzyme activities (IOM, 2001).

Toxicity   The most commonly reported adverse heath effects of excess oral copper intake are gastrointestinal distress. Nausea, vomiting, and abdominal pain have been reported shortly after drinking solutions of copper sulfate or beverages stored in containers that readily release copper (Pizarro *et al.*, 1999). Ingestion of drinking water with >3 mg Cu/L will produce gastrointestinal symptoms. Ingestion of large amounts of copper salts, most frequently copper sulfate, may produce hepatic necrosis and death. Epidemiological studies have not found any relation between copper exposure and cancer (WHO, 1998).

Hereditary Disease of Copper Metabolism

Menkes Disease   This is a rare sex-linked genetic defect in copper metabolism resulting in copper deficiency in male infants. It is characterized by peculiar hair, failure to thrive, severe metal retardation, neurologic impairment, and death usually by 5 years of age. Bones are osteoporotic with flared metaphases of the long bones and bones of the skull. There is extensive degeneration of the cerebral cortex and of white matter. The gene responsible for Menkes disease, *ATP7A*, belongs to the family of ATPases and is a copper transporter (Fig. 23-8). Deficiency in this copper transporter in Menkes disease blocks copper transport across the basolateral membrane of intestinal cells into the portal circulation, resulting in accumulation of copper in the entrocytes and systemic copper deficiency in the body. The transport of copper to the brain is also blocked, causing severe neurological abnormalities (Mercer, 2001). Animal models for copper deficiency support the importance of adequate copper intake during embyrogenesis and early development (Shim and Harris, 2003).

Wilson Disease   This is an autosomal recessive genetic disorder of copper metabolism characterized by the excessive accumulation of copper in liver, brain, kidneys, and cornea. Serum ceruloplasmin is low and serum copper not bound to ceruloplasmin is elevated. Urinary excretion of copper is high. Clinical abnormalities of the nervous system, liver, kidneys, and cornea are related to copper accumulation. Patients with Wilson disease have impaired biliary excretion of copper, which is believed to be the fundamental cause of the copper overload. Genetic studies have identified the defect in copper transport as mutations of the Wilson disease locus (WND) on chromosome 13, encoding P-type ATPase (*ATP7B*) (WHO, 1998; Harris, 2000). There appears to be several polymorphisms of the defect, which may explain the clinical variability in the disorder. Diagnosis may be suspected with elevated serum copper but must be confirmed by liver biopsy and elevated liver copper (normally 15–55 μg/g versus > 250 μg/g in Wilson disease). Animal models of Wilson disease include the toxic milk (Tx) mouse and the Long–Evans Cinnamon (LEC) rats. Both rodent models develop hepatocellular damage from abnormal copper accumulation associated with mutations in *ATP7B*, but do not exhibit the neurological symptoms associated with the human disease (Shim and Harris, 2003).

Hereditary Aceruloplasnaemia   This is the autosomal recessive genetic disorder of copper-binding protein ceruloplasmin, associ-
Figure 23-8. Pathways of Copper in the Body and Defects in Menkes' and Wilson Diseases.

Copper is absorbed by the enterocytes of the small intestine and transported across the basolateral membrane of enterocytes into the portal circulation. This later process is defective in Menkes' disease patients and results in accumulation of copper in the enterocytes and overall copper deficiency in the body. Most of the newly absorbed copper is normally taken up by the liver. In cases of copper overload, excess copper is excreted in the bile and this process is blocked in Wilson disease, as is the delivery of copper to ceruloplasmin, the principal copper carrier in the blood. Other low molecular weight proteins such as Cu–metallothionein and Cu–histine are also proposed to be important sources of copper to tissues. The transport of copper to the brain is blocked in patients with Menkes' disease, leading to the severe neurological abnormalities (Adapted from Mercer, 2001, with permission from Elsevier).

ated with the iron-overload syndrome. Clinical signs and symptoms include mental confusion, memory loss, dementia, cerebellar ataxia, altered motor function, retinal degeneration, and diabetes (WHO, 1998). Ceruloplasmin-null mice accumulate iron predominantly in organs of reticuloendothelial system. In these mice, hematologic indices and serum iron are abnormal by 10 weeks of age, with profound iron overload in the spleen and liver. Hepatic copper deposition is also approximately doubled in these mice. However, neurodegeneration and diabetes are not observed in these mice (Shim and Harris, 2003).

Indian Childhood Cirrhosis (ICC)   This is a disorder occurring in young children characterized by jaundice due to an insidious and progressive liver disease. Two distinguishing features are a widespread brown orcein staining (indicating copper) and intralobular hepatic fibrosis progressing to portal cirrhosis and chronic inflammation. The etiology is not known but it is suspected that bottle feeding of milk contaminated with copper from storage in brass vessels may be important. However, epidemiological studies also suggest an autosomal recessive genetic component because of strong familial occurrence and high consanguinity among affected children (WHO, 1998).

Idopathic Copper Toxicosis or Non-Indian Childhood Cirrhosis
This is a rare disorder in children similar to ICC occurring in some Western countries. The largest series of cases are reported from the Tyrol region of Austria. This population also used copper vessels to store milk, and the incidence of the disorder has declined since replacement of the copper vessels. A number of other cases have been reported from other parts of the world, some from increased amounts of copper in drinking water (WHO, 1998).

Treatment   Clinical improvement can be achieved by chelation of copper with D-penicillamine, Trien [triethylene tetramine 2HCl)], zinc acetate, and tetrathiomolybdate. The combination of tetrathiomolybdate and zinc acetate is more effective (Brewer, 2005). *N*-Acetylcystein amide can cross the blood–brain barrier and was developed to help prevent neurodegenerative disorders (Cai *et al.*, 2005).

Iron

Iron (Fe) is a very abundant transition metal. Iron came into use around 4000 BC. An early source of iron was from fallen meteorites and the name may derive from the Ethruscan word *aisar* which means "the gods." Iron is an essential metal for erythropoiesis and a key component of hemoglobin, myoglobin, heme enzymes, metalloflavoprotein enzymes, and mitochondrial enzymes. In biological systems, iron mainly exists as the ferrous (2+) and ferric (3+) forms. Toxicologic considerations are important in terms of iron deficiency, accidental acute exposures, and chronic iron overload due to idiopathic hemochromatosis or as a consequence of excess dietary iron or frequent blood transfusions (Yip and Dallman, 1996; IOM, 2001; Papanikolaou and Pantopoulos, 2005).

Toxicokinetics   Iron metabolism is regulated by a complex series of events that maintain homeostasis, mainly involving absorption, storage, and excretion. Heme iron from meat, poultry, and fish is highly bioavailable. Nonheme iron absorption is influenced by its solubility and by other dietary factors, such as vitamin C (ascorbic acid) which enhances uptake. Absorption involves movement of ferrous ions from the intestinal lumen into the mucosal cells via the divalent metal transporter protein-1 (DMT-1) and then transfer from the mucosal cell to the plasma, where iron is bound to transferrin for transport and distribution. Transferrin is a β1-globulin with a molecular weight of 75,000 and is produced in the liver. Transferrin delivers iron to tissues by binding to transferrin receptor-1(TfR1) on the cell membrane, followed by endocytosis. Iron is then released in the acidic endosomal vesicle. The human body contains $\sim$3–5 g of iron. About two-thirds of body iron is in hemoglobin, 10% is in myoglobin and iron-containing enzymes, and the remainder is bound to the iron storage proteins like ferritin and hemosiderin, stored in liver and reticuloendothelial cells in the spleen and bone marrow. Iron stores serve as a reservoir to supply cellular iron needs, mainly for hemoglobin production. Erythrocyte destruction and production are responsible for most iron turnover. Hepcidin, a small peptide of liver origin, modulates iron absorption in response to erythropoiesis (Papanikolaou and Pantopoulos, 2005). The major route of excretion of iron is into the gastrointestinal tract and eventually the feces. Daily iron losses from urine, gastrointestinal tract, and skin are $\sim$0.08, 0.6, and 0.2 mg/day, respectively.

Essentiality and Deficiency   Iron deficiency is the most common nutritional deficiency worldwide, affecting infants, young children, and women of child-bearing age. The critical period for iron deficiency in children is between the ages of 6 months and 2 years. The major manifestation of iron deficiency is anemia with microcytic hypochromic red blood cells. Other effects of iron deficiency include impaired psychomotor development and intellectual performance, decreased resistance to infection, adverse pregnancy outcomes, and possibly increased susceptibility to lead and cadmium toxicity. Oral ferrous sulfate is the treatment of choice for iron deficiency.

Toxicity   Acute iron poisoning from accidental ingestion of iron-containing dietary supplements is the most common cause of acute toxicity. It most often occurs in children. A decrease in occurrence of this type of poisoning followed the introduction of childproof lids on prescription medicines and vitamin supplements. Severe toxicity occurs after the ingestion of more than 0.5 g of iron or 2.5 g of ferrous sulfate. Toxicity occurs about 1–6 hours after ingestion. Symptoms include abdominal pain, diarrhea, and vomiting. Of particular concern are pallor or cyanosis, metabolic acidosis, and cardiac collapse. Death may occur in severely poisoned children within 24 hours. Supportive therapy and iron chelation with deferoxamine should be used as soon as possible. Inhalation of iron oxide fumes or dust may cause pneumoconiosis in occupational settings (Dotherty *et al.*, 2004).

Chronic iron toxicity from iron overload in adults is a relatively common problem. There are three basic ways in which excessive amounts of iron can accumulate in the body. The first is hereditary hemochromatosis due to abnormal absorption of iron from the intestinal tract. Hereditary hemochromatosis is an autosomal recessive disorder attributed to mutation in the hemochromatosis gene. About 90% of patients are homozygous for C282Y mutation, while a few patients are heterozygotes for C282Y with a second mutation for H63D. The frequency of homozygosity is $\sim$0.3–0.4% in populations of European ancestry. The second possible cause of iron overload is excess intake via the diet or from oral iron preparations. The third circumstance in which iron overload can occur is repeated blood transfusions for some form of refractory anemia and is referred to as *transfusional siderosis*. The pathologic consequences of iron overload are similar regardless of the basis. *Hemosiderosis* refers to increased iron stores in the form of hemosiderin. The body iron content can increase 20–40 g, up to 10 times higher than normal levels. *Hemochromatosis* refers to excessive deposition of iron that causes organ damage, often resulting in fibrosis. Inhalation of iron oxide fumes or dust by workers in hematic mines (mainly Fe_2O_3), steel workers, and welders may produce siderosis (nonfibrotic), and in some cases silicosis (fibrotic) in the lung, with increases in total body iron (Doherty *et al.*, 2006). Liver iron overload from hereditary hemochromatosis is associated with a high risk for hepatocellular carcinoma, as well as with other malignancies (Papanikolaou and Pantopoulos, 2005).

Increased body iron may play a role in the development of cardiovascular disease. It is suspected that iron may act as a catalyst to produce free radical damage resulting in artherosclerosis and ischemic heart disease (Alpert, 2004). This iron hypothesis is controversial, but it is clear that mortality from cardiovascular disease is correlated with liver iron overload (Yuan and Li, 2003). Several neurodegenerative disorders are associated with aberrant iron metabolism in the brain, such as neuroferritinopathy,

aceruloplasminemia, and manganism (Aschner *et al.*, 2005; Papanikolaou and Pantopoulos, 2005).

Treatment   Desferrioxamine is the chelator of choice for the treatment of acute iron intoxication and chronic iron overload. Iron chelators have also been proposed for the treatment of cancers with iron overload (Buss *et al.*, 2004).

Magnesium

Magnesium (Mg) was recognized as an element in 1755. The name originates from the Greek word for a district in Thessaly called *Magnesia*. Magnesium is a nutritionally essential metal that plays a key role in a wide range of important fundamental cellular reactions (Shils, 1996). Nuts, cereals, seafood, and meats are good dietary sources of magnesium. The drinking water content of magnesium increases with hardness of the water. Magnesium citrate, oxide, sulfate, hydroxide, and carbonate are widely taken as antacids or cathartics. Magnesium hydroxide, or milk of magnesia, is one of the universal antidotes for poisoning. Topically, the sulfate is also used to relieve inflammation. Parenteral administration of magnesium sulfate has been used in the treatment of seizures associated with eclampsia of pregnancy and acute nephritis.

Toxicokinetics   Oral magnesium is absorbed mainly in the small intestine. The colon also absorbs some magnesium. Calcium and magnesium are competitive with respect to absorption, and excess calcium will partially inhibit magnesium absorption. Serum magnesium levels are remarkably constant. Magnesium is excreted into the digestive tract by the bile and in pancreatic and intestinal juices. Approximately 60–65% of the total body magnesium is in the bone, 27% in muscle, 6–7% in other organs, and only 1% is in extracellular fluid. Of the magnesium filtered by the glomeruli about 95% is reabsorbed, an important factor in maintaining homeostasis.

Essentiality and Deficiency   Magnesium is a cofactor of many enzymes. In the glycolytic cycle, there are seven key enzymes that require divalent magnesium. Magnesium-containing enzymes are also involved in the citric acid cycle and in beta oxidation of fatty acids. Deficiency may occur as a complication of various disease states such as malabsorption syndromes, renal dysfunction, and endocrine disorders. Magnesium deficiency in humans causes neuromuscular irritability, frank tetany, and even convulsions. Magnesium deficiency induces an inflammatory syndrome (Mazur *et al.*, 2007), and is a risk factor for diabetes mellitus, hypertension, hyperlipidemia, and ischemic heart diseases (Ueshima, 2005). Supplementation of magnesium, either by intravenous or oral administration, is beneficial.

Toxicity   In industrial exposures, no ill effects are produced with a twofold increase in serum magnesium, although concurrent increases occur in serum calcium. Inhaled freshly generated magnesium oxide can cause metal fume fever, similar to that caused by zinc oxide. In nonoccupationally exposed individuals, toxicity can occur when magnesium-containing drugs, usually antacids, are ingested chronically by persons with serious renal failure. The toxic effects may progress from nausea and vomiting to hypotension, electrocardiograph abnormalities, central nervous system effects, coma, and systolic cardiac arrest (Shils, 1996). Magnesium toxicity can sometimes be counteracted with calcium infusion.

Manganese

Manganese (Mn) was in use in prehistoric times. Paints that were pigmented with manganese dioxide can be traced back to ancient times. The pure element was isolated in 1774 and named after the Latin *magnes*, meaning "magnet." Manganese is an essential metal required for many metabolic and cellular functions. Manganese metalloenzymes include arginase, glutamine synthetase, phosphoenolpyruvate decarboxylase, and manganese superoxide dismutase (Aschner and Aschner, 2005). Manganese is also a cofactor for a number of enzymatic reactions. Manganese exists in many valences but the divalent cation is by far the predominant species within cells. Divalent manganese may be oxidized to the more reactive and toxic trivalent form. The major source of manganese intake is from the food. Vegetables, grains, fruits, nuts, and tea are rich in manganese. Daily manganese intake ranges from 2 to 9 mg (ATSDR, 2000). The Adequate Intake is 2.3 and 1.8 mg/day for adult men and women, respectively (IOM, 2002).

Occupational exposures to high concentrations of manganese can occur in a number of settings, including manganese dioxide mines and smelters. Significant exposure can also occur in factories making manganese steel alloys, electrical coils, batteries, glass, welding rods, and during production of potassium permanganate ($KMnO_4$). The industrial use of manganese has expanded in recent years as a ferroalloy in the iron industry and as a component of alloys used in welding (Crossgrove and Zheng, 2004).

Environmental exposures are often associated with manganese-based organometallic pesticides, maneb and mancozeb. Manganese intoxication has also been reported after ingestion of contaminated water (ATSDR, 2000; Crossgrove and Zheng, 2004). There is current interest in the toxicology of manganese-containing fuel additive methylcyclopentadienyl manganese tricarbonyl (MMT). In addition, manganese compounds, such as mangafodipir are increasingly used as MRI enhancers in clinical imaging techniques.

Toxicokinetics   Approximately 1–5% of ingested manganese is normally absorbed. Interactions between manganese, and iron, as well as other divalent elements, occur and impact the toxicokinetics of manganese especially following oral exposure (Roth and Garrick, 2003). Iron and manganese can compete for the same binding protein in serum (transferrin) and the same transport systems (divalent metal transporter, DMT1). Inhalation of particulate manganese may result in direct transfer to brain tissue via the olfactory system (Tjalve and Henriksson, 1999). Within the plasma, manganese is largely bound to gamma globulin and albumin, with a small fraction bound to transferrin. Manganese concentrates in mitochondria, so that tissues rich in these organelles, like pancreas, liver, kidneys, and intestines, have the highest concentrations of manganese. Manganese readily crosses the blood–brain barrier and accumulates in specific brain regions (Crossgrove and Zheng, 2004). Manganese is eliminated in the bile and reabsorbed in the intestine. The principal route of manganese excretion is with the feces. Biliary excretion is poorly developed in neonates and exposure during this period may result in increased delivery of manganese to the brain and other tissues (Aschner and Aschner, 2005).

Essentiality and Deficiency   Manganese deficiency has been produced in many species of animals, but questions remain about whether deficiency has actually been demonstrated in humans

(WHO, 1996). Deficiency in animals results in impaired growth, skeletal abnormalities, and disturbed reproductive function.

Toxicity   Chronic manganese-induced neurotoxicity (manganism) is of great concern and the brain is considered the most sensitive organ to manganese. Neurotoxicity due to inhalation of airbone manganese ranging from 0.027 to 1 mg Mn/m^3 has been reported in a number of occupational settings. Overt manganism occurs in workers exposed to aerosols containing extremely high levels (>1–5 mg Mn/m^3). Neurotoxicity also occurs following ingestion of manganese contaminated water (1.8 to 14 ppm; Aschner *et al.*, 2005). Manganism is associated with elevated brain levels of manganese, primarily in those areas known to contain high concentrations of nonheme iron, such as the substantia nigra, basal ganglia, caudate-putamen, globus pallidus, and subthalamic nuclei. Early manifestations of manganese neurotoxicity include headache, insomnia, memory loss, muscle cramps, and emotional instability. Initial outward symptoms progress gradually and are mainly psychiatric. As exposure continues and the disease progresses, patients may develop prolonged muscle contractions (dystonia), decreased muscle movement (hypokinesia), rigidity, hand tremor, speech disturbances, and festinating "cock-walk" gait. These signs are associated with damage to dopaminergic neurons that control muscle movement (Crossgrove and Zheng, 2004; Aschner *et al.*, 2005). Specialized T1-weighted magnetic resonance brain imaging of manganism patients indicates high levels in the basal ganglia and especially in the globus pallidus.

Inhalation of manganese-containing dust in certain occupational settings can lead to an inflammatory response in the lung. Symptoms of lung irritation and injury may include cough, bronchitis, pneumonitis, and occasionally, pneumonia (ATSDR, 2000). Men working in plants with high concentrations of manganese dust show an incidence of respiratory disease that is 30 times greater than normal. Manganese exposure also alters cardiovascular function in animals and humans, as evidenced by abnormal electrocardiogram and the inhibition of myocardial contraction. Manganese dilates blood vessels and induces hypotension (Jiang and Zheng, 2005). When manganese is combined with bilirubin, it produces intrahepatic cholestasis by acting on the synthesis and degradation of cholesterol and the inhibition of the transport pump Mrp2 (Akoume *et al.*, 2003). Liver cirrhosis is a major contributing factor for hepatic encephalopathy, often associated with increased manganese levels in the brain (Mas, 2006).

Interactions between manganese and iron play a role in manganese toxicity. The coaccumulation of iron with manganese in the globus pallidus raises the concern that iron may be a contributing factor facilitating neuronal cell loss during manganese intoxication. Chronic exposure to manganese alters iron concentrations in blood and cerebrospinal fluid, presumably due to manganese–iron interaction at certain iron–sulfur containing proteins, which regulate iron homeostasis. Manganese intoxication in monkeys causes elevated iron deposition in the globus pallidus and substantia nigra. The excess iron may produce oxidative stress via the Fenton reaction, leading to neuronal damage. Dysfunctional iron metabolism has also been seen in manganism patients. Serum parameters associated with iron metabolism, such as ferritin, transferrin, and total-iron-binding capacity are significantly altered (Roth and Garrick, 2003; Crossgrove and Zheng, 2004). High levels of total iron and iron-associated oxidative stress, decreased ferritin, and abnormal mitochondrial complex-1 have been repeatedly re-

ported in postmortem samples of substantia nigra from manganism patients.

Available data indicate that inorganic manganese is not carcinogenic in humans or rodents, and negative in Ames test, but may cause DNA damage and chromosome aberrations in vitro in mammalian cells (Gerber *et al.*, 2002).

Molybdenum

Molybdenum (Mo) was first separated from lead and graphite in 1778. Molybdenum was derived from Greek *molybdos* meaning "lead-like." As an essential element, molybdenum acts as a cofactor for at least three enzymes in humans: sulfite oxidase, xanthine oxidase, and aldehyde oxidase. Molybdenum exists in five oxidation states but the predominant species are Mo^{4+} and Mo^{6+}. Molybdenum concentration in food varies considerably depending on the local environment. Molybdenum is added in trace amounts to fertilizers to stimulate plant growth. The human requirement for molybdenum is low and easily provided by a common US diet. The RDA for molybdenum is 45 μg/day (IOM, 2001).

The most important mineral source of molybdenum is molybdenite (MoS$_2$). The industrial uses of this metal include the manufacture of high temperature-resistant steel alloys for gas turbines and jet aircraft engines and in the production of catalysts, lubricants, and dyes. Ammonium tetrathiomolybdate is used as a molybdenum-donating copper chelator in treatment of Wilson disease (Brewer, 2003).

Toxicokinetics   Water-soluble molybdenum compounds are readily absorbed when ingested. In laboratory animals, gastrointestinal absorption varies between 75% and 95%. In humans, absorption of molybdenum after oral intake varies from 28% to 77% (Vyskocil and Viau, 1999). Once absorbed, molybdenum rapidly appears in blood and most tissues. The highest molybdenum concentrations are found in kidneys, liver, and bones. Very little molybdenum appears to cross the placenta. When elevated exposure is ceased, tissue concentrations quickly return to normal levels. Molybdenum metabolism is related to copper and sulfur. Exposure to molybdenum decreases intestinal absorption of copper and sulfate, and impairs the sulfation of chemicals (Boles and Klaassen, 2000). Excretion, primarily via the urine, is rapid and 36–90% of a dose of molybdenum is excreted in urine in experimental animals. In humans, the urinary excretion ranges from 17% to 80% of the total dose. Very little (<1%) of molybdenum excretion is via bile (Vyskocil and Viau, 1999). When consuming a low-molybdenum diet, the intestinal molybdenum absorption and tissue uptake are increased, while urinary excretion is decreased to reduce the molybdenum loss. With high dietary intake, urinary excretion can be dramatically increased to help eliminate excess molybdenum (Novotny and Turnlund, 2006).

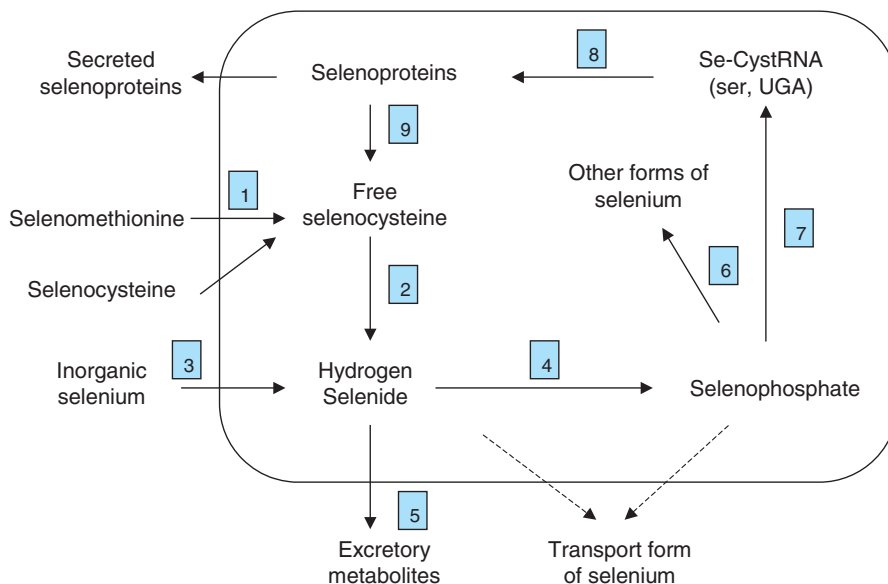
Essentiality and Deficiency   Molybdenum deficiency has been described in various animal species and consists of disturbances in uric acid metabolism and sulfite metabolism. Molybdenum cofactor (Moco) deficiency is a pleiotropic genetic disorder characterized by the loss of the molybdenum-dependent enzymes sulfite oxidase, xanthine oxidoreductase, and aldehyde oxidase, due to mutations in the genes involved with Moco biosynthesis. This rare human genetic metabolic disorder is characterized by severe neurodegeneration resulting in early childhood death (Schwarz, 2005).


Figure 23-9. Selenium Metabolism Pathways.

(1) The transulfuration pathway; (2) seleno-cysteine β-lyase; (3) reduction by glutathione; (4) selenophosphate synthetase; (5) methylation; (6) replacement of sulfur in tRNA by selenium; (7) replacement of oxygen in serine to produce selenocysteine; (8) decoding of UGA in mRNA with insertion of selenocysteine into primary structure of protein; and (9) proteolytic breakdown of proteins. The origin and identity of the transport form for selenium is unknown, as indicated by the broken lines.

Toxicity   Molybdenum is of low toxicity. Chronic exposure to excess molybdenum in humans is characterized by high uric acid levels in serum and urine. A gout-like syndrome has been observed in inhabitants exposed to high levels of environmental molybdenum or among workers exposed to molybdenum in a copper–molybdenum plant (Vyskocil and Viau, 1999). When inhaled, both metallic molybdenum and sparingly soluble molybdenum trioxide have been reported to cause pneumoconiosis. Molybdenosis (teart) is a form of molybdenum poisoning that produces a disease in ruminants similar to copper-deficiency (Barceloux, 1999). Generally, soluble molybdenum compounds are more toxic than insoluble compounds. In many ways molybdenum toxicity resembles copper deficiency. Treatment with supplemental copper can often reverse the adverse effects of excess molybdenum (Vyskocil and Viau, 1999). Conversely, treatment of Wilson disease with molybdenum compounds is used to reduce copper burden. Molybdenum treatment may also be beneficial for angiogenesis, inflammation, and other disorders associated with excess copper (Brewer, 2003).

Selenium

Selenium (Se) was discovered in 1817, and named after the Greek word *selene* meaning moon. Although technically a nonmetal, certain forms have metal-like properties. Selenium is an essential element found in selenoproteins and deficiency is recognized in humans and animals (Ziegler and Filer, 1996). Selenium is also toxic and high doses cause overt selenium poisoning (*selenosis*). The availability and the toxic potential of selenium compounds are related to their chemical forms and, most importantly, to solubility. Selenium occurs in nature and biological systems as selenate (Se^{6+}), selenite (Se^{4+}), selenide (Se^{2+}), and elemental selenium (Se^0) (ATSDR, 2003).

Foods are a good source of selenium. Seafood (especially shrimp), meat, milk products, and grains provide the largest amounts in the diet. Levels of selenium in river water vary, depending on environmental and geological factors. Combustion of coal and other fossil fuels are the primary sources of airborne selenium compounds. Occupational exposure come from selenium refining operations, metal smelting, and milling operations, incineration of rubber tires and municipal waste (ATSDR, 2003).

Toxicokinetics   Orally administered selenite, selenate, and selenomethione are readily absorbed, often greater than 80%, whereas elemental selenium and selenides are virtually insoluble and poorly absorbed. Because of their insolubility, these forms may be regarded as an inert selenium sink. Monogastric animals have higher intestinal absorption than ruminants, probably because selenite is reduced to an insoluble form in rumen. Selenium accumulates in many tissues, with the highest accumulation in the liver and kidney. Selenium is transferred through the placenta to the fetus, and it also appears in milk. Levels in milk are dependent on dietary intake. Selenium in red blood cells is associated with glutathione peroxidase and is about three times more concentrated than in plasma. Selenium is primarily eliminated in urine and feces. In cases of acute exposure to toxic concentrations of selenium, significant amounts are eliminated in expired air, causing the characteristic "garlic breath" (ATSDR, 2003).

Selenium metabolism is well regulated in order to meet several metabolic needs (Fig. 23-9). Inorganic selenium and selenocysteine undergo stepwise reduction to the key intermediate hydrogen selenide, which is either transformed to selenophosphate for selenoprotein synthesis or excreted into breath or urine after being transformed into methylated metabolites of selenide (ATSDR, 2003). Selenophosphate is involved in the synthesis of selenocystein tRNA

according to the UGA code for the selenocysteine residue. The translation of selenoprotein mRNA requires *cis*-acting sequences in the mRNA and transacting factors dedicated to selenocysteine incorporation (Driscoll and Copeland, 2003). Selenoprotein synthesis is highly dependent on selenium availability.

Essentiality and Deficiency   Selenium is notable for its actions in antioxidant systems through involvement in over 20 selenoproteins (Tapiero *et al*., 2003). For instance, glutathione peroxidase is the selenium-dependent enzyme that reduces peroxides using glutathione, and thereby protects membrane lipids, proteins, and nucleic acids from damage by oxidants or free radicals. The enzyme thioredoxin reductase is another selenium-dependent enzyme that has an important role in body's defense against oxidative damage. Selenoprotein P is the major plasma selenoprotein, and serves as an antioxidant in the extracellular space and transports selenium from the liver to other tissues. Selenium W is a low-molecular-weight selenoprotein and may have redox functions. Iodothreonine deiodinases are selenoproteins contributing to systemic or local thyroid hormone homeostasis. Selenium content in endocrine tissues (thyroid, adrenals, pituitary, testes, and ovary) is higher than many other organs. Hormones and growth factors also regulate expression of selenoproteins (Kohrle *et al*., 2005).

The most extensively documented deficiency of selenium in humans is Keshan disease. This is an endemic cardiomyopathy first discovered in Keshan County in China where there are very low concentrations of selenium in the soil and food, and Keshan disease patients show very low plasma selenium levels. This deficiency occurs most frequently in children under 15 years of age and in women of child-bearing age and is characterized by various degrees of cardiomegaly and cardiac decompensation. Deficiency of selenium also occurs in domestic animals and rodents. Selenium supplement reduces these adverse effects (WHO, 1987; Tinggi, 2003).

Kashin-Beck disease is an osteoarthropathy found in areas where combined deficiency of selenium and iodine occur with elevated exposure to mycotoxin and fulvic acids (Sudre and Mathieu, 2001). Selenium deficiency is a major contributing factor in this disease. Other potential effects of selenium deficiency include immune dysfunction, and susceptibility to cancer or infectious/inflammatory diseases (Tapiero *et al*., 2003; Ryan-Harshman and Aldoori, 2005).

The National Research Council's Food and Nutrition Board recommends 200 μg/day as the safe upper limit in adults (Duffield-Lillico *et al*., 2002). Metabolic balance studies in adults indicate about 70 μg/day is required to maintain selenium balance and presumably to satisfy selenium requirement. Data indicate that daily intake less than 20 μg can cause Keshan disease.

Toxicity   Acute selenium toxicity in humans is rare. Intentional or accidental ingestion of a large dose of sodium selenate or sodium selenite can be life-threatening. Symptoms of fatal selenium intoxication include nausea and vomiting, followed by pulmonary edema and rapid cardiovascular collapse (Hunsaker *et al*., 2005).

Chronic selenium toxicity (*selenosis*) can occur with environmental exposure when the intake exceeds the excretory capacity. Effects are mainly dermal and neurological including hair and finger nail loss, tooth discoloration, numbness, paralysis, and occasional hemiplegia. Selenosis occurred in several villages in China where people were exposed to very high selenium in food (ATSDR, 2003). Intoxication from environmental selenium has also been noted in

people residing in Venezuela and South Dakota. Selenium toxicity in animals was recognized in South Dakota when the livestock that had been grazed in areas with high soil selenium developed *alkali disease* and *blind staggers*. In a study of people living in this area, poor dentition, a yellowish discoloration of the skin, skin eruptions, and diseased fingernails and toe nails were found (WHO, 1987).

Plants vary in their ability to accumulate selenium. Grasses, grains, and most weeds do not accumulate selenium even when grown in high selenium areas, so that these plants add little to the selenium content of livestock feed. But there are several plant species that are classified as "selenium accumulators" and they may contain selenium at very high concentrations (100–10,000 mg/kg). These plants usually grow in nonagricultural areas and when consumed by livestock may cause selenium intoxication. Selenium has produced loss of fertility and congenital defects and is considered embryotoxic and teratogenic in animals (WHO, 1987).

Selenium has various bioinorganic interactions, which may affect the toxicity of selenium or other metals. Selenium forms insoluble complexes with various metals, as for example, with arsenic. Selenium complexation can increase the biliary excretion of various metals. Selenium forms complexes with copper, and toxicity of either selenium or copper is influenced by the intake of the other elements. The methylation of selenium can influence other methylation reactions, and can alter arsenic metabolism and toxicity (Zeng *et al*., 2005). Selenium prevents the toxic effects of cadmium and can reduce the toxic effects of methylmercury. The mechanisms for these interactions are only partially understood, but their occurrence influences the determination of safe and toxic levels of selenium for the general population (WHO, 1987, 1996).

Some epidemiologic data have linked low blood selenium levels and increased cancer risk in various populations (ATSDR, 2003). Selenium supplementations appear to decrease human cancer rates, especially for prostate cancer (Duffield-Lillico *et al*., 2002). Increasing selenium content of forage crops has been shown to be beneficial in reducing cancer risk. Some experimental evidence supports a role for selenium in reduction of spontaneous tumors or tumors formed by organic carcinogens in rats and mice. Synthetic organoselenium compounds have been under trial as chemotherapeutics (Tapiero *et al*., 2003).

Trivalent Chromium

Essentiality   Trivalent chromium (Cr^{3+}) is a naturally occurring essential trace nutrient serving an important role in glucose metabolism by enhancing insulin signaling (IOM, 2001). The glucose tolerance factor is a complex of trivalent chromium, nicotinic acid, and amino acids, and physiologically potentiates the action of insulin in glucose, lipid, and protein metabolism (IOM, 2001). Other effects of trivalent chromium include the beneficial roles in growth, immune response, and stress (Ziegler and Filer, 1996). The tissue levels of chromium are reduced among diabetic individuals, but the effects of chromium supplementation in type-2 diabetes are still controversial (Cefalu and Hu, 2004). The adequate intake of chromium is now proposed as 35 and 25 μg/kg/day for men and women, respectively, which is lower than previous 50–200 μg/day. Chromium picolinate, the best-selling nutritional supplement was thought to have adverse effects and might have potential to cause cancer (Vincent, 2004), but more evidence is needed to make conclusions.

Zinc

Zinc (Zn) was named after the German word *zink* meaning tin. Zinc has been used since ancient times, including uses in alloys and medicines. An essential metal, zinc deficiency results in severe health consequences. However, zinc toxicity is relatively uncommon and occurs only at very high exposure levels. Zinc is ubiquitous in the environment so that it is present in most foodstuffs, water, and air. The major route of zinc intake is through the diet, the contents of which vary from 5.2 to 16.2 mg Zn/day (ATSDR, 2005f). Recommend Dietary Allowance for zinc is 11 and 8 mg/day for men and women, respectively (IOM, 2001).

Occupational exposure to dusts and fumes of metallic zinc occurs in zinc mining and smelting. The zinc content of substances in contact with galvanized copper or plastic pipes may be high. Many countries regulate workplace levels of zinc oxide fume and dust at levels between 5 and 10 mg/m^3 (WHO, 1998).

Toxicokinetics The absorption of zinc from the gastrointestinal tract is homeostatically regulated. About 20–30% of ingested zinc is absorbed. Zinc uptake from the intestinal lumen involves passive diffusion and a carrier-mediated process through specific zinc transporters such as ZnT-1. Intestinal absorption of zinc can be reduced by dietary fiber, phytates, calcium and phosphorus, while amino acids, picolinic acid, and prostaglandin E2 can enhance zinc absorption. Once absorbed, zinc is widely distributed throughout the body. The total zinc content of the human body is in the range of 1.5–3 g. Most of this is found in muscle (60%), bone (30%), skin/hair (8%), liver (5%), and pancreas (3%). The highest concentrations of zinc are found in prostate, pancreas, liver, and kidney. In plasma, zinc concentration is about 1 mg/L, and is bound to albumin (60–80%), which represents the metabolically active pool of zinc. The remainder is bound to α_2-macroglobulin and trasferrin. Zinc is excreted in both urine and feces. The concentration of zinc in the plasma is not a sensitive indicator of zinc status and does not reflect the dose–response relationship between zinc levels in the body and effects at various target sites. Zinc ions are involved as inter- and intracellular messengers and the homeostasis of zinc has to be tightly controlled. The most reliable index of zinc status is the determination of zinc balance, using a U-shaped homeostatic model to analyze the relationship between intake and excretion (WHO, 1998).

Zinc is an effective inducer of metallothionein synthesis and, when metallothionein is saturated in intestinal cells, zinc absorption is decreased. Metallothionein is also an important storage depot for cellular zinc. Liver metallothionein concentration is influenced by hormonal factors, including adrenocorticotropic hormone and parathyroid hormone, and various stimuli that impact zinc metabolism. The high concentration of zinc in the prostate is probably related to the rich content of zinc-containing enzyme acid phosphatase.

Essentiality and Deficiency More than 300 catalytically active zinc metalloenzymes and 2000 zinc-dependent transcription factors exist (Ziegler and Filer, 1996; Cai *et al.*, 2005). Zinc participates in a wide variety of metabolic processes, supports a healthy immune system, and is essential for normal growth and development during pregnancy, childhood, and adolescence. Zinc deficiency is related to poor dietary zinc intake, dietary phytate intake, chronic illness, or over-supplementation with iron or copper (Prasad, 2004). Symptoms of zinc deficiency include growth retardation, appetite loss, alopecia, diarrhea, impaired immune function, cognitive impairments, dermatitis, delayed healing of wounds, taste abnormalities, and impaired sexual function (Prasad, 2004; Cai *et al.*, 2005; Cousins, 2006). *Acrodermatitis enteropathica* is a rare genetically based, heredity disorder involving zinc deficiency due to poor intestinal absorption (Perafan-Riveros *et al.*, 2002). Zinc supplementation, alone or with other micronutrients, is recommended for zinc-deficient children, especially in developing countries.

Therapeutic uses of zinc include the treatment of acute diarrhea in infants with severe zinc deficiency, the treatment of common cold by its antiviral and immunomodulatory effects, therapy for Wilson disease to help reduce copper burden and to induce metallothionein, and in the prevention of blindness in age-related macular degeneration (Prasad, 2004).

Toxicity Acute zinc toxicity from excessive ingestion is uncommon, but gastrointestinal distress and diarrhea have been reported following ingestion of beverages standing in galvanized cans. Following inhalation of zinc oxide, and to a lesser extent other zinc compounds, the most common effect is "metal-fume fever" characterized by fever, chest pain, chills, cough, dyspnea, nausea, muscle soreness, fatigue, and leukocytosis. Acute inhalation of high levels of zinc chloride as in the military use of "smoke bombs" results in more pronounced damage to the mucous membrane including interstitial edema, fibrosis, pneumonitis, bronchial mucosal edema, and ulceration. Following long-term exposure to lower doses of zinc, symptoms generally result from a decreased dietary copper absorption, leading to early symptoms of copper deficiency, such as decreased erythrocyte number or decreased hematocrit.

Neuronal Toxicity Zinc has dual effects in the brain. As an essential cofactor for numerous enzymes and proteins, zinc deficiency may alter activity of the antioxidant enzyme Cu–Zn–superoxide dismutase (SOD), resulting in excess free radicals that are damaging to cell membranes (Valko *et al.*, 2005). A genetic abnormality of Cu–Zn–SOD may be the basis of a familial form of amyotrophic lateral sclerosis (Selverstone Valentine *et al.*, 2005). Zinc can also act as a neurotransmitter for normal brain functions (Frederickson *et al.*, 2005; Cousins *et al.*, 2006). Zinc modulates the solubility of β-amyloid in the brain and protects against β-amyloid toxicity, but excess zinc may trigger neuronal death that is independent or synergistic with the toxic effect of β-amyloid (Valko *et al.*, 2005). In addition, excess zinc released by oxidants can act as a potent neurotoxin (Frederickson *et al.*, 2005). Synaptically released zinc might contribute to excitotoxic brain injury, and the release of excess, toxic free zinc into the brain that occurs during excitotoxic brain injury could be a factor that sets the stage for the later development of Alzheimer's disease.

Pancreatic Toxicity Because large amounts of zinc accumulate in secretory granules of pancreatic islet beta-cells, zinc released under certain conditions can affect the function or survival of islet cells and cause beta-cell death. Excess dietary zinc is associated with damage to exocrine pancreas. A single, high-dose injection of zinc increases plasma α-amylase activity and can produce fibrosis and necrosis of pancreatic exocrine cells, but does not affect the islets of Langerhans cells (Cai *et al.*, 2005).

Zinc and Carcinogenicity Epidemiological studies of workers in electrolytic zinc and copper refining industries have not found an

increased incidence of cancer associated with occupational zinc inhalation. Oral zinc supplementation does not appear to have a significant effect on cancer incidence (ATSDR, 2005f). In addition, zinc deficiency may be associated with increased risk of cancer in humans (Prasad and Kucuk, 2002). Zinc supplementation could decrease oxidative stress and improve immune function, which may be a possible mechanism for its cancer preventive activity (Prasad and Kucuk, 2002). In experimental animals, zinc prevents cadmium-induced testicular cancer, but facilitates cadmium-induced prostate tumors (Waalkes, 2003).

METALS RELATED TO MEDICAL THERAPY

Aluminum

Aluminum (Al) is the third most abundant metal in the earth's crust after oxygen and silicon. Elemental aluminum was first identified in 1827. Due to its high reactivity, aluminum is not found in the free-state in nature. Chemical compounds of aluminum occur typically in the trivalent valence state (Al^{3+}). As a hard trivalent ion, aluminum binds strongly to oxygen-donor ligands such as citrate and phosphate. The chemistry of aluminum compounds is complicated by a tendency to hydrolyze and form polynuclear species, many of which are sparingly soluble (Harris *et al*., 1996).

Aluminum has many uses, mainly in the form of alloys, and finds use in packing, construction, transportation, electrical applications, and beverage cans. Aluminum compounds are also used as food additives. Human exposure to aluminum comes primarily from food and secondarily from drinking water. The amount of aluminum in the food supply is small compared to pharmaceutical use of aluminum in antacids and buffered analgesics (Soni *et al*., 2001). Occupational exposures to aluminum occur during mining and processing, as well as in aluminum welding. The levels of exposure can vary greatly according to the type of industry and hygiene conditions. Inhalation of aluminum-containing dust particles is of health concern (WHO, 1997).

Aluminum exists predominantly in forms that are innocuous to humans and most species. However, acid conditions, such as acid rain or dry acid deposition, can dramatically increase the amount of aluminum in ecosystems, resulting in well-described destructive effects on plants, fish, and other wildlife. However, aluminum is not bioaccumulated to any significant extent except in the tea plant (Sparling and Lowe, 1996).

Toxicokinetics   Aluminum is poorly absorbed following either oral or inhalation exposure and is essentially not absorbed dermally. Inhalation of particulate aluminum may result in direct transfer to brain tissue via the olfactory system (Tjalve and Henriksson, 1999). Less than 1% of aluminum in the diet is absorbed. Absorption from the gut depends largely on pH and the presence of complexing ligands, particularly carboxylic acids, through which aluminum becomes absorbable. For example, intestinal absorption is enhanced in the presence of citrate. Biological speciation is also of major importance in distribution and excretion of aluminum in mammals (Harris *et al*., 1996). In plasma, 80–90% of aluminum binds to transferrin, an iron-transport protein with receptors in many tissues. The transferrin pathway is also considered a mechanism for aluminum transport across the blood–brain barrier (Van Landeghem *et al*., 1998). Lung, liver, and bone have the highest concentrations of aluminum (WHO, 1997). Aluminum is removed from blood by the kidneys and excreted in urine. In patients with impaired renal function, tis-

sue aluminum concentrations can increase and are associated with encephalopathy and osteomalacia.

Aluminum compounds can alter absorption of other elements in the gastrointestinal tract. For instance, aluminum inhibits fluoride absorption and may decrease the absorption of calcium and iron compounds and salicylic acid, which, in turn, may affect the absorption of aluminum (Exley *et al*., 1996). The binding of phosphorus by aluminum in the intestinal tract can lead to phosphate depletion and potentially, osteomalacia. Aluminum interacts with calcium in bone and kidney, resulting in aluminum osteodystrophy (Goyer, 1997). Aluminum may also alter gastrointestinal tract motility by inhibition of acetylcholine-induced contractions, which is probably why aluminum-containing antacids often cause constipation.

Toxicity   Acute aluminum toxicity is rare. Most cases of aluminum toxicity in humans are observed in patients with chronic renal failure, or in persons exposed to aluminum in the workplace, with the lung, bone, and central nervous system as major target organs. Aluminum affects similar target organs in animals and can produce developmental effects.

Lung and Bone Toxicity   Occupational exposure to aluminum dust can produce lung fibrosis in humans, but this effect is probably due to lung overload caused by excessive deposition of dust (Morrow, 1992). Osteomalacia has been associated with excessive intake of aluminum-containing antacids in otherwise healthy individuals. This is assumed to be due to interference with intestinal phosphate absorption. Osteomalacia also can occur in uremic patients exposed to aluminum in the dialysis fluid. In these patients, osteomalacia may be a direct effect of aluminum on bone mineralization as bone levels are high (Soni *et al*., 2001).

Neurotoxicity   Aluminum is neurotoxic to experimental animals, with wide species- and age-variations. In susceptible animals, such as rabbits and cats, aluminum toxicity is characterized by progressive neurological impairment resulting in death associated with status epilepticus (WHO, 1997). The most prominent early pathologic change is the accumulation of neurofibrillary tangles (NFTs) in large neurons, proximal axons, and dentrites of neurons of many brain regions. This is associated with loss of synapses and atrophy of the dendritic tree. Not all species show this reaction to aluminum. For instance, rats fail to develop NFTs or encephalopathy and monkeys develop NFTs only after more than a year of aluminum infusion. Impairment of cognitive and motor function and behavioral abnormalities are often observed. Whereas studies in animals have provided some insights into the mechanisms of the neurotoxicity of aluminum in experimental models, the relationship to any human disease is still uncertain.

Dialysis Dementia   This is a progressive, neurologic syndrome reported in patients on long-term intermittent hemodialysis for chronic renal failure (Alfrey, 1993). The first symptom in these patients is a speech disorder followed by dementia, convulsions, and myoclonus. The disorder, which typically arises after 3–7 years of dialysis treatment, may be due to aluminum intoxication. The aluminum content of brain, muscle, and bone increases in these patients. Sources of the excess aluminum may be from oral aluminum hydroxide commonly given to these patients or from aluminum in dialysis fluid derived from the tap water used to prepare the dialysate fluid. The high serum aluminum concentrations may be related to increased

parathyroid hormone levels which are due to low blood calcium and osteodystrophy common in patients with chronic renal disease. The syndrome may be prevented by avoiding the use of aluminum-containing oral phosphate binders and by monitoring of aluminum in the dialysate.

The Chamorro people of the Marina Islands in the Western Pacific Ocean, particularly Guam and Rota, have an unusually high incidence of neurodegeneration of the Alzheimer's type. Garruto *et al*. (1984, 1985) noted that the volcanic soils of the regions of Guam with a high incidence of Amyotrophic Lateral Sclerosis and Parkinsonism-Dementia Syndromes (ALS-PD) contained high concentrations of aluminum and manganese and were low in calcium and magnesium. They postulated that a low intake of calcium and magnesium induced secondary hyperparathyroidism, resulting in an increase in the deposition of calcium, aluminum, and other toxic metals, and eventually in neuronal injury and death. How and why aluminum enters the brain of these people is unclear. The incidence of these disorders dramatically decreased or disappeared during the past 60 years, possibly as the result of radical socioeconomic, ethnographic, and ecologic changes brought about by the rapid westernization of Guam, rather than genetic factors (Garruto *et al*., 1985; Plato *et al*., 2003).

Alzheimer's Disease   A possible relationship between aluminum and Alzheimer's disease has been a matter of speculation for decades. The basis for this relationship is the finding of increased aluminum levels in Alzheimer brains, neurofibrillary lesions in experimental animals, and the fact that aluminum is associated with various components of the pathologic lesions in Alzheimer brain tissue. However, elevated aluminum levels in Alzheimer brains may be a consequence and not a cause of the disease. The reduced effectiveness of the blood–brain barrier in Alzheimer's might allow more aluminum into the brain. Also, recent studies have raised the possibility that the staining methods in earlier studies may have lead to aluminum contamination (Makjanic *et al*., 1998). Furthermore, the neurofibrillary tangles seen in aluminum encephalopathy differ structurally and chemically from those in Alzheimer's (WHO, 1997). Epidemiological studies examining the role of aluminum exposure in Alzheimer's disease arrive at conflicting conclusions. An examination of 20 epidemiological studies concluded that there is not enough evidence to support a primary causative role of aluminum in Alzheimer's disease, and aluminum does not induce Alzheimer's pathology in vivo in any species, including humans (WHO, 1997). However, there is increasing evidence suggesting a link between aluminum in the brain and other neurodegenerative diseases (Kawahara, 2005).

Treatment   Chelation therapy for aluminum, mostly in dialyzed and/or uremic patients, resembles that for iron overload, with deferoxamine and deferiprone (Blanusa *et al*., 2005).

Bismuth

Bismuth (Bi) is a metal with a stable valence of 3+. The name *bisemutum* is from German *Wismuth*, perhaps from the term *weiße Masse*, for "white mass." It was confused in early times with tin and lead due to its resemblance to those elements. Bismuth was shown to be distinct from lead in 1753. The solubility of most bismuth salts is low but can be affected by pH and the presence of sulfhydryl- or hydroxy-containing ligands. The significance of environmental

and occupational bismuth exposure is unknown. Human exposure to bismuth generally is due to medicinal use.

Trivalent insoluble bismuth salts such as bismuth subnitrate, subcarbonate, and subgallate, are used for various gastrointestinal disorders including diarrhea, flatulence, constipation, cramps, and dyspepsia. Colloidal bismuth subcitrate, bismuth subsalicylate, and the more recently developed ranitidine bismuth citrate, are widely used to treat peptic ulcer and *Helicobacter pylori* associated gastritis. Outdated medicinal applications include the use of bismuth salts for treatment of syphilis, malaria, warts, stomatitis, and infections of the upper respiratory tract (Slikkerveer and de Wolf, 1996). A new potential application includes the use of bismuth subnitrate to prevent cisplatin nephrotoxicity, probably due to a specific induction of renal metallothionein (Kondo *et al*., 2004). The use of alpha-particle emitting bismuth compounds as radio-therapeutic agents, and the use of certain bismuth compounds as antitumor agents show some promise (Tiekink, 2002).

Toxicokinetics   Most bismuth compounds are insoluble and poorly absorbed from the gastrointestinal tract or when applied to the skin. The three widely used compounds, colloidal tripotassium dicitrato bismuthate, bismuth subsalicylate, and ranitidine bismuth citrate are all poorly absorbed (<1%) (Tillman *et al*., 1996). The highest concentrations of bismuth are found in kidneys, and to a lesser extent in the brain, liver, and bone (Slikkerveer and de Wolf, 1996; Larsen *et al*., 2005). Passage of bismuth into the amniotic fluid and fetus has been demonstrated. Bismuth is cleared from the body through urine and feces (Gregus and Klaassen, 1986). Traces of bismuth can be found in milk and saliva. The elimination half-life is reported to be about 21 days, depending on bismuth compounds.

Toxicity   Bismuth-containing medications are consumed worldwide and the risk of bismuth-related toxicity in the general population is relatively low. The main target organs for bismuth toxicity are kidney, brain, and bone (Slikkerveer and de Wolf, 1996; Tillman *et al*., 1996; Larsen *et al*., 2005). Acute renal injury is related to very high doses of bismuth, or to oral intake of organic bismuth compounds such as bismuth sodium triglycocollamate or thioglycollate, particularly in children. The tubular epithelium is the primary site of toxicity, where bismuth produces degeneration of renal tubular cells and nuclear inclusion bodies composed of bismuth–protein complex analogous to those found with lead exposure (Fowler and Goyer, 1975). A large single oral dose of colloidal bismuth subcitrate damages the proximal tubes, but the damage is reversible in both humans and animals (Leussink *et al*., 2001).

An episode of bismuth-associated encephalopathy in France in the 1970s revealed a potential neurotoxic effect of bismuth, although it cannot be exclusively attributed to bismuth alone (Slikkerveer and de Wolf, 1996). Using autometallography, high amounts of bismuth were found in the reticular and hypothalamic nuclei, in the oculomotor and hypoglossal nuclei and in Purkinje cells following 8-month exposure to bismuth. Axonal transport seems to influence the distribution of bismuth. Ultrastructurally, accumulation of bismuth was seen in lysosomes (Larsen *et al*., 2005).

Treatment   The most effective treatment of bismuth toxicity is to discontinue bismuth intake. Chelation therapy using dimercaprol (BAL), 2,3-dimercaptoduccinic acid (DMSA), and 2,3-dimercapto-propane-1-sulfonic acid (DMPS) reduces the bismuth concentration in most organs (especially kidney and liver) and increase elimination

of bismuth in urine. BAL was the only chelator effective in lowering brain bismuth concentrations (Slikkerveer and de Wolf, 1996).

Gallium

Gallium (Ga) has a very low melting point with the main valence state of 3+ (gallic), although the 2+ (gallous) form can also form stable gallium compounds. Gallium, stemming from *Gallia* meaning Gaul or France, was predicted to exist prior to being discovered in 1875 by its characteristic spectrum. Gallium is of interest because of the use of radiogallium as a diagnostic tool for the localization of bone lesions. Nonradioactive gallium nitrate has been used as an antitumor agent and in the treatment of hypercalcemia. Gallium is obtained as a by-product of copper, zinc, lead, and aluminum refining and is used in high-temperature thermometers, as a substitute for mercury in arc lamps, as a component of metal alloys, and as a seal for vacuum equipment. Gallium arsenide is a widely used semiconductor material. Gallium is the only metal other than mercury that is liquid at, or near room temperature.

Toxicokinetics   Gallium salts are sparingly absorbed from the gastrointestinal tract, but accumulation in tissues can be observed after repeated administrations. The oral bioavailability is improved with gallium complexes such as gallium maltolate. Gallium accumulates mainly in bone, inflammatory lesions, and tumors, as well as in the liver, spleen, and kidney. Gallium binds to plasma transferrin and enters cells by iron transport mechanisms. Urine is the major route of gallium excretion (Bernstein, 1998; Jakupec and Keppler, 2004).

Toxicity   The trivalent gallium cation biologically resembles ferric iron. It affects cellular acquisition of iron by binding to transferrin and interacts with the iron-dependent enzyme ribonucleotide reductase, resulting in decreased dNTP pools and inhibition of DNA synthesis (Bernstein, 1998). The abundance of transferrin receptors and ribonucleotide reductase renders tumor cells susceptible to the cytotoxicity of gallium. Use of bolus intravenous injection of gallium nitrate in the treatment of lymphoma and bladder cancer is limited by potential nephrotoxicity, which can be reduced by slow continuous infusion over several days (Jakupec and Keppler, 2004). Gallium nitrate is an effective treatment for cancer-related hypercalcemia and diseases associated with accelerated bone loss including myeloma, bone metastasis, Paget's disease, and osteoporosis. It accumulates in metabolically active regions of bone and favorably alters the mineral properties to enhance hydroxyapatite crystallization and reduce mineral solubility. Gallium inhibits osteoclastic bone resorption without poisoning the osteoclast cells, yielding a skeletal system with increased calcium and phosphate content and improved strength (Bockman, 2003). Adverse effects may include nausea, vomiting, and anemia. Less frequent are gallium-induced neurologic, pulmonary, and dermatologic effects.

Acute and chronic toxicity to lung, testes, and kidney are associated with exposures of gallium arsenide in animals, although the role of the individual metals in this response is unclear (Tanaka, 2004). There is little information regarding adverse effects of gallium compounds following occupational exposure.

Gold

Gold (Au) was well known and highly valued since prehistoric times. Gold is widely distributed but usually in small quantities. The metal has a number of industrial uses because of its electrical and thermal conductivity. Monovalent organogold salts (e.g., auranofin, aurothioglucose, gold sodium thiomalate) are used for the treatment of rheumatoid arthritis. Mono- and trivalent coordinated gold complexes have antitumor potential (Kostova, 2006). The health risks associated with gold mining, especially miners who used elemental mercury to amalgamate and extract gold, have been recently reviewed (Eisler, 2003).

Toxicokinetics   Gold salts are poorly absorbed from the gastrointestinal tract. The more water-soluble, therapeutic gold compounds are absorbed after intramuscular injection, and peak concentration in blood is reached in 2–6 hours. Gold is initially bound to serum albumin, and then distributes to various tissues. With continued therapy, the concentration of gold in synovium of affected joints is 10 times that of muscle, bone, or fat. Gold deposits are also found in macrophages, kidney, liver, testes, and skin. About 60–90% of gold is excreted via the kidney while 10–40% occurs via biliary excretion into feces. Chelators such as dimercaprol may increase the excretion of gold. Gold has a long biological half-life, and elevated tissue and blood levels can be demonstrated for months after cessation of treatment.

Toxicity   Contact dermatitis is the most frequently reported toxic reaction to gold and is sometimes accompanied by stomatitis, probably involving an allergic mechanism. Gold-induced allergic responses include delayed hypersensitivity, formation of intracutaneous nodules and immunogenic granuloma, as well as the occurrence of eczema (Hostynek, 1997).

The use of gold in the form of organic salts to treat rheumatoid arthritis may be complicated by the development of proteinuria and the nephrotic syndrome, which morphologically consists of immune-complex glomerulonephritis, with granular deposits along the glomerular basement membrane and in the mesangium (Hostynek, 1997; Bigazzi, 1999). The pathogenesis of the immune-complex disease is not certain, but gold may behave as a hapten and generate the production of antibody complexes for the glomerular deposits (Voil *et al*., 1977).

Gold miners have increased frequency of pulmonary diseases, including tumors, and increased prevalence of infectious diseases. Mercury intoxication associated with gold mining activities is well documented (Eisler, 2003).

Lithium

Lithium (Li) is one of the lightest metallic elements. Lithium was discovered in 1817, and the name was derived from the Greek *lithos* for stone. Lithium shares its group with sodium and potassium, and is widely distributed in nature. Lithium is used in batteries, alloys, catalysts, photographic materials, and in the space industry. Lithium hydride produces hydrogen on contact with water and is used in manufacturing electronic tubes, in ceramics, and in chemical analysis. Groundwater contamination with lithium from man-made waste disposal could be a risk factor for the aquatic environment (Kszos and Stewart, 2003). Lithium carbonate and lithium citrate are widely used for mania and bipolar disorders. In this regard, lithium is active possibly through its effects on signal transduction, such as phosphoinositide hydrolysis, glycogen synthase kinase-3, and neurotropic cascades (Lenox and Hahn, 2000; Quiroz *et al*., 2004). Topical applications of lithium succinate are still used in the treatment of seborrhoic dermatitis (Sparsa and Bonnetblane, 2004).

Toxicokinetics Lithium is readily absorbed from the gastrointestinal tract, with peak therapeutic levels at 30 minutes to 3 hours postingestion. Lithium is not bound to plasma proteins but is associated with red blood cells. Lithium is distributed to total body water with higher levels in kidney, thyroid, and bone as compared to other tissues. Excretion is chiefly through the kidneys with 80% of the filtered lithium reabsorbed. The usual elimination half-life is 12–27 hours, but it may rise to nearly 60 hours if renal function is compromised. Lithium can substitute for sodium or potassium on several transport proteins. It enters cells via the amiloride-sensitive sodium channel or the Na/H^+ exchanger. The greater part of lithium is retained in the cells, perhaps at the expense of potassium. In general it may be competing with sodium at certain sites, such as in renal tubular reabsorption (Timmer and Sands, 1999).

Toxicity From the industrial point of view, except for lithium hydride, none of the other salts is considered hazardous, nor is the metal very toxic itself. Lithium hydride is intensely corrosive and may produce burns on the skin because of the formation of hydroxides (Cox and Singer, 1981). Intoxications related to lithium exposure are mainly related to its medicinal uses (Timmer and Sands, 1999), as the therapeutic index of lithium is very narrow. In this regard, 0.7–1.2 mmol/L is considered an adequate therapeutic blood level, while blood levels only threefold higher commonly result in severe symptoms such as seizures and coma. The toxic responses to lithium include neuromuscular changes (tremor, muscle hyperirritability, and ataxia), central nervous system disorders (blackout spells, epileptic seizures, slurred speech, coma, psychosomatic retardation, and increased thirst), cardiovascular disturbances (cardiac arrhythmia, hypertension, and circulatory collapse), gastrointestinal symptoms (anorexia, nausea, and vomiting), and renal damage (albuminuria and glycosuria). The renal lesions are believed to be due to temporary hypokalemic nephritis. Long-term sequelae from acute lithium poisoning include cognitive losses such as impaired memory, attention and executive functions, and visuospatial deficits (Brumm *et al.*, 1998).

Chronic lithium nephrotoxicity and interstitial nephritis may occur with long-term exposure even when lithium levels remain within the therapeutic range. Lithium nephrotoxicity primarily targets distal and collecting tubes, with a higher incidence of proteinuria and associated glomerular pathology (Markowitz *et al.*, 2000). Chronic lithium-induced neurotoxicity, nephritis and thyroid dysfunction may occur, especially in susceptible patients with identifiable clinical risk factors such as nephrogenic diabetes insipididus, older age, abnormal thyroid function, and impaired renal function (Oakley *et al.*, 2001).

Lithium overdose and toxicity may be treated by the administration of diuretics (amiloride) and lowering of blood levels via hemodialysis. Treatment with diuretics must be accompanied by replacement of water and electrolytes (Timmer and Sands, 1999).

Platinum

Platinum (Pt) is a malleable, ductile, silvery-white noble metal. Naturally occurring platinum and platinum-rich alloys have been known for a long time. The first European reference to platinum appeared in 1557 and the element was isolated in 1741. In platinum compounds, the maximum oxidation state is 6+, while the 2+ and 4+ valences are most stable. Platinum is found in nature either in the metallic form or in a number of mineral forms in various ores. Environmental platinum levels are very low. Platinum compounds are used as automobile catalysts, in jewelry, in electronics, and in dental alloys. Platinum coordination complexes are very important antitumor agents. Occupational exposure can be higher than the exposure limit of 2 $\mu g/m^3$ in some settings (WHO, 1991).

Toxicokinetics Following a single inhalation exposure, most of the inhaled platinum is rapidly cleared from the lungs by mucociliary action, swallowed, and excreted in the feces, with half-life of about 24 hours. A small portion is detected in the urine, indicating very little platinum is absorbed. After intravenous administration of clinical doses, the drug has an initial elimination half-life in plasma of 25–50 min. More than 90% of the platinum in the blood is covalently bound to plasma proteins. After administration of the main metallochemotherapeutic form, cis-dichlorodiammine platinum(II) (cisplatin), high concentrations are found in the kidney, liver, intestine, spleen, and testes, but there is poor penetration into the brain. Only a small portion of the drug is excreted by the kidney during the first 6 hours. By 24 hours up to 25% is excreted, while by 5 days up to 43% of the administered dose is recovered in the urine (WHO, 1991; Hardman *et al.*, 2001).

Toxicity Platinum can produce profound hypersensitivity reactions in susceptible individuals (WHO, 1991). The signs of hypersensitivity include urticaria, contact dermatitis of skin, and respiratory distress, ranging from irritation to an asthmatic syndrome, following exposure to platinum dust. The skin and respiratory changes are termed *platinosis*. They are mainly confined to persons with a history of industrial exposure to soluble compounds such as sodium chloroplatinate, although cases resulting from the wearing of platinum jewelry have been reported (WHO, 1991). The complex salts of platinum may act as powerful allergens, particularly ammonium hexachloroplatinate and hexachloroplatinic acid. Platinum salt sensitization may persist for years after cessation of exposure (Brooks *et al.*, 1990). Halogeno complex salts of platinum are potent allergens provoking Type I allergic symptoms in platinum refining workers. Skin prick tests can detect sensitization at an early stage and is the mainstay of surveillance programs (WHO, 1991; Linnett, 2005).

Antitumor Effects of Platinum Complexes The platinum-coordinated complexes are important antitumor agents, including cisplatin, carboplatin, and oxaliplatin (Hardman *et al.*, 2001). They are routinely administered, often in combination with other anticancer drugs, in the treatment of a wide spectrum of malignancies, especially epithelial cancers. They have become the foundation for curative regimens for advanced testicular cancer and have notable activity against cancers of head and neck, bladder, esophagus, lung, and ovary (Hardman *et al.*, 2001). Platinum complexes are neutral and have a pair of *cis*-leaving groups. Low intracellular chloride concentrations favor hydrolysis of chloride-leaving groups in cisplatin to yield a positively charged molecule, which then reacts with DNA and proteins, forming both intrastrand and interstrand DNA cross-links with guanine and/or adenine. In tumor cells, the replication of DNA is impaired due to cisplatin-induced DNA cross-links, while in normal cells, guanine is repaired before replication. The formation of DNA-adducts with platinum is also responsible for cytotoxicity (WHO, 1991; Hardman *et al.*, 2001).

Carcinogenic Effects of Platinum Complexes Although cisplatin has antitumor activity in humans, it is considered to be a probable

carcinogen in humans (IARC, 1987) and is clearly carcinogenic in rodents. In fact, in mice deficient in metallothionein, cisplatin can induce tumors at clinically relevant doses (Waalkes *et al.*, 2006c). Cisplatin is a strong mutagen in bacterial systems and causes chromosomal aberrations in cultured hamster cells and a dose-dependent increase in sister chromatid exchanges.

Toxicities of Platinum Antitumor Complexes Cisplatin is a nephrotoxin, which often compromises its usefulness as a therapeutic agent. Platinum compounds with antitumor activity produce proximal and distal tubular cell injury, mainly in the corticomedullary region, where the concentration of platinum is highest (Madias and Harrington, 1978). Associated with cisplatin nephrotoxicity is the risk for electrolyte abnormalities. In comparison, carboplatinum and oxaliplatinum, given at standard chemotherapeutic doses, are not considered as highly nephrotoxic (Markman, 2003).

Neurotoxicity is another dose-limiting factor, particular when platinum complexes are combined with other potential neurotoxic drugs such as paclitaxel. Hearing loss can occur and can be unilateral or bilateral but tends to be more frequent and severe with repeated doses. Marked nausea and vomiting occur in most patients receiving the platinum complexes but can be controlled with ondanserton or high-dose of corticosteroids. Bone marrow suppression, manifested as anemia, neutropenia, and thrombocytopenia are relatively common during treatment with platinum complexes, especially when given in combination with fluorouracil. Carboplatin treatment has a higher myelotoxic risk than cisplatin and oxaliplatin (Hardman *et al.*, 2001; Markman, 2003).

MINOR TOXIC METALS

Antimony

Antimony (Sb) is a metalloid that belongs to the same periodic group as arsenic. Antimony was recognized in antiquity (3000 BC or earlier) in various compounds for its fine casting qualities, and the description of its isolation appeared in 1540. The name antimony may come from the Greek words "anti" and "monos," which means "opposed to solitude" as it was thought never to exist in its pure form. Most antimony compounds are of tri- and pentavalent states. Antimony has many uses including in alloys, and in production of fireproofing chemicals, ceramics, glassware, and pigments. Antimony potassium tartrate has been used medically in the treatment of schistosomiasis, and pentavalent antimony compounds are preferred drugs for leishmaniasis (DeBoeck *et al.*, 2003). Similar to arsenic trioxide, trivalent antimony compounds also show some antitumor potential (Tiekink, 2002). Occupational antinony exposure comes from industrial emissions. Food is the major route for environmental exposure, but the exposure levels are generally low. The average daily intake from food and water is estimated at about 5 μg (ATSDR, 1992).

The disposition of antimony in the body resembles that of arsenic (Gebel, 1997). Most antimony compounds are absorbed from the lung and the gastrointestinal tract. The major sites of antimony accumulation are the liver, kidney, lung, spleen, and blood. The accumulation of antimony in blood may be due to high affinity of trivalent antimony for erythrocytes (ATSDR, 1992). In humans and rodents, pentavalent antimony is only sparingly reduced to the trivalent form, and evidence of antimony methylation in mammals is low (Gebel, 1997). The pentavalent form is predominantly excreted in urine, whereas trivalent antimony is conjugated to GSH and is excreted via the bile and found mainly in feces.

Toxicity Most information about antimony toxicity has been obtained from industrial experiences. Occupational exposures are usually by inhalation of dust containing antimony compounds, such as the pentachloride, trichloride, trioxide, and trisulfide. Acute toxicity from the pentachloride and trichloride exposures include rhinitis and, in severe exposures, even acute pulmonary edema. Chronic exposure by inhalation of other antimony compounds results in rhinitis, pharyngitis, trachitis, and, over the longer term, bronchitis and eventually pneumoconiosis with obstructive lung disease and emphysema. Transient skin eruptions (antimony spots) may occur in workers with chronic exposure (Elinder and Fridberg, 1986). Trivalent forms of antimony appear more toxic and may produce cardiotoxicity involving arrhythmias, myocardial damage, and cardiac arrest (Winship, 1987). In rodent subchronic/chronic studies with antimony potassium tartrate, relatively low toxicity was reported (Lynch *et al.*, 1999).

The chemico-toxicological similarity between arsenic and antimony has prompted research on mutagenic and carcinogenic potential of antimony compounds. Antimony trioxide is considered an animal carcinogen (IARC, 1987), but human data is difficult to evaluate given frequent co-exposure to arsenic (Leonard and Garber, 1996; DeBoeck *et al.*, 2003). Antimony compounds are generally negative in nonmammalian genotoxicity tests, while mammalian tests usually give positive results for trivalent but negative results for pentavalent antimony compounds. The in vivo potential of antimony to induce chromosome aberrations appears inconsistent (Leonard and Gerber, 1996; DeBoeck *et al.*, 2003).

The metal hydride of antimony, stibine (SbH_3), is a highly toxic gas that can be generated when antimony is exposed to reducing acids or when certain batteries are overcharged. High-purity stibine is also used in the production of semiconductors and, like arsine (AsH_3), causes hemolysis.

Barium

Barium (Ba) is an alkaline earth metal found in environment in the 2+ oxidation state. Barium was first identified in 1774, and named after the Greek word *barys* meaning "heavy." Barium and barium compounds are used in electronics (barium alloys), as rodenticides (barium carbonate), as pigments (barium carbonate and sulfate), and as X-ray contrast media (barium sulfate). Barium is relatively abundant in nature and is found in plants and animal tissue. Some foods, such as Brazil nuts, pecans, and seafood, may contain high amounts of barium. Barium from natural sources may exceed Federal government standards in some freshwater, although the amount of barium found in food and water usually is not high enough to be a health concern. Occupational exposure to barium primarily occurs in workers who inhale barium sulfate from working with the ore, barite, and barium carbonate dust during the mining and manufacturing (ATSDR, 2005b).

Insoluble barium sulfate is not absorbed from the gastrointestinal tract, and is nontoxic to humans. Ingested soluble compounds are absorbed, but vary greatly and are affected by many factors such as age, duration, dose, and amounts of other elements in the intestine. Aerosols of soluble barium compounds are well absorbed in the lung. Bone and teeth are the major sites of barium deposition, containing up to 90% of the body burden. The remainder of barium in the body is found in soft tissues, such as the lung, aorta, brain,

heart, spleen, liver, and pancreas (Dallas and Williams, 2001). Once filtered by the glomeruli, barium is reabsorbed by the renal tubules with only small amounts appearing in the urine. The major route of barium excretion is the feces. The elimination half-life is about 3 to 4 days.

Toxicity   Occupational poisoning by barium is uncommon, but a benign pneumoconiosis (*baritosis*) may result from inhalation of barium sulfate (barite) dust or barium carbonate. This is not incapacitating and is usually reversible with cessation of exposure. Accidental poisoning from ingestion of an acute toxic dose (over 200 mg) of soluble barium salt results in intractable vomiting, severe diarrhea, and gastrointestinal hemorrhage. Cardiac arrest is often the cause of death (ATSDR, 2005f). Profound hypokalemia and muscle weakness progressing to flaccid paralysis are the hallmarks of barium poisoning (Johnson and VanTassell, 1991). The mechanism of toxicity probably involves the blocking of calcium activated potassium channels responsible for cellular efflux of potassium. As a result, intracellular potassium rises and extracellular levels fall leading to hypokalemia. The progressive muscle weakness seen in barium intoxication in humans could be due to barium-induced hypokalemia rather than a direct effect on muscles, which is not observed in experimental animals. Treatment with intravenous potassium appears beneficial.

Following long-term exposure to barium, nephrotoxicity has been observed in rats and mice. Animal studies designed to assess cardiovascular function have not found significant alterations. Barium compounds are not considered carcinogenic in rodents and there is no evidence in humans (ATSDR, 2005f; Dallas and Williams, 2001).

Cesium

Cesium (Cs) is a soft silvery-gold alkali metal discovered in 1860, and named after the Latin word *caesius* meaning "sky blue." Similar to mercury and gallium, metallic cesium exists in the liquid state at slightly above room temperature, and is used in vacuum tubes and in atomic clocks. Cesium compounds only have the 1+ oxidation state, and are used as catalysts in inorganic chemistry, in pharmaceuticals, as well as in scintillation counters. ^{137}Cesium is a by-product of nuclear reactions and is used in radiation therapy (ATSDR, 2004).

The Chernobyl nuclear plant accident in 1986 resulted in a large release of cesium into atmosphere, which then spread as radioactive fallout into the soil, rivers, and lakes, causing serious ecological problems in the Northern Europe. The transfer of radio-cesium into the food chain and into sheep and reindeer may contribute to human cesium exposure (Howard and Howard, 1997). These ecological issues remain in some areas even decades after the original accident (Bell and Shaw, 2005).

Most cesium compounds are water soluble and are well absorbed through inhalation, ingestion, or skin contact. Once in the blood, cesium is rapidly distributed throughout the body, with higher concentrations in muscles. Cesium can cross the placenta and appears in milk. Cesium mimics potassium for cellular transport. Urinary excretion is the primary route of elimination of cesium from the body. The biological half-life of cesium is variable, ranging from 50 to 150 days (ATSDR, 2004). A physiologically based kinetic model has been developed to describe the distribution and retention of cesium in humans (Leggett *et al.*, 2003).

Toxicity

Radioactive Cesium   Exposure to radioactive cesium (^{134}Cs and ^{137}Cs) is of much greater human health concern than nonradioactive cesium. The initial symptoms following radioactive cesium exposure include nausea, vomiting, and diarrhea. Local skin blistering is common when there is significant dermal contact. With continued exposure to radioactive cesium, adverse neurological and developmental effects can be observed. Symptoms can eventually progress to bone morrow suppression, infection, hemorrhage, and even death (ATSDR, 2004).

Non-radioactive Cesium Compounds   Stable (nonradioactive) cesium compounds are relatively less toxic. High-dose exposure can cause irritation to the gastrointestinal tract and to the eye (ATSDR, 2004). Cardiac arrhythmia and QT wave prolongation have been observed in several case reports following ingestion of cesium salts as homeopathic remedies for cancer treatment (ATSDR, 2004; Dalal *et al.*, 2004). Adverse developmental effects of cesium chloride have been observed in rodents (Messiha, 1994). Prussian blue has been approved in the treatment of cesium poisoning (Thompson and Callen, 2004).

Fluorine

Fluorine (F) was isolated in 1886 by Henri Moissan for which he was awarded the 1906 Nobel Prize in Chemistry. Fluorides are organic and inorganic compounds containing the nonmetallic element fluorine. Fluoride is an essential component for normal mineralization of bones and dental enamel, and it has been widely used to reduce the prevalence and severity of dental caries in children and adults. Flurosilicic acid and sodium fluorosilicate have been used in water fluoridation since 1940s. Adequate intake level is about 0.05 mg/kg/day in adults but is much lower for infants (Ziegler and Filer, 1996; ATSDR, 2003). Toxicologically important fluoride compounds include hydrogen fluoride and sodium fluoride. The major sources of fluorides intake in the general population are water, food, and fluoride-containing dental products. However, excessive intake of fluorides has been observed from environmental sources, including from drinking water with naturally high fluoride (Meenakshi and Masheshwari, 2006), or from exposure to indoor fluoride air pollution from the use of high fluoride-containing coal (Ando *et al.*, 1998; Liu *et al.*, 2002).

Fluorides are readily absorbed (75–90%) from the gastrointestinal tract. Once absorbed, fluorides are rapidly distributed throughout the body. Approximately 99% of the fluoride in the body is found in bones and teeth. Fluoride is incorporated into bone by replacing the hydroxyl ion in hydroxyapatite to form hydroxyfluoapatite. Fluoride in bone can be remobilized slowly as a result of the ongoing process of bone remodeling, especially in the young children. Fluoride is readily transferred across the placenta but poorly transferred to breast milk. Fluorides are mainly excreted in urine. Plasma and urine fluoride levels are related to fluoride intake and are a biomarker for excess exposure, while hair, fingernails, and tooth enamel are indicators of long-term response (ATSDR, 2003).

Toxicity

Dental Fluorosis   Excessive fluoride intake from water during the period of enamel formation in children can cause dental fluorosis. In its mild form, dental fluorosis is characterized by white, opaque areas

on the tooth surface. In its severe form, it is manifested as yellowish brown to black stains and severe pitting of the teeth. Dental fluorosis incidence and severity in some instances can be decreased by the cessation of water fluoridation (Clark *et al*., 2006). Inappropriate use of fluoride toothpaste and fluoride supplements in young children is a risk factor for dental fluorosis (Browne *et al*., 2005). Dental fluorosis is more common and severe in areas of endemic environmental fluorosis (Ando *et al*., 1998; Meenakshi and Masheshwari, 2006).

Skeletal Fluorosis   Long-term exposure to very high oral doses of fluoride or occupational exposure to cryolite dusts can result in skeletal fluorosis. Cases of skeletal fluorosis are predominantly found in developing countries, particularly in India and China, and are associated with high fluoride intake coupled with malnutrition (Ando *et al*., 1998; ATSDR, 2003; Meenakshi and Masheshwari, 2006). Skeletal fluorosis does not usually manifest symptomatically until the disease attains an advanced stage. Fluoride is mainly deposited in the neck, knee, pelvic, and shoulder joints and/or bones, which makes it difficult to move or walk. The symptoms of skeletal fluorosis are similar to arthritis, and early on include sporadic pain, back stiffness, burning-like sensation, pricking and tingling in the limbs, muscle weakness, and chronic fatigue. These symptoms are associated with abnormal calcium deposits in bones and ligaments. In the advanced stage, symptoms include osteoporosis in long bones, and bone outgrowth. The vertebrae may fuse together and eventually the victim may be crippled (crippling skeletal fluorosis), a disability often accompanied by kyphosis (humbacked) or lordosis (arched back).

There are conflicting data regarding the association between fluoride exposure and the incidence of osteosarcoma, a rare bone malignancy (ATSDR, 2003). A recent case-control study in the United States found an association between fluoride exposure in drinking water during childhood and the incidence of osteosarcoma among males but not among females (Bassin *et al*., 2006). This pattern is similar to the findings from the National Toxicology Program rodent study in which osteosarcoma occurred in male rats exposed to sodium fluoride in the drinking water, with a weak but statistically significant dose–response trend (NTP, 1990). However, caution should be taken to make conclusions and more studies are needed in this regard (Douglass and Joshipura, 2006).

Other health effects include respiratory tract, skin, and eye irritation following inhalation exposure to hydrogen fluoride or fluorine gas. Gastrointestinal symptoms occur with excess ingestion of fluoride (ATSDR, 2003). Chronic endemic fluorosis may also lead to muscle fiber degeneration, low hemoglobin levels, skin ruches, neurological manifestations, compromised immunity, and endocrine effects (Meenakshi and Masheshwari, 2006). Endemic fluorosis from coal burning in China often occurs concurrently with arsenicosis (Liu *et al*., 2002).

Germanium

Germanium (Ge) is a metalloid-like antimony and arsenic. The discovery of germanium as a predicted analog of silicon in the 1880s was a key confirmation of the developing theory of elemental periodicity. Chemically similar to tin, germanium can form a large number of organometallic compounds such as dimethyl germanium and germanium tetrahydride. Stable oxidation states include divalent and tetravalent germanium. In the semiconductor industry, germanium transistors found countless uses in solid-state electronics up to the mid-1970s, but then were largely replaced by silicon. Currently it is used in infrared night vision systems, fiber optics, as a polymerization catalyst, and in alloys with other metals. Silicon germanide (SiGe) is emerging as an important semiconductor metal for use in high speed integrated circuits. Germanium is commercially derived from zinc ore processing or as a combustion by-product of certain coals. Ultra pure germanium can be obtained from other metals by fractional distillation of the volatile germanium tetrachloride.

The diet is the dominant source of germanium exposure in the general population while occupational exposure is predominantly by inhalation. Germanium concentrations in most foods are similar to the natural abundance level of about 0.6 to 1.0 ppm in soils, although higher levels have been reported in some canned foods (Vouk, 1986b). Daily germanium intake from food in humans is reported to be about 1.5 mg of which 96% is absorbed (Vouk, 1986b). Intake of germanium from drinking water appears negligible. Considerable amounts of germanium are emitted into the air by coal combustion although exposure from air is limited in the general population. There is no evidence of any essential function of germanium.

Inorganic germanium compounds are rapidly and effectively absorbed after oral exposure. Elemental germanium particles are likewise rapidly cleared from the lung and soon appear in distant tissues (Vouk, 1986b). Absorbed germanium is widely distributed throughout the body with the highest concentrations occurring in many tissues including the liver, kidney, and spleen. Absorption and distribution appears to be largely independent of the germanium compound, as both sodium germanate and tetraethylgermanium are widely distributed without evidence of selective retention or storage after oral exposure in mice (Vouk, 1986b). In both humans and laboratory animals, germanium is excreted mainly via the kidneys with whole-body half-life of 1 to 4 days. Hair and nails may be useful media for biological monitoring.

There appear to be no reports on systemic toxicity of germanium after occupational exposure. There are, however, at least 31 case reports of renal failure in humans after ingestion of inorganic or organometallic germanium compounds mainly through consumption of germanium-containing dietary supplements or elixirs for various diseases (Takeuchi *et al*., 1992; Tao and Bolger, 1997). Among these cases nine deaths were reported (Tao and Bolger, 1997). Levels of germanium consumed were ~15 to 300 g and were ingested over a period of 2 to 36 months (Tao and Bolger, 1997). Excessive germanium consumption from such sources induces various symptoms including renal dysfunction involving tubular degeneration, anemia, muscle weakness, and peripheral neuropathy. Recovery of renal function is slow and incomplete (Tao and Bolger, 1997). Although reports on the efficacy of germanium supplementation against diseases like cancer and AIDS persist, germanium supplementation has not been clearly shown to be of value and the USFDA considers such germanium products to present a potential human health risk (Tao and Bolger, 1997).

Spirogermanium (2-aza-8-germanspiro[4,5] decane-2-propamine-8,8-diethyl-*N*,*N*-dimethyl dichloride) was neurotoxic to humans after intravenous injection for the treatment of cancer (Vouk, 1986b). The effects were reversible and included ataxia and seizures. Neurotoxic effects are also observed in dogs (Vouk, 1986).

There is no evidence of germanium carcinogenicity in humans. In rodents limited testing indicates germanium is not carcinogenic in rats and it has no mutagenic activity (Gerber and Leonard, 1997). Dimethyl germanium oxide can produce embryonic resorption and fetal malformations in animals.

Indium

Indium (In) is a posttransitional metal, named after the indigo line in its atomic spectrum, which was discovered and isolated in the 1860s. Indium is a rare metal with a principal valence state of 3+ and is recovered as a by-product of zinc smelting. In its metallic forms, indium is used in liquid displays, semiconductors, alloys, solders, and as a hardening agent for bearings. Indium arsenide and indium phosphide are chemical forms commonly used in semiconductors (Tanaka, 2004). The most common isotope of indium is slightly radioactive, a characteristic exploited in medical imaging and nuclear medicine. Indium is considered to be a nonessential metal.

The human daily intake of indium has been estimated in the range of 8 to 10 μg. The most common routes of exposure for the general population are inhalation and ingestion while in occupational exposure inhalation predominates. Indium compounds are poorly absorbed when ingested or after intratracheal instillation but may show moderate absorption after inhalation (Fowler, 1986; Zheng et al., 1994). Indium derived from oral or intratracheal instillation of indium phosphide is uniformly distributed between major organs and is excreted in the urine and feces (Zheng et al., 1994). Ionic indium is transported bound to transferrin and is cleared from the blood within 3 days of an intravenous injection in mice (Fowler, 1986).

Toxicity   There appear to be no meaningful reports of local or systemic indium toxicity in humans after oral or inhalation exposure. Animal data on indium indicate that toxicity is related to the chemical form and route of exposure (NTP, 2001). Acute toxicity in animals is generally greatest after inhalation or intravenous injection, and limited after oral exposure (NTP, 2001). In this regard, intravenous injection of indium chloride in mice or rats produces extensive renal and liver necrosis (Fowler, 1986). Intratracheal instillation of the indium chloride produces severe inflammation and pulmonary damage with fibrosis in mice (Blazka et al., 1994). Lung instillation of indium phosphide can produce alveolar or bronchiolar cell hyperplasia in hamsters (Tanaka et al., 1996). The intratracheal instillation of indium phosphide produces little systemic toxicity (Oda, 1997). Indium trichloride showed no evidence of reproductive toxicity in mice, although it did adversely affect fetal survival (Chapin et al., 1995). Teratogenic effects have been observed with intravenously injected indium compounds in rats and hamsters (Ferm and Carpenter, 1970; Nakajima et al., 1998, 2000), but not in mice (Nakajima et al., 2000). Oral indium is teratogenic only at doses that induce maternal toxicity (Ungvary et al., 2000). Inhalation of indium phosphide or oral exposure to indium chloride by pregnant rats results in fetal indium concentrations that are similar to maternal blood levels (Ungvary et al., 2000; NTP, 2001) indicating the placenta does not perturb indium.

Because of its use in the microelectronics industry, indium phosphide was tested recently by the National Toxicology Program (NTP, 2001). After inhalation of indium phosphide for up to 2 years there was clear evidence of pulmonary carcinogenic activity in both male and female rats and mice. This included production of lung adenoma and carcinoma after inhalation of indium phosphide. Concurrent genetic toxicity testing, specifically micronucleated erythrocytes in peripheral mouse blood, was negative (NTP, 2001). Further study indicated inhaled indium phosphide particles likely acted through chronic inflammation in conjunction with production of reactive oxygen species and epithelial cell proliferation (Gottschling et al., 2001).

Palladium

Palladium (Pd) belongs to the platinum group metals. Palladium was discovered in 1803, and named after the asteroid Pallas. Palladium occurs together with other platinum group metals (platinum, rhodium, ruthenium, iridium, and osmium) at very low concentrations in earth crust, and is recovered as a by-product of refining nickel, platinum, and other base metals. Palladium compounds commonly exhibit oxidation state of 2+, although compounds with the oxidation state 4+ are observed. Organopalladium compounds also exist. Palladium is used in automobile catalysts, in dentistry (for crowns and bridges), in electrical appliances, and in jewelry. Environmental palladium levels are increasing, but exposure in the general population is low. Dental alloys and work in metal refining or catalyst manufacture can be major sources of palladium exposure (WHO, 2002; Kielhorn et al., 2002).

Palladium chloride is poorly absorbed from the gastrointestinal tract or from subcutaneous injection sites. After intravenous administration of palladium compounds, palladium is distributed to kidney, liver, spleen, lung, and bone. In cells, palladium compounds likely complex with amino acids, proteins, DNA, and other macromolecules. Orally administered palladium is poorly absorbed and eliminated in feces, whereas intravenous palladium is mainly eliminated in the urine. Half-lives range from 5 to 12 days (WHO, 2002).

Toxicity   Palladium sensitization is a major health concern, as very low doses are sufficient to cause allergic reactions in susceptible individuals. Persons with known nickel allergy may be especially susceptible (Kielhorn et al., 2002). Contact dermatitis is a main manifestation of palladium sensitivity, unlike that with platinum. Immediate hypersensitivity (type I) reactions to palladium have been reported in refinery workers sensitized to platinum (Ravindra et al., 2004). Palladium sensitization is often from dental alloys or jewelry. Occupational exposure to palladium salts may cause skin and eye irritation, and occasionally asthma (Kielhorn et al., 2002; WHO, 2002).

There is some evidence that palladium chloride is carcinogenic after oral exposure in rodents, but the validity of this study was questioned due to methodology deficiencies (Ravindra et al., 2004). Palladium compounds are negative in bacterial mutagenicity tests and in micronucleus test in human peripheral lymphocytes. Tetraammine palladium hydrogen carbonate induced a clastogenic response to lymphocytes in vitro but did not produce positive results in the micronucleus test (WHO, 2002). Some organopalladium complexes have been shown to have antitumor potential similar to that of cisplatin (WHO, 2002; Abu-Surrah and Kettunen, 2006).

Silver

Sliver (Ag) is a rare, naturally occurring element found as a soft, "silver" colored metal. Silver was known since ancient times and was separated from lead as early as the 4000 BC. The chemical symbol for silver is Ag, and is from its Latin name *argentum*. Metallic silver and 1+ oxidation forms are common. Silver metal is used for jewelry, silverware, electronic equipment, and dental filling. Soluble silver salts (e.g., silver nitrate and silver sulfide) have been used to treat bacteria infection. Silver halide is used in the manufacture of photographic plates, while silver sulfadiazine is used in the treatment of burns. Occupational exposure occurs mainly from inhalation of silver fumes and dusts in a number of settings (ATSDR,

1990; Drake and Hazelwood, 2005). Dietary intake is in the range of 70 to 90 μg/day, which is much less than the silver intake from medicinal uses. For drinking water disinfection, WHO permissible level is 0.1 mg silver/L (Pelkonen *et al*., 2003)

Sliver compounds can be absorbed orally, by inhalation, and through damaged skin. Ingested silver compounds are absorbed at a level of less than 10%, and only 2–4% is retained in tissues. Metallic silver and insoluble silver compounds are not readily taken up by the body, and pose minimal health risk (Drake and Hazelwood, 2005). In mice given drinking water containing silver nitrate (0.03 mg/L for 2 weeks), silver was widely distributed to most tissues including muscle, cerebellum, spleen, duodenum, heart, lung, liver, and kidney (Pelkonen *et al*., 2003). Silver can cross the blood–brain barrier and produce long-lasting deposits in many structures of the nervous system (Rungby, 1990) and is located almost exclusively in lysosomes of neuronal cells (Stoltenberg *et al*., 1994). Uptake of silver into lysosomes probably occurs through a carrier-mediated process (Havelaar *et al*., 1998). Autopsy findings after silver treatment of burn victims indicate the highest levels occur in skin, gingiva, cornea, liver, and kidneys. Urine silver analysis as a biomarker is useful only following a high degree of exposure because little silver is excreted in urine.

Toxicity The most common health effects associated with prolonged exposure to silver compounds are the development of a characteristic, irreversible pigmentation of the skin (argyria) and/or the eyes (argyrosis). The affected area becomes bluish-gray or ash gray. This is most prominent in the areas of the body exposed to sunlight, as light acts as a catalyst by triggering the photoreduction of these compounds to form metallic silver, similar to the process of developing a photographic negative. Metallic silver is subsequently oxidized by tissue and is bound as silver sulfide. Black silver sulfide and silver selenide complexes bound to tissue are identified as silver particle deposits. Argyria has two forms, local and general. Localized argyria is caused by direct, local contact with silver such as through jewelry, and involves the formation of gray-blue patches on the skin or may manifest itself in the conjunctiva of the eye. In generalized argyria, the skin shows widespread pigmentation, often spreading from the face to most uncovered parts of the body.

Chelating therapy and dermal abrasion are ineffective in removing silver deposits from the body and there is no effective treatment for argyria. Argyria can be considered a mechanism for detoxication of silver by sequestering it in the tissues as nontoxic silver–protein complexes or silver sulfide (ATSDR, 1990; Drake and Hazelwood, 2005).

The respiratory tract may be affected in severe cases of silver intoxication. Chronic bronchitis has also been reported to result from medicinal use of colloidal silver (ATSDR, 1990). Large oral doses of silver nitrate may cause severe gastrointestinal irritation due to its caustic action. Lesions of the kidneys and lungs and arteriosclerosis have been attributed to both industrial and medicinal exposures. Animal experiments indicate that silver may disturb copper metabolism (Hirasawa *et al*., 1994) and that metallothionein may protect against the toxic action of silver (Shinogi and Maezumi, 1993).

Tellurium

Tellurium (Te) is a metalloid chemically related to selenium and sulfur. Discovered in the 1780s, tellurium is named after the Latin word for earth (*tellus*). It is naturally found as the telluride of gold or combined with various other metals. Produced most often as a by-product of electrolytic copper refining, tellurium is used as an additive to improve metallurgic characteristics of copper, steel, and lead alloys (Gerhardsson *et al*., 1986). Tellurium vapor is used in "daylight" lamps and as a semiconductor in combination with other metals. It is also used in explosives, specialized glass, and in thermoelectric and electronic devices.

Tellurium in food is probably in the form of tellurates. The estimated human daily intake is about 100 μg. Condiments, dairy products, nuts, and fish have relatively high concentrations of tellurium. Some plants, such as cactus, accumulate tellurium from the soil. The average body burden in humans is about 600 mg, mainly in bone.

The biochemistry and toxicity of inorganic and organometallic tellurium compounds have been reviewed (Taylor, 1996; Nogueira *et al*., 2004). Soluble tetravalent tellurates, absorbed into the body after oral administration, are reduced to tellurides, partly methylated, and then exhaled as dimethyl telluride. The dimethylated form is responsible for the characteristic garlic odor in persons intoxicated by tellurium compounds. Food is the main source of tellurium for the general population, while in industrial exposure inhalation would predominate. Some organometallic tellurium compounds are absorbed through the skin. Respiratory absorption data are limited, but inhaled tellurium compounds are likely well absorbed. After oral exposure of tellurides 10–20% of the ingested dose is absorbed (Gerhardsson *et al*., 1986). The kidney, bone, and liver accumulate tellurium and it is estimated that bone stores may have a half-life of up to 2 years or more (Gerhardsson *et al*., 1986). The urine and bile are the principal routes of excretion. Tellurium crosses the blood–brain barrier and the placenta.

Toxicity Of toxicological importance are elemental tellurium, the gases hydrogen telluride and tellurium hexafluoride, and the water-soluble sodium or potassium tellurites and tellurates (Gerhardsson *et al*., 1986). Many organometallic forms of tellurium exist. Tellurates and tellurium are of generally low toxicity, but tellurites are typically more toxic. Acute intoxication by inhalation results in sweating, nausea, a metallic taste, and garlic smelling breath. In fact, garlic breath is an indicator of exposure to tellurium by dermal, inhalation, or oral routes. The cases of tellurium intoxication reported from industrial exposure do not appear to have been life threatening. Two deaths occurred within 6 hours of accidental poisoning by mistaken injection of sodium tellurite (instead of sodium iodine) into the ureters during retrograde pyelography (Gerhardsson *et al*., 1986). The victims had garlic breath, renal pain, cyanosis, vomiting, stupor, and loss of consciousness. The amount of sodium telluride injected was about 2 g.

In rats, chronic exposure to high doses of tellurium dioxide produces renal and hepatic injury (Gerhardsson *et al*., 1986). Rats fed metallic tellurium at 1% of the diet develop demyelination of peripheral nerves (Goodrum, 1998), probably due to the inhibition of cholesterol biosynthesis (Laden and Porter, 2001). Remyelination occurs after cessation of tellurium exposure (Morell *et al*., 1994).

There are no data on human carcinogenicity of tellurium. Lifetime exposure to sodium tellurite at 2 mg Te/L drinking water had no effect on tumor incidence in rats. Some tellurium compounds show mutagenic potential (Gerhardsson *et al*., 1986). Tellurium compounds produce hydrocephalus in rats after gestational exposure between day 9 and 15.

Thallium

Thallium (Tl) is one of the most toxic metals. Thallium (from the Greek word *thallos* meaning "a green shoot or twig") was discovered in 1861. The thallium ion has a similar charge and ion radius as the potassium ion, and its toxic effects may result from interference with the biological functions of potassium. Thallium is obtained as a by-product of the refining of iron, cadmium, and zinc, and is used as a catalyst in alloys, and in optical lenses, jewelry, low-temperature thermometers, semiconductors, dyes, pigments, and scintillation counters. It has been used medicinally as a depilatory. Thallium compounds, chiefly thallous sulfate, were used as rat poisons and insecticides. Once the commonest sources of human thallium poisoning, the use of thallium as rodenticides or insecticides is now banned (WHO, 1996; Peter and Viraraghavan, 2005). Industrial poisoning is a risk in the manufacture of fused halides for the production of lenses and windows. Naturally high thallium concentration in soils and consequent uptake into edible plants in Southwest Guizhou, China caused locally chronic thallium poisoning (Xiao *et al.*, 2004).

Thallium is absorbed through the skin and gastrointestinal tract. The highest concentrations of thallium poisoning are in the kidney. Following the initial exposure, large amounts are excreted in urine during the first 24 hours, but after that urinary excretion becomes slow and the feces becomes an important route of excretion. The half-life of thallium in humans has been reported to range from 1 to 30 days and depends on the initial dose. Thallium undergoes enterohepatic recirculation. Prussian blue, the most commonly used antidote, is given orally to break the enterohepatic recycling by trapping thallium secreted into bile and carried it into the feces (WHO, 1996). Thallium can transfer across the placenta and is found in breast milk, and may cause toxicity in the offspring (Hoffman, 2000).

Toxicity   The triad of gastroenteritis, polyneuropathy, and alopecia is regarded as the classic syndrome of thallium poisoning (WHO, 1996). Other signs and symptoms also occur depending on the dose and duration of exposure. The estimated acute lethal dose in humans is 10 to 15 mg/kg. Death is due mainly to renal, central nervous system, and cardiac failure within a few days to two weeks (WHO, 1996; Galvan-Arzate and Santamaria, 1998; Peter and Viraraghavan, 2005).

Alopecia is the best-known effect of thallium poisoning. Depilation begins about 10 days after ingestion and complete hair loss can occur in about 1 month. Other dermal signs may include palmar erythema, acne, anhydrosis, and dry scaly skin due to the toxic effects of thallium on sweat and sebaceous glands. After oral ingestion of thallium, gastrointestinal symptoms occur, including nausea, vomiting, gastroenteritis, abdominal pain, and gastrointestinal hemorrhage. Neurological symptoms usually appear 2–5 days after acute exposure, depending on the age and the level of exposure. A consistent and characteristic feature of thallium intoxication in humans is the extreme sensitivity of the legs, followed by the "burning feet syndrome" and paresthesia. Central nervous system toxicity is manifest by hallucinations, lethargy, delirium, convulsions, and coma. The acute cardiovascular effects of thallium initially manifested by hypotension and bradycardia due to direct effects of thallium on sinus node and cardiac muscle. This is followed by hypertension and tachycardia due to vagal nerve degeneration. In severe cases, cardiac failure occurs (Milkey and Oehme, 1993).

Major symptoms of chronic thallium poisoning include anorexia, headache, and abnormal pain. Other toxic effects of thallium include fatty infiltration and necrosis of the liver, nephritis, pulmonary edema, degenerative changes in the adrenals, and degeneration of the peripheral and central nervous system. In severe cases, alopecia, blindness, and even death have been reported as a result of long-term systemic thallium intake.

A recent review on thallium poisoning during pregnancy in humans gives a range of fetal effects from severe toxicity to normal development. The only consistent effect identified is a trend toward prematurity and low birth weight in children exposed to thallium during early gestation (Hoffman, 2000). Evidence that thallium is mutagenic or carcinogenic is scanty (Leonard and Gerber, 1997). However, it may be teratogenic, especially with regard to cartilage and bone formation, but most of the evidence comes from birds and not mammals.

Treatment   Therapy for thallium intoxication combines forced diuresis, use of activated charcoal, prevention of reabsorption by administration of Prussian blue, and administration of potassium ferric hexacyanoferrate (WHO, 1996). Prussian blue is the recommended drug of choice in acute thallium poisoning (Hoffman, 2003).

Tin (Sn)

Tin (Sn) is a silver–white metal. The name tin derives from the Anglo-Saxon, *tin*, through the Latin, *stannum*. Tin is one of the earliest metals known and was used as a component of bronze from antiquity. Because of its hardening effect on copper, tin was used in bronze implements as early as 3500 BC. However, the pure metal was not used until 600 BC. Metallic tin can combine with chloride, sulfur, or oxygen to form inorganic tin compounds (stannous, Sn^{2+} and stannic, Sn^{4+}). Tin can also bind with carbon to form a number of toxicologically important organotin compounds including dimethyltin, dibutyltin, dioctyltin, triphenyltin, and tricyclohexyltin (ATSDR, 2005e). Currently, tin is used in the manufacture of various alloys, such as bronze and brass, for fabricating window glass and in solders, but was previously widely used in food packaging. Stannic chlorides are used in dyeing textiles. Organic tin compounds have been used in fungicides, bactericides, and slimicides, as well as in plastics as stabilizers. The average daily intake of tin from all sources is about 4.0 mg, considerably lower than the 17 mg estimated in previous decades, thanks to better food packaging technology (Winship, 1988; Blunden and Wallace, 2003). Organotin compounds are ubiquitous contaminants in the environment. Bioconcentration in aquatic organisms and ecotoxicity are dependent on the bioavailability of the particular compounds. Some tin compounds, especially organotins, show high bioavailability and may pose adverse effects toward aquatic ecosystems (Fent, 1996).

Inorganic tin compounds are poorly absorbed after oral, inhalation, or dermal exposures. For example, only 3% of stannous and <1% of stannic compounds are absorbed from the gastrointestinal tract (Rudel, 2003). The majority of an oral dose of inorganic tin ends up in the feces, while only a small portion of absorbed tin is eliminated via urine (Rudel, 2003). Studies on animals reveal that administration of inorganic tin compounds reduces copper absorption (Yu and Beynen, 1995). The organotin compounds, particularly trimethyltin and triethyltin compounds are better absorbed than inorganic tins. The tissue distribution of tin from these organometallic compounds shows the highest concentration in the bone, liver, kidney, and lung, with smaller amounts in the muscle, spleen, heart, or brain. Tetra-, tri-, and diethyltin undergo dealkylation to ethyltin compounds, whereas tributyltin is dealkylated to

di- and mono-butyltin compounds. Phenyltin compounds undergo dearylation, mainly by microsome monooxygenase and P450 enzymes (Winship, 1988; ATSDR, 2005e).

Toxicity Metallic tin and inorganic tin compounds are relatively nontoxic. Ingestion of food items contaminated with high levels of inorganic tins may cause acute gastroenteritis, while chronic inhalation of inorganic tins (e.g., stannic oxide dust or fumes) may lead to benign nonfibrotic pneumoconiosis called *stannosis* (Blunden and Wallace, 2003; ATSDR, 2005e).

Some organic tin compounds are highly neurotoxic, particularly triethyltin and trimethyltin, and cause encephalopathy and cerebral edema. Toxicity declines as the number of carbon atoms in the chain increases. An outbreak of neurotoxicity of almost epidemic nature took place in France in the 1950s due to the oral ingestion of a preparation (Stalinon) containing diethyltin diodide for the treatment of skin disorders (WHO, 1980). Trimethyltin produces degenerative lesions in the hippocampus and associated structure of the limbic system in primates and rodents. The lesions are characterized by neuron cell apoptosis with astrocyte swelling and gliosis. Microglia and astrocyte activation with the production of proinflammatory cytokines may well contribute to the lesion. Triethyltin produces cerebral edema in experimental animals (Rohl and Sievers, 2005; ATSDR, 2005e).

Triphenyltin, tributyltin, dibutyltin, and dioctyltin compounds produce immunotoxicity in experimental animals, characterized by thymic atrophy, and suppression of T-cell-mediated immune response (ATDSR, 2005e). Acute burns or subacute dermal irritation has been reported among workers as a result of dermal tributyltin exposure (Winship, 1988). Exposure of pregnant animals to organotin compounds such as tributyltin may induce developmental and endocrine disrupting effects (Adeeko *et al.*, 2003; ATSDR, 2005e).

Experimental studies have failed to find convincing evidence of carcinogenicity, mutagenicity, or teratogenicity of inorganic tin compounds (Winship, 1988). There is inadequate information to assess carcinogenic potential of organotin compounds in animals, and they are considered not classifiable as to human carcinogenicity (ATSDR, 2005). Studies of genotoxicity of organotin compounds have give mixed results depending on the specific compound and test system. Triphenyltin compounds are positive for induction of micronuclei and sister chromatid exchange in Chinese hamster cells.

Titanium

Titanium (Ti) was discovered in 1791. Titanium is named for the *Titans* of Greek mythology. Most titanium compounds are in the 4+ oxidation state (titanic), but the 3+ oxidation state (titanous) and 2+ compounds can occur. Titanium can form organometallic compounds. Because of its resistance to corrosion, inertness, and tensile strength, titanium has many metallurgic applications, and finds use in aircraft, armor plating, naval ships, missiles, and as a component of surgical implants and prostheses. Titanium dioxide, the most widely used titanium compound, is used as a white pigment in paints, paper, toothpaste, and plastics, as a food additive to whiten flour, in dietary products, and confections, and as a whitener in cosmetics. Titanium complexes (such as titanium diketonate and budotitane) and titanocene complexes (such as titanocene dichloride) have undergone clinical trials as cancer chemotherapeutics (Melendez, 2002; Caruso and Rossi, 2004). Titanium tetrachloride is used to make titanium metal and other titanium-containing compounds. Occupation exposures to titanium tetrachloride can be of toxicological concern (ATSDR, 1997).

Approximately 3% of an oral dose of inorganic titanium is absorbed. The majority of the absorbed dose is excreted in the urine. The normal urinary concentration of titanium has been estimated at 10 μg/L (Kazantzis, 1981), and the estimated total body burden of titanium is about 15 mg. As a result of inhalation exposure, the lungs accumulate titanium where it remains for long periods. Lung burdens increase with age and vary according to geographic location. Concentration in liver (8 μg/g) and kidney (6 μg/g) are similar. Titanium may circulate in plasma bound to transferrin (Messori *et al.*, 1999), which is thought to be a mediator for delivery of titanium to tumor cells (Desoize, 2004).

Toxicity Occupational inhalation exposure to titanium tetrachloride (TiCl$_4$) can produce mild to severe pulmonary injury because it undergoes rapid hydrolysis upon contact with water to form hydrochloric acid, titanium oxychloride, and titanium dioxide (TiO$_2$). Occupational exposure to titanium dioxide occurs during production. Titanium dioxide is classified as a nuisance particulate with a threshold limit value of 10 mg/m^3 (ATSDR, 1997). Inhalation and instillation of titanium particles coated with alumina and/or amorphous silica produce mild and reversible pulmonary effects. The base pigment-grade and/or nanoscale titanium dioxide particles produce minimal pulmonary toxicity, regardless of particle size and surface area (Warheit *et al.*, 2005, 2006). In general, titanium dioxide has been considered toxicologically inert regardless of route of exposure.

Epidemiological studies have not found the association of titanium exposure with increased risk of lung cancer and chronic respiratory diseases (Fayerweather *et al.*, 1992; Fryzek *et al.*, 2003). Titanium dioxide is not carcinogenic in rats or mice (NCI, 1979; Bernard *et al.*, 1990).

Titanium compounds and related metallocenes have recently shown chemotherapeutic activity toward gastrointestinal, breast, lung, and skin cancer (Melendez, 2002; Caruso and Rossi, 2004; Desoize, 2004). The mechanism of action of titanium compounds appears different from platinum compounds, and nephrotoxicity and myelotoxicity are not prominent.

Uranium

Uranium (U) is a heavy metal and its use dates at least back to AD 79. Uranium was discovered by the German chemist Martin Kloproth in 1789 in a mineral called pitchblende, and was named after Uranus, the planet, which had been discovered 8 years earlier. Uranium naturally occurs in three radioisotopes: [234]U, [235]U, and [238]U. [235]U is of particular interest in nuclear weapons and nuclear reactions. Thus, uranium ore is chemically enriched to increase [235]U content from 0.72% to 2–4%. The by-product of this process is called depleted uranium, which has decreased [235]U and has 40% less radioactivity than natural uranium (ATSDR, 1999). Depleted uranium has been used in military applications as warheads and tank armor. Nonmilitary uses include counterweights in airplanes and shields against radiation in hospitals (Craft *et al.*, 2004). The chemical toxicity of uranium compounds is a health concern, rather than their radiation. Depleted uranium has the same chemical toxicity potential as natural uranium (ATSDR, 1999; Craft *et al.*, 2004).

Uranium has five oxidation states but only the 4+ and 6+ forms are stable enough to be of practical importance. The 6+ oxidation state forms the uranyl ion (UO$_2$$^{2+}$), which further forms

water-soluble compounds and is an important species of uranium in body fluids. The uranyl ion is also the most prevalent form in the environment (Sheppard *et al.*, 2005). The ecotoxicity of uranium and uranyl carbonate complexes to plants, aquatic life, and birds has been recently reviewed (Sheppard *et al.*, 2005).

Absorption of uranium compounds is low by all exposure routes. Absorption of inhaled uranium compounds occurs in respiratory tract via transfer across cell membranes, and is dependent on the particle size and solubility. Absorption from the gastrointestinal tract can vary from 0.1% to 6%, depending on the specific uranium compound. Once in the blood, uranium is distributed to the organs of the body. Uranium in body fluids generally exists as uranyl ion complexed with citrate and bicarbonate. Uranium preferentially distributes to bone (66%), liver (16%), kidney (8%), and then other tissues (10%). Two-thirds of the uranium in the blood is excreted in urine over the first 24 hours, but bone deposits of uranium last for about 1.5 years (ATSDR, 1999; Craft *et al.*, 2004).

Toxicity   The kidney is the most sensitive organ for uranium toxicity. The primary target is the renal proximal tubule, but the glomeruli may also be affected. Biomarkers of tubular effects include enzymuria, and increased excretion of low molecular weight proteins, amino acids, and glucose. Glucosuria is the most persistent biomarker for uranium-induced tubular dysfunction. Biomarkers for glomerular toxicity include urinary albuminuria, and elevated blood creatinine and urea nitrogen. Pathological and functional changes occur within days following acute exposure and are manifested by injury to renal tubular epithelial cells. Renal effects from acute exposure to uranium appear to have some relationship to peak kidney concentrations regardless of chemical form and route of exposure and are usually transient or reversible (Diamond *et al.*, 2005). Overt renal effects are observed with peak kidney uranium concentrations above 2 μg U/g, but mild renal tubular dysfunction from chronic exposure may occur at even lower renal concentrations. There appears to be a trend toward increase in severity of renal toxicity with increase in length exposure and urinary uranium levels (Thun *et al.*, 1985; Squibb *et al.*, 2005).

Challenges remain for establishing any causal relationship between human uranium exposure and birth defects and/or gonadal endocrine dysfunction, since these studies are confounded by co-exposure to other toxicants and inadequate exposure assessments (Craft *et al.*, 2004; Hindin *et al.*, 2005). However, uranium and depleted uranium can be developmental toxicants when given orally or subcutaneously to mice. Decreased fertility, embryo/fetal toxicity, teratogenicity, and reduced growth of the offspring have been observed in rodents following uranium exposure during different periods of gestation. Bone is a major site of uranium accumulation, and chronic uranium intoxication may result in diminished bone growth and osteoporosis. There is also increasing concern of potential neurotoxicity of uranium (Craft *et al.*, 2004; Jiang and Aschner, 2006).

A higher incidence of lung cancer has been found in uranium miners and is probably due to radon and its daughter products, but not to uranium itself (ATSDR, 1999). Gulf war veterans who were wounded subsequent to the explosion of armor-piercing shells containing depleted uranium often retain small fragments of the metal. This has created concern for the potential long-term effects of such embedded uranium fragments. Although there are no human data, a recent study in rats indicates that embedded depleted uranium fragments can cause localized proliferative reactions and soft tissue sarcomas in rats (Hahn *et al.*, 2002). Embedded tungsten alloy containing depleted uranium rapidly induced malignant rhabdomyosarcomas as early as one month postimplantation in rats (Kalinich *et al.*, 2005).

Vanadium

Vanadium (V) is a transition metal discovered in the early 1800s and is named after the goddess of beauty in Scandinavian mythology, *Vanadis*, because of its beautiful multicolored chemical compounds. Vanadium may be an essential trace element, but definitive evidence that a vanadium-deficiency disease occurs in humans is lacking (Mukherjee *et al.*, 2004). It does appear to be an essential nutrient metal for ascidians, chickens, and rats (Lagerkvist *et al.* 1986). It has several oxidation states, the most common being 3+, 4+, and 5+. The metal can be found as halides, such as the tetrachloride, and oxides, such as vanadium pentoxide. Organometallic vanadium compounds are generally unstable. Vanadium is recovered from vanadium containing ores and from fossil fuels. Vanadium compounds are used in the hardening of steel, in the manufacture of pigments, in photography, and as catalysts.

Food is the major source of human exposure. Significant amounts of vanadium are found in seafood, mushrooms, dill seed, milk, meat, cereals, and vegetables (Lagerkvist *et al.* 1986; Mukherjee *et al.*, 2004). Concentrations in the drinking water largely depend on geographic location. Concentrations in rural air are much lower than in urban air, largely due to fossil fuel combustion (Lagerkvist *et al.*, 1986). The daily intake is estimated in the US population to range from 10 to 60 μg. The normal blood and urine levels are estimated to be around 1 and 10 nmol/L, respectively (Sabbioni *et al.*, 1993).

The lungs absorb about 25% of soluble vanadium compounds, but the absorption of vanadium salts from the gastrointestinal tract is generally poor (Lagerkvist *et al.*, 1986). Some dermal absorption of soluble compounds is possible but probably represents a minor route for humans. Once absorbed, extracellular vanadium will be in the form of vanadate (5+) and most likely in the vanadyl (4+) form after entering cells. After experimental exposure by various routes in rodents, the highest amounts of vanadium are found in the bone, kidney, liver, and spleen (Lagerkvist *et al.*, 1986). Brain levels are considerably lower than other tissues indicating limited transport across the blood–brain barrier. After parenteral exposure, vanadium is rapidly excreted in the urine with a biological half-life of 20 to 40 hours.

Toxicity   The toxicity of vanadium compounds usually increases as the valence increases and the pentavalent compounds are the most toxic. After occupational exposure to airborne vanadium, its toxic actions are largely confined to irritation of the respiratory tract, eyes, and skin (Lagerkvist *et al.*, 1986). Interestingly, there is usually a latent period of 1 to 6 days before the adverse effects of vanadium appear, although the effects are usually reversible. Bronchitis and bronchopneumonia are more frequent in workers exposed to vanadium compounds. In industrial exposures to vanadium pentoxide dust, a characteristic greenish-black discoloration of the tongue occurs due to deposition of vanadium. There is some evidence that a sensitization reaction may occur with repeated exposures (Lagerkvist *et al.*, 1986). Gastrointestinal distress, nausea, vomiting, abdominal pain, cardiac palpitation, tremor, nervous depression, and kidney damage have also been linked with industrial vanadium exposure (Lagerkvist *et al.*, 1986; Barceloux, 1999).

There are a variety of proposed pharmacological uses for vanadium compounds, including lowering cholesterol, triglycerides, and glucose levels, and some evidence indicates it can prevent tumor growth or formation in rodents (Mukherjee *et al*., 2004). There are no data indicating a carcinogenic potential for vanadium compounds in animals or man, and vanadium compounds are only weakly mutagenic (Leonard and Gerber, 1994). Reproductive toxicology data are sparse but may indicate some potential (Domingo, 1994), and there is some evidence of teratogenic potential in hamsters or mice (Lagerkvist *et al*., 1986).

CHAPTER 24

TOXIC EFFECTS OF SOLVENTS AND VAPORS

James V. Bruckner, S. Satheesh Anand, and D. Alan Warren

</div>

INTRODUCTION

The term *solvent* refers to a class of liquid organic chemicals of variable lipophilicity and volatility. These properties, coupled with small molecular size and lack of charge, make inhalation the major route of solvent exposure and provide for ready absorption across the lung, gastrointestinal (GI) tract, and skin. In general, the lipophilicity of solvents increases with increasing numbers of carbon and/or halogen atoms, while volatility decreases. Organic solvents are frequently used to dissolve, dilute, or disperse materials that are insoluble in water. As such they are widely employed as degreasers and as constituents of paints, varnishes, lacquers, inks, aerosol spray products, dyes, and adhesives. Other uses are as intermediates in chemical synthesis, and as fuels and fuel additives. Most organic solvents are refined from petroleum. Many such as naphthas and gasoline are complex mixtures, often consisting of hundreds of compounds. Early in the twentieth century, there were perhaps a dozen or so known and commonly used solvents. By 1981, this number had climbed to approximately 350 (OSHA, 2006).

Solvents are classified largely according to molecular structure or functional group. Classes of solvents include aliphatic hydrocarbons, many of which are chlorinated (i.e., halocarbons); aromatic hydrocarbons; alcohols; ethers; esters/acetates; amides/amines; aldehydes; ketones; and complex mixtures that defy classification. The main determinants of a solvent's inherent toxicity are: (1) its number of carbon atoms; (2) whether it is saturated or has double

or triple bonds between adjacent carbon atoms; (3) its configuration (i.e., straight chain, branched chain, or cyclic); and (4) the presence of functional groups. Some class-wide generalizations regarding toxicity can be made. For example, the more lipophilic a hydrocarbon, the more potent a central nervous system (CNS) depressant it is; amides/amines tend to be potent sensitizers; aldehydes are particularly irritating; hydrocarbons that are extensively metabolized tend to be more cytotoxic/mutagenic; and many unsaturated, short-chain halocarbons are animal carcinogens. The toxicity of solvents within the same class can vary dramatically. For example, 1,1,1-trichloroethane (TRI) and 1,1,2-trichloroethylene (TCE) are both halocarbons with three chlorine atoms, yet the unsaturated TCE is carcinogenic in the rat and mouse, but TRI is not. Similar results have been reported for 2,4- and 2,6-diaminotoluene in rodents, as only the 2,4 isomer is capable of inducing significant hepatocyte proliferation and liver tumors. Slight structural differences in solvent metabolites are also of toxicological consequence. The peripheral neuropathy induced by *n*-hexane and 2-hexanone is dependent on the production of the γ-diketone metabolite, 2,5-hexanedione. Diketones lacking the gamma structure are not neurotoxic. Thus, subtle differences in chemical structure can translate into dramatic differences in toxicity.

Nearly everyone is exposed to solvents in the conduct of their normal activities. Consider, for example, a person who works in an aircraft factory as a metal degreaser (TCE exposure); drives to the neighborhood bar after work and has a few drinks (ethanol exposure) and cigarettes (benzene and styrene exposure); stops on the way home at a self-service filling station for gasoline (benzene, toluene, 1,3-butadiene exposure) and the dry cleaner's for laundry [tetrachloroethylene (PERC) exposure]; and after dinner enjoys his

hobby of model shipbuilding that requires the use of glue (toluene exposure). While everyone may not identify with the above scenario, detailed surveys of indoor and outdoor air, such as the EPA's Total Exposure Assessment Methodology (TEAM) and National Human Exposure Assessment Survey (NHEXAS) studies, indicate that airborne solvent exposure is unavoidable (Wallace, 1990; Clayton *et al*., 1999). Drinking water is also a common source of solvent exposure due to discharge of solvents into surface and groundwaters and the presence of disinfection by-products, including the animal carcinogen chloroform ($CHCl_3$). Trichloroacetic acid (TCA), and dichloroacetic acid (DCA), metabolites of TCE and PERC, are also common disinfection by products.

Environmental exposures to solvents in air and groundwater are frequent subjects of toxic tort litigation, despite concentrations that are typically in the low parts per billion (ppb) range. Multiple exposure pathways frequently exist (Fig. 24-1). Although not represented in Fig. 24-1, household use of solvent-contaminated water may result in solvent intake from inhalation and dermal absorption as well as ingestion (Weisel and Jo, 1996; Nuckols *et al*., 2005). In many cases, environmental risk assessments require that risks be determined for physiologically diverse individuals who are exposed to several solvents by multiple exposure pathways. As an aid to the risk assessment process, the U.S. EPA has derived toxicity factors for many of the most toxic solvents. These toxicity factors are referred to as reference concentrations (RfCs), reference doses (RfDs), and cancer slope factors (CSFs). Values for a number of these are available from the EPA's online Integrated Risk Information System (IRIS). Additional sources of exposure guidelines for noncancer end points are found in the *Toxicologic Profiles* of the U.S. Agency for Toxic Substances and Disease Registry (ATSDR).

These profiles often contain minimal risk levels that are derived in a similar manner to EPA's RfCs and RfDs, but are frequently based on different critical studies or derived with different uncertainty factors.

Occupational solvent exposures involve situations ranging from a secretary using typewriter correction fluid to the loading and off-loading of tanker trucks with thousands of gallons of gasoline. The greatest industrial use of solvents is as metal degreasers. This work environment is typically where the highest exposures occur, mainly via inhalation and secondarily via dermal contact. An estimated 10 million people are potentially exposed to organic solvents in the workplace (OSHA, 2006). Many of the most severe exposures to solvents have occurred as a result of their use in confined spaces with inadequate ventilation. While the U.S. Occupational Safety and Health Administration (OSHA) has established legally enforceable permissible exposure limits (PELs) for over 100 solvents, most PELs are outdated. The majority of existing PELs were adopted from the list of threshold limit values (TLVs) published some years ago by the American Conference of Governmental Industrial Hygienists (ACGIH). Many current TLVs are more stringent than the PELs but do not carry the weight of law. Whereas the ACGIH's TLVs for an 8-hour workday, 40-hour workweek are designed to be protective for a working lifetime, its short-term exposure limits (STELs) and ceiling values are designed to protect against the acute effects of high-level, short-term solvent exposure. If warranted, ACGIH will assign a skin notation to a solvent, indicating that a significant contribution to overall exposure is possible by the dermal route, either by contact with vapors or direct skin contact with the liquid. Biological monitoring in the workplace should find increasing use as technologic advances are made, because it often provides a better measure of exposure than classic industrial hygiene monitoring. The ACGIH has published over 50 Biological Exposure Indices (BEIs), on which bases the safety of internal measures of exposure can be judged (ACGIH, 2006).

Most solvent exposures involve a mixture of chemicals, rather than a single compound. Our knowledge of the toxicity of solvent mixtures is rudimentary relative to the toxicology of individual solvents. While the assumption is frequently made that the toxic effects of multiple solvents are additive, solvents may also interact synergistically or antagonistically. For example, repetitive alcohol consumption induces certain cytochrome $P450$s (CYPs), and may therefore enhance the metabolic activation of other solvents to cytotoxic metabolites. Ethanol intake near the time of exposure to such solvents, in contrast, may competitively inhibit their metabolism and be protective. Another well-characterized example of solvent antagonism is the competitive metabolic interaction between benzene and toluene (Medinsky *et al*., 1994). Coexposure to these chemicals results in diminished benzene metabolism, genotoxicity, and erythropoietic toxicity relative to that which follows benzene exposure alone. It is now recognized that significant data gaps exist in the area of mixtures toxicology, and that these can be significant sources of uncertainty in risk assessments. Physiologically based toxicokinetic (PBTK) models are being developed by different research groups to predict the impact of metabolic induction and inhibition on the kinetics of individual components of specific mixtures (Barton *et al*., 1995; Haddad *et al*., 2000; Dobrev *et al*., 2001).

Although some solvents are less hazardous than others, virtually all can cause adverse effects. Provided that the dose or concentration is sufficient, most have the potential to induce some level of narcosis and cause respiratory and mucous membrane irritation. A number of solvents are animal carcinogens, but only a handful have been classified as known human carcinogens. Herein lies a major challenge for toxicology—determining the human relevance of tumors observed in chronic, high-dose rodent studies. As with other chemicals, whether adverse health effects occur from solvent exposure is dependent on several factors: (1) toxicity of the solvent; (2) exposure route; (3) amount or rate of exposure; (4) duration of exposure; (5) individual susceptibility; and (6) interactions with other chemicals. Adverse health effects may occur acutely and be readily discernible, or they may be the result of chronic exposure and have insidious onset. Numerous epidemiologic studies of environmentally- and occupationally-exposed populations have been conducted for some solvents, but most human risk assessments remain heavily reliant upon extrapolation from high-dose animal studies. One must bear in mind that the toxic effects and their underlying mechanisms discussed herein may be operative only in certain animal species or strains and under certain exposure conditions. Care must therefore be taken in generalizing beyond the experimental conditions under which data are collected. While a relatively small number of commercially available solvents is discussed in this chapter, those selected for discussion are thought to best demonstrate principles of solvent toxicology, are of particular commercial importance, and/or are currently garnering significant attention from the toxicological and regulatory communities. A book chapter that examines solvents from an organ systems standpoint, in contrast to the discussion of individual solvents herein, is that of Gerr and Letz (1998).

IS THERE A SOLVENT-INDUCED CHRONIC ENCEPHALOPATHY?

The CNS-depressant effects of acute, high-level exposures and the potential for permanent neurologic damage in chronic solvent abusers are not a matter of debate. It is also clear that chronic, moderate-to-high-level exposure to a few solvents such as *n*-hexane and carbon disulfide can cause specific degenerative changes in the CNS or the peripheral nervous system (PNS). Far less clear is whether chronic, low-level exposure to virtually any solvent or solvent mixture can produce a pattern of neurologic dysfunction referred to as *painters' syndrome*, *organic solvent syndrome*, *psychoorganic syndrome*, and *chronic solvent encephalopathy* (CSE). CSE is characterized by nonspecific symptoms (e.g., headache, fatigue, mood disturbances, and sleep disorders) with or without changes in neuropsychological function. There is a reversible form of CSE referred to as *neuroasthenic syndrome* that consists of symptoms only, and both "mild" and "severe" forms accompanied by objective signs of neuropsychological dysfunction that may or may not be fully reversible. This syndrome was first described in the Scandinavian occupational literature in the late 1970s in solvent-exposed painters (Axelson *et al*., 1976; Arlien-Soborg *et al*., 1979). Since that time, numerous studies from Scandinavia have been published purporting that solvents as a class have chronic neurotoxic properties. These countries, as well as few others in Europe (i.e., Germany, Austria, and Belgium) have passed legislation recognizing CSE as a compensable occupational disability (Triebig and Hallermann, 2001). Scientists outside of Scandinavia, including many in the United States, have generally been less willing to recognize CSE as a legitimate disease state and have published studies to the contrary (Triebig *et al*., 1988; Bleecker *et al*., 1991; Spurgeon *et al*., 1994).

In response to the numerous reports of CSE, two conferences were convened in 1985. The first was held in Copenhagen by the Nordic Council of the World Health Organization (WHO, 1985).

Table 24-1

Proposed Categories of Solvent-Induced Encephalopathy

CATEGORY	CLINICAL MANIFESTATIONS
Type 1	*Symptoms only*: The patient complains of nonspecific symptoms such as fatigability, memory impairment, difficulty in concentration, and loss of initiative. These symptoms are reversible if exposure is discontinued, and there is no objective evidence of neuropsychiatric dysfunction.
Type 2A	*Sustained personality or mood change*: There is a marked and sustained change in personality involving fatigue, emotional lability, impulse control, and general mood and motivation.
Type 2B	*Impairment in intellectual function*: There is difficulty in concentration, impairment of memory, and a decrease in learning capacity. These symptoms are accompanied by objective evidence of impairment. There may also be minor neurologic signs. The complete reversibility of type 2B is questionable.
Type 3	*Dementia*: In this condition, marked global deterioration in intellect and memory is often accompanied by neurologic signs and/or neuroradiologic findings. This condition is, at best, poorly reversible, but is generally nonprogressive once exposure has ceased.

The second, in Raleigh, NC, was attended by an international group of scientists from academia, industry, and government (Cranmer, 1986). The categorization scheme that resulted from the Raleigh meeting is presented in Table 24-1. The WHO scheme is similar. Among those who utilize the categorization scheme, it is generally believed that the most severe CSE category, type 3, results from repeated, severe intoxications like those experienced by solvent abusers. CSE types 1 and 2, on the other hand, are thought to be associated with prolonged, low-to-moderate-level exposure common to work environments. A major criticism of the categorization scheme is the lack of consideration of inhaled solvent concentration and exposure duration. While no consensus exists, even most CSE proponents believe that solvent exposure must occur for some 10 years before clinical symptoms are manifest. Citing growing acceptance of CSE outside of Scandinavia, some scientists and physicians advocate for refinement of existing diagnostic criteria and a unified categorization scheme (van der Hoek *et al*., 2000, 2001).

CSE researchers typically rely upon self-reported symptoms and a clinical neuropsychological evaluation (Table 24-2), and to a much lesser extent on diagnostic tests such as electroencephalography and computerized brain tomography. It has been argued that the neuropsychological tests are of questionable validity, sensitivity, specificity, and predictive value. It has also been noted that many investigations of CSE are fraught with methodologic flaws. For example, CSE investigators frequently fail to measure premorbid function or intellect; employ a reference population; control adequately for the potential confounders of age, alcohol use, other CNS diseases, and other chemicals; corroborate functional deficits with objective evidence of brain disease; and/or examine exposure–response relationships. The importance of doing so is best exemplified by the reanalysis of individuals originally reported in the seminal study by Arlien-Soborg *et al*. (1979) to have "painters' syndrome." When the influences of age, education, and intelligence were considered, the previously reported reduction in neuropsychological test scores disappeared (Gade *et al*., 1988). Another example is that of Cherry *et al*. (1985), who demonstrated the importance of matching solvent-exposed and control groups for preexposure intellect before making a diagnosis of CSE. More recently, Albers *et al*. (2000) reportedly found no objective evidence of toxic encephalopathy among 52 railroad workers with long-term solvent exposure and diagnosis of CSE.

It is evident that resolution of the controversial issue of CSE will come only through the conduct of well-designed and controlled epidemiological studies, especially considering the absence of an appropriate animal model. Brief, but insightful reviews of CSE by Rosenberg (1995) and Schaumburg and Spencer (2000) have been published. These reviews conclude that the current literature, including the "landmark" North American study of 187 paint-manufacturing workers (Bleecker *et al*., 1991), does not support chronic low-level solvent exposure as a cause of *symptomatic* CNS or PNS dysfunction. This does not preclude, however, the possibility that such exposure can be associated with *subclinical* cognitive dysfunction in the form of slight psychomotor and attentional deficit disorders. For the viewpoint of CSE proponents, readers are directed to texts by Arlien-Soborg (1992) and Kilburn (1998).

SOLVENT ABUSE

Inhalants are volatile substances that can be inhaled to induce a psychoactive or mind-altering effect. Their abuse has become a major drug problem worldwide, particularly in disadvantaged populations and among adolescents (Dinwiddie, 1994; Marelich, 1997). The epidemiology of inhalant abuse in the United States is receiving considerable attention (Spiller, 2004; Wu *et al.*, 2004), with almost one in five 8th graders claiming to have used inhalants according to the most recent National Institute on Drug Abuse (NIDA)-sponsored survey (Johnston *et al.*, 2006). Solvents are among the most popular classes of drugs of abuse, given their presence in a multitude of inexpensive, readily available products that are legal to buy and possess. These products are used for common household and industrial purposes and include paint thinners and removers, dry-cleaning fluids, degreasers, gasoline, glues, typewriter fluid, nail polish remover, felt-tip marker fluids, and aerosols such as fabric protector sprays and spray paints. Solvents are often among the first drugs used by children and adolescents. Early use of inhalants is often a precursor to abuse of multiple illegal substances (Wu *et al.*, 2004). Research suggests that adverse socioeconomic conditions, a history of child abuse, poor grades, and dropping out of school are all factors contributing to inhalant abuse (NIDA, 2005).

Solvent abuse is a unique exposure situation in that participants repeatedly subject themselves to vapor concentrations high enough to produce effects that resemble alcohol intoxication. Solvents can be breathed in through the nose or the mouth by "sniffing" or "snorting" vapors from containers; spraying aerosols directly into the nose or mouth; "bagging" by inhaling vapors from substances sprayed or deposited inside a plastic or paper bag; or "huffing" from a solvent-soaked rag stuffed into the mouth (NIDA, 2005). Although dependent on the pattern of inhalation, blood levels of solvents typically peak minutes after inhalation begins, and the abuser can begin to experience intoxication after a matter of seconds. While intoxication may last only a few minutes, abusers frequently seek to prolong the "high" by inhaling repeatedly over the course of several hours. In extreme circumstances, death may be a consequence of cardiac arrhythmias, asphyxiation, and/or cachexia.

Relatively little is known about the neuropharmacology of abused solvents, although they appear to have much in common with the classical CNS-depressant drugs like ethanol and barbiturates, including the potential for tolerance and dependence (Balster, 1998). Commonly used solvents have been shown to alter the function of a variety of ligand-gated ion channels, including those activated by glycine, gamma-aminobutyric acid (GABA) and *N*-methyl-D-aspartate (NMDA) (Beckstead *et al.*, 2000; Cruz *et al.*, 2000). Recent evidence links high-level toluene exposure in rats to increased dopaminergic neurotransmission within the mesolimbic reward pathway, an effect thought to underlie the abuse potential of numerous drugs (Reigel and French, 2002; Reigel *et al.*, 2004). Toluene, as well as TCE and TRI, have been shown to enhance serotonin-3 receptor function, which has also been implicated in the reinforcing properties of abused drugs (Lopreato *et al.*, 2003).

Whereas the intoxicating effects achieved through acute solvent abuse are reversible, abuse may be continued for years and result in residual organ damage. For example, chronic abuse of products containing *n*-hexane and methyl-*n*-butyl ketone can cause peripheral neuropathies. Blood dyscrasias, liver damage, kidney injury, and hearing impairment are seen in patients who have abused solvents injurious to these organs. It has been known for some time that the brain is not spared residual damage, with long-term

neurologic and psychological sequelae (Ron, 1986; Caldemeyer *et al.*, 1996). More recently, Rosenberg *et al.* (2002) reported increased incidences of neurologic and neuropsychological effects in chronic solvent abusers compared to a control group of chronic drug abusers. Solvent abusers did significantly worse on tests of working memory and executive cognitive function, and a much higher percentage of the patients (44 vs. 25.5%) had structural abnormalities in subcortical regions of the brain (i.e., basal ganglia, cerebellum, pons, and thalamus) as visualized by MRI (Fig. 2). Solvent abusers also showed moderate to severe, diffuse abnormality of the cerebral white matter, consistent with that seen in earlier studies of neuropsychologically impaired toluene abusers (Rosenberg *et al.*, 1988a,b; Filley *et al.*, 1990). Nearly two decades ago, Rosenberg and colleagues termed this condition "white matter dementia" (myelinated neurons are white in appearance) that was characterized primarily by diffuse cerebral, cerebellar and brainstem atrophy, and ventricular enlargement (Fig. 24-2). More recently, dementia in toluene abusers has been referred to as "toluene leukoencephalopathy" (Filley and Kleinschmidt-DeMasters, 2001; Filley *et al.*, 2004). Leukoencephalopathy, also known as multifocal demyelinating disease, involves structural alteration of cerebral white matter, in which the myelin sheaths that cover nerve fibers are destroyed but axons are largely spared. Thus, toluene is among the long list of white matter toxins identified to date.

ENVIRONMENTAL CONTAMINATION

Widespread use of solvents has resulted in their dissemination throughout the environment (Fig. 24-1). Everyone is exposed daily to solvents, albeit in minute amounts (Ashley *et al.*, 1994; Churchill *et al.*, 2001; Blount *et al.*, 2006). Because solvents as a chemical class are volatile, the preponderance of solvents entering the environment do so by evaporation. The majority of the more volatile organic chemicals (VOCs) volatilize when products containing them (e.g., aerosol propellants, paint thinners, cleaners, and soil fumigants) are used as intended. Solvent loss into the atmosphere also occurs during production, processing, storage, and transport activities, resulting in elevated concentrations in air in the proximity of point sources. Winds dilute and disperse solvent vapors across the world. Atmospheric concentrations of most VOCs are usually extremely low [i.e., nondetectable to nanograms or a few micrograms per cubic meter (m^3) of air]. Relatively high concentrations of certain solvents (e.g., 10–520 $\mu g/m^3$, or 3–163 ppb of benzene) have been measured in urban areas, around petrochemical plants, and in the immediate vicinity of hazardous waste sites (Bennett, 1987). Motor vehicle exhaust is a major contributor to hydrocarbon emissions (Mohamed *et al.*, 2002). Fraser *et al.* (1998) measured extremely high levels of benzene, toluene, ethylbenzene, and xylenes in a Los Angeles roadway tunnel.

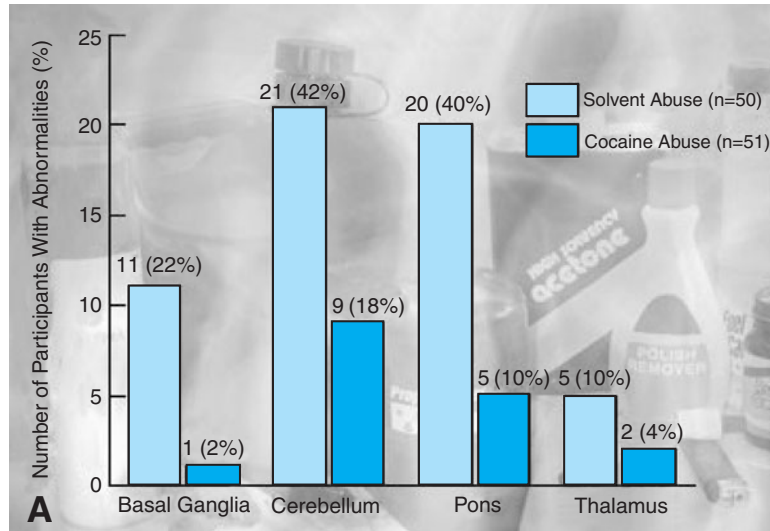
Solvent contamination of drinking water supplies is of major health concern. Although the majority of a solvent spilled onto the ground evaporates, some may permeate the soil and migrate through it until reaching groundwater or an impermeable material. In years past, the more lipophilic solvents were generally regarded as water insoluble. It is now recognized that all solvents are soluble in water to some extent. Some (e.g., alcohols, ketones, glycols, and glycol ethers) are freely water soluble. Maximum solubilities of some common hydrocarbon solvents range from 10 mg/L (ppm) for *n*-hexane to 24,000 mg/L for bromochloromethane. High concentrations of VOCs are sometimes found in the effluent of facilities of rubber producers, chemical companies, petrochemical plants, and


Figure 24-2. (A): Inhalant and cocaine abusers with subcortical abnormalities, by brain region affected. (B–C): Brain damage in a toluene abuser.

(A) Magnetic resonance imaging (MRI) scans of chronic inhalant abusers and chronic cocaine abusers showed more frequent occurrence of abnormalities in the basal ganglia, cerebellum, pons, and thalamus for those who abused solvents. (Available at http://www.drugabuse.gov/NIDA_notes/NNVol17N4/Chronic.html): [From NIDA Notes, 2002]. MRI shows marked atrophy (shrinkage) of brain tissue in a toluene abuser (C) compared to a nonabusing individual (B). paper mills. Concentrations diminish rapidly after VOCs enter bodies of water, primarily due to dilution and evaporation. VOCs in waters rise to the surface or sink to the bottom, according to their density. VOCs on the surface will largely evaporate. VOCs on the bottom must depend on solubilization in the water or upon mixing by current or wave action to reach the surface. VOCs in groundwater tend to remain trapped until the water reaches the surface, although some are subject to microbial modification. Concentrations in well water are rarely high enough for acute or subacute toxicity to be of concern. The very low levels of some solvents typically found in water have, however, caused a great deal of concern and debate about their carcinogenic potential.

Potential health effects of solvent contaminants of water have received considerable attention over the past 30+ years. A report by Mason and McKay (1974), of an increased incidence of cancer in persons who drank water from the Mississippi River, prompted the EPA to analyze the water supply of New Orleans. The finding of some 76 synthetic organic chemicals, many of which were solvents, prompted passage of the Safe Drinking Water Act in 1974. $CHCl_3$ is the most frequently found VOC in finished drinking water supplies in the United States (ATSDR, 1997a). It and certain other trihalomethanes are formed by reaction of the chlorine added as a disinfectant with natural organic compounds present in the water. Levels of solvents found in drinking water in the United States are

typically in the nanogram per liter (ppt) to microgram per liter (ppb) range, though concentrations in the low milligram per liter (ppm) range are found in water from wells situated in solvent plumes from hazardous waste sites and other point discharges. Of the thousands of chemicals found at hazardous waste sites, six of the ten most commonly present in groundwater are solvents (Fay and Mumtaz, 1996; Fay, 2006).

People are subjected to solvents in environmental media by inhalation, ingestion, and skin contact. Considerable effort was devoted by the EPA, from 1979 to 1985, to assess personal exposure to solvents in different locales of the United States. TRI, PERC, benzene, xylenes, and ethylbenzene were most frequently found in highest concentrations ($\sim$1–32 μg/m^3) in air (Wallace *et al.*, 1987). Exhaled breath levels of some chemicals (e.g., CHCl$_3$, ethylbenzene) corresponded to indoor air levels. Personal activities (e.g., smoking, visiting a dry cleaner and service station) and occupational exposures were believed to be largely responsible for relatively high exposures to other VOCs (e.g., benzene, toluene, xylenes, and PERC) (Ashley *et al.*, 1994). Subsequent studies, accounting for all pertinent exposure pathways, were conducted by the EPA in the mid-1990s (Gordon *et al.*, 1999). Elliott *et al.* (2006) recently reported indoor exposures to VOCs did not have adverse effects on the respiratory function of 953 adults surveyed, with the exception of 1,4-dichlorobenzene, a component of air fresheners, toilet bowl deodorants, and mothballs. CHCl$_3$ was found to be the most prevalent VOC in drinking water. It should be recognized that CHCl$_3$ and other VOCs volatilize to some degree during home water usage, particularly when the water is heated. Thus, a significant proportion of one's total exposure to VOCs in tap water can occur via inhalation (Weisel and Jo, 1996), though the contribution of dermal exposure is relatively modest (Thrall *et al.*, 2002).

TOXICOKINETICS

Toxicokinetic (TK) studies are playing an increasingly important role in reducing uncertainties in risk assessments of solvents (Leung and Paustenbach, 1995; Andersen, 2003; Clewell and Andersen, 2004). The fundamental goal of TK studies is to delineate the uptake and disposition of chemicals and certain of their metabolites in the body. It is now recognized that toxicity is a dynamic process, in which the degree and duration of injury of a target tissue are dependent on the net effect of toxicodynamic (TD) and TK processes including systemic absorption, tissue deposition, metabolism, interaction with cellular components, elimination, and tissue repair. Estimation of risk of toxicity from TK data is based on the fundamental concept that the intensity of response from an administered dose is dependent on the amount(s) of biologically active chemical moiety(ies) present in a target tissue (i.e., the tissue dose). A related concept is that the tissue dose in a given target organ in one species will have the same degree of effect as an equivalent target organ dose in a second species. This concept of tissue dose equivalence appears to be applicable in many cases to solvents (Andersen, 1987), although TD differences are possible. Gaining an understanding of how the processes that govern solvent kinetics vary with dose, route of exposure, species, and even different individuals greatly reduces the number of assumptions that have to be made in assessment of health risks from exposure and toxicity/carcinogenicity data.

Volatility and lipophilicity are two of the most important properties of solvents that govern their absorption and deposition in the body. Most solvents are volatile under normal usage conditions, though volatility varies from compound to compound. Lipophilicity

can also vary substantially, from quite water soluble (e.g., glycols, esters, and alcohols) to quite lipid soluble (e.g., halocarbons and aromatic hydrocarbons). Many solvents of particular concern at present are relatively lipid soluble and volatile, hence their designation as VOCs. These compounds have a relatively low molecular weight and are uncharged. Thus, they pass freely through membranes from areas of high-to-low concentration by passive diffusion.

Absorption

The majority of systemic absorption of inhaled VOCs occurs in the alveoli, although limited absorption has been demonstrated to occur in the upper respiratory tract (Stott and McKenna, 1984). Gases in the alveoli are thought to equilibrate almost instantaneously with blood in the pulmonary capillaries (Goldstein *et al.*, 1974). Blood:air partition coefficients (PCs) of VOCs are important determinants of the extent of their uptake. A PC is defined by Gargas *et al.* (1989) as the ratio of concentration of VOC achieved between two different media at equilibrium. As blood is largely aqueous, the more hydrophilic solvents have relatively high blood:air PCs, which favor extensive uptake. Gargas *et al.* (1989) determined in vitro PCs for 55 VOCs in F-344 rats. Human blood:air values were measured for 36 of the compounds. Because VOCs diffuse from areas of high-to-low concentration, increases in respiratory rate (to maintain a high alveolar concentration) and in cardiac output/pulmonary blood flow (to maintain a large concentration gradient by removing capillary blood containing the VOC) enhance systemic absorption.

Systemic uptake of solvents during ongoing inhalation exposures is dependent on tissue loading and metabolism, in addition to the factors noted above. Percent uptake is initially high, but progressively declines as the chemical accumulates in tissues, and the level of chemical in venous blood returning to the pulmonary circulation increases. A near steady state, or equilibrium will soon be reached upon inhalation of a fixed concentration of lipophilic solvents. The approach to equilibrium is asymptotic. Despite continued inhalation of lipophilic solvents, levels in the blood and tissues (other than fat) generally only increase modestly. Percent uptake remains relatively constant for the duration of exposure, with metabolism and accumulation in adipose tissue largely responsible for the continuing absorption. Hydrophilic solvents take considerably longer to reach steady-state, due to the extended time required for equilibration of chemical in the inspired air with that in the total body water (Goldstein *et al.*, 1974).

Solvents are well absorbed from the GI tract. Peak blood levels are observed within a few minutes of dosing fasted subjects, although the presence of fatty food in the GI tract can significantly delay absorption. It is now usually assumed that 100% of an oral dose of most solvents is absorbed systemically. The vehicle or diluent in which a solvent is ingested can affect its absorption and TK. Kim *et al.* (1990a,b), for example, found that a corn oil vehicle served as a reservoir in the gut to delay GI absorption of carbon tetrachloride (CC1$_4$) in rats. Although bioavailability of CC1$_4$ given in corn oil and in an aqueous emulsion was the same, peak blood CC1$_4$ levels and acute hepatotoxicity were much lower in the corn oil group. Other factors that can influence the oral absorption of other classes of chemicals have relatively little influence on most lipophilic solvents, due to their rapid passive diffusion throughout the GI tract.

Absorption of solvents through the skin can result in both local and systemic effects. Skin contact with vapors and concentrated solutions of solvents is a common occurrence in the workplace. Dermal contact with solvent contaminants of water can also occur

in the home and in recreational settings (Weisel and Jo, 1996). Lipophilic solvents penetrate the stratum corneum, the skin's barrier to absorption, by passive diffusion. Important determinants of the rate of dermal absorption of solvents include the chemical concentration, surface area exposed, exposure duration, integrity and thickness of the stratum corneum, and lipophilicity and molecular weight of the solvent (EPA, 1998). Skin penetration can be quantified in laboratory animals and humans by a variety of in vitro and in vivo techniques (Morgan *et al*., 1991; Nakai *et al*., 1999). Although absorption rates measured by these methods may vary numerically, there is often good agreement in their relative ranking of chemicals' ability to penetrate the skin. Dermal permeability constants are typically two to four times lower for human than for rodent skin (McDougal *et al*., 1990). The extent of dermal absorption in occupational and environmental exposure settings should be taken into account when conducting risk assessments of solvents.

Transport and Distribution

Chemicals and nutrients absorbed into portal venous blood from the GI tract can be removed from the bloodstream by first-pass, or presystemic elimination. As VOCs are rapidly absorbed and human intestinal epithelium apparently does not contain cytochrome *P*450 2E1 (Paine *et al*., 2006), the primary CYP isoform that metabolizes low doses of many VOCs, their first-pass GI metabolism should be negligible. Blood in the portal venous circulation passes through the liver before reentering the venous circulation. Solvents are also subject to exhalation by the lungs during their first pass through the pulmonary circulation. Those solvents that are well metabolized and quite volatile are most efficiently eliminated before they enter the arterial blood. The efficiency of the hepatic first-pass elimination is thus dependent on the chemical, as well as the rate at which it arrives in the liver. Pulmonary first-pass elimination, in contrast, is believed to be a zero-order process, as a fixed percentage of the chemical was hypothesized to exit the pulmonary blood at each pass through the pulmonary circulation (NAS, 1986). Indeed, Lee *et al*. (1996) demonstrated in rats that pulmonary first-pass elimination of TCE was relatively constant over a range of doses, but that hepatic elimination was inversely related to dose. Andersen (1981) concludes that the liver is capable of removing "virtually all" of an orally administered VOC, if the amount in the portal blood is not great enough to saturate metabolism. This hypothesis, if demonstrated experimentally, could have a profound effect on extrahepatic cancer and noncancer risk estimates of environmentally encountered levels of solvents in ingested media.

Solvents are transported by the arterial blood and taken up according to tissue blood flow and mass and tissue:blood PCs (Astrand, 1983). Relatively hydrophilic solvents solubilize to different extents in plasma. Nevertheless, as much as 50% of such compounds may still be carried by erythrocytes (Lam *et al*., 1990). These researchers found that lipophilic solvents do not bind appreciably to plasma proteins or hemoglobin, but partition into hydrophobic sites in these molecules. Lipophilic solvents also partition into phospholipids, lipoproteins, and cholesterol present in the blood. The brain is an example of a rapidly perfused tissue with a relatively high lipid content. Lipophilic solvents therefore quickly accumulate in the brain after the initiation of exposures (Warren *et al*., 2000). Inhalation of halothane, TCE, and CHC1$_3$ can produce CNS effects as profound as surgical anesthesia within as little as 1–2 minutes. Redistribution to poorly perfused, lipoidal tissues will subsequently occur. Adipose

tissue gradually accumulates relatively large amounts of VOCs, and slowly releases them back into the blood due to high fat:blood PCs and low blood perfusion rates.

Route of exposure can significantly influence target organ deposition and toxicity of solvents. Much of the pre-1980s toxicology database for solvents comprised results of inhalation studies. Inhalation is the major route of occupational exposure to these chemicals. Since then, much attention has been focused on potential health effects of VOC contaminants of food and drinking water. Due to the initial paucity of oral data, regulatory agencies sometimes extrapolated directly from inhalation data to predict risks of ingested VOCs. Such a practice is obviously not scientifically valid, when physiological differences in the absorption pathways are taken into account. All the cardiac output passes through the pulmonary circulation versus ~20% for the GI tract. Also, the alveolar surface area for absorption is approximately 20 times that of the entire GI tract in humans. VOCs absorbed in the lungs directly enter the arterial circulation and are transported throughout the body. In contrast, VOCs absorbed from the GI tract largely enter the portal circulation and are subject to first-pass elimination by both the liver and the lungs. The human GI epithelium contains certain monooxygenases, such as CYP3A4 (Ding and Kaminsky, 2003), though they do not participate to a significant extent in metabolism of most solvents. It is not surprising then that extrahepatic organs receive a greater dose following inhalation of VOCs. The liver should take up and metabolize a portion of many VOCs following ingestion. This has been demonstrated in rats receiving the same systemic dose of CC1$_4$ over the same time frame by inhalation and gastric infusion (Sanzgiri *et al*., 1997).

The pattern of ingestion of solvents can significantly influence their TK and health effects. For convenience, test chemicals are typically given daily to animals as a single bolus by gavage in short- and long-term oral toxicity and carcinogenicity studies. Actual human exposures to solvents in drinking water are quite different, in that people typically ingest water in divided doses. High, daily gavage doses of CHC1$_3$ and other halocarbons have produced hepatocellular carcinoma in B6C3F1 mice. No evidence of hepatic tumorigenesis was seen, however, when these mice were given the same doses of the chemical in their drinking water (Jorgenson *et al*., 1985; Klaunig *et al*., 1986). Female B6C3F1 mice exhibited hepatocellular necrosis and regenerative hyperplasia when gavaged with CHC1$_3$. Consumptions of the same doses in water were without ill effect (Larson *et al*., 1994). Similarly, the maximum blood level of CC1$_4$ was found to be 35 times higher and hepatotoxicity more severe in rats dosed with CC1$_4$ by gavage, than in those given the same dose over 2 hours by gastric infusion (Sanzgiri *et al*., 1995). Oral bolus doses of solvents can cause damage by exceeding the capacity of hepatic and pulmonary first-pass elimination, as well as protection and repair processes of cells.

The rate of systemic elimination of different solvents varies considerably. The two major routes of systemic elimination of VOCs are metabolism and exhalation. The rate and extent of metabolic clearance are dose- and compound-dependent. Exhalation is determined largely by the rate of pulmonary blood flow, the chemical's air:blood PC, and the alveolar ventilation rate. The more volatile, lipophilic VOCs are exhaled the most readily, because they have the higher air:blood PCs (Gargas *et al*., 1989). A good "case in point" is the comparison of toluene with acetone. The extent of CNS depression caused by each chemical is dependent on the concentration of the parent compound present in the brain (Bruckner and Peterson, 1981). As can be seen in Fig. 24-3, recovery of rats from toluene
Figure 24-3. Comparison of the induction of and recovery from toluene and acetone narcosis.

Rats inhaled 45 mg/L of toluene or acetone for 20 minutes or 3 h, respectively. Animal performance/reflexes were monitored periodically as measures of the degree of CNS depression. [Reproduced from Bruckner and Peterson (1981), with permission from Elsevier.]

anesthesia occurs within minutes of exposure cessation. This can be attributed to redistribution of toluene from the brain to body fat and other tissues, as well as to relatively rapid metabolism and exhalation. In contrast, recovery from acetone narcosis does not occur for at least 9 hours post exposure. As acetone is water soluble, limited amounts are deposited in the brain. It is instead distributed in the considerable volume of the blood and other body water. Clearance of acetone is slow due to its large volume of distribution and its relatively slow metabolism and exhalation. Acetone's water solubility is responsible for its relatively low air:blood PC and retention in the pulmonary blood. Thus, acetone is available for diffusion into the brain and induction of a modest degree of CNS depression for a prolonged time.

Body fat plays an important role in the elimination of lipophilic solvents. Blood levels of such solvents drop very rapidly during the initial elimination phase following cessation of exposure. This so-called redistribution phase is characterized by rapid diffusion of solvents from the blood into tissues. Equilibration of adipose tissue is prolonged due to the small fraction of cardiac output ($\sim$3%) supplying fat depots (Goldstein *et al.*, 1974). Body fat increases the volume of distribution and total body burden of lipophilic solvents. Deequilibration from adipose tissue during the terminal elimination phase is prolonged, due to slow blood flow and high fat:blood PCs. Sato *et al.* (1975) demonstrated slower elimination of benzene from females than from male rats and humans, due to the female's higher body fat content. Rats with more body fat exhibited leukopenia during chronic benzene exposure.

Metabolism

Biotransformation plays a key role in modulating the toxicities of many solvents. Many solvents are poorly soluble in water. Certain cellular enzymes can convert them to relatively water-soluble derivatives, which may be more readily eliminated in the largely aqueous urine and/or bile. Conversion of a bioactive parent compound to a less bioactive or inactive metabolite(s) that (is/are) efficiently eliminated is termed *metabolic inactivation*, or *detoxification*. Toluene, for example, accumulates in neuronal membranes and inhibits their functions. Toluene is metabolized to hydroxyl and carboxyl metabo-

lites, which are too polar to accumulate or remain in substantial quantities in neuronal membranes. Thus, metabolism serves to detoxify and to accelerate the elimination of toluene. Metabolism of other solvents can produce reactive metabolites that are cytotoxic and/or mutagenic. This phenomenon is known as *metabolic activation*, or *bioactivation*. Benzene, for example, is oxidized to a variety of quinones and semiquinones that can produce hematopoietic toxicities and leukemia (Snyder, 2004). Benzene and many other VOCs are converted via multiple metabolic pathways to products of varying toxicity. Some of these competing pathways are considered bioactivation, others detoxification pathways. A variety of factors can influence the prominence of the different pathways and hence alter toxicity outcomes.

The initial step in biotransformation of relatively lipophilic solvents is catalyzed primarily by microsomal CYPs. They are a "superfamily" of hemoproteins that act as terminal oxidases of the mixed-function oxidase system. Their mode of action is described in Chap. 6. CYPs can catalyze a number of oxidative reactions, as well as certain reductive reactions (Omiecinski *et al.*, 1999). Some 40 different human CYP isoforms have been identified to date, but six of them (CYPs 2D6, 2C9, 3A4, 1A2, 2C19, and 2E1) account for the majority of xenobiotic metabolism (Smith *et al.*, 1998; Rendic, 2002). CYPs are generally thought to have broad, overlapping substrate specificities, as demonstrated by Kobayashi *et al.* (2002) in rats. It is believed by some authorities that enzyme kinetics under physiological conditions may favor one or two isoforms as the primary catalysts for a given chemical (Wrighton and Stevens, 1992). Different isoforms can predominate at different concentrations of a chemical.

The outcome of exposure to a potentially toxic solvent can depend on the relative abundance of CYP isoforms. Expression of CYPs can differ considerably as a result of genetic polymorphisms and exposure to chemicals that induce or inhibit specific isoforms. A number of factors have been found to be sources of individual variability in CYP induction (Tang *et al.*, 2005). Inheritable gene alterations, such as base changes and deletions, can result not only in functionally deficient enzymes, but also in the absence of certain P450s (Daly *et al.*, 1993). As CYPs have different modes of regulatory control, their expression in response to various inducers and inhibitors varies. It should also be recognized that frequently there are interspecies differences in the presence, regulation, and catalytic activities of P450s (Lewis *et al.*, 1998).

There has been a focus on identification of CYPs that participate in the metabolism of individual solvents. Nakajima *et al.* (1992a) found that low concentrations of TCE in rat liver were metabolized primarily by CYP2E1, a constitutive, high-affinity, low-capacity isoform. CYP2B1/2, a low-affinity, high-capacity form predominated under high-dose (substrate) conditions. CYP2E1 was observed to be a major contributor to the metabolism of TCE and benzene, but not toluene. CYP1A1 catalyzed the formation of *o*-cresol, but not benzyl alcohol from toluene. CYP1A1 oxidized TCE in mice but not in rats. Thus, CYP isoforms exhibit species selectivity, substrate selectivity, and regioselectivity for solvents (Nakajima, 1997).

CYP2E1 is a major catalyst of the oxidation of a variety of low-molecular-weight xenobiotics, including many solvents. CYP2E1 is found predominantly in liver, with lower levels present in kidneys, lungs, brain, testes, and other extrahepatic tissues of rodents and humans (Lieber, 1997). Guengerich *et al.* (1991) reported that human CYP2E1 is primarily responsible for oxidation of some 16 halogenated and aromatic hydrocarbons, including benzene,

styrene, $CHCl_3$, TCE, and vinyl chloride. These compounds are oxidized to electrophilic metabolites, capable of causing cytotoxicity and/or mutagenicity (Raucy *et al.*, 1993). The isozyme is also responsible for reduction of CCl_4 to free radicals (see the discussion of CCl_4 in this chapter). CYP2E1 activity is associated with the pathogenesis of alcoholic cirrhosis, through formation of highly reactive oxygen radicals and acetaldehyde from ethanol (Lieber, 1997; Caro and Cederbaum, 2004). CYP2E1 is inducible by ethanol, acetone, pyridazine, chlorzoxazone, isoniazid, and other of its substrates. Activity of the isoform varies from species to species (Nakajima, 1997) and from human to human (Lipscomb *et al.*, 1997). Overnight fasting is widely recognized to induce CYP2E1, due in part to release of acetone during lipolysis (Bruckner *et al.*, 2002). Starving rats, however, apparently must engage in coprophagy for induction to occur (Chung *et al.*, 2001). Such differences in CYP2E1 activity/levels may play a major role in susceptibility to the toxicity and carcinogenicity of ethanol and a number of other solvents.

A variety of environmental factors can predispose people to harmful effects of solvents by altering P450s (Lof and Johanson, 1998). Ethanol is an effective CYP2E1 inducer when ingested repeatedly in substantial amounts. The person who drinks in such a manner may be subject to potentiation of solvent toxicity, due to increased solvent metabolic activation (Manno *et al.*, 1996). Conversely, ethanol consumed at about the same time as a solvent exposure can be protective by competitively inhibiting metabolic activation of the solvent (Lieber, 1997). Thus, the timing of exposures is important. Folland *et al.* (1976) reported severe CCl_4-induced hepatorenal injury in workers at an isopropyl alcohol bottling plant. These subjects' preexposure to the alcohol, which is metabolized to acetone, had markedly induced CYP2E1. Their induced condition resulted in a substantial increase in the metabolic activation and cytotoxicity of CCl_4, upon inhalation of normally nontoxic concentrations of the halocarbon.

The metabolic basis of solvent interactions receives considerable attention. The consequence of CYP2E1 induction by one solvent or drug depends on the nature of the second solvent. Kaneko *et al.* (1994) reported that ethanol pretreatment of rats has a more profound effect on the TK of TRI (poorly metabolized) than TCE (well metabolized). Similarly, ethanol pretreatment of rats results in a greater increase in metabolism and hepatotoxicity of CCl_4 (relatively poorly metabolized) than $CHCl_3$ (well metabolized) (Wang *et al.*, 1997). As capacity- (i.e., metabolic capacity of the liver) limited metabolism prevails for poorly metabolized solvents, irrespective of dose, induction of their metabolism could be toxicologically significant in high (occupational) or low (environmental) exposure settings. In contrast, alterations of the bioactivation of low doses of well-metabolized solvents should be of little consequence, as their biotransformation is perfusion (i.e., hepatic blood flow) limited. Lipscomb *et al.* (2003) utilized a PBTK model to calculate that a six-fold interindividual difference in TCE metabolism resulted in <2% change in the total amount of TCE oxidized by persons inhaling 50 ppm for 8 hours or drinking 2 L of water containing 5-ppb TCE. Under such circumstances, interindividual metabolic differences would have little influence on cancer risks posed by trace levels of such solvents.

Physiological Modeling

PBTK models have been developed to provide predictions of chemical concentrations in blood and tissues as a function of time. PBTK models are thus used to relate the administered dose to the blood and/or tissue dose of parent compound and/or bioactive moiety. If there is, sufficient knowledge of the physiology of the test animal/tissue and interactions of the bioactive moiety with cellular components and ensuing responses, physiologically based toxicodynamic (PBTD) models can be developed (Conolly and Andersen, 1991). Few PBTD models have been published to date. Tan *et al.* (2003) linked an existing PBTK model for $CHCl_3$ with data for hepatocellular death and regenerative hyperplasia to predict liver tumor response in mice. Development of PBTK models for anesthetic gases and other pharmaceutical agents was initially undertaken in the 1920s and 1930s. Modeling enjoyed widespread use in the design of experiments and dosage regimens for drugs, but the practice was not extended to industrial chemicals until the 1970s and 1980s. A "benchmark" paper by Ramsey and Andersen (1984) described the development of a PBTK model for styrene. By 1995, PBTK models had been developed for ~50 chemical environmental contaminants (Leung and Paustenbach, 1995). Some 28 of these 50 chemicals were solvents. Andersen (2003) more recently identified some 700 papers that dealt with PBTK models and/or their applications to toxicology and risk assessment. Thus, it is clear that physiological models are being developed and used with increasing frequency to incorporate dosimetry and mechanistic data into noncancer and cancer risk assessments (Krishnan and Johanson, 2005).

Physiological modeling accounts for species- and dose-dependent shifts from linear to nonlinear kinetics, which impact tissue doses of bioactive moiety or moieties. The models are well suited for species-to-species extrapolations, because human physiological and metabolic parameter values can be inputted into animal models, and simulations of target tissue doses and effects in humans generated. Thus, solvent exposures necessary to produce the same target organ dose in humans, as those found experimentally to cause unacceptable cancer or noncancer risks in test animals, can be determined in some cases with reasonable certainty. In the limited number of cases where there may be species differences in tissue sensitivity, PBTD models can be used to forecast toxicologically effective target organ doses. The influence of interindividual variability in model parameters is now receiving considerable attention (Price *et al.*, 2003a). Several groups of investigators are performing model fitting in a Bayesian framework using Markov chain Monte Carlo simulation to reduce parameter uncertainty (Jonsson and Johanson, 2001, 2002).

POTENTIALLY SENSITIVE SUBPOPULATIONS

There is considerable variability in responses of humans to solvents and other xenobiotics (Hattis *et al.*, 1987). Although information on interindividual differences in the kinetics and toxicity of solvents is usually limited, some significant differences are reported and should be taken into account in risk assessments (Grassman *et al.*, 1998; Hattis *et al.*, 1999). Children within specific age groups appear to be even more variable than adults (Hattis *et al.*, 2003). Current EPA cancer and noncancer risk assessment practices are generally considered to be quite protective of potentially vulnerable subgroups, due to the use of multiple uncertainty factors and conservative default assumptions.

Endogenous Factors

Children   Currently, there is considerable interest in regulatory and scientific issues related to protection of children's health. The

potential sensitivity of infants and children to pesticides and other chemicals was brought to the public's attention by a National Academy of Sciences' report (NAS, 1993; Bruckner, 2000). The ensuing Presidential Executive Order 13045 in 1997, directed all federal agencies to make protection of children a high priority and to consider risks to children when making policies and setting standards. The Food Quality and Protection Act of 1996, dictated that an additional 10-fold safety/uncertainty factor be used in pesticide risk assessments when pediatric toxicity and TK data are unavailable. This is almost always the case for insecticides, solvents, and other chemical contaminants. Application of the 10-fold children's safety factor to non-pesticides has been considered. The Pediatric Research Equity Act of 2003 requires pharmaceutical companies seeking FDA's approval of new drugs to frequently assess a compound's safety and efficacy at different doses in pediatric patients.

Very little information is available on the toxic potential of solvents and most other chemicals in infants and children. There are several well-known examples of compounds (e.g., lead, thalidomide, chloromycetin, and valium) to which fetuses or neonates are particularly susceptible. Results of experiments with chlorpyrifos in immature rats raised enough concern about possible neurodevelopmental disorders in children that use of a number of organophosphates was severely restricted, and they have largely been removed from the market (Colborn, 2006). Compilations of maximally tolerated doses (MTDs) of chemotherapeutic drugs are among our most definitive data on age-dependent toxicity in humans. Clinical trials of diverse groups of antineoplastic drugs revealed that their toxic effects are often similar qualitatively, and usually differ quantitatively by a factor of ≤ 2 (NAS, 1993). MTDs for children are frequently higher than that for adults (Bruckner, 2000). Ginsberg et al. (2002) assembled a database with which TK parameters for adults and children can be compared for 45 drugs. These developmental metabolic profiles are relevant to some solvents and other environmental chemicals.

Increasing numbers of toxicology studies are being carried out in immature laboratory animals. The most comprehensive data sets available are still compilations of LD_{50} values from experiments with immature rodents (Done, 1964; Goldenthal, 1971). These data, like the aforementioned MTD compilations, reveal that immature animals are more sensitive to some but not to all chemicals. Variances are usually no more than two- to three-fold, but can be as much as 10-fold. The younger and more immature a subject, the more different its response from that of the adult. The newborn mouse and rat more nearly resemble the human fetus during the third trimester than during the neonate's initial weeks and months of life. Thus, it is not surprising that newborn rodents are usually much more sensitive to many toxicants than are human newborns. Growth and maturation are, of course, much more rapid in rodents. A few days growth of mice and rats can result in substantial changes in metabolism, disposition, and toxicity (Ginsberg et al., 2004). It is generally accepted that there are "windows of vulnerability," or periods during the development of the nervous, audiovisual, immune, endocrine, and other organ systems when the intricate, fragile maturational processes may be particularly sensitive to xenobiotics (Faustman et al., 2000; Dorman et al., 2001; Scheuplein et al., 2002). These windows occur at different ages and last for different periods of time in different species. This makes the choice of an appropriate animal model for children complex and cross-species comparisons more difficult than usual with adult risk assessments (Ginsberg et al., 2004; Morford et al., 2004).

Despite a paucity of data, some logical assumptions can be made about age-dependent changes in the TK and toxicity of solvents. GI absorption of solvents would not be expected to vary with age, as most solvents are absorbed rapidly and completely by passive diffusion from the entire GI tract. Systemic absorption of inhaled solvents may be greater in infants and children. Their cardiac output and respiratory rates are relatively high, although their alveolar surface area is lower than that of adults (Sarangapani et al., 2003). Reduced plasma protein binding in neonates and infants may be of consequence for certain solvent metabolites. Low-binding capacity for TCA, for example, could result in more of the mouse hepatocarcinogen being available for hepatic uptake, as well as for renal clearance. Extracellular water, expressed as percent of body weight, is highest in newborns and diminishes through childhood. The larger volume of distribution for water-soluble solvents results in their slower clearance and longer duration of action. Body fat is high from ∼6 months to 3 years of age, then steadily decreases until adolescence, when it increases again in females. As lipophilic solvents accumulate in adipose tissue, more body fat would result in higher body burdens, slower clearance, and longer duration of action (NAS, 1993).

Changes in xenobiotic biotransformation during maturation may have the greatest impact on susceptibility to chemical toxicity and carcinogenicity. Low liver P450-mediated and liver and plasma carboxylesterase-mediated detoxification of deltamethrin, a pyrethroid insecticide, results in elevated blood and brain levels of the neurotoxic parent compound and severe acute poisoning of neonatal and preweanling rats (Anand et al., 2006a). Poisonings of premature and term human newborns by benzyl alcohol, hexachlorophene, valium, chloramphenicol, and certain other compounds are primarily attributable to deficits in hepatic Phase II metabolic (i.e., conjugative) capacity. Maturational studies of human liver reveal that CYP isoforms are expressed asynchronously (Cresteil, 1998). More recently there have been comprehensive efforts to characterize the ontogeny of human hepatic Phase I (Hines and McCarver, 2002; Stevens et al., 2003; Johnsrud et al., 2003) and Phase II (McCarver and Hines, 2002) enzymes from gestation through adolescence. Levels of CYP2E1, the primary catalyst of oxidation of a variety of solvents, are very low in fetal liver, increase steadily for the first year, and remain relatively constant through adolescence (Cresteil, 1998; Johnsrud et al., 2003). Blanco et al. (2000) failed to find an age-related difference in the maximal in vitro activity of CYP2E1 or other CYP isoforms in liver microsomes from donors 0.5 to– 93 years old. More rapid systemic clearance of many compounds by young children than by adults (Ginsberg et al., 2002) is generally believed to result from the child's liver's larger volume and more rapid perfusion rate (Murry et al., 1995; Noda et al., 1997; Sarangapani et al., 2003). Glomerular filtration and renal tubular secretion are quite low at birth, but increase substantially during the first 6 months to 1 year (Scheuplein et al., 2002). The half-life of creatinine, a substance eliminated entirely by glomerular filtration, is about half the adult value at 1 year. The net result of multiple age-related TK changes, some with offsetting effects, is usually difficult to predict.

A number of authorities have advocated the use of PBTK/TD models to collectively account for the unique and changing characteristics of children (Clewell et al., 2004; Daston et al., 2004; Landrigan et al., 2004). Considerable attention is being devoted to this pursuit, but the number of models published to date for solvents and other chemicals is quite limited. Pelekis et al. (2001) used simplified PBTK model-based algebraic equations and ranges of

physiological and biochemical parameters (in lieu of measured values) to simulate tissue doses of a series of solvents in children and adults. The authors concluded that the child–adult differences of parent compounds were modest for inhalation exposures. Sarangapani *et al*. (2003) developed a PBTK model that integrated key age-specific respiratory tract parameters, such that the disposition of four VOCs (styrene, vinyl chloride, isopropanol, and PERC) could be forecast in children and adults. Differences in blood levels of parent compounds in infants and adults were comparable or varied <2-fold during the first year of life. Blood metabolite concentrations or the amounts metabolized in the liver or lung, microsomes, however, often varied substantially with age. Price *et al*. (2003b) utilized some age-specific physiological and biochemical data to model the kinetics of inhaled furan in blood of children and adults. Physiological parameter values (e.g., metabolic and alveolar ventilation rates) for some or all age groups were unavailable and had to be estimated. Nong *et al*. (2006) incorporated measured age-specific liver volumes and CYP2E1 content into a PBPK model for toluene to predict internal doses (blood levels) of the parent compound in adults and in children of different age groups. CYP2E1 content was the key model input parameter for neonates, whereas liver blood-flow rate was predominant after a few months of age. Combined interindividual and interage variability in blood level versus time curves was within a factor of 2, except for the neonates, which had somewhat higher AUCs.

Clewell *et al*. (2004) recently developed what they termed a life-stage model to simulate blood levels of four solvents [isopropanol, vinyl chloride, methylene chloride (MC), and PERC] and their primary metabolite in different life stages. This was intended to be a preliminary model, in view of the lack of validated models for the younger groups and the required number of simplifying assumptions in the face of uncertainties about many age-specific parameters. In general, dose metrics for the chemicals across life stages were within a factor of 2, except during the early postnatal period when the largest TK differences occurred. These and the observations of Pelekis *et al*. (2001) and Nong *et al*. (2006) are well within the TK component of 3.2 of the classical 10-fold interspecies factor. Potential PD differences, of course, are not taken into account here. Gentry *et al*. (2003) took a similar approach to forecast internal dosimetry of vinyl chloride, isopropanol, MC, and PERC in human offspring during pregnancy and lactation. In general, blood concentrations of the VOCs were lower in neonates during lactation than in the fetus during gestation. Fetal/neonatal VOC exposures were generally several orders of magnitude lower than maternal exposures. The relatively low systemic exposures and low metabolic capacity should reduce the risks from reactive metabolites of these solvents during these periods.

Elderly   The elderly, like infants and children, may be more or less sensitive to the toxicity of solvents than younger adults. Data are sorely lacking on the relative susceptibility of geriatric populations to solvents and other industrial chemicals. The aging CNS undergoes changes (e.g., neuronal loss, altered neurotransmitter and receptor levels, and reduced adaptability to effects of toxicants) (Ginsberg *et al*., 2005), that may predispose to more pronounced neurologic effects by solvents. Older people do appear to be more sensitive to the CNS-depressant effects of ethanol, due in part to lower gastric alcohol dehydrogenase (ADH) activity (Seitz *et al*., 1993). Kiesswetter *et al*. (1997) observed the most pronounced neurobehavorial effects in older workers with the highest single or mixed organic sol-

vent exposures. Memory, attention, visual perception, and motor skills diminish with aging, even in the absence of chemical exposure. The aforementioned experimental findings could be interpreted as merely additive, or as exacerbation during a vulnerable life stage. Paradoxically, a subsequent investigation by Kiesswetter *et al*. (2000), this time of toluene-exposed rotogravure printers, revealed fewer symptoms and better psychometric performance in older workers with higher exposure levels. A limited number of studies of this phenomenon by other investigators are no more definitive.

Investigations of adverse effects of solvents on old animals have been quite limited. Attention has been primarily focused on age-related susceptibility of rodents to liver damage. Susceptibility varies dramatically from one chemical to another. Rikans and Hornbrook (1997) reviewed studies showing increased susceptibility of geriatric F-344 rats to allyl alcohol, but there was no apparent age dependency with bromobenzene. Results varied with species, strain, and gender. $CC1_4$ hepatotoxicity was less severe in 28-month-old female F-344 rats than in young adults (Rikans *et al*., 1999), but more severe in 28-month-old male F-344 rats (Schoeffner *et al*., 1996). No effects of aging on hepatic CYP2E1 levels, $CC1_4$ metabolic activation, glutathione (GSH) levels, antioxidants, or ability to suppress oxidative damage were found. Wauthier *et al*. (2004) saw no changes in CYP2E1 protein or mRNA in 18-month-old male Wistar rats, but did observe decreased CYP2E1 activity. The investigators attributed this phenomenon to oxidative stress on the isoform. More severe $CC1_4$-induced DNA damage in hepatocytes from older mice was shown to be due to preexisting oxidative DNA damage and a higher incidence of DNA strand breaks in the older animals (Lopez-Diazguerrero *et al*., 2005). Thus, normal aging processes can be accentuated by chemical stressors.

TK changes during aging have primarily been of interest in the field of drug therapeutics (Bressler and Bahl, 2003; McLean and LeCouteur, 2004). Federal agencies including the EPA are now focusing more attention on exposures and potential vulnerabilities of the elderly to toxic chemicals (Geller and Zenick, 2005). As there are few pertinent geriatric animal or human toxicology studies, it would be worthwhile to consider information on age-specific factors that govern the TK of solvents. Data for a substantial number of geriatric TK indices are inadequate. Clewell *et al*. (2002) and Sarangapani *et al*. (2003) have compiled comprehensive reviews and evaluations of the age-specific TK parameters that are available. Splanchnic blood flow decreases with age more rapidly than cardiac output. This seems unlikely to affect the GI absorption of solvents, as they are readily absorbed by passive diffusion. Dermal absorption could be influenced by loss of integrity of the stratum corneum, reduction in skin surface lipids and atrophy of the dermal capillary network (Roskos *et al*., 1989). Total lung capacity does not change with age, but vital capacity (mobile volume) diminishes progressively due to loss of lung elasticity and strength of the respiratory muscles. Residual capacity (fixed volume) increases with progressive narrowing and closure of small airways (Ritschel, 1988). Other alterations contributing to lower pulmonary absorption include decreases in alveolar surface area, membrane permeability and capillary blood volume, and thicker alveolar cell membranes (Clewell *et al*., 2002). Nevertheless, inhalation PBPK model predictions of steady-state blood concentrations of isopropanol, styrene, vinyl chloride, and PERC differed very little among 10-, 15-, 25-, 50-, and 75-year-old humans (Sarangapani *et al*., 2003).

Age influences the distribution of xenobiotics in the body, as well as their metabolism and elimination (Bressler and Bahl, 2003). With aging, body fat content usually increases substantially at the

expense of the lean mass (i.e., skeletal muscle) and body water. Thus, polar solvents tend to reach higher blood levels during exposures. Relatively lipid-soluble solvents accumulate in adipose tissue and are released slowly to sites of action, metabolism, and elimination. Ginsberg *et al*. (2005) assembled clearance and half-life ($t^1/_2$) data for 46 drugs in 4500 subjects. Clearance was typically slower and half-life longer after the age of 60 years, particularly in those 80–84 years old. Cardiac output diminishes 30–40% between the ages of 25 and 65 years, as do renal and hepatic blood flows (Woodhouse and Wynne, 1992; Cody, 1993; McLean and Le Couteur, 2004). The latter two research groups and Clewell *et al*. (2002) concluded that reduced hepatic clearance of flow- and capacity-limited xenobiotics in the elderly was due primarily to reductions in liver blood flow and liver size. McLean and Le Couteur (2004) presented evidence that aging of the sinusoidal endothelium reduced oxygen delivery and drug transfer from blood to hepatocytes. Schmucker (2005) and Herrlinger and Klotz (2001) did not find significant relationships between aging and P450 activities in human liver. Cotreau *et al*. (2005) did describe some reports of age-related decreases in CYP3A4, an isoform of limited relevance to solvent metabolism. Kinirons and O'Mahony (2004) reviewed reports of declining drug metabolism in frail versus healthy elderly. With the exception of an ∼70% decline in male-specific CYP2C11, senescence had little effect on pre- or post-phenobarbital induction of expression of some 12 constitutive and inducible P450s in Sprague–Dawley rats (Agrawal and Shapiro, 2003).

Information is available on certain age-related aspects of xenobiotic clearance other than metabolism. Plasma protein binding of drugs generally remains unaltered or diminishes modestly with age (Grandison and Boudinot, 2000). Hepatic and/or renal dysfunction more often account for altered protein binding. No information apparently exists on effects of aging on most transporters (Kinirons and O'Mahony, 2004). Renal clearance diminishes with advancing age, due to parallel annual decreases of ∼0 .65% in glomerular filtration and maximal tubular secretory capacity beyond the age of 30 years. The foregoing TK factors may significantly influence tissue dosimetry and in turn responses of geriatric populations to solvents and other chemicals.

PBTK models should be useful for integrating the age-related physiological and metabolic changes into a quantitative framework to forecast their net effect on blood and tissue time courses of parent compounds and metabolites. Very few such "geriatric" models have been published. McMahon *et al*. (1994) employed a PBTK model to demonstrate that reduced urinary elimination of benzene metabolites by geriatric mice was due to decreased renal blood flow rather than altered formation of metabolites. Corley *et al*. (2005c) incorporated a number of age-, gender-, and species-specific physiological and biochemical parameters into a preexisting PBTK model for 2-butoxyethanol (BE), in order to predict the kinetics of BE and butoxyacetic acid (BAA), BE's major metabolite, in male and female mice and rats of different ages. The life-stage PBTK model of Clewell and colleagues was used to simulate human blood concentrations of several VOCs and their major metabolite (or metabolic rate) from infancy through the age of 75 years. Blood levels of the parent compounds remained relatively constant during adulthood, but metabolite levels or amounts metabolized frequently varied during the pediatric and geriatric years (Sarangapani *et al*., 2003). In a subsequent publication, blood levels of PERC and its major metabolite, TCA, were predicted to progressively rise during adulthood and old age by a PBTK model. Clewell *et al*. (2004) attributed this phenomenon to relatively low pulmonary and metabolic clear-

ance, coupled with accumulation of the lipophilic solvent in ample amounts of adipose tissue. Much work remains to be done to refine these generic PBTK models and to integrate them with significant geriatric PD changes (Burton *et al*., 2005).

Gender   Some of the physiological and biochemical differences between men and women have the potential to alter tissue dosimetry and health effects of certain solvents. Clewell *et al*. (2002) have provided one of the most recent and comprehensive reviews of the potential impact of gender differences on chemicals' TK. There was no convincing evidence of sex differences in GI absorption rate constants. The investigators located few data on gender-dependent dermal or pulmonary absorption of solvents or other chemicals. Sarangapani *et al*. (2003) published tables of a number of age-specific factors (e.g., cardiac output, pulmonary ventilation rate, and pulmonary surface area) that dictate pulmonary absorption of VOCs. These rates and values were generally higher for males, but a PBPK model's predictions of steady-state blood concentrations for inhaled isopropanol, styrene, vinyl chloride, and PERC were largely sex independent (Sarangapani *et al*., 2003).

Distribution of water- and lipid-soluble solvents can vary substantially between men and women (Schwartz, 2003). Most men have more lean body mass and larger body size. Women typically have smaller volumes of distribution for polar solvents, but larger volumes of distribution for lipophilic solvents (Gandhi *et al*., 2004). Lean body mass decreases from 76 to 52%, and body fat increases from 33 to 49% in females between the ages of 25 years and 65–70 years. Nomiyama and Nomiyama (1974) found that women retain less inhaled acetone and ethyl acetate than similarly exposed men. Levels of toluene and TCE in expired air of females are lower, reflecting greater fat deposition and retention of these lipophilic chemicals. Similarly, women exhibit significantly higher respiratory uptake of 1,3-butadiene, another lipophilic VOC (Lin *et al*., 2001b). Clewell *et al*. (2004) utilized their life-stage PBPK model to predict blood levels of PERC and TCA, its major metabolite, in men and women over a lifetime of daily ingestion of 1 μg PERC/kg. The women were predicted to attain significantly higher blood PERC and TCA concentrations, ostensibly due to PERC's greater storage in fat and relatively low pulmonary and metabolic clearance.

The major sex differences in P450-mediated hepatic metabolism in rats are not seen in humans or most other mammals (Nakajima, 1997). Rinn *et al*. (2004) did recently find many significant differences in gene expression in the liver, kidney, and reproductive tissues of male and female mice. Some of the differentially expressed genes involve drug and steroid metabolism, but the biological significance of these variances is unknown. No marked gender differences in P450-catalyzed oxidation reactions have been identified in humans (Schmucker *et al*., 1990; Mugford and Kedderis, 1998). Other investigators have described modestly higher levels and activities of certain liver P450s in males, including CYP2E1, CYP1A2, and CYP2D6 (Schwartz, 2003). Many CYP3A substrates do not exhibit sex-dependent differences in clearance, though some researchers reported differences for certain substrates (Cotreau *et al*., 2005). Gender-specific metabolism data for most hydrocarbon solvents are lacking. Men exhibit somewhat lower blood ethanol levels than women upon ingestion of equal doses, due in part to more extensive ADH-catalyzed metabolism of the alcohol by the male gastric mucosa (Frezza *et al*., 1990). UDP glucuronyl transferase activity appears to be somewhat higher in males. Women seem to have modestly lower glomerular filtration rates, though

information on renal tubular secretion and reabsorption processes is lacking.

A gender-specific PBTK model was developed to assess the relative risks (RRs) of benzene exposures (Brown *et al*., 1998). Women were found to have a higher blood:air partition coefficient, a higher percent of body fat and higher maximum rate of benzene metabolism than men. Women exhibited higher blood benzene levels and a 23–26% increase in benzene metabolism, potentially placing them at greater risk than men with equivalent exposures.

Relatively little is known about potential influences of contraceptives, hormone replacement therapy, or pregnancy on the metabolism and disposition of xenobiotics (Gleiter and Gundert-Remy, 1996). The menstrual cycle with its hormone changes may influence the metabolism of some xenobiotics (Fletcher *et al*., 1994). Watanabe *et al*. (1997) found that estradiol changes during the estrous cycle of rats affected both UDP-glucuronyl transferase and NADPH-cytochrome *c* reductase activities. Experiments by Nakajima *et al*. (1992b) demonstrated that pregnancy of rats resulted in significant reductions in hepatic P450 content, as well as the metabolism of both toluene and TCE. Pregnancy results in a 40% increase in tidal volume, which may increase the absorption of inhaled VOCs. Plasma volume increases ~50% in pregnant women, resulting in a decrease in albumin concentration and plasma protein binding of many drugs (Fletcher *et al*., 1994). Cardiac output increases ~50%, due to increases in stroke volume and heart rate (Silvaggio and Mattison, 1994). Uterine blood flow, renal plasma flow, and glomerular filtration rise substantially, though no information on hepatic blood flow is apparently available. These TK factors need to be considered when assessing risks and setting occupational exposure limits for this subpopulation.

Gentry *et al*. (2003) described an approach for use of PBTK modeling to compare maternal and fetal/neonatal blood and tissue dosimetry during pregnancy and lactation. In general, blood levels of isopropanol, vinyl chloride, MC, and PERC were predicted to be lower in the human neonate during lactation than in the fetus during gestation. Simulated vinyl chloride levels, for example, were 4 orders of magnitude lower in the neonates. Fetal/neonatal isopropanol levels were forecast to be orders of magnitude lower than maternal levels. Corley *et al*. (2003) evaluated the state-of-the-science in PBTK/TD modeling of the developing embryo, fetus, and neonate.

Genetics   A variety of genetic polymorphisms for biotransformation have been found to occur at different frequencies in different ethnic groups (Daly *et al*., 1993). Polymorphisms for xenobiotic-metabolizing enzymes may affect the quantity and quality of enzymes and the outcomes of exposures to solvents (Ingelman-Sundberg *et al*., 1994). It is important to note that culturally linked environmental factors also contribute to ethnic differences in metabolism and disposition of solvents and other chemicals. It is often difficult to disentangle the influences of genetic traits from those of different lifestyles, socioeconomic status, and geographic settings.

Ethnic differences in regulating the expression of CYP isozymes and other enzymes are associated with some variations in drug and solvent metabolism (Ingelman-Sundberg *et al*., 1994; Weber, 1999). Shimada *et al*. (1994) found that Caucasians had higher total hepatic CYP levels than Japanese. Caucasians exhibited higher CYP2E1 activities, as reflected by aniline *p*-hydroxylation and 7-ethoxycoumarin *O*-deethylation. Individuals with two linked

polymorphisms in the transcription regulatory region of the CYP2E1 gene exhibited greater expression of the isoform. Reported frequencies of these rare alleles were 2% in Caucasians, 2–5% in African Americans, and 24–27% in Japanese (Kato *et al*., 1992). Kawamoto *et al*. (1995) found that a CYP2E1 polymorphism in Japanese workers did not affect metabolism of toluene to benzoic acid, but that CYP1A1 and aldehyde dehydrogenase (ALDH2) polymorphisms did. ALDH2 deficiency can result in elevated CNS levels of toluene and benzaldehyde (Wilkins-Haug, 1997) in toluene-exposed individuals. About half of the Japanese population lacks ALDH2, due to a structural point mutation in the ALDH2 gene. Pronounced interethnic differences in rates of ethanol metabolism have been associated with a number of ADH and ALDH polymorphisms (Pastino *et al*., 2000).

Ethnic differences have been demonstrated for some phase II biotransformation reactions. Glutathione *S*-transferases (GSTs) are a family of enzymes, some of which promote the detoxification of electrophilic metabolites by catalyzing their conjugation with reduced glutathione (GSH). GST theta-mediated conjugation with GSH is the first step in metabolic activation of MC to formaldehyde, a putative carcinogen. Individuals with a null/null genotype for GST theta are thus at a lower risk of developing cancer from MC (El-Masri *et al*., 1999). The prevalence of this genotype ranges from 10% in Mexican Americans to 60–65% in Chinese and Koreans (Nelson *et al*., 1995). GSTs participate in conjugating relatively small percentages of doses of TCE (Lash *et al*., 2000b) and PERC (Lash and Parker, 2001). These pathways, however, can lead to production of cytotoxic, mutagenic metabolites in the kidney. No information was located on the influence of GST polymorphisms on TCE kidney cancer risks.

Increased susceptibility to different cancers has been reported to be associated with certain genetic polymorphisms, which occur with different frequencies in different ethnic groups (Daly *et al*., 1993; Raunio *et al*., 1995). Significant variations in allelic distributions for isoforms including CYP2E1, CYP2D6, CYP1A1, and GSTM1 have been observed in different racial groups. Results of investigations of relationships between occurrence of defective alleles for CYP2E1 and cancer incidence have been contradictory. Studies with more statistical power of selected ethnic groups need to be conducted to clarify the roles of CYP polymorphisms in cancers. Although molecular markers clearly indicate variances in CYP genes, biologically plausible mechanisms linking specific genotypes with specific outcomes are lacking at present.

Genetic polymorphisms, variable transporter activities, genetic variants of receptors and regulatory proteins, and environmental factors can play roles in individual variability in P450 induction (Tang *et al*., 2005). Lipscomb *et al*. (1997) described substantial differences in activity and/or content of CYP2E1 within the U.S. population. Lipscomb (2004) incorporated extremes in CYP2E1-mediated metabolism into a PBTK model for TCE and learned there was very little impact on TCA dosimetry. Intersubject differences in hepatic blood flow did have a pronounced effect on TCE biotransformation, as TCE is an extensively metabolized (liver blood flow limited) compound. Wenker *et al*. (2001) similarly reported that interindividual genetic polymorphisms in CYP2E1 and several other CYPs did not affect the metabolism of styrene, another flow-limited compound. Kedderis (1997) utilized a PBTK-modeling approach to confirm this phenomenon, but found the opposite to be true for poorly metabolized (capacity limited) VOCs such as PERC and $CC1_4$ (i.e., interindividual differences in metabolic capacity may significantly affect their biotransformation). Haber *et al*. (2002) integrated human

data on the incidence of a GST null polymorphism with a PBTK model for MC to forecast an ∼30% decrease in the mean population cancer risk.

Exogenous Factors

P450 Inducers   Considerable effort has been devoted to investigation of effects of enzyme inducers on solvent metabolism and toxicity. Preexposure to drugs and other chemicals, which induce CYP isoforms that metabolically activate particular solvents, can markedly potentiate the solvents' toxicity. As described in the subsection on Metabolism, CYP2E1 is a high-affinity, low-capacity isoform responsible for activation of a wide variety of low-molecular-weight hydrocarbon and halocarbon solvents to cytotoxins and mutagens (Guengerich *et al.*, 1991). A number of CYP2E1 substrates (e.g., ethanol and other alcohols, acetone and other ketones, pyridine and pyridazine, isoniazid, acetaminophen, and chlorzoxazone) can act as inducers of the isoform. Preexposure to many of these can thus markedly increase the metabolic activation and adverse effects of certain solvents. The minimal hepatocytotoxicity caused by CCl_4 alone (Panel B, Fig. 24-4) can be contrasted with the centrilobular necrosis (Panel C, Fig. 24-4) in rats pretreated with 2-butanol before the same CCl_4 dose (Traiger and Bruckner, 1976). CYP2E1 is present in many organs and tissues, as are other CYPs that metabolize solvents. Although levels/activities are highest in liver, induction in extrahepatic tissues can result in increased metabolic activation in situ that may be toxicologically significant. It is worthy of note that many chemicals that induce P450s also induce detoxifying enzymes (e.g., epoxide hydrolase, glucuronyl- and sulfotransferases). A number of naturally occurring organosulfur compounds in allium vegetables have been demonstrated to induce these enzymes in the liver, kidney, intestines, and lungs of Wistar rats (Guyonnet *et al.*, 1999).

It should be recognized that timing of exposures to ≥ 2 P450 inducers is important. Sato *et al.* (1991) demonstrated that alcohol competitively inhibited the biotransformation of TCE when the exposures were concurrent. Alternatively, preexposure to ethanol stimulated TCE metabolism. As described previously in the Metabolism subsection, increased metabolic capacity in an individual is of little consequence for environmentally encountered levels of blood-flow-limited (i.e., extensively metabolized) solvents (e.g., TCE, vinyl chloride, MC, and $CHCl_3$). Thus, genetically predisposed or induced individuals should be at no greater cancer risk from these solvents than the average person.

P450 Inhibitors   An increasing number of drugs and other chemicals, dietary supplements, fruit juices, and vegetable constituents are being identified as inhibitors and/or inducers of P450s, Phase II enzymes, and efflux transporters (Halpert *et al.*, 1994; Lin and Lu, 2001; Huang and Lesko, 2004). It should be recalled that mechanisms of P450 inhibition can be categorized as reversible, quasi-reversible, and irreversible. Reversible inhibition is transient, with the normal function of the CYP continuing after elimination of the inhibitor. Both quasi- and irreversible inhibitions result from the enzyme's formation of a reactive metabolite. With quasi-reversible inhibition, the metabolite and enzyme form a complex that is so stable that the intact enzyme may be unavailable for further metabolism. With mechanism based or suicide inhibition, the reactive metabolite irreversibly inhibits the enzyme by binding to its active site. Experiments by Lilly *et al.* (1998) indicate that this is the mechanism by which epoxide metabolites of *trans*- and *cis*-1,2-dichloroethylene
Figure 24-4. Potentiation of CCl_4 hepatotoxicity by 2-butanol.

Rats were (A) untreated; (B) given 0.1 mL/kg CCl_4/kg IP; or (C) pretreated with 2-butanol (2.2 mL/kg PO) 16 hours before 0.1 mL/kg CCl_4 IP. Cenral veins and portal triads are designated V and P, respectively. Occasional hepatocytes adjacent to the central vein are vacuolated in (B). Note the demarcation between vacuolated/necrotic centrilobular and midzonal cells, and normally appearing periportal cells in (C). Hematoxylin and eosin stain. (A) and (C) ×315; (B) ×480. [Reproduced from Traiger and Bruckner, 1976, with permission from ASPET.]

inhibit CYP2E1. Fisher *et al.* (2004) subsequently reported that metabolites generated from a single oral dose of CC1$_4$ as low as 1 mg/kg are suicide inhibitors of CYP2E1 and CYP2B2 in B6C3F1 mice. The net result of this action by CC1$_4$ is reduced formation of TCA from coadministered PERC. However, Blobaum (2006) recently described reversible inactivation of CYP2E and CYP2B isoforms during their mechanism-based inactivation by small *tert*-butyl terminal alkynes.

Flavanoids in grapefruit juice were one of the first classes of naturally occurring compounds to be documented to produce clinically significant increases in levels of therapeutic agents metabolized by CYP3A4 (Chan *et al.*, 1998). Flavanoids in red wine exerted a similar effect on intestinal CYP3A4, but white wine had little influence. Bergamottin, a furanocoumarin in grapefruit and lime juice, was subsequently found to inhibit human CYP3A4 activity (Bailey *et al.*, 2003) as well as intestinal P-glycoprotein efflux transporters (Dresser and Bailey, 2003). St. John's wort, a top-selling dietary supplement taken for depression, selectively induced CYP3A4 in the small intestine (Huang and Lesko, 2004). Echinacea inhibited human intestinal CYP3A, but induced hepatic CYP3A. Ginsenosides exhibited no or weak inhibition of several human CYPs, but some of the compounds' major intestinal metabolites inhibited a wide range of CYPs (Liu *et al.*, 2006). Certain components of ginko biloba, frequently used for memory impairment, were potent inhibitors of human recombinant CYP1B1, CYP1A1, and CYP1A2 (Chang *et al.*, 2006). Identification of isoform-selective, nontoxic inhibitors may eventually lead to modulation of human xenobiotic metabolism for therapeutic purposes (Halpert *et al.*, 1994). There are large interindividual responses to CYP enzyme inducers and inhibitors (Lin and Lu, 2001).

Physical Activity   Exercise can significantly affect the kinetics of xenobiotics (van Baak, 1990), but is often not considered in occupational risk assessments of solvents. Exercise increases two of the major determinants of VOC uptake, alveolar ventilation rate, and cardiac output/pulmonary blood flow. Polar solvents with relatively high blood:air PCs (e.g., acetone, ethanol, and ethylene glycol) are very rapidly absorbed into the pulmonary circulation. Alveolar ventilation is rate limiting for these chemicals. In contrast, pulmonary blood flow and metabolism are rate limiting for uptake of the more lipophilic solvents (Johanson and Filser, 1992). Heavy exercise can increase pulmonary uptake of relatively polar solvents as much as five-fold in human subjects (Astrand, 1983). Light exercise doubles uptake of relatively lipid-soluble solvents, but no further increases occur at higher workloads. Blood flow to the liver and kidneys diminishes with exercise, so biotransformation of well-metabolized solvents and urinary elimination of polar metabolites may be diminished (Lof and Johanson, 1998). Dankovic and Bailer (1994) modified the human PBTK model of Reitz *et al.* (1989) for MC to reflect light work conditions. The modified model predicted that light exercise would result in a two-fold increase in hepatic MC deposition and in metabolite formation via P450- and GSH-dependent pathways. Jonsson *et al.* (2001) developed a population PBTK model for humans inhaling MC during moderate-to-heavy exercise. The focus of the study was on interindividual variability in MC metabolism and TK introduced by increased hepatic perfusion rates.

Diet   Dietary habits can influence the absorption, metabolism, and toxicity of solvents in several ways. Factors that influence gastric emptying would not be expected to influence systemic absorption of

VOCs, as they are so rapidly absorbed by passive diffusion throughout the GI tract. The mere bulk of food in the GI lumen, however, can inhibit absorption by preventing contact of the chemical with the GI epithelium. VOCs in the GI tract partition into dietary lipids, largely remaining there until the lipids are emulsified and absorbed. This serves to substantially delay uptake of lipophilic solvents such as CC1$_4$, resulting in lower, prolonged blood CC1$_4$ levels and diminished hepatotoxicity in rats (Kim *et al.*, 1990a). Food intake increases splanchnic blood flow, which favors GI absorption. The elevation in liver blood flow would be expected to enhance the biotransformation of low doses of well-metabolized solvents, but to have little effect on first-pass metabolism of relatively high (i.e., saturating) doses (Tam, 1993). Consumption of a high-fat diet results in a selective increase in hepatic CYP2E1 activity and protein levels in male Sprague–Dawley rats (Raucy *et al.*, 1991). Elevation of plasma ketone bodies appears to be implicated in this process, because acetone is a potent CYP2E1 inducer. Carbohydrate deficiency has been recognized for many years to enhance the metabolism of a series of VOCs in rats, but not to alter their conjugation (Sato and Nakajima, 1985). High protein diets and diets low in protein and high in carbohydrates lead to CYP1A2 increases and decreases, respectively (Glue and Clement, 1999). Psoralens (found in parsley, parsnip, and celery) reduce CYP1A2 activity, whereas food cooked over charcoal enhances it. Effects of other foods, fruit juices, and food supplements are addressed in the preceding subsections on P450 Inducers and Inhibitors.

Fasting results in decreased liver GSH levels due to interrupted intake of amino acids required for its synthesis. GSH plays a key role in the detoxification of electrophilic metabolites of a number of solvents. Short-term fasting (∼8–24 hours) results in induction of liver CYP2E1 and increase in metabolism of a number of aromatic hydrocarbons and halocarbons (Nakajima *et al.*, 1982). The hepatotoxicity of CC1$_4$, which requires CYP2E1-catalyzed metabolic activation, is more severe in fasted animals. In contrast, long-term food deprivation (i.e., starvation) results in decreased synthesis and activity of P450s.

Clock Time   Many physiological and biochemical processes that impact solvent TK exhibit circadian, or diurnal rhythms. A series of investigations have been conducted to delineate molecular control mechanisms of diurnal oscillation in mammals. The phenomenon appears to be controlled by a "master pacemaker" in the suprachiasmatic nuclei (SCN) of the hypothalamus of mice (Panda *et al.*, 2002). Genetic and genomic analyses of the SCN and liver indicate that a relatively small number of output genes are directly regulated by core oscillator components. Rate-limiting steps in major cellular pathways/processes are being identified as key sites of circadian regulation. Recent experiments reveal that transcriptional feedback is required for maintenance of circadian rhythmicity (Sato *et al.*, 2006).

Several research groups have discovered circadian rhythms in susceptibility of rats to liver damage by various VOCs, including CC1$_4$, CHC1$_3$, 1,1-dichloroethylene (1,1-DCE), ethanol, and styrene (Labrecque and Belanger, 1991). In each instance, the chemicals were most toxic when given during the initial part of the rodents' dark/active cycle. Low hepatic GSH levels at this time were an important contributing factor to the increased liver injury by 1,1-DCE and CHC1$_3$. Restricted food intake during sleep resulted in lipolysis and formation of acetone, which contributed to the diurnal induction of CYP2E1 and the ensuing increases in hepatic

metabolic activation and cytotoxicity of $CC1_4$ in male rats during the early part of the animals' active cycle (Bruckner *et al.*, 2002). Skrzypinska-Gawrysiak *et al.* (2000) also observed that male mice were most susceptible to $CC1_4$ hepatotoxicity when dosed at a similar time. Furukawa *et al.* (1999) attributed high hepatic microsomal 7-alkoxycoumarin *O*-dealkylase activity during male rats' active cycle to diurnal secretion of growth hormone. Clearance rates for a number of well-metabolized compounds, including ethanol (Sturtevant *et al.*, 1978) and nicotine (Gries *et al.*, 1996), are maximal in human subjects during the first part of their active/wake cycle. Hepatic blood flow and acetone levels in expired air of humans peak before breakfast. Thus, humans may also be more susceptible during this time to the toxicity of solvents that undergo metabolic activation.

Diseases   Illness can be a major source of variability in response to solvents. Impaired drug metabolism and clearance are commonly seen in patients with cirrhosis and hepatitis (Welling and Pool, 1996). Reduced metabolism of solvents may result from decrease in hepatic parenchymal mass, diminished enzymatic activity, and/or decreased portal blood flow (McLean and Morgan, 1991). Lower levels of CYP2E1, CYP1A2 and GSH are seen in livers of patients with cirrhosis (Murray, 1992). Reduced P450-catalyzed metabolic activation of certain solvents can be protective, but diminished capacity to conjugate electrophilic metabolites with GSH would have the opposite effect. Plasma levels of albumin and a_1-acid glycoprotein fall in cirrhotic patients. Thus, plasma protein binding of many xenobiotic metabolites decreases and their rate of elimination increases (McLean and Morgan, 1991). Definitive information is lacking, however, on the net effect of common liver diseases on solvents.

Chronic kidney disease is becoming increasingly prevalent in the United States over the past decade (Dowling, 2002). Progressive loss of kidney function leads to impaired renal excretion of numerous chemicals and metabolites that may be toxic or pharmacologically active. Renal failure can result in downregulation of the expression of some liver P450s, but have no effect on others (Leblond *et al.*, 2001). Effects on hepatic clearance of therapeutic chemicals can thus vary widely. The mechanisms of these effects on gene expression are unclear, as is their applicability to solvents. The plasma protein binding of many xenobiotics is reduced in patients with compromised renal function, apparently due to retention of substances that compete for protein-binding sites, as well as reduced albumin synthesis. Clearance of highly metabolized xenobiotics thus appears to depend on potentially offsetting influences of altered metabolism, decreased plasma protein binding, and decreased renal excretion (Yuan and Venitz, 2000). Impairment of renal metabolic activation via oxidation or β-lyase-mediated conversion of GSH metabolic intermediates of TCE and PERC (see subsections on these chemicals for details) to reactive, mutagenic metabolites would be protective.

Diabetes mellitus is a metabolic disease characterized by hyperglycemia as a result of insulin deficiency (Type I) or insulin resistance (Type II). Type II accounts for 90% of cases. Approximately 21 million people suffer from diabetes in the United States. A prominent effect of chemically induced Type I diabetes in rats is induction of CYP2E1. Elevation of acetone, but apparently not the other ketone bodies is responsible for the CYP2E1 increase. Hypoinsulinemia may play a role, in that insulin downregulates CYP2E1 mRNA in rat hepatoma cells and primary cultures of rat hepatocytes (Cheng and Morgan, 2001). In contrast, CYP2E1 is not affected in Type II diabetic animals (Sawant *et al.*, 2004). Neither Type I nor Type II diabetes influences CYP2E1 activity in humans (Lucas *et al.*, 1998; Cheng and Morgan, 2001). Nevertheless, animal studies show that Type II diabetes increases susceptibility to hepatotoxicants including allyl alcohol and $CC1_4$ (Sawant *et al.*, 2004), apparently due to inhibition of tissue repair. Devi and Mehendale (2005, 2006) subsequently demonstrated inhibition of expression of genes involved in cell division and protease inhibitors, as well as enhanced gene expression of proteases in Type I diabetic rats. These events may be important in delayed tissue repair following chemical cytotoxicity in diabetics.

Persons with bacterial infections may be more sensitive to cytotoxic actions of solvents. Endotoxin, which includes a lipopolysaccharide, is released from the cell wall of gram-negative organisms. The lipopolysaccharide causes the release of inflammatory mediators, which alter cell membranes, intercellular signaling, and gene expression (Roth *et al.*, 1997). These effects may render cells more susceptible to damage by solvents and other chemicals. Exposure of animals to small amounts of endotoxin potentiates liver injury by $CC1_4$, halothane, allyl alcohol, ethanol, and other solvents (Roth *et al.*, 1997). Endotoxin apparently activates Kupffer cells to release inflammatory mediators and cytotoxic moieties to hepatocytes (Thurman, 1998).

CHLORINATED HYDROCARBONS

Trichloroethylene

TCE is a widely used solvent identified at over one-half of the nearly 1300 hazardous waste sites that make up the EPA's National Priorities List (ATSDR, 2006a). TCE is released into the atmosphere from vapor degreasing operations; however, direct discharges to surface waters and groundwater from disposal operations have been frequent occurrences. As a result, TCE can be released to indoor air by vapor intrusion through underground walls and floors and by volatilization from the water supply. TCE has recently received a great deal of attention from the scientific and regulatory communities, due in large part to the EPA's efforts to update the chemical's two-decade-old risk assessment.

Moderate-to-high doses of TCE, as with other halocarbons, are associated with a number of noncancer toxicities (Barton and Das, 1996). TCE has been implicated in the development of autoimmune disorders and immune system dysfunction (Gilbert *et al.*, 1999; Blossom and Gilbert, 2006), and has been investigated for its potential as a male reproductive toxicant (Forkert *et al.*, 2003; Xu *et al.*, 2004). The effect of gestational exposure to TCE or its oxidative metabolites on cardiac development is a subject that has invoked considerable debate, as conflicting results exist (Fisher *et al.*, 2001; Johnson *et al.*, 2003; Watson *et al.*, 2006). The issue of TCE's effect on ocular development has also recently reemerged (Warren *et al.*, 2006). Cancer remains the dominant issue for TCE, however. Attempts to understand the mechanistic underpinnings of TCE's carcinogenicity in rodent models and their relevance to humans have resulted in a massive body of published data. Nonetheless, uncertainties remain that plague the risk-assessment process. Even so, TCE provides a stellar example of how research can be utilized to generate experimental and epidemiological data for use in a regulatory context. A 16-article series of state-of-the-science papers, upon which the EPA relied heavily for its 2001 draft risk assessment, was published (Scott and Cogliano, 2000).

Cancer Epidemiology There are many published studies of cancer incidence and mortality among TCE-exposed populations including Morgan *et al*. (1998), Blair *et al*. (1998), Boice *et al*. (1999), and Ritz (1999), of whom all but the latter examined cancer mortality or incidence among aircraft-manufacturing or maintenance workers. In addition to these U.S. studies, the mortality/incidence experiences of Swedish, Finnish, German, and Danish worker cohorts have been examined (Axelson *et al*., 1994; Anttila *et al*., 1995; Henschler *et al*., 1995; Hansen *et al*., 2001; Raaschou-Nielsen *et al*., 2003). Most of the studies mentioned above constitute what the meta-like analysis of Wartenberg *et al*. (2000) referred to as Tier I studies, meaning TCE exposure was better characterized than in cohort studies in lower tiers. Thus, Tier I studies received a greater weighting from Wartenberg and colleagues when making causal inferences than lower-tier cohort studies, case–control studies, and community-based studies. Among the Tier I studies, evidence for an excess incidence of cancer was strongest for the kidney (RR = 1.7, 95% confidence interval (CI) = 1.1–2.7), liver (RR = 1.9, 95% CI = 1.0–3.4), and non-Hodgkin's lymphoma (NHL) (RR = 1.5, 95% CI = 0.9–2.3). These investigators also contend that the data support weak associations between TCE exposure and multiple myeloma, Hodgkin's disease, and cancers of the prostate, skin, and cervix.

While not as comprehensive as that of Wartenberg *et al*. (2000), other reviews of epidemiological studies have been conducted. Weiss (1996) concluded that the evidence for the carcinogenicity of TCE was "quite limited." He acknowledged that there was some suggestive evidence that TCE could possibly be associated with NHL and cancers of the liver, biliary tract, and kidney. Another review of cohort and case–control studies concluded that the totality of the evidence did not support a role for TCE in renal cell cancer (RCC) (McLaughlin and Blot, 1997). Morgan *et al*. (1998) combined their data with that of others in a meta-analysis-like approach that resulted in slight, statistically insignificant elevations in meta-standardized mortality ratios for cancers of the liver, prostate, kidney, bladder, and NHL. More recent reviews of the epidemiological literature have reported either no significant increases in cancer risk (Wong, 2004; Alexander *et al*., 2006), or a modest positive association in the case of TCE exposure and NHL (Mandel *et al*., 2006).

The report of Henschler *et al*. (1995) was the first in a series of German studies that has provided the strongest evidence to date for an association between TCE and RCC. These authors reported on a cohort of male cardboard factory workers who were exposed to moderate to extremely high concentrations of TCE. By the closing date of the study, five of the 169 exposed workers had been diagnosed with kidney cancer versus none of the 190 controls. This resulted in standardized incidence ratios (SIRs) of 7.97 (95% CI = 2.59–18.59) and 9.66 (95% CI = 3.14–22.55), using Danish and German Cancer Registry data for comparison, respectively. A single U.S. study had previously reported a weaker, but significantly elevated SIR for RCC (SIR = 3.7, 95% CI = 1.4–8.1) among paperboard workers exposed to TCE (Sinks *et al*., 1992). German researchers also conducted a hospital-based case–control study with 58 RCC patients and 84 patients from accident wards who served as controls. Of the 58 RCC patients, 19 had histories of occupational TCE exposure for at least 2 years, compared to only five of the controls. After adjustment for potential confounders, an association between RCC and long-term exposure to TCE was reported [odds ratio (OR) = 10.80, 95% CI = 3.36–34.75] (Vamvakas *et al*., 1998). These studies find some support in a recently published case–control study of TCE exposure and RCC risk conducted in France (Charbotel *et al*., 2006).

The studies detailed above provide some evidence of a link between kidney cancer and TCE, although the link may be operative only under very high exposure conditions. As will be discussed later, the application of molecular biology techniques to the issue of TCE and kidney cancer has strengthened the argument for a causal association. Controversy surrounds the German studies, as indicated in a critical review by Green and Lash (1999) to which the researchers responded (Vamvakas *et al*., 2000).

Metabolism With rare exception, the toxicities associated with TCE are thought to be mediated by metabolites rather than parent compound. Even the CNS-depressant effects of TCE are due in part to the sedative properties of the metabolites, trichloroethanol (TCOH) and chloroform. Understanding TCE's metabolism is thus a prerequisite to elucidating its mechanisms of action and accurately assessing human risks. Much experimental effort has been expended to this end.

TCE is rapidly absorbed into the systemic circulation via the oral and inhalation routes. The majority of TCE undergoes oxidation in the liver by CYPs, with a small proportion being conjugated with GSH via GSTs. Thus, two distinct metabolic pathways exist for TCE. The oxidative pathway is shown to the left in Fig. 24-5, and the GSH pathway is shown to the right (Lash *et al*., 2005). This schematic represents a simplification of what is a complex metabolic scheme, as detailed in the state-of-the-science paper by Lash *et al*. (2000a). As shown, TCE may be oxidized to yield one of three initial metabolites: chloral, TCE-epoxide, and dichloroacetylchloride. These metabolites rapidly undergo oxidation and/or reduction to yield trichloroacetate (TCA) and TCOH, the major end products of the oxidative pathway. TCOH is either oxidized to TCA or glucuronidated. TCOH glucuronide is excreted via the urine and bile. That in the bile may undergo enterohepatic recirculation by hydrolysis to TCOH in the gut, with reabsorption and the possibility of conversion to TCA. TCA accumulates in the body due to strong plasma protein binding and slow excretion. In contrast, blood levels of DCA, formed by TCA dechlorination or from TCOH, are very low or nondetectable in humans.

Relatively small amounts of TCE can be conjugated in the liver with GSH to form S-(1,2-dichlorovinyl)glutathione (DCVG). DCVG is then effluxed from the hepatocyte into plasma and bile for translocation to the kidney and small intestine, respectively. The plasma DCVG is intrarenally converted by γ-glutamyltransferase and dipeptidases to the cysteine conjugate S-(1,2-dichlorovinyl)-L-cysteine (DCVC). The DCVG secreted into bile can undergo extrarenal processing to DCVC, that is subsequently delivered to the kidney by enterohepatic recirculation. DCVC represents a branch point in the pathway. It may be detoxified through N-acetylation or bioactivated to reactive thiols via renal β-lyase located in renal proximal tubular cells (or to a lesser extent, bioactivated to DCVC sulfoxide via flavin-containing monooxygenases).

Modes of Action in Target Tissues Both metabolic pathways are implicated in the carcinogenicity of TCE: reactive metabolite(s) of the GSH pathway in kidney tumors in rats, and oxidative metabolites in liver and lung tumors of mice. That tumor formation in many cases is species-, strain-, sex-, and route of exposure–dependent has provided clues as to TCE's modes of carcinogenic action. Whereas substantial progress has been made on the mechanistic front, the reader should not infer from the text that follows that all modes of action are known with absolute certainty. Rather, they should
Figure 24-5. General scheme of metabolism for TCE.

Abbreviations: β-lyase, cysteine conjugate β-lyase; DCA, dichloroacetate; DCVC, S-(1,2-dichlorovinyl)-L-cysteine; DCVSH, 1,2-dichlorovinylthiol; DCVCSO, DCVC sulfoxide; DCVG, S-(1,2-dichlorovinyl)glutathione; DP, dipeptidase; FMO, flavin-containing monooxygenase; GGT, γ-glutamyltransferase; GST, GSH S-transferase; P450, cytochrome P450; TCA, trichloroacetate; TCOH, trichloroethanol; TCOG, TCOH glucuronide.

be considered working hypotheses that await further experimental confirmation.

Liver Cancer   TCE induces malignant liver cancer in B6C3F1 mice but not in other strains of mice or in rats. This differential susceptibility can be explained by the greater capacity of the mouse to metabolize TCE via the oxidative pathway. B6C3F1 mice also develop liver tumors when chloral hydrate (CH), TCA, and DCA are administered in high doses, suggesting that one or more of these metabolites are ultimately responsible for TCE-induced liver cancer. Of the three, TCA and/or DCA are/is most likely responsible, as TCE metabolism results in extremely low blood levels of CH due to its rapid oxidation to TCA or reduction to TCOH. The sensitivity of B6C3F1 mice to TCE further suggests that liver tumor formation might be related to the abnormally high frequency of spontaneously initiated cells in this mouse strain, which manifests itself as an unusually high background liver tumor incidence. While TCA and/or DCA might induce liver tumors in B6C3F1 mice by simply promoting preexisting initiated cells, the finding that DCA (but not TCA) also induces liver tumors in F-344 rats suggests that another mechanism might also be operable.

As for a promotional mechanism for TCE, peroxisome proliferation represents a more viable mechanism than does overt cytotoxicity and reparative cell proliferation. As peroxisomes contain a variety of oxidative enzymes, peroxisome proliferation results in an increased potential for oxidative DNA damage and decreased gap junctional intercellular communication, both of which have been im-

plicated in neoplastic transformation. At tumorigenic doses, TCA induces sustained peroxisome proliferation in B6C3F1 mice. The peroxisome-proliferative response to DCA is transient, however, and requires a dose higher than that capable of inducing tumors. Therefore, a primary role for TCA is likely if liver tumor promotion occurs via peroxisome proliferation. Research supports a dominant role for the peroxisome proliferator-activated receptor alpha (PPAR-α) in mediating the effects associated with hepatocarcinogenesis upon TCE exposure of mice, including hepatocellular proliferation and most gene expression changes in the liver (Laughter *et al.*, 2004).

An alternative promotional mechanism is suggested by evidence that TCA and DCA depress replication rates of normal hepatocytes, conferring a selective growth advantage to initiated tumorigenic cells. This is referred to as *negative selection*. At high tumorigenic doses, DCA (but not TCA) is thought to stimulate cell replication within tumors. Interestingly, DCA tumors overexpress the insulin receptor relative to surrounding normal tissue. As overexpression of the insulin receptor is associated with the suppression of transforming growth factor-β 1 (TGF-β1)-induced apoptosis in human liver cells, it is conceivable that DCA could promote cancer by a dual mechanism: enhanced mitotic activity and decreased apoptotic activity of preneoplastic cells.

Experimental efforts continue to discern the contributions of TCA and DCA to the induction of liver tumors in mice by TCE (Bull *et al.*, 2002). Data suggest that if both contribute, they do so by distinct mechanisms, because DCA-promoted liver tumors differ phenotypically from those of TCA. DCA- and TCA-induced tumors also differ as to whether their depression of cytosine methylation is

reversible upon cessation of treatment (Tao *et al.*, 1998). This is particularly important as DNA hypomethylation, including that of the proto-oncogenes c-jun and c-myc, may be an epigenetic mechanism for the tumorigenicity of DCA and TCA (Tao *et al.*, 2004). It appears that hypomethylation due to TCA and DCA induces DNA replication and prevents the methylation of newly synthesized strands of DNA (Ge *et al.*, 2001). Tao *et al.* (2000) have reported that DCA and TCA do so by virtue of their depletion of *S*-adenosylmethionine (SAM), which normally supplies the methyl group for the methylation process. A comprehensive review of mechanisms by which TCE may induce liver cancer can be found in the state-of-the-science paper by Bull (2000).

Kidney Cancer   TCE exposure by inhalation or ingestion results in kidney tumors in male but not female rats. The susceptibility of the male rat can be explained by its greater capacity for TCE metabolism via the GSH pathway. TCE-induced kidney tumors are believed to result from reactive metabolite(s) of this pathway, particularly DCVC. DCVC is bioactivated in proximal tubular cells to a reactive thiol, *S*-(1,2-dichlorovinyl)thiol, which is chemically unstable and rearranges to reactive species capable of alkylating cellular nucleophiles, including DNA. The resulting DNA mutations can lead to alterations in gene expression, which in turn apparently lead to neoplastic transformation and tumorigenesis via a genotoxic mode of action.

Alternatively, there are many processes that can lead to proximal tubular cytotoxicity and subsequent tumor formation via a nongenotoxic mode of action. Reactive metabolites formed within proximal tubular cells exposed to high doses of DCVC result in oxidative stress, alkylation of cytosolic and mitochondrial proteins, marked ATP depletion, and perturbations of Ca^{2+} homeostasis. Tubular necrosis ensues, with subsequent reparative proliferation that can alter gene expression and, in turn, alter the regulation of cell growth and differentiation. Modes of action for TCE-induced kidney tumor formation are discussed in greater detail by Lash *et al.* (2000b) in their state-of-the-science paper, and more recently by Lock and Reed (2006).

Animal studies typically provide insight into mode of action, but in the case of TCE-induced RCC, human studies have been of significant value. Bruning *et al.* (1997a) analyzed tumor tissues from 23 RCC patients with occupational histories of long-term, high-level TCE exposure. Tumor cell DNA was isolated and analyzed for somatic mutations of the von-Hippel Lindau (VHL) tumor suppressor gene. Compared to VHL gene mutation rates of 33–55% in TCE-unexposed RCC patients, all 23 TCE-exposed RCC patients exhibited aberrations of the VHL gene. In a follow-up study, Brauch *et al.* (1999) sought to determine whether TCE produced a specific mutational effect in the VHL gene. These investigators analyzed VHL gene sequences in DNA isolated from renal cell tumors from patients exposed to high levels of TCE in metal-processing factories. Renal cell tumors of TCE-exposed patients showed somatic VHL mutations in 33 of 44 cases (75%). Of the 33 cases with VHL mutations, a specific mutational hot spot at VHL nucleotide 454 was observed in 13 cases. The nucleotide 454 mutation was not found in any of the 107 RCC patients without TCE exposure or among 97 healthy subjects, 47 of whom had a history of TCE exposure. These data suggest that the VHL gene might be a specific and susceptible target of TCE, a concept strengthened by a more recent study reporting the VHL mutation frequency among TCE-exposed versus nonexposed RCC patients (Brauch *et al.*, 2004).

Bruning and Bolt (2000) suggest that reactive metabolite(s) of the GSH pathway may have a genotoxic effect on the proximal tubule of the human kidney, but that full development of a malignant tumor requires a promotional effect such as cell proliferation in response to tubular damage. If this is true, then RCC secondary to TCE exposure would be a threshold response. The question of whether chronic tubular damage occurs in renal tumor formation is thus an important one. Answers have come from the use of electrophoresis to examine protein excretion patterns in the urine of RCC patients with and without a history of chronic, high-level TCE exposure (Bruning *et al.*, 1996). Protein excretion patterns indicative of tubular damage were identified in all 17 TCE-exposed cases, but in only about one-half of the 35 controls. This observation suggests that chronic tubular damage may be a prerequisite to TCE-induced RCC. Bruning *et al.* (1999) subsequently published a larger study supportive of this concept.

That TCE induces kidney tumors via a threshold-dependent process is supported by the occurrence of human RCC only among cases with unusually high and prolonged TCE exposure. However, factors other than the intensity and duration of exposure may determine one's susceptibility to TCE-induced RCC. Bruning *et al.* (1997b) have investigated the influence of GST isozyme polymorphisms on RCC risk using long-term, highly exposed workers with or without RCC. These investigators reported an unequal distribution of GSTμ1 and GSTθ1 polymorphisms among RCC cases and controls, which suggested a higher risk for RCC in TCE-exposed persons carrying either the GSTθ1 or GSTμ1 polymorphic gene. GSTμ is thought to function to detoxify reactive electrophiles, while GSTθ is primarily involved in conjugation reactions.

Harth *et al.* (2005) have published a recent review that concludes that TCE can be considered a renal carcinogen for which a practical threshold exists. Further support for a threshold comes from the use of the Eker rat model that carries a germline alteration of the tuberous sclerosis 2 (Tsc-2) tumor suppressor gene. This mutation results in an increased susceptibility to spontaneous and carcinogen-induced RCC, as tumors arise after inactivation of the remaining normal allele of the Tsc-2 gene. Mally *et al.* (2006) exposed Eker rats to TCE and rat kidney epithelial cells carrying the Tsc-2 mutation to DCVC. TCE did not initiate malignant transformation of renal epithelial cells in vivo, whereas DCVC reduced cell survival by 50% and transformed rat kidney epithelial cells in vitro to a neoplastic phenotype. Importantly, DCVC's transformation did not involve mutations in the VHL or Tsc-2 tumor suppressor genes, suggesting that renal tumor formation by DCVC is not the result of altered genes critical for renal tumor development, but rather toxic injury and regenerative repair. While the above study was conducted with rat kidney epithelial cells, efforts to understand the action of DCVC at the molecular level are being explored in cultured human renal proximal tubular cells (HRPTC) (Lash *et al.*, 2005). Such efforts include that of Lock *et al.* (2006), who have reported gene expression changes in HRPTC following DCVC treatment. Interestingly, DCVC has been a model nephrotoxicant in a series of recent studies to investigate the circumstances under which renal tissue repair might occur after exposure rather than a progression to renal failure (Vaidya *et al.*, 2003; Korrapati *et al.*, 2006; Dnyanmote *et al.*, 2006).

Lung Cancer   As discussed in the state-of-the science paper by Green (2000), inhaled TCE is carcinogenic to the mouse lung but not to that of the rat. Oral TCE is not carcinogenic to the lung,

probably due to first-pass hepatic metabolism that limits the amount of TCE reaching the organ. The primary target of TCE in the mouse lung is the nonciliated Clara cell. Cytotoxicity is characterized by vacuolization and increased replication of these cells in the bronchiolar epithelium. A dose-dependent reduction in the CYP activity in Clara cells is observed as well. This loss of metabolic activation capacity can be thought of as an adaptive response. Clara cells recover morphologically during repeated daily inhalation exposures to TCE.

Chloral is the putative toxicant responsible for pulmonary tumor formation. Clara cells of the mouse efficiently metabolize TCE to TCA and chloral. Chloral accumulates, due to its efficient production and the low activity of ADH, the enzyme responsible for its reduction to TCOH. The Clara cells' lack of glucuronosyltransferase, the enzyme that normally catalyzes the formation of TCOH glucuronide, has also been implicated in chloral accumulation. Species differences in susceptibility of the lung to TCE are due in part to mouse lung Clara cells having a much higher level of CYP2E1 than those of the rat, and thus a much higher capacity to metabolize TCE to chloral. Also, Clara cells in mice are much more numerous than in rats. A critical role for chloral is supported by the findings that its administration to mice, but not that of TCA or TCOH, causes Clara cell toxicity identical to that of TCE. Chloral does appear to have some genotoxic potential, especially in regard to inducing aneuploidy. However, the fact that tumors are not seen in species where cytotoxicity does not occur strongly implicates cytotoxicity and reparative proliferation in tumor formation. In an effort to test the hypothesis that bronchiolar damage by TCE is associated with bioactivation within Clara cells, Forkert *et al.* (2006) administered TCE i.p. to CD-1 mice. The result was dose-dependent production of dichloroacetyl lysine adducts in Clara cells (used as an in vivo marker of TCE metabolism) that correlated with bronchiolar damage. The study also suggested that CYP2F2 may play a more important role than CYP2E1 in TCE metabolism and cytotoxicity within the lung.

Risk Assessment   The human relevance of TCE-induced rodent tumors is an unresolved issue. For liver tumors, humans appear to be more similar to rats than mice in their capacity for oxidative TCE metabolism. For kidney tumors, evidence exists that TCE bioactivation via the GSH pathway is greater in rats than in humans. As for promotional mechanisms, rodent liver is much more responsive to the action of peroxisome proliferators than human liver, and α_{2u}-globulin nephropathy is thought to be specific to the male rat. With regard to lung cancer, the CYP content and the number of Clara cells in the human lung are fraction of those in the mouse. This suggests that the risk for chloral accumulation in humans is minimal. It thus appears as though direct extrapolation from rodent data would substantially overstate human TCE cancer risk.

Numerous hypotheses are available concerning carcinogenic modes of action in the liver, lung, and kidney of rodents, in particular. Just how compelling these hypotheses are is still the subject of debate, as exemplified by the critical response of EPA scientists (Caldwell *et al.*, 2006) to a recent attempt to apply a margin of exposure approach (i.e., a nonlinear dose–response extrapolation) in TCE risk assessment (Clewell and Andersen, 2004, 2006). In 2001, EPA issued its draft risk assessment on TCE (EPA, 2001). The document elicited much debate, which prompted the EPA and other federal agencies to request a scientific review of TCE by a NAS expert panel. Their report was released in 2006. It recommended,

among other things, a new meta-analysis of the epidemiological data and the precautionary extrapolation of cancer risk using a linear model, because modes of action are not known with certainty.

Tetrachloroethylene

Tetrachloroethylene (perchloroethylene, PERC) is commonly used as a dry cleaner, fabric finisher, degreaser, rug and upholstery cleaner, paint and stain remover, solvent, and chemical intermediate. The highest exposures usually occur in occupational settings via inhalation. Much attention is now focused on adverse health effects that may be experienced by dry cleaners and other persons living in the proximity of such facilities (Garetano and Gochfeld, 2000). Echeverria *et al.* (1995), for example, reported adverse effects on visuospatial functions of dry cleaners. PERC is frequently detected in the low ppt range in the breath and blood of the general populace (Ashley *et al.*, 1994; Churchill *et al.*, 2001; Blount *et al.*, 2006). Although releases are primarily to the atmosphere, PERC enters surface and groundwaters by accidental and intentional discharges (ATSDR, 1997c). Levels in the ppb range are reported in municipal water in areas of New England, where PERC was used in a process to treat plastic water pipe (Paulu *et al.*, 1999). Fay (2006) reports that PERC is the third most frequently found chemical contaminant in groundwater at hazardous waste sites in the United States.

The systemic disposition and metabolism of PERC and trichloroethylene (TCE) are similar in many respects. Both chemicals are well absorbed from the lungs and GI tract, distributed to tissues according to their lipid content, partially exhaled unchanged, and metabolized by hepatic CYPs, primarily CYP2E1. PERC is initially oxidized by the CYPs to PERC oxide. PERC is oxidized to a much lesser degree than TCE, though the two have a common major metabolite, TCA. Some of the TCA may be converted to DCA (Lash and Parker, 2001). GSH conjugation is a minor metabolic pathway, quantitatively for TCE and PERC. The resulting conjugates of TCE and PERC are *S*-(dichlorovinyl)glutathione (DCVG) and *S*-(trichlorovinyl)glutathione (TCVG), respectively. These are excreted into the bile, where they are cleaved to *S*-(dichlorovinyl)-L-cysteine (DCVC) and *S*-(trichlorovinyl)-L-cysteine (TCVC) (Birner *et al.*, 1994). TCVC can be detoxified by acetylation in the liver and excreted in the urine, or metabolically activated by cleavage by a β-lyase in the kidney to dichlorothioketene and other reactive metabolites. These can covalently bind to proteins and other macromolecules, or react with water to form DCA. DCA is also believed to be formed in small amounts from TCE (see previous subsection on TCE). Dichlorothioketene is purported to be the ultimate PERC metabolite responsible for nephrotoxicity and mutagenicity by Volkel *et al.* (1998). Other reactive metabolites include 1,2,2-trichlorovinylthiol and mercapturate sulfoxide (Lash and Parker, 2001).

PERC's capacity to produce acute or chronic hepatorenal toxicity in laboratory animals and humans is quite limited. Near-lethal i.p. doses of PERC were required to cause acute liver or kidney injury in mice (Klaassen and Plaa, 1966). Liver injury was not seen in B6C3F1 mice or Osborne–Mendel rats gavaged with up to ~1000 mg/kg daily for 78 weeks (NCI, 1977). Dose-dependent karyomegaly was observed in the renal proximal tubular epithelium of mice and rats inhaling PERC for 103 weeks (NTP, 1986). This change was most prominent in the male rats. Green *et al.* (1990) found increases in protein droplets and cell proliferation in the proximal tubular epithelium of male F-344 rats gavaged with 1500 mg PERC/kg daily for up to 42 days. These alterations are
Figure 24-6. Proposed mechanism of solvent-induced kidney cancer in male rats involving α_{2u}-globulin.

[Used with permission of Borghoff *et al.*: *CIIT Activities* 16(10): 1–8, 1996.]

accompanied by an increase in α_{2u}-globulin, a male rat-specific protein (Fig. 24-6). Modest changes in a few indices of liver or kidney cell function in dry-cleaning workers (Gennari *et al.*, 1992; Brodkin *et al.*, 1995; Verplanke *et al.*, 1999) suggest that relatively minor effects may occur in humans with relatively high, chronic exposures. Philip *et al.* (2007) recently found that aqueous gavage of mice with 150, 500 or 1000 mg PERC/kg/day produced mild to moderate liver injury that regressed over a 30-day dosing period. No evidence of kidney damage was seen.

PERC's potential to cause cancer in humans continues to be a subject of considerable controversy. Male and female B6C3F1 mice, gavaged with very high doses of PERC for up to 78 weeks, exhibited an increase in hepatocellular carcinoma (NCI, 1977). No increase in tumor incidence was seen in Osborne–Mendel rats. Hepatocellular carcinoma was seen again in B6C3F1 mice inhaling 100 or 200 ppm PERC over a 2-year period (NTP, 1986). There was a low incidence of renal adenomas and carcinomas in male F-344 rats exposed to 200 or 400 ppm PERC. Such tumors are *rare* in this species. There was also a significant increase over controls in mononuclear-cell leukemia in the male and female rats, but ~50% of the controls had this disease.

There have been many epidemiological studies of cancer incidence and mortality in groups of dry cleaners and other persons occupationally exposed to PERC (ATSDR, 1997c). Some researchers have reported findings of excess incidences of different cancers, while others have not. Frequently, there was not a determination of the degree or duration of PERC exposure, or consideration of major confounding factors (e.g., exposure to other solvents/chemicals, smoking, alcohol consumption, and socioeconomic status). Nevertheless, there was sufficient information for Weiss (1995) to conclude that cigarette smoking and alcohol consumption could only partially account for an increased rate of esophageal cancer in dry cleaners. Kidney cancer incidences did not appear to be elevated. McLaughlin and Blot (1997) reevaluated available epidemiological data, and concluded that they did not support a cause-and-effect relationship between either PERC or TCE and kidney cancer. Boice *et al.* (1999) and Mundt *et al.* (2003) similarly concluded that there did not appear to be a relationship between occupational PERC exposure and cancer at any specific site.

The relevance of the male rat kidney tumor findings to humans has received considerable attention. Several mechanisms have been proposed for the development of renal cell carcinoma in PERC-exposed male rats. Some oxidative metabolites (TCA and DCA) modify cell signaling pathways, while reactive metabolites of the GSH pathway are cytotoxic and mutagenic (Lash and Parker, 2001). Chronic exposure to high doses of PERC can cause ongoing cell death, regenerative hyperplasia, and the opportunity for fixation of DNA damage and spontaneous errors in replication during repair. Increased cell replication, protein droplet accumulation, and enhanced α_{2u}-globulin levels in the P2 segment of renal proximal tubules appear to be unique to male rats (Green *et al.*, 1990). Melnick and Kohn (1999), however, have pointed out that mechanism(s) of interaction between α_{2u}-globulin accumulation and kidney cancer is(are) unknown, and that quantitative relationships between key biological processes have yet to be demonstrated. They offered an alternative hypothesis, namely the α_{2u}-globulin may bind to and thereby increase the renal concentration and action of a proximate carcinogen. As described above, a limited amount of PERC can be metabolized to TCVC, which in turn is detoxified or cleaved in the kidneys to cytotoxic and mutagenic products such as dichlorothioketene. Upon equivalent inhalation exposures of Wistar rats and humans to PERC, the rats excreted substantially larger amounts of DCA and acetylated TCVC (Volkel *et al.*, 1998). These observations were consistent with in vitro findings of greater conversion of PERC to TCVC by rat liver cytosol and of a 10-fold higher β-lyase-mediated metabolism of TCVC by rat than by human kidney (Green *et al.*, 1990; Cooper, 1994). These data indicate that human kidney has limited capacity to generate reactive metabolites from PERC by the GSH and β-lyase pathways.

Such metabolic and physiological differences between species (Lash *et al.*, 1998) can be input into PBTK models and used to predict inter- and intraspecies differences in metabolite dosimetry and cancer risks. Clewell *et al.* (2005) reviewed published PBTK PERC models and found just one, that by Gearhart *et al.* (1993), included a description of TCA kinetics. A second model with a TCA pathway (Jang and Droz, 1997) was subsequently located in the literature. Their data and model predictions showed that Asians exhibited higher PERC blood and breath levels and lower urinary TCA levels than Caucasians, consistent with slower PERC metabolism by the Asians. Quite recently, Covington *et al.* (2006) published a human model that provided for metabolism of PERC to TCA in the liver and kidney. A hierarchial Bayesian analysis was conducted to characterize the variability of estimates of the fractional metabolism of PERC in a population. Lash and Parker (2001) recommended that future PBTK models for PERC include a submodel for the GSH pathway.

1,1,1-Trichloroethane

1,1,1-Trichloroethane (methyl chloroform, TRI) is a widely used organic solvent. Its popularity as a metal degreaser, general purpose solvent, spot cleaner, and component of aerosols and a variety of household products increased substantially with the decline in manufacture of other halocarbons found to be high-dose rodent carcinogens and potential human carcinogens. TRI has not been shown to be carcinogenic in mice, rats, or humans (ATSDR, 2006b). Utilization of TRI declined during the 1990s, however, due to its ozone-depleting properties (Doherty, 2000). The VOC was to be phased out of use under the Montreal Protocol by 2002, but it continues to be manufactured and sold in large quantities in the United States and other countries.

The highest exposures to TRI occur via inhalation in occupational settings, but many persons encounter the VOC at home by use of commercial products and tap water containing it. Ashley *et al.* (1994) reported TRI and other VOCs in the blood of >75% of 600+ nonoccupationally exposed individuals. TRI and trichloroethylene (TCE) were also frequently detected in a subset of 982 adults examined in the NHANES III survey (Churchill *et al.*, 2001), and more recently in 951 other members of the general population (Blount *et al.*, 2006). TRI, TCE, and PCE comprise the most common ternary chemical mixture in groundwater at hazardous waste sites in the United States (Fay, 2006). TRI and other VOCs in groundwater can remain trapped for years and serve as a source of low-level exposure for large populations.

The primary pharmacological manifestation of acute or chronic inhalation of TRI is CNS depression, ranging in severity from slight headache or dizziness to anesthesia and death (ATSDR, 2006b). The current threshold limit value (TLV) of 350 ppm was established to prevent decrements in workers' mental and physical functions, though slight sedative effects have been reported by one group of investigators at 200 ppm (Muttray *et al.*, 2000). TRI has a very limited cytotoxic potential, ostensibly due to its quite limited biotransformation to relatively nontoxic metabolites (e.g., TCA and TCOH). Male rats gavaged five times weekly for as long as 12 days with up to 5 g TRI/kg died from effects of repeated, protracted CNS depression, but exhibited only slight hepatotoxicity (Bruckner *et al.*, 2001). Quast *et al.* (1988) saw only minimal histological changes in the liver of F-344 rats inhaling 1500-ppm TRI 6 h/d, 5 d/week for up to 2 years. It is worthy of note that even higher inhaled concentrations of TRI, particularly when accompanied by hypoxia and stress, can sensitize the myocardium to catecholamines, producing cardiac arrhythmias (Reinhardt *et al.*, 1973).

There is a relatively large rodent and human kinetic database for inhaled TRI. Inhalation experiments with human volunteers have been limited to monitoring blood and exhaled breath levels. The EPA has recently evaluated a number of TRI PBTK models for use in derivation of RfDs for its IRIS database. The model of Reitz *et al.* (1988) proved satisfactory, in that it accurately predicted the time–course of TRI in human, rat, and mouse blood for different inhalation scenarios. No brain deposition data were available then, so it was necessary to assume that blood TRI levels accurately reflect brain levels. Warren *et al.* (1998, 2000) demonstrated a high degree of correlation between brain and blood TRI levels in TRI-exposed mice and rats, as well as reasonable correlation between brain levels and CNS effects.

Methylene Chloride

Methylene chloride (dichloromethane, MC) enjoys widespread use as a solvent in industrial processes, food preparation, degreasing agents, aerosol propellants, and agriculture. Thus, large numbers of people are exposed occupationally and in the home. The primary route of exposure to this very volatile solvent is inhalation. The preponderance of MC escaping into the environment does so by volatilization (ATSDR, 1998b). The VOC is also frequently found in wastewater discharges and in air and water at hazardous waste sites (Fay and Mumtaz, 1996).

The TK of MC have been well characterized in humans and rodents. Inhaled MC was extensively absorbed and reached a near steady state in the blood of human subjects with 1–2 hours of continuous exposure (DiVincenzo and Kaplan, 1981). Less than 5% of the absorbed dose was exhaled unchanged. Some 25–34% was exhaled as carbon monoxide, the major end metabolite of MC. Exposure of the volunteers to 50, 100, 150, and 200 ppm for 7.5 hours produced peak blood carboxyhemoglobin saturations of 1.9, 3.4, 5.3, and 6.8%, respectively. MC was very rapidly eliminated from the body and did not accumulate over a 5-day-exposure regimen. Metabolism of MC in humans and rodents is believed to occur via three pathways (Andersen *et al.*, 1987). One entails CYP2E1-catalyzed oxidation to carbon monoxide via formyl chloride, a reactive intermediate. The second, a GSH-mediated pathway, involves a theta-class GST, GSTT1-1. The P450 pathway is a high-affinity, low-capacity pathway that predominates at MC concentrations present in occupational and environmental settings. The GST pathway is a low-affinity, high-capacity pathway operative at the high exposure levels used in cancer bioassays (Green, 1997). With the third pathway, it is postulated that CO_2 is also formed via the oxidative pathway by reaction of formyl chloride with a nucleophile such as GSH (Fig. 24-7).

MC has only a limited systemic toxicity potential. High, repeated inhalation exposures are required to produce slight, reversible changes in the liver of rodents. Centrilobular vacuolization and focal necrosis occur in the livers of rats exposed 6 h/d, 5 d/week for 2 years to 500–4000-ppm MC (Burek *et al.*, 1984; Mennear *et al.*, 1988). Manifestations of kidney injury are infrequent in laboratory animals, but are occasionally reported in persons subjected to high vapor levels. As described above, the carbon monoxide that is formed from MC binds to hemoglobin to produce dose-dependent increases in carboxyhemoglobin. It is generally accepted that tissue hypoxia can contribute to acute CNS effects of MC. There are few reports of residual neurologic dysfunction in MC-exposed employees (Lash *et al.*, 1991; ATSDR, 1998b).

Occupational and environmental MC exposures are of concern primarily because of MC's carcinogenicity in rodents and its potential as a human carcinogen. Burek *et al.* (1984) saw increased numbers of salivary gland sarcomas in male rats and benign mammary tumors in female rats exposed to very high MC vapor levels 5 times weekly over 2 years. Hamsters were not affected. Benign mammary tumors in female rats were also seen in subsequent inhalation bioassays (Nitschke *et al.*, 1988; Mennear *et al.*, 1988). Dose-dependent increases in lung and liver tumors in male and female B6C3F1 mice were also found in the latter investigation. Epidemiology studies of workers exposed to MC have not revealed increases in mortality from lung or liver tumors (ATSDR, 1998b). There have been occasional reports of cancer excess in other organs, including the pancreas (Hearne *et al.*, 1990) and the prostate and cervix (Gibbs *et al.*, 1996). Upon a comprehensive review of the epidemiology literature, Dell *et al.* (1999) and Starr *et al.* (2006) concluded that occupational studies to date provide little evidence of MC carcinogenicity in humans.

There has been a great deal of research to define mechanisms of MC carcinogenicity, in order to more clearly understand the relevance of the murine tumors to humans (Green, 1997). Liver and lung

tumors in mice do not seem to be associated with overt cytotoxicity or increased replicative DNA synthesis (Maronpot *et al.*, 1995). Induction of the tumors in mice is generally believed to be due to a reactive intermediate generated via the GST pathway (Andersen *et al.*, 1987). GSTT1-1 in liver and lung catalyzes conversion of MC to *S*-chloromethylglutathione (GSCH$_2$Cl), which apparently breaks down rapidly to GSH and formaldehyde. GSCH$_2$Cl has yet to be isolated and quantified. Metabolism of MC via the GST pathway is an order of magnitude greater in mouse than in rat liver. Metabolic rates in hamster and human liver are even lower (Reitz *et al.*, 1989; Thier *et al.*, 1998). High GSTT1-1 activity was measured in the nuclei of mouse centrilobular hepatocytes. Mice may be unique in that extensive metabolic activation of MC to an unstable intermediate occurs in the proximity of the DNA. It would be useful in future PBTK models to include subcompartments for cytosolic and nuclear GST activities (Starr *et al.*, 2006). GSTT1-1 was also detected in relatively high levels in mouse lung Clara cells and ciliated cells at alveolar/bronchiolar junctions. GSCH$_2$Cl apparently causes single-strand breaks in vivo and in vitro in DNA of mouse liver and lung (Graves *et al.*, 1995). No DNA breaks were detected in hamster or human hepatocytes in vitro. Casanova and coworkers have proposed an alternate mechanism of MC carcinogenicity, namely formation of DNA–protein cross-links (DPX) by formaldehyde. Upon incubation of MC with hepatocytes from mice, rats, hamsters, and humans, DPX were found only in the mouse samples (Casanova *et al.*, 1996). Formaldehyde–RNA adducts, a more sensitive marker than DPX, were subsequently found in human hepatocytes incubated with MC, although the adducts were seven times more prevalent in mouse hepatocytes (Casanova *et al.*, 1997).

We now have a substantial amount of information on the TK and mechanism(s) of carcinogenicity of MC. Considerable time and money have been spent on MC research by federal agencies, academia, and industry. MC was one of the first chemicals for which PBTK modeling was employed by the EPA in cancer risk estimation. Although uncertainties remain, species differences appear to be largely quantitative rather than qualitative. Flux through both the P450 and GST pathways is substantially greater in mice than in rats or humans. Interindividual variability in the rate of MC oxidation by 13 human subjects is reported to be quite small (Sweeney *et al.*, 2004). Persons with a GSTT1-1 null genotype (Nelson *et al.*, 1995; Haber *et al.*, 2002) may not be at risk from certain MC-induced tumors. This concept has been incorporated into cancer risk assessments based upon PBTK estimation of DPX formation in humans (El-Masri *et al.*, 1999; Jonsson and Johanson, 2001).

Carbon Tetrachloride

CCl$_4$ previously enjoyed widespread use as a solvent, cleaning agent, fire extinguisher, synthetic intermediate, grain fumigant, and human anthelmintic. Its use has steadily declined since the 1970s, due to its hepatorenal toxicity, carcinogenicity, and contribution to atmospheric ozone depletion (ATSDR, 2005). Nevertheless, CCl$_4$ appears to be ubiquitous in ambient air in the United States, and it is still found in groundwater from some wells and waste sites. CCl$_4$ is a classic hepatotoxin, but kidney injury is often more severe in humans. There does not appear to be a good animal model for CCl$_4$-induced kidney toxicity.

The time–course of CCl$_4$-induced acute liver injury has been well characterized (ATSDR, 2005). Early signs of hepatocellular injury in rats include dissociation of polysomes and ribosomes from rough endoplasmic reticulum, disarray of smooth endoplasmic reticulum, inhibition of protein synthesis, and triglyceride accumulation. Hypomethylation of RNA is thought to contribute to inhibition of lipoprotein synthesis, thereby playing a role in steatosis (Clawson *et al.*, 1987). Ingested CCl$_4$ reaches the liver, undergoes metabolic activation, produces lipid peroxidation, covalently binds, and inhibits microsomal ATPase activity within minutes in rats. Single cell necrosis, evident 5–6 hours post dosing, progresses to maximal centrilobular necrosis within 24–48 hours. Most microsomal enzyme activities are significantly depressed (Recknagel *et al.*, 1989).

A variety of cytoplasmic enzymes are released from dead and dying hepatocytes into the bloodstream. The activity of these enzymes in serum generally parallels the extent of necrosis in the liver. Cellular regeneration, manifest by increased DNA synthesis and cell cycle progression, is maximal 36–48 hours post dosing (Rao *et al.*, 1997).

Development of cellular resistance and tissue repair are important in limiting CCl_4 hepatotoxicity, and in recovery (Mehendale, 2005). Alterations in transmembrane carrier proteins have been discovered in hepatocytes of CCl_4-treated mice. CCl_4 results in reduced expression of genes associated with extraction of bile acids and organic ions from sinusoidal blood, as well as upregulation of certain detoxification genes (Aleksunes *et al.*, 2005). CCl_4 also produces differential upregulation in multidrug resistance proteins that are involved in export of oxidative stress products and metabolites. Hepatocellular regeneration has been shown to begin within 6 hours of a small dose of CCl_4, just as centrilobular necrosis is becoming evident (Lockard *et al.*, 1983). This early-phase regeneration (arrested G_2 hepatocytes activated to proceed through mitosis) is followed at ∼24 hours by the secondary phase of regeneration (hepatocytes mobilized from G_0/G_1 to proceed through mitosis (Bell *et al.*, 1988).

It is likely that the mechanism of liver injury by CCl_4 has received more attention than that of any other chemical. Nevertheless, there is still considerable debate about the relative importance of different actions of CCl_4, notably covalent binding and lipid peroxidation. CCl_4 is known to be metabolized by P450-dependent reductive dehalogenation to a trichloromethyl radical ($CCl_3 \cdot$). This radical can bind covalently to nucleic acids to initiate liver cancer, and bind to lipids and proteins, causing structural damage of membranes and inhibition of a variety of enzymes. $CCl_3 \cdot$ may also react with oxygen to produce Cl_3OO, the highly reactive trichloromethyl peroxyl radical. $CCl_3 \cdot$ can also attack enoic fatty acids, leading to organic free radicals, which may in turn react with oxygen to form peroxides and other cytotoxic metabolites (Recknagel *et al.*, 1989; Plaa, 2000; Weber *et al.*, 2003). This self-perpetuating process is known as lipid peroxidation. It destroys polyunsaturated fatty acids, especially those associated with phospholipids, altering permeabilities of organelles, and resulting in a loss of calcium homeostasis. Numerous studies have shown various antioxidants to ameliorate CCl_4 cytotoxicity in vitro and in vivo. Chemicals that inhibit CCl_4 covalent binding are also protective. In vivo experiments in rats by Padron *et al.* (1996) demonstrated that both of these degenerative processes (i.e., covalent binding and lipid peroxidation) were necessary for CCl_4 cytotoxicity. Liu *et al.* (1995) have proposed that CCl_4 oxidative stress in the liver enhances nuclear factor kappa B activity, which in turn promotes expression of proinflammatory cytotoxic cytokines. Shi *et al.* (1998) proposed apoptosis as an additional/alternate mechanism of CCl_4-induced cell death.

Perturbation of intracellular calcium (Ca^{2+}) homeostasis appears to be an integral part of CCl_4 cytotoxicity (Stoyanovsky and Cederbaum, 1996). Increased cytosolic Ca^{2+} levels may result from influx of extracellular Ca^{2+} due to plasma membrane damage and from decreased intracellular Ca^{2+} sequestration. Elevation of intracellular Ca^{2+} in hepatocytes can cause activation of phospholipase A_2 and exacerbation of membrane damage (Glende and Recknagel, 1992). Elevated Ca^{2+} may also be involved in alterations in calmodulin and phosphorylase activity, as well as changes in nuclear protein kinase C activity (Omura *et al.*, 1999). High intracellular Ca^{2+} levels activate a number of catabolic enzymes including proteases, endonucleases, and phospholipases, which kill cells via apoptosis or necrosis (Weber *et al.*, 2003). The hydrolytic enzyme calpain medi-

ates progression of acute CCl_4-induced liver injury by leaking from dying hepatocytes and attacking neighboring cells (Limaye *et al.*, 2003). Ca^{2+} may stimulate the release of cytokines and eicosanoids from Kupffer cells. Edwards *et al.* (1993) demonstrated that destruction of Kupffer cells prior to CCl_4 dosing of rats resulted in significant reductions in neutrophil infiltration and hepatocellular injury. Macrophages are known to release a number of inflammatory mediators, such as tumor necrosis factor alpha (TNF-α), that are cytotoxic (Morio *et al.*, 2001). CCl_4 hepatocytotoxicity is obviously a complex, multifactorial process that is likely to continue to receive considerable attention.

CCl_4 has frequently been used as a model hepatotoxic compound with which to examine the influence of various factors that alter P450s. CYP2E1 is primarily responsible for catalyzing the bioactivation of low doses of CCl_4 in humans. CYP3A contributes to the metabolism of higher doses (Zangar *et al.*, 2000). The preeminent role of CYP2E1 in animals is clearly demonstrated by the protection afforded CCl_4-treated rodents by CYP2E1 antibody (Castillo *et al.*, 1992), the CYP2E1 inhibitor 3-amino-1,2,4-triazole (Padron *et al.*, 1996), and the absence of CYP2E1 expression (Wong *et al.*, 1998). As discussed previously, a variety of conditions that induce CYP2E1 potentiate CCl_4 hepatotoxicity in test animals and humans. Sufficient doses of CYP2E1 inhibitors, including natural constituents of foods (described in the subsection on P450 inhibitors), can inhibit CCl_4 toxicity (Lieber, 1997). Taieb *et al.* (2005) recently discovered protein 8, a transcription factor that regulates the expression of genes that protect cells from stress, rapidly triggered CYP2E1 downregulation in CCl_4-dosed mice, thereby minimizing CCl_4 bioactivation.

Chloroform

The primary use of chloroform ($CHCl_3$, trichloromethane) is in the production of the refrigerant chlorodifluoromethane (Freon 22), but this use is expected to diminish as chlorine-containing fluorocarbons are phased out under the Montreal Protocol. $CHCl_3$ was among the first inhalation anesthetics, but it was replaced by safer compounds after about 1940. $CHCl_3$ is a by-product of drinking water chlorination and has been measured in municipal drinking water supplies in concentrations as high as several hundred ppb, although levels are usually <25 ppb (ATSDR, 1997a). $CHCl_3$ has also been found in ppb concentrations in swimming pool water and surrounding air (Aggazzotti *et al.*, 1995). Like many other halocarbons, $CHCl_3$ can invoke CNS symptoms at subanesthetic concentrations similar to those of alcohol intoxication and can sensitize the myocardium to catecholamines, possibly resulting in cardiac arrhythmias.

The reproductive and developmental toxicities of $CHCl_3$ are rather unremarkable. Schwetz *et al.* (1974) found that inhalation of 100–300-ppm $CHCl_3$ by pregnant rats caused a high incidence of fetal resorption, retardation of fetal development, and a low incidence of fetal anomalies. Murray *et al.* (1979) reported that gestational exposure to 100-ppm $CHCl_3$ resulted in the decreased ability of mice to maintain pregnancy, as well as cleft palate, decreased fetal weight and length, and decreased ossification in pups. Very high $CHCl_3$ concentrations retarded development and induced diffuse cell death in cultured rat embryos (Brown-Woodman *et al.*, 1998). These studies support $CHCl_3$ as a weak teratogen, but negative studies employing maternally toxic doses argue against this characterization (Thompson *et al.*, 1974; NTP, 1997a). The EPA's IRIS profile for $CHCl_3$ notes that in reproductive/developmental studies, maternal toxicity and fetal effects occurred at doses higher than those that produced liver toxicity in the dog study by Heywood *et al.* (1979).

The latter study serves as the basis for EPA's benchmark dose-based RfD (EPA, 2006a).

Under certain conditions $CHCl_3$ is hepatotoxic and nephrotoxic. These toxicities are potentiated by aliphatic alcohols, ketones, and DCA and TCA (Davis, 1992). Albeit at low doses, numerous disinfection by-products such as the rodent carcinogens TCA and DCA are routinely consumed with $CHCl_3$ in finished drinking water. For this reason, mixture studies are particularly relevant. Consider, for example, the studies of Pereira *et al.* (2001) in which *N*-methyl-*N*-nitrosourea-initiated B6C3F1 mice were exposed to DCA with or without $CHCl_3$. $CHCl_3$ prevented the hypomethylation and increased mRNA expression of the proto-oncogene c-myc and the promotion of liver tumors by DCA. Conversely, $CHCl_3$ increased DCA-induced DNA hypomethylation and enhanced the DCA promotion of kidney tumors. Thus, concurrent exposure to two rodent carcinogens, $CHCl_3$ and DCA, resulted in less than additive activity in one organ and synergism in another (Pereira *et al.*, 2001; Tao *et al.*, 2005). This exemplifies the difficulty in assessing the risks posed by solvent mixtures.

Tolerance or adaptation to $CHCl_3$'s hepatorenal toxicity and carcinogenicity has been observed in some mouse strains after repeated exposure. This phenomenon was first investigated by Pereira and Grothaus (1997), who reported preexposure of mice to low doses of $CHCl_3$ in drinking water-induced resistance to hepatotoxicity and cell proliferation following a higher gavage dose. This was presumed at the time to result from suicidal inhibition of the P450s responsible for $CHCl_3$'s activation. More recently, mice exposed daily for 7, 14, and 30 days were found to have a robust regenerative response in target tissues, which prevented the progression of injury (Anand *et al.*, 2006b). Blood and tissue levels of $CHCl_3$ after repeated exposure were substantially lower than those following a single exposure, owing to increased elimination of $CHCl_3$ via exhalation. These same researchers also reported that priming mice with $CHCl_3$ prior to a lethal dose stimulated compensatory hepato- and nephrogenic repair, limiting the progression of injury and resulting in 100% survival. Relative to unprimed mice, there was no difference in hepatic or renal CYP2E1 activity, though GSH and GSH reductase activity were upregulated in the kidney (but not in the liver), with a consequent decrease in renal covalent binding. The area under the blood $CHCl_3$ versus time curve (AUC) was 40% lower in primed versus unprimed mice, but increased elimination via exhalation was not responsible for the reduction in internal exposure in this particular case (Philip *et al.*, 2006). Taken together, these studies suggest that TK and TD factors contribute to the tolerance observed to $CHCl_3$ toxicity. Mehendele and colleagues have conducted a series of studies with $CHCl_3$, alone or in combination with other hepatotoxicants, to further discern the role of tissue repair in toxicant-induced injury. These studies have provided valuable insight into the importance of both the timing of the tissue repair response and its magnitude as pivotal determinants of the outcome of toxicant-induced injury and emphasize the need to consider repair processes in predictive toxicology (Anand *et al.*, 2003, 2005; Mehendale, 2005).

The status of $CHCl_3$ as a rodent carcinogen is indisputable. It causes liver and kidney tumors that are species-, strain-, sex-, and route of exposure-dependent. $CHCl_3$-induced liver tumors in mice and their dependence on ongoing liver necrosis were reported near the end of World War II (Eschenbrenner and Miller, 1945). These same authors observed that male but not female mice suffered kidney necrosis. This observation was supported by the report of Roe *et al.* (1979) that $CHCl_3$ ingested in a toothpaste base resulted in
Figure 24-8. Hepatocyte liver LI in female B6C3F1 mice given CHCl₃ orally in corn oil (A) or drinking water (B) for 4 days or 3 weeks.

The LI is defined as the percent of hepatocyte nuclei positive for 5-bromo-2′-deoxyuridine immunohistochemical staining (i.e., percent of cells in the S phase, the period of DNA synthesis during the cell cycle). Values represent the mean ± SD for five mice. Asterisks (∗) denote a significant difference from similarly treated control mice (<0.05). Note that 1800-ppm CHCl₃ in water corresponds to a cumulative uptake of 329 mg/kg/d. [Reproduced with permission of Larson *et al.* (1994).]

renal tumors in male but not female mice. This sex difference is thought to be attributable to testosterone-mediated differences in renal CYP activity (Smith *et al.*, 1984). The NCI (1976) cancer bioassay demonstrated renal tumors in male rats and an extremely high incidence of liver tumors in both sexes of B6C3F1 mice gavaged with $CHCl_3$ in corn oil. In 1985, Jorgenson and colleagues reported that daily doses of $CHCl_3$ in drinking water comparable to those in the NCI gavage assay also produced renal tumors in rats, but failed to cause liver tumors in B6C3F1 mice. This finding provided evidence that the dose rate of $CHCl_3$ was a determinant of liver tumor formation, supporting the existence of a threshold mechanism. Hard *et al.* (2000) have reevaluated the kidneys from the Jorgenson *et al.* (1985) study and have confirmed the presence of chronic renal tubule injury, indicative of renal tumor formation via an epigenetic mechanism. In what may be a landmark study, Larson *et al.* (1994) compared cytotoxicity and cell proliferation in female B6C3F1 mice given $CHCl_3$ by gavage in corn oil versus ad libitum ingestion in drinking water. As seen in Fig. 24-8, the

hepatocyte-labeling index, a measure of the proliferative response, differed between the two dosage regimens at comparable doses. Pereira (1994) reported essentially the same observation. This suggests that ingestion of $CHCl_3$ in small increments, similar to drinking water patterns of humans, fails to produce a sufficient amount of cytotoxic metabolite(s) per unit time to overwhelm detoxification and other protective mechanisms.

Potentiation of $CHCl_3$'s toxicity by CYP inducers and protection by GSH and P450 inhibitors suggest that a metabolite, presumably phosgene, is responsible for $CHCl_3$'s hepatorenal toxicity. Both target organs metabolize $CHCl_3$ to phosgene. There is evidence that CYP2E1 and CYP2B1/2 metabolically activate $CHCl_3$, but the former isoform is thought to catalyze $CHCl_3$ metabolism at a lower concentration than the latter (Nakajima *et al.*, 1995). By using an irreversible CYP2E1 inhibitor and CYP2E1-knockout mice, Constan *et al.* (1999) have demonstrated that metabolism of $CHCl_3$ by CYP2E1 is required for liver and kidney necrosis and cell proliferation. The electrophilic intermediate generated by $CHCl_3$'s metabolism (i.e., phosgene) is initially detoxified by covalently binding to cytosolic GSH. Once GSH is depleted, phosgene is free to covalently bind hepatic and renal proteins and lipids. Such binding damages membranes and other intracellular structures, leading to necrosis and subsequent reparative cellular proliferation. Sustained proliferation with repeated exposures promotes tumor formation in rodents by irreversibly "fixing" spontaneously altered DNA and clonally expanding initiated cells. The expression of certain genes, including *myc* and *fos*, is altered during regenerative cell proliferation in response to $CHCl_3$-induced cytotoxicity (Sprankle *et al.*, 1996; Kegelmeyer *et al.*, 1997). While the identity of phosgene's intracellular targets is largely unknown, Guastadisegni *et al.* (1999) have reported that phosgene reacts with phosphatidylethanolamine (PE). The adduct formed appears to consist of two PE moieties cross-linked at the amino head groups by the carbonyl moiety of phosgene. $CHCl_3$-modified PE preferentially accumulates on inner mitochondrial membranes, inducing ultrastructural modifications and inhibiting functions of the organelle. These researchers observed the induction of hepatic apoptosis and necrosis in $CHCl_3$-treated Sprague–Dawley rats and pointed out that apoptosis may be initiated by the release of regulatory factors normally sequestered in mitochondria, in particular Ca^{2+}. Evidence that Ca^{2+} perturbation plays a role in $CHCl_3$ toxicity comes from a report of Ca^{2+} mobilization in Madin–Darby canine kidney cells using Fura-2 as a Ca^{2+} probe. $CHCl_3$, albeit in millimolar concentrations, increased the cytosolic Ca^{2+} levels by releasing Ca^{2+} from multiple sites within the cell (Jan *et al.*, 2000).

There is no evidence of covalent binding of $CHCl_3$ metabolites to nucleic acids. There is binding to nuclear histone, which plays a key role in controlling DNA expression and might be a mechanism of $CHCl_3$'s carcinogenicity (Diaz and Castro, 1980; Fabrizi *et al.*, 2003). It has been hypothesized that the induction of oxidative stress and depletion of GSH by $CHCl_3$ may lead to indirect genotoxicity that could contribute to carcinogenicity. This hypothesis is supported by the small dose-dependent increase in M(1)dG adducts (malondialdehyde reacts with DNA to form adducts to deoxyguanosine), DNA strand breakage, and lipid peroxidation in $CHCl_3$-treated rat hepatocytes in the absence of any increase in DNA oxidation (Beddowes *et al.*, 2003). Such a mechanism would still be threshold dependent, given its reliance on the initial depletion of antioxidants.

Currently, the EPA classifies $CHCl_3$ as a probable human carcinogen (group B2), meaning there is sufficient evidence for carcinogenicity in animals and inadequate or no evidence in humans.

Experimental evidence and the prevailing opinion that $CHCl_3$ is nongenotoxic, indicates that the relationship between $CHCl_3$ dose and tumor formation is nonlinear. The EPA has, as is called for in its new *Guidelines for Carcinogen Risk Assessment* (EPA, 2005), considered mode of action in the determination of $CHCl_3$'s cancer risk and relied on a nonlinear dose–response approach and the use of margin-of-exposure analysis. In doing so, the Agency concluded that the RfD for noncancer effects, based on the dog study of Heywood *et al.* (1979), was adequately protective for cancer by the oral route on the basis of cancer and noncancer effects having a common link through cytotoxicity. The wealth of mechanistic data available continues to inform the risk assessment for $CHCl_3$. For example, Constan *et al.* (2002) exercised a PBTK dosimetry model to compare hepatic responses in mice and humans to inhaled $CHCl_3$. They concluded that no safety factor was needed to account for interspecies differences in inhalation cancer risk. Additionally, Tan *et al.* (2003) have published a PBTK/TD model for $CHCl_3$ to describe the plausible mechanism linking the hepatic metabolism of $CHCl_3$ to hepatocellular killing and regenerative proliferation, thereby creating a predictive model that most accurately reflects the current science.

AROMATIC HYDROCARBONS

Benzene

Benzene produced commercially in the United States is derived primarily from petroleum. Benzene has been utilized as a general purpose solvent, but it is now used principally in the synthesis of other chemicals (ATSDR, 2006c). The percentage by volume of benzene in gasoline is 1–2%. Benzene plays an important role in unleaded gasoline due to its antiknock properties. Inhalation is the primary route of exposure in industrial and in everyday settings. Cigarette smoke is the major source of benzene in the home (Wallace, 1996). Smokers have benzene body burdens that are six to 10 times greater than those of nonsmokers. Passive smoke can be a significant source of benzene exposure to nonsmokers. Gasoline vapor emission and auto exhaust are the other key contributors to exposures of the general populace.

The most important adverse effect of benzene is hematopoietic toxicity. Chronic exposure to benzene can lead to bone marrow damage, which may be manifest initially as anemia, leukopenia, thrombocytopenia, or a combination of these. Bone marrow depression appears to be dose dependent in both laboratory animals and humans. Continued exposure may result in marrow aplasia and pancytopenia, an often fatal outcome. Survivors of aplastic anemia frequently exhibit a preneoplastic state, termed myelodysplasia, which may progress to myelogenous leukemia (Snyder, 2002; Bird *et al.*, 2005).

There is strong evidence from epidemiological studies that high-level benzene exposures result in an increased risk of acute myelogenous leukemia (AML) in humans (Bergsagel *et al.*, 1999; ATSDR, 2006a). Evidence of increased risks of other cancers in such populations is less compelling. Only AML incidence was significantly elevated in the largest cohort study to date, in which ~75,000 benzene-exposed workers in 12 cities in China were evaluated (Yin *et al.*, 1996). Marginal, nonsignificant increases were seen for lung cancer and chronic myelogenous leukemia. A subsequent study of some 250 Chinese shoe workers who inhaled low (≤ 1 to ≥ 10 ppm) levels of benzene revealed dose-dependent hematotoxicity (Lan *et al.*, 2004). Exposures of 100 of these employees
Figure 24-9. Biotransformation of benzene.

A question mark leads from the oxepin-oxide compartment to muconaldehyde because the substrate for the ring opening has yet to be identified. The dotted line leading to 1,2,4-trihydroxybenzene (1,2,4-T) indicates that it is not clear what the relative contributions of hydroquinone and catechol are to 1,2,4-T. [Modified and used with permission of Rangan and Snyder (1997).]

to ≤1 ppm reduced mature white cell and platelet counts, as well as myeloid progenitor cell colony formation. The progenitors were more sensitive to benzene than mature white cells. Polymorphisms in myeloperoxidase (an enzyme that metabolizes benzene to toxic quinones and free radicals) and NAD(P)H:quinone oxidoreductase (an enzyme that protects against these moieties) conferred increased susceptibility to white cell decreases. Turtletaub and Mani (2003) found that formation of DNA and protein adducts in mouse liver and bone marrow was dose dependent over a range of benzene doses, the lowest of which was 5 μg/kg.

Types of cancer other than AML have been tentatively attributed to benzene. Some investigations of persons exposed to engine exhausts have reported a significant association with multiple myeloma. Bezabeth *et al.* (1996) and Bergsagel *et al.* (1999) have concluded, however, that there is no scientific evidence to support a causal relationship between benzene exposure and multiple myeloma. Increased incidences of malignant lymphomas and a variety of solid tumors were found in male and female B6C3F1 mice dosed orally with high doses of benzene for up to 103 weeks (Huff *et al.*, 1989). Male and female F-344 rats in this bioassay exhibited excesses of Zymbal gland, skin, and oral cavity carcinomas. Thus, benzene is clearly an animal and human carcinogen, but major species differences exist.

It is essential to understand the metabolism of benzene in order to address its mechanisms of toxicity. The initial metabolic step (Fig. 24-9), oxidation of benzene to an epoxide (i.e., benzene oxide),

is catalyzed primarily by hepatic CYP2E1. Valentine *et al.* (1996) demonstrated that benzene-treated transgenic CYP2E1 knockout mice had relatively low levels of all benzene metabolites in their urine. A 5-day, 200-ppm benzene inhalation regimen produced severe genotoxicity and cytotoxicity in wild-type B6C3F1 mice, but no adverse effects in the knockout mice. Benzene oxide, which is in equilibrium with its oxepin form, is further metabolized by three pathways: (1) conjugation with GSH to form a premercapturic acid, which is converted to phenyl-mercapturic acid; (2) rearrangement nonenzymatically to form phenol; and (3) hydration by epoxide hydrolase to benzene dihydrodiol, which in turn can be oxidized by dihydrodiol dehydrogenase to catechol. If phenol is hydroxylated in the *ortho* position, more catechol will be formed. Catechol can be converted to *o*-benzoquinone. If benzene is hydroxylated in the *para* position, *p*-hydroquinone is formed. It can be oxidized to *p*-benzoquinone. The *o*- and *p*-benzoquinones are believed to be among the ultimate toxic metabolites of benzene. Another potentially toxic metabolite, muconaldehyde, may arise from ring opening of benzene oxide. Muconaldehyde undergoes a series of reactions that ultimately lead to *t,t*-muconic acid, an end metabolite found in the urine (Golding and Watson, 1999; Snyder, 2004).

Metabolism of benzene occurs primarily in the liver, though metabolism in bone marrow is believed by many authorities to play the key role in myelotoxicity. Levels of DNA and protein adducts were significantly higher in bone marrow than liver of benzene-dosed mice (Turtletaub and Mani, 2003). It has been generally

accepted that phenolic conjugates are formed in the liver and transported via the blood to the bone marrow, where they are hydrolyzed and oxidized to quinones. Researchers have been unable to reproduce benzene toxicity, however, by giving individual phenolic metabolites to animals. The quinones are believed to be too reactive to be transported in the bloodstream. Lindstrom et al. (1997) have reported that benzene oxide has an estimated half-life of 7.9 minutes in rat blood, and thus may be able to travel from the liver to the bone marrow. Ring-opened metabolites of muconaldehyde, which are less reactive, could be transported to bone marrow and reoxidized. Bernauer et al. (1999) measured activity and levels of CYP2E1 in the liver and bone marrow of five strains of mice of varying sensitivity to benzene. CYP2E1 amounts and activities were considerably greater in the liver than the marrow, but no interstrain differences were seen in either tissue. It is likely that non-CYP enzymes (e.g., peroxidase, myeloperoxidase, and cyclooxygenase) play an important role in generation of semiquinones and quinones in bone marrow (Ross et al., 1996). Snyder (2004) concluded that benzene hematopoietic toxicity and leukemogenesis are primarily a function of the bone marrow, a site remote from the liver where most benzene metabolism occurs.

Benzene's metabolic pathways appear to be qualitatively, though not quantitatively similar in species studied to date (Henderson, 1996). Mice have a greater overall capacity to metabolize benzene than do rats or primates. Mani et al. (1999) reported good correlation between protein–DNA adduct levels in bone marrow and susceptibility to benzene genotoxicity and carcinogenesis in F-344 rats and three strains of mice. The B6C3F1 mouse shows the highest adduct levels and is the most sensitive of the animals tested. Powley and Carlson (1999) reported similar findings upon measurement of benzene metabolism in mouse, rat, rabbit, and human lung and liver microsomes. A paucity of information is available on the ability of human bone marrow to metabolically activate benzene.

Factors that alter the metabolism of benzene have the potential to influence the hematopoietic toxicity and carcinogenicity of the VOC. Pretreatment of rats with ethanol, a CYP2E1 inducer, enhanced metabolism of benzene and potentiated its acute and subacute myelotoxicity in rats (Nakajima et al., 1985) and mice (Marrubini et al., 2003). Phenobarbital had a negligible effect. Pretreatment of male B6C3F1 mice with acetone, another CYP2E1 inducer, increased benzene oxidation by about five-fold (Kenyon et al., 1996). Pretreatment with diethyldithiocarbamate, a CYP2E1 inhibitor, completely abolished benzene oxidation. Co-exposure of F-344 rats to gasoline and benzene resulted in competitive metabolic inhibition (Travis et al., 1992). Metabolism of benzene by hepatic microsomes from 10 human donors was directly proportional to CYP2E1 activity in the samples (Seaton et al., 1994). Thus, it would be anticipated that CYP2E1 polymorphisms may influence susceptibility to benzene toxicity. Male mice have consistently been found to be more sensitive than females to genotoxic effects of benzene. PBTK analysis of data from gas uptake experiments with B6C3F1 mice of both sexes revealed that the optimized maximum rate of benzene metabolism was twice as high in males (Kenyon et al., 1996). It is not known whether there is a sex-dependent difference in benzene metabolism in humans. Sato et al. (1975) saw a more rapid rate of pulmonary elimination of benzene in men than in women following inhalation of 25 ppm for 2 hours. Benzene was retained longer in the females due to their higher body fat content. Unfortunately, most epidemiology studies of benzene-exposed workers have not provided a gender comparison. Li et al. (1994) did not see a statistically significant difference in cancer mortality between male and female workers exposed to benzene, though risks tended to be somewhat higher for males.

There are a number of cell populations in the bone marrow that may serve as targets for benzene metabolites. Benzene exposure in vivo results in inhibited growth and development of pluripotential bone marrow stem cells. More mature precursors, such as stromal cells and erythroid and myeloid colony-forming units, are also affected. Trush et al. (1996) point out that hydroquinone-induced inhibition of interleukin (IL)-1 synthesis by stromal macrophages results in altered differentiation of myeloid and lymphoid cells that are normally active in immune responses. These investigators also note that killing of stromal macrophages and fibroblasts could result in such a pronounced reduction of cytokines and growth factors that immature and committed hematopoietic progenitors would die from apoptosis. The erythroid series is more susceptible than the myeloid series to benzene-induced cytotoxicity. Immature myeloid cells can proliferate when the development of erythroid cells is restricted and acquire neoplastic characteristics upon dedifferentiation. The end result is AML (Golding and Watson, 1999).

Investigations of benzene toxicity/leukemogenesis have uncovered a variety of potential mechanisms (Golding and Watson, 1999; Snyder, 2002; Bird et al., 2005). As mentioned before, experimental evidence indicates that the complementary actions of benzene and several of its metabolites are required for myelotoxicity. It has been recognized for 20 years that a number of benzene metabolites can bind covalently to GSH, proteins, DNA, and RNA. This can result in disruption of the functional hematopoietic microenvironment by inhibition of enzymes, destruction of certain cell populations, and alteration of the growth of other cell types. Covalent binding of hydroquinones to spindle-fiber proteins will inhibit cell replication (Smith, 1996). In vitro studies have established that reactive benzene metabolites bind covalently to DNA of several tissues of different species. Through the use of accelerator mass spectrophotometry, Creek et al. (1997) have demonstrated DNA binding in mice exposed to extremely low ^{14}C-benzene levels. The binding was dose dependent over a wide range of doses. DNA adduct levels were so low, however, that this mechanism alone may be insufficient to fully account for leukemogenic effects.

It appears likely that oxidative stress contributes to benzene toxicity. As the bone marrow is rich in peroxidase activity, phenolic metabolites of benzene can be activated there to reactive quinone derivatives. Ross et al. (1996) discovered that myeloperoxidase present in murine and human progenitor cells could bioactivate hydroquinone to p-benzoquinone. Electron spin resonance experiments by Hiraku and Kawanishi (1996) revealed the formation of a semiquinone radical in p-benzoquinone-treated HL-60 cells (a human myeloid cell line). This suggested that reactive oxygen moieties (e.g., O_2- and H_2O_2) are produced via the formation of the semiquinone radicals. These active oxygen species can cause DNA strand breaks or fragmentation, leading to cell mutation or apoptosis, respectively. Ross et al. (1996), however, pointed out that quinones can also inhibit proteases involved in induction of apoptosis. These authors noted that modulation of apoptosis may lead to aberrant hematopoiesis and neoplastic progression.

A number of biomarkers of exposure to benzene have been developed and carefully evaluated. Concentrations of the parent compound in exhaled breath parallel blood concentrations. Clayton et al. (1999) reported a high correlation between the extent of smoking-related activities and levels of benzene in exhaled breath of humans. Urinary excretion of a variety of benzene metabolites (i.e., phenol, catechol, hydroquinone, 1,2,4-trihydroxybenzene,

S-phenylmercapturic acid, and *t*,*t*-muconic acid) have been shown to be correlated with benzene exposure in occupational settings. Phenol, catechol, and hydroquinone, however, are neither sensitive nor specific biomarkers, because relatively high levels are found in nonexposed individuals (Medeiros *et al*., 1997). Similarly, *t*,*t*-muconic acid is not specific, because it is a metabolite of sorbic acid, a common food additive. Boogaard and van Sittert (1996) conclude that *S*-phenylmercapturic acid, an end product of the conjugation of benzene oxide and GSH, is a suitable urinary biomarker for low-level benzene exposure because of its specificity and relatively long half-life. Adducts to hemoglobin and cysteine groups of proteins have been demonstrated in rodents, but not in humans. DNA damage has been detected in benzene-exposed workers (Liu *et al*., 1996; Andreoli *et al*., 1997), though such measures have not yet found widespread acceptance as biomarkers of effect.

A number of PBTK models have been developed to aid in predicting risks of myelotoxicity and leukemia posed to humans by benzene. Medinsky *et al*. (1989) published one of the first such models for benzene. They assumed that benzene metabolism followed Michaelis–Menten kinetics and occurred via benzene oxide. B6C3F1 mice, which are more sensitive than F-344 rats to benzene myelotoxicity, were predicted to metabolize two to three times more inhaled benzene. This and other PBTK models do not accurately simulate some laboratory data sets. Modeling benzene metabolism and disposition is difficult because of its inherent complexity and variability. In light of intricate dose–response relationships, Medinsky *et al*. (1996) emphasized the importance of considering competitive metabolic interactions between benzene and its metabolites, as well as the balance between enzymatic activation and inactivation processes. Cole *et al*. (2001) employed in vitro metabolic parameters for several pathways to construct a PBTK model that simulated most tissue dosimetry data sets for benzene-exposed mice quite well. Recently, Yokley *et al*. (2006) described a PBTK model that simulated tissue doses of benzene, benzene oxide, phenol, and hydroquinone in humans exposed orally and by inhalation. A Markov Chain Monte Carlo statistical technique was used to assess dissimilarities in population distributions of key model parameters. Variability in metabolic parameters and certain physiological parameters (e.g., organ weight) had to be inputed to accurately predict the range of human values.

Toluene

Toluene is present in paints, lacquers, thinners, cleaning agents, glues, and many other products. Toluene is also used in the production of other chemicals. Gasoline, which contains 5–7% toluene by weight, is the largest source of atmospheric emissions and exposure of the general populace (ATSDR, 2000). Inhalation is the primary route of exposure, though skin contact occurs frequently. Toluene is a favorite of solvent abusers, who intentionally inhale high concentrations to achieve a euphoric effect (Filley *et al*., 2004). Large amounts of toluene enter the environment each year by volatilization. Relatively small amounts are released in industrial wastewater. Toluene is frequently found in water, soil, and air at hazardous waste sites (Fay and Mumtaz, 1996).

Toluene TK has been thoroughly characterized in humans and laboratory animals. Toluene is well absorbed from the lungs and GI tract. It rapidly accumulates in and affects the brain, due to that organ's high rate of blood perfusion and relatively high lipid content. Toluene subsequently is deposited in other tissues according to their lipid content, with adipose tissue attaining the highest levels.

Toluene is well metabolized, but a portion is exhaled unchanged. Hepatic P450s catalyze metabolism of toluene primarily to benzyl alcohol and lesser amounts of cresols. Benzyl alcohol is converted by ADH and aldehyde dehydrogenase (ALDH) to benzoic acid, which is primarily conjugated with glycine and eliminated in the urine as hippuric acid. Nakajima *et al*. (1992a) reported that CYP2E1 and CYP2C11 are primarily responsible for catalyzing the initial hydroxylation step in rat liver at low and high toluene levels, respectively. CYP2E1 is most active at low doses in humans (Nakajima *et al*., 1997). Benignus *et al*. (1998) attempted to use a PBTK model to relate toluene blood levels to behavioral effects in rats and humans. It appeared that humans were more sensitive to increases in blood levels, but more rat data and much more human data are needed for model validation.

The CNS is the primary target organ of toluene and other alkylbenzenes. Manifestations of acute exposure range from slight dizziness and headache to unconsciousness, respiratory depression, and death. Occupational inhalation exposure guidelines are established to prevent significant decrements in psychomotor functions. Acute encephalopathic effects are rapidly reversible upon cessation of exposure (Fig. 24-3), and are not associated with neuroimaging changes (Filley *et al*., 2004). Subtle neurologic effects have been described in some groups of occupationally exposed individuals. Exposure to ~100-ppm toluene for years may result in subclinical effects, as evidenced by altered brainstem auditory-evoked potentials (Abbate *et al*., 1993) and changes in visual-evoked potentials (Vrca *et al*., 1995). Foo *et al*. (1990) reported good correlation between toluene exposure and poor scores on neurobehavioral tests of 30 female rotogravure workers. Severe neurotoxicity is often diagnosed in persons who have abused toluene for a prolonged period. A relatively specific neurobehavioral profile is manifest including inattention, apathy, memory dysfunction, diminished visuospatial skills, frontal lobe dysfunction, and psychiatric status (Ron, 1986; Filley *et al*., 2004). Magnetic resonance imaging reveals ventricular enlargement, cerebral atrophy and white matter hyperintensity, a characteristic profile termed toluene leukoencephalopathy. Such changes represent severe, chronic myelintoxicity. More advanced neuroimaging techniques may be able to reveal mild, subtle changes associated with early alterations in myelin of workers as well as toluene abusers (Caldemeyer *et al*., 1996; Filley *et al*., 2004). Rat pups subjected to high doses of toluene on days 6–19 of gestation exhibited a significant reduction in myelination per forebrain cell when they were 21 days old (Gospe and Zhou, 1998).

There is limited information on mechanisms by which toluene and similar solvents produced acute or residual CNS effects (Balster, 1998). The Meyer–Overton theory of partitioning of the lipophilic parent compounds into membrane lipids has been widely accepted for a century. It has been proposed that the presence of solvent molecules in cholesterol-filled interstices between phospholipids and sphingolipids changes membrane fluidity, thereby altering intercellular communication and normal ion movements (Engelke *et al*., 1996). Such a process is reversible. An alternate hypothesis is that toluene partitions into hydrophobic regions of proteins and interacts with them, thereby altering membrane-bound enzyme activity and/or receptor specificity in a reversible manner (Balster, 1998). Other evidence suggests that toluene and other VOCs may act acutely by enhancing GABA$_A$ receptor function (Mihic *et al*., 1994), attenuating NMDA receptor-stimulated calcium flux (Cruz *et al*., 1998), and/or activating dopamingeric systems (von Euler, 1994). The mechanism of chronic toluene neurotoxicity is unknown. Toluene is known to be deposited in brain areas with the highest

myelin content. Astrocytosis frequently accompanies myelin disruption (Gotohda *et al.*, 2000; Filley *et al.*, 2004).

As toluene is metabolized by CYPs, ADH, and ALDH, the chemical can interact with other xenobiotics metabolized by these enzymes. Concurrent exposure to solvents metabolized by the same CYP isoforms can result in competitive metabolic inhibition. Inoue *et al.* (1988) observed that benzene and toluene suppressed one another's metabolism in humans. Thus, the risk of leukopenia in workers exposed to benzene and toluene should be less than that in workers exposed to benzene alone. Pryor and Rebert (1992) found that toluene greatly reduced manifestations of peripheral neuropathy caused by *n*-hexane in rats. Although no interaction between toluene and xylenes was seen in humans inhaling low levels of each, simultaneous exposure to higher levels results in mutual metabolic suppression (Tardif *et al.*, 1991). Prior exposure to P450 inducers can result in increased rates of toluene metabolism/elimination and more rapid recovery from toluene-induced CNS depression. Nakajima and Wang (1994) observed that high concentrations of inhaled toluene moderately induced four of the six P450 isoforms that metabolize it, but inhibited the other two in rat liver.

High-level prenatal toluene exposures have produced growth and skeletal retardations in offspring of rodents and humans. The term "fetal solvent syndrome" was used to describe toluene-abusing women's children who exhibit microcephaly and cranial facial features similar to those with fetal alcohol syndrome (FAS) (Wilkins-Haug, 1997). The reproductive and developmental toxic potential of toluene was evaluated in a two-generation study of Sprague–Dawley rats (Roberts *et al.*, 2003). Both sexes of each generation were essentially exposed to 0, 100, 500, or 2,000 ppm toluene vapor 6 h/d, 7 d/week for 80 days premating and for 15 days of mating. Pregnant animals were also exposed from gestation days 1–20 and lactation days 5–21. No adverse effects were seen at any dose on fertility, reproductive performance, or maternal or pup behavior. Reduced fetal body weight and skeletal anomalies associated with growth retardation were manifest in the offspring of both generations subjected to 2000 ppm, but not to lower vapor levels (Roberts *et al.*, 2003).

Xylenes and Ethylbenzene

Large numbers of people are exposed to xylenes and ethylbenzene occupationally and environmentally (Wallace *et al.*, 1987). Xylenes (ATSDR, 2006d) and ethylbenzene (ATSDR, 1999), like benzene and toluene, are major components of gasoline and fuel oil. The primary uses of xylenes industrially are as solvents and synthetic intermediates. Most of these aromatics that are released into the environment evaporate into the atmosphere. They may also enter groundwater from oil and gasoline spills, leakage of storage tanks, and migration from waste sites.

The TK and acute toxicity of toluene, xylenes, and other aromatic solvents are quite similar. Xylenes and the others are well absorbed from the lungs and GI tract, distributed to tissues according to tissue blood flow and lipid content, exhaled unchanged to some extent, well metabolized by hepatic P450s, and largely excreted as urinary metabolites (Lof and Johanson, 1998). Nielsen and Alarie (1982) state that the potency of benzene and a series of alkylbenzenes, as sensory irritants of the upper respiratory tract of mice, increases with increasing lipophilicity. Acute lethality of hydrocarbons (i.e., CNS-depressant potency) also varies directly with lipophilicity (Swann *et al.*, 1974). There is limited evidence that chronic occupational exposure to xylenes is associated with residual neurologic effects (ATSDR, 2006c). Exposure con-

ditions, including the presence of other solvents, have usually not been characterized in such reports. Uchida *et al.* (1993), for example, reported increased subjective CNS symptoms in workers exposed for ~7 years to a mean of 21 ppm xylenes. The prevalence of symptoms was not dose dependent, nor were other solvent exposures characterized. This vapor concentration is significantly lower than current occupational exposure standards in the United States, which are established on the basis of acute irritancy or CNS effects. Savolainen *et al.* (1981) observed improved performance on a series of psychophysiological tests by humans inhaling 200 ppm *m*-xylene for 4 hours. An excitatory stage is often initially manifest in subjects, followed by functional inhibition with higher vapor concentrations and/or longer exposure periods. The current permissible exposure limit in the United States is 100 ppm.

Xylenes and ethylbenzene appear to have very limited capacity to adversely affect organs other than the CNS. Mild, transient liver and/or kidney toxicity have/has occasionally been reported in humans exposed to high vapor concentrations of xylenes. Little evidence of hepatorenal injury is typically manifest in laboratory animals (ATSDR, 2006c). Generally, hepatic P450s are moderately induced by alkylbenzenes (Gut *et al.*, 1993). Many investigators have reported xylenes to increase liver weight and to induce liver P450s in rats and other rodents. The *o*, *p*, and *m* isomers of xylene vary somewhat in their capacity to induce different P450 isoforms in different organs of rats (Backes *et al.*, 1993). Concurrent exposure to an alkylbenzene and another compound metabolized by P450s generally results in their competitive metabolic inhibition. Preexposure to an alkylbenzene, conversely, can result in increased metabolism of the other chemical.

The majority of alkylbenzenes do not appear to be genotoxic or carcinogenic. Ethylbenzene and styrene are two exceptions. Kidney injury and an increased incidence of renal adenoma and carcinoma (combined) were found in male F-344 rats exposed to 750 ppm ethylbenzene for up to 2 years (NTP, 1997b). Styrene's carcinogenic potential is discussed below.

Styrene

Styrene is primarily used in the manufacture of polystyrene items and in copolymers with acrylonitrile or 1,3-butadiene to produce synthetic rubber, latex, and reinforced plastics (Gibbs and Mulligan, 1997). Worker exposures in the rubber industry are of greatest concern toxicologically. Styrene is also often detected in the blood of nonoccupationally exposed populations (Churchill *et al.*, 2001; Blount *et al.*, 2006). Sources include tobacco smoke, auto exhaust, and emissions from building materials. Discharges from industry are the major source of environmental pollution (ATSDR, 1992).

There is considerable debate as to whether styrene is a human carcinogen. Styrene is toxic to the nasal epithelium of rats and mice, and hepatotoxic and pneumotoxic in mice. Workers exposed to ~25 ppm exhibit signs of mild hepatic injury and cholestasis (Brodkin *et al.*, 2001). Styrene is metabolized principally by CYP2E1- and CYP2F2-catalyzed side-chain oxidation to styrene-7,8-oxide (SO) in mouse lung and liver (Linhart *et al.*, 2000; Carlson, 2003). This epoxide is detoxified by the actions of epoxide hydrolase and GST. SO is detoxified much more efficiently by epoxide hydrolase in humans than in mice. SO can bind covalently to proteins and nucleic acids. It is carcinogenic to the forestomach of orally dosed mice and rats (Roe, 1994). Results of in vitro and in vivo mutagenicity and genotoxicity studies of styrene have been mixed

(ATSDR, 1992). Chromosomal aberrations, micronuclei, and/or sister chromatid exchange have been reported in employees in some high-exposure occupational settings, but not in others. Increased rates of different cancers have been reported in workers exposed to 1,3-butadiene and styrene in the synthetic rubber industry. The excesses of cancers have largely been attributed to 1,3-butadiene, though styrene may modify the actions of 1,3-butadiene and/or be implicated itself (Matonoski *et al*., 1997). Occasional findings of small increases in incidences of lymphatic and hematopoietic neoplasms in workers exposed primarily to styrene are not very robust (IARC, 2002). An inhalation cancer bioassay revealed increases in pulmonary adenomas and/or carcinomas in male and female mice, but four gavage studies were negative. (No reliable evidence of increased cancer incidence was seen in the four gavage, two other inhalation or one drinking water bioassay in rats (IARC, 2002).)

Workers in the reinforced plastics industry are exposed to styrene and SO. Tornero-Velez and Rappaport (2001) used a modified PBTK model to predict the relative contributions of inhaled styrene and SO to systemic levels of SO in humans. SO was forecast to present the greater cytogenetic hazard. Sarangapani *et al*. (2002) created a PBTK model with a multicompartment representation of the respiratory tract that included species-specific quantitative information on physiology, cellular composition, and metabolic capacity. The model-based analysis indicated that humans would be 100-fold less susceptible than mice to pulmonary tumors, based on predictions of SO concentrations in terminal bronchioles. Wenker *et al*. (2002) attempted to correlate key P450 metabolic capacities of 20 male volunteers with styrene clearance. The lack of correlation was attributed to the low inhaled vapor concentrations and styrene's blood flow-limited metabolism.

ALCOHOLS

Ethanol

Many humans experience greater exposure to ethanol (ethyl alcohol and alcohol) than to any other solvent. Not only is ethyl alcohol used as an additive in gasoline, as a solvent in industry, in many household products, and in pharmaceuticals, but it is also heavily consumed in intoxicating beverages. Frank toxic effects are less important occupationally than injuries resulting from psychomotor impairment. Driving under the influence of alcohol is, of course, the major cause of fatal auto accidents. In many states in the United States, a blood alcohol level of 80 mg/100 mL blood (80 mg%) is prima facie evidence of "driving while intoxicated." One's blood alcohol level and the time necessary to achieve it are controlled largely by the rapidity and extent of consumption of the chemical. Ethanol is distributed in body water and to some degree in adipose tissue. Alcohol is eliminated by urinary excretion, exhalation, and metabolism. The blood level in an average adult decreases by $\approx$16 mg% per hour. Thus, a person with a blood alcohol level of 120 mg% would require $\approx$8 hours to reach negligible levels.

Ethanol is metabolized to acetaldehyde by three enzymes: (1) The major pathway involves ADH-catalyzed oxidation to acetaldehyde. ADHs are present in various tissues including stomach, lung, eye, and liver, but the highest concentrations are found in the cytoplasm of hepatocytes (Yin *et al*., 1999). While hepatic ADH largely contributes to ethanol oxidation in humans (Lee *et al*., 2006), a PBTK model indicates both hepatic and gastric ADH contribute to first-pass metabolism of ethanol in rats, with gastric ADH playing a greater role at lower ethanol doses (Pastino and Conolly, 2000).

The oxidation they catalyze is reversible, but the acetaldehyde that is formed is rapidly oxidized by acetaldehyde dehydrogenase (ALDH) to acetate. Liver mitochondrial ALDH is the major enzyme responsible for acetaldehyde clearance. However, a recent PBTK model predicted the reversible conversion of acetaldehyde to alcohol by ADH to be an essential step in the systemic clearance of acetaldehyde (Umulis *et al*., 2005). (2) A second enzyme, catalase, utilizes H_2O_2 supplied by the actions of NADPH oxidase and xanthine oxidase. There is usually little H_2O_2 available in hepatocytes to support the reaction, so it is unlikely that catalase will normally account for more than 10% of ethyl alcohol metabolism. (3) The third enzyme, CYP2E1, is the principal isoform of the hepatic microsomal ethanol-oxidizing system.

Ethanol interacts with other solvents that are also metabolized by ADH and CYP2E1. Ethanol can be an effective antidote for poisoning by methanol, ethylene glycol, and diethylene glycol. As ethyl alcohol has a relatively high affinity for ADH, it competitively inhibits the metabolic activation of other alcohols and glycols. Pre-exposure to a single high dose or multiple doses of ethanol can induce CYP2E1, thereby enhancing the metabolic activation and potentiating the toxicity of a considerable number of other solvents and drugs such as acetaminophen (Lieber, 1997; Klotz and Ammon, 1998). Manno *et al*. (1996), for example, describe heavy drinkers who developed severe hepatorenal toxicity from CCl$_4$ exposures, which caused no ill effects in nondrinkers. Other alcohols, such as 2-butanol (Fig. 24-4), can have analogous effects (Traiger and Bruckner, 1976). Chronic heavy drinkers may develop more severe hepatotoxicity associated with acetaminophen overdosing than nonalcoholics, due to increased formation and reduced detoxification of toxic metabolites (Riordan and Williams, 2002; Rumack, 2004). Such interactions are also described under the Metabolism and Exogenous Factors subsections in this chapter.

A variety of factors that modulate ADH, CYP2E1, and ALDH can influence adverse effects experienced by drinkers. Relatively low ADH and CYP2E1 activities increase systemic alcohol levels and prolong its effects, while low ALDH results in elevated acetaldehyde levels. Long-term ingestion of high alcohol doses can lead to alcohol dependency and cirrhosis, whereas high acetaldehyde levels may result in acute toxicity due to covalent binding to proteins and other macromolecules (Niemela, 1999). Ethanol-metabolizing enzymes exist in multiple molecular forms that are genetically controlled. Genetic polymorphisms of these enzymes contribute to different disease outcomes in different ethnic and racial populations (Crabb *et al*., 2004; Russo *et al*., 2004). Asians have higher frequencies of an ADH1*2 variant, which encodes for a rapidly metabolizing form of ADH, preventing alcoholism. White and black populations in the United States predominantly have an ADH1*1 allele (Russo *et al*., 2004), which encodes for a relatively inactive ADH (Lee *et al*., 2006), leading to increased risk of alcohol dependency. As for ALDH, some 50% of Asians have high levels of the inactive allele, ALDH2*2. Hence, this population experiences acetaldehyde-induced flushing, tachycardia, nausea, vomiting, and hyperventilation upon alcohol consumption. Whereas this syndrome offers protection against developing alcoholism, it increases the risk of acetaldehyde-related cancers, including esophageal, stomach, colon, lung, head, and neck tumors (Vasiliou *et al*., 2004). Hispanics, on the other hand, have very low levels of ADH1*2 and ALDH2*2, predisposing them to alcoholism and their offspring to fetal alcohol syndrome (FAS). Disulfiram, an ALDH inhibitor, is used to treat alcoholism, by enhancing acetaldehyde levels when alcohol is consumed. Whereas CYP2E1 polymorphism is reported

in humans (Zintzaras *et al.*, 2006), its role in the pathogenicity of alcoholism is still unclear.

Gender differences in responses to ethanol are well recognized. Women are more sensitive to alcohol, and exhibit higher mortality at lower levels of consumption than men (Sato *et al.*, 2001; Brienza and Stein, 2002). Women exhibit somewhat higher blood levels than men following ingestion of equivalent doses of ethanol (Pikaar *et al.*, 1988). This phenomenon appears to be due in part to more extensive ADH-catalyzed metabolism of ethanol by the male gastric mucosa (Frezza *et al.*, 1990; Seitz *et al.*, 1993). Kinetic data indicate that hepatic ADH does not play a role in the sex difference in first-pass elimination of ethanol, though Chrostek *et al.* (2003) did report higher activities of ADH isoforms that efficiently oxidize ethanol in the liver of male subjects. Sex differences in ethanol metabolism in the remainder of the body appear to be small or nonexistent. A second factor contributing to the higher blood ethanol levels and greater CNS effects in women is their smaller volume of distribution for relatively polar solvents such as alcohols. It is well known that women are more susceptible to alcohol-induced hepatitis and cirrhosis (Thurman, 2000). A postulated mechanism for this sex difference is described below.

FAS is the most common, preventable cause of mental retardation. Diagnostic criteria for FAS include: (1) heavy maternal alcohol consumption during gestation; (2) pre- and postnatal growth retardation; (3) craniofacial malformations including microcephaly; and (4) mental retardation. Less complete manifestations of gestational ethanol exposure also occur and are referred to as fetal alcohol effects or alcohol-related neurodevelopmental disorder. The prevalence of FAS in the United States ranges from 0.5–2 cases per 1000 live births (May and Gossage, 2001; CDC, 2002). Although the total amount of alcohol consumed and the pattern of drinking are both important factors, peak maternal blood alcohol level is apparently the most important determinant of the likelihood of FAS and the severity of its effects. Overconsumption during all three trimesters of pregnancy can result in certain manifestations, dependent on the period of gestation during which ingestion occurs.

Despite an intensive research effort for three decades, the mechanisms underlying FAS remain unclear. Exposure of embryonic tissue to ethanol adversely affects many cellular functions critical to development, including protein and DNA synthesis, uptake of critical nutrients such as glucose and amino acids, and changes in several kinase-mediated signal transduction pathways (Shibley and Pennington, 1997). Alcohol may also harm the fetus indirectly as a result of the mother's malnutrition. Numerous mechanisms have been suggested as contributing to alcohol-induced fetal damage, although none has been established with certainty (Goodlett and Horn, 2001). Some studies have suggested that oxidative stress on fetal tissues is responsible (Henderson *et al.*, 1999), while others have implicated ethanol's effects on neurotransmitter-gated ion channels, particularly the NMDA receptor (Costa *et al.*, 2000), and its ability to trigger cell death via necrosis and apoptosis (Ikonomidou *et al.*, 2000; Goodlett and Horn, 2001). Others have reported that ethanol produces a long-lasting reduction in synaptic efficacy (Bellinger *et al.*, 1999) and alters the fetal expression of developmentally important genes such as msx2 and insulin-like growth factors (Singh *et al.*, 1996; Rifas *et al.*, 1997). Recent studies suggest that NMDA and GABA receptor-mediated apoptosis play critical roles in learning impairment (Ikonomidou *et al.*, 2000; Olney *et al.*, 2002; Toso *et al.*, 2006). Acetaldehyde may also contribute to the development of FAS, as it is shown to accumulate in the fetal brain after prenatal alcohol exposure (Hamby-Mason *et al.*, 1997)

and to be cytotoxic to cultured embryonic brain cells (Lee *et al.*, 2005).

A role for CYP2E1 in the induction of FAS has been hypothesized, given its expression in human cephalic tissues during embryogenesis (Boutelet-Bochan *et al.*, 1997). Results of in vitro experiments indicate that human CYP2E1 is effective in production of reactive oxygen intermediates (e.g., hydroxy radicals, superoxide anion, and H_2O_2) and in causation of lipid peroxidation (Dai *et al.*, 1993). Membrane lipids and a variety of enzymes are targets for free radical attack. Albano *et al.* (1999) have demonstrated a marked increase in covalent binding of hydroxyethyl radicals to hepatic microsomal proteins from rats following chronic ethanol administration. There is not yet direct evidence that hydroxyethyl radicals contribute to lipid peroxidation, but they do readily react with α-tocopherol, GSH, and ascorbic acid, thereby potentially lowering liver antioxidant levels in vivo. Albano *et al.* (1999) also describe evidence that hydroxyethyl radical-protein adducts in hepatocytes induce immune responses, which may contribute to chronic ethanol hepatotoxicity.

Alcohol-induced hepatotoxicity is postulated to be caused by elevation of endotoxin in the bloodstream. Endotoxin, released by the action of ethanol on gram-negative bacteria in the gut, is believed to be taken up by Kupffer cells, causing the release of inflammatory mediators that are cytotoxic to hepatocytes and chemoattractants for neutrophils (Bautista, 2000; Diehl, 2000). These mediators include interleukins, prostaglandins, free radicals, and TNF-α. Proinflammatory cytokines and oxidative stress stimulate collagen synthesis by hepatic stellate cells, leading to alcoholic fibrosis (Lieber, 2004). Acetaldehyde is also capable of upregulating collagen synthesis either directly or indirectly by inducing TGF-β1. Hence, polymorphisms of ALDH can increase the risk of fibrosis (Purohit and Brenner, 2006). Kupffer cells of female rats are more sensitive to endotoxin than those of males. Estrogen increases the sensitivity of Kupffer cells of rats to endotoxin, leading to increased production of TNF-α and death of hepatocytes (Thurman, 2000; Yin *et al.*, 2000; Colantoni *et al.*, 2003). This phenomenon is believed to account in part for the more severe hepatitis and cirrhosis commonly seen in female alcoholics (Thurman, 2000).

Alcohol-induced damage of the liver and other tissues is believed to result in part from nutritional disturbances, as well as toxic effects (Lieber, 2004; DiCecco and Francisco-Ziller, 2006). Lack of money, poor judgment, prolonged inebriation, and appetite loss contribute to poor nutrition and weight loss in alcoholics. A high percentage of calories in the alcoholic's diet is furnished by alcohol. Malabsorption of thiamine, diminished enterohepatic circulation of folate, degradation of pyridoxal phosphate, and disturbances in the metabolism of vitamins A and D can occur (Mezey, 1985). Prostaglandins released from endotoxin-activated Kupffer cells may be responsible for a hypermetabolic state in the liver. With the increase in oxygen demand, the viability of centrilobular hepatocytes would be most compromised, due to their relatively poor oxygen supply (Thurman, 1998). Metabolism of ethanol via ADH and ALDH results in a shift in the redox state of the cell. The metabolites and the more reduced state can result in hyperlactacidemia, hyperlipidemia, hyperuricemia, and hyperglycemia, leading to increased steatosis and collagen synthesis (Lieber, 2004).

Alcoholism can result in damage of extrahepatic tissues. Alcoholic myopathy is one of the more common consequences, occurring in 50% of alcohol abusers. The condition is characterized by reductions in skeletal muscle mass and strength (Adachi *et al.*, 2003; Preedy *et al.*, 2003). Alcoholic cardiomyopathy is a complex process

that occurs in 20–25% of alcoholics. It results from decreased synthesis of cardiac contractile proteins, attack of oxygen radicals, increases in endoplasmic reticulum Ca^{2+}-ATPase and an antibody response to acetaldehyde–protein adducts (Richardson *et al.*, 1998; Preedy *et al.*, 2003). Interestingly, light-to-moderate drinking is reported to protect against atherosclerosis in the carotid artery, a major cause of ischemic stroke (Hillbom, 1999). Alcohol increases high-density lipoprotein (HDL) cholesterol by inducing the constituents, apo I and II, by increasing catabolism of very low-density lipoproteins and chylomicrons, and by delaying HDL catabolism (Kolovou *et al.*, 2006). It is also hypothesized that ethanol metabolism in the vascular wall may inhibit oxidation of low-density lipoproteins (LDL), a requisite for atherogenesis. Phenolic antioxidants in wines may also inhibit LDL oxidation as well as reduce platelet aggregation. Conversely, heavy drinking appears to deplete antioxidants and have the opposite effects (Hillbom, 1999; Kolovou *et al.*, 2006). Recent heavy drinking increases the risk of both hemorrhagic and ischemic strokes. Other organ systems can be adversely affected in alcoholics including the brain and GI tract (Kril *et al.*, 1997; Rajendram and Preedy, 2005).

There is concern about the role of ethyl alcohol in carcinogenesis, due to the frequent consumption of alcoholic beverages by millions of people. IARC (1988) concluded that there was "sufficient evidence" for causation of tumors of the oral cavity, pharynx and larynx, esophagus, and liver of humans. Use of alcohol is also linked to a moderate increase in risk of lobular and hormone receptor-positive breast cancer in women (Li *et al.*, 2003). Genotoxic effects by acetaldehyde and elevated estrogen levels are likely mechanisms (Boffetta and Hashibe, 2006). The original associations between alcohol and cancers came primarily from epidemiological case–control and cohort studies. One such cohort study of 276,000 American men showed increase in total cancer risk with increasing ethanol consumption (Boffeta and Garfinkel, 1990). In support of epidemiological studies, a rat study showed that ethanol induces tumors in various organs including oral cavity, tongue, and lips (Soffritti *et al.*, 2002). Evidence suggests that the risk of alcohol-induced cancer in humans is modulated by genetic polymorphisms in enzymes responsible for alcohol metabolism, folate metabolism, and DNA repair (Boffetta and Hashibe, 2006). Ethanol and smoking act synergistically to cause oral, pharyngeal, and laryngeal cancers. It is generally believed that alcohol induces liver cancer by causing cirrhosis or other chronic liver damage and/or by enhancing the bioactivation of other carcinogens (Table 24-3).

Table 24-3
Possible Mechanisms of Ethanol Carcinogenicity

Congeners: additives and contaminants in alcoholic beverages influence carcinogenicity.
CYP2E1 induction by ethanol increases metabolic activation of procarcinogens.
Ethanol acts as a solvent for carcinogens, enhancing their absorption into tissues of the upper Gl tract.
Ethanol affects the actions of certain hormones on hormone-sensitive tissues.
Immune function is suppressed by alcohol.
Absorption and bioavailability of nutrients are reduced by alcohol.

SOURCE: Adapted with permission of Ahmed (1995).

An international symposium (Purohit *et al.*, 2005), sponsored by the National Institute on Alcohol Abuse and Alcoholism in 2004, concluded that chronic ethanol consumption may promote carcinogenesis by: (1) production of acetaldehyde, a weak mutagen and carcinogen; (2) induction of CYP2E1 and its associated oxidative stressors and conversion of procarcinogens to carcinogens; (3) depletion of SAM and, consequently, induction of global DNA hypomethylation; (4) increased production of inhibitory guanine nucleotide regulatory proteins and components of extracellular signal-regulated kinase-mitogen-activated protein kinase signaling; (5) accumulation of iron and associated oxidative stress; (6) inactivation of the tumor suppressor gene *BRCA1* and increased estrogen responsiveness (primarily in the breast); and (7) impairment of retinoic acid metabolism.

Methanol

Methanol (methyl alcohol, wood alcohol, and CH_3OH) is primarily used as a starting material for the synthesis of chemicals such as formaldehyde, acetic acid, methacrylates, ethylene glycol, and methyl tertiary-butyl ether (MTBE). CH_3OH is found in windshield washer fluid, carburetor cleaners, antifreeze, and copy machine toner, and serves as fuel for Sterno™ heaters, model airplanes, and Indianapolis 500 racecars. It also functions as a denaturant for some ethyl and isopropyl alcohols, rendering them unfit for consumption. It is used to a limited extent as an alternative fuel for fleet vehicles (usually in a mixture of 85% CH_3OH and 15% gasoline) and is being explored as a gasoline additive and hydrogen source for fuel cell vehicles. Exposure of the general population also occurs via the consumption of fruits, fruit juices, vegetables, and alcoholic beverages that contain free CH_3OH or CH_3OH precursors. Indirect exposure occurs via the hydrolysis of the artificial sweetener, aspartame, and subsequent CH_3OH absorption from the gut. Very low-level exposures may occur via ambient air and drinking water. Of all chemicals reported, CH_3OH was ranked No. 1 for fugitive air emissions, No. 3 for point source air emissions, and No. 2 for surface water discharges according to the 2004 Toxic Release Inventory (EPA, 2006b). Persistence and bioaccumulation in the environment are not expected. The consumption of adulterated "bootleg" whiskey is a major cause of CH_3OH poisoning. Serious CH_3OH toxicity is most commonly associated with ingestion. Left untreated, acute CH_3OH poisoning in humans is characterized by an asymptomatic latent period of 12–24 hours followed by formic acidemia, ocular toxicity, coma, and in extreme cases death (Lanigan, 2001). Visual disturbances generally develop between 18 and 48 hours after ingestion and range from mild photophobia and misty or blurred vision to markedly reduced visual acuity and complete blindness (Eells *et al.*, 1996). Although there is considerable variability among individuals in susceptibility to CH_3OH, a frequently cited lethal oral dosage is 1 mL/kg. Blindness and death have been reported with dosages as low as 0.1 mL/kg (ATSDR, 1993). CH_3OH's target within the eye is the retina, specifically the optic disk and optic nerve. Optic disk edema and hyperemia are seen, along with morphological alterations in the optic nerve head and the intraorbital portion of the optic nerve. Both axons and glial cells exhibit altered morphologies (Kavet and Nauss, 1990). Rods and cones, the photoreceptors of the retina, are also altered functionally and structurally (Seme *et al.*, 1999). Evidence is accumulating that Müller cells, neuroglia that function in the maintenance of retinal structure and in intra- and intercellular transport, are early targets of CH_3OH (Garner *et al.*, 1995a). There are indications of mitochondrial disruption in Müller

and photoreceptor cells, which is consistent with the long-held view that formate inhibits the energy-generating mitochondrial enzyme, cytochrome c oxidase, which is critical for the proper functioning of highly oxidative organs like the retina. This mechanism might explain, at least in part, CH_3OH's selective toxicity to photoreceptors and other highly metabolically active cells (Eells *et al.*, 1996). Interestingly, exposure of rats to monochromatic red radiation from light-emitting diode arrays can aid in the recovery of rod and cone function in CH_3OH-treated rats and protect the retina from histopathological changes characteristic of formate toxicity (Eells *et al.*, 2003). This "photobiomodulation" is thought to be mediated by the ability of monochromatic red to near-IR light to improve mitochondrial respiratory chain function (i.e., increase cytochrome c oxidase activity), thereby initiating a signaling cascade that promotes cellular proliferation and cytoprotection.

As with CH_3OH's chronic toxicity, elucidation of the mechanism of CH_3OH's acute toxicity was hampered for years by species differences in susceptibility and the lack of appropriate animal models. Largely based on the work of Gilger and Potts (1955), it became apparent that only non-human primates respond to CH_3OH similarly to humans. The severe metabolic acidosis frequently seen in humans does not occur in rodents. In all mammalian species studied, CH_3OH is metabolized in the liver by ADH to formaldehyde (HCOH), which in turn is very rapidly converted via ALDH to formate. The conversion of formate to CO_2 then occurs via a two-step, tetrahydrofolate (THF)-dependent pathway. First, formate is converted to 10-formyl-THF by formyl-THF synthetase, after which 10-formyl-THF is oxidized to CO_2 by formyl-THF dehydrogenase (F-THF-DH). The species differences in susceptibility to CH_3OH are thought to result primarily from differences in the rate of THF-dependent oxidation of formate to CO_2. Because rodents have much higher hepatic THF levels than primates, formate does not accumulate as it does in humans and monkeys (Medinsky and Dorman, 1995; Martinasevic *et al.*, 1996). Another possible explanation is the lower F-THF-DH activity in primate liver (Johlin *et al.*, 1989). It is further speculated that primates are more susceptible to CH_3OH and formate toxicity due to their relative inability to excrete excess formate via the kidneys (Smith and Taylor, 1982). Regardless, susceptibility to CH_3OH-induced ocular toxicity is dependent on the relative rate of formate clearance. Dietary and chemical depletion of endogenous folate cofactors in rats have been shown to increase formate accumulation following CH_3OH, resulting in the development of metabolic acidosis and ocular toxicity similar to that observed in humans (Eells *et al.*, 1996, 2000). A simplified scheme of CH_3OH metabolism is presented in Fig. 24-10.

For years there was considerable debate whether HCOH or formate was responsible for CH_3OH's ocular toxicity. The finding that HCOH does not accumulate following CH_3OH treatment, even in folate-deficient monkeys that are profoundly sensitive to CH_3OH, argues against a role for HCOH. Also, species of differing susceptibility exhibit comparable blood HCOH half-lives. In contrast, formate has been shown to accumulate in the human and monkey following CH_3OH treatment. CH_3OH-derived formate has also been quantified in the vitreous humor, retina, and to a lesser extent the optic nerve (Eells *et al.*, 1996). Moreover, CH_3OH-induced retinal dysfunction, as indicated by diminution of the amplitude of electroretinogram (ERG) *a* and *b* waves, is negatively correlated in a linear fashion with blood formate concentrations (Eells *et al.*, 1996). Others have reported similar relationships between blood formate and ERG responses indicative of photoreceptor dysfunction (Seme *et al.*, 1999). Formate has also been shown to induce ocular toxicity
Figure 24-10. Scheme for the metabolism of methanol.

Major enzymes are listed for primates (*left*) and rodents (*right*). Conversion of formate to CO_2 is rapid in rodents, but relatively slow in primates. [Used with permission of Dorman DC, Welsch F: *CIIT Activities* 16:1–7, 1996.]

in monkeys and formate oxidation-inhibited rats in the absence of metabolic acidosis or a reduction in blood pH (Martin-Amat *et al.*, 1978; Eells *et al.*, 1996). Direct incubation of formate with cultured ocular cells caused ATP depletion and cytotoxicity (Treichel *et al.*, 2003). Thus, formate appears to act as a direct ocular toxin and not indirectly through the induction of an acidotic state, though acidosis may potentiate formate toxicity (since the inhibition of cytochrome oxidase increases as pH decreases and acidosis allows for greater diffusion of formic acid into cells).

The question has been raised whether ocular toxicity is simply a function of circulating formate reaching the visual tract, or whether metabolism in retinal or optic nerve tissues generates toxic metabolites locally. This is a legitimate question considering that metabolism of CH_3OH to HCOH via peroxisomal enzymes (catalase) has been demonstrated in rat retina in vitro (Garner *et al.*, 1995a), and the presence of cytoplasmic ALDH activity has been demonstrated in several regions of the rat and mouse eye, including the retina (Messiha and Price, 1983; McCaffery *et al.*, 1991). By use of a folate-deficient rat model, Garner *et al.* (1995b) showed that a level of blood formate generated by i.v. infusion of pH-buffered formate did not diminish the ERG *b*-wave amplitude generated by Müller cells of the retina, as did a comparable blood level of formate derived from CH_3OH. This suggests that the intraretinal metabolism of CH_3OH is necessary for the initiation of retinal toxicity by formate. Not only are the enzymes necessary to produce formate present in the retina, but so too are folate and F-THF-DH. F-THF-DH was found to be localized in the mitochondria of Müller cells, prompting the suggestion that F-THF-DH may serve a dual role, one protective of the Müller cell and the other toxic. Protection would come in the form of formate oxidation; toxicity from the overconsumption or depletion of ATP required for formate metabolism via the folate pathway (Martinasevic *et al.*, 1996).

The aforementioned findings raise concerns about the safety of CH_3OH exposure. Chamber studies of human volunteers exposed to 200 ppm CH_3OH for 4 or 6 hours showed no blood formate accumulation above background (Lee *et al.*, 1992; d'Alessandro *et al.*, 1994). Whereas this might be considered evidence that exposure at the current ACGIH TLV and OSHA PEL of 200 ppm poses no risk of ocular toxicity, such an interpretation may not be valid given that ocular toxicity may be a function of intraretinal CH_3OH metabolism rather than circulating formate levels.

The effects of acute, high CH_3OH exposures are well characterized compared to those of chronic, low-level exposures. Few reproductive/developmental studies and even fewer cancer bioassays have been conducted, due to the fact that rodents are not an ideal animal model for CH_3OH. Nonetheless, Soffritti *et al.* (2002) conducted a bioassay in which Sprague–Dawley rats received CH_3OH in their drinking water (0, 500, 5000, or 20,000 ppm) ad libitum for 104 weeks. The investigators concluded that CH_3OH was a multipotent carcinogen. However, they did reference two Japanese bioassays that found no evidence of carcinogenicity in B6C3F1 mice or F-344 rats exposed 20 h/d to 10-, 100-, or 1000-ppm CH_3OH by inhalation for 18 and 24 months, respectively (NEDO, 1987; Katoh, 1989).

The NTP Center for the Evaluation of Risks to Human Reproduction released a monograph on CH_3OH's reproductive/developmental toxicity, largely based on an expert panel report (NTP, 2003, 2004b). Among the conclusions was that CH_3OH is a potential developmental toxicant in humans, provided a high enough blood concentration of the parent compound (assumed to be the proximate teratogen) is achieved. As this conclusion was largely based on data in rodents that metabolize CH_3OH much differently than humans, its validity has been called into question (Clary, 2003). As such, the few reproductive/developmental studies in non-human primates are particularly informative. These studies reported that maternal exposure of monkeys to inhaled CH_3OH (200, 600, or 1800 ppm, 2.5 h/d, 7 d/week prior to breeding and throughout pregnancy) was not associated with maternal toxicity, reproductive loss, or congenital malformations in offspring, but was associated with a 6–8-day reduction in the mean length of pregnancy (Burbacher *et al.*, 2004a,b). Studies in rodents and rodent whole embryo cultures have implicated dysregulated cell death in the pathogenesis of CH_3OH-induced malformations, examined GSH status in the developing conceptus as it relates to vulnerability, and explored the basis for the increased sensitivity of the mouse embryo compared to the rat (Harris *et al.*, 2003, 2004; Degitz *et al.*, 2004; Hansen *et al.*, 2005).

Whereas there is still much to be learned about the mechanisms of CH_3OH toxicity, what is known allows for effective therapies if they are applied in a timely manner. The American Academy of Clinical Toxicology has published practice guidelines for the treatment of CH_3OH poisoning (Barceloux *et al.*, 2002). In cases of severe CH_3OH poisoning, there is a direct correlation between the formic acid concentration and increased morbidity and mortality. Sodium bicarbonate is usually given i.v. to correct severe acidosis, and case reports suggest that it may enhance renal formate excretion. Metabolic blockade is usually achieved with ethanol or 4-methylpyrazole (fomepizole), both acting as effective competitive inhibitors of ADH. Folate or folinic acid (activated folate) therapy is also indicated to increase the efficiency of formate oxidation. Hemodialysis is generally indicated when acidemia, high CH_3OH concentrations, or visual symptoms are present, although there is conflicting data on whether it appreciably shortens the elimination half-life of formate (Kerns *et al.*, 2002; Hantson *et al.*, 2005). Lastly, the treatment threshold of 20 mg CH_3OH/dL in a nonacidotic patient arriving early for care has been questioned as being overly conservative. This stems from a comprehensive review of worldwide CH_3OH poisonings that identified 126 mg/dL as the lowest early blood CH_3OH level ever clearly associated with acidosis (Kostic and Dart, 2003). CH_3OH exemplifies the benefits of knowing a chemical's mode of action when treating the poisoned patient. This knowledge also aids in identifying potentially sensitive subpopulations, such as those suffering from dietary folate deficiency. Research suggests, however, that even in a state of folate deficiency, the body probably contains sufficient folate stores to effectively detoxify small doses of CH_3OH-derived formate from exogenous sources (Medinsky *et al.*, 1997).

GLYCOLS

Ethylene Glycol

Ethylene glycol (1,2-dihydroxyethane, EG) is a constituent of antifreeze, deicers, hydraulic fluids, drying agents, and inks, and is used to make plastics and polyester fibers. Workers may be exposed dermally or by inhalation when solutions containing EG are heated or sprayed. The most important exposure route is ingestion, as EG may be accidentally swallowed, taken deliberately in suicide attempts, or used as a cheap substitute for ethanol. "Antifreeze" poisoning occurs frequently in cats and dogs that find its taste appealing. In 2004, there were 5562 human cases of EG exposure reported by the American Association of Poison Control Centers (23 fatal), nearly 40% of which were treated in a health-care facility (Watson *et al.*, 2005). EG enters the environment as a result of disposal of industrial and consumer products containing the chemical. It partitions into surface water and groundwater, but does not persist in any environmental medium and is practically nontoxic to aquatic organisms (Staples *et al.*, 2001).

The TK profile of EG is well characterized. All laboratory mammals and humans metabolize EG similarly. A series of papers has been published describing the TK of EG in Sprague–Dawley rats and CD-1 mice after administration of a single dose by the i.v., oral, or percutaneous routes (Frantz *et al.*, 1996a–c). Absorption from the GI tract of rodents and humans is very rapid and virtually complete, with cutaneous and pulmonary absorption are relatively slow and less extensive. Once absorbed, EG is distributed throughout the total body water. As illustrated in Fig. 24-11, EG is metabolized by NAD^+-dependent ADH to glycolaldehyde and on to glycolic acid (GA). GA is oxidized to glyoxylic acid by GA oxidase and lactic dehydrogenase. Glyoxylic acid may be converted to formate and CO_2, or oxidized by glyoxylic acid oxidase to oxalic acid (OA) (Wiener and Richardson, 1988; Frantz *et al.*, 1996b). The rate-limiting step in the metabolism of EG is the conversion of GA to glyoxylic acid, which results in accumulation of GA in the blood. EG has a half-life in humans of 3–8.6 hours (Leth and Gregersen, 2005). Under conditions of repetitive, low-dose exposure, EG is not expected to bioaccumulate given its rapid metabolism and elimination. Pregnancy status has no bearing on the TK of EG, GA, or OA, as demonstrated by comparisons of pregnant and nonpregnant Sprague–Dawley rats (Pottenger *et al.*, 2001).

The minimum acute lethal dose of EG in humans is estimated at ~1.4 mL/kg, which equates to 100 mL for a 70-kg adult (LaKind *et al.*, 1999; Hess *et al.*, 2004). Acute poisoning entails three clinical stages after an asymptomatic period, during which EG is metabolized: (1) a period of inebriation, the duration and degree depending on dose; (2) the cardiopulmonary stage 12–24 hours after exposure, characterized by tachycardia and tachypnea, which may progress to cardiac failure and pulmonary edema; and (3) the renal toxicity stage 24–72 hours postexposure. Metabolic acidosis, due largely to GA accumulation, can develop and become progressively more severe during stages 2 and 3 (Jacobsen *et al.*, 1984; Moreau *et al.*, 1998; Egbert and Abraham, 1999). Hypocalcemia can result from Ca^{2+} chelation by OA to form Ca^{2+} oxalate monohydrate (COM) crystals. Deposition of these crystals in kidney tubules is associated with
Figure 24-11. Metabolic scheme for ethylene glycol in animals.

Key metabolites that have been observed in vivo are highlighted in boxes. Dashed lines are theoretical pathways that have not been verified in vivo or in vitro. [Used with permission of Corley *et al.* (2005a).]

organ damage and potentially acute renal failure. Nephrotoxicity appears to be an acute, high-dose phenomenon, as no demonstrable kidney damage has been reported in occupational studies of groups such as airport deicing workers or Finnish auto mechanics (Laitinen *et al.*, 1995; Gerin *et al.*, 1997). COM crystal deposition has been reported in the walls of CNS blood vessels, with associated inflammation, edema, and sometimes neuropathy (Froberg *et al.*, 2006).

Based on high-dose rodent studies, including two lifetime dietary studies, EG has very limited chronic toxicity potential, exhibits no evidence of carcinogenicity, and does not appear to be a reproductive toxicant (DePass *et al.*, 1986; NTP, 1993). However, it can cause adverse developmental effects such as skeletal and soft tissue malformations and delayed ossification when administered during gestation at high doses (≥500 mg/kg/d) (ATSDR, 1997c). GA appears to be the proximate developmental toxicant, with metabolic acidosis playing an exacerbating, but not obligatory role (Carney *et al.*, 1996, 1999). Pottenger *et al.* (2001) have demonstrated that at teratogenic doses of EG, blood levels of GA are disproportionately high relative to the EG dose, further supporting GA as the proximate teratogen and implying a role for metabolic saturation. Corley *et al.* (2005d) have detailed the key events in EG-induced developmental toxicity and suggest the disruption of *hox* gene expression, fluid imbalance, and dysregulation of cell death in the embryo as mechanistic possibilities. The mechanism of GA's teratogenic action remains largely unknown, however, as does the relevance of defects in rodents given the absence of reported developmental effects in humans. The NTP Center for the Evaluation of Risks to Human Reproduction has released a monograph on EG's reproductive/developmental toxicity largely based on an expert panel report (NTP, 2004d,f). The over-

all conclusion was that EG exposures below the level of metabolic saturation should not result in developmental toxicity in humans. Further, because environmental and occupational exposures to humans are 2 to 3 orders of magnitude lower than those expected to result in metabolic saturation, such exposures are of negligible concern. Corley *et al.* (2005a) have developed a PBTK model of EG and GA and compared internal dose surrogates in rats and humans. Based on the comparisons, they also concluded that occupationally- or environmentally-exposed humans are unlikely to achieve blood levels of GA that have been associated with developmental toxicity in rats.

The chief concern about EG is renal toxicity after high dose, acute exposure. Although EG must be metabolized to toxic intermediates to induce kidney damage, the specific metabolite(s) and underlying mechanism(s) responsible remain to be fully elucidated. There is agreement, however, that the process involves a toxicant-induced proximal tubular necrosis leading to loss of renal function. Poldelski *et al.* (2001) exposed isolated mouse proximal tubule segments and human proximal tubular epithelial cells (HK-2) to GA, glycoaldehyde, glyoxylate, or OA for 15–60 minutes, on which basis they concluded glycoaldehyde and glyoxylate are the principal metabolites responsible for EG nephrotoxicity. This is contrary to the prevailing opinion that renal toxicity is due to the terminal metabolite, OA, which precipitates in the kidney in the form of COM crystals (Guo and McMartin, 2005). Corley *et al.* (2005d) have listed the key mechanistic events in the renal toxicity of EG: (1) metabolism of EG to OA via GA; (2) concentration of OA in tubular urine → precipitation of OA with Ca^{2+} → buildup of COM crystals in renal tubular epithelium → adherence of COM crystals to the plasma membrane of proximal tubular cells → subsequent

intracellular uptake of COM crystals by endocytosis; and (3) physical trauma by COM crystals and/or production of free radicals and lipid peroxidation leading to cell necrosis, apoptosis and renal tubular degeneration. Clearly, the weight of evidence implicates OA is critical in the induction of renal damage, but a possible role for less frequently observed hippuric acid crystals and direct cytotoxicity by other metabolites cannot be ruled out. In vitro assays have indicated that both oxalate and COM crystals are injurious to renal epithelial cells (Thamilselvan and Khan, 1998). Also, renal damage has been observed occasionally following exposure to EG, without documentation of crystals in the kidney.

The intracellular target(s) of COM crystals is(are) not known with certainty, but it is well established that mitochondrial damage is a major mechanism for chemically mediated renal tubular necrosis. As such, COM crystals in the cytoplasm could directly affect mitochondria or be metabolized to release the oxalate ion that could do so. McMartin and Wallace (2005) hypothesized as much and demonstrated that COM produced a dose-dependent decrease in State 3 respiration in isolated rat kidney mitochondria, which they believe may be responsible for induction of a phenomenon known as mitochondrial permeability transition (MPT). MPT is characterized by an otherwise inpenetrant inner mitochondrial membrane undergoing transformation, whereby it becomes penetrable to solutes or large molecules. As a result of MPT induction, mitochondria undergo a rapid and progressive osmotic swelling, depolarization of mitochondrial membrane potential, and inhibition of oxidative phosphorylation/ATP synthesis, all of which can lead to either oncotic/ischemic cell death or apoptotic cell death. Additional insight into the pathogenesis of EG-induced renal damage has been provided by Chen et al. (2004), who provided male rats with 0.75% EG in their drinking water for 2, 4, and 8 weeks, after which the kidneys were processed for RNA isolation and microarray analysis using a rat-based chip. Changes in the expression of genes associated with tubular structure and function, oxidative damage, and inflammation were common. Increased expression of mitochondrial uncoupling protein was also observed, providing additional evidence of a mitochondrial target. EG has also been used as a model crystal-forming renal toxicant to determine the basis for COM crystal retention in the kidney. Studies with EG suggest that crystal retention in the kidney may depend on the expression of the proteins hyaluronan, osteopontin, and their mutual cell surface receptor CD44, all of which are upregulated in response to renal injury/inflammation, and under normal circumstances play a role in reestablishment of epithelial barrier integrity and restoration of renal function. However, their upregulation could turn a non-crystal-binding epithelium into a crystal-binding one, thereby setting the stage for crystal retention and renal injury (Asselman et al., 2003; Verhulst et al., 2003).

In cases of severe EG poisoning, early diagnosis and aggressive therapeutic intervention are essential for a favorable clinical outcome. A plasma EG level of 20 mg/dL is considered the threshold for kidney toxicity, if therapeutic strategy is based on EG concentration alone (Hess et al., 2004). However, no signs of renal injury have developed in patients at initial plasma GA concentrations of up to 10.1 mM or 76.7 mg/dL (Brent et al., 1999; Hess et al., 2004). In any case, treatment of EG poisoning involves three primary goals: (1) correction of the patient's metabolic acidosis; (2) inhibition of EG metabolism to its toxic metabolites; and (3) removal of EG and its toxic metabolites by hemodialysis, if necessary. As Guo and McMartin (2005) demonstrated that the renal cytotoxicity of COM crystals is potentiated by severe acidosis, its correction with bicarbonate should help ameliorate the development of renal toxicity. As with

CH_3OH, ethanol and 4-methylpyrazole (fomepizole) are frequently given as antidotes for EG poisoning and can prevent renal injury if given early in the course of intoxication. These ADH inhibitors block EG's metabolic bioactivation, thus minimizing the formation of toxic metabolites and allowing EG to be eliminated unchanged by the kidneys. There is increasing evidence that i.v. fomepizole may be more efficacious than ethanol as an antidote and obviate the need for hemodialysis in most EG-poisoned patients with normal renal function (Moreau et al., 1998; Brent et al., 1999; Sivilotti et al., 2000; Scalley et al., 2002). Watson (2000) has even stated that the results of fomepizole therapy support the recommendation that ethanol's use should be limited to settings where fomepizole is not available or contraindicated. The same editorial by Watson also supports the use of hemodialysis for renal insufficiency or metabolic acidosis rather than the traditional criterion of serum EG concentrations > 50 mg/dL. Interestingly, Corley and McMartin (2005) have refined a previously published PBTK model for EG and its GA metabolite in rats and humans to include hemodialysis, ethanol, and fomepizole as therapeutic interventions. This enabled the model to describe data from several human case reports of EG poisoning and demonstrated that fomepizole, if administered early enough, can indeed be more effective than ethanol or hemodialysis in inhibiting EG metabolism.

From a regulatory standpoint, EPA has established a RfD of 2 mg/kg/d based on kidney toxicity in the chronic rat feeding study by DePass et al. (1986) (EPA, 2006b). Palmer and Brent (2005) have recently derived a "chemical-specific adjustment factor" of 43.7 mg/kg/d based on a NOAEL for acute renal toxicity in humans. Although considerably higher than EPA's RfD, it is comparable to the Benchmark Dose 0.5 ($BMD_{0.5}$) for EG-induced nephrotoxicity of 49 mg/kg/d derived by Health Canada (2000).

Diethylene Glycol

Diethylene glycol (DEG) is similar in physicochemical properties to EG, but has a higher boiling point, viscosity, and specific gravity. DEG serves as a chemical intermediate in the production of polyester resins and polyurethanes, and as a solvent for shellacs and printing ink. It is hygroscopic, which leads to applications as a drying agent for natural and industrial gases, a humectant for cork and paper, and an additive in cosmetics.

DEG's use as an excipient in a liquid sulfanilamide preparation resulted in 105 deaths in the United States in 1937. This incident prompted passage of the Food, Drug and Cosmetic Act of 1938 (Wax, 1995). Use of DEG-contaminated propylene glycol or glycerin in various pharmaceuticals has caused multiple fatalities from renal failure in Nigeria, Bangladesh, India, and Haiti. In the Haitian incident, 109 cases of acute renal failure (with 88 deaths) were identified in children who received a locally manufactured acetaminophen syrup containing DEG-contaminated glycerin (O'Brien et al., 1998). The median lethal dose of DEG was estimated at 1.34 mL/kg. Renal failure was the "hallmark" finding in these cases, but hepatitis, pancreatitis, and severe neurologic manifestations (e.g., encephalopathy, optic neuritis with retinal edema, and unilateral facial paralysis) were frequently seen. Alfred et al. (2005) have presented seven cases of DEG poisoning characterized by metabolic acidosis, renal failure, and in three patients, neurotoxicity.

Compared to EG, toxicological data for DEG in animals are quite limited. Consistent with observations in human poisonings, Fitzhugh and Nelson (1946) reported dose-dependent hepatorenal injury in rats that consumed diets containing DEG. Kraul et al.

(1991) reported oliguria or polyuria, proteinuria, and other manifestations indicative of renal tubule injury in rats given a single i.p. dose of DEG. Similar to EG, renal tubular necrosis and COM crystal deposition in tubules have been observed following acute exposure of male rats (Hebert *et al.*, 1978). As for reproductive/developmental effects, high-dose gavage and dietary studies during gestation in mice, rats, and rabbits have largely been negative for embryotoxicity and teratogenicity (Ballantyne and Snellings, 2005). One study in mice employing a continuous breeding protocol has revealed diminished reproductive performance and fertility, as well as limited data on craniofacial malformations in live born and dead pups at drinking water exposures equivalent to 6.1 g/kg/d (Williams *et al.*, 1990). Citing this lone positive result and the developmental toxicity profile of EG, Ballantyne and Snellings (2005) gavaged CD-1 mice and CD rats with a range of DEG doses (559–11,180 mg/kg/d) on gestation days 6–15. They reported no embryotoxic or teratogenic effects at any dose in either species, except for delayed ossification consistent with reduced fetal body weight in rats.

Like EG, DEG is well absorbed from the GI tract, distributed throughout total body water and organs on the basis of blood flow, and initially metabolized by ADH and subsequently by ALDH (Heilmair *et al.*, 1993). The ether linkage of DEG is not cleaved and no appreciable amounts of EG or EG metabolites are formed from DEG, although small amounts of OA have occasionally been reported (Hebert *et al.*, 1978; Winek *et al.*, 1978). Based on studies in rats and dogs, unchanged DEG recovered in urine constitutes the majority of oral doses, with a single urinary metabolite, (2-hydroxyethoxy) acetic acid, accounting for most of the remainder (Lenk *et al.*, 1989; Wiener and Richardson, 1989; Mathews *et al.*, 1991). Differences in the toxicity/potency of DEG and EG can thus be explained by differences in their TK profiles. DEG's nephrotoxic moiety(ies) has (have) not been positively identified. As with EG, ADH inhibitors can be effective antidotes for DEG, as demonstrated by the use of fomezipole and hemodialysis to successfully treat a 17-month-old girl who ingested DEG (Brophy *et al.*, 2000).

Propylene Glycol

Propylene glycol (PG) is used as an intermediate in the synthesis of polyester fibers and resins, as a component of automotive antifreeze/coolants, and as a deicing fluid for aircraft. As PG is "generally recognized as safe" by the FDA, it is a constituent of many cosmetics, processed foods, and tobacco products, and serves as a diluent for oral, dermal, and i.v. drug preparations (ATSDR, 1997b). The most important routes of exposure in the general population are ingestion and dermal contact with products containing the compound. The use and disposal of deicing solutions is the major means by which PG is released to the environment. PG has a high mobility in soil and the potential to leach into groundwater, but is neither persistent nor bioaccumulative. Its soil and water half-lives are a few days under aerobic or anaerobic conditions. Workers in industries involved in manufacturing or use of products containing PG may be exposed to concentrations higher than the general population, particularly when these materials are heated or sprayed.

PG has a very low order of acute and chronic toxicity (ATSDR, 1997b; LaKind *et al.*, 1999). No organ system has been identified as a target for acute or chronic injury by PG, and there have been no accounts of human fatalities. Glover and Reed (1996) reported a typical clinical case in which a 2-year-old child experienced CNS depression and anion-gap acidosis after ingesting a hair gel containing PG. Clinical studies and case reports speak of individuals

with reactions to PG-containing drug preparations where preexisting conditions exist. For example, a patient with renal insufficiency secondary to chronic cocaine use developed metabolic acidosis after receiving lorazepam for sedation in which PG was a component of the i.v. formulation (Cawley, 2001). Wilson *et al.* (2000) reported a case of nearly fatal PG toxicity after i.v. diazepam in high doses for alcohol withdrawal. These same authors report on a case series detailing the risk of PG toxicity from i.v. benzodiazepine therapy (Wilson *et al.*, 2005).

Toxicity studies of PG in lab animals can be found in the literature, but findings of adverse effects are rare. Christopher *et al.* (1990) noted increases in anion-gap acidosis, CNS depression, and ataxia in cats ingesting high doses of PG, consistent with progressively elevated plasma lactate levels. PG has not been shown to be mutagenic and was negative for carcinogenicity in a chronic feeding study of male and female rats (Gaunt *et al.*, 1972). As for PG's reproductive/developmental toxicity, the NTP Center for the Evaluation of Risks to Human Reproduction released a monograph on the subject largely based on an expert panel report (NTP, 2004e,g). The overall conclusion was that there is negligible concern for adverse developmental/reproductive toxicity from PG exposures in humans, since animal studies have shown no such effect even at the highest doses tested.

PG's TK profile explains its relative lack of toxicity. As with other glycols, PG is readily absorbed from the GI tract and distributed throughout total body water and to organs on the basis of blood flow. Approximately 55% of PG is metabolized by ADH to lactaldehyde, while a significant percentage (~45%) is excreted unchanged by the kidneys (Morshed *et al.*, 1988). PG has a mean serum half-life in humans of 2–4 hours. Whereas excessive lactic acid from lactaldehyde metabolism is primarily responsible for metabolic acidosis observed in extreme exposures, lactate is a good substrate for gluconeogenesis, an efficient detoxification mechanism (NTP, 2004e,g). This detoxification mechanism typically does not allow lactic acid to accumulate to toxic levels, even under saturable metabolic conditions. The rate-limiting step in PG metabolism is its conversion to lactaldehyde. Saturation of this metabolic step in humans occurs at doses 8- to 10-fold lower than observed in laboratory animals. This is protective, because PG has a lower general toxicity than its metabolites (NTP, 2004e,g). As for EG and DEG, ADH inhibitors may competitively inhibit PG metabolism and thus be beneficial in the PG-poisoned patient. This is exemplified by a case of co-ingestion of ethanol and PG-containing antifreeze by a 61-year-old man absent of significant acid–base disturbance and minimal lactate elevation (Brooks and Wallace, 2002).

Two structural analogues of PG also have low hazard profiles. DPG (dipropylene glycol) and tripropylene glycol (TPG) are both widely used in personal care products such as perfumes, facial makeup, stick deodorants, and shaving and skin-care preparations. Their low hazard profiles are predictable, given that DPG is rapidly converted to PG, and TPG is rapidly hydrolyzed to DPG, which is further hydrolyzed to PG. The toxicity of these compounds has been summarized (UNEP, 1994, 2001). A negative DPG cancer bioassay was conducted in F-344 rats and B6C3F1 mice receiving the chemical via drinking water (Hooth *et al.*, 2004; NTP, 2004c).

GLYCOL ETHERS

If one alcohol residue of ethylene glycol (HO—CH_2—CH_2—OH) is replaced by an ether, the resulting compound is a monoalkyl glycol ether such as ethylene glycol monomethyl ether, also
Figure 24-12. Metabolism of glycol ethers.

R denotes alkyl group of —CH$_3$,—CH$_2$—CH$_3$, or—CH$_2$—CH$_2$—CH$_2$—CH$_3$ for methoxy-, ethoxy-, or bu-
toxyethanol, respectively. The formation of alkoxy glucuronide or sulfate conjugates has been identified only
for butoxyethanol. [Reproduced from Medinsky *et al.* (1990), with permission from Elsevier.]

called 2-methoxyethanol (2-ME; **CH$_3$—O—CH$_2$—CH$_2$—OH**).
If both alcohols are replaced by ethers, the result is a di-
alkyl glycol ether such as ethylene glycol dimethyl ether
(**CH$_3$—O—CH$_2$—CH$_2$—O—CH$_3$**). The alkyl group at the end
of the ether linkage may be a straight or branched short-chain
moiety (e.g., methyl, ethyl, n-propyl, isopropyl, or butyl). The
butyl moiety results in one of the most widely used glycol
ethers, 2-BE (**CH$_3$—CH$_2$—CH$_2$—CH$_2$—O—CH$_2$—CH$_2$—OH**).
Acetates of monoalkyl ethers such as 2-ME acetate
(**CH$_3$—CO—O—CH$_2$—CH$_2$—O—CH$_3$**) are also common sol-
vents that undergo rapid ester hydrolysis to their parent glycol
ethers in vivo, and thus tend to exhibit the same toxicity profiles
as unesterified glycols. Glycol ethers exhibit properties of both
alcohols and ethers and are thus soluble in water and most organic
solvents. This dual solubility and a favorable evaporation rate,
make glycol ethers very popular solvents for surface coatings such
as varnishes and latex paints. Glycol ethers also find use as solvents
in paint thinners and strippers, inks, metal cleaning products, liquid
soaps, and household cleaners, and are used as jet fuel anti-icing
additives and in semiconductor fabrication. Human exposure
occurs mainly via inhalation, but also by dermal absorption.

Although glycol ether metabolism varies with chemical
structure, some generalizations are possible (Fig. 24-12). For
ethylene glycol monoalkyl ethers, the major metabolic path-
way is oxidation via ADH and ALDH to alkoxyacetic acids.
For example, 2-ME and 2-BE are metabolized to methoxy-
acetic acid (MAA; CH$_3$—CO—O—CH$_2$—O—CH$_3$) and BAA
(CH$_3$—CO—O—CH$_2$—O—CH$_2$—CH$_2$—CH$_2$—CH$_3$), respectively.
The competing O-dealkylase pathway results in the cleavage of
the ether linkage to form ethylene glycol and an alkyl aldehyde.
Medinsky et al. (1990) reported that the relative contribution of
the oxidative pathway to metabolism of ethylene glycol ethers
increases with increasing alkyl chain length, whereas that of the

O-dealkylase pathway decreases. In contrast, the propylene series
of glycol ethers [e.g., propylene glycol monomethyl ether (PGME)]
is predominantly biotransformed to PG via O-dealkylation. Glycol
ethers may also be conjugated with glucuronide or sulfate, but
this is thought to occur mainly after saturation of other metabolic
pathways.

In vitro and in vivo toxicity studies demonstrate that some gly-
col ethers and their oxidative metabolites are reproductive, devel-
opmental, hematologic, and immunologic toxicants by all exposure
routes. A few have also tested positive in rodent cancer bioassays.
The metabolism of glycol ethers is considered a prerequisite to their
toxicity, as the alkoxyacetic acids are usually regarded as the ulti-
mate toxicants. Their acetaldehyde precursors have also been im-
plicated on occasion. A critical role for metabolism is supported by
the differential toxicities of glycol ethers metabolized via the ox-
idative and O-dealkylase pathways (Miller *et al.*, 1984; Ghanayem
et al., 1987). This differential toxicity has resulted in a dramatic
shift away from the production and use of certain low-molecular-
weight ethylene glycol ethers and their acetate esters (e.g., 2-ME
and 2-ethylene glycol monoethyl ether or 2-EE) toward those with
more favorable toxicity profiles such as ethylene, diethylene, and tri-
ethylene glycol butyl ethers and those in the low-molecular-weight
propylene series like PGME (de Ketttenis, 2005; Spencer, 2005).
Like several glycol ethers of the ethylene series, PBTK models
have been developed for PGME and its acetate in rats and humans
and exercised for risk assessment, including derivation of a RfC
and a RfD (Corley *et al.*, 2005b; Kirman *et al.*, 2005; Lemazurier
et al., 2005). Structure-activity relationships have been discerned in
studies of glycol ethers with various chemical substitution patterns
(Hardin *et al.*, 1984; Rawlings *et al.*, 1985; Hardin and Eisenmann,
1987; Ghanayem *et al.*, 1989). The reproductive and developmen-
tal toxicities of the monoalkyl glycol ethers, for example, tend to
decrease with increasing alkyl chain length, whereas hematotoxicity

increases. Thus, structure-activity relationships may not be universally applicable across multiple toxicological end points.

Reproductive Toxicity

Epidemiological studies have reported associations between glycol ether exposure and increased risk for spontaneous abortion, menstrual disturbances, and subfertility among women employed in the semiconductor industry (Schenker *et al*., 1995; Correa *et al*., 1996; Chen *et al*., 2002; Hsieh *et al*., 2005). These associations appear biologically plausible, given the reproductive toxicity of 2-ME and its active metabolite, MAA, is manifested as ovarian luteal cell hypertrophy and increased progesterone production in the female rat. Furthermore, MAA increased progesterone production in cultured human luteal cells at the same concentration it did in rat luteal cells, implying that it has the potential to alter ovarian luteal function in women (Almekinder *et al*., 1997; Davis *et al*., 1997). Reproductive effects, primarily reversible spermatotoxicity, have also been described for men exposed to glycol ethers, in some cases at concentrations well below current OSHA PELs for 2-ME (25 ppm) and 2-EE (200 ppm). For instance, Welch *et al*. (1988) found that painters exhibited oligospermia and azoospermia following average exposure to 2-EE and 2-ME at 2.7 and 0.8 ppm, respectively. In addition, men exposed to a mean level of 6.6-ppm 2-EE in a foundry had decreased numbers of sperm per ejaculate (Ratcliffe *et al*., 1989). Lastly, a large case–control study of male fertility clinic patients revealed a highly significant association between a diagnosis of impaired fertility and the detection of ethoxyacetic acid in urine (Veulemans *et al*., 1993).

Testicular effects in men are supported by experimental observations in animals including seminiferous tubule atrophy, abnormal sperm head morphology, necrotic spermatocytes, decreased sperm motility and count, and infertility (Lamb *et al*., 1984; Foote *et al*., 1995; Watanabe *et al*., 2000). Spermatocytes are among the first cells to be visibly affected following glycol ether exposure and their death involves apoptosis (Chapin *et al*., 1984; Brinkworth *et al*., 1995; Ku *et al*., 1995). Creasy and Foster (1984) noted a consistent order of spermatocyte susceptibility following oral administration of 2-ME or 2-EE to rats: dividing spermatocytes > early-pachytene spermatocytes > late-pachytene spermatocytes > mid-pachytene spermatocytes. Spermatocytes in the leptotene/zygotene stages of cell division, late-stage spermatids, and spermatogonia can be affected if the dose is increased and exposure prolonged.

As for mechanism of action, studies suggest several possibilities. Beattie *et al*. (1984) reported that rates of lactate accumulation in cultured rat Sertoli cells were significantly decreased by MAA. Lactate is the preferred metabolic substrate of spermatocytes. Also, 2-EE has been shown to increase oxygen consumption and decrease ATP levels in pachytene spermatocytes in a manner consistent with an uncoupled oxidative state (Oudiz and Zenick, 1986). Mebus *et al*. (1989) have, in addition, demonstrated that serine, acetate, sarcosine, and glycine attenuated the spermatotoxicity of 2-ME in the rat, suggesting MAA may interfere with the availability of one-carbon units for incorporation into purine and pyrimidine bases necessary for nucleic acid synthesis in pachytene spermatocytes. A mechanistic role for Ca^{2+} has been hypothesized and investigated in a series of studies by Chapin and colleagues. Ghanayem and Chapin (1990) observed that a Ca^{2+} channel blocker afforded protection against 2-ME-induced pachytene spermatocyte cell death. These authors reasoned that 2-ME perturbed Ca^{2+} homeostasis, which is consistent with observations of spermatocyte mitochondrial dis-

ruption. Involvement of Ca^{2+} was further suggested by observations that 2-ME activates a Ca^{2+}-dependent nuclease, cyclophilin A, found in pachytene spermatocytes and associated with spermatocyte apoptosis (Wine *et al*., 1997). Whereas an increase in intracellular Ca^{2+} is thought to trigger endonuclease activation, the protection afforded by Ca^{2+} channel blockers against MAA-induced spermatocyte apoptosis is apparently not mediated by preventing a rise in intracellular free Ca^{2+} (Li *et al*., 1997). Rather, because an intact relationship between Sertoli and germ cells is necessary for the morphological expression of MAA-induced spermatocyte apoptosis, it was reasoned that spermatocyte apoptosis is mediated by Sertoli cell-generated factor(s). This hypothesis proposes that transfer of this factor(s) from Sertoli cells into germ cells (or initiation of spermatocyte apoptosis by 2-ME-damaged Sertoli cells through direct Sertoli cell to germ cell communication), can be inhibited by Ca^{2+} channel blockers through their membrane-stabilizing effects and/or interaction with protein kinase C and/or calmodulin, both of which have demonstrated roles in apoptosis. The inhibition of protein kinase C and calmodulin has been shown to block MAA-induced spermatocyte cell death (Li *et al*., 1997).

Jindo *et al*. (2001) advanced the research of their predecessors by using cultured seminiferous tubules of juvenile rats to demonstrate that MAA-induced spermatocyte apoptosis could be blocked with protein kinase inhibitors. Several kinases (e.g., Src) increased immediately *around* dying spermatocytes in the immediate proximity of Sertoli cells. An increase was also noted in the phosphorylation of the endoplasmic reticulum chaperone glucose-regulated protein 94, known also as endoplasmin, that was located *inside* dying spermatocytes. This work implicates a role for kinase activity in the pathogenesis of MAA-induced spermatocyte apoptosis and suggests the involvement of Sertoli cells. Yet another investigation examined the role of tyrosine kinase pp60 (rat testicular Src), a tyrosine kinase encoded by the Src gene and involved in an array of cell signaling pathways, for its involvement in 2-ME-induced spermatocyte apoptosis. Sertoli cell cytoplasm was observed to be the principal site of Src immunoreactivity in control testis, while 2-ME treatment significantly induced Src expression in dying spermatocytes. In addition, MAA-induced apoptosis was blocked using Src inhibitors, further supporting a role for rat testicular Src in Sertoli-germ cell communication and spermatocyte toxicity of 2-ME (Wang *et al*., 2000). Furthermore, a suppression subtractive hybridization technique using whole testes from 2-ME-treated mice was employed to create mouse testis cDNA libraries enriched for gene populations either upregulated or downregulated by 2-ME (Wang and Chapin, 2000). A total of 70 clones was screened, and six of them were shown to be differentially expressed in the 2-ME lesion, three with increased expression, and three were suppressed. Interestingly, predicted peptide sequences of the six genes revealed several conserved motifs such as phosphorylation sites for protein kinase C and tyrosine kinase. Importantly, these gene changes were apparent at multiple germ cell stages and were localized in multiple germ cell types (Sertoli, interstitial, and peritubular cells). This further suggests the involvement of cell types other than the dying spermatocyte in the pathogenesis of 2-ME-induced spermatocyte death and helps explain the requirement for *intact* seminiferous tubules for in vitro replication of the pathology observed in vivo.

Developmental Toxicity

Exposure to certain glycol ethers during organogenesis (e.g., 2-ME and 2-EE) is toxic to the developing embryo, with effects seen

in several animal models including non-human primates (Hardin *et al.*, 1986; Scott *et al.*, 1989). Others such as ethylene glycol butyl, propyl, and monohexyl ethers, and most PG ethers have either not induced fetal malformations or have a lower potential for developmental toxicity (Tyl *et al.*, 1989; Spencer, 2005). Structural anomalies in rodents have included a variety of minor skeletal variations, hydrocephalus, exencephaly, cardiovascular malformations, dilatation of the renal pelvis, craniofacial anomalies, and digit malformations. In the absence of structural defects, electrocardiograms of fetal rats from dams treated with 2-ME during gestation showed persistent, aberrant QRS waves, suggestive of an intraventricular conduction delay (Toraason and Breitenstein, 1988). Neurobehavioral changes and regional brain alterations of several neurotransmitters in offspring of rats treated with 2-ME or 2-EE have been reported (Nelson and Brightwell, 1984).

Little is known about the mechanism by which glycol ethers exert their developmental effects. 2-ME has served as a model toxicant to investigate the disposition of weak acids in the maternal–fetal unit and the hypothesis that weak acids such as MAA exert their effects by altering embryonic pH at critical stages of organogenesis (Nelson *et al.*, 1989; Clarke *et al.*, 1992; O'Flaherty *et al.*, 1995; Terry *et al.*, 1995). Ambroso *et al.* (1998) have applied confocal laser scanning microscopy, classical histopathology, and in situ immunohistochemistry to demonstrate that 2-ME caused a dose-dependent increase and expansion of apoptosis in gestation day 8 mouse embryos that could underlie 2-ME-induced neural tube defects. Such a mechanism has also been hypothesized for malformations induced by several prototypical teratogens like retinoic acid and ethanol.

Few epidemiological studies have addressed developmental effects of glycol ethers. Saavedra *et al.* (1997) described facial malformations and varying degrees of mental retardation in 44 offspring of mothers who were exposed occupationally to 2-ME and ethylene glycol at a factory producing capacitors in Mexico. There are a few reports published from a multicenter case–control study in Europe designed to investigate the role of maternal exposures at work and congenital malformations (Ha *et al.*, 1996; Cordier *et al.*, 1997; Lorente *et al.*, 2000). Preliminary results (Ha *et al.*, 1996) among mothers who were exposed to glycol ethers at work during pregnancy found excesses of oral clefts (OR = 2.0; 95% CI = 1.1–4.1) and CNS malformations (OR = 1.8; 95% CI = 1.1–3.3). In a study of 984 cases of major congenital malformations, Cordier *et al.* (1997) reported an overall OR of congenital malformations associated with glycol ether exposure of 1.44 (95% CI = 1.10–1.90), with significant associations for glycol ether exposure with cleft lip, multiple anomalies, and neural tube defects. Lorente *et al.* (2000) studied 100 mothers of babies with oral clefts and 751 mothers of healthy babies and reported a nonsignificant OR of 1.7 (95% CI = 0.9–3.3) for maternal occupational exposure to glycol ethers and cleft lip, with or without cleft palate. Maldonado *et al.* (2003) have reviewed the epidemiological evidence and determined that it is insufficient to determine whether occupational exposure to glycol ethers causes human congenital malformations.

Out of concern for the potential of ethylene glycol monoalkyl ethers as developmental toxicants, several PBTK models have been developed. Hays *et al.* (2000) developed a PBTK model for 2-ME and MAA in the pregnant rat that was capable of predicting embryonic concentrations. Gargas *et al.* (2000a,b) applied a PBTK model to estimate inhaled concentrations of 2-EE, its acetate ester, and 2-ME in humans that would result in blood levels equivalent to those observed at the rat NOAELs and LOAELs for developmental effects. Sweeney *et al.* (2001) applied Monte Carlo simulations to

the models of Gargas and coworkers to account for the variability in TK and TD factors among humans and animals and derived occupational exposure limits to protect workers from developmental effects of 2-ME and 2-EE that were 1 to 2 orders of magnitude lower than current OSHA PELs. It is worthy of note that 2-ME has been largely removed from commerce due to its teratogenic potency.

Hematotoxicity

Some glycol ethers are hemolytic to red blood cells (RBCs). Typically, the osmotic balance of cells is disrupted, they imbibe water and swell, their ATP concentration decreases, and hemolysis occurs (Ghanayem, 1989). Nyska *et al.* (1999) reported that subchronic exposure to 2-BE causes disseminated thrombosis and bone infarctions in female, but not male rats, likely due to impedance of blood flow by intravascular hemolysis. It is thought that females might be susceptible, because they are less efficient in eliminating BAA, the hemolytic metabolite of 2-BE, and exhibit higher peak blood BAA levels. Young adult rats are more resistant to the hematologic effects of 2-BE than older rats, an observation attributed to depressed degradation and renal clearance of BAA in the older rats.

Species differ dramatically in their sensitivities to glycol ether-induced RBC deformity and hemolysis. Humans are less susceptible than rodents. This lower susceptibility even applies to RBCs from potentially sensitive subpopulations, such as the elderly and persons with hereditary blood disorders (Udden, 1994; Udden and Patton, 1994). A good example of using PBTK models in human risk assessment has been published by Corley *et al.* (1994). Based on comparisons of model output with data collected by Udden and colleagues on levels of 2-BE required to affect osmotic fragility of human RBCs, Corley and coworkers concluded that humans are unlikely to achieve hemolytic blood levels of BAA unless very large volumes of 2-BE are intentionally ingested. Udden (2005) has recently reported on the hemolytic effects of diethylene glycol butyl ether (DGBE) and its principal metabolite, butoxyethoxyacetic acid (BEAA), using rat and human RBCs in vitro. BEAA had weak hemolytic activity on rat erythrocytes, which is consistent with the finding of mild hemolysis when DGBE is administered to rats by gavage. However, such effects were absent in human RBCs exposed to DGBE or BEAA, indicating that it is unlikely hemolysis will occur in humans exposed to DGBE. Johnson *et al.* (2005) recently confirmed DGBE's low order of hematotoxicity in a 13-week drinking water study in F-344 rats that identified a NOAEL of 250 mg/kg/d, with minimal but statistically significant decreases in RBC count, hemoglobin, and hematocrit at 1000 mg/kg/d.

Hoflack *et al.* (1997) have shown 2-BE capable of inducing apoptosis in a human leukemia cell line and have hypothesized that the hematopoietic toxicity of 2-BE may be the result of its ability to induce apoptotic cell death. However, once inside the cell it is not entirely clear how hemolysis is accomplished, although the RBC membrane has long been the suspected target. Udden and Patton (2005) have utilized BAA to examine the mechanism of glycol ether hemolysis in rat RBCs in vitro. They concluded that the mode of action of BAA is to cause a colloid osmotic lysis of the RBC and speculated the following scenario: BAA causes Na^+ and Ca^{2+} to enter the cell → Ca^{2+} initially has a protective effect via the Ca^{2+}-activated potassium channel, which facilitates the loss of potassium, thereby compensating for the osmotic effect of increased cell Na^+ → Ca^{2+} subsequently has deleterious effects through activation of proteases and the loss of the normal asymmetric distribution of phospholipids (e.g., phosphatidylserine) in the membrane bilayer. These authors

noted that preliminary studies in their laboratory have shown the movement of phosphatidylserine from the inner to the outer leaflet of the lipid bilayer of rat RBCs incubated with BAA. This "externalization" of phospatidylserine is associated with adhesion of RBCs to endothelial cells and the generation of thrombin, which is most interesting given reports of disseminated thrombosis and infarction in 2-BE-treated rats (Nyska *et al.*, 1999; Ghanayem *et al.*, 2001).

Immunotoxicity/Carcinogenicity

Based on changes in thymus and splenic weights/cellularities and a variety of in vitro and in vivo immune function assays, the immune system is a potential target for the oxidative metabolites of some glycol ethers. 2-ME and MAA have been employed almost exclusively in immunotoxicity investigations of glycol ethers. Not only have adult animals proven susceptible, but 2-ME exposure of pregnant mice induces fetal thymic atrophy/hypocellularity and a reduction in fetal liver prolymphocytes with potential implications for fetal immunity (Holladay *et al.*, 1994). Using B6C3F1 mice and gavage exposure, House *et al.* (1985) were among the first to report that 2-ME and MAA reduced thymus weight. Kayama *et al.* (1991) subsequently reported that 2-ME selectively depleted immature thymocytes in mice. Exon *et al.* (1991) not only reported thymic atrophy in rats exposed to 2-ME in drinking water, but also decreased antibody production, decreased splenocyte production of interferon-γ, and a reduction in spleen cellularity. Around the same time, the first in a lengthy series of studies by Smialowicz and colleagues was published (Smialowicz *et al.*, 1991a,b, 1992, 1994; Williams *et al.*, 1995; Kim and Smialowicz, 1997). This series has reported decreased thymus weights, reduced lymphoproliferative responses to mitogens, and reduced IL-2 production in splenocytes of F-344 rats exposed to 2-ME by gavage. It has also generated data indicating that not all glycol ethers are immunosuppressive, that mice are relatively insensitive to glycol ether immuosuppression compared to rats, and that rats of various strains show differential sensitivities. The Smialowicz series has further demonstrated that the relative insensitivity of mice is not a function of their more rapid clearance of MAA; that 2-ME is immunotoxic when applied dermally to F-344 rats; and that questions remain as to 2-ME's proximate immunotoxicant, as 2-methoxyacetaldehyde is more immunotoxic than MAA based on the ability to suppress IgM and IgG production by lymphocytes in F-344 rats.

As for cancer, only a few chronic bioassays have been conducted with glycol ethers. Two-year inhalation bioassays of 2-BE in F-344 rats and B6C3F1 mice revealed some evidence of carcinogenicity in male mice, based on increased incidences of hemangiosarcoma of the liver, as well as some evidence of carcinogenic activity in female mice, based on increased incidences of forestomach squamous cell papilloma or carcinoma (mainly papilloma) (NTP, 2000). In June 2004, an IARC working group evaluated the cancer risk of 2-BE and concluded that it is not classifiable as to its human carcinogenicity (Cogliano *et al.*, 2005). Likewise, EPA's IRIS profile for 2-BE currently indicates that the human carcinogenic potential of 2-BE cannot be determined at this time (EPA, 2006c). Since NTP's bioassays were completed, numerous studies have shed light on 2-BE's possible modes of action related to liver hemangiosarcomas and forestomach tumors and their implications for risk assessment (Park *et al.*, 2002; Siesky *et al.*, 2002; Poet *et al.*, 2003; Boatman *et al.*, 2004; Klaunig and Kamendulis, 2005; Corthals *et al.*, 2006). As discussed by Gift (2005), these studies suggest the following scenario: 2-BE consumed while grooming is metabolized to irritant

metabolites in the forestomach and/or irritant metabolites are formed in the upper respiratory tract and swallowed → chronic irritation → inflammation → hyperplastic effects → forestomach tumors. As for liver hemangiosarcomas, the following is suggested: 2-BE is metabolized to BAA → BAA causes hemolysis of RBCs → hemosiderin (iron) derived from released hemoglobin is taken up by and stored in phagocytic cells (e.g., Kupffer cells) of the spleen and liver → oxidative damage and increased synthesis of endothelial DNA are initiated by reactive oxygen species from excess iron or Kupffer cells, producing cytokines/growth factors that suppress apoptosis and promote cell proliferation → endothelial DNA mutations → potentiation and promotion of hepatic neoplastic cell populations. As further discussed by Gift (2005), the evidence suggests nonlinear modes of action in both cases and questionable human relevance of both tumor types. Several PBTK models have been developed and subsequently refined for 2-BE and BAA to aid in risk assessments (Corley *et al.*, 1994, 2005c; Lee *et al.*, 1998; Franks *et al.*, 2006).

Spencer *et al.* (2002) have reported a 2-year inhalation bioassay of PGME in F-344 rats and B6C3F1 mice that did not result in increases in neoplasia in either species except for kidney adenomas in male rats related to α_{2u}-globulin nephropathy. In contrast, a 2-year inhalation bioassay with propylene glycol mono-*t*-butyl ether (PGMBE) in F-344 rats and B6C3F1 mice also resulted in α_{2u}-globulin nephropathy in male rats, as well as liver tumors in male and female B6C3F1 mice at the highest concentration tested (1200 ppm) (NTP, 2004a; Doi *et al.*, 2004). Dill *et al.* (2004) have published information on PGMBE TK in rats and mice that demonstrate saturation of PGMBE metabolism/elimination at this tumor-producing concentration. The genotoxicity of some glycol ethers and their metabolites has been evaluated, with most exhibiting a lack of genotoxic potential and others yielding weakly positive responses in certain tests. Therefore, the role of genetic toxicology in the toxicities discussed above cannot be summarily dismissed, but is of unknown significance (Elliot and Ashby, 1997; NTP, 2000; Ballantyne and Vergnes, 2001).

FUELS AND FUEL ADDITIVES

Automotive Gasoline

Automotive gasoline is a complex mixture of hundreds of hydrocarbons predominantly in the C_4 to C_{12} range. The sheer number of people exposed in the manufacture, distribution, and use of gasoline make characterization of its acute and chronic toxicities important. Generalizations regarding gasoline toxicity must be made with care, because its composition varies with the crude oil from which it is refined, the refining process, and the use of specific additives. Experiments conducted with fully vaporized gasoline may not be predictive of actual risk, because humans are exposed primarily to the more volatile components in the range of C_4 to C_5. These hydrocarbons are generally regarded as less toxic than their higher-molecular-weight counterparts. Concern about gasoline exposure is fueled in part by the toxicities of certain components, some of which are classified by EPA as known or probable human carcinogens (e.g., benzene and 1,3-butadiene). The ACGIH has established a TLV for gasoline of 300 ppm to prevent ocular and upper respiratory tract irritation and a STEL of 500 ppm to avoid acute CNS depression.

Inhalation exposure to gasoline has been measured for service station attendants, self-service customers, truck drivers, distribution workers, and workmen removing leaking underground storage tanks (Kearney and Dunham, 1986; Shamsky and Samimi, 1987). In

one survey, short-term exposures of self-service customers averaged about 6 ppm. The TLV is rarely exceeded in occupationally exposed individuals, due in part to the use of vapor scavenging systems. Brief exposures in excess of the STEL have, however, been documented for workers engaged in bulk handling operations (Phillips and Jones, 1978). The most extreme exposures occur to those intentionally sniffing gasoline for its euphoric effects. Several case reports of acute and chronic encephalopathies are testament to the dangers of this habit (Valpey *et al*., 1978; Fortenberry, 1985). In these cases, the identity of the offending agent(s) is often unclear. Gasoline is one of the most popular and lethal inhalants (Spiller, 2004; Wu *et al*., 2004), with deaths reported even among Aboriginal people in South Australia (Byard *et al*., 2003). An all too common occurrence is the ingestion of gasoline during siphoning events. This is typically followed by a burning sensation in the mouth and pharynx, as well as nausea, vomiting, and diarrhea resulting from GI irritation. If aspirated into the lungs, gasoline may produce pulmonary epithelial damage, edema, and pneumonitis. Thus, emetic therapy for gasoline ingestion is usually contraindicated.

Between 1986 and 2004, EPA identified 447,233 releases from underground petroleum storage tanks, many of which threaten groundwater that serves as the primary drinking water source for nearly one-half the U.S. population. Despite the number of releases, few community health studies have been conducted, and those that have are typically driven by concerns over leukemia risk owing to gasoline's benzene content. Consider for example the retrospective cohort study of the "Tranguch Gasoline Spill" in northeastern Pennsylvania (Patel *et al*., 2004). The standard incidence ratio for leukemia of all types was significantly elevated (4.40; 95% $CI = 1.09–10.24$), consistent with that reported by the Pennsylvania Department of Health. However, the excess was based on only four cases, two of whom had a history of smoking, a potential confounder. In addition, exposure was not well characterized, and only two of the subjects had acute myelogenous leukemia (AML), the leukemia type most strongly associated with benzene. Such a study exemplifies the problem with inferring causation for environmentally-exposed populations based on limited data.

Reese and Kimbrough (1993) and Caprino and Togna (1998) have reviewed the acute toxicity of gasoline and its additives. Like some other solvents, gasoline can sensitize the heart to catecholamines, defat the skin upon repeated contact, and induce hepatic P450s and UDP-glucuronyltransferase activities (Poon *et al*., 1995). The question of whether there is a "fetal gasoline syndrome" has been raised, although case reports are confounded by tetraethyl lead, alcohol abuse, and the possibility that an aberrant gene is distributed within the small Amerindian population where the cases reside (Hunter *et al*., 1979). There is a paucity of data on the reproductive toxicity of gasoline, but reports of enhanced estrogen metabolism and uterine atrophy among unleaded gasoline (UG)-treated mice suggest that this end point warrants investigation (Standeven *et al*., 1994a). Although dated, the study of Lykke and Stewart (1978) is of interest, because rats exposed to leaded gasoline at one-third the ACGIH TLV (i.e., 100 ppm) for 40 h/week for 6–12 weeks were observed to have a progressive interstitial fibrosis of the lungs associated with irregular alveolar collapse.

Prior to the identification of α_{2u}-globulin as the principal accumulating protein in the syndrome referred to as α_{2u}-globulin nephropathy, Kuna and Ulrich (1984) reported regenerative epithelium and dilated tubules in the kidneys of male rats exposed to 1552 ppm UG for 90 days. At about the same time, a chronic inhalation study revealed not only nephropathy, but also increased

renal tumors in male rats (MacFarland *et al*., 1984). Subsequent studies by Halder *et al*. (1986) and Aranyi *et al*. (1986) showed that such nephropathy could not be produced by exposure of rats to a mixture of the butane and pentane components of gasoline or the $0°F$ to $145°F$ gasoline distillation fraction. These are thought to be more representative of human occupational exposures than wholly vaporized gasoline. In addition, the authors of a gavage screening study of 15 pure hydrocarbons and gasoline fractions concluded that branched aliphatic alkane components were primarily responsible for the nephropathy (Halder *et al*., 1985).

Investigations of mechanisms of the nephropathy and renal tumors included an assessment of unscheduled (a measure of genotoxicity) and replicative DNA synthesis (a measure of cell proliferation) in rat kidney cells exposed in vitro and in vivo to UG. No unscheduled DNA synthesis occurred, even at a tumorigenic dose, while a five- to eightfold increase in cell proliferation was observed (Loury *et al*., 1987). In a publication the same year by Olson *et al*. (1987), UG was reported to result in an increase in hyaline droplets harboring large accumulations of α_{2u}-globulin within proximal convoluted tubule epithelial cells. It was hypothesized that α_{2u}-globulin accumulated secondary to a defect in renal lysosomal degradation of the protein (Fig. 24-6). Supportive evidence for this hypothesis came from the demonstration that inhibition of the lysosomal peptidase, cathepsin B, caused a rapid accumulation of phagolysosomes and α_{2u}-globulin in the kidney similar to that of UG (Olson *et al*., 1988).

Further progress in elucidating the mechanism of α_{2u}-globulin nephropathy came from the demonstration that the UG component, 2,2,4-trimethylpentane (TMP), itself an inducer of α_{2u}-globulin nephropathy, was metabolized to 2,4,4-trimethyl-2-pentanol (TMPOH), which was selectively retained by the kidney of male rats. Subsequently, it was demonstrated that the sex-specific retention of TMPOH in the kidney was due to reversible binding with α_{2u}-globulin. This binding rendered the protein less digestible by lysosomal enzymes, which accounted for its accumulation (Charbonneau and Swenberg, 1988). This accumulation, in turn, led to cellular degeneration and necrosis, primarily in the P_2 segment of the proximal tubule. In response, regenerative proliferation occurs and promotes formation of renal cell tumors by irreversibly "fixing" spontaneously altered DNA and clonally expanding initiated cells. The promotional effects of gasoline and TMP on atypical cell foci and renal cell tumors have been demonstrated in male rats following initiation with *N*-ethyl-*N*-hydroxyethylnitrosamine (Short *et al*., 1989). NCI–Black–Reiter male rats, the only rat strain not to synthesize α_{2u}-globulin, are resistant to gasoline- and TMP-induced nephropathy (Dietrich and Swenberg, 1991). Thus, gasoline and TMP have been of great value in elucidating the mechanism of α_{2u}-globulin nephropathy and shedding light on its implications for renal tumorigenesis. Most toxicologists, and indeed the EPA, have concluded that renal tumors secondary to α_{2u}-globulin nephropathy are of little relevance, because humans do not synthesize α_{2u}-globulin.

Chronic inhalation of gasoline at high concentrations has also resulted in increased hepatocellular adenomas and carcinomas in female B6C3F1 mice, possibly due to the promotion of spontaneously initiated cells that occur with unusually high frequency in this mouse strain (MacFarland *et al*., 1984). This possibility is supported by reports that UG is a CYP inducer, mitogen, and liver tumor promoter in *N*-nitrosodiethylamine (DEN)-initiated female B6C3F1 mice (Standeven and Goldsworthy, 1993; Standeven *et al*., 1995; Moser *et al*., 1996a). CYP induction by UG has been attributed to "heavy UG" (components with boiling points $> 100°C$),

whereas mitogenic activity is highly concentrated in UG components boiling from 100 to 132°C, for which the 2,2,3-, 2,2,4-, and 2,3,4-trimethylpentane isomers appear at least partially responsible (Standeven and Goldsworthy, 1994). It has been hypothesized that the liver tumor-promoting activity of UG is secondary to its estrogen antagonism, given that (1) UG is not a hepatocarcinogen in male mice; (2) estrogen inhibits liver tumor development initiated in mice but potentiates liver tumor promotion by UG; and (3) UG induces hepatic estrogen metabolism (Standeven *et al*., 1994b). The hypothesis that liver tumor promotion by UG depends on its interaction with estrogen is supported by the demonstration that tumor-promoting activity of UG was greatly attenuated in ovariectomized mice relative to intact mice (Moser *et al*., 1997). Further, the addition of estrogen to DEN-treated mice substantially reduces the percentage of hepatic foci with decreased levels of TGF-β1 compared to DEN-treated control mice or DEN + UG-treated mice, suggesting a promotional mechanism involving estrogen and the dysregulation of tumor growth factor(s) (Moser *et al*., 1996c). Whereas much attention has been given to its promotional potential, UG may also damage DNA, as it reportedly induces unscheduled DNA synthesis in hepatocytes from male and female mice treated in vivo and in cultured mouse, rat, and human hepatocytes (IARC, 1989b). The epidemiological evidence for an association between gasoline exposure and cancer in humans is inconclusive. Raabe (1993) has reviewed the carcinogenic potential of gasoline. IARC (1989b) classifies it as possibly carcinogenic to humans (Group 2B) primarily due to its benzene content. A comprehensive review of gasoline toxicity is provided in ATSDR's (1995) *Toxicological Profile for Gasoline*.

Vehicle emissions from gasoline combustion are a major contributor to urban air pollution, which is at unhealthy levels in numerous cities. In response, the Clean Air Act Amendments of 1990 require the use of oxygenated gasoline in such areas. Oxygenated gasoline contains additives that add oxygen to gasoline, thereby boosting its octane quality, enhancing combustion, and reducing exhaust emissions. MTBE and ethanol are the two most common oxygenates, although use of the former is being rapidly phased out due to widespread groundwater contamination and health concerns. As a result, the demand for ethanol–gasoline blends is increasing dramatically, raising concerns about how the two components might interact toxicologically. There is a dearth of information on this issue, but a 4-week inhalation study of an ethanol–gasoline mixture (6130-ppm ethanol and 500-ppm gasoline) in rats concluded that co-exposure showed additive and possibly some synergistic effects on growth, neurochemistry, and histopathology of the adrenal gland and respiratory tract. Effects were described as generally mild and adaptive in nature, and returned to normal after exposure cessation (Chu *et al*., 2005). The risks and benefits of ethanol as an oxygenate are discussed in detail by Williams *et al*. (2003), who point out several reasons why ethanol in gasoline can increase groundwater plume lengths and persistence of gasoline constituents in groundwater if ethanol blends are released into the environment. The most obvious concern is that longer or more persistent gasoline plumes could lead to a higher probability of gasoline constituents affecting public water wells. Meanwhile, another fuel additive, methylcyclopentadienyl manganese tricarbonyl (MMT), is receiving attention due to concerns that it could increase manganese inhalation exposures and pose a risk for neurotoxicity. The combustion of MMT gasoline results in the emission of fine Mn particulates mainly as Mn sulfate and Mn phosphate and smaller amounts of oxides. Several studies characterizing vehicular exhaust using MMT gasoline and describing the pharmacokinetics and neurobehavioral toxicity of Mn have

been recently published, some of which were mandated by EPA (Normandin *et al*., 2004; Dorman *et al*., 2006; Reaney *et al*., 2006; Tapin *et al*., 2006). Gasoline engine exhaust has been classified as possibly carcinogenic to humans (Group 2B), based largely on sufficient evidence in animals when condensates and exhaust extracts are tested (IARC, 1989a).

Methyl Tertiary-Butyl Ether

MTBE's high octane rating made it a logical replacement for tetraethyl lead as an octane booster for gasoline, and later as a gasoline oxygenator. As an oxygenator, MTBE makes fuel combustion more complete, thereby reducing pollutant emissions from automobile exhaust. MTBE may be added to gasoline at levels up to 15% by volume in order to comply with the 1990 Amendments to the Clean Air Act. By 1997, it was being used at the rate of 10 million gal/d, with more than one-third of the usage in California. While routine, low-level exposure of customers occurs at self-service stations, heightened concern about MTBE has resulted primarily from its contamination of groundwater by leaking underground gasoline tanks. It is highly water soluble, travels faster and farther in water than other gasoline components, and is resistant to degradation.

MTBE is well absorbed following oral, inhalation, and dermal exposure of humans and rats (Dekant *et al*., 2001; Prah *et al*., 2004; McGregor, 2006). The majority of absorbed MTBE is exhaled unchanged. Some MTBE is oxidized to *tert*-butyl alcohol (TBA) and HCOH. Whereas this oxidation is primarily CYP2A6 mediated in humans (Hong *et al*., 1999), it is largely CYP2B1 mediated in rats (Turini *et al*., 1998). TBA is relatively water soluble, so it tends to remain in the blood and extracellular fluid, and is slowly exhaled. TBA is further metabolized, first to 2-methyl-1,2-propanediol and then to 2-hydroxyisobutyrate, the major urinary metabolites of MTBE. In addition, glucuronide and sulfate conjugates of TBA are found in trace amounts in urine. Although HCOH is one of the oxidative metabolites of MTBE, it is undetectable after MTBE exposure in humans and rats, presumably due to its rapid metabolism. PBTK models have been developed to describe the dosimetry of MTBE and TBA following inhalation and oral exposures in rats and humans (Borghoff *et al*., 1996; Licata *et al*., 2001).

Concern about MTBE has led to numerous toxicity studies in humans and rodents, and a number of reviews of MTBE's toxicity are available (ATSDR, 1996b; EPA, 1997; Borak *et al*., 1998; McGregor, 2006). The review of Borak *et al*. (1998) focuses upon the acute human health effects of MTBE. It concludes, based on 19 reports of inhalation exposure to MTBE alone or in gasoline and 12 reports of parenteral MTBE administration to dissolve cholesterol gallstones, that no significant association exists between MTBE exposure and the acute symptoms commonly attributed to it. These symptoms include headache, eye, nose and throat irritation, cough, nausea, dizziness, and disorientation. The more recent review of McGregor (2006) is supportive of this conclusion.

In 1988, the EPA and industry developed a Testing Consent Order for MTBE under the Toxic Substances Control Act that precipitated investigations of MTBE's potential two-generation reproductive toxicity, developmental toxicity, in vivo mutagenicity, subchronic inhalation toxicity, oncogenicity, and neurotoxicity. Results of these studies are a major addition to the toxicity literature on MTBE and define several NOAELs (Bevan *et al*., 1997a,b; Bird *et al*., 1997; Daughtrey *et al*., 1997; Lington *et al*., 1997; McKee *et al*., 1997). The publication of Bird and colleagues is actually a recapitulation of reports by Chun *et al*. (1992) and Burleigh-Flayer

Table 24-4
Summary Results of MTBE Cancer Bioassays

AUTHORS	ANIMAL STRAIN/SPECIES	EXPOSURE ROUTE	POSITIVE RESULTS
Chun *et al*. (1992)	Fischer 344 rats	Inhalation	Kidney and testicular tumors (males)
Burleigh-Flayer *et al*. (1992)	CD-1 mice	Inhalation	Liver adenomas (females)
Belpoggi *et al*. (1995)	Sprague–Dawley rats	Oral	Testicular tumors (males)
			Leukemia + lymphoma (females)

et al. (1992), both of which are of particular value, as they represent two of only three MTBE cancer bioassays. In the Chun *et al*. study, male and female F-344 rats were exposed to 0-, 400-, 3000-, or 8000-ppm MTBE vapor 6 h/d, 5 d/week for 24 months. In the other inhalation study, Burleigh-Flayer *et al*. (1992) subjected male and female CD-1 mice to the same exposure regimen for 18 months. The only oral chronic bioassay is that by Belpoggi *et al*. (1995, 1997), who subjected male and female Sprague–Dawley rats by olive oil gavage to 0, 250, or 1000 mg/kg MTBE 4 d/week for 2 years. The results of the three MTBE animal cancer bioassays are presented in Table 24-4. In addition, Cirvello *et al*. (1995) and NTP (1995) have reported some evidence for the carcinogenicity of TBA in the kidney and thyroid after long-term drinking water exposure.

Taken at face value, one might interpret these cancer bioassay findings as ample evidence of carcinogenicity in animals and suggestive of a cancer risk for humans. The relevance of these findings to humans, however, has been a source of debate among toxicologists. Critics have questioned these studies on the basis of (1) the appropriateness of a combined incidence category for leukemias and lymphomas; (2) the possibility that renal tumors were secondary to male rat-specific α_{2u}-globulin nephropathy; (3) the possibility that Leydig cell tumors were a function of abnormally low testicular tumor rates in control animals or increased survival time of treated rats; (4) the questionable relevance of testicular tumors in rats to humans, given the species' differential responses of Leydig cells to proliferative stimuli; (5) the possibility that liver and kidney tumors are the result of high dose-induced chronic cytotoxicity, cell death, and reparative cell proliferation; (6) the questionable relevance of inhalation bioassays to prediction of drinking water risks; and (7) the use of an oil rather than a water-dosing vehicle, which could unduly influence MTBE's oral TK. Mennear (1997) and McGregor (2006) have discussed a number of these issues.

As an outgrowth of the uncertainties surrounding MTBE's human carcinogenicity risk, several mechanistic studies have been published. For example, after only 10 days of MTBE inhalation exposure, a strong positive linear relationship between renal α_{2u}-globulin concentration and cell proliferation was seen in the male F-344 rat (Prescott-Matthews *et al*., 1997). This study, unlike the chronic bioassay of Chun *et al*. (1992), definitively identified the accumulating protein as α_{2u}-globulin. Williams and Borghoff (2001) have shown that TBA interacts with α_{2u}-globulin, which explains its accumulation in the male rat kidney following MTBE or TBA exposure. MTBE has been shown to be a hepatic mitogen in the female mouse, but not a promoter of tumor formation in DEN-initiated female mouse liver (Moser *et al*., 1996b). It has been suggested in light of these findings, that MTBE may promote the growth of spontaneously initiated cell populations having genetic lesions different from those produced by DEN. Casanova and Heck (1997)

have reported a lack of concentration-, species-, and sex dependence in the formation of HCOH-induced DNA–protein cross-links and RNA–HCOH adducts in isolated female CD-1 mouse hepatocytes incubated with MTBE. As the cancer bioassay data suggest that hepatocarcinogenicity varies with all of these factors, these results do not support a role for HCOH in MTBE-induced liver tumor formation. Studies also indicate that MTBE causes endocrine dysregulation in rodents at high doses, suggesting the possibility that MTBE-induced tumor formation is hormonally mediated (Moser *et al*., 1998; Williams *et al*., 2000b). Changes in triiodothyronine, luteinizing hormone, testosterone, and estradiol levels have been discussed as possible mechanisms of MTBE-induced Leydig cell cancer (Williams and Borghoff, 2000; Williams *et al*., 2000b; de Peyster *et al*., 2003). Although it is generally accepted that MTBE induces certain tumors in animals through non-genotoxic mechanisms, experiments indicate that MTBE is mutagenic in some in a few in vitro test systems (Williams-Hill *et al*., 1999; Zhou *et al*., 2000).

Several mechanistic issues surrounding MTBE's toxicity, particularly its carcinogenicity, have yet to be resolved. Nonetheless, citing widespread groundwater contamination and health concerns, numerous states have instituted phased-in partial or complete bans of MTBE. This is in keeping with the opinion of EPA's *Blue Ribbon Panel on Oxygenates in Gasoline* that, in 1999, agreed that the use of MTBE and other gasoline additives that threaten drinking water supplies should be substantially reduced. To date, independent expert review groups who have assessed MTBE inhalation health risks (e.g., "Interagency Assessment of Oxygenated Fuels") have not concluded that the use of MTBE-oxygenated gasoline poses an imminent threat to public health. EPA's Office of Water has concluded that available data are not adequate to estimate potential health risks of MTBE at low exposure levels in drinking water, but that the data support the conclusion that MTBE is a potential human carcinogen at high doses. Fortunately, water-containing MTBE has an unpleasant taste and odor, which may alert consumers to the fact that their water is contaminated. Based on the results of studies of taste and odor thresholds for humans, an advisory guidance range of 20–40 μg/L has been set by the EPA to assure consumer acceptance and provide a large margin of safety from toxicity and carcinogenicity. California has derived both a cancer potency estimate and adopted a Public Health Goal of 13 ppb for MTBE in drinking water (Wang *et al*., 1997). While many advocate for the suspension of MTBE's use in reformulated gasoline, such a decision should weigh the benefits against the risks associated with increased auto emissions of carcinogenic VOCs and the public health impact of increased CO_2 emissions and ozone formation. Two articles that discuss this subject in considerable detail are those of Spitzer (1997) and Erdal *et al*. (1997).

Jet Fuel

Jet A, jet propellant-8 (JP-8), and JP-8+100 are the predominant jet fuels in use today. All are kerosene-like mixtures of hundreds of aliphatic and aromatic hydrocarbons. Jet A is commercial aviation fuel, whereas JP-8 and JP-8+100 are military fuels. JP-8 is a mixture of Jet A plus three additives, whereas JP-8+100 contains JP-8 and an additional additive package. JP-8 is now the recognized battlefield fuel for all NATO forces and is used not only for aircraft, but also for ground vehicles and other equipment such as generators, cooking stoves, and tent heaters (NRC, 2003). Owing to slight differences in hydrocarbon composition and additives, JP-8 differs from its predecessor fuels (e.g., JP-4 and JP-5) in ways that impart added safety, enhance combat aircraft survivability, simplify battlefield logistics, and promote standardization with commercial jet fuel.

Civilian and military personnel are exposed to jet fuel by inhalation and dermal contact. Exposure can occur to liquid, vapor, or aerosol, each phase having a distinct composition and toxicity profile. Exposure is prevalent in aircraft refueling and maintenance operations and ground crews positioned behind jet aircraft during "cold starts" can become "drenched" in aerosol emissions. Jet fuel can be released into the environment by in-flight jettisoning and spills or leaks to soil or water during use, storage, or transportation. In many cases, the U.S. Department of Defense (DoD) is responsible for the cost of remediating contaminated military sites and contractor facilities, not to mention its responsibility to safeguard the health of military personnel. It is thus in DoD's interest to accurately characterize the toxicity of jet fuel. Much of the research conducted to date has been funded by the military. The Navy's Occupational Safety and Health Standards Board has proposed an 8-hour time-weighted average (TWA) PEL of 350 mg/m^3 and a 15-minute STEL of 1800 mg/m^3 for jet fuel vapors, but notes that exposure to aerosols that are much more toxic may necessitate reevaluation. The National Research Council (NRC) Subcommittee on Jet Propulsion Fuel 8 recommended that the 8-hour TWA be considered interim until further research is completed, and that the STEL be lowered to 1000 mg/m^3 to avoid acute CNS effects (NRC, 2003).

The complexity of jet fuel mixtures presents multiple challenges to toxicologists and risk assessors alike. One such challenge is to generate experimental exposures to jet fuel that accurately reflect those occurring in humans. The NRC Subcommittee on JP8 has reviewed the methods used to generate exposure atmospheres in several published studies using aerosol/vapor mixtures and suspects that the JP-8 concentrations may have been underreported, particularly in studies by Witten and colleagues (NRC, 2003). Therefore, it seems prudent at this time to discuss aerosol/vapor exposures in qualitative terms only. Because of concerns surrounding the quantitative accuracy of the exposure atmospheres, the NRC Subcommittee recommended an examination of the methods used for their characterization. To this end, Dietzel et al. (2005) have developed and validated a GC/MS method for JP-8, which was subsequently used to characterize the aerosol and vapor fractions of aerosolized fuel in one of the University of Arizona-based inhalation chambers previously utilized by Witten and colleagues.

Jet A, JP-8, and JP-8+100 have similar toxicity profiles, which suggests their toxicities are largely a function of hydrocarbon content rather than additives. Toxicity data on jet fuels have been well summarized (ATSDR, 1998a; NRC, 2003; Ritchie et al., 2003), but there remain several data gaps including genotoxicity. Most toxicity studies of jet fuels have focused on the two main portals of entry

(i.e., lung and skin) and the immune system. In subchronic and chronic rodent inhalation studies of jet fuel vapor, the chief finding has been renal toxicity and neoplasia in male rats consistent with α_{2u}-globulin nephropathy (Mattei et al., 1991; Bruner et al., 1993). Whereas the liver, kidneys, and testes in humans are not considered particularly sensitive targets of jet fuels, proteomic analyses of these tissues have been conducted in male rats subchronically exposed to JP-8 vapor (Witzmann et al., 2000a,b, 2003). Similarly, gene expression in the whole brain of rats repeatedly exposed to JP-8 vapor has been examined (Lin et al., 2001a, 2004), driven largely by reports of cognitive and motor deficits and neurochemical changes in jet fuel-exposed workers and experimental animals (Baldwin et al., 2001; Ritchie et al., 2001; Rossi et al., 2001; Bell et al., 2005).

Pulmonary Effects   The pulmonary effects of an aerosol/vapor mixture of JP-8 were initially investigated in rats with nose-only exposures designed to simulate military flightline exposures (Hays et al., 1995; Pfaff et al., 1995, 1996). Functional changes in the form of increases in pulmonary resistance and alveolar permeability were accompanied by a decrease in the concentration of the tachykinin Substance P (SP) in bronchoalveolar lavage fluid. Pathological changes were observed in lower pulmonary structures including inflammation of the terminal bronchioles, degeneration of alveolar type II epithelial (AIIE) cells and disruption of terminal bronchial airway epithelium. Most interestingly, the activity of neutral endopeptidase (NEP), an enzyme responsible for the metabolism of SP in the lung, was increased by exposure and a significant inverse relationship between SP and NEP activity demonstrated. Thus, JP-8 appears to exhibit a rather novel mechanism of lung injury that involves the reduction or depletion of SP due to its enhanced metabolism by NEP.

Because SP participates in the maintenance of airway epithelial cell competency, the effect of JP-8 and n-tetradecane (C$_{14}$), a primary constituent of JP-8, on epithelial barrier integrity was examined in vitro using paracellular mannitol flux in BEAS-2B human bronchial epithelial cells (Robledo et al., 1999). Noncytotoxic concentrations of JP-8 and C$_{14}$ produced dose-dependent increases in transepithelial mannitol flux that spontaneously reversed to control values over a 48-hour recovery period. This suggests that JP-8 and C$_{14}$ compromise the integrity of intercellular tight junctions that may precede and initiate the pathological alterations observed in whole animal studies. Evidence was also collected that SP's protective effect on the lung is largely mediated through the plasma membrane-bound neurokinin receptor, NK$_1$, present on airway epithelium from the trachea to the respiratory bronchioles (Robledo and Witten, 1999).

Among the most affected alveolar cells in rodent studies are AIIE cells. In support of the hypothesis that apoptotic cell death is responsible at least partially for JP-8's cytotoxicity in the lung, Stoica et al. (2001) reported that JP-8 results in morphological and biochemical changes characteristic of apoptosis in the rat AIIE cell line, RLE-6TN. Further, Boulares et al. (2002) have collected data that strongly suggest JP-8 triggers apoptosis in rat lung epithelial cells by inducing the generation of reactive oxygen species, depleting/reducing intracellular GSH, and markedly decreasing mitochondrial membrane potential, thereby initiating the apoptotic cascade (i.e., caspase-3 activation and DNA fragmentation).

A characteristic feature of the lung inflammatory response to JP-8 in rodents is vacuolization of AIIE cells and accumulation of pulmonary alveolar macrophages (PAM). The findings of Wang

et al. (2002) suggest that JP-8 causes proinflammatory cytokine secretion not only by PAM, but also AIIE cells. The prolonged production of proinflammatory cytokines, together with the proteases produced by activated macrophages and neutrophils, are capable of producing a sustained immune response with increased risk for lung damage. Moreover, cocultures of AIIE cells and primary PAM indicate that the balance of cytokines released in response to JP-8 could possibly be regulated in vivo by cross-communication between the two cell types. Most recently, Espinoza *et al.* (2005) showed that the JP-8-induced expression of proinflammatory cytokine genes in AEII cells was mediated by the activation of PARP-1 (an enzyme coactivator of NF-kappaB) and NF-kappaB (a transcription factor that controls the expression of a variety of genes involved in inflammatory responses). The release of cytokines in the lung in response to JP-8 is similar to cytokine release from epidermal cells, which is thought to mediate, at least in part, the dermal and immune toxicities of JP-8 (see below). Further insight into the pulmonary effects of jet fuel has come from examinations of aerosolized JP-8's effect on gene and protein expression in lung cytosol and lung tissue of rats and mice (Witzmann *et al.*, 1999; Drake *et al.*, 2003; Espinoza *et al.*, 2005).

Immune Effects   The immune system appears to be as susceptible to jet fuel as the lung, if not more so. Detrimental effects on the immune system of mice have been reported for aerosolized Jet A, JP-8, and JP-8+100 (Harris *et al.*, 2001a). Some effects were apparent just 1 hour after a single inhalation exposure with continued deterioration with each successive exposure (Harris *et al.*, 2002). As first reported by Harris *et al.* (1997a), mice exposed nose-only to a JP-8 aerosol/vapor mix exhibited decreased spleen and thymus weights and cellularities and an altered number of viable immune cells in lymph nodes, bone marrow, and peripheral blood. Depending on the immune tissue examined, different immune cell subpopulations were lost, including T and B cells and macrophages. In addition, JP-8 affected immune function as demonstrated by a concentration-dependent suppression of T-cell proliferation upon stimulation with the mitogen concanavalin A. In a short-term exposure study, Harris *et al.* (1997b) determined that JP-8-induced immunotoxicity persisted for at least 1 month after insult. These same authors later expanded the number of immune parameters examined and reported that aerosolized JP-8 exposure of mice nearly completely ablated natural killer cell function, suppressed the generation of lymphokine-activated killer cell activity, suppressed the generation of cytotoxic T lymphocytes from precursor T cells and inhibited helper T-cell activity (Harris *et al.*, 2000).

Ullrich (1999) has demonstrated that dermal application of JP-8 to mice can induce immune suppression. Ullrich found IL-10, a cytokine with potent immunosuppressive activity, in the serum of JP-8 dermally treated mice. He interpreted this as suggestive of an immune suppressive mechanism involving the upregulation of cytokine release. In a follow-up study, Ullrich and Lyons (2000) demonstrated that the immunosuppressive effect of dermally applied JP-8 appears to be specific to cell-mediated immune reactions (i.e., T-helper cell-driven cell-mediated immunity), as JP-8 had no effect on antibody production in immunized mice. Further, their study again implicated the release of cytokines from epidermal cells in immunosuppression, particularly prostaglandin E2 (PGE2) and IL-10. Ramos *et al.* (2004) have subsequently used platelet-activating factor (PAF) receptor antagonists to show that the PAF receptor, a signaling phospholipid which upregulates PGE2 synthe-

sis by keratinocytes, plays a critical role in jet fuel-induced immune suppression. Ramos *et al.* (2002) have also demonstrated that the dermal application of JP-8 and Jet A suppresses delayed-type hypersensitivity and immunologic memory upon rechallenge with a fungal pathogen, suggesting that jet fuel exposure may depress the protective effect of prior vaccination. Similar to that seen for pulmonary toxicity, aerosolized SP can both prevent and reverse some facets of JP-8-induced immunotoxicity, suggesting a key mechanistic role for the neuropeptide (Harris *et al.*, 1997c, 2001b). As reported for AIIE cells, JP-8 also induces apoptosis in primary mouse thymocytes (Stoica *et al.*, 2001). Exposure of mice to JP-8 in utero reportedly has implications for the immune system (Keil *et al.*, 2003).

Dermal Effects   Owing to reports of severe contact dermatitis among military personnel, the dermal toxicity of jet fuel has been the subject of intensive investigation. A recent examination of dermal exposure in 124 U.S. Air Force fuel-cell maintenance workers, using a noninvasive tape-strip technique and naphthalene as a surrogate, confirmed that the skin provides a significant exposure route for JP-8 (Chao *et al.*, 2005). Dermal absorption and penetration of JP-8 and its component hydrocarbons have been examined in vitro using dermatomed rat skin and static diffusion cells and in vivo in weanling pigs (McDougal *et al.*, 2000; Singh *et al.*, 2003). Their cutaneous toxicity has been explored in pigs, rats, rabbits, and in vitro using human epidermal keratinocytes (HEK) (Kabbur *et al.*, 2001; Monteiro-Riviere *et al.*, 2001; Chou *et al.*, 2003; Singh and Singh, 2004). Dermal exposure to jet fuel can lead to skin irritation and sensitization and the disruption of skin barrier function. Research implicates cytokine release, oxidative stress and DNA damage/fragmentation as mechanistic underpinnings (Allen *et al.*, 2000; Rogers *et al.*, 2001; Gallucci *et al.*, 2004). Chronic dermal application of middle distillate fuels such as jet fuel can be weakly carcinogenic, though it has been effectively argued that such tumorigenicity is secondary to chronic irritation (Nessel, 1999; Nessel *et al.*, 1999).

The ultrastructural analysis of pig skin exposed to cotton fabric saturated with jet fuel suggests that the primary effect of exposure is damage of the stratum corneum barrier (Monteiro-Riviere *et al.*, 2004). This same publication reported that IL-8 release from HEK after JP-8 exposure was decreased by SP, which is an agonist for the NK_1 receptor present in keratinocytes and mechanistically linked to IL release. The attenuation of IL release in keratinocytes by SP and the protection SP affords against pulmonary and immunotoxicity suggests that there may be a common mechanistic linkage to these toxicities. However, studies suggest that jet fuel-induced cell death in skin is via necrosis, not apoptosis as observed in some other cell types such as AIIE cells and T lymphocytes (Stoica *et al.*, 2001). This was also demonstrated by Rosenthal *et al.* (2001), who observed JP-8-induced necrotic rather than apoptotic cell death in mouse skin fibroblasts and HEK in culture or grafted onto nude mice. These authors used immunoblot analysis to determine that necrosis of HEK appeared to be associated with the perturbation of the ratio between anti- and pro-survival members of the Bcl-2 family of proteins (i.e., the toxic, higher level of JP-8 decreased levels of the pro-survival proteins Bcl-2 and Bcl-x_L, while simultaneously elevating levels of the anti-survival proteins Bad and Bak). This has led to the suggestion that high intrinsic levels of Bcl-2 and Bcl-x_L may prevent apoptotic death of keratinocytes at low concentrations of JP-8, whereas modulation of Bcl-2 family members by high doses may lead to necrotic cell death.
Figure 24-13. Metabolism of carbon disulfide (CS$_2$).

CS$_2$ is metabolized by the mixed-function oxidase (MFO) system to carbonyl sulfide, atomic sulfur and HS$^-$. Reaction of CS$_2$ with sulfhydryls of cysteine or GSH yields trithiocarbonates, which can cyclize to form thiazolidine-2-thione-4-carboxylic acid (TTCA). Reaction of CS$_2$ with amino groups of amino acids results in dithiocarbamate derivatives, which can cyclize to yield 2-thio-5-thiazolidinones; reaction of cysteine amine could also produce TTCA. CS$_2$ is also metabolized in the liver by P450s to an unstable oxygen intermediate, which spontaneously generates atomic sulfur, carbonyl sulfide (COS), and CO$_2$. [Reproduced with permission of Graham *et al.* (1995).]

As the skin allows for the selective absorption and penetration of various jet fuel components, one cannot assume that the internal or target tissue dose of chemical is qualitatively or quantitatively the same as that of the external dose (McDougal and Robinson, 2002). This has led to efforts to identify the offending components of jet fuel mixtures. Using static diffusion cells, McDougal *et al*. (2000) identified 12 components of JP-8 that fully penetrated rat skin and six components, all aliphatic hydrocarbons, which were partially absorbed or retained by the skin. This led these researchers to speculate that the aliphatic components of jet fuel may be the cause of skin irritation. Allen *et al*. (2001) exposed HEK to micromolar concentrations of four aliphatic hydrocarbon components of jet fuel and found that they all induced IL-8 release at subtoxic doses, further implicating aliphatic components. However, Chou *et al*. (2002) exposed HEK to 10 aliphatic jet fuel hydrocarbons (C6–C16) and found that the higher cytotoxicity of the shorter chain aliphatics did not correlate with their ability to induce IL-8 release, which peaked at mid-chain lengths (i.e., C9–C13). The toxicological interactions of jet fuel's aromatic and aliphatic components on HEK cells have also been explored (Yang *et al*., 2006). The cytotoxicity and IL-8 release from these "mixed" hydrocarbon exposures were not always predictable based on the cytotoxic and IL-8 profiles of individual components. Muhammad *et al*. (2005) have exposed pigs topically to cotton fabric soaked with one of eight aliphatic hydrocarbons or one of six aromatic hydrocarbons and monitored skin irritation. Based on these data, coupled with data on IL-8 release, in vitro absorption and cytotoxicity, they postulate that tridecane and tetradecane may be the two most important hydrocarbons responsible for jet fuel-induced skin irritation. Jet fuel exemplifies well the difficulty in accurately predicting the dermal risk posed by a complex mixture based on limited knowledge of a few individual components. Progress toward this end has recently been made, as Kim *et al*. (2006) have published a dermatotoxicokinetic model of the skin that quantitatively characterizes the TK of three aromatic and three aliphatic jet fuel components following application

of a single dose of JP-8 to the forearm of human volunteers. As in lung tissue and lung cytosol of rodents, the capacity of JP-8 to alter gene or protein expression in HEK has been thoroughly examined (Espinoza *et al*., 2004; Witzmann *et al*., 2005; Chou *et al*., 2006).

CARBON DISULFIDE

The major uses of carbon disulfide (CS$_2$) are in the production of rayon fiber, cellophane, and CCl$_4$ and as a solubilizer for waxes and oils (ATSDR, 1996a). Historically, exposures were particularly high during the early period of rayon production, and studies of these workers have been very informative as to CS$_2$'s toxicity. Human exposure is predominantly occupational, although CS$_2$ has been identified in at least 200 current or former EPA National Priority List hazardous waste sites (ATSDR, 1996a). Most industrial releases are to the atmosphere. The general public may be subjected to low vapor levels as demonstrated by detection of CS$_2$ in samples of breath and indoor and outdoor air surveyed in and around New York City (Phillips, 1992). Exposure to dithiocarbamate pesticides and drugs (e.g., the alcohol aversion drug, disulfiram) can result in indirect exposure to CS$_2$, as it is a product of their metabolism. However, there is evidence that the metabolic production of CS$_2$ is not unifying explanation for the neuropathies frequently associated with dithiocarbamate exposure (Tonkin *et al*., 2000; Mulkey, 2001).

The relative contributions of parent compound and metabolites to most CS$_2$-induced toxicities are unknown. Two distinct metabolic pathways for CS$_2$ exist: (1) the direct interaction of CS$_2$ with free amine and sulfhydryl groups of amino acids and polypeptides to form dithiocarbamates and trithiocarbonates; and (2) microsomal metabolism of CS$_2$ to reactive sulfur intermediates capable of covalently binding tissue macromolecules (Graham *et al*., 1995) (Fig. 24-13). The conjugation of CS$_2$ with sulfhydryls of cysteine or GSH results in the formation of 2-thiothiazolidine-4-carboxylic acid (TTCA), which is excreted in urine and has been frequently used as a biomarker of CS$_2$ exposure, especially among viscose

rayon workers (Riihimaki *et al.*, 1992; Lee *et al.*, 1995). Several limitations of TTCA as a biomarker have been noted, and covalently cross-linked erythrocyte spectrin and hemoglobin have been discussed as potential alternatives (Valentine *et al.*, 1993, 1998). Nonetheless, the current ACGIH Biological Exposure Index (BEI) for CS_2 is 5 mg of TTCA per g of creatinine for a urine sample collected at the end of a workshift. Commentary on the derivation of this BEI has been published by Cox *et al.* (1992).

A few comprehensive reviews of CS_2's toxicity have been published (Beauchamp *et al.*, 1983; ATSDR, 1996a; WHO, 2002). CS_2 is capable of targeting multiple organ systems. There are numerous reports of enhanced noise-induced hearing loss and ophthalmological changes among workers exposed in the United States and abroad (Morata, 1989; Vanhoorne *et al.*, 1996; Chang *et al.*, 2003). The nervous and cardiovascular systems have garnered the most attention. The most common chronic effect is a distal sensorimotor neuropathy that preferentially affects long axons in the PNS and CNS (particularly the ascending and descending tracks of the spinal cord and the visual pathways). Encephalopathy with motor and congnitive impairment has also been reported following chronic, low-level exposure to CS_2 (Graham *et al.*, 1995). Several MRI studies report diffuse white matter lesions in chronically exposed workers similar to that described for "toluene leukoencephalopathy" among solvent abusers (Cho *et al.*, 2002; Ku *et al.*, 2003). For those particularly interested in the nervous system, the classic paper by Richter (1945) detailing his observations of chronic CS_2 poisoning in monkeys is recommended. Aftre 50 years, Rosenberg (1995) described the following clinical syndromes associated with CS_2:

(1) acute and chronic encephalopathy (often with prominent psychiatric manifestations); (2) polyneuropathy (both peripheral and cranial); (3) Parkinsonism; and (4) asymptomatic CNS and PNS dysfunction.... Pathologic changes occur in both the CNS and PNS.... CNS pathology consists of neuronal degeneration throughout the cerebral hemispheres, with maximal diffuse involvement in the frontal regions. Cell loss is also noted in the globus pallidus, putamen and cerebellar cortex, with loss of Purkinje cells. Vascular abnormalities with endothelial proliferation of arterioles may be seen, sometimes associated with focal necrosis or demyelination. PNS changes consist primarily of myelin swelling and fragmentation and large focal axonal swellings, characteristic of distal axonopathy.

Significant contributions to the understanding of CS_2's neurotoxicity have come from collaborative research by the NIEHS, EPA, and several universities (Harry *et al.*, 1998; Sills *et al.*, 1998, 2005). Studies were conducted with F-344 rats subchronically exposed to a range of CS_2 concentrations, in order to define the onset and temporal progression of neurotoxicity as manifest by multiple end points. These specific end points included TK changes in blood CS_2 levels and urinary TTCA, covalent cross-linking of blood and spinal cord proteins, alterations in axon/Schwann cell interactions as indicated by nerve growth factor mRNA expression, morphology of distal axonopathy, nerve conduction velocity and compound nerve action potential, and behavioral assessment using a Functional Observational Battery. This research showed sensitive end points at the cellular level that progressed to alterations in hindlimb and forelimb function, followed by electrophysiological and morphological changes. It supports the theory that the axonal degeneration that underlies CS_2's central–peripheral neuropathy results from the reaction of CS_2 [and perhaps carbonyl sulfide (COS)] with protein amino groups to yield initial adducts (dithiocarbamate derivatives). The adducts decompose to an electrophile (isothiocyanate for CS_2

and isocyanate for COS), which in turn reacts with protein nucleophiles on neurofilaments to cause covalent protein cross-linking. Progressive cross-linking of neurofilaments occurs during neurofilament transport along the axon, and covalently cross-linked masses of neurofilaments are thought to occlude axonal transport at the nodes of Ranvier, ultimately resulting in axonal swelling and degeneration (similar to that seen with 2,5-hexanedione). It should be noted that several other mechanisms for the disruption of neurofilament transport that underlie CS_2's axonopathy have been proposed including impaired energy metabolism, metal ion chelation by CS_2's dithiocarbamate derivatives, induction of vitamin deficiency, and disruption of cytoskeletal protein association by the increased phosphorylation of neurofilaments (Wilmarth *et al.*, 1993; Graham *et al.*, 1995).

One of the potentially more important outcomes of the collaborative research effort described above was the identification of thiourea cross-linking structures on erythrocyte spectrin and hemoglobin. This cross-linking exhibited a linear dose–response over the range of inhaled CS_2 concentrations examined, was detectable at subneurotoxic exposure levels, preceded axonal structural damage, and was positively correlated with neurofilament cross-linking (i.e., spectrin and hemoglobin cross-linking reflects neurofilament cross-linking). These findings suggest the utility of spectrin and hemoglobin cross-linking as sensitive biomarkers of exposure and effect, and potential alternatives or supplements to TTCA that was found to lack dose proportionality in the same studies (Valentine *et al.*, 1997, 1998; Moorman *et al.*, 1998).

Numerous worker studies support an association between CS_2 exposure and cardiovascular disease and related mortality. Elevated mortality from cardiovascular disease has been reported among viscose rayon workers in Finland, the United Kingdom, the United States, Scandinavia, and Poland (WHO, 2002). Viscose rayon worker studies reporting excess cardiovascular morbidity expand the range to Germany (Drexler *et al.*, 1996) and Japan (Takebayashi *et al.*, 2004). Further support for a CS_2–cardiovascular disease link comes from the examination of cardiovascular disease risk factors in workers, and to a lesser extent, experimental rodent studies. In workers, CS_2 exposure has been associated with elevations in blood pressure, total and LDL cholesterol, triglycerides, apolipoproteins, and lipid peroxidation in plasma, as well as reductions in HDL and antioxidant status (Egeland *et al.*, 1992; Vanhoorne *et al.*, 1992; Wronska-Nofer *et al.*, 2002; Luo *et al.*, 2003). Wronska-Nofer (1979) conducted studies in rats supporting a role for CS_2 in the elevation of blood cholesterol, whereas Lewis *et al.* (1999) found that exposure to as little as 50 ppm CS_2 significantly enhanced the rate of arterial fat deposition in mice placed on a western style, high-fat diet. Sulsky *et al.* (2002) have reviewed 37 studies addressing the CS_2–cardiovascular disease association and concluded that epidemiological evidence for an association was "mixed", with an effect on total and/or LDL cholesterol being the most consistent finding but of limited magnitude and uncertain clinical significance. Tan *et al.* (2002) conducted a meta-analysis of 11 cohort studies on CS_2's cardiovascular effects, that showed a small but significant correlation between CS_2 exposure and cardiovascular disease prevalence (pooled RR = 1.56; 95% CI = 1.12–2.1).

Taken together, studies suggest that CS_2 has the ability to accelerate atherosclerosis. Further, some have speculated that like neurotoxicity, protein cross-linking may also be involved in CS_2's promotion of the atherosclerotic process (Lewis *et al.*, 1999). As Price *et al.* (1997) point out, the cardiovascular mortality excesses seen in most published studies are among workers chronically exposed to

high concentrations that no longer are observed in the workplace. These authors reviewed historical exposure and mortality data in the viscose rayon industry and estimated that chronic exposures of 15–20 ppm would not be associated with an increased risk of mortality due to ischemic heart disease. They were also instrumental in applying the benchmark dose method toward the establishment of EPA's RfC for CS_2 of 0.7 mg/m^3 (~0.22 ppm), that is based on reduced maximum motor conduction velocity in the peroneal

nerves of the NIOSH cohort of viscose rayon workers reported by Johnson *et al.* (1983) (Price *et al.*, 1996; EPA, 2006d). For the protection of workers, OSHA has established a PEL of 20 ppm as an 8-hour TWA and an acceptable ceiling concentration of 30 ppm. The ACGIH TLV was reduced from 10 to 1 ppm in 2006, as an 8-hour TWA based on neurologic end points. As a result, the ACGIH has placed CS_2's BEI under study and may move forward with a "notice of intended change" proposal in 2007.
